Preface to the Second Edition

It has been our pleasure to compile the second edition of the *Genetics of Bone Biology and Skeletal Disease*, which contains details of many exciting advances that have occurred since the publication of the first edition in 2013. These past 5 years have seen a rapid pace of fruitful research that has resulted in major achievements particularly in the fields of genome and epigenetic analysis, stem cells, osteoimmunology, osteocyte biology, and translational studies with new therapies. The aim of the second edition is to harness this progress in an easily understandable manner for the reader, and to provide a reference framework that will inspire further investigation and innovation. Thus, the second edition of the *Genetics of Bone Biology and Skeletal Disease* has >20% new chapters, as well as the previous chapters that have been extensively expanded and updated to incorporate these important advances.

The second edition, now containing 43 chapters, is aimed at all students of bone biology and genetics, and with this in mind it includes general introductory chapters concerning genetics and bone biology, followed by more specific disease orientated chapters, which comprehensively summarize the clinical, genetic, diagnostic, molecular genetic, *in vitro* and *in vivo* pathophysiology, and treatment aspects of each disorder. The chapters are organized into five sections that each emphasize particular themes, which are: General background to genetics; General background to bone biology; Disorders of bone and joint, Parathyroid and related disorders; and Vitamin D and renal disorders. The first section "General Background to Genetics" provides an introduction to genetics of skeletal and mineral metabolic diseases, followed by similarly erudite reviews of: epigenetics; genome-wide association studies (GWAS), copy number variation; genomic profiling; functional genomics; mouse models and approaches to generate in vivo models; prospects of gene therapy; pharmacogenomics and pharmacogenetics of osteoporosis with a personalized medicine outlook; and genetic testing and counseling. The second section "General Background to Bone Biology" is specifically devoted to providing an overview of: bone and cartilage biology; bone structure; joint and cartilage biology; osteocyte biology; stem cells; osteoimmunology; integration of endocrine and paracrine influences on bone; the principles of endocrine regulation of bone and fat, with the role of neuronal regulation and energy homeostasis; and the control of mineral and skeletal homeostasis during pregnancy and in the fetus. The third section "Disorders of Bone and Joint" details the advances in the genetics and molecular biology of: the osteoporosis genes identified by GWAS; monogenic forms of osteoporosis; osteoarthritis; Paget's disease; Mendelian disorders of RANKL, OPG, RANK, and NF-KB signaling; skeletal dysplasias and hypophosphatasia; sclerosing bone disorders; fibrodysplasia (myositis) ossificans progressive; thyroid hormone in bone and joint disorders; and extraosseous calcification. The fourth section "Parathyroid and Related Disorders" highlights the central role of the parathyroids in calcium and skeletal homeostasis by reviewing the molecular genetics of: hyperparathyroidism, hypoparathyrodism, pseudohypoparathyroidism, and the McCune–Albright syndrome; disorders of the PTH receptor, its ligands, and downstream effector molecules; disorders of the calcium-sensing receptor; and the multiple endocrine neoplasia MEN syndromes. The fifth section "Vitamin D and Renal Disorders" details the molecular and cellular advances in: genetic disorders of vitamin D synthesis and action; renal phosphate wasting disorders; the Fanconi syndromes, Dent's disease, and Bartter's syndrome; magnesium disorders; and hypercalciuria. Each chapter has been written to provide an authoritative and comprehensive account that can stand alone. Thus, there is inevitably some overlap among the information in some chapters, and this is advantageous, as it provides different viewpoints and interpretations. It is our sincere hope that this second edition will contribute to a better understanding of the complexity at the genetic, cellular, and physiological levels of bone biology and skeletal disorders while guiding and inspiring clinicians and researchers in many related disciplines (including endocrinology, metabolism, nephrology, rheumatology, orthopedics, pediatrics, genetics, biochemistry, physiology, pathology, and pharmacology) to strive to bring improvements for the diagnosis and safe treatment of patients.

The authorship of the second edition has been broadened to include the foremost and internationally outstanding individuals in the field. We are privileged to

have the honor of working with such wonderful people, who have delivered their chapters on time, and remained friends.

Finally, such an endeavor succeeds only with the help of a dedicated and committed team. In particular, we are grateful to Mara Conner, Tari Broderick, and Timothy Bennett at Elsevier, who encouraged us in this venture and who have worked tirelessly with us to bring this highly informative and exciting book to you. We hope you will find this book rewarding and inspiring; we certainly have!

Michael P. Whyte

Preface to the First Edition

Bone and joint disorders are common and represent a major burden on health economics costs. For example, osteoporosis and related fractures are the leading cause of hospital admission in women over the age of 50 years, and >80% of adults over 55 years of age will suffer from osteoarthritis. Treatments of some metabolic disorders have been greatly improved by an increased understanding of bone and joint biology that has been facilitated by advances in unravelling underlying genetic contributions. These interactions between bone and joint biology, physiology and genetics have also greatly enhanced the understanding of normal bone function as well as the molecular pathogenesis of metabolic bone disorders.

The maintenance of bone and mineral metabolism involves a multiorgan system that includes endocrine and neuronal pathways, the kidneys, adipose tissue, gut, vitamin D metabolism and the specialized cells of the bone. These organs and pathways act in a coordinated manner with feedback systems between bone and the internal environment, and characterization of these has greatly clarified the regulation of skeletal biology and the underlying homeostatic mechanisms. These advances in bone biology have been facilitated by the advances in human genetics, such as the sequencing of the human genome. The application of these advances in human genetics has facilitated identification of the genetic abnormalities causing skeletal disease and this, in turn, has advanced our understanding of normal bone biology as well as the development of new therapies.

The purpose of this book is to identify and analyse the genetic basis of bone disorders in humans and to demonstrate the utility of mouse models in furthering the knowledge of mechanisms and evaluations of treatments. The book is aimed at all students of bone biology and genetics and, with this in mind, it includes general introductory chapters on bone and biology, and genetics; and more specific disease orientated chapters, which comprehensively summarize the clinical, genetic, molecular genetic, animal model, functional and molecular pathology, diagnostic, counseling and treatment aspects of each disorder. The book is intended to be comprehensive but readable, and each chapter is relatively brief yet complete in itself. As a consequence, there is some overlap among some of the information in some chapters, and this is advantageous in providing different viewpoints and interpretations.

The book is organised into five sections that each emphasize particular themes, which are: General background to bone biology; General background to genetics; Disorders of bone and joint; Parathyroid and related disorders; and Vitamin D and renal disorders. The first section "General Background to Bone Biology" is specifically devoted to providing an overview of: bone biology and structure; joint and cartilage biology; principles of endocrine regulation of bone and the role of neuronal regulation and energy homeostasis. The second section "General Background to Genetics" reviews the principles and progress in: genome-wide association studies (GWAS); genomic profiling; copy number variation; prospects of gene therapy; pharmacogenomics; genetic testing and counseling; the generation and utilizing of mouse models and how these have helped increase our understanding of mineral and skeletal homeostasis during pregnancy and in the fetus. The third section "Disorders of Bone and Joint" details the advances in the genetics and molecular biology of: monogenic forms of osteoporosis; GWAS of complex forms of osteoporosis; osteoarthritis; Paget's disease; heritable disorders of RANKL, OPG, RANK and NF-κB signaling; skeletal dysplasias, hypophosphatasia; disorders of high bone mass; and fibrodysplasia (myositis) ossificans progressiva. The fourth section "Parathyroid and Related Disorders" highlights the central role of the parathyroids in calcium and skeletal homeostasis by reviewing the molecular genetics of: hyperparathyroidism; hypoparathyrodism; pseudohypoparathyroidism and the McCune–Albright syndrome; disorders of the PTH receptor; disorders of the calcium-sensing receptor; multiple endocrine neoplasia type 1 (MEN1) and type 2 (MEN2). The fifth section "Vitamin D and Renal Disorders" details the advances in the molecular and cellular advances in: renal phosphate wasting disorders; vitamin D dependent rickets type I and II, and the vitamin D receptor; the Fanconi syndromes, Dent's disease and Bartter's syndrome; magnesium disorders; and hypercalciuria. It is our hope that this book and chapters will contribute to a better understanding of the complexity at the genetic, cellular and physiological levels of bone biology and skeletal disorders, and thereby to improvements in diagnosis and treatments for patients.

The task of assembling such a large number of international experts, who agreed to work together and complete

this ambitious venture, was daunting and formidable. However, friendship and good humor prevailed, and the book has been completed in a timely manner and still remains fresh. We are indebted to all authors for delivering their chapters on time, and for remaining friends.

Finally, such an immense undertaking succeeds only with the help of a dedicated and committed team. In particular, we are grateful to Mara Conner, at Elsevier, who encouraged us in this venture and who has worked tirelessly with us to bring this exciting book to you. In addition, we thank Megan Wickline, who with Mara, has helped us to keep on schedule and on course. We hope you will find this book enjoyable and educational; we certainly have!

1 INTRODUCTION

Many skeletal and mineral metabolic diseases have a genetic basis, which may be due to a germline single gene abnormality (i.e., a monogenic or Mendelian disorder), a somatic single gene defect (i.e., a postzygotic mosaic disorder) or involve several genetic variants (i.e., oligogenic or polygenic disorder).[1–4] Genetic mutations causing Mendelian diseases usually have a large effect (i.e., penetrance), whereas oligogenic or polygenic disorders are associated with several genetic variations, each of which may have smaller effects with greater or smaller contributions from environmental factors (i.e., multifactorial disorders).[1–4] While the majority of monogenic disorders result from rare mutations affecting the coding sequence of the responsible gene, the majority of common genetic variants identified in association with polygenic traits are located in noncoding regions, typically in proximity to candidate genes implicated in the respective phenotype. Notably, considerable overlap exists between the genes responsible for monogenic skeletal disorders and those contributing to polygenic bone phenotypes. Identification of many of these loci have provided key insights into the molecular pathogenesis of skeletal disease, and provided targets for the development of novel therapeutic agents.[2,3,5] In this chapter, the genetics of bone and mineral metabolic disease, the clinical approach to those that are heritable, and use of the different available genetic tests, are reviewed.

2 GENETICS OF SKELETAL AND MINERAL METABOLIC DISEASES

2.1 Modes of Inheritance

The genetic architecture of skeletal and mineral disease is broadly divided into single-gene monogenic disorders and polygenic complex traits.

Inheritance of monogenic skeletal and mineral metabolic disorders may occur as one of six broad traits (Fig. 1.1, Table 1.1): autosomal dominant [e.g., osteogenesis imperfecta (OI) due to type-I collagen alpha-1 and alpha-2 chain (*COL1A1* and *COL1A2*) mutations, achondroplasia due to fibroblast growth factor receptor 3 (*FGFR3*) mutations]; autosomal recessive (e.g., vitamin D-dependent rickets types I and II due to mutations of the renal 1 alpha hydroxylase and vitamin D receptor genes, respectively); X-linked recessive (e.g., Dent disease due to mutations of a chloride/proton antiporter referred to as CLC-5); X-linked dominant [e.g., X-linked hypophosphatemic rickets due to mutations of the phosphate endopeptidase on the X chromosome (*PHEX*) gene]; Y-linked [e.g., Swyer syndrome (46XY complete gonadal dysgenesis) due to mutations of the sex determining region Y (*SRY*) gene, and azoopermia and oligospermia due to deletions of regions of the Y-chromosome]; and non-Mendelian mitochondrial disorders [e.g., forms of hypoparathyroidism associated with the Kearns–Sayre syndrome and mitochondrial encephalopathy, lactic

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00001-0

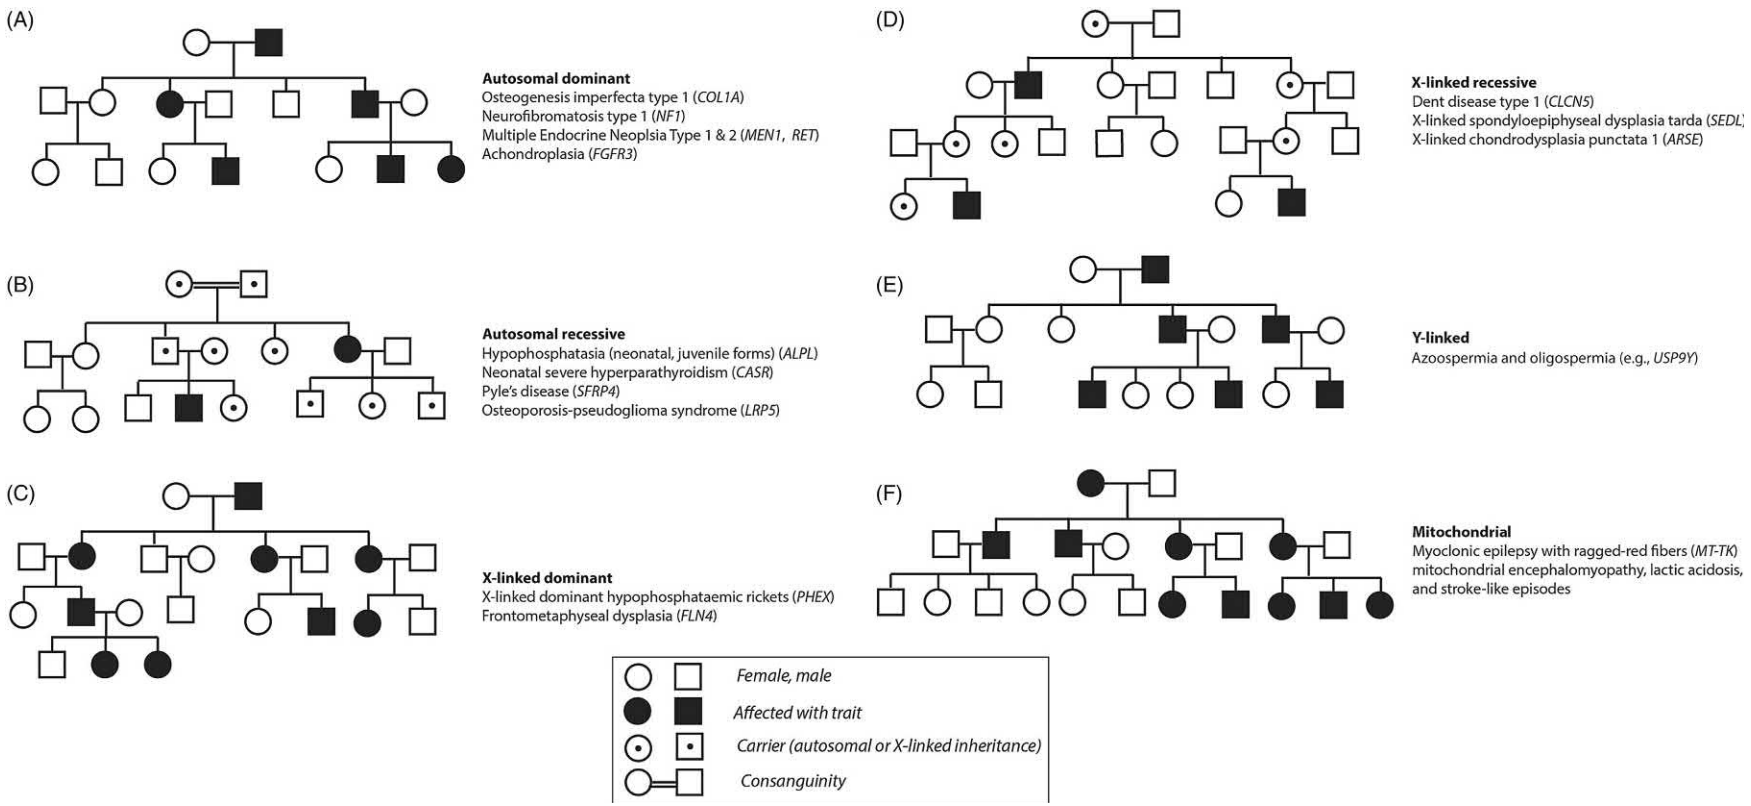

FIGURE 1.1 Modes of inheritance of monogenic skeletal disease. Inheritance of monogenic mineral metabolism and skeletal disorders may occur as one of six main traits: (A) autosomal dominant; (B) autosomal recessive; (C) X-linked dominant; (D) X-linked recessive; (E) Y-linked; and (F) non-Mendelian mitochondrial disorders. Examples of conditions associated with each mode of inheritance are provided with the main causative gene provided in parentheses.

TABLE 1.1 Examples of Monogenic Skeletal Disorders, Modes of Inheritance and Genetic Etiology

Mode of inheritance/disease	Gene(s)	Estimated prevalence	Diagnostic genetic test	Notes
Autosomal dominant				
Osteogenesis imperfecta (OI)	*COL1A1*[a,b]	6–7/100,000	Single gene/gene panel	*COL1A* and *COLA2* responsible for >90% of OI
	COL1A2		Single gene/gene panel	
Stickler syndrome type 1	*COL2A1*	1:10,000	Single gene/gene panel	Represents 80%–90% of cases of Skickler syndrome
Stickler syndrome type 2	*COL11A1*	See above	Single gene/gene panel	Represents 10%–20% of cases of Skickler syndrome. Other rare forms (type 3 and 4) also exist due to mutations in other genes
Hypophosphatemic rickets, autosomal dominant	*FGF23*	Rare	Single gene/gene panel	
Achondroplasia	*FGFR3*	1:15–40,000	Single gene/gene panel	~80% of individuals have a de novo mutation
Multiple epiphyseal dysplasia (MED)	*COMP* (genetic heterogeneity)	1:10,000	Gene panel	Mutations also reported in *COL9A1*, *COL9A2*, *COL9A3*, *MATN3* associated with dominant MED
Neurofibromatosis type 1 (NF1)	*NF1*	1:3,000	Single gene/gene panel	Large gene size makes evaluation by Sanger sequencing costly and time consuming
"High bone mass" (worth-type endosteal hyperostosis)	*LRP5*	Rare	Single gene/gene panel	
Early-onset osteoporosis/juvenile primary osteoporosis	*WNT1/LRP5*	Uncertain	Single gene/gene panel	
Familial hypocalciuric hypercalcemia type 1	*CASR*	1:15–30,000	Single gene/gene panel	Associated with loss of function mutation in *CASR*. Gain of function mutations associated with autosomal dominant hypocalcemia type 1 (ADH1)
Familial hypocalciuric hypercalcemia type 2	*GNA11*	Rare	Single gene/gene panel	Associated with loss-of-function mutations in *GNA11*. Gain of function mutations are associated with autosomal dominant hypocalcemia type 2 (ADH2)
Familial hypocalciuric hypercalcemia type 3	*AP2S1*	Rare	Single gene/gene panel	Associated with loss-of-function mutations in *AP2S1* at arginine residue at codon 15
Familial expansile osteolysis	*TNFRSF11A*	Rare	Deletion/duplication analysis	Associated with duplication within the *TNFRSF11A* gene, which encodes RANK protein
Hypophosphatasia	*TNSALP/ALPL*	Uncertain	Single gene/gene panel	Can also be inherited as autosomal recessive trait
Autosomal recessive				
Osteogenesis imperfecta (OI) Types VII	*CRTAP*	Rare	Single gene/gene panel	Associated with severe clinical features although milder variants may occur

(*Continued*)

TABLE 1.1 Examples of Monogenic Skeletal Disorders, Modes of Inheritance and Genetic Etiology (*cont.*)

Mode of inheritance/disease	Gene(s)	Estimated prevalence	Diagnostic genetic test	Notes
Osteogenesis imperfecta (OI) Type VIII	*P3H1*	Rare	Single gene/gene panel	Associated with severe clinical features including slow growth and early fracture
Osteogenesis imperfecta (OI)Type XV	*WNT1*	Rare	Single gene/gene panel	
Hypophosphatasia	*TNSALP/ALPL*	1:100,000	Single gene/gene panel	Milder forms may occur with autosomal recessive and dominant inheritance patterns
Neonatal severe primary hyperparathyroidism (NSHPT)	*CASR*	Rare	Single gene/gene panel	Typically presents in first 6 months of life often with life-threatening hypercalcemia
Vitamin D-dependent rickets, type 1	*CYP27B*	<1:200,000	Single gene/gene panel	
Vitamin D-dependent rickets, type 2	*VDR*	<1:200,000	Single gene/gene panel	
Multiple epiphyseal dysplasia (MED)	*SLC26A2*	Rare	Single gene/gene panel	
Osteoporosis-pseudoglioma syndrome	*LRP5*	1:2,000,000	Single gene/gene panel	Impaired vision present at birth or during early infancy due to retinal disease
Sclerosteosis type 1	*SOST*	Rare	Single gene/gene panel	More severe than van Buchem disease, occurring in Afrikaner population
Sclerosteosis type 2	*LRP4*	Rare	single gene/gene panel	Can also demonstrate autosomal dominant inheritance
van Buchem disease	*SOST*	Rare	Single gene/gene panel	Identified in individuals of Dutch ancestry. Disease associated with a 52 kb deletion of a regulatory region neighboring the *SOST* gene
Pyle's disease	*SFRP4*	Rare	Single gene/gene panel	Characterized by expanded trabecular metaphyses and increased fracture risk
Juvenile Paget disease	*TNFRSF11B*	Rare	Single gene/gene panel	*TNFRSF11B* encodes the protein OPG which binds RANKL
X-linked dominant				
Hypophosphatemic rickets, X-linked	*PHEX*	1:20,000	Single gene/gene panel	
X-linked recessive				
Dent disease type 1	*CLCN5*	Rare	Single gene/gene panel	~250 families reported in literature
Spondylo-epiphyseal dysplasia tarda, X-linked	*TRAPPC2 (SEDL)*	1:150,000	Single gene/gene panel	
Y-linked				
Azoospermia and oligospermia	Azoospermia factor regions	1:2–3,000	Y-chromosome deletion analysis	Typically results from deletion of multiple genes in "azoospermia factor regions." Deletions of all or part of a single gene *USP9Y* observed in some cases
Swyer syndrome (46, XY gonadal dysgenesis)	*SRY*	1:80,000	Gene panel/FISH/array analysis	15% of cases of Swyer syndrome are due to mutation of the *SRY* gene. Female patients (carrying a male karyotype) may develop osteoporosis because of gonadal dysgenesis

TABLE 1.1 Examples of Monogenic Skeletal Disorders, Modes of Inheritance and Genetic Etiology (*cont.*)

Mode of inheritance/disease	Gene(s)	Estimated prevalence	Diagnostic genetic test	Notes
Mitochondrial				
Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS)	*MT-TL1*	<1:4,000	Single gene/mitochondrial gene panel	Maternal inheritance pattern. m.32423A > G mutation observed in ~80% of patients. Short stature observed in ~50% of patients
Kearns–Sayre syndrome	—	1–3:100,000	Mitochondrial deletion/duplication analysis	Typically presents with progressive external ophthalmoplegia. Most common genetic abnormality involves ~5 kb DNA deletion including 12 mitochondrial genes
Mosaicism				
McCune–Albright syndrome (polyostotic fibrous dysplasia)	*GNAS*	1:100,000–1,000,000	Single gene/gene panel	Postzygotic somatic mosaicism
OI[b]	*COL1A1/COL1A2*	See above	Single gene/gene panel	Germline mosaicism may mimic autosomal recessive inheritance pattern
Neurofibromatosis type 1	*NF1*	Rare	Single gene/gene panel	Postzygotic somatic mosaicism may give rise to "segmental" NF1 with disease limited to region of the body
Melorheostosis	Gene uncertain	~1:1,000,000	Not applicable	Presumed postzygotic mosaicism perhaps involving KRAS
Proteus syndrome	*AKT1*	Rare	Single gene/gene panel	Postzygotic somatic mosaicism

MED, Multiple epiphyseal dysplasia; NF1, neurofibromatosis type 1, NSHPT, neonatal severe primary hyperparathyroidism; OI, osteogenesis imperfecta.
Different conditions may be due to mutations in the same gene. For example, mutations in *COL1A1* are most commonly associated with OI (although may manifest different clinical features), but may also result in Caffey disease (characterized by infantile cortical hyperostosis) and arthrochalasia type Ehlers–Danlos syndrome.
a Apparently similar condition may be due to mutations in different genes and may display different patterns of inheritance. For example, OI and MED may occur as autosomal dominant or autosomal recessive disease due to mutations in several different genes.
b Some autosomal disorders may also arise in the context of mosaicism, either from postzygotic somatic mosaicism in the developing fetus, or from germline mosaicism in an apparently unaffected parent.

acidosis, and stroke (MELAS) syndrome].[6] Inheritance of underlying polygenic disorders may be revealed by a familial occurrence but the pattern of transmission may be complex because of environmental factors. Examples of polygenic skeletal and mineral disorders include osteoporosis, osteoarthritis, and hypercalciuria. In addition, it is important to note that polygenic traits, such as osteoporosis, may rarely occur in monogenic forms, and in this setting can be easily overlooked, for example, X-linked osteoporosis due to mutations of the Plastin 3 (*PLS3*) gene, or early-onset osteoporosis due to heterozygous mutations of the Wnt family member 1 (*WNT1*) gene.[7–9] In addition to the "classical" Mendelian modes of inheritance, occasional kindreds exhibit apparent inherited disease but due to alternate mechanisms. For example, germline mosaicism (in which a postzygotic mutation occurs during or prior to gametogenesis in a parent) may give rise to a seemingly autosomal recessive pattern of inheritance with multiple affected offspring of apparently unaffected parents.[10] Finally, disease traits may be conditioned by epigenetic mechanisms (e.g., methylation), although the current understanding of such processes remains limited. In fact, combinations of genetic and epigenetic changes occasionally influence disease expressivity, which may include parent-of-origin effects. For example, germline mutations plus epigenetic changes at the guanine nucleotide-binding protein alpha subunit gene (*GNAS*; protein GSα) locus are responsible for a spectrum of pseudohypoparathyroidism phenotypes; thus, maternally inherited inactivating coding region mutations in *GNAS* give rise to pseudohypoparathyroidism type 1A (PHP1A), while the equivalent paternally inherited mutations give rise to pseudopseudohypoparathyroidism. However, a related phenotype of pseudohypoparathyroidism type 1B (PHP1B), which occurs in both familial and sporadic forms, is observed

in association with the loss-of-methylation of regulatory regions at the maternal *GNAS* locus, which results in reduced Gsα expression and parathyroid hormone resistance.[11]

While polygenic traits, such as bone mineral density (BMD) and to a lesser extent fracture risk, are highly heritable, the majority of "heritability" remains unexplained. On an individual patient basis in the clinical setting, assessing the genetic contribution to such polygenic traits remains challenging, although it is important to recognize that polygenic traits may rarely occur as part of either isolated or wider syndromic monogenic disorders.

2.2 Genetic Heterogeneity and Monogenic Skeletal Diseases

The appropriate evaluation, investigation, and treatment of patients with skeletal and mineral metabolic disorders requires familiarity with the great diversity of phenotypes which may occur due to underlying hereditary disease. For example, a recent classification indicates that there are >400 specific genetic skeletal disorders.[1] Thus, arriving at the correct diagnosis will depend on a combination of careful clinical work-up, appropriate laboratory investigation and genetic testing, and an awareness of the potential pitfalls that may be present along the way.[1] While the diagnosis of some monogenic disorders may be apparent from pathognomonic or characteristic clinical or radiographic features, many disorders share overlapping or phenotypically indistinguishable findings (e.g., reduced bone mass, skeletal fragility, abnormal mineralization). Similarly, while certain disorders result from mutation(s) in a single culpable gene, other diseases represent marked genetic heterogeneity with mutation(s) in one of many candidate genes. Although establishing the likely mode of inheritance together with careful clinical and routine laboratory evaluation may provide further diagnostic clues, in some situations a broad genetic differential persists. For example, although most cases of OI are due to mutations in the type-I collagen genes (i.e., *COL1A1*, *COL1A2*) many additional genes (~10–15), which are typically involved in posttranslational processing of collagen, account for a small percentage of OI cases.[5,7,12,13] Similarly, heritable disorders characterized by impaired bone mineralization including hypophosphatemic rickets have "genetic heterogeneity"; that is, several genetic etiologies, as do many other conditions including osteopetrosis and Ehlers–Danlos syndrome.[14]

In contrast to the situation in which phenotypically similar disorders may be caused by mutations in one of many different genes (e.g., osteopetroses), sometimes mutations in the same gene underlie a spectrum of clinical phenotypes with some considered distinctive diseases (e.g., disorders from constitutive activation of receptor activator of NF-κB, RANK). In some instances, disease severity is determined by whether a mutation is carried in the heterozygous or homozygous state, or the type or location of the mutation within the gene (i.e., loss-of-function, missense amino acid change). For example, the severity of hypophosphatasia, the inborn-error-of-metabolism featuring low serum alkaline phosphatase activity, reflects the number and nature of the mutation(s) involving the *TNSALP* (*ALPL*) gene that encodes the tissue-nonspecific isoenzyme of alkaline phosphatase (Chapter 28). The severe perinatal and infantile forms of hypophosphatasia are inherited in an autosomal recessive manner, while the later-onset and more mild forms are often inherited in an autosomal dominant fashion.[15] In contrast, single heterozygous mutations in genes, such as *FGFR3*, collagen type-II alpha-1 (*COL2A1*) and collagen type XI, alpha-1 (*COL11A1*) and alpha-2 (*COL11A2*) each give rise to what have been considered separate or unique disorders despite similar patterns of inheritance. For example, for different individual mutations in *FGFR3*; missense mutations resulting in the amino acid change Gly380Arg cause most cases of achondroplasia; mutations resulting in Pro250Arg and Lys650Met cause Muenke syndrome (characterized by craniosynostosis) and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), respectively; while a number of different *FGFR3* missense mutations are reported in patients with hypochondroplasia and type 1 thanatophoric dysplasia.[1] Given this apparent genetic/phenotypic complexity despite genetic "homogeneity," establishing the genetic diagnosis may be challenging, yet crucial for the evaluation of patients and kindreds in establishing the likely mode of inheritance.

2.3 Identifying Genetic Abnormalities Causing Monogenic Diseases

Traditionally, the identification of causative genes for Mendelian monogenic diseases involved characterization of the involved genes and then determining the DNA sequence alterations (i.e., mutations) either after: (1) cytogenetic analysis to detect chromosomal abnormalities, and/or (2) after studying affected kindreds for cosegregation with genetic markers (polymorphisms) to define the chromosomal location.[2,5] These "classical" gene-discovery approaches are now increasingly replaced by next-generation DNA sequencing of affected kindreds or patients (i.e., whole-exome or whole-genome approaches).[16,17] Together, these methods have defined the genetic basis of many monogenic skeletal disorders, which typically result from mutations affecting the coding sequence of their causative genes, which in turn compromise the gene's function.

2.4 Identifying Genes Causing Polygenic Traits

In contrast to Mendelian disorders, the genetic investigation of common polygenic traits (e.g., osteoporosis, osteoarthritis) have utilized increasingly large populations of cases and controls (or the extreme spectra of phenotype), which facilitate genome-wide association studies (GWAS).[2–5] Such studies typically involve direct or imputed genotyping of large numbers of common (e.g., minor allele frequency >5%) and infrequent (e.g., minor allele frequency 1%–5%) single nucleotide polymorphisms/variants (SNPs/SNVs) to identify genetic loci enriched for the trait. Usually, each variant is associated with modest effect sizes and is often under strong environmental influence. Most frequently, these loci are outside of gene coding regions, and therefore ascribing functionality may be challenging.[2–5] Candidate genes contributing to the trait are commonly selected from their proximity to the identified variant; for example, >100 candidate genes have been identified from GWAS studies investigating osteoporosis, although it is important to note that these large number of loci only account for a small percentage of the heritability of the trait.[2–5] This indicates that either many more additional common genetic variants with small effect sizes remain to be identified, or that rare variants with larger effect sizes may contribute. Alternatively, it is also possible that other mechanisms, such as epigenetic regulation (e.g., methylation status of specific genes) contribute to the heritability of specific polygenic traits, although investigating these mechanisms remains challenging (e.g., due to limited availability of relevant tissue for evaluation). For example, a recent genome-wide methylation study using cartilage tissue from a small number of patients with osteoarthritis, identified a number of differentially methylated genomic regions including several implicated in skeletal system morphogenesis and development.[18]

2.5 Molecular Insights From the Investigation of Monogenic Disorders and Polygenic Traits

In the clinical setting, the main value of genetic testing resides in the identification of information that may benefit the patient and wider family (Table 1.2). However, one of the major rewards of the genetic investigation of monogenic disease and polygenic traits has been the fundamental insights that they have provided into the molecular regulation of skeletal health and mineral homeostasis. In particular, these approaches have delineated roles for genes regulating key skeletal processes, which include: signaling pathways involved in bone development; maintenance of skeletal microarchitecture (i.e., through bone modeling and remodeling); and transmission of endocrine and paracrine signals. Indeed, bone and mineral health is orchestrated by a highly complex interplay of elements, which includes: matrix proteins; osteoclast and osteoblast function; hormones (e.g., parathyroid hormone, 1,25-dihydroxycholecalciferol); and developmental and regulatory transcription factors and signaling pathways.[2,5] Roles for several of these components have primarily been established through genetic investigation including the Wnt and osteoprotegrin (OPG)—receptor activator of NF-κB ligand (RANKL) signaling cascades.[2,5] For example, mutations in several Wnt pathway components are associated with monogenic disorders: autosomal-recessive loss-of-function mutations of the low-density lipoprotein receptor-related

TABLE 1.2 Value of Genetic Testing in Clinical Practice

Value of genetic testing in patients with skeletal and mineral metabolic diseases
Benefits for the patient
• Appropriate investigation and treatment of disease • Screening/surveillance for associated features not clinically apparent • Prognostic information regarding disease course
Benefits for first-degree relatives and/or progeny
• Identification of first-degree family members at risk of disease or those at risk of passing on to their progeny • Identification of family members who do not harbor the genetic abnormality thereby alleviating the anxiety and burden of disease from them and/or their progeny • Where appropriate, to enable preconception genetic counseling • Where appropriate, to enable prenatal diagnosis
Academic/research benefits
• Improved molecular characterization and understanding of associated disorder • Development of novel therapeutic targets/pathways
Potential future clinical benefits
• Advent of personalized medicine—matching therapies to genetic defects

protein 5 (*LRP5*) gene that encodes a key Wnt coreceptor, result in osteoporosis-pseudoglioma syndrome, while heterozygous activating mutations in *LRP5* result in autosomal dominant high bone mass.[2,5,19] Additionally, individuals with autosomal recessive loss-of-function mutations of the Wnt-β-catenin regulator sclerostin (*SOST*), manifest the sclerosing bone dysplasias sclerosteosis, while patients carrying a biallelic 52 kb deletion of an enhancer element downstream of the *SOST* gene express van Buchem disease.[20,21] Biallelic loss-of-function mutations of *WNT1* causes an autosomal recessive form of OI, while heterozygous carriers of such *WNT1* missense mutations develop autosomal dominant early-onset osteoporosis.[7,22] More recently, biallelic truncating mutations in secreted frizzled-related protein 4 (*SFRP4*), which encodes a soluble Wnt inhibitor, were reported in patients with Pyle's disease, a disorder characterized by cortical-bone thinning, limb deformity, and fracture.[23] Further supporting a key role in bone biology, many Wnt pathway components (>15 genes), including *LRP5* and *SOST*, have been identified as candidate genes from GWAS studies of BMD, and these genetic approaches are defining increasingly specific functions of Wnt components, including the discovery that *WNT16* is reportedly a key determinant of cortical bone strength.[2–5]

A similar overlap of genes implicated in monogenic and polygenic phenotypes is observed for members of the OPG/RANKL/RANK/NF-κB pathway, which is a major regulator of osteoclast differentiation and function. Thus, patients harboring mutations of the tumor necrosis factor receptor superfamily member 11B (*TNFRSF11B*), which encodes OPG, and *TNFRSF11A* that encodes RANK, manifest the monogenic disorders juvenile Paget disease (autosomal recessive) and familial expansile osteolysis and its variant disorders (autosomal dominant), respectively. Furthermore, both these genes (and other components of the OPG/RANKL/RANK/NF-κB pathway) have been identified from GWAS studies to be quantitative trait or loci associated with BMD.[2–5]

In addition to the investigation of common variants in polygenic traits, recent studies have established a role for rare and/or low-frequency variants with larger effect sizes, which provide additional insight into bone biology. For example, specific to the Icelandic population, a rare truncating variant of the leucine-rich receptor containing G-protein-coupled receptor (*LGR4*) gene was reported to be associated with a variety of phenotypic traits including low BMD and osteoporosis,[24] while two rare coding region variants in *COL1A2* were also identified in this population in association with low BMD.[25] A further study of individuals of European ancestry reported a low-frequency noncoding variant in close proximity to the Engrailed homeobox-1 (*EN1*) gene, which was associated with ~four- and ~threefold larger effect size on BMD and fracture risk, respectively, than previously reported common variants.[26] Furthermore, this and other studies support a key role for the *EN1* gene in bone biology, likely through an interaction with Wnt factors, and regulation of bone turnover, thereby highlighting the potential utility of these genetic approaches for investigating the molecular pathogenesis of skeletal and mineral metabolic diseases.[27,28]

2.6 Genetic Understanding and Application to Development of Novel Therapeutics

A principal aim of refined genetic characterization of skeletal disease and disorders or bone mineral homeostasis is the identification of genes and pathways that may be targeted therapeutically. The considerable overlap in genes identified from the investigation of monogenic disease and polygenic traits indicates that these genes and the pathways regulated by them, likely represent good candidates. Indeed, many existing therapies, as well as those in development, target key components identified from these studies. For example, the monoclonal antibody denosumab blocks RANKL within the OPG/RANKL/RANK/NF-κB signaling pathway to inhibit the formation and activity of osteoclasts, thereby inhibiting bone resorption.[5] Similarly, several drugs in development are directed at the Wnt pathway. This includes antisclerostin antibodies (e.g., romosozumab), which are being evaluated as an anabolic treatment for osteoporosis, with the aim of simultaneously increasing bone formation and inhibiting bone resorption through direct and indirect targeting of osteoblast and osteoclast function, respectively. Future drug and biologic development will surely include the targeting of genetically identified pathways, perhaps with greater specificity with the aim of personalized therapies. For example, the multinational approval in 2015 of the bone-targeted enzyme-replacement biologic asfotase-alfa to treat typically pediatric-onset hypophosphatasia, emphasizes the importance of determining the genetic, molecular, and biochemical basis for a skeletal/mineral metabolic disease.[15] Similarly, assessing treatment response according to genetic etiology has been investigated, as illustrated by a recent study, in which patients with early-onset low-turnover osteoporosis due to *WNT1* or *PLS3* mutations, were demonstrated to respond to teriparatide treatment.[29]

3 APPROACH TO THE PATIENT WITH GENETIC SKELETAL/MINERAL METABOLIC DISEASE

3.1 Clinical Approach

Skeletal and mineral metabolic disorders may present with an array of clinical symptoms and signs and

an awareness of the spectrum of potential phenotypes is key to appropriate assessment, further investigation, and treatment.[30–33] The diagnosis and treatment of these hereditary disorders requires clinical skill. Clinicians have at their disposal many biochemical and radiological tools to aid diagnosis, but they should be used judiciously and following the acquisition of a detailed personal and family history and the undertaking of a careful clinical examination.[34–37] The possibility of hereditary disease could tempt the physician into hasty genetic testing, but this should be avoided until as much relevant information has been acquired to ensure the maximum utility of the available tests. As the range and complexity of molecular genetic testing increases, selecting among them may be challenging and many factors need to be considered. In addition, the appropriate interpretation of genetic test results requires the physician to recognize and assess potential uncertainties and limitations. Finally, it is important to fully include the patient in decision-making processes and ensure that informed consent is acquired beforehand.

3.2 Medical History and Physical Examination

Diagnosis and treatment of metabolic and dysplastic skeletal disease, perhaps especially those that are heritable, begins by acquiring information that can come from the patient's stated medical history and the findings from thorough physical examination.[38] The importance of the medical history cannot be overemphasized. It determines if any of the many adverse exogenous factors that complicate dysplastic or metabolic bone disease will be uncovered. A questionnaire may be a beginning, but is hardly a substitute. Only by talking with his/her patient will the physician sense how knowledgeable this individual might be and judge the value of the information. Subsequently, the medical history should be reported as a narrative to capture the clinical problem(s). Paramount is orderly accumulation, documentation, and consideration of the information acquired directly from patients. This effort helps to disclose potentially important medical records, guide the physical examination, and laboratory studies including any genetic testing, and choose safe and effective therapy.

Most genetically based dysplastic and metabolic bone diseases are chronic conditions. The "history of present illness" may be lengthy, but provides infrastructure for diagnosis and therapy. Critical clues concerning etiology and pathogenesis should emerge perhaps with a glimpse at prognosis. Here the physician can learn if previous medical records, radiographs, laboratory tests, etc., can help in diagnosis and prognostication. Have the signs and symptoms been lifelong, or begun recently prompting very different diagnostic considerations and interventions? Has the patient been compliant with medical care; if not, will therapy be safe? With this effort, the physician can also provide the basis for sound clinical research. Physical examination can reveal a considerable variety of findings for diagnosis including skeletal deformities especially common and unique in children, but there are also complications, which may include bone abnormalities that require attention for successful treatment. The diagnosis of such a disorder may emanate from recognition of a single physical finding; for example, blue or gray sclerae (OI), large café-au-lait spots (McCune–Albright syndrome), premature loss of deciduous teeth (hypophosphatasia), hallux valgus (fibrodysplasia ossificans progressiva), alopecia in some patients with hereditary vitamin D-resistant rickets (vitamin D-dependent rickets, type II), brachydactyly (pseudohypoparathyroidism, type IA), or numerous surgical scars [multiple endocrine neoplasia (MEN) syndromes]. For some genetic metabolic bone diseases, a constellation of physical findings suggests the diagnosis; for example, rickets featuring craniotabes at birth, a rachitic rosary (enlargement of the costochondral junctions) appearing during the first year of life. In infancy or childhood, bowed legs, short stature, flared wrists, and ankles reflect metaphyseal widening. There can be Harrison's groove (rib cage ridging from diaphragmatic pull producing a horizontal depression along the lower border of the chest at costal insertions of the diaphragm). Although weight bearing typically bows rachitic lower limbs, knock-knee deformity may instead occur especially if the rachitic disturbance occurs during the adolescent growth spurt. In adults, skeletal deformation perhaps originating in childhood can cause much of the morbidity from metabolic bone disease. Bowing of the lower limbs predisposes to osteoarthritis, especially in the knees. Without a complete physical examination, these important problems may go unnoticed.

3.3 Family Medical History for Determining Mode of Disease Inheritance

Many mineral metabolic and skeletal disorders have a monogenic etiology, and this may be suspected because of an early age of onset, occurrence of other abnormalities consistent with a syndromic disease, or a family history of the disease. The "family history" (or FH) concerning metabolic bone disease is vital for revealing the mode of inheritance of the disorder (Fig. 1.1). For example, consanguinity that is apparent, or inapparent involving geographical location and a "founder" mutation, can be an important clue for autosomal recessive conditions; whereas the autosomal dominant disorders may be disclosed by prior or prospective study of relatives [e.g., familial benign (hypocalciuric) hypercalcemia or OI]. Inborn errors of vitamin D bioactivation or resistance are rare, and the FH may be key to considering

one, because of national or ethnic background. Furthermore, significant information can come from screening studies to identify and treat or counsel affected relatives who may provide important clues to the patient's future complications and prognosis, or represent "carriers." Medical records from similarly affected living or deceased family members may establish the diagnosis, guide prognostication, and indicate a safe and effective treatment. Reporting that the FH is "negative" without first considering the basis for this information might be misleading. If the patient is adopted, he/she is less likely to give useful details. Knowing the size of the family is essential before dismissing possible transmission of a heritable disorder. The only child of only children, or the patient from a disrupted family, is not as likely to disclose a heritable disorder as one from a large cohesive kindred.

A detailed FH will help to reveal a pattern of inheritance that will provide critical clues regarding the mode of Mendelian inheritance (Table 1.1, Fig. 1.1). Thus, in autosomal dominant diseases, the affected person (unless a "new mutation" sporadic case) will have one affected parent and the disease occurs in both sexes and may be transmitted by the father or mother. In autosomal recessive diseases, which affect both sexes, the affected person is usually born to asymptomatic "carriers" who may be related (i.e., consanguineous). In X-linked recessive diseases, only males are usually affected, who are born to often unaffected parents of whom the mother is an asymptomatic carrier with affected male relatives, and there is no male-to-male transmission. In X-linked dominant diseases, both males and females are affected, although the females are typically more mildly and variably affected than males, and 50% of children (girls and boys) from an affected woman will have the disease, and 100% of the daughters, but 0% of sons, of an affected man will have the disease. In Y-linked diseases, only males are affected, and the affected males will have an affected father (patrilineal), and all the sons of an affected man will be affected. Mitochondrial (non-Mendelian) inherited disorders can affect both sexes and are transmitted only by an affected mother in her mitochondrial, not genomic, DNA. This is because the small volume of a sperm precludes it from contributing mitochondria to the zygote, and thus all mitochondrial DNA is inherited from mothers (i.e., matrilineal inheritance). These patterns of inheritance may be complicated by: nonpenetrance or variable expression in autosomal dominant disorders [e.g., MEN type 1 (MEN1)]; imprinting whereby expression of an autosomal dominant disorder depends whether it is maternally or paternally transmitted (e.g., pseudohypoparathyroidism type 1A and pseudopseudohypoparathyroidism); anticipation, whereby some dominant disorders become more severe (or have earlier onset) in successive generations; pseudodominant inheritance involving autosomal recessive disorders reappearing in successive generations within small-/medium-sized populations; and mosaicism in which an individual, who has developed from a single fertilized egg, has two or more populations of cells with different genotypes because of postzygotic mutations (e.g., McCune–Albright syndrome). However, germline mosaicism within eggs or sperm, arising from somatic mutation during gametogenesis, may lead to diagnostic and recurrence risk confusion, because seemingly unaffected parents may have multiple affected offspring, suggesting autosomal recessive inheritance but actually reflecting an autosomal dominant disorder (e.g., OI II). Similarly, separating individuals with apparent polygenic disease traits from those with monogenic disease may be difficult, and may only be revealed by the acquisition of a full family history. In summary, these patterns of inheritance, which can help to establish a genetic disorder in a family and identify additional individuals at risk of disease, may only be elucidated by taking a detailed family history.

4 CURRENT GENETIC TESTS, THEIR CLINICAL UTILITY, AND INTERPRETATION

4.1 Clinical Value of Genetic Testing

The identification and delineation of a genetic basis for a patient's disorder has many potential benefits (Table 1.2). They include the appropriate investigation and treatment of the disorder, as well as evaluating the patient for any associated features that may not be clinically apparent at initial evaluation. For some individuals, a genetic diagnosis may offer prognostic information and also facilitate appropriate genetic counseling, as well as the testing of relatives who may be asymptomatic "carriers." Furthermore, family members found not at risk of the disease (or of passing the disease to their children) can be reassured. For parents with children affected with significant skeletal disease, the identification of a genetic diagnosis may facilitate appropriate preconception genetic counseling and/or prenatal genetic testing in future pregnancies. As emphasized earlier, genetic testing may also directly or indirectly lead to an improved understanding of disease pathogenesis, which in turn may ultimately provide avenues for novel drug discovery and personalized treatment approaches.[3–5]

4.2 Pretest Considerations—Which Test?

Several factors must be considered before requesting genetic testing. These include: the phenotype of the patient in question, likely mode of inheritance, availability of additional pedigree members to aid the diagnosis, and

potential type(s) of genetic abnormality present. Indeed, the ability to undertake sequencing of "trios" (i.e., both parents and the affected offspring) may allow the identification of autosomal recessive, compound heterozygous, or de novo mutations in the patient, which might not be possible in the absence of parental samples.[39]

Many types of genetic abnormality [e.g., single gene defect, copy number variation (CNV), or aneuploidy] may result in skeletal or mineral metabolism disease. Thus, most monogenic disorders typically involve either SNVs or small insertions or deletions (indels) affecting the coding region of a given gene. For example, disease-associated SNVs typically result in nonsynonymous amino acid substitutions, nonsense mutations (i.e., resulting in the introduction of a stop codon), or splicing defects (i.e., due to disruption of donor or acceptor splice sites at the intron/exon boundary); in contrast, indels frequently disrupt protein function through either in-frame or out-of-frame insertions or deletions leading to either the insertion or loss of one or more amino acids, or an alteration in both the amino acid sequence and stop codon location, respectively. The detection of the majority of these monogenic defects will typically require high-resolution DNA sequencing for their identification. However, whole or partial gene deletions (see later) may also account for a variable percentage of patients with monogenic syndromes, which may go undetected by direct sequencing methods. In contrast to small genetic changes responsible for the majority of monogenic disease (i.e., SNVs, indels) some disorders are characterized by marked chromosomal abnormalities. This may include an alteration in the correct number of chromosomes (e.g., aneuploidy in Turner's syndrome), CNVs, which represent large gains or losses of genetic material (e.g., deletion on chromosome 15 in Prada–Willi syndrome), or other structural variants including translocations or inversions. The detection of these large-scale genomic abnormalities has typically involved approaches (e.g., karyotyping) other than direct DNA sequencing, although these are now increasingly identified by next-generation sequencing (NGS) methods [e.g., whole genome sequencing (WGS)].

When undertaking genetic testing it is important to remember that a negative result does not necessarily exclude the presence of genetic disease but rather may reflect: an alternative genetic etiology to the one being tested; limitations of the genetic methodology employed (i.e., inadequate resolution or coverage); or incorrect assumptions regarding the clinical phenotype or mode of inheritance. Details of some of the available tests are provided in Table 1.3. The most appropriate genetic approach is likely to be governed by the estimated pretest probability of identifying a defect in a given gene. For example, where the clinical presentation points to a likely causative gene, single gene sequencing may be appropriate, whereas, when the potential genetic etiology is broad or unknown, the sequencing of multiple genes or genome-wide approaches may be required. Additional considerations may include cost, availability of NGS platforms, and access to bioinformatic expertise.

Currently, genetic testing for those with apparent solitary polygenic traits (e.g., reduced BMD) is rarely indicated, although it may occasionally be used if specific features in the history, examination, or investigation (i.e., early age of onset, family history, atypical clinical features), indicate a significant genetic component. In the future, genetic testing based on genotyping of large numbers of risk alleles may be developed to stratify future risk of bone disease (i.e., fracture risk), although to date the evaluation of such tools has not proved clinically useful, and this likely reflects the relatively modest amount of heritability such loci currently explain, and the limited proportion of variants associated with BMD that are also associated with osteoporotic fracture.[40,41]

4.3 Detection of Chromosomal Abnormalities, Copy Number Variations, and Mutations Causing Disease

An increasing number of molecular genetic tests are available to the clinician, and it is important to note that many of the tests can have overlapping utility. Thus, selecting the most appropriate test(s) requires understanding of both the resolution of the test and its potential limitations. A brief description of the main molecular genetic tests currently available is provided below.

4.3.1 Karyotype

Conventional karyotyping is frequently the first test to evaluate for major chromosomal abnormalities including aneuploidy (i.e., abnormal number of chromosomes), insertions, deletions, duplications, inversions, or reciprocal translocations.[42,43] Such abnormalities may be suspected in the presence of major congenital abnormalities, marked developmental delay, or features of a specific chromosomal abnormality disorder. Typically, karyotyping is performed using peripheral blood leucocytes (isolated from a heparinized blood sample), which are initially cultured, prior to evaluation by high-resolution G-banding (Giemsa staining) of at least 20 metaphase nuclei. The evaluation of multiple cells not only allows a reliable assessment of each chromosome, but also facilitates the identification of mosaicism.[42,43] Occasionally, evaluation of tissues other than blood is required to identify forms of mosaicism (e.g., fibroblasts). Although high-resolution G-band karyotype analysis will identify the majority of major chromosomal defects, its resolution is limited to ~5–10 Mb of DNA, and will therefore not identify smaller abnormalities (e.g., CNVs).[42,43]

TABLE 1.3 Examples of Genetic Tests, Their Molecular Resolution, and Utility

Genetic test	Resolution	Abnormalities detected	Additional notes
Detection of chromosomal abnormalities including CNVs			
Karyotype: G-banding (trypsin-giemsa staining)	5–10 Mb	Aneuploidy Large chromosomal deletions, duplications, translocations, inversions, insertions	Limited resolution Requirement to study many cells to detect mosaicism
Fluorescence in situ hybridization (FISH)	50 kb–2 Mb (dependent on size of probes employed)	Structural chromosomal abnormalities (e.g., microdeletions, translocations)	Labor-intensive Low resolution limits its use Unsuitable where unknown genetic etiology
Multiplex-ligation probe amplification (MLPA)	Probe dependent 50–70 nucleotides Single exon deletion or duplication possible	CNVs including (partial) gene deletions or duplications)	Low cost, technically simple method Simultaneous evaluation of multiple genomic regions Not suitable for genome-wide approaches Not suitable for analysis of single cells
Array comparative genomic hybridization (aCGH)	10 kb (high resolution) 1 Mb (low resolution) (dependent on probes set)	Genome-wide CNVs	Inability to detect balanced translocations Useful for detection of low level mosaicism
Single nucleotide polymorphism (SNP) array	~50–400 kb (dependent on probe set)	Genome-wide detection of SNP genotypes CNVs	Inability to detect balanced translocation Useful for detection of low level mosaicism Detection of copy number neutral regions of absence of heterozygosity (i.e., due to uniparental disomy)
Detection of monogenic disorders (and *CNVs*)			
First-generation sequencing (Sanger)			
Single gene test	Single nucleotide (exonic regions and intron/exon boundaries of candidate gene)	SNVs Small insertions or deletions (indels)	Relative high cost/base May miss large deletions/duplications Unsuitable where unknown genetic etiology
Next-generation sequencing			
Disease-targeted gene panels	Single nucleotide (exonic regions and intron/exon boundaries of candidate genes)	SNVs Small insertions or deletions (indels)	May lack complete coverage of exomic regions (may require Sanger sequencing to fill in "gaps") Increased likelihood of identifying variants of uncertain significance (VUS) as number of genes increases Unsuitable where unknown genetic etiology
Whole exome sequencing (WES)	Single nucleotide (all exonic regions and intron/exon boundaries)	SNVs Small insertions or deletions (indels) CNVs	Not all exons may be covered/captured Difficulties with GC-rich regions and presence of homologous regions/pseudogenes Small indels may not be captured Bioinformatic expertise required for data analysis High likelihood of IFs and VUSs Detection of CNVs requires additional data analysis (i.e., LOH mapping across exonic regions) Suitable for disease-associated gene discovery
Whole genome sequencing (WGS)	Single nucleotide	SNVs Small insertions or deletions (indels) CNVs (Translocations/ rearrangements)	Relative high cost Large data sets generated and complex data analysis requiring bioinformatic expertise Very high likelihood of IFs and VUSs CNV analysis possible but may present specific challenges Suitable for disease-associated gene discovery

CNVs, Copy number variations; FISH, fluorescence in situ hybridization; IFs, incidental findings; LOH, loss of heterozygosity; WES, whole exome sequencing; WGS, whole genome sequencing.

4.3.2 Fluorescence In Situ Hybridization (FISH)

The detection of chromosomal abnormalities and genomic imbalances not detected by a conventional karyotype requires alternate methods. Fluorescence in situ hybridization (FISH) is a technique that employs molecular DNA probes, which are designed to hybridize to specific target regions on metaphase chromosomes, enabling visualization under a fluorescence microscope.[42,43] A variety of chromosomal abnormalities may thus be identified resulting from: the absence of probe binding (e.g., due to a deletion), additional probe binding (e.g., due to a duplication), or probes binding to an aberrant chromosomal region (e.g., due to a translocation or inversion). The molecular resolution of FISH depends on the size of probes used but is typically in the region of 50 kb–2 Mb. The major limitation is that it does not allow genome-wide analysis, but rather is very narrowly limited to detecting abnormalities covered by the probe sets. Alternate FISH-based methods that allow the simultaneous evaluation of several regions of interest have been developed including use of whole-chromosome painting probes [termed multiplex FISH (M-FISH) and spectral karyotyping], with each chromosome labeled a different color.[42,43] While such techniques allow the identification of interchromosomal abnormalities including translocations, they will not identify small deletions, duplications, or inversions.[42,43]

4.3.3 Multiplex-Ligation Dependent Probe Amplification (MLPA)

Multiplex-ligation dependent probe amplification (MLPA) is a method that employs a pool of custom-designed probes to specific genomic regions of interest, and is used to detect specific small chromosomal abnormalities (i.e., single or partial gene deletions).[42] Adjacent probes hybridize to each other and undergo ligation followed by polymerase chain reaction (PCR) amplification of the ligated product, with products separated by electrophoresis. Detection of abnormalities is dependent on the probes employed, which are typically designed to identify specific small gene deletions (e.g., *MEN1* partial or complete deletion). In addition, MLPA may be used in specific circumstances to evaluate for alterations in methylation [e.g., pseudohypoparathyrodism 1b (PHP1b) in which deletion of one or more of four differentially methylated regions is typically observed].[11]

4.3.4 Whole Genome Arrays

The use of whole genome arrays negates the requirement for prior knowledge of the likely chromosomal abnormality responsible for the clinical phenotype.[42,44] Their increased resolution has transformed the field of molecular cytogenetics; although this resolution presents several challenges, not least the recognition that all healthy individuals harbor small CNVs (e.g., 5–10) without any discernable impact on health, while several apparently pathogenic CNVs do not result in disease in all individuals because of reduced penetrance.

4.3.5 Microarray-Comparative Genomic Hybridization (aCGH)

The use of microarray-comparative genomic hybridization (aCGH) for clinical "molecular karyotyping" is increasingly popular and is often employed as a first-line test to detect small chromosomal abnormalities (i.e., CNVs), particularly in young children with early developmental delay, congenital abnormalities, abnormal growth, or additional features, such as autism or epilepsy. The technique of aCGH is based on comparing the DNA from the patient (i.e., from an EDTA blood sample) with that of a control sample. In practice, the patient's DNA is fragmented and compared with a set of immobilized control DNA sequences, which have been deposited on the array platform.[42–44] The resolution of the test will depend on the number and distance between the DNA clones selected on the array. The analysis is performed by mixing the patient's sample (DNA labeled green) with a reference sample (DNA labeled red), prior to applying the samples to the array platform for competitive hybridization with the immobilized reference DNA fragments. Automated analysis of the array measuring red–green fluorescence enables the identification of deletions (appearing as an excess of red) and duplications (appearing as an excess of green) in the patient's sample.[42,44] Interpretation of the result may be challenging and needs to take into account the size and location of the deletion or duplication, whether it has occurred de novo, and whether the region contains genes of known importance (i.e., deletion of a known haploinsufficiency gene).

4.3.6 Single Nucleotide Polymorphism Arrays

SNP arrays, which were originally designed for genotyping a patient's DNA for GWAS and cosegregation studies to determine linkage between a disease locus and a chromosomal region, can also be used to detect CNVs.[42] For example, deletions (or uniparental disomy) spanning several of adjacent SNPs included on the array will demonstrate loss of heterozygosity (LOH), while copy number gains (e.g., duplication) may be detected by the automated identification of an increased number of different genotypes.[42] The resolution of the array will depend on the number of SNPs included (and their relative spacing). Furthermore, SNP array platforms may now also include a large number of probes specifically for the detection of CNVs. SNP and aCGH arrays provide accurate tools for detecting small deletions and duplications, although they will not be able to detect balanced translocations.

4.3.7 Single Gene Testing (Sanger Sequencing)

The sequencing of a patient's DNA for abnormalities in a single or small number of genes by the Sanger method of DNA sequencing (first-generation sequencing) has been the mainstay of clinical genetic testing for monogenic disorders over the past 20 years.[16,17] In this process individual DNA fragments up to a 1000 bp in length are amplified by using the PCR, followed by a process in which a single primer is employed to initiate a reaction employing DNA polymerase to add nucleotides according to the complementary DNA strand, while randomly incorporating terminator nucleotides which harbor nucleotide-specific fluorescent labels.[16,17] This results in a mix of DNA fragments of varying length, which may be resolved by gel electrophoresis, and the sequence established from the resulting chromatogram. Sequencing reactions are typically designed to include the coding region (exons) and splice sites (intron–exon boundaries) and may also include regulatory regions [e.g., parts of the promoter, as well as 5′ and 3′ untranslated regions (UTRs)]. The high fidelity of DNA polymerase results in a high degree of accuracy such that Sanger sequencing achieves a base accuracy of >99.99%, and remains the gold standard for DNA sequencing. Indeed the advantages of this method include the ease of data interpretation and reliability of the method. However, the process is only cost effective for the evaluation of single or very small numbers of genes and is of limited value when there is weak support for a given genetic etiology.[16,17]

4.3.8 Next-Generation Sequencing or Second-Generation Sequencing

The scale, speed, and declining cost of NGS approaches has provided a paradigm shift in both the investigation and diagnosis of genetic disease and is increasingly incorporated into routine clinical care. While the principles of NGS do not differ markedly from those of Sanger sequencing (i.e., utility of DNA polymerase to incorporate fluorescently labeled nucleotides into a template DNA strand), the fundamental difference is that rather than being limited to individual DNA fragments, NGS enables simultaneous sequencing of millions of DNA fragments (i.e., "massively parallel sequencing").[16,17] Furthermore, the amount of DNA required for such a procedure is very small, so that a typical EDTA blood sample (i.e., 5–10 mL) provides far in excess of that required. The typical workflow comprises several stages: first, the DNA sample undergoes random fragmentation, followed by the addition of adapters at each end of the fragments. The resulting fragments are denatured and PCR amplified prior to immobilization on a surface by oligonucleotides complementary to the adapter sequences. The fragments then undergo amplification to form small clonal clusters, which then progress to sequencing. The sequencing process, referred to as "sequencing by synthesis", results from the incorporation of fluorescently labeled nucleotides, which enables the identification of single bases as they are incorporated into the DNA template strand.[16,17] In contrast to Sanger sequencing the incorporation of the labeled nucleotide does not terminate the reaction and thus the sequence is established through successive cycles of nucleotide addition captured by an automated camera. Typically both ends of the fragments are sequenced in a process known as "paired end sequencing," which aids the final part of the process in which the sequence reads are aligned with a reference genome.[16,17] These principles form the basis for the three most widely employed uses of NGS: WGS, whole exome sequencing, (WES) and disease-targeted gene panels.

WGS: WGS represents the most comprehensive DNA sequencing approach as it spans the entire genome including coding and noncoding regions.[16,17] While particularly suited to the identification of SNVs and small indels, it may also be used to detect CNVs although this requires increased bioinformatics expertise. Sufficient depth of coverage is required when used in the clinical setting (i.e., ~100× coverage of each base). The inclusion of all genomic regions allows the detection of mutations in both coding regions and regulatory regions (e.g., enhancers, promoters) which may not only aid diagnosis but may provide new insights into mechanisms of gene regulation. However, the inclusion of the entire genome results in several challenges, not least the huge amount of data generated and the requirement for bioinformatics expertise in its analysis. Thus, WGS remains expensive, and the frequent need to include additional family members to aid variant interpretation further increases the cost. Other limitations include difficulties sequencing parts of the genome (i.e., GC-rich regions), while highly homologous regions of DNA (e.g., due to pseudogenes) may lead to difficulties in aligning sequence reads to the reference genome. Finally, WGS will identify huge numbers of variants (i.e., ~4 million) many of them unique (i.e., never encountered in reference genomes) whose interpretation may lead to considerable diagnostic uncertainty.[16,17] The value of WGS to identify both rare coding and noncoding variants associated with skeletal phenotypes including BMD has recently been demonstrated.[24,26]

WES: In contrast to WGS, WES focuses its sequencing efforts on the 1%–2% of the genome which encodes the ~20,000 protein coding genes (i.e., the "exome") on the premise that these regions will most likely harbor disease-associated

mutations. Indeed, WES has been the mainstay of highly successful disease–gene discovery studies over the past decade, including the identification of several genes responsible for skeletal dysplasias and metabolic bone disorders [e.g., *WNT1* and *SEPINF1* mutations as rare causes of OI; *SFRP4* mutations in Pyle's disease; adaptor protein 2 sigma subunit (*AP2S1*) mutations in FHH type 3; and *PLS3* mutations in X-linked osteoporosis].[7,8,12,23,45] Thus, a major benefit of WES has been the identification of the genetic etiology of several monogenic skeletal diseases even in the absence of prior genetic linkage. Furthermore, the more manageable amount of sequence data makes analysis more straightforward, although this still may present challenges (see later). WES is achieved through an additional early step in the NGS workflow in which, following DNA fragmentation, probe sets are used to capture only the exomic regions, prior to sequencing. However, the capture may not be complete (e.g., missing exons, uneven capture due to SNPs or indels) and this needs to be considered during analysis.[16,17] Similar to WGS, GC-rich and highly homologous regions may present difficulties, while the lack of coverage of noncoding regions will exclude the identification of mutations occurring in regulatory regions. WES may also be used for the detection of large CNVs (e.g., by LOH mapping) but has deficiencies in detecting small deletions or insertions particularly if involving gene-sparse regions. Relative to WGS, WES is inexpensive and is increasingly a cost-effective approach to clinical diagnosis.

Disease-targeted sequencing: The broadest use of NGS sequencing in the clinical arena is that of targeted gene sequencing to enable the simultaneous analysis of a collection of genes specifically selected as relevant to a given disease presentation. The principle is similar to that of WES, but only specific genes of interest undergo capture with custom-designed probes.[16,17,46] Potential advantages of this approach include: the reduced cost; simplified data analysis; and the simultaneous evaluation of multiple genes that enables a rapid turnaround time, when compared to the sequential analysis of genes by Sanger sequencing. It also avoids or reduces the likelihood of several of the issues associated with WES and WGS including the identification of incidental findings (IFs) (i.e., mutations or abnormalities in genes independent from the initial reason for undertaking genetic testing). However, its limitations include the requirement to know in advance the potential causative genes (i.e., unsuitable for "gene-discovery" studies) and as the number of genes increase the likelihood of identifying variants of uncertain significance (VUSs) increases. However, the use of disease-targeted panels continues to gain increasing traction with many now offered in the field of skeletal dysplasia and metabolic bone disease (registered diagnostic genetic testing providers may be found at: https://www.ncbi.nlm.nih.gov/gtr/). For example, NGS disease-targeted panels have been established for OI, skeletal dysplasia, high and low BMD phenotypes, mineralization defects including hypophosphatemic rickets, and many others.[14] The number of genes included in such panels varies considerably from <10 to >150 genes. The utility of such panels depends on the clinical scenario. For example, when referred a child for whom OI is suspected because of severe skeletal fragility yet no *COL1A* or *COL1A2* mutation has been detected, additional genetic testing employing a skeletal-fragility gene panel may provide a useful and cost-effective approach.[5,14]

4.4 Challenges of Data Interpretation and Approaches to the Analysis of Variants Identified by NGS Platforms

A major challenge arising from the increasing clinical and research application of genetic testing, including the use of each of the main NGS platforms, is accurate data interpretation. For example, WES and WGS may require the analysis of hundreds of SNVs, while disease-targeted gene panels may also identify several different SNVs in plausible candidate genes, and in each case the relevance to the clinical phenotype needs to be determined. In these settings, ascribing pathogenicity to individual variants may be challenging and as a result, guidelines have been recommended by several international bodies suggesting a systematic approach to variant analysis. These guidelines recommend that all variant classification systems utilize the terms "pathogenic," "variant of uncertain significance (VUS)," and "not pathogenic or benign," and that evidence for pathogenicity is gathered from multiple sources.[47,48] In addition, an increasing number of computational tools are now available to aid the analysis of variants, which can be utilized both in the clinical and research setting, although an over-reliance on such tools in the absence of robust clinical and/or functional support may result in inaccurate estimates of pathogenicity. These potential considerations and processes that are typically included in the variant identification and interpretation pipeline are briefly reviewed, below.

4.4.1 Variant Identification

For all NGS platforms, sequencing is followed by a series of analyses to map the data and identify variants. This begins with the alignment of the sequence reads to a reference genome, which should be obtained from a

reputable source, such as the Genome Reference Consortium human genome (GRCh). Several tools can be utilized to align sequences to reference genomes (e.g., BWA-MEM, Bowtie2, and Novoalign) and a combination of these tools is recommended to improve accuracy.[49] These tools estimate the probabilities of possible genotypes at each locus, based on quality scores of the reads and the number of times an allele has been observed. As such, a high depth of coverage is advantageous in accurate alignment. Annotation of SNPs is then performed using variant calling tools, of which the Genome Analysis Tool Kit HaplotypeCaller (GATK-HC), Samtools mpileup, Freebayes, and Torrent Variant Caller are widely used.[49] However, there may be discrepancies between these tools, including biases toward the detection of certain variant types, which may result in false positive annotations. Thus, employing a combination of tools is recommended, and caution is required when examining results, such that variants identified as pathogenic or to be further investigated should be verified by an alternative sequencing technique, like Sanger DNA sequencing.

4.4.2 Variant Interpretation

Following the identification of one or more SNVs from the initial variant calling algorithm, further analysis is required to identify those that may be relevant to the disease phenotype. Although the pipeline used to interrogate variants will vary according to whether the sequencing is being performed for clinical testing of known disease genes (e.g., OI or skeletal dysplasia gene panels), or for exploratory studies to investigate novel phenotypes, the principles for ascribing potential pathogenicity are similar (Fig. 1.2). In most instances it is reasonable to exclude all synonymous variants from further analysis (i.e., those not changing the amino acid sequence of the encoded protein). The initial analysis of nonsynonymous variants should consider and report the frequency of the variant in large population databases including dbSNP, 1000 Genomes, Exome Aggregation Consortium, and the Exome Variant Server.[47,48,50,51] A frequency of >1% in such databases indicates that the variant is a likely benign polymorphism and therefore unlikely to be pathogenic. This is particularly pertinent in rare diseases in which the frequency of a variant in the population database should not exceed that within the disease population.[50] Furthermore, for disorders that are fully penetrant, the presence of the identified variant at a frequency of >1% within control population databases indicates that it is unlikely to be disease causing.[47,50] However, the presence of variants at low frequencies (<1%) in these databases does not exclude their pathogenicity as the databases may contain representative individuals from the disease population (e.g., The Cancer Genome Atlas).[47] In addition to these population databases, clinical variant, and disease databases (e.g., ClinVar, Human Gene Mutation Database) should be consulted to determine if the gene has previously been linked with the condition.[51] A degree of caution must be exercised with many such databases because robust support for the pathogenicity of variants is often absent, and many do not undergo regular curation leading to inaccuracies. Where possible the primary source of information supporting previous reports of variant pathogenicity should be consulted.[47,51] Meanwhile, determining whether the variant segregates only with affected family members is key to attributing disease causality. Segregation in close family members is not evidence of causality per se, as the variant may actually be in linkage disequilibrium with the causative gene, and thus samples should be sought also from distant family members if possible. Likewise, in the research setting, prior cosegregation studies in a family, which may have identified putative chromosomal locations shared by affected individuals, may markedly narrow the focus on specific variants.

Further investigation of variants for likely functional effects relies on an assessment using computational tools and/or employing in vitro and or in vivo assays. Thus, variants can be subdivided into: those that are missense, nonsense, or frameshift variants; those within exons and introns predicted to affect splice sites; and those within UTRs. One can then assume that nonsense, frameshift, and splicing mutations that lead to whole exon deletions are more likely to be pathogenic. However, the biological function of the gene must also be considered as some diseases are only caused by heterozygous missense mutations, while many genes harbor high frequencies of heterozygous null variants without any detrimental effect on health.[47] Similarly, truncating or frameshift mutations that affect the extreme 3′ end of a gene are less likely to be pathogenic as key functional domains of the protein may be retained.[47,48] For splice-site variants, the variant may lead to exon skipping, exon truncation, or use of an alternate donor or acceptor site and a number of freely available programs may be employed to predict whether a coding or intronic variant is likely to influence splicing (Alternative Splice Site Predictor, The Human Splicing Finder), although confirmation of a functional effect is usually required to verify this. For variants in UTRs, the possibility that there is disruption of a promoter or microRNA binding site should be considered, and this can be predicted using online tools (mirdb, UCSC Genome Browser).[47,48]

For missense variants a number of computational predictive software packages examine different parameters; for example, SIFT uses evolutionary conservation, Polyphen-2 and MutationTaster use combined protein structure–function and evolutionary conservation, while Provean predictions are based on multiple

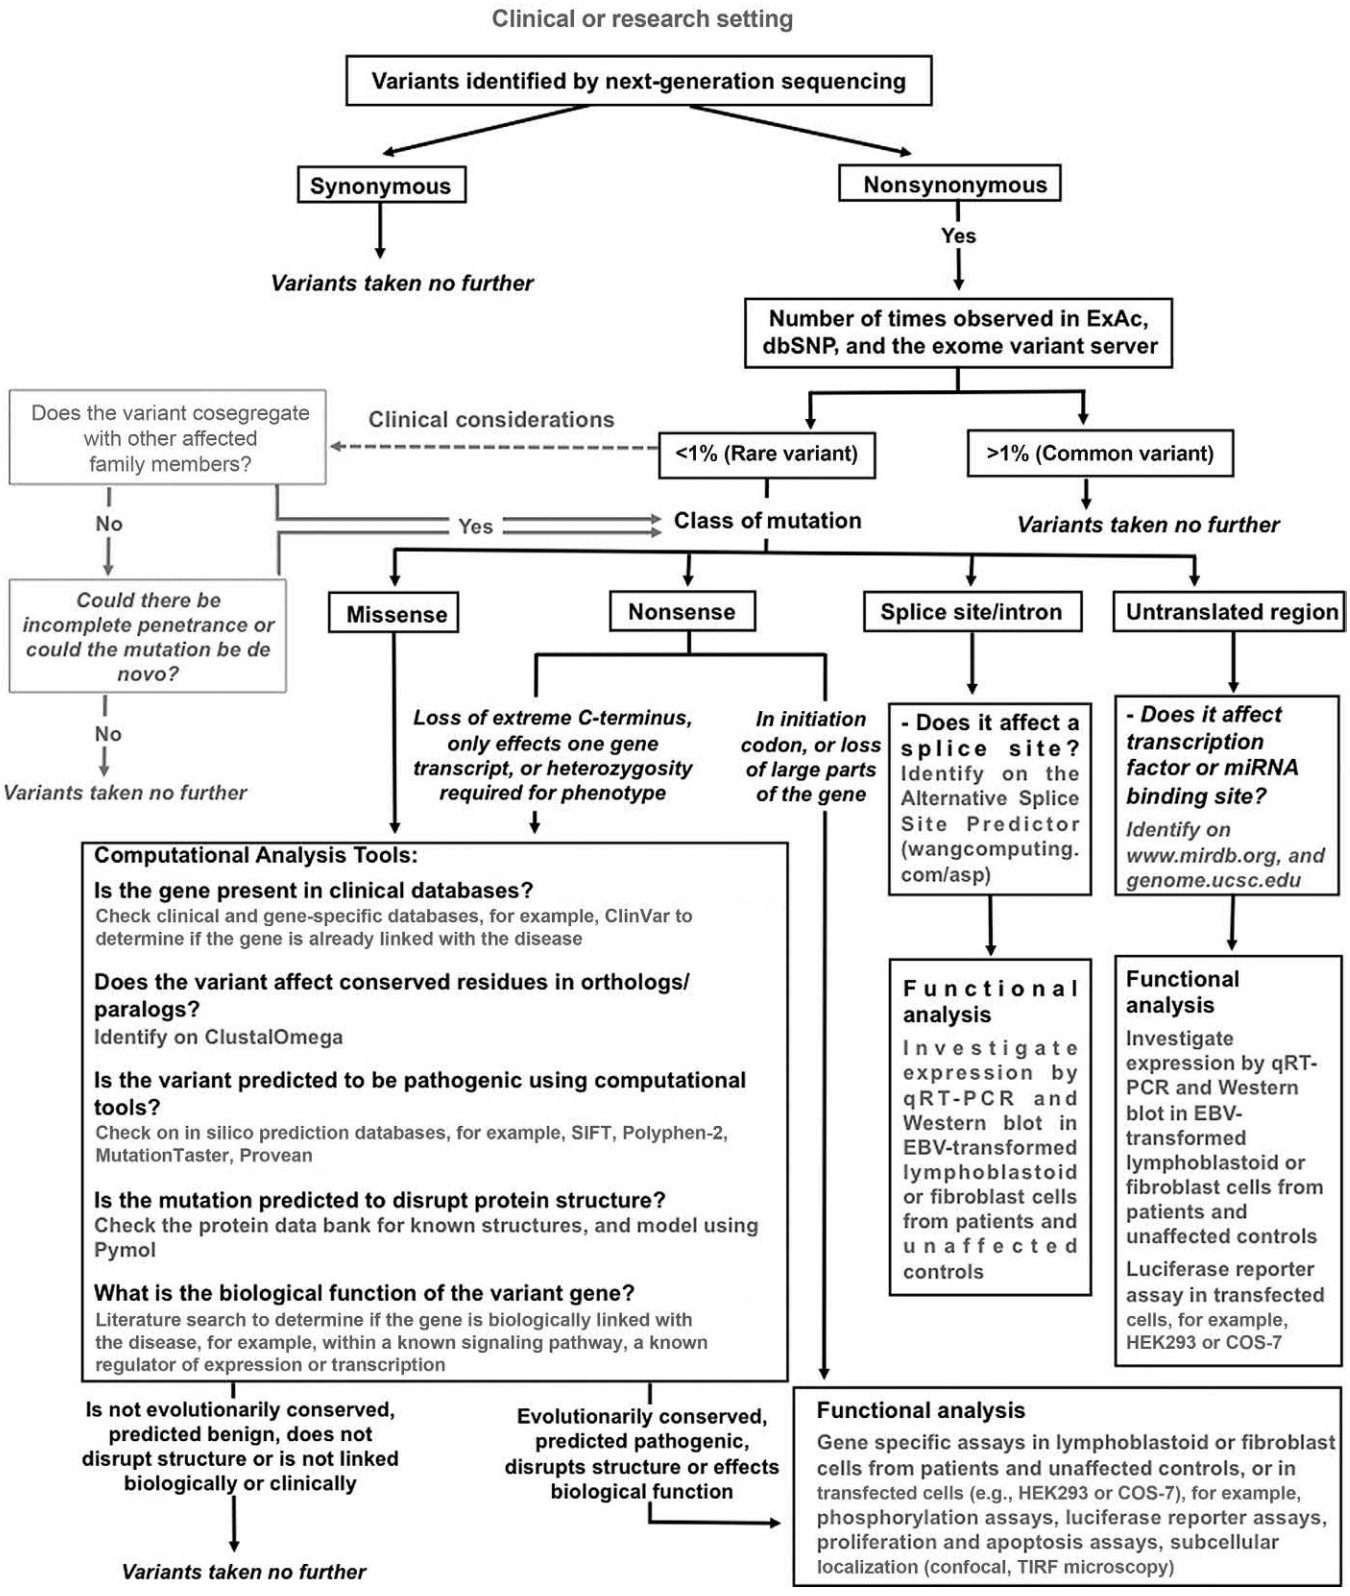

FIGURE 1.2 **Flow diagram outlining methods to assess the potential pathogenicity of genetic variants identified by next-generation sequencing (NGS).** Within the clinical or research setting, variants identified by NGS platforms require a systematic approach to ascribing potential pathogenicity. Initially, single nucleotide variants (SNVs) are broadly categorized into synonymous or nonsynonymous variants, with synonymous variants typically excluded from further analysis. For evaluation of nonsynonymous variants, an evaluation of the population frequency is an essential step, typically allowing the exclusion of variants which are observed with an allele frequency of >1%. Concurrently, it is important to consider the clinical evidence for the pathogenicity by evaluating whether the variant cosegregates with affected individuals in the kindred (i.e., all affected should harbor the variant) or occurs in regions shared by affected individuals from prior positional cloning studies. Variants are then divided by functional type into missense, nonsense, splice site variants, or those affecting untranslated regions (UTRs), as approaches to analyses differ for each variant class. For missense and nonsense variants, a number of computational analysis tools exist to examine frequency in clinical populations, evolutionary conservation and the effect on protein structure. While these can be informative, they should not be used as the only indicator of pathogenicity as they have low specificity. In the absence of very strong support for pathogenicity (e.g., nonsense mutation in gene in which similar mutations previously confirmed as disease causing, or clear enrichment for variant in disease cohorts relative to controls) variants suspected of being pathogenic should be analyzed functionally using an appropriately designed assay.

sequence alignment.[47] Although these algorithms can assess the pathogenicity of a variant, studies of known disease-causing variants using in silico predictive tools have shown that this is only 65%–80% accurate.[52] Thus, protein-prediction software cannot be the sole provider of evidence supporting pathogenicity in the clinical or research settings. Identification of evolutionary conservation or location of the variant residue within a critical structural domain of the affected protein can also provide evidence that a variant may be pathogenic. Several computational tools are available to assess these parameters including ClustalOmega that can align sequences based on homology, the Protein Data Bank that catalogs published protein structures, and Pymol that can be used to model structures downloaded from Protein Data Bank. In the research setting, an important consideration in the analyses of variants identified by NGS in genes not previously associated with disease is establishing the plausibility of the gene being disease causing. A literature search should be performed to determine the biological function of the affected gene. For example, if the gene is known to regulate a signaling pathway already known to be important in the condition (i.e., Wnt or OPG/RANKL/RANK/NF-κB pathway in many skeletal disorders), or if the gene regulates expression or transcription of pathway genes, this provides support to the likely pathogenicity.

Once a variant has been assessed by these bioinformatics tools and still remains a plausible candidate, functional analysis should be performed. Some care must be taken to select the appropriate experimental technique and this may depend on: the type of variant (e.g., splice site variants are best assessed by measurement of RNA and protein expression, while missense mutations may require functional cellular assays); the tissue affected in the disease; and the availability of samples.[53] Ideally assessments should be made in patient tissue where possible, for example in cell lines derived from lymphoblastoids or skin fibroblasts, or histological sections of tissues removed by biopsy or surgery. In choosing an in vitro assay the heritability of the variant should also be considered as overexpression systems may exaggerate the effect of a variant, and therefore may not accurately reflect the effect of a heterozygous variant. Further important evidence to implicate a gene causing a disease can come from screening additional affected families and individuals for further mutations in the gene.

4.5 Special Circumstances for Genetic Testing

4.5.1 *Detection of Mosaicism*

Mosaicism may arise by a number of genetic mechanisms, and its detection requires specific consideration.[54] Mosaicism refers to an individual who has developed from a single fertilized egg but has two or more populations of genetically distinct cells. Typically, this involves a postzygotic de novo mutational event (e.g., aneuploidy, CNV, SNV) leading to the distinct population of cells, and a given phenotype. While certain disorders only manifest as mosaicism (e.g., McCune–Albright syndrome), another class of mosaic disorders is those harboring mutations more frequently associated with autosomal dominant disorders. This includes some individuals with relatively mild OI, as well as others with "segmental" neurofibromatosis type 1 in which the manifestations are limited to a single region of the body presumably due to somatic *NF1* mutation during organogenesis.[54] Germline mosaicism, arising from somatic mutation during gametogenesis, also may lead to diagnostic and recurrence risk confusion. In this setting, apparently unaffected parents (with one carrying the mutation limited to their gametes) may give rise to more than one affected child, suggesting possible autosomal recessive inheritance, in contrast to the underlying autosomal dominant inheritance pattern. For example, germline mosaicism has been reported in OI type II, in which apparently unaffected parents can have recurrently affected babies.[54]

The ability to detect mosaicism has evolved with the development of improved genome-wide genetic testing including aCGH, SNP arrays, and NGS. Specifically, these tests provide far greater sensitivity to detect low levels of mosaicism (e.g., 5% for SNP array) when compared with traditional approaches (e.g., karyotyping, Sanger sequencing). However, the most appropriate diagnostic test will depend on the clinical picture, the suspected type of mutation (e.g., aneuploidy, CNV, SNV, "indel") and the likely extent of mosaicism. Often lymphocyte DNA will suffice, but this will depend on the affected tissue(s). For example, exome sequencing of affected biopsy tissue from individuals with the Proteus syndrome, which is the disease that probably affected Joseph Merrick "The Elephant Man" and is characterized by overgrowth of skin, bone, and other tissue, revealed its genetic etiology to be due to somatic mosaic mutations in an oncogenic transforming (T) gene originally derived from mice referred to as stock A and strain K theme 1 (*AKT1*).[54,55]

4.5.2 *Prenatal Diagnosis*

The ability to undertake prenatal genetic diagnosis may be important for families at risk of transmitting heritable disease.[56] This may include potential parents: with a specific genetic disorder or those who are known carriers of disease-associated mutations; with previously affected children with genetic disease; or in whom routine antenatal screening (e.g., ultrasonography) raises the possibility of a genetic skeletal or

metabolic disorder. The potential indications, nature, and timing of genetic testing will therefore depend on the clinical scenario.

Preimplantation genetic diagnosis: For individuals at risk of a serious genetic disorder, in vitro fertilization offers the opportunity to screen embryos for the specific defect prior to establishing pregnancy. In this process, a few days after egg fertilization, a single cell is removed from the embryo for genetic analysis, which allows the detection of major chromosomal abnormalities (i.e., by aCGH or FISH) or the evaluation for single gene defects (i.e., conventional PCR and sequencing). Screening of serial embryos allows up to two unaffected embryos to be subsequently implanted for pregnancy to develop.
Prenatal genetic testing: If pregnancy is already established the ability to identify fetuses at risk of genetic disease traditionally involves invasive genetic testing through chorionic villous sampling (CVS) or amniocentesis. However, recent progress in the detection of cell-free circulating fetal DNA in the maternal circulation now offers the potential for noninvasive prenatal genetic diagnosis (NIPD) and/or testing (NIPT).[56]
Invasive genetic testing: Typically prenatal genetic testing has been performed on cells obtained from CVS or amniocentesis samples. These samples have been used in tests that include: conventional karyotyping for the detection of aneuploidy (i.e., Down's syndrome); FISH or aCGH for the detection of alternate chromosomal abnormalities (e.g., deletions, duplications); and DNA sequence analysis to test for single gene defects responsible for monogenic disorders. In theory, DNA samples may be evaluated by NGS approaches (e.g., gene panel, WES) but experience in the prenatal setting remains limited. While these tests may reliably identify the genetic risk to the fetus, the CVS and amniocentesis procedure carry potential risks to the pregnancy (e.g., miscarriage, infection), which need to be discussed prior to testing.
NIPD/NIPT: While the majority of the cell-free DNA in the maternal circulation arises from the mother, 10%–20% arises from the placenta, and the ability to detect this cell-free fetal DNA provides the basis for NIPD/NIPT, which involves a maternal blood test at an appropriate stage of gestation (e.g., after 10 weeks).[56] Such clinical use of NIPD/NIPT is a recent development, although it has a growing number of potential applications. Currently, in the clinic it is most frequently used to screen for aneuploidy (Down, Edwards, Patau, and Turner syndromes) and for fetal sex determination (important for X-linked disorders or conditions that severely affect one sex, for example, females with congenital adrenal hyperplasia). However, it is increasingly offered on a clinical basis for the detection of monogenic disorders including severe skeletal dysplasia, although currently its clinical use is limited to assess for paternally inherited mutations or those arising de novo as it is not possible to distinguish abnormalities inherited from the mother (due to the presence of maternal cell-free DNA in the sample).[56] In the research setting, a great number of potential applications for cell-free fetal DNA are being evaluated, including the ability to determine the entire fetal genome, enabling both the detection of CNVs and SNVs although further optimization of these methods is required before being implemented in a clinical setting. At the same time, the prospect of such technology raises important ethical issues.

4.6 Informed Consent and Ethical Considerations

Establishing a genetic diagnosis may benefit the patient and family. However, such genetic testing may also give rise to clinical and ethical challenges.[47,50,53,57] For example, the increasing implementation of genome-wide approaches (e.g., aCGH, SNP arrays, WES, WGS) has led to far better understanding of the degree of rare genetic variation in the population including both SNVs and CNVs.[50] Nevertheless, our current ability to accurately interpret genome-wide data sets remains limited, and in many circumstances diagnostic uncertainty may persist after such genetic testing. Thus, multiple gene testing or whole genome approaches employing NGS inevitably identifies variants of uncertain significance (VUSs). Communicating this uncertainty to the patient (and perhaps the wider family) remains a major clinical challenge. However, it is clear that the likelihood of such ambiguous results should constitute part of informed consent prior to genetic testing. Recent studies have also demonstrated that for several disorders many variants reported as pathogenic may instead be either benign or far less penetrant than previously recognized, and the potential implications of such misclassifications for patients and family members may be substantial (i.e., through inappropriate investigation or treatment, or decisions regarding conception).[47,50,57] Thus, caution is required in data interpretation and both the clinician and patient must have an understanding of the genetic test result and its potential limitations. In addition, clinicians and academics both have a responsibility for accurate reporting of genetic data coupled with phenotype data to improve the reliability of disease-specific mutation databases.[47,53] Plans to deal with IFs, which are genetic abnormalities not related to the clinical question but of potential clinical significance to the patient and

their family, also need to be considered. For example, the inadvertent identification of penetrant pathogenic mutations in hereditary cancer genes (e.g., *BRCA1*, *BRCA2*) may result in complex ethical considerations, and plans for managing these findings appropriately should be in place and be a key part of the informed consent pathway.

5 CONCLUSIONS

Many skeletal and mineral metabolic diseases have a genetic basis, which may be a germline single gene abnormality (i.e., a monogenic or Mendelian disorder), a somatic single gene defect (i.e., a postzygotic mosaic disorder), or involve several genetic variants (i.e., oligogenic or polygenic disorders). Recognition of these heritable disorders is clinically important, as it can facilitate relevant and timely investigation and treatment for the patients and families. Recent advances in genetics and DNA sequencing methods have resulted in new ways to detect genetic abnormalities, making it increasingly important for the clinician to gain an appreciation of these complex tests and to couple this with the fundamental skills of history taking and physician examination to ensure appropriate and judicious use of these genetic tests for the benefit of patients.

CHAPTER

2

Epigenetics

Sunita K. Agarwal, Lee S. Weinstein

National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, United States

1 INTRODUCTION

Genetic information is stored in DNA and faithfully transmitted from one cell to its daughter cells and to the next generation through the germline. Genetic changes are irreversible alterations of the DNA sequence that are heritable somatically and through the germline. These alterations include single nucleotide variants or polymorphisms, tandem repeats (short tandem repeats or variable number of tandem repeats), small indels (insertions or deletions of short DNA sequences), large deletions or duplications that alter the copy number of DNA segments, and chromosomal rearrangements associated with inversions and translocations (copy-neutral variations).[1] A vast majority of the genetic variations observed in the human population are well tolerated and do not adversely affect phenotype or normal functions. Genetic variations that cannot be tolerated can cause susceptibility to various disease states and abnormal functions. Genetic linkage studies and targeted sequencing together with recent advances, such as genome-wide association study and next-generation sequencing approaches have provided valuable insight into normal and abnormal genetic variations (see Chapter 3).

Translation of the same genetic information (genotype) to produce cell-type-specific phenotype is achieved by epigenetic control mechanisms that establish, regulate, and maintain specialized gene expression programs without altering the underlying DNA sequence. In 1942, the developmental biologist Conrad Waddington used the term "epigenetic landscape" to describe the phenotypic alterations that occur from cell to cell during development in multicellular organisms (this article from 1942 was reprinted in 2012).[2] From biochemical studies and experiments conducted in model organisms and human cells we now know that epigenetic control is achieved by changes to posttranslational modifications (PTMs) of histones, chromatin structure, DNA methylation state, and noncoding RNA interactions.[3] Therefore, epigenetics has been molecularly defined as "the sum of the alterations to the chromatin template that collectively establish and propagate different patterns of gene expression (transcription) and silencing from the same genome."[4] Epigenetic changes are retained through successive cell divisions and evidence also suggests transgenerational transmission, particularly of DNA methylation associated with imprinting. Unlike genetic alterations epigenetic changes are reversible, a property that is desirable for the development of drugs that can combat disease states associated with epigenetic defects. This chapter presents a general background of epigenetic control mechanisms and the contribution of epigenetics to human disease.

2 EPIGENETIC CONTROL MECHANISMS

DNA in eukaryotic cells is packaged and organized into chromatin. Nucleosomes are the basic units of chromatin. Each nucleosome consists of 147 bp of DNA wound almost twice around a histone octamer containing two copies each of the four histone proteins H2A, H2B, H3, and H4.[5–7] In addition, linker histones (histone H1 family) are incorporated where the DNA enters and exits the nucleosome. Nucleosomes are assembled in an array connected by 10–70 bp of linker DNA, often described as "beads on a string." This DNA compaction surrounded by histones as well as the folding of the nucleosomal arrays acts as a barrier to enzymes and other factors that require access to DNA to affect gene transcription and DNA replication and repair. Various epigenetic control mechanisms cooperate to regulate gene "ON" and "OFF" states by affecting access to DNA by transcription factors and the general transcriptional machinery and posttranscription regulation of RNA, and help to maintain genome integrity. These mechanisms include posttranslational modifications of histones, chromatin remodeling, DNA methylation, and noncoding RNA interactions.

2.1 Histone Modifications and Chromatin Remodeling

Histone proteins are highly conserved from yeast to humans. They contain a globular domain and a flexible unstructured amino terminal tail (the histone tail) that protrudes from the nucleosome. Many amino acid residues on the histone tails and some residues in the globular domain, particularly of histone H3 and H4, undergo covalent PTMs contributing to chromatin variability. Several different histone PTMs and the corresponding, enzymes that catalyze or reverse these modifications have been characterized, including acetylation, methylation, phosphorylation, ubiquitination, ADP-ribosylation, crotonylation, GlcNAcylation, and others that are being functionally characterized (Table 2.1, Fig. 2.1).[8,9] Mechanisms of reversible incorporation of acetyl, phosphate, and methyl groups within histone tails are best understood. Specific enzymatic activities that reside in large multisubunit complexes govern the steady state balance of each modification such that each is established (written), removed/reversed (erased), or recognized (read).[10]

Histone acetyl transferases acetylate specific lysine residues in histones that are reversed by histone acetyl deacetylases (HDACs).[11] Histone acetylation often correlates with active chromatin regions that are accessible to the transcriptional machinery. Histone acetyl transferases belong to five different families, of which members of the Gcn5-*N*-acyltransferases and MYST families are the most abundant, followed by the steroid receptor coactivator family and the activating transcription factor (ATF-2) and TAFII250 families. Sequence homology among the families is low. However, they all show structural similarity in the core enzymatic region. Mammalian HDACs have been categorized into four major classes, class-I: HDACs 1, 2, 3, and 8; class-IIa: HDACs 4, 5, 7, and 9; class-IIb: HDACs 6 and 10; class-III: the sirtuins (SirT1-7); and class IV, HDAC11.

Enzymes of the histone kinase family phosphorylate specific serine, threonine, or tyrosine residues, and phosphorylation can be reversed by the action of phosphatases.[12] Phosphorylation of histone amino acid residues have been observed at condensed chromatin associated with transcriptional silencing.

Histone lysine methyltransferases (KMTs) are SET domain and non-SET domain-containing methyltransferases that methylate lysine residues that can be removed by histone lysine demethylases (KDMs).[13] Protein arginine methyltransferases methylate arginine residues that can be indirectly removed by arginine deiminases that convert methyl-arginine to a citrulline residue.[13,14] Lysine methylation can be present in mono-, di-, or trimethylated states. For example, di- or trimethylation of histone H3 at lysine 4 (H3K4me2 and H3K4me3) and monomethylation of H3K9 (H3K9me1) are marks of active transcription. However, di- and trimethylation of H3K9

TABLE 2.1 Histone Posttranslational Modifications

Modifications	Abbreviations	Amino acids
Acetylation	Ac	K, S, T
ADP ribosylation	Ar	K, E
Butyrylation	Bu	K
Citrullination	Cit	R
Crotonylation	Cr	K
Formylation	Fo	K
2-Hydroxyisobutyrylation	Hib	K
Hydroxylation	OH	Y
Malonylation	Ma	K
Methylation	Me	K, R
O-GlcNAcylation	Og	S, T
Phosphorylation	Ph	S, T, Y, H
Propionylation	Pr	K
Succinylation	Su	K
Ubiquitination	Ub	K

Histone modifications from Huang H, Sabari BR, Garcia BA, Allis CD, Zhao Y. SnapShot: histone modifications. Cell *2014;***159**(2)*:458.*[9]

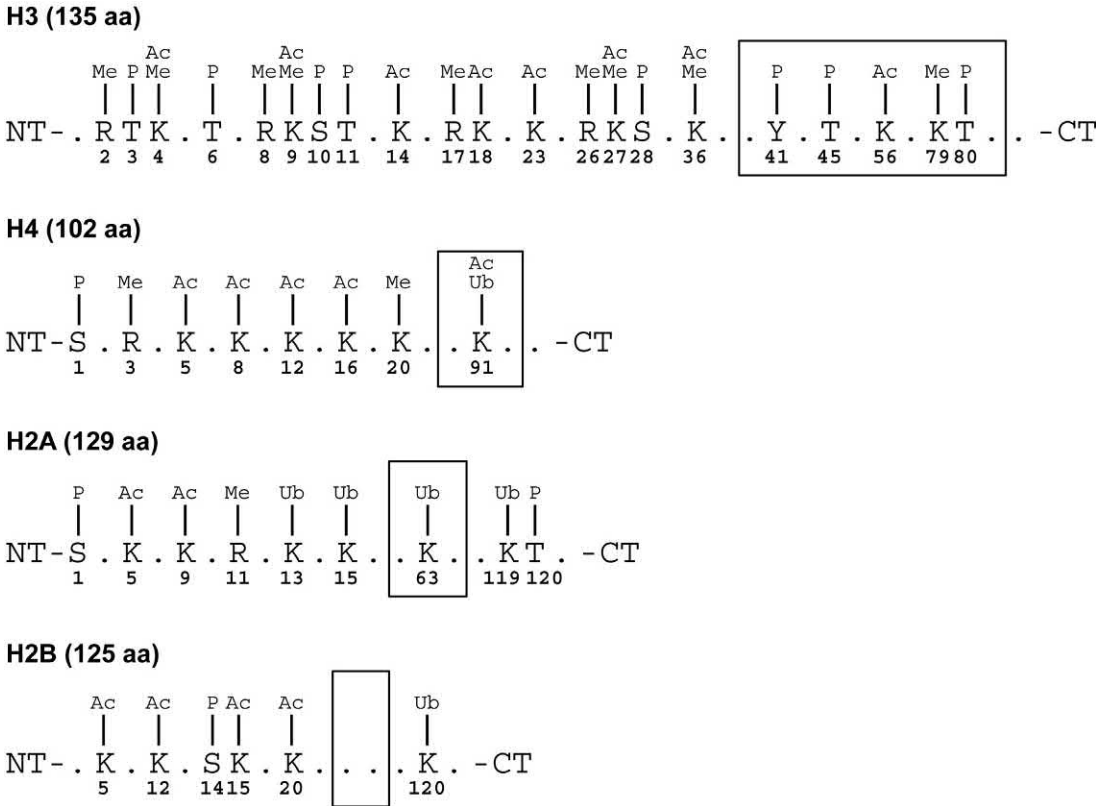

FIGURE 2.1 Histone posttranslational modifications (PTMs). Commonly observed and well-studied histone PTMs of the four canonical core histones are shown: acetylation (Ac), methylation (Me), phosphorylation (P), and ubiquitination (Ub).[4,9] Only the amino acids that are modified are shown. The amino acid position in the histone protein sequence is written below each amino acid. The boxed area in each histone marks the globular domain. NT and CT are N and C terminus, respectively, of each histone protein.

(H3K9me2 and H3K9me3), and H3K27 (H3K27me2 and H3K27me3) are repressive marks that block gene expression. Lysine-specific histone demethylase 1 (LSD1 or KDM1A) and lysine-specific histone demethylase 2 (LSD2 or KDM1B) remove mono- and dimethylation of H3K4 and H3K9. Another family of KDMs shares the jumonji C domain (JMJC) (JHMD1, JMJD3, and JMJD2D) to mediate demethylation, each targeting specific methyllysine groups.

Various combinations of PTMs can occur on the same histone tail (in *cis*), or on another tail (in *trans*), that constitute a "histone code" or a signature.[10] This code can be deciphered by proteins, which contain binding motifs specific for each modification (readers) that are part of reader-containing complexes, eventually resulting in chromatin remodeling.[15] Reader domains of specific methyllysine residues are the best-characterized group and include ATRX-DNMT3-DNMT3L (ADD), ankyrin, bromo-adjacent homology (BAH), chromobarrel, chromodomain, double chromodomain (DCD), malignant brain tumor (MBT), plant homeodomain (PHD), Pro-Trp-Trp-Pro (PWWP), tandem Tudor domain (TTD), Tudor, WD40, and the zinc finger CW (zf-CW). Acetylated residues are read by proteins that contain PHD or by the bromodomain extraterminal (BET) motif. The BRCT and BIR domains can bind to specific phosphorylated residues. Reader-domain containing subunits are essential for ATP-dependent nucleosome-remodeling complexes, such as switching defective/sucrose nonfermenting (SWI/SNF) for binding and remodeling activity to slide or displace histones, working at promoters and enhancers to regulate transcriptional responses.

The polycomb group (PcG) and trithorax group (TrxG) proteins are evolutionarily conserved regulators that maintain transcriptional "OFF" and "ON" states, respectively, of development control genes, such as *HOX* and other target genes.[16] They function to remodel chromatin in concert with chromatin-modifying enzymes by altering the accessibility of DNA to factors required for gene transcription.[17,18] PcG proteins consist of two separate multimeric protein complexes that are associated with repressed chromatin states, such as the PcG repressive complex 1 (PRC1) and the PcG repressive complex 2 (PRC2). PRC1 monoubiquitinates histone H2A on lysine 119 (H2AK119Ub1). PRC2 trimethylates histone H3 at lysine 27 (H3K27me3) through the activity of PRC2 component enzymes EZH1 or EZH2 (enhancer of zeste homolog 1 or 2) in association with EED or SUZ12. TrxG proteins also exist as several multimeric protein complexes containing histone methyltransferase

activity that are associated with active chromatin states where they induce trimethylation of histone H3 at lysine 4 (H3K4me3). Therefore, the functions of the PcG and TrxG proteins are described as "antagonistic" to each other promoting transcription repression and activation, respectively.

2.2 Histone Variants

During the process of transcription elongation, nucleosomes obstruct the passage of RNA polymerase (Pol) II or RNA Pol I. Chromatin remodeling activity facilitates transcriptional initiation and elongation allowing the passage of the RNA polymerase through nucleosomal arrays by displacing histone H2A/H2B dimers, which can lead to the exchange of core histones with histone variants.[19] All of the core/canonical histones except histone H4 have variant isoforms (nonallelic isoforms of the canonical histone proteins) that differ by a few amino acids. They localize on the newly synthesized daughter strands following DNA replication and also play an important role in regulating gene expression (a replication-independent function). The histone H1 family includes multiple isoforms; H2A variants include H2A.Z, MacroH2A, H2A-Bbd, H2AvD, and H2A.X; and H3 variants include H3.3 and centromeric-specific isoform (CENP-A). Histone variants and their modifications contribute to nucleosome and chromatin structure and function.[8] For example, transcriptionally active genes exchange the canonical H3 with the H3.3 variant contributing to the active epigenetic signature.[20] Also, the incorporation of H2A.Z together with H3.3 leads to an unstable chromatin state associated with open chromatin at enhancer elements.[21]

2.3 DNA Methylation

One of the most common epigenetic control mechanisms associated with gene repression/silencing is DNA methylation at cytosine residues.[22,23] This modification mainly occurs at CpG dinucleotides where a cytosine nucleotide is followed by a guanine nucleotide in which cytosine is converted to 5-methylcytosine (5mC). CpG islands are DNA regions up to several hundred base pairs in length that are CG-rich and that contain many CpG sites. CpG islands often occur in promoter regions and their methylation usually prevents gene expression. Emerging evidence shows that DNA methylation can also occur at nonCpG sites (CpA, CpT, and CpC) and may control gene expression.[24]

Cytosines are methylated by DNA methyltransferases (DNMT3A and DNMT3B). This modification is maintained during DNA replication and can be passed on after cell division to daughter cells. DNA replication leads to hemimethylated CpGs and the methylation is maintained by DNMT1 that methylates the CpG on the unmethylated strand.[23] DNMT3A and DNMT3B are responsible for de novo DNA methylation and associate with DNMT3L that is a catalytically inactive DNA methyltransferase required for DNA methylation. DNMT3L recognizes unmethylated histone H3 lysine 4 (H3K4) to induce DNA methylation by recruitment or activation of DNMT3A and DNMT3B. On the other hand, the presence of H3K4me3 protects CpG islands from DNA methylation by inhibiting DNMT3L binding. Thus there is an antagonism between H3K4me3 and DNA methylation.[25] Studies in mouse models have shown that *Dnmt* genes are essential for development as targeted deletion of *Dnmt* genes leads to early embryonic lethality.[26,27]

DNA methylation is reversible in that 5mC can be converted to 5-hydroxymethylcytosine (5hmC) by the ten-eleven translocation (TET) family of methylcytosine hydroxylases.[28,29] The hydroxylase activity of the TET family of 5mC hydroxylases (TET1, TET2, and TET3) promotes DNA demethylation by converting 5mC to 5hmC and further to 5-formylcytosine (5fC) and finally to 5-carboxylcytosine (5caC). Further reactions, such as decarboxylation of 5caC could then lead to DNA demethylation and conversion back to cytosine. Whether these intermediates of DNA demethylation by themselves have functional significance in epigenetic control is being actively investigated.[23] Drugs, such as 5-azacitidine (5AC) and 5-aza-2′-deoxycytidine (DAC) can inhibit and degrade DNMTs to block DNA methylation.

How DNA methylation functions to silence gene expression is not clearly understood. There is some evidence for transregulation through methyl-CpG binding (MBD) domain proteins, such as methylcytosine-binding protein 2 (MeCP2) that binds to methylated cytosines to recruit HDACs thereby removing the gene activation-associated acetylation marks.[23] Also, DNA methylation has been shown to silence gene expression by affecting the recognition sites of transcription factors or other transcriptional regulators.[30]

Allelic differences in DNA methylation are seen at imprinted loci to differentially silence the paternal or the maternal allele, and at the inactive X-chromosome.[30] Such differentially methylated regions (DMRs) in the genome are also capable of controlling gene expression of multiple genes associated with the DMR, such as at the *SNRPN-UBE3* and *DLK1-MEG3* gene clusters.[30] Defects in DNA methylation have been observed in several human disorders, such as disorders of genomic imprinting and cancer.[31,32]

2.4 Noncoding RNAs (ncRNAs)

The draft sequence of the human genome published in 2001 and more recent data estimate the presence of ~21,000 protein-coding genes encoded by the DNA.[33,34]

A large proportion of the genome is transcribed into small RNAs or long noncoding RNAs (lncRNAs) that lack open reading frames for translation into proteins. Some of these RNAs have been shown to silence gene expression by triple helix formation with DNA or base-pairing at target regions, by acting as a scaffold for chromatin-modifying and -remodeling protein complexes, and also by recruiting factors, such as the PcG complexes that silence the chromatin or factors that facilitate transcription.[35] The long intergenic ncRNA (lincRNA) X-inactive specific transcript (Xist) is expressed from one female X-chromosome as a 17 kb polyadenylated noncoding RNA. Xist "coats" the X chromosome from which it is transcribed and leads to the recruitment of PcG proteins, such as PRC2 to silence transcription across this chromosome in *cis* (X-chromosome inactivation).[36] Another lincRNA Hox transcript antisense intergenic RNA (HOTAIR) transcribed from the *HOXC* cluster silences the *HOXD* cluster located on another chromosome in *trans* by physically interacting with the PRC2 complex and targeting PRC2 to the appropriate target site.[37] Similarly, several other lncRNAs have been shown to associate with PRC2 to localize the epigenetic regulatory machinery at target sites in *cis* or *trans*.[38,39]

Two classes of small RNA, short (or small) interfering RNA (siRNA) and microRNA (miRNA) play a central role in RNA interference-mediated gene silencing mechanisms.[40] They differ in biogenesis, processing, and mechanism of action. The precursors of siRNA and miRNA are double-stranded RNA structures formed due to base pairing of complementary RNAs, or from intramolecular RNA folding into stem-loop hairpin structures, respectively. After a series of processing steps an RNase III class ribonuclease, Dicer, cleaves the double-stranded RNA molecules into siRNA or miRNA. These processed small RNAs, 21–24 nucleotides in size, associate with effector protein complexes that contain Argonaut and other factors for gene silencing by targeting either messenger RNAs posttranscriptionally for degradation or chromatin regions through complementary base-pair interactions, or by blocking translation.[40,41] Two related complexes that incorporate siRNA or miRNA, RNA-induced silencing complex (RISC) and RNA-induced transcriptional silencing (RITS) complex target messenger RNAs and chromatin, respectively.[41]

3 TRANSGENERATIONAL EPIGENETIC INHERITANCE

The structure of the DNA double helix and selfpropagation of DNA through semiconservative replication allows for storage and maintenance of both normal and abnormal genetic information, and transmission to daughter cells somatically and to the next generation through the germline. Epigenetic modifications can be passed on to daughter cells somatically after cell division.[42] However, a vast majority of the epigenetic modifications reset during meiosis. This reprogramming resets the epigenome (epigenetic marks across the entire genome) of the early embryo to render the cells totipotent (the potential to form every cell type in the body). To pass to the next generation through the germline, epigenetic marks must avoid being erased during embryonic reprogramming.[43] Imprinted genes have been shown to bypass epigenetic reprogramming postfertilization. Recent work shows that the DNA binding factor Zfp57 together with Kap1/Trim28 may be critical for postfertilization maintenance of maternal and paternal DNA methylation imprints.[44,45] The precise mechanisms that allow transgenerational retention of DNA methylation imprints and other epigenetic modifications are being investigated.[43]

4 EPIGENETICS AND HUMAN DISEASE

Epigenetic changes have been observed in many disease states that can occur as a result of mutations in factors that control epigenetic modifications (writers, erasers, or readers) or in response to environmental stimuli (endogenous or exogenous signals). Such epigenetic changes can be the cause or consequence of the disease process serving as disease drivers, biomarkers, and therapeutic targets.

4.1 Imprinting Disorders

Most genes show a biparental (diploid) mode of expression. However, a subset of "imprinted" genes are expressed in a monoallelic parent-of-origin dependent manner in which one parental allele is partially or completely silenced. Some of the imprinted genes have been well characterized.[30] Paternally expressed imprinted genes that normally function as growth promoters include *DLK1*, *IGF2*, *PEG1*, *PEG3*, and *RASGRF1*. Maternally expressed imprinted genes that normally function as growth repressors include *CDKN1C*, *GNAS*, *GRB10*, *H19*, and *IGF2R*. Another class of imprinted genes are associated with behavioral and neurological defects, such as *KCNQ1*, *NESP*, and *UBE3A*. Imprinted genes are located in clusters where the parental alleles possess differential DNA methylation marks at DMRs and other epigenetic modifications at imprinting control elements.[46] Tissue-specific imprinting (silencing of one allele in a tissue- or temporal-specific manner) occurs in some genes (e.g., *GNAS*) (see Chapter 35). Imprinting disorders can result from mutations in the nonsilenced allele or from DNA methylation defects, such as loss of

imprinting causing two active copies of a gene or from inactivation of the nonimprinted allele causing two inactive copies.[30] Such conditions can lead to severe developmental abnormalities, cancer, and other diseases. Some of the well-characterized imprinting disorders include Prader–Willi syndrome, Angelman syndrome, Beckwith–Wiedemann syndrome, Silver–Russell syndrome, Albright hereditary osteodystrophy, and pseudohypoparathyroidism type 1B (see Chapter 35).[32]

4.2 Cancer

Aberrant DNA methylation has been observed in various cancers that can lead to global alterations in gene expression. DNA hypomethylated regions in the genome are prone to chromosomal translocations and genome instability that can lead to cancer.[47] Focal DNA methylation changes can result in activation of oncogenes (DNA hypomethylation) or inactivation of tumor suppressor genes (DNA hypermethylation). Mutations in *DNMT3A* are frequently found in acute myeloid leukemia and peripheral T-cell lymphomas.[48–50] Loss of ATRX, the DNA translocase component of the ATRX-DAXX-H3.3 pathway, was described as a cause of α-thalassemia mental retardation on the X (ATRX) syndrome leading to frequent nucleosome loss at CpG islands at the α-globin gene promoter.[51] Defects in DAXX and ATRX are also relevant in various tumors. Exome sequencing of human pancreatic neuroendocrine tumors (PanNETs) has revealed that ~40% of such tumors possess loss-of-function mutations in either *DAXX* or *ATRX*.[52]

Aberrant histone modifications that contribute to carcinogenesis have been observed in various cancers and may serve as diagnostic tools to investigate tumor progression and malignancy.[53] This can result from the process of tumorigenesis or from mutations of factors that comprise the epigenetic machinery. Among such mutations are translocations of the *MLL* genes in acute myeloid leukemia that lead to loss of the SET domain (KMT activity) in the MLL proteins, and recurrent somatic mutations of the *UTX* (*KDM6A*) and *EZH2* genes in various tumor types.[54–56] Mutated histones associated with cancer have been named "oncohistones." For example, missense mutations in the variant histone H3.3 (H3.3K27M or G34R/V) occur in pediatric glioblastomas, and H3.3K36M in pediatric chondroblastomas.[57–59] The "K-to-M" mutant histones can prevent histone methylation by HMTs, such as EZH2 (which methylates H3K27) and SETD2 (which methylates H3K36). Reduction in repressive H3K27 methylation and inhibition of PRC2 activity leads to gain of active H3K4 methylation which promotes the cancer state by blocking differentiation of a neural stem cell causing uncontrolled growth and tumors (pediatric glioblastoma).[57,58] Reduction in active H3K36 methylation leads to a genome-wide gain in repressive H3K27 methylation and redistribution of PRC1 causing derepression of its target genes that block mesenchymal differentiation and accumulation of immature chondroblasts (pediatric chondroblastoma).[60]

4.3 Other Diseases

Defects in epigenetic control mechanisms (mutations, improper deposition, removal, or misreading of epigenetic marks) are not only restricted to imprinting disorders and cancer, but also have been shown to underlie other human diseases, such as cardiopulmonary diseases, diabetes, neuropsychiatric disorders, inflammation, autoimmune diseases, and developmental abnormalities.[32] Studies in model organisms and human tissues have shown epigenetic changes that correlate with aging.[61] The impact of epigenetics on aging in turn can impinge on age-related diseases, such as diabetes, cardiovascular diseases, neurodegenerative diseases, and cancer.

4.4 Epigenetic Therapy

The reversible nature of epigenetic modifications highlights the possibility of epigenetic therapy for various disease states. Comprehensive characterization of genome-wide epigenetic marks has been informative to reveal the status of the epigenome in various diseases, particularly cancers. Targeting the disease-associated epigenome holds promise irrespective of whether it is the cause or consequence of the disease process. Some of the therapies that are under investigation include blocking the enzymatic activity of epigenetic regulators, disrupting crucial protein–protein interactions in the protein complexes that control epigenetic processes, and targeting relevant proteins for degradation.[62] Such therapeutic options could ultimately help to reset the abnormal epigenetic profiles of the diseased state back to normal. Small molecule chemical inhibitors of epigenetic enzymes have been developed (e.g., DNMTi, HDACi, KTMi, KDMi, and BETi). Currently, the two types of epigenetic therapies approved by the US Food and Drug Administration are HDACi (panobinostat, vorinostat, and romidepsin), and DNA hypomethylating agents (decitabine and azacitidine that target DNMT1 and 3A).[63] They have been used in the treatment of specific hematological malignancies. Other classes of drugs under development and/or in clinical trials are those that target-specific interactions in chromatin modification protein complexes or specific epigenetic modifications.[62] Current challenges of epigenetic therapy include cellular heterogeneity of the affected tissue and disease cell-specific targeting, side effects, resistance, and constant, consistent and long-lasting inhibition of the target.

5 CONCLUSIONS

Epigenetic control mechanisms have been grouped into three broad classes, such as posttranslational histone modifications and chromatin remodeling, DNA methylation, and ncRNA interactions. The interplay of these mechanisms in intra- and internucleosomal interactions over short and long distances generate a variety of chromatin states. The sum of these mechanisms is fundamental to the regulation of diverse cellular processes through differential transcriptional readout of the same genetic material. The importance of epigenetics is underscored by many diseases that can develop due to mutations in epigenetic regulatory proteins, misregulation of the epigenetic machinery, and aberrant placement or removal of epigenetic marks. The reversible nature of epigenetic alterations is an attractive target for therapeutics that can help reset the epigenome to the normal state. The fact that some of these epigenetic drugs have been efficacious in the treatment of cancers, such as hematological malignancies reinforces the importance of epigenetics. The recent developments in high throughput sequencing techniques have enabled epigenome profiling of various cell types in their normal or pathological states. These epigenome signatures can be valuable for disease diagnosis, prognosis, and treatment opportunities. Ongoing and future research in the field hopes to shed light on epigenetic changes from a host of inputs, such as aging, metabolic, nutritional, physiological states, environmental conditions, early and late life exposures, chemical, and immunological challenges.

CHAPTER

3

Genome-Wide Association Studies

Emma L. Duncan, Matthew A. Brown

Institute of Health and Biomedical Innovation at the Translational Research Institute, Queensland University of Technology, Woolloongabba, QLD, Australia

1 INTRODUCTION

In 1989, Lander and Botstein suggested and developed approaches for using markers (initially restriction fragment length polymorphisms and subsequently microsatellites) in multicase families to map quantitative trait loci by linkage.[1] Over the next 15 years, hundreds of genome-wide linkage studies were performed for both dichotomous and quantitative trait diseases, with very little success. While these approaches were adequately powered to identify major gene effects, such as the contributions of HLA loci in immunological diseases, for most common diseases they lacked adequate power to identify disease susceptibility loci robustly. Even if such loci were established, linkage approaches lacked sufficient resolution to pinpoint the responsible genetic variants underneath the linkage peaks. This was certainly true for studies in osteoporosis.[2]

Candidate gene association studies were another widely employed approach that were similarly unproductive. As we do not plan to review these in detail in the current chapter, no candidate gene association reported prior to the genome-wide association studies (GWAS) era in genetic studies of bone mineral density (BMD) variation has been confirmed as a definite osteoporosis gene, since the introduction of robust GWAS design with the single exception of *LRP5*.[3–5]

The development of the GWAS approach and its application over the past decade has completely revolutionized common disease gene mapping. In contrast to previous studies, standard design and analysis approaches in GWAS have led to far more robust and reproducible results. These features include: better quality control of genotypes and cohorts, including identification of cryptic relatedness among the cohort, identification and control of population stratification, and generally more stringent exclusion of poorly performing samples or markers. Further, the sample sizes in GWAS are much bigger than typical candidate gene studies. Considerably more stringent statistical thresholds are used for claiming identification of positive findings, with genome-wide significance set at $P < 5 \times 10^{-8}$. Thereby increasing both the prior and posterior probabilities of a positive finding being a true result, the findings of GWAS have proven much more robust than previous candidate gene studies.

Since the introduction of GWAS for common disease gene mapping, over 10,000 robust genome-wide significant associations have been reported, an extraordinarily rich return (cataloged results at http://www.ebi.ac.uk/gwas/home).[6] Several GWAS in osteoporosis have now been reported,[7–22] and large metaanalyses have now reported 190 genome-wide significant associations, although many of these are replication findings, and the true number of independent associations is smaller than this (NHGRI-EBI Catalog of published GWAS, accessed 14/04/2016). These findings nonetheless only contribute to a small fraction of the overall heritability of osteoporosis phenotypes; and thus far some major traits of interest, such as fracture, have proven harder to dissect using the GWAS approach. The assumptions underlying GWAS, the methodology involved, the strengths and weaknesses of the approach, and likely future developments will be discussed later.

2 LINKAGE DISEQUILIBRIUM MAPPING

In 1996, Risch and Merikangas recognized the limitations of linkage approaches to map genes determining common diseases, and instead proposed that wide-scale association studies using unrelated cases and controls could detect those genes, each of relatively modest effect, underlying most complex common human diseases.[23] At the time, the number of genes in the human genome was unknown, as was the extent of variability and linkage

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00003-4

disequilibrium (LD) in the genome. However, Risch and Merikangas suggested that testing a million alleles for association in cohorts of achievable size (<1000 individuals) would be an efficient and powerful way to detect genes with modest effects (genotypic relative risk of 1.5).

Risch and Merikangas recommended that the threshold for declaring significance should be $p = 5 \times 10^{-8}$, corresponding to the same risk of type 1 error as represented by a LOD score of 3 when typing 500 markers, while recognizing that this was conservative given the likelihood of LD between variable alleles. Although this remains a stringent threshold for declaring association, most geneticists still regard significant association as proven only when replicated in an independent cohort.

While this threshold has been widely accepted as representing a "significant" finding in GWAS,[24] using such a fixed threshold has weaknesses. For example, the posterior probability of a true GWAS finding depends on the study power (prior probability); thus studies with lower power are more likely to produce false positive findings for the same given *P*-value as larger and/or more powerful studies.[25] Nonetheless, the majority of findings that achieve genome-wide significance have subsequently been replicated in independent cohorts. It is often argued that this threshold is too stringent for candidate gene/locus association studies, in which far fewer markers are studied than in GWAS. While this may be mathematically true, a high proportion of findings at lower significance values prove to be false positives, and thus candidate gene studies achieving "experiment-wise" significance should be interpreted with some caution, if genome-wide significance is not achieved.

At the time of their publication, the study design proposed by Risch and Merikangas was theoretical, as the full extent of variability across the genome was unknown and an efficient means of capturing that variability was technically impossible. Within a decade, both challenges were met. Major technological advances in fields as diverse as chemistry, optics, and computational processing lead to high-throughput array genotyping; and large collaborative genetic programs, such as the International HapMap and Human Genome Project characterized the extent of variability in the genome.[26] This variability includes microsatellites, copy number variants (CNV), and structural variants including insertion/deletions; but the greatest source of variability is single-nucleotide polymorphisms (SNPs). Currently, the number of known SNPs with a minor allele frequency (MAF) >1% is 30 million (source: dbSNP 132). As there are 3 billion bases in the human genome, this represents a SNP every 100 base pairs on average, although variability is not uniform throughout the genome. The number of SNPs being added to public databases is increasing rapidly, and therefore this is an underestimate of the true extent of variation in the human genome.

LD refers to the coinheritance of alleles at two (or more) loci more often than would be expected by chance. To illustrate how LD arises across the genome, a new mutation will arise on a particular ancestral haplotype; the mutation will then be inherited together with the surrounding background stretch of DNA. Thus, unless a meiotic event occurs to separate them, SNPs that are close to the new mutation on the ancestral chromosomal strand will all be inherited together along with the new mutation. At a population level, LD across the genome has decayed through multiple meiotic events such that LD extents only a short distance, typically estimated at approximately 10–20 kB depending on the age of the population.

Through LD, it is possible to build haplotypes or stretches of DNA with a series of correlated markers (such as SNPs); only one SNP needs to be genotyped to allow the genotype of all the other SNPs on the haplotype to be inferred. The International HapMap project was established to characterize the haplotypic structure of the genome [initially for just 4 populations (white Europeans, Chinese, Japanese, and Yoruban Nigerians) but now including 11 other global ancestry groups]. Such data inform and enable such genotyping projects.[26] The earliest commercial SNP chips could not be said to truly capture the whole genome; but with SNP choices informed by LD coupled with technological advances in the number of genotypable SNPs, current commercial whole-genome SNP chips can type up to 5,000,000 SNPs. Further, imputation—by which genotypes at loci not directly genotyped are predicted based on findings from nearby directly assayed genotypes and known haplotypic findings across the locus—can be used to increase the number of genotyped SNPs several-fold above the number directly genotyped.[27]

From a disease-mapping point of view, then, it became possible to look for association across all genes in the genome simultaneously, without bias or assumptions of biological activity. Although the true disease-associated (disease causing) SNP at a particular locus might not be directly genotyped, LD between the disease-causing SNP and the genotyped SNP would mean that association would be detected at the locus, though further fine mapping would be necessary to determine the exact disease-causing polymorphism driving the observed association at this site.

This argument assumes that common diseases are caused by common variants in the population that have arisen in a common founder to whom carriers of the disease-associated variant are distantly related, the so-called "common disease–common variant" hypothesis. To illustrate how this might occur, at some point in the past an ancestor developed a genetic mutation that resulted in a disease. If all current individuals with this disease have arisen from this common founder, then all

cases will share the haplotype carrying the mutation. In contrast, the rest of the population will not carry the disease-associated haplotype. Association with the disease-causing haplotype will be evident even in relatively modest-sized cohorts, depending on the relative risk of disease conferred by the mutation and the number of genes involved in determining disease.

The publication of the Wellcome Trust Case-Control Consortium studies in 2007 illustrated that at least for some diseases the common disease–common variant hypothesis held true.[28,29] Since 2007, hundreds of GWAS have been reported; an up-to-date summary of all published associations at genome-wide significance can be found at http://www.ebi.ac.uk/gwas/home.

In recent times, though, there has been much discussion of the relative contribution of rare variants of greater individual effect size upon a trait than common variants. In one sense this is not surprising: for common variants to become common they cannot exert a major negative effect upon a phenotype or natural selection would result in their removal from the population. How much of the observed association with common variants and disease is due to rare versus common variants remains conjectural; this is discussed in depth later.

3 STUDY DESIGN ISSUES IN GENOME-WIDE ASSOCIATION STUDIES

In GWAS the search is for variants with generally modest effects in a very large experimental space. Thus very careful quality control is required to reduce potential sources of error that could easily translate into false-positive findings. The key aspects of this quality control process are described later.

3.1 Quality Control

Spurious association can arise from SNP misgenotyping, especially if this is different between cases and controls. SNPs that genotyped poorly should be excluded from analysis because of this potential bias, and most studies would exclude SNPs that are genotyped in <90% of the population. Further, individuals who genotyped poorly should also be excluded from analysis as they have a higher proportion of incorrectly called genotypes. Typically a call-rate (proportion of SNPs successfully genotyped in an individual) threshold of 95%–98% per individual is applied.

Individual SNPs should be assessed for deviation from Hardy–Weinberg equilibrium; significant deviation implies unreliable genotyping and the genotyping should be reviewed. This deviation may also occur due to strong, true association, so thresholds tend to be liberal here ($p < 10^{-7}$ being a common threshold).

Per subject heterozygosity is also used as a filter. Excess heterozygosity may indicate DNA mixing/contamination, and low heterozygosity may indicate either low-quality genotyping or population stratification.

Identification and exclusion of related individuals is critical in GWAS studies as the statistical analysis assumes that subjects are unrelated. It is quite common for relatives to be recruited accidentally into studies, and even for the same individuals to be rerecruited. Screening for identical names, date of birth, and gender before genotyping can identify some duplicate individuals; however, this approach cannot identify siblings or other types of relative pairs. This can be achieved genetically by measuring the extent of sharing of SNP genotypes between all pairs of individuals in the study. Related individuals have excess sharing of SNP genotypes; this approach can be used reliably to identify and exclude individuals who are up to third-generation relatives (cryptic relatedness).

The robustness of association depends critically on an overall common genetic background between cases and controls. If these subjects are drawn from different ethnic groups, there will be differential SNP sharing simply due to their different ethnic background unrelated to the presence or absence of disease; this is referred to as population stratification and is a potent cause of inflation of GWAS findings. Investigators should make concerted efforts to minimize ethnic heterogeneity in their study subjects, but some diversity is inevitable. This is particularly the case where a common control data set is used, as the controls are not necessarily recruited from the same geographic region as the cases. To address this, principal components analysis methods have been developed that identify groups of SNPs that distinguish strata of the population from one another.[30] This is a powerful method for distinguishing even minor differences in ethnic background between subjects in GWAS studies (Fig. 3.1). Typically, subjects who are ethnically remote to the main cohort are excluded from further analysis. Weighted scores of ethnicity defined by principal components analysis or related methods can then be used to control for minor differences in ethnicity between the remaining subjects.

Another method of assessing population stratification is to compare the number of observations to the number expected by chance (presented as a quantile–quantile plot). Significant deviation implies that there are differences between the cases and controls not simply due to differences in disease prevalence. The extent of this deviation is assessed using the mean or median association strength statistic compared with the null hypothesis across all SNPs studied (referred to as the genomic inflation factor[32]). This factor can be inflated by error (such as cryptic relatedness of samples, genotyping error, or population stratification), or by true association. A genomic

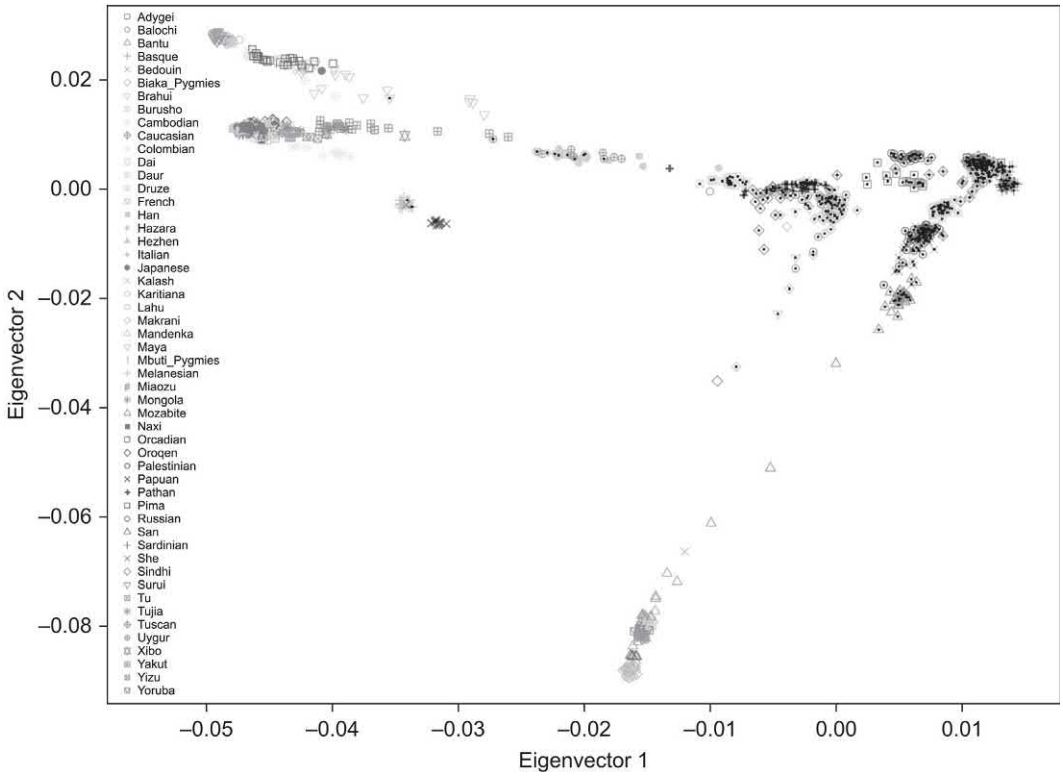

FIGURE 3.1 Principal components analysis ancestry assessment. Forty-nine ancestry-informative markers were used to distinguish the ethnicity of 1104 samples from the Illumina iControl database, reported to be from 52 ethnic groups. Those marked with a black dot were confirmed not to be of white European ancestry.[31] Those with African or Asian ancestry were easily distinguished; and ancestry was able to be determined for even quite closely related ethnic groups.

inflation factor of 1.0 indicates no evidence of inflation of association findings from the null (and in fact if truly exactly 1.0 would represent a negative study), and values up to 1.10 are generally considered acceptable for GWAS studies. The genomic inflation factor increases with sample size; to provide a measure comparable across sample sizes, corrected statistics for a sample size of 1000 subjects are usually also reported.

The genomic inflation factor can be used to correct average inflation of test statistics across the genome, but this approach assumes that the test statistics are equally inflated at each locus across the genome, which is not usually the case. Rather, stratification tends to affect loci that are under selection pressure, such as genes involved in immunological and nutritional pathways.[28] Therefore other quality control measures are essential to provide robust results. The gene encoding lactase (*LCT*), of obvious potential importance in osteoporosis, is highly subject to population stratification; this is likely to account for early studies reporting its association with BMD. *LCT* has not been identified as a susceptibility locus in osteoporosis GWAS, probably because GWAS can properly control population stratification effects.

4 THE "MISSING HERITABILITY" QUESTION

Despite ever larger and more powerful GWAS and metaanalyses, the proportion of genetic variance explained in different common diseases has, with few exceptions, remained low. This is also the case in osteoporosis and related phenotypes, such as height. One of the largest studies yet performed concerning osteoporosis is the second Genetic Factors in Osteoporosis study, which in its discovery arm involves 32,961 individuals, and in its replication arm 50,933 subjects. This study identified and replicated 56 loci associated with BMD, substantially increasing understanding of the genetic architecture of BMD variation. However, a total of just 5.6% of BMD variation was explained, compared with the heritability of BMD of over 60%.[17] In the fracture component of this study, 31,016 cases and 102,444 controls were studied, identifying 14 SNPs associated with fracture (at "experiment-wide" significance, in this case $p < 5 \times 10^{-4}$), explaining just 2.3% of fracture risk.

The failure of GWAS to identify larger proportions of the variance of traits has led to much discussion as to why this might be the case, and consideration of alternate

study designs to capture more of the variance.[33] Potential repositories of unmapped genetic variance include rare variants, CNVs, insertion/deletions, and epigenetic factors, such as methylation.

The number of common variants identified in GWAS scales are almost linear as the sample size increases, almost independent of the heritability of the disease or trait studied,[34,35] and thus it is possible that simply by further increasing sample sizes, a higher proportion of the variance will be explained. Against this, it is hard to imagine that GWAS of hundreds of thousands of subjects will be possible for most traits or diseases. Further, with ever larger GWAS, the effect size of new SNPs being identified diminishes. For example, in Crohn's disease, the initial 30 loci explained 20% of the variance, and the next 39 loci only added a further 3.2% of the variance explained.[36] This diminishing return with ever larger datasets indicates that while increasing the sample size will be helpful, other variants not captured by GWAS chips must exist.

GWAS chips are designed to optimally tag common variants across the genome. Chip manufacture companies, such as Illumina (San Diego, California) and Affymetrix (Santa Clara, California) have adapted their products to improve capture of CNVs and rare variants. There is now good evidence that common CNVs that can be typed by our best available technology do not contribute significantly to missing heritability, and indeed have largely been tagged by SNPs on chips already. In a large Wellcome Trust Case-Control Consortium study of CNVs in eight different diseases, it was demonstrated that any common CNV associations observed had already been identified through SNP marker studies.[37] It remains possible that rare CNVs or those too small to be detected by SNP chips (such as insertion–deletion polymorphisms, termed "indels") may contribute to missing heritability, but it will require large studies using improved genotyping technology to address these.

The relative contribution of rare and common variants to common disease heritability is unclear currently. Research using the model trait of height provides insights as to the likely repositories of unmapped genetic variants. Considering GWAS data from height studies, it has been demonstrated that 45% of the narrow-sense heritability (due to additive effects of individual loci, without interaction between then) of height is due to common variants. At this point genetic associations that determine 5% of the variation in height have been identified, leaving 45% − 5% = 40% of total height variation to be due to common variants that have yet to be pinpointed. Thus 40%/45% or 88% of genetic variation in height is due to variants that have yet to be pinpointed. As the heritability of height at the time of this analysis was thought to be ~80%, 80% − 45% = 35% of the heritability of height is due to genetic factors other than common variants captured by GWAS.[38]

The ability to detect rare variants using imputation has substantially improved with increasingly large reference haplotype datasets. Using the 1000 Genomes project reference haplotype data for imputation, with genotyping performed using a standard GWAS chip (the Illumina CoreExome chip), 96% of common genetic variation and 73% of rare variation detected in the UK10K whole genome sequencing dataset could be identified. The heritability of height estimated from pedigree studies is thought to be not greater than 69% (and may be lower than this). Heritability estimates from imputed data in 44,126 individuals estimated common variant heritability captured by the GWAS-imputation approach as 56%. This is close to the likely overall heritability.[39] Thus missing variation in height is negligible at this sample size. This study also confirmed that rarer variants contribute more in total to height variance than more common variants, as well as individually having larger effects in carriers; there is some support that this is also the case in BMD variation.[22] It is very likely that these findings can be extrapolated to BMD and osteoporosis risk, and that very large-scale GWAS will be required to capture sufficient genetic variation to enable more accurate genetic risk prediction in osteoporosis.

Skeletal phenotypes are those areas where there is clear overlap between rare and common variant associations. For example, in a GWAS using a unique extreme-ascertainment design, we recently demonstrated association of BMD with common variants in six novel loci (*GALNT3*, *RSPO3*, *CLCN7*, *IBSP*, *LTBP3*, and *SOX4*), and replicated 21 of the then 26 known BMD loci.[40] Of the novel associations, rare variants in *GALNT3*, *CLCN7*, and *LTBP3* were already known to influence BMD. Thus, while BMD may be largely determined by common variants, there is strong a priori evidence that rare variants are also associated with osteoporosis, validating further studies to identify these.

Although gene–gene interaction has been demonstrated in many model organisms,[41,42] it does not contribute to narrow-sense heritability, as assessed in twin studies, and therefore does not explain missing heritability. Few examples of replicated established gene–gene interaction exist for any common human diseases, the most established involving variants of the endoplasmic reticulum aminopeptidase gene *ERAP1* and HLA Class I loci, in ankylosing spondylitis[43] and psoriasis,[44] although epistasis affecting gene-expression appears much more commonly.[45] Gene–gene interaction may be widespread, but current studies are underpowered to detect such effects.

Methylation studies in common human diseases are in their infancy. Affordable, high-throughput, and robust methods for genome-wide analysis of methylation

status have only recently been developed. While more comprehensive whole genome assessment of methylation status by sequencing is possible, such methods are not yet suitable for large-scale studies due to cost and complexity issues. The heritability of DNA methylation has been shown to be significant (0.199 average in peripheral blood, corrected to 0.176 once cellular composition of blood is accounted for) though this figure is somewhat lower than most diseases. Thus methylation varies both from modestly heritable transgenerational effects and from environmental exposures (as methylation is one mechanism by which the genome responds to the environment, reviewed in Ref. 46). Methylation varies between tissues, as well as at different time points in the same individual, and it is not yet clear to what extent methylation patterns in accessible tissues, such as peripheral blood reflect patterns in nonaccessible tissue, such as bone, obviously of critical importance to such studies in osteoporosis. Methylation studies not only require tight control for major environmental covariates, particularly smoking but also age, to avoid spurious results. Nonetheless, it is possible given the heritability of methylation that it too may contribute to unmapped heritability.

5 RARE VARIANT STUDY DESIGNS

Rare variant studies pose significantly greater challenges for gene-mapping studies to common variant studies. These include sample size requirements, genotyping issues, and analysis approaches.

Power for gene-mapping studies depends on the sample size, extent of LD between the genotyped and disease-causing variants, the allele frequencies of those variants and effect size of the disease-causing variant. For variants with a given odds ratio for disease, less-frequent variants have a lower effect size in the population. Thus rare variant studies require much larger cohort sizes than are required for identification of common variants. Sample sizes for GWAS of a quantitative trait (such as BMD) and a dichotomous trait (fracture) are illustrated in Fig. 3.2 shows that rare variant studies require very large sample sizes unless the individual effect size of the rare variants are large, and much larger than that observed for common variants to date. For example, a study of 10,000 fracture cases and 10,000 no-fracture controls would have 80% power to detect a SNP with MAF of 0.1 with a heterozygote odds ratio of 1.2; but for a rare variant SNP with MAF of 0.01, the same study would only have 80% power if the SNP were associated with fracture risk with a heterozygote odds ratio of 1.63, which odds ratio would generally be considered quite high for a common disease. These theoretical estimates are supported by the experience in real-world

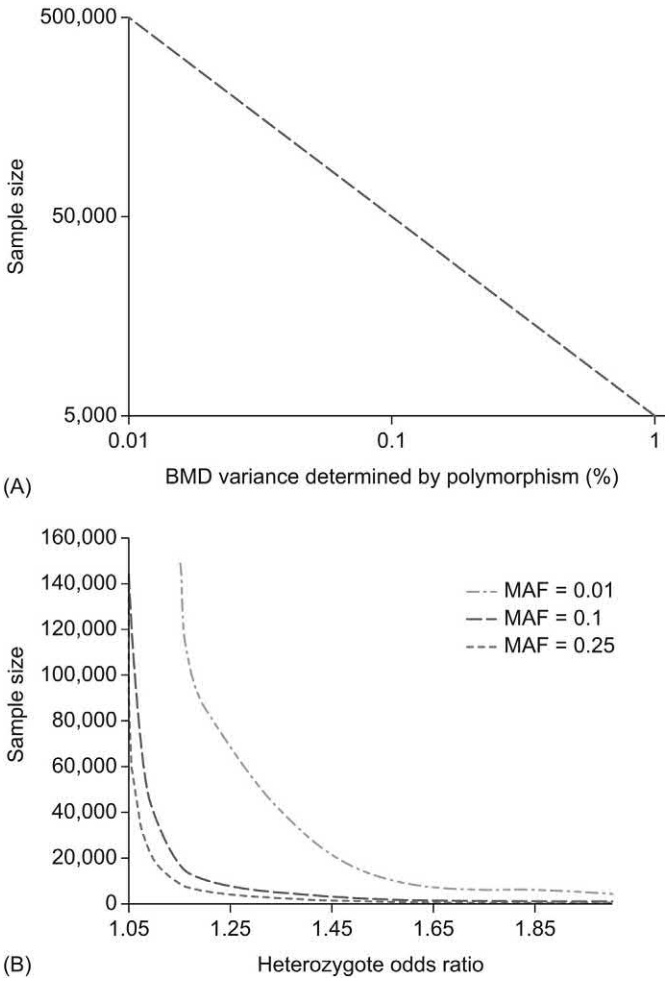

FIGURE 3.2 Sample size requirements for genome-wide association studies (GWAS). Model assumes linkage disequilibrium (LD) (D′) between marker and disease-causative variant of 0.9, equal marker and disease-causative variant allele frequencies, power = 0.8, and $\alpha = 5 \times 10^{-8}$. (A) Sample size for the quantitative trait bone mineral density. (B) Sample size for fracture studies, assuming fracture risk of 20% and an equal number of cases and controls. *MAF*, Minor allele frequency.

gene-mapping studies. For example, a recent study involving 2882 whole genome sequenced subjects, 3549 whole exome sequenced subjects, and 26,534 GWAS genotype and imputed subjects identified one additional novel locus associated through a low frequency but not rare variant (*EN1*, rs11692564, MAF 1.7%).[22] This high-quality study illustrates how hard identifying true rare variants is going to be without much larger sample sizes.

Again considering height as a model trait, Fig. 3.3 shows the proportion of variation captured by height GWAS studies plotted against sample size. Assuming that the genetics of height and BMD variation are similar, it can be extrapolated from Fig. 3.3 that studies of the order of 500,000 samples will be required to capture >90% of BMD variance at genome-wide significance. Such

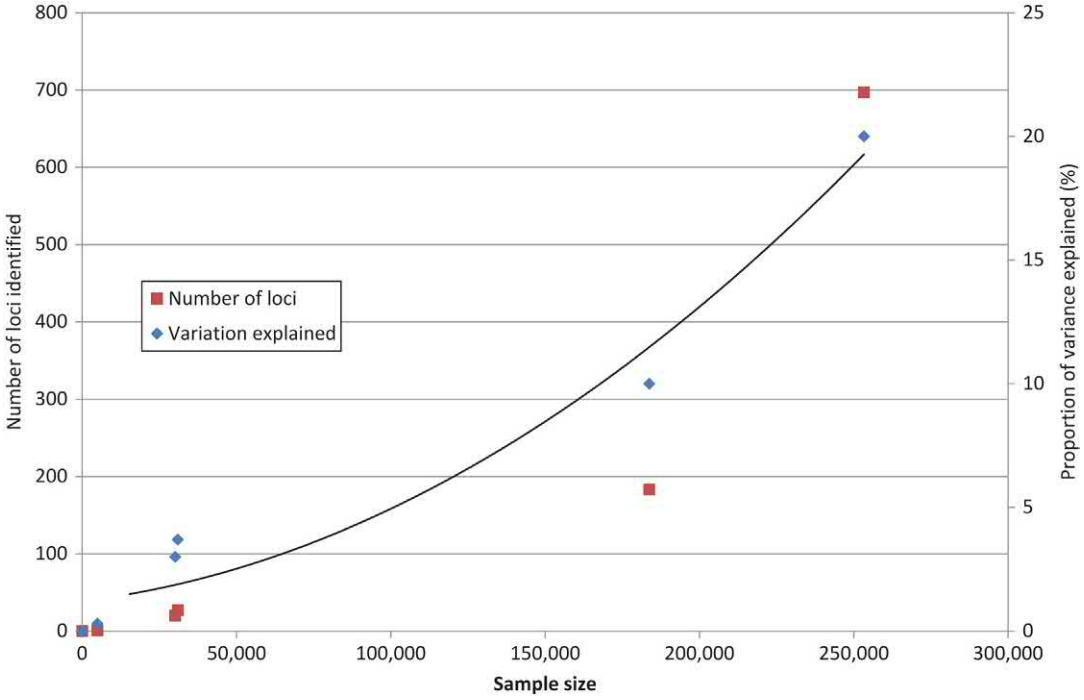

FIGURE 3.3 Genetic studies of height, comparing sample size with number of loci identified and proportion of variance explained. A polynomial trend line has been fitted to the proportion of variance data (r2 = 0.97).

studies [e.g., the UK Biobank study (http://www.ukbiobank.ac.uk/)], are currently in progress, and should provide a definitive view of common and rare genetic variation in BMD. Similarly, large-scale cohort studies will be required to capture a high fraction of variation in fracture risk due to both rare and common variants. Sequencing studies (either whole exome or genome) in either families or cohorts of unrelated individuals with extreme bone phenotypes are likely to be more efficient at identifying disease-associated rare variants or mutations than general population cohort studies. Gene mapping using this approach has been highly successful for extreme bone phenotypes.[47,48] Early studies have shown that studying cases or small families with extreme bone density shows an overrepresentation of mutations in genes known to be involved in high and low bone density diseases.[49] This suggests that more comprehensive genetic screening of similar cohorts would an efficient method for discovering further bone density associated genes.

Sequencing studies (either whole exome or genome) in either families or cohorts of unrelated individuals with extreme bone phenotypes are likely to be more efficient at identifying disease-associated rare variants or mutations than general population cohort studies. Gene mapping using this approach has been highly successful for extreme bone phenotypes.[47,48] Early studies have shown that studying cases or small families with extreme bone density shows an overrepresentation of mutations in genes known to be involved in high and low bone density diseases.[49] This suggests that more comprehensive genetic screening of similar cohorts would an efficient method for discovering further bone density associated genes.

The rapid improvement in the quality and accuracy of imputation allowing in silico genotyping means that this approach is currently the preferred option for capturing rare genetic variant associations. As the known number of rare variants in public databases is extremely large, and is still increasing, existing publically available reference haplotype sets can be used for high-quality imputation of both rare and common variants in already GWAS-genotyped samples. This is a much more cost-effective means of studying rare variants than adopting sequencing approaches wholesale. Whole exome and whole genome sequencing are becoming cheaper—but so are genotyping chips, currently about 100× cheaper than a whole genome scan. Given the large sample sizes needed for adequately powered rare variant studies, the additional cost of sequencing makes this approach currently unaffordable. As many reference imputation datasets are based on healthy controls, they may not contain low-frequency risk or protective variants for diseases, and thus study designs involving sequencing of extreme BMD cases or low trauma fracture cohorts to increase the capture of relevant genetic variants in the reference imputation datasets seems a logical and more cost-effective alternative study design.

6 CONCLUSIONS

GWAS has become the tool of choice for hypothesis-free investigation of the causes of common heritable diseases. With careful quality control and appropriate conservative interpretation, this approach has been very successful in identifying thousands of genetic loci involved in human diseases. Imputation methods now mean that nearly all common genetic variation, including the majority of rare genetic variation, can be captured by low cost microarray SNP GWAS studies followed by imputation, rather than whole genome sequencing. Very large-scale (~500,000) subject studies are going to be required to capture the high proportion (>90%) of genetic variance required for genetic risk prediction to become clinically useful. Such studies are currently underway, making it likely that within the next couple of years the genetic architecture of osteoporosis will be largely characterized. The priority has now shifted from gene mapping to translating these advances into clinically relevant contributions, such as the development of novel therapies for osteoporosis.

1 INTRODUCTION

Humans manifest substantial phenotypic heterogeneity [e.g., height, body mass index (BMI), hair color, eye color, skin color, and susceptibility to diseases]. Nevertheless, one striking conclusion from The Human Genome Project is the similarity of DNA sequences among different individuals; approximately 99.9% of the DNA sequence from any two unrelated humans is identical.[1–3] Therefore, the extent to which phenotypic heterogeneity can be explained by differences in DNA sequence seems attributable only to relatively minor variations. Consequently, single-nucleotide polymorphisms (SNPs) have become the focus of a large number of studies designed to identify critical differences in DNA sequence, which contribute to phenotypic variation for specific traits.[4] Although this approach has been highly productive, resulting in the identification of numerous associations between novel SNPs and a range of common and complex diseases, only a modest degree of phenotypic variation has been explained by SNPs.[5–7] This has led to broader hypotheses regarding the potential genetic basis of this "missing heritability."[6]

Copy number variation (CNV) has been proposed as one other type of genetic variation that contributes to phenotypic variance.[8] For nearly all genes in the human genome, we inherit one copy from each parent, and thereby have two copies in the nucleus of every diploid cell. For some genes, however, the copy number varies from this norm. For example, several β-defensin genes represent examples of common CNVs, with between two and seven copies per diploid cell.[9] Another common example of a CNV involves the UDP glucuronosyltransferase 2 family, polypeptide B17 gene, *UGT2B17*. East Asian populations often have a homozygous deletion of this gene resulting in zero copies in diploid cells.[10,11] CNVs, then, are defined as structural variations in chromosomes representing DNA segments of 1 kb or more that are present at varying copy numbers in the genome of different individuals.[8,12] CNV may either be inherited from a parental genome, or caused by mutation designated de novo CNV. In this case, the region of de novo CNV in both parent's genome is expected to be normal. CNVs may manifest as simple deletions, insertions, or duplications (Fig. 4.1). A CNV that reaches a population frequency greater than 1% is defined as a common CNV, or as a copy number polymorphism (CNP). CNVs that are found in less than 1% of the population, in contrast, are referred to as rare CNVs.

The first discovery of CNV in humans can be traced back to the early 1900s when a man was identified with a single X chromosome and no Y chromosome.[13] Trisomy 21 represents the first discovery of human autosomal CNV. Identification of these CNVs relied on relatively insensitive techniques that only permitted detection of variations that could be detected using optical microscopes, such as aneuploidies, marker chromosomes, gross rearrangements, and variations in chromosome size.[14,15] The population frequency of these early discoveries of gross CNVs, however, was very low and was directly related to specific genomic disorders.[16–18] Accordingly, the contribution of smaller CNV toward more subtle phenotypic variations was not yet generally appreciated. Now, we recognize that most CNVs or CNPs represent submicroscopic chromosomal structural variations that escape detection with even the most powerful optical microscopes. A major contribution to our understanding of these submicroscopic CNVs was attributable to Redon et al.[8] who constructed the first comprehensive

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00004-6

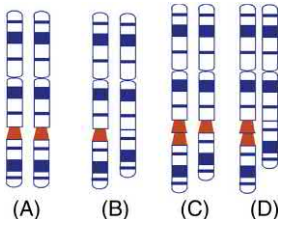

FIGURE 4.1 Copy number variation (CNV). The *trapezoid* delineates the region with variation. (A) Normal copy numbers; (B) deletion; (C) duplication; and (D) multiallelic loci with a duplication on one chromosome and a deletion on the other chromosome.

human CNV map, using 270 HapMap individuals,[8] and observed that CNVs exist in healthy people. Among their 270 study subjects, almost 12% on an average of the whole genome in each individual, approximately 360 Mb, had CNVs. Most of these CNVs were of relatively small size (less than 20 kb), and many were present at >1% in this population, thus being categorized as polymorphisms (CNPs). With the increasing number of published high-quality data, Zarrei et al.[19] constructed an updated CNV map of the human genome recently. They estimated that 4.8%–9.5% of the genome contributes to CNV, which is lower than that of what Redon et al. reported. In the meantime, they found approximately 100 genes that can be completely deleted without producing any apparent phenotypic consequences.[19] Likewise, Shen et al. also observed general gene "knocked out" and provided a comprehensive characterization of human genomic variation as well, by performing a whole genome sequencing study in 44 unrelated healthy Caucasian adults.[20] As it became increasingly apparent that there are interpopulation differences in gene copy numbers,[8,21] it was hypothesized that CNVs could be comparable to SNPs in playing important roles in adaptation to different environments, susceptibility to common diseases, and evolution. However, if SNPs can serve as proxies for CNVs,[22,23] it is not necessary to investigate CNVs, as the methods of SNP genotyping and data analysis are much easier than those of CNVs. To validate this hypothesis, Stranger et al.[24] studied the relative contribution of CNVs and SNPs to variations in gene expression in lymphoblastoid cell lines from 210 unrelated HapMap individuals. They found that SNPs and CNVs captured about 80 and 20%, respectively, of the detected variation in gene expression. Importantly, there was little overlap in the signals from these two sources of variation.[24] This finding strongly supports the conclusion that CNVs critically regulate gene expression.

1.1 Potential Mechanisms for Formation of CNVs

CNVs often occur in regions that contain segmental duplications.[25–28] Segmental duplications are blocks of DNA that typically share more than 90% sequence identity and occur at more than one site within the genome.[29] The well-known mechanism for CNV that is associated with segmental duplications are nonallelic homologous recombination mechanisms (NAHR).[30] Homologous recombination is thought to be a classical mechanism for promoting genetic diversity.[31] For instance, in a meiotic diploid cell, recombination can switch allele combinations along a linear chromosome. Therefore, a novel haploid in the subsequent generation is produced. NAHR is a form of homologous recombination that occurs between two lengths of DNA that have high sequence homology, but are not alleles.[32] When NAHR occurs between sequences of DNA that have different low-copy repeats, copy number changes (deletions or duplications) of the DNA can occur.[33,34] For example, in a diploid cell, each allele has two copies at a specific chromosome site. There is no deletion or duplication in this generation. However, when NAHR occurs, there is an exchange between the two copies from one allele and one copy from another allele, thereby producing a novel allele (one copy or three copies) for the subsequent generation.

Not all CNVs are associated with segmental duplications. Some CNVs are thought to arise via another recombination-based mechanism, nonhomologous end joining (NHEJ).[35] This is a pathway that repairs double-strand breaks in DNA. In NHEJ, when double strand DNA breaks are detected, the broken DNA ends will be bridged, modified, and then ligated. During this process, the product of repair often contains additional sequence at the DNA end junction, leaving a "DNA scar."[36,37] After NHEJ, for this additional sequence, it might be a duplication in contrast to cells with no NHEJ.

Another formation of nonhomologous junctions linked to DNA replication has been regarded as the replicative mechanism. During replication, the sequence between the homologous regions, expected to be single stranded, is often deleted or duplicated. This deletion or duplication has been attributed to a mechanism of replication slippage along the exposed template during DNA replication.[38,39] There is growing evidence for the involvement of replication in underling copy number change. For example, aphidicolin, an inhibitor of replicative DNA polymerases, induces CNV at chromosomal fragile sites and throughout the genome.[40–42]

2 CNV DETECTION

Several methods have been developed for analysis of unbalanced chromosomal structural variants, we have summarized the most common used methods in Table 4.1. For CNV detection, the common approaches are array-based analyses[8,11,26,27,43–49] and quantitative, primarily polymerase chain reaction (PCR)–based,

TABLE 4.1 Summary of CNV Detection Methods

Schemes	Technologies	Characteristics	Platforms for examples	References
Genome-wide CNV detection	CGH arrays	Reference and test DNA comparing by labeling different fluorescent tags	Roche NimbleGen, Inc.	55
	SNP arrays	SNP genotyping	Affymetrix Genome-Wide Human SNP Array 6.0	11

Candidate CNV detection	qPCR	CNV candidate regions genotyping by detecting the C_t value		8
	MLPA and MAPH	Simultaneous analysis of multiple genomic regions		50,54

CGH, Comparative genome hybridization; SNP, single-nucleotide polymorphism; qPCR, quantitative real-time polymerase chain reaction.

assays.[8,11,12,50–54] Array-based comparative genome hybridization (array-CGH) approaches[8,55,56] and SNP arrays[8,11] are the most powerful and robust methods for genome-wide CNV detection.

1. *Genome-wide CNV detection*
   - **a.** *Comparative genomic hybridization arrays*: CGH arrays represent the most widely used method for genome-wide CNV identification. This approach uses different fluorescent tags to label normal control (reference) DNA and test DNA. Then, reference and test DNA are simultaneously hybridized to the array, and CNV genotype can be inferred by comparing the respective signal intensities. Bacterial artificial chromosome (BAC) clones, which can cover most of the human genome, serve as the source for standard CGH arrays.[55] Although BAC arrays provide robust coverage of the genome and a high signal-to-noise ratio, the resolution is relatively low; they cannot detect CNVs smaller than 50 kb, due to the large size of BAC probes.[18,58,59]

     As a result of the development of microarray technology, high-density oligonucleotide arrays are available for CNV detection. For example, a 385K human tiling array and a 2.1-million oligonucleotide array are commercially available through Roche NimbleGen, Inc. (Madison, Wisconsin, USA). Compared to BAC arrays, the resolution of these arrays is significantly improved, but the signal-to-noise ratio from hybridization intensities is decreased.[60]
   - **b.** *SNP arrays*: SNPs have received considerable attention as a major source of human variation.[4] The development of high-throughput array technologies for SNP genotyping has made genome-wide association study (GWAS) feasible.[61] Although these arrays were initially designed for simple SNP genotyping, they are increasingly "mined" for CNV analysis by reanalyzing probe intensity information.[8,11] For the Affymetrix GeneChip 500K (Santa Clara, California, USA), although SNPs have a median spacing of 2.5 kb, the resolution of this array is better because it has a lower limit of 10–40 kb due to the uniformity of probe distribution across the genome.[60] Another problem for this array is that the boundary of a CNV can only be determined by the position of the analyzed SNPs, which are unlikely to be present at the exact start or end point of the CNV. Thus, SNP arrays cannot be used to delineate the precise boundaries of each CNV. Arrays available from both Affymetrix and Illumina (San Diego, California, USA) have added specific probes for CNV detection. For example, the Affymetrix Genome-Wide Human SNP Array 6.0 features 1.8 million genetic markers, including more than 906,600 SNPs and an additional 946,000 CNV-specific probes. Thus, the resolution and boundary problems mentioned previously are significantly improved with these latter arrays.
   - **c.** *Resequencing*: The precise sequence of nucleotides in a DNA sample can be determined by DNA sequencing, and analysis of these data can provide highly accurate information about CNVs. For example, by comparing two completed sequence assemblies, Khaja et al.[57] successfully identified 13,066 previously undescribed structural variations in the human genome, including 419 CNVs. Unlike array-based approaches, DNA sequencing provides revolution on understanding the structure and specifying the location. The most important benefit of this technology is that it is possible to discover a multitude of variant classes with a single sequencing experiment.[62]

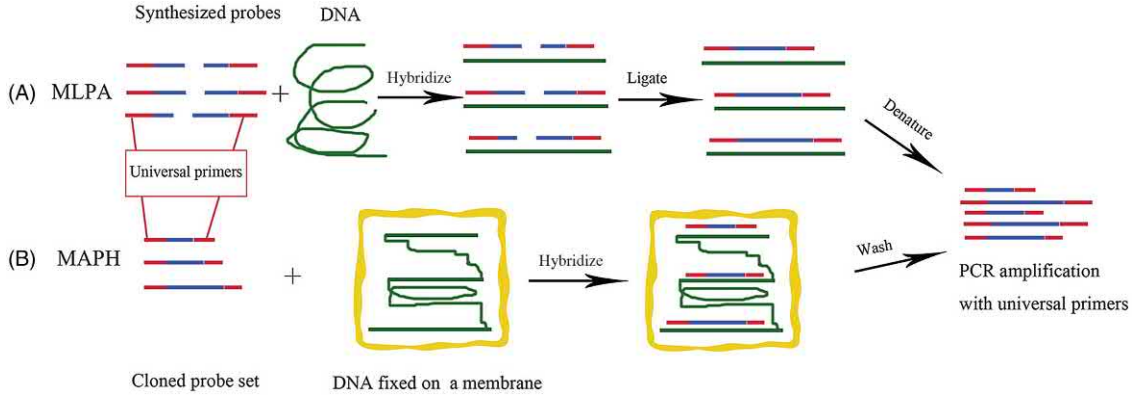

FIGURE 4.2 (A) Multiplex ligation-dependent probe amplification (MLPA) and (B) multiple amplifiable probe hybridization (MAPH).

With the rapid development of high-throughput DNA sequencing ("next-generation" sequences), such as Roche/454FLX, the Illumina/Solexa Genome Analyzer, and the Applied Biosystems SOLiDTM System,[63,64] it is feasible to sequence complete genomes of increasing numbers of subjects and contribute to accurate identification of genomic variations. Based on the next-generation sequencing technologies, Duan et al. practically developed different procedures for CNV detection. For instance, they proposed a method by optimizing a total variation penalized least square criterion,[65] as well as a novel and robust method to detect CNV from short sequencing reads derived from the next-generation sequencing data.[66] As this approach is increasingly utilized, genome comparisons and CNV identification will become more robust and reliable.[67]

2. *Candidate CNV detection*

a. *Quantitative real-time PCR* (*qPCR or RTPCR*): Although quantitative real-time PCR is not suitable for the simultaneous amplification of a large number of targets, it has been one of the most commonly used methods for genotyping candidate regions for CNV.[8] qPCR uses a fluorescent tag to monitor signal intensity for each cycle. The greater the number of copies of a target sequence within a DNA fragment, the lower the C_t value (i.e., the number of cycles required for the fluorescent signal to exceed background levels). Thus, qPCR is an efficient method for detecting deletions or duplications at a single locus. Alternatively, as the developing technology, digital or single-molecular PCR allows screening of samples and sites in an emulsion or a microfluidic device.[68,69] With the benefit of accurate enumeration of PCR results, these technologies allow the detection of events located on a single DNA fragment, which allows analysis of rare subpopulations or individual alleles.[70]

b. *Multiplex ligation-dependent probe amplification* (*MLPA*) *and multiple amplifiable probe hybridization* (*MAPH*): MLPA and MAPH both represent targeted PCR-based methods that simultaneously analyze multiple genomic regions.[50,54,71] MLPA works by quantifying probes that hybridize to genomic DNA and amplified by PCR.[72] The clever design of MLPA is the synthesized probe (Fig. 4.2A). Each probe includes two oligonucleotides, one synthetic "left probe" oligonucleotide and one "right probe" oligonucleotide. Both of them are flanked by a universal primer sequence and are derived from the M13 bacteriophage. When both probe oligonucleotides are hybridized to their respective targets, they are ligated into a complete probe and amplified by PCR with universal primers. The products of the universal primers have unique sizes that can then be separated by capillary electrophoresis. In the MAPH technique (Fig. 4.2B), genomic DNA must be fixed to a membrane, and then hybridized with a set of probes. The probes must be of different sizes, and their products must be distinguishable by electrophoresis. Multiple amplifiable probes are prepared by PCR amplification using common primers flanking the vector-cloning site. Amplification products are analyzed by slab gel or capillary electrophoresis. For both MLPA and MAPH, reduced peaks are indicative of deletions whereas enhanced peaks indicate duplications.

3 CNV AND DISEASE

CNVs, including duplications and deletions, can influence gene expression by disrupting gene coding sequences, perturbing long-range gene regulation, or altering gene dosage. Through these mechanisms, CNVs are believed to cause, or affect susceptibility to, human diseases.[18,37,73] The CNV-related diseases investigated so far are summarized in Table 4.2.

1. *CNV and rare human diseases*: The relatively crude methodology of microscopic chromosomal examination to detect variations in chromosome structure or number has contributed to our recognition of associations between CNVs and human disease.[37] For example, the duplication of chromosome 21 (trisomy 21) results in Down syndrome (DS)[74] and deletion of chromosome 15q11.2-q12 causes Prader–Willi syndrome

TABLE 4.2 Summary of CNV-Related Diseases

	Diseases	Pathomechanisms	References
Rare human diseases	DS	Duplication of chromosome 21 (trisomy 21)	74
	PWS	Deletion of chromosome 15q11.2–q12	75
	Williams–Beuren syndrome	Microdeletion on chromosome 7q11.23	76
	SMA	Deletion of exons 7 and 8 of *SMN* gene	77
	VCFS	Deletion of ~3 Mb in chromosome 22q11	78
	CHARGE syndrome	De novo 4.8-Mb deletion in 8q12	49
	Syndactyly and craniosynostosis	A 9-kb duplicated region located at 40-kb upstream of *IHH*	79
	Monogenic diseases (deletions and duplications involving the X chromosome)	*AR* gene of Xq11-q12 in androgen-insensitivity syndrome	49,80,81
		COL4A5 gene of Xq22.3 in X-linked Alport syndrome	
		IDS gene of Xq28 in mucopolysaccharidosis type II	
		RS1 gene of Xp22.2–p22.1 in X-linked juvenile retinoschisis	
		DMD gene of Xp21.2 in Duchenne muscular dystrophy	
		Insertion on chromosome Xq27.1 in X-linked recessive hypoparathyroidism	82
Common human diseases	Obesity	Deletion near the *NEGR1* gene	83
		CNV of *PPYR1* gene	84
		CNV on chromosome 11q11	85
		CNV on chromosome 15q11–q13	86
	Schizophrenia	CNVs on chromosome 1q21.1 and 15q13.3	87,88
		Deletion on chromosome 17q12	89
		Large duplications (1.5–3.0 Mb) at 22q11.2	90
	Autism	600-kb deletions and duplications on 16p11.2	91
		CNV of *NLGN1* and *ASTN2* genes	92
	Cancer	CNV of *PAX5* gene in ALL	93
		MICA and *HCP5* gene deletions on chromosome 6p21.3 in NPC	94
		Amplifications of *NFE2L2*, *MYC*, *CDK6*, *MDM2*, *BCL2L1*, and *EYS*; deletions of *FOXP1*, *PTEN*, and *NF1* in lung squamous cell carcinoma	95
	CHD	CNV of *NODAL*, *CFC1*, and *NOMO3* genes	96

ALL, Acute lymphoblastic leukemia; CHARGE, a pleiotropic disorder characterized by coloboma, heart defects, choanal atresia, and retarded growth and development; CHD, congenital heart disease; DS, Down syndrome; NPC, nasopharyngeal carcinoma; PWS, Prader–Willi syndrome; SMA, spinal muscular atrophy; VCFS, velo–cardio–facial syndrome.

(PWS).[75] As technology has improved, our ability to determine the contribution of CNVs to human disease has increased dramatically, and CNVs are now known to contribute to cause several additional rare human diseases. In 1993, a microdeletion on chromosome 7q11.23, that included the elastin gene, was found to cause Williams–Beuren syndrome, a disease characterized by mental retardation, infantile hypercalcemia, and a variety of congenital heart defects.[76] In 1997, Campbell et al. [77] found that exons 7 and 8 of the telomeric SMN gene, located on chromosome 5q13, were not detectable in more than 90% of patients with spinal muscular atrophy (SMA). Subsequent examination of point mutations and gene conversions in the *SMN* gene confirmed that CNV played a major causal role in SMA disease. In the same year, Carlson et al. determined that 83% of 151 patients with velo–cardio–facial syndrome (VCFS), a developmental disorder characterized by craniofacial anomalies, conotruncal heart defects, and disturbance in calcium levels, had a deletion of ~3 Mb in chromosome 22q11.[78] This region contains many genes, including *GSCL*, *CTP*, *CLTD*, *HIRA*, and *TMVCF*. Further study of hamster–human somatic hybrid cell lines derived from VCFS patients, showed that the breakpoints occurred within similar low-copy repeats termed LCR22s.[97] Additionally, 18 patients with CHARGE syndrome, a pleiotropic disorder characterized by coloboma, heart defects, choanal atresia, and retarded growth and development, were tested for CNV using a 1-Mb resolution genome-wide BAC array.[49] One de novo 4.8-Mb deletion was identified on 8q12 in a patient. Sequence analysis revealed that the causative mutation involves the *CHD7* gene, a novel member of the chromodomain helicase DNA-binding gene family. Later in 2011, Klopocki et al.[79] identified duplications at the Indian hedgehog (*IHH*) locus, a morphogen of the hedgehog family, in three unrelated families affected by syndactyly and craniosynostosis. These syndromes related to the disorder of bone formation. After describing a 9-kb duplicated region located at 40-kb upstream of *IHH*, which encompassed potential *cis*-regulatory elements, the authors speculated that the duplications interfere with the looping and interaction mechanism of the *IHH* promoter and several *cis*-regulatory elements.

Large deletions and duplications involving the X chromosome have been implicated in a number of serious monogenic diseases. Pertinent examples include the *AR* gene of Xq11–q12 in androgen-insensitivity syndrome, the *COL4A5* gene of Xq22.3 in X-linked Alport syndrome, the *IDS* gene of Xq28 in mucopolysaccharidosis type II, the *RS1* gene of Xp22.2-p22.1 in X-linked juvenile retinoschisis, and the *DMD* gene of Xp21.2 in Duchenne muscular dystrophy.[49,80,81] Moreover, Bowl et al.[82] identified a large insertion on chromosome Xq27.1 in X-linked recessive hypoparathyroidism patients.

2. *CNV and common human diseases/complex traits*: Several common complex human diseases, including obesity, schizophrenia, autism, and cancer, have been shown to be associated with CNVs.[37]

3.1 Obesity

Obesity is a serious health problem with strong genetic determination, characterized by a high BMI. Several studies have been performed to analyze associations between CNVs and obesity. For example, a common deletion near the *NEGR1* gene was determined to be associated with BMI in a metaanalysis of 15 GWASs comprising more than 32,000 individuals.[83] This result was replicated by another study in nearly 300,000 subjects using the same approach.[98] Interestingly, a research focused on severe early-onset obesity identified another 43-kb deletion of *NEGR1*, partially overlapped with reported segment, significantly associated with severe obesity.[99] They also found that this signal was entirely driven by a flanking 8-kb deletion that provided a protective effect. *NEGR1* encodes neuronal growth regulator 1, which may be involved in cell adhesion. The protein encoded by this gene is a member of the type 3 G protein–coupled receptor family and may mediate the cellular effects of retinoic acid on the G protein signal transduction cascade.[100,101] However, there is no evidence for a direct connection between this gene and obesity. Neuropeptide Y receptor (pancreatic polypeptide 1, *PPYR1*) is a member of the seven transmembrane domain G protein–coupled receptor family. Peripheral administration of pancreatic polypeptide inhibits gastric emptying and decreases food intake in humans.[102,103] A CNV of *PPYR1* was detected in a Chinese population, thus suggesting that the CNV of *PPYR1* might be important for BMI variation.[84] However, a conflict is reported for deletion of *PPYR1* between human and mice.[104] For instance, null *PPYR1* mice have reduced body weight, but *PPYR1* gene deletion was associated with obesity.[84,85] This requires further studies for validation.

Using the Affymetrix Genome-Wide Human SNP Array 6.0, Jarick et al.[85] performed a GWAS between common CNVs and early-onset extremely obese children in 424 case–parent obesity trios, an independent sample of 453 extremely obese children and adolescents, and

435 controls. They found a novel CNV on chromosome 11q11 that was significantly associated with obesity. Wang et al.[105] performed another genome-wide CNV survey using 430 obese case subjects (BMI > 35) and 379 never-overweight control subjects (BMI < 25), and found that large CNVs are enriched in the obese individuals. The CNV that was found to be associated with PWS (chromosome 15q11–q13) has also been found to be associated with obesity in a study of 1000 unrelated US Caucasians.[86]

3.2 Schizophrenia

Schizophrenia is a highly heritable, psychiatric disease that often causes substantial social and occupational dysfunction.[106] Using high-density microarrays, two powerful large-scale association studies identified CNVs on chromosome 1q21.1 and 15q13.3 associated with schizophrenia.[87,88] These two CNVs were rare, with frequencies of ~0.1%–0.3% in schizophrenia cases and 10-fold less in control subjects. The sample sizes of these two studies were large and provided sufficient power to detect these rare CNVs. One study used 3,391 schizophrenic patients and 3,181 controls,[87] and the other [88] investigated 4,187 schizophrenic patients and 41,201 controls. A number of highly plausible schizophrenia candidate genes are located in these two regions. For example, at 1q21.1, the gene connexin-50 (*GJA8*), which encodes a gap junction subunit, was previously suggested as a schizophrenia gene.[107] Also, 15q13.3 contains another schizophrenia candidate gene, α7 nicotinic receptor gene *CHRNA7*.[108] Another large schizophrenia sample comprised of 6,882 cases and 11,255 controls was genotyped on Illumina arrays, aiming to discover novel susceptibility CNV loci.[109] However, after replication analysis in additional 14,568 cases and 15,274 controls, 12 distinct loci were identified with nominal levels of significance. There was another study performing cytogenomic array within 15,749 cases and 4,519 controls.[89] A rare deletion on chromosome 17q12 was identified to be significantly associated with schizophrenia. Moreover, 18 of 15,749 patients, but none of the controls, had this deletion. Fifteen genes are located in the deletion interval. Among them, *LHX1* is dosage sensitive and essential for normal brain development and function.

Besides the deleterious effect, large, rare CNVs could play a protective role in neurodevelopmental disorders as well. The largest CNV analysis of schizophrenia (47,005 individuals) to date reported that large duplications (1.5–3.0 Mb) at 22q11.2 were less common in schizophrenia cases than in the general populations (0.014% vs. 0.085%),[90] representing the first putative mutation for schizophrenia.

3.3 Autism

Autism spectrum disorders (ASDs) represent a neurodevelopmental disease characterized by impairment of social interactions, a restricted range of behaviors, and problems in communication.[110] In 2007, two landmark studies showed that de novo CNVs were important genetic factors for the pathogenesis of ASDs.[111,112] The Autism Genome Project Consortium used Affymetrix 10K SNP arrays to investigate 1181 families with at least 2 affected individuals, and found 154 CNVs in the autism cases.[112] By examining 264 families with at least one case of ASD, Sebat et al. [111] found that 10% of sporadic cases had de novo CNVs, compared with 3% of healthy members within case families, whereas 1% in control families had de novo CNVs. Marshall et al.[113] obtained similar results by analyzing 427 unrelated ASD cases via SNP microarrays and karyotyping. Weiss et al.[114] and Kumar et al.[91] determined that ~1% of patients with autism had common recurrent 600-kb deletions and duplications on 16p11.2. Using SNP microarrays and examining 2195 patients with ASD and 2519 healthy controls, Glessner et al.[92] determined that several new susceptibility genes, such as *NLGN1* and *ASTN2*, were enriched within CNV regions in cases compared to controls. Additionally, to estimate the effect of CNVs in the 1–30 kb range in an autism case–control sample, Poultney et al.[115] made use of the eXome Hidden Markov Model (XHMM) program to identify exonic CNV from whole-exome sequencing data, and observed significant increase in the burden of rare CNVs in ASD. eXome Hidden Markov Model is an approach that uses principal component analysis to normalize exome read depth and a Hidden Markov Model to identify exonic CNVs.[116]

3.4 Cancer

Although the exact pathogenic mechanisms leading to many cancers are unclear, the consensus view is that cancer results from dysregulation of the activity or expression of genes that control cell growth and differentiation, leading to abnormal cell proliferation.[117] CNVs have been reported in many kinds of cancers,[18] and presumably contribute to this dysregulation.

Using high-resolution SNP arrays, Mullighan et al.[93] performed a genome-wide analysis of leukemic cells from 242 pediatric patients with acute lymphoblastic leukemia (ALL). They found copy number changes in *PAX5*, a gene within the B-cell development pathway, in 57 of 192 ALL cases. CGH analysis has also shown that CNVs are associated with prostate cancer,[118] breast cancer, and colorectal cancer.[119] Utilizing genome-wide SNP-based arrays, Tse et al.[94] identified eight regions with CNVs including six deletions (on chromosomes 3, 6, 7, 8, and 19), and two duplications (on chromosomes 7

and 12) that were significantly overrepresented in nasopharyngeal carcinoma (NPC) patients compared with healthy controls. Among these CNVs, *MICA* and *HCP5* gene deletions on chromosome 6p21.3 showed the highest association signal. Examining 51 BRCA1-associated ovarian cancer patients, and 47 healthy women via Affymetrix Genome-Wide Human SNP Array 6.0, Yoshihara et al.[120] identified germline CNVs in BRCA1-associated ovarian cancer patients. Besides, in the year of 2012, as part of The Cancer Genome Atlas (TCGA) project, a comprehensive study of lung squamous cell carcinoma was conducted, and a landscape of genomic and epigenomic characteristics, including CNVs identification, was descripted subsequently.[95] Using the SNP 6.0 array platform and GISTIC 2.0, they identified 50 peaks of significant amplification or deletion regions, among which included the regions reported for the first time, including amplifications of *NFE2L2*, *MYC*, *CDK6*, *MDM2*, *BCL2L1*, and *EYS* and deletions of *FOXP1*, *PTEN*, and *NF1*.

3.5 Congenital Heart Disease

Congenital heart disease (CHD) usually refers to abnormalities in the heart's structure or function that arise before birth,[121] and affects 0.8% of live birth.[122] The presence of mutations in regulators of heart development during embryogenesis is reported as the major cause of CHD,[123] which relies on the identification of *TBX5*, *NKX2-5*, *GATA4*, *TBX1*, and *SALL4* one after another.[121]

Several studies have shown that rare de novo and inherited copy number variants were enriched in classified CHD patients. For example, Warburton et al. used the NimbleGen HD2-2.1 CGH platform to identify CNVs from 223 consecutively ascertained families.[96] They established 12 CNVs and several implicated genes that were likely causes of CHD after fluorescent in situ hybridization and qPCR confirmation, including *NODAL*, *CFC1*, and *NOMO3*, which have interaction in the nodal pathway. Similarly, Erdogan et al.[124] performed a submegabase resolution array CGH on 105 patients with CHD, as well as subsequent qPCR and fluorescent in situ hybridization verification. As the result, three de novo and eight inherited CNVs were identified, which provide the elucidation of the pathogenetic mechanisms underlying CHD. Additionally, Sailani et al.[125] reported genomic variations that determine the risk for CHD in DS. It is said that CHD occurs in 40% of DS cases.[125] The authors performed a case–control GWAS study, including 187 DS with CHD as cases, and 151 DS without CHD as controls. Finally, two regions were successfully replicated, which are both located at chromosome 21. The result highlights the potential role of the CNV architecture on the CHD risk of DS.

4 CNV AND OSTEOPOROSIS

CNVs have also been found to be associated with susceptibility to Parkinson disease, Alzheimer disease, HIV infection, and Crohn disease.[18,37] However, few studies have been performed to detect the association between CNVs and bone-related diseases.[11,126,127] In this section, we discuss in detail the relationship between CNVs and the most common bone diseases, osteoporosis (OP).

OP is the most common metabolic bone disease in humans, generally characterized by low–bone mineral density (BMD), poor bone quality (characterized by bone geometry etc.), and/or increased susceptibility to low-impact osteoporotic fractures (OF). It is widely accepted that variation in BMD and bone geometry, and risk for OFs, are largely determined by genetic factors, but the overwhelming majority of genetic variation accounting for OP risk has not been determined.[128] Previous investigations,[128] including recent GWASs,[129–135] have focused on SNPs, and have shown that a number of genes or SNPs appear to enhance the risk of developing OP. Collectively, however, all of these implicated genes or SNPs account for only a small portion of the risk of OP. Consequently, it has become important to explore whether some remaining undiscovered genetic factors that influence risk of OP are due to genomic mechanisms other than individual mutation changes, such as CNVs.

The first investigation of CNVs in OP was performed by Yang et al.[11] who studied 350 elderly Chinese Han subjects with a history of hip OF and 350 healthy age-matched controls. They constructed a genomic map containing 727 CNV regions, using Affymetrix Human Mapping 500K Arrays. Subsequently, 116 common CNVs with frequencies exceeding 1% were detected. CNV 4q13.2 was determined to have a significant distribution difference between patients and controls, with a P value of 2.0×10^{-4}. Five protein-coding genes, *UGT2B17*, *YTHDC1*, *TMPRSS11E*, *TMPRSS11E2*, and *UGT2B15*, are located within CNV 4q13.2 and its flanking region. After fine mapping, these investigations found that gene copy number deletions were only observed for *UGT2B17*. Subjects with one or two copies of *UGT2B17* had a greater risk of OF than those with homozygous deletions. These results were replicated in another Chinese sample of 399 patients with hip OF and 400 controls. They further examined this CNVs relevance to major risk factors for OF (i.e., hip BMD and femoral neck bone geometry, i.e., cortical thickness and buckling ratio) in both Chinese and Caucasian DNA samples, and found that copy number deletions of *UGT2B17* are much more common in Chinese than in Caucasians. Further, although the signal of association tests was less significant in

Caucasians than in Chinese, the relationship between CNV of *UGT2B17* and risk of OP exhibited the same trend within both Chinese and Caucasian populations, that is, higher *UGT2B17* gene copy numbers were associated with lower BMD, thinner cortical thickness, higher buckling ratio, and an increased risk of OF in both populations. The *UGT2B17* gene encodes a key enzyme responsible for glucuronidation of androgens and their metabolites in humans.[136,137] Androgen is a major source for estrogen, and both androgen and estrogen have direct effects in stimulating bone formation.[138] The authors also examined the relationship between serum total testosterone or estradiol levels and the *UGT2B17* gene copy number in 236 Chinese young men. Testosterone and estradiol concentrations were significantly reduced in the men with homozygous deletions of *UGT2B17*.

Subsequently, Chew et al.[126] genotyped *UGT2B17* copy number in 1347 elderly Caucasian women, and in contrast found no evidence of an effect of *UGT2B17* CNV and OP risk. These conflicting results might be attributed to differences in patient populations and the differences in CNVs between these populations. For example, in the Caucasian sample of 1000 unrelated subjects, Yang et al.[11] determined that 11.9% of the study subjects had a homozygous deletion of *UGT2B17*, 44.4% had a heterozygous deletion, and 43.7% had two copies. In marked contrast, in the Chinese DNA samples, 76.8% had homozygous deletions of *UGT2B17*, 21.6% had heterozygous deletions, and 1.6% had two copies.[11] In the study of Yang et al., the association signal between *UGT2B17* CNVs and risk factors for OP was only moderate in Caucasians.[11] Consequently, it is not totally unexpected that Chew et al.[126] did not detect this association in Caucasians.

Deng et al.,[127] using the same 1000 unrelated Caucasian subjects studied by Yang et al.,[11] detected a CNV in the *VPS13B* gene that was significantly associated with spine, hip, and femoral neck BMD, as well as bone geometry at the femoral neck.

Later in 2013, Oei et al. performed another genome-wide CNV association study in 5178 individuals from a prospective cohort in The Netherlands and executed in silico lookups, as well as de novo genotyping to replicate.[139] As the result, they successfully observed a rare 210-kb deletion located on chromosome 6p25.1 significantly associated with the risk of fracture. However, this signal was indicated to be predisposed to higher risk of fracture only in the population of European origin.

Collectively, these studies lend fairly strong support for the conclusion that CNVs can contribute to the genetic predisposition to develop OP. Further studies are needed to validate the relationship between CNVs and OP.

5 CONCLUSIONS

CNVs represent regional chromosomal mutations. Therefore, they contain more sequence information and have higher per-locus mutation rates than SNPs. Likely, they are responsible for changes in gene function and genome evolution via gene deletion, duplication, or exon shuffling. Studies of CNVs in human disease have progressed rapidly. CNVs play an important role in a range of human disorders, but these CNVs can be rare, common, or de novo. However, the mechanism(s) by which CNVs alter susceptibility to diseases remains unknown, but will undoubtedly be the subject of future investigations.

1 INTRODUCTION

This year marks the 14th anniversary of the completion of the Human Genome Project,[1,2] a landmark achievement that has provided the road map for human genetics to query every base pair against possible functional attributes contributing to tissue patterning, metabolism, or disease. While the advantages of embracing genomic technologies to advance our understanding of gene function and association to disease may seem obvious, many scientific disciplines have lagged behind in adopting genomic approaches to further their scientific studies. A PubMed query using the keyword "genomics" returns ~150,000 entries; "bone genomics" contributes less than 1% in contrast to "cancer genomics" which is the most populous category representing >17% of this total collection. Of ~2100 publications associated with the keyword "bone genomics" >50% (~1200) of them were published in the past 5 years, suggesting that the bone biology field is making rapid progress in embracing the new genomic technologies. However, more specialized searches, such as "osteoblast genomics" or "chondrocyte genomics," narrow the search to 235 and 170 publications, respectively, highlighting the need for the field of skeletal biology to more aggressively adopt genomic methods and technologies.

Generating the sequence of human and other model organisms' genomes has helped define the precise location of all known genes. Bioinformatic tools have helped predict novel genes, alternative isoforms, and protein domains, but have provided little guidance concerning the putative function of novel transcripts. In addition to defining protein domains that may be associated with known cellular functions, quantifying transcript expression across diverse cell types is critical for understanding human biology and this task is far from being exhausted. Until recently, production of such data was prohibitively expensive and experimentally laborious. The major method for annotating a transcriptome required the slow and costly process of cloning cDNAs or expressed sequence tag (EST) libraries, followed by capillary sequencing.[3–5] Owing to the high costs and limited data yield intrinsic to this approach, it only provided a glimpse of the true complexity of cell type–specific splicing and transcription. Analysis of these data required sophisticated computational tools, many of which provide the basis for the programs used today for high-throughput RNA sequencing (RNAseq) data.[6] Alternative strategies, such as genome-wide tiling arrays, allowed for the identification of transcribed regions at a larger and more cost-efficient scale but with limited resolution. Splicing arrays with probes across exon–exon junctions enabled researchers to analyze predefined splicing events but could not be used to identify previously uncharacterized events.[7]

The entire repertoire of transcripts in a cell, tissue, or organism, also known as the *transcriptome,* represents the connecting bridge of information that links what is encoded in our DNA to the phenotypes that are driven by genetics, environment, and disease. Therefore, a better understanding of the transcriptome will facilitate the extrapolation of genotypes to phenotypes and enhance our ability to discover biomarkers that can accurately predict emerging phenotypes as a function of disease progression. The tools for examining RNA levels have been available for many decades through the use of northern blots, reverse-transcription PCR, ESTs, and serial analysis of gene expression.[8] It was, however, the development of gene expression microarrays in the late 1990s that expedited our ability to survey many gene transcripts in parallel.[9–11] More recently, direct sequencing of transcriptomes has allowed for a fully unbiased and unrestricted characterization of all transcribed sequences within a given sample.[6]

In the field of skeletal biology, most "genome-scale" progress has occurred in the area of genome profiling or expression quantification,[12] using gene-expression

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00005-8

microarrays. Microarrays come in two flavors: cDNA or oligonucleotide arrays. The main distinction between the platforms is that cDNA microarray are home manufactured by printing full-length cDNA spots in an investigator's facility,[13] while the other platforms are commercially mass produced (Affymetrix, NimbleGen, Qiagen, Agilent, Illumina) through printing of high-density short oligonucleotides.[14] For example, the newest Affymetrix GeneChip Human Gene ST Array provides coverage for >30,000 coding transcripts and >11,000 long intergenic noncoding transcripts. While this process is limited to studying the expression of validated transcripts for defined isoforms, it does however provide a glimpse of the repertoire of "genes" that are transcribed as a function of cell type, or biological process, and genome profiling in this field has led to some intriguing discoveries. Recent advances in RNAseq technology have enabled us to overcome several limitations of microarrays; it provides a powerful tool to decipher gene expression changes at a global scale, allowing the detection of novel transcripts, allele-specific expression, single nucleotide variants, and indels. However, skeletal biology is far behind in embracing the potentials of this technology compared to other fields, such as cancer biology.

Comprehensive analysis of gene expression patterns and regulatory networks involved in skeletal development and remodeling is a prerequisite to completely understand physiological bone structure, function, and homeostasis. It also has a crucial role in the development of appropriate therapeutic strategies for various diseases affecting the skeleton. Here we will review the genome profiling body of work that has been generated in the last decade, with emphasis on: (1) skeletal cell type gene expression; (2) spatial and temporal differences in skeletal gene expression; (3) profiling biomechanical effects on bone; (4) gene expression in osteoporosis (OP) and other bone mineral density (BMD) animal models; (5) gene expression profiling in patients with OP, and (6) profiling noncoding RNA expression in bone. While many profiling reports have focused on in vitro models of cell differentiation, mineralization, or signaling perturbations, here we will primarily focus on literature that describes profiling of homogenous cell samples, tissue microdissection or organ isolation from live animals, or human samples to provide a snapshot of genomic profiling that may more faithfully adhere to in vivo bone physiology. The data described later is also summarized in Table 5.1.

1.1 Profiling Skeletal Cells and Bone Metabolism

Three dominant cell types maintain the function of the adult mineralized bone: osteoblasts, osteocytes, and osteoclasts (Fig. 5.1). Osteoblasts are responsible for the synthesis, deposition, and mineralization of extracellular matrix. Osteocytes are osteoblasts that have become embedded within the extracellular matrix, residing in cavities termed lacunae.[41] These cells communicate with each other, as well as with osteoblasts on the bone surfaces by means of cytoplasmic extensions that extend through long, intricate channels called canaliculi that are present throughout the mineralized bone. Osteoclasts are large multinucleated cells that reside on bone surfaces and function primarily to resorb bone through direct chemical and enzymatic reactions. A minority of cells in the bone are represented by undifferentiated mesenchymal stem cells (MSCs) that reside in the bone marrow, along vascular channels, and in the condensed fibrous tissue covering the outside of the bone, the periosteum. MSCs give rise to the osteoblast and osteocyte progenitors while osteoclasts are derived from hematopoietic stem cells housed in the bone marrow, or spleen.[42]

The principal role of osteoblasts is to form new bone via the synthesis of various proteins and polysaccharides that assist or contribute to the formation of mineralized bone matrix. Other functions include the regulation of bone remodeling and mineral metabolism. Studies of osteoblastic cells isolated from trabecular bone, embryonic calvaria, and osteosarcoma have established a set of molecular makers that help scientists distinguish the osteoblast phenotype. These markers involve the synthesis of type I collagen, the expression of alkaline phosphatase (ALP), the secretion of osteocalcin, and the production of mineralized matrix. While individually these markers are not unique to osteoblasts, as a cohort they are universally accepted in evaluating the osteoblast's identity or function. Osteoblasts also express receptors for various hormones including parathyroid hormone (PTH), 1α,25-dihydroxyvitamin D_3 [1α,25(OH)2D_3], estrogen, and glucocorticoids, all of which are also involved in regulating osteoblast differentiation. Over the years, much attention has been given to commitment of osteoprogenitor cells, lineage progression, and differentiation into osteoblasts, processes that have been studied in various cell lines[43–46] and primary cultures derived from humans and rodents.[47–50] These studies reported a generalized pattern of suppression of genes associated with differentiation of mesenchymal progenitors into other cell lineages, including myocytes and adipocytes, induction of genes associated with cell proliferation followed by matrix maturation, and mineralization. However, the gene expression profiles obtained from in vitro osteogenic differentiation experiments represent only an approximation of changes occurring in vivo, which necessitates their validation in appropriate in vivo models.

Osteocytes represent terminally-differentiated osteoblasts. They are the most abundant cellular component of mature mammalian mineralized bones and constitute

TABLE 5.1 Summary of Differentially Expressed Genes Identified in the Studies Described Here

Functions	Models	Cells/tissues	Platform	No. of differentially regulated genes	Genes[a]	References
Bone remodeling	Transgenic mice: Col2.3GFPcyan, Dmp1GFPtopaz	Osteoblasts/ osteocytes	Illumina MouseWg-6v1 BeadChip	Osteocyte versus osteoblast: 249 upregulated, 136 down regulated	**Up**: *Col15a1, Col18a1, Col4a1, Col22a1, Cola2, Col16a1, Col27a1, Col3a1, Col9a2, Col9a1, Col8a2, Col12a1, Col14a1, Col2a1, Col8a1, Dmp1, Bmp4, Bmp8a, Bmp3, Dkk1, Notch1, Notch3, Dlk1, Pitx2, Tbx3, Irx5, Irx6* **Down**: *Mmp9, Mmp23, Adamts18, Reln, Tingal, Htra1, Prss12, Cpxm1, Cfb, Kera, Acan, Prg4, Hapln1, Aspn, Chad, Fmod, Fbln1, Fbln2, Thsb2, Thsb3, Spon1, Comp, Prelp, Mant1, Postn, Wnt9a, Wnt10a, Dkk3, Gdf10, Ptn, Zic1, Gsc, Runx1t1, Pax1, Scx*	Paic et al.[15]
Anatomical location dependent differences in gene expression	Rat ulnar limb and parietal skull bone	Total bone RNA and osteoblasts	Affymetrix GeneChip	Skull bone versus limb: 1236 differentially expressed genes. Skull bone-derived osteoblasts versus limb derived osteoblasts: 249 genes	**(Skull vs Limb) Up**: *Opg, Pthr1, Calcr, Lrp5, Sost, Ibsp, Bmp3, Bmp6, Cthrc1, Ptn, Wif1, Sfrp2, Vdr, Prelp, Gpnmb, Tcf7, Nog, Cthrc1, Csf1, Mmp9, Fos, Dlx5, Dlx3, Tbx2 and Ctsk*. **Down**: *Comp, Mmp8, Ctnnb1, Wnt16, Bmp5 and Hoxa5, Hoxa7, Hoxa10, Hoxc5, Sox6, Gata1, Gata3, Cited4*. **(Skull bone-derived osteoblasts vs limb derived osteoblasts) Up**: *Sfrp2, Apoe, Irx5, and Msx2*. **Down**: *Hoxa1, Hoxa4, Hoxa5, Hoxa7, Hoxa10, and Hoxa13*	Rawlinson et al.[16]
Anatomical location dependent differences in gene expression	Rat mandible, ulna, and calvaria	Total bone RNA	Affymetrix GeneChip	Common to mandible and calvaria, but not ulna: 1014. Common to mandible and ulna, but not calvaria: 873	**Common to mandible and calvaria, but not ulna**: *Fos, Maf, Myo6, Smad3, Gata6, Ankrd1, Gli1, Nfatc4, Sox2, Gli2, Tcf7, Bmpr2, Irx2, Irx4, Klf15, Klf9, Dlx3*. **Common to mandible and ulna, but not calvaria**: *Pax6, Tnf, Cdh1, Cited4, Shox2, Myog*	Kingsmill et al.[17]
Age dependent differences in gene expression	Needle bone biopsies from the posterior iliac crest of young and old women	Total bone RNA	RNAseq	Old versus young subjects: 446 up; 232 down	**Up**: *S0X17, S0X7, FZD4, CDH3, SFRP1, S0X18, S0X13, CCND1, N0TCH3, N0TCH4, JAG2, DLL4, HES1, HEY1*. **Down**: *S0X4, SFRP5, LEF1*	Farr et al.[18]
Mechanical loading	Mouse tibia subjected to ankle loading	Total bone RNA	Agilent Technologies	22 > 2-fold up 15 < 2-fold down	**Up**: *Mmp3, Has, Mrgpra2a, Thbs3, Timp1, Cola1, Matn2, Matn4, Cdz48, Cspg4, Fosb, Aspn, Cdh13, Aqp1, Moxd1, Anxa8, Atf3, Aebp1, Prrx2, Cma1, Hapln1, Il1*. **Down**: *Btc, Senp6, Crrc34, Barhl2, Tnfp, Phf20l1, Kirrel3, Crisp1, Npy2r, Krt82, Ptgs2, Pax7a, Tnf236, Crlf1*	Zhang et al.[19]

BMD, Bone mineral density; LC, lining cells; OP, osteoporosis.
a Not all data have been fully respresented from each reference; for a full list of genes altered see referenced literature.

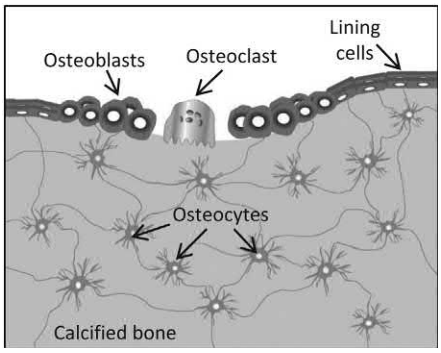

FIGURE 5.1 Cell types of the bone. Osteoblasts and osteoclasts reside on bone surfaces, where the osteoblasts secrete extracellular matrix and contribute to osteoid formation. Osteoclasts are multinucleated cells that resorb bone through enzymatic digestion. Osteoblasts entrapped in the bone matrix, morph into osteocytes, which communicate with each other and the bone surface through cytoplasmic projections. Nonremodeling bone surfaces are covered by lining cells.

as much as 95% of all bone cells. Osteocytes are thought to be mechanosensors, meaning that they can perceive changes in tissue stress to ultimately remodel bone mass, and may coordinate the remodeling process carried out by both osteoblasts and osteoclasts. While the question of how osteocytes differ from osteoblasts at the gene expression level has been an important one, the technical limitations of in vitro assays, the lack of appropriate cell surface markers, or the inability to purify large quantities of homogenous population of cells have prevented a global analysis of their entire transcriptome. It was not until the generation of transgenic mice carrying fluorescent markers expressed by osteoblast lineage directed promoters that relatively homogeneous populations of osteoblasts and osteocytes were isolated and the gene expression profiles of these cells were examined.[15]

To purify osteoblasts and osteocytes from animal bone, Paic et al.[15] utilized two transgenic mice: one in which a 2.3 kilobase (kb) *collagen type I* promoter fragment directs the expression of the cyan variant of green fluorescent protein (GFP) to mature osteoblast lineage cells [$Col2.3^{Cyan}$ (blue)], and one in which a 7.9 kb region of the *Dmp1* promoter, along with a 4.4 kb region containing the first exon, the entire 1st intron, and a small part of the 2nd exon, to direct GFP topaz expression in osteocytes [$Dmp1^{Topaz}$ (yellow)]. Prior to cell purification, the authors evaluated cell-type specificity through histological evaluation of reporter expression in calvaria of double transgenic neonatal mice. They detected strong $Col2.3^{Cyan}$ reporter expression within the osteoblasts lining the bone surfaces and in some, but not all, osteocytes. In contrast $Dmp1^{Topaz}$ expression was found exclusively in cells fully or partially embedded in the bone matrix, highlighting the ability of this method to discriminate between osteoblasts and osteocytes in neonatal calvarial bone based on specific GFP expression. Pools of calvaria obtained from double transgenic GFP-reporter mice were subjected to sequential enzymatic digestion regimes followed by FACS sorting to facilitate the enrichment of $Col2.3^{Cyan+}/Dmp1^{Topaz-}$ and $Dmp1^{Topaz+}$ (both positive and negative for $Col2.3^{Cyan+}$) cells designated as highly enriched osteoblast and osteocyte/preosteocyte fractions, respectively. The global gene expression profiles of three sorted cell populations: GFP negative, $Col2.3^{Cyan+}$ (osteoblasts), and $Dmp1^{Topaz+}$ (preosteocytes and osteocytes) were analyzed using the MouseWG-6 v1BeadChip Illumina expression platform. To determine the comprehensive gene expression pattern behind the process of osteoblast-to-osteocyte transformation they also compared gene expression profiles of fluorescence-sorted, ($Col2.3^{Cyan+}$) versus ($Dmp1^{Topaz+}$) cell populations. Of the 3444 genes found, to be expressed in all 3 populations, 385 genes were differentially expressed between $Col2.3^{Cyan+}$and $Dmp1^{Topaz+}$ cell populations (of which 249 were ≥2-fold changed and 136 were ≤0.5-fold changed in the $Dmp1^{Topaz+}$ population).

One category of genes (87 genes; 66 low/21 high in osteocytes) found to be differentially expressed between osteoblasts and osteocytes included genes encoding bone abundant extracellular proteins typically secreted by osteoblasts.[15] Many of these genes encode collagen proteins (*Col15a1*, *Col18a1*, *Col4a1*, *Col22a1*, *and Col4a2* high in osteocytes; *Col16a1*, *Col27a1*, *Col3a1*, *Col9a2*, *Col9a1*, *Col8a2*, *Col12a1*, *Col14a1*, *Col2a1*, and *Col8a1* high in osteoblasts). Various metalloproteinases (*Mmp9*, *Mmp23*, *Adamts18*) exhibited less expression in osteocytes along with other genes with peptidase activity: reelin (*Reln*), tubulointerstitial nephritis antigenlike gene (*Tingal*), Htra serine peptidase 1 (*Htra1*), serine protease 12 (*Prss12*), metallocarboxypeptidase CPX-1 (*Cpxm1*), and complement factor (*Cfb*); *Reln* and *Tingal* peptidases had higher expression in osteocytes.[15] Members of the proteoglycan family, such as: keratocan (*Kera*), aggrecan 1 (*Acan*), proteoglycan 4 (*Prg4*), hyaluronan, proteoglycan link protein 1 (*Hapln1*), asporin (*Aspn*), chondroadherin (*Chad*), and fibromodulin (*Fmod*), were also downregulated in osteocytes. Other noncollagenous structural components normally present in the extracellular matrix of bone and cartilage were also dramatically reduced in osteocytes; these included fibulins (*Fbln1*, *Fbln2*), thrombospondins (*Thbs2*, *Thbs3*), spondin 1 (*Spon1*), cartilage oligomeric matrix protein (*Comp*), proline arginine-rich and leucine-rich repeat protein (*Prelp*), and matrilin 1 (*Matn1*).[15]

Several other genes previously identified as contributors to bone-related functions were found to be differentially expressed between osteoblasts and osteocytes.[15] Dentin matrix protein 1 (*Dmp1*), as expected, was 7.3-fold enriched in osteocytes, while periostin (*Postn*) was upregulated in osteoblasts. Several members of the transforming growth factor beta (*TGF-βs*), bone

morphogenetic proteins (*Bmps*), insulin-like growth factors (*Igfs*), and fibroblast growth factor families (*Fgfs*) were also found differentially expressed between these two related cell types. Strikingly, BMP signaling ligands *Bmp4*, *Bmp8a*, and *Bmp3* and WNT signaling antagonist *Dkk1* were more than twofold upregulated in osteocytes, while WNT signaling ligands *Wnt9a*, *Wnt10a*, and WNT antagonist *Dkk3* were more than twofold enriched in osteoblasts. Several other growth factors, such as glial cell line-derived neurotrophic factor (*Gdnf*), growth differentiation factor 10 (*Gdf10*), and pleiotrophin (*Ptn*) had lower levels in osteocytes. In particular, WNT signaling has recently emerged as a major regulator of bone formation and bone mass where loss of function mutations in the low-density lipoprotein receptor-related protein 5 (*LRP5*) cause low bone mass (LBM) in humans and mice,[51,52] while certain single amino-acid substitutions (e.g., G171V) in *LRP5* cause high bone mass (HBM). In addition, regulating WNT signaling at the receptor level, via protein antagonists, such as sclerostin (*Sost*) or Dickkopf homolog 1 (*Dkk1*) generate complementary phenotypes in mice (*Sost* knock-outs have HBM[53] and *Sost* transgenics have LBM) and humans (sclerosteosis[54]). While generally *Sost* has been described as an "osteocyte-specific negative regulator of bone formation" and is accepted as a marker of osteocyte function and activity, the authors of the osteoblast/osteocyte comparison did not find *Sost* among the transcripts significantly upregulated in osteocytes.[55] As an explanation for this observation they suggested that *Sost* may be regulated differently in neonatal calvaria, hence their samples may have lower levels of *Sost* expression than the expression in cortical osteocytes of adult mice.

Significant transcriptional differences were also observed between osteoblasts and osteocytes among 76 genes encoding plasma membrane associated proteins (52 genes ≥twofold in osteocytes), including *Phex*, *Ank*, *Gnas*, *Enpp1*, as well as *Pdpn* (podoplanin), which is known as the earliest osteocyte-selective protein expressed during osteoblast–osteocyte differentiation. Several members of the Notch signaling were also upregulated in osteocytes, including *Notch1*, *Notch3*, and *Dlk1*. Interestingly several FGF receptors were highly expressed in osteoblasts, but not in osteocytes, including *Fgfr2* and *Fgfr3*. Among known transcription factors, 31 were differentially expressed, 23 of which were ≥twofold enriched in osteocytes. These included: *Hey1*, *Dlx3*, *Pitx2*, *Tbx3*, *Irx5*, and *Irx6*. The group of genes with high expression in osteoblasts included *Zic1*, *Gsc*, *Runx1t1*, *Pax1*, and *Scx* a transcription factor with a basic helix-loop-helix motif known to function in tendons[56] and developing cartilage.[57] Some unexpected osteocyte-enriched candidates included genes previously shown to regulate muscle function, such as transcription factors *Myocd* and *Smyd*; structural myofibril components, such as *Myh11*, *Csrp3*, *Sync*, *Acta1*, *Dmd*, *Ttn*, *Tcap*, *Tnnt2*, *Tnni1*, *Myoz2*, *Tnnt3*, *Atp2a1*, *Tnnc2*, *Pdlim3*, *Tnnt1*, *Actn2*, *Tpm2*; and genes involved in myogenesis, such as *Casq2*, *Atp2a2*, *Gucy1a3*, *Atp1a2*, *Srpk3*, and *Csrp3*. In particular, one surprising discovery was that skeletal muscle actin alpha 1 (*Acta1*), skeletal muscle protein troponin 2 (*Tnni2*), fast skeletal muscle myosin light chain (*Mylpf*), troponin C2 (*TnnC2*), myosin heavy polypeptide 11 (*Myh11*), and myosin light polypeptide 1 (*Myl1*) all topped the upregulated gene list with ≥20-fold upregulation in osteocytes.

Thus, the approach presented by Paic et al.[15] is unique in bone biology and the data generated has the potential to highlight new important regulators of both osteoblast and osteocyte function. In particular, the role of myogenic genes is intriguing since recently it has been reported that PTH mediates *Sost* expression via an unlikely candidate: the *Mef2C* transcription factor, a well-established regulator of cardiac and muscle development.[58] It is however important to highlight several caveats which may limit the generalization based on the experimental design of Paic et al.[15] of the "osteocyte" and "osteoblast" transcriptome to adult bone function. These include: (1) the age of the purified cells which were derived from neonatal bone that may differ from cells obtained from the adult skeleton; (2) the anatomical location of the cells collected: *calvaria* versus *long bones*; and (3) the potential for intrinsic differences in mechanosensitivity of cells derived from *axial* versus *appendicular* bones. In the Paic et al.[15] study, these cells were obtained from neonatal mice when the organism is undergoing rapid growth and development. The bone therefore is metabolically very active and the balance of bone formation is in a "modeling" phase, with relatively very little remodeling. As an organism reaches maturity, bone formation slows down, and bone metabolism is driven by a balance between formation and resorption characteristic of bone remodeling. Therefore, from a metabolic point of view, the osteoblasts and osteocytes may display different "transcriptional profiles" as a function of age. In addition, there are distinct differences between bone patterning that occurs in intramembranous versus endochondral bone formation and subsequent ossification. Accordingly, it is prudent to assume that osteoblasts and osteocytes derived from the axial skeleton may differ molecularly from those derived from the appendicular skeleton. Another source of molecular difference may stem from how cells interpret mechanical forces. While osteocytes and osteoblasts are mechanosensitive, it is very likely that the biophysical forces perceived by resident cells within the calvaria are fundamentally different than in long bones. While some of the candidate genes highlighted by this study may overlap with genes that control biomechanical function in loaded long bones, this represents a hypothesis and requires further validation.

Osteoclast differentiation is a complex process that takes roughly 4 days in vivo, during which mononuclear precursor cells migrate to the site of resorption, fuse to form multinucleated osteoclasts, form specialized structures including actin ring and ruffled borders, and attach firmly to bone, sealing them to the bone surface. Subsequently, these osteoclasts secrete protons to demineralize the bone and proteases to degrade the proteinaceous extracellular matrix. Gene expression studies using bone marrow precursors[59–63] or RAW264 macrophage cell line[64–65] differentiating toward osteoclasts in vitro, have significantly enhanced our understanding of osteoclastogenesis. Notably, Takayanagi et al.[60] and Ishida et al.,[64] using microarrays, identified several genes differentially regulated during osteoclastogenesis including NFATC-1which was subsequently validated in animal models and identified as a key regulator of osteoclast differentiation.[66,67] Together, these studies further our knowledge of genomic changes during osteoclastogenesis. However, more in vivo functional studies are required to determine the precise functions of these genes in osteoclastogenesis.

1.2 Profiling Location and Age Dependent Changes in Skeletal Gene Expression

Numerous studies have identified several differences in the adult bones derived from distinct primary ossification processes including differences in matrix composition, mineral density, and calcium concentration. It has also been shown that the skull bone responds differently to mechanical strain compared to limb bones; furthermore osteocytes of mouse calvaria have a more spherical shape compared to the more elongated osteocytes of long bone.[16] It is therefore reasonable to hypothesize that there is a difference in the transcriptome of bone cells collected from different anatomical locations, reflecting their specific functions and origin. To address this question, using Affymetrix microarrays, Rawlinson et al. profiled the transcriptome of rat ulnar limb and parietal skull bone, and osteoblasts derived from skull and limb bones.[16] For the majority of genes, calvaria and ulna showed very similar expression patterns confirming a high degree of similarity among bone tissues, irrespective of their origin and location. However, they identified 1236 genes significantly differentially expressed between skull and long bones. Several genes known to be associated with bone development including *Opg*, *Pthr1*, *Calcr*, *Lrp5*, *Sost*, *Ibsp*, *Bmp3*, *Bmp6*, *Cthrc1*, *Ptn*, and *Ctsk* were upregulated in skull bone compared to long bone while genes, such as *Wnt16*, *β-catenin*, *Bmp5*, and *Comp* showed an elevated expression in long bones. Rawlinson et al. also identified several transcription factors differentially expressed between these anatomically distinct bone locations, which may account for their site-specific properties. Transcription factors including *Sp7*, *Vdr*, *Tcf7*, *Fos*, *Dlx5*, *Dlx3*, *Tbx2*, and *Twist1* were found to be upregulated in calvarial bone whereas transcription factors *Sox6*, *Gata1*, *Gata3*, *Cited4*, and several members of Hox family including *Hoxa5*, *Hoxa7*, *Hoxa10*, and *Hoxc5* were found to be upregulated in long bone. They also observed that the number of osteocytes per unit volume was significantly higher in limb bone compared with skull bone.

Rawlinson et al. found that majority of the differences identified between skull and limb bone transcriptome profiles were lost in cultured osteoblasts. However, they identified 249 genes significantly differentially expressed between skull and limb bone-derived osteoblasts, in vitro. Consistent with the regional differences observed in whole bone gene expression profiles, they detected an elevated expression of Hoxa cluster genes (*Hoxa1*, *Hoxa4*, *Hoxa5*, *Hoxa7*, *Hoxa10*, *Hoxa13*) in limb derived osteoblasts compared to skull derived osteoblasts, which was further confirmed by quantitative PCR (qPCR). Genes upregulated in skull derived osteoblasts include *Sfrp2*, *Apoe*, *Irx5*, and *Msx2*. These findings suggest that at least some of the regional changes in gene expression are independent of local microenvironment but represent an inherent property of these cells.

In a subsequent study, Kingsmill et al. compared the gene expression profiles of adult rat mandible to ulna and calvaria.[17] Approximately 84% (23,232) of the transcripts analyzed had similar expression levels in the three functionally distinct skeletal locations. They also identified 1850 transcripts unique to a single site whereas 1014 transcripts were found to be common only to mandible and calvaria, and 873 transcripts were common only to mandible and ulna. Genes highly expressed in mandible and calvaria, but not in the ulna included *Fos*, *Gli1*, *Gli2*, *Tcf7*, *Bmpr2*, and *Smad3*. Genes highly expressed in mandible and ulna, but not in the calvaria included *Pax6*, *Cited4*, *Cdh1*, *Shox2*, and *Tnf*. These two studies support the hypothesis that genomic profiles of osteoblasts differ based on their anatomical location and suggest that these differences are established, at least in part, by the developmental origin and history of the cells at different anatomical sites.

While Rawlinson et al. and Kingsmill et al. investigated how the gene expression profiles of bones from different skeletal sites differ in relation to their origin and location, Farr et al.[18] studied the transcriptional changes in bone as a function of age. Farr et al. obtained needle bone biopsies (1–2 mm diameter) from the posterior iliac crest of 20 young women (mean age ± SD, 30.0 ± 5.4 years, range 22–40 years) and 20 old women (72.9 ± 6.5 years, 65–88 years) and profiled the transcriptome using RNAseq. This study identified 678 genes (446 up- and 232 downregulated genes) with altered expression in old relative to young women.

Expression levels of several genes from the Notch pathway including *NOTCH3*, *NOTCH4*, *JAG2*, *DLL4*, *HES1*, and *HEY1* were significantly higher in bone biopsies of old versus young women. They also observed alterations in the expression of several WNT-signaling pathway members. WNT pathway members *SFRP5* and *LEF1* were found to be decreased, whereas levels for *FZD4*, *SFRP1*, and *CCND1* were found to be increased in bone biopsies of old women. However, there were no changes in the expression of *SOST*, *LRPs* (*LRP4-6*), and *DKKs*, WNT family members previously linked to bone metabolism. They also identified several genes from eNOS signaling pathway, PDGF signaling, and Oncostatin M signaling with altered expression in old versus young subjects.

Farr et al. also profiled the gene expression changes induced by estrogen therapy in old subjects and identified several genes including *LGR5*, *PPARGC1A*, *INHBB*, and *C19orf80* with altered expression in response to estrogen. Estrogen therapy restored the expression of *INHBB*, which was significantly decreased with aging, to young levels, suggesting that alterations in estrogen levels might be responsible for some of the changes observed between young and old women. However, estrogen therapy only changed the expression of 21 genes of the 678 genes altered with age. These studies suggest that genes associated with bone mass and mineral density are differentially expressed in functionally distinct skeletal sites,[16,17] and also as a function of age.[18,68] These spatial and temporal differences in gene expression must be taken into account when generalizing the results from different gene expression studies.

1.3 Profiling Biomechanical Effects on Bone

Mechanical stimuli, such as vibration, axial loading, and bending regulate bone shape and strength, activate bone formation, and increase BMD.[69] To identify genes and signal pathways responsible for mechanical loading-induced bone formation, Zhang et al.[19] examined the global gene expression changes resulting from joint loading.[19] Joint loading induces an anabolic response and the authors were interested to determine if ankle loading promotes bone formation in the tibia. Accordingly, the left ankle of 14-week-old C57BL/6 mice was loaded 3 min/day for 3 consecutive days (0.5 N/5 Hz). Bone RNA was collected from the right (control) and left (loaded) tibia at 1 h after the 3rd loading and processed using Agilent microarrays. Using histomorphometry the authors determined that there was a corresponding 10% increase in cross-sectional cortical bone area in response to loading. The microarray comparison identified 242 transcripts upregulated ≥1.2-fold and 199 transcripts downregulated ≤ 0.8-fold in response to ankle loading. A more stringent comparison of genes that changed more than twofold from loading identified a group of 50 transcripts including *Mmp3*, *Has*, *Mrgpra2a*, *Thbs3*, *Timp1*, *Col3a1*, *Matn2*, *Matn4*, *Cd248*, *Cspg4*, *Fosb*, *Aspn*, *Cdh13*, *Aqp1*, *Moxd1*, *Anxa8*, *Atf3*, *Aebp1*, *Prrx2*, *Cma1*, *Hapln1*, *Il1rl1* (upregulated); and *Btc*, *Senp6*, *Lrrc34*, *Barhl2*, *Tnfp*, *Phf20l1*, *Kirrel3*, *Crisp1*, *Npy2r*, *Txnax*, *Krt82*, *Ptgs2*, *Pax7a*, *Znf236*, *Crlf1* (downregulated).[19]

In a more recent study, Mantila Roosa et al.[20] evaluated loading-induced gene expression in rat ulna over a time course of 4 h to 32 days (d) (4 h, 12 h, 1 d, 2d, 4d, 6d, 8d, 12d, 16d, 24d, and 32d). Using Affymetrix microarrays they identified 1051 genes that were differentially expressed in at least one time point, in response to loading. After performing a gene expression clustering they identified six distinct patterns of differential gene expression: an early-response cluster in which the genes were upregulated early but not late in the time course, three matrix-formation (up) clusters that followed the pattern of matrix synthesis, and two matrix-formation (down) clusters that were downregulated during matrix formation. Several chemokines (*Ccl2*, *Ccl7*, *Cxcl1*, *Cxcl13*), calcium signaling genes (*Anxa2*, *S100a4*, *S100a10*), matrix proteins (*Adamts1*, *Ecm1*, *Serpina3n*, *Serpine1*, *Tfpi2*), and AP-1 transcription factors (*Fosl1*, *Junb*) were identified as upregulated early on, primarily at 4 h. Mantila Roosa et al. also identified several extracellular matrix genes (upregulated: *Alpl*, *Bglap*, *Col1a2*, *Cthrc1*, *Fn1*, *Ibsp*, *Lox*, *Sparc*, *Vcan*, *Bgn*, etc.; downregulated: *Efemp1*, *Mmp8*, *Prelp*, *Serpinb2*, *Spon1*) and growth factors (upregulated: *Fgf14*, *Pdgfa*, *Pdgfc*, *Pdgfrl*, *Pgf*; downregulated: *Egf*, *Fgf1*, *Fgf7*, *Fgf23*, *Fgl2*, *Hgf*) as differentially regulated during matrix formation, in response to loading. Several ion channels and solute carriers were also differentially regulated during matrix formation. Interestingly, several muscle-related genes were identified as downregulated in loaded ulna (*Acta1*, *Dmd*, *Myocd*, *Myl1*, *Myplf*, *Tnni2*, *Tnnt3*, *Tpm2*), genes that were also identified as enriched in osteocytes compared to osteoblasts by Paic et al. Other important bone metabolism genes differentially regulated during matrix formation included *Vdr*, *Tgfb1*, *Tgfb3*, *Bmp2*, *Wif1*, *Wisp1*, *Pthr1*, *Sp7*, *Jund* (upregulated genes), *Grem1*, *Bmpr1b*, *Tgfbr3*, *Chrdl1*, and WNT pathway inhibitors *Sost* and *Sfrp4* (downregulated genes).

While studies by Zhang et al.[19] and Mantila Roosa et al.[20] identified changes in whole bone transcriptome in response to loading, Wasserman et al.[21] studied transcriptional changes specifically in trabecular osteocytes from mouse vertebra subjected to controlled compression loading. Using Affymetrix microarrays they profiled gene expression changes in osteocytes isolated from vertebrae receiving a single 8 N loading dose or repetitive loading compared to osteocytes from sham-loaded

vertebral trabecular bone. By this approach, Wasserman et al. identified 287 up- and 52 downregulated genes in response to a single load in osteocytes. Upregulated genes included *Wnt5a*, *Aspn*, *Igf1*, *Emilin2*, *Ccl12*, *Adamts4*, and *Adamts1* whereas *Olfm3* and *Spock2* were identified as downregulated. 1339 genes were differentially regulated (778 up- and 561 downregulated) in osteocytes isolated from vertebra subjected to repetitive loading. Genes upregulated by repetitive loading included *Ptn*, *Vcan*, *Aspn*, *Thbs4*, *Sema3c*, *Sema3d*, *Thbs2*, *Thbs1*, *Mmp2*, *Cyr61*, *Grem1*, *Fgf18*, *Grem2*, *Pdgfd*, *Wnt5a*, and *Dmp1* whereas *Ltbp1*, *Muc4*, and *Apoa5* were downregulated. In summary, Wasserman et al. identified several genes, in particular those encoding extracellular proteins, differentially regulated in osteocytes in response to loading. It is interesting to note that *Sost* was not detected among the significantly downregulated transcripts though it is generally recognized that mechanical loading downregulates *Sost* expression in osteocytes.[70,71]

Multiple studies have suggested that mechanical loading differentially increases bone mass in cortical and cancellous sites. In a recent study, Kelly et al.[22] investigated transcriptional changes in cortical and cancellous bone in response to mechanical loading. In this study the left tibia of 10-week-old C57Bl/6 female mice was subjected to a single load and cortical and cancellous bone was collected 3 and 24 h after loading and changes in gene expression were profiled using RNAseq. At 3 h postloading, 43 and 18 genes were found differentially expressed in loaded cortical and cancellous bones, respectively. Genes upregulated in both cortical and cancellous bone included *Wnt1*, *Wnt7b*, *Timp1*, *Ptgs2*, and *Opg*. Enriched signaling pathways included WNT signaling in both cortical and cancellous bone and hedgehog signaling in cortical bone only. Apart from *Wnt1* and *Wnt7b*, an increased expression of *Wnt10b* was also observed at 3 h after a single loading session, in the cortical bone, while *Lrp5* was modestly decreased. WNT inhibitors *Sost* and *Dkk1* were found to be downregulated in cancellous bone 3 h after loading, but were not significantly changed in the cortical bone. At 24 h postloading, 58 genes were differentially expressed in cortical and 32 genes in cancellous bone. 12 genes (*Ptn*, *Vcan*, *Cthrc1*, *Hapln4*, *Tubb3*, *etc.*) were commonly changed in both cortical and cancellous bone. *Wnt1* and *Wnt10b* remained upregulated at 24 h postloading in cortical bone. Interestingly, several muscle-related genes (*Myh4*, *Tnnc2*, *Smpx*, *Tnnt3*, *Mylk2*, *Myoz1*, *Myom2*, *Actn3*, *Myl1*, *Casq1*, *Mybpc2*, *Myh2*, *Mylpf*, *Tnni2*) were found to be downregulated in cancellous bone at 24 h postloading. It is important to note that several of these muscle-related genes including *Tnnc2* and *Tnnt3* were also identified by Paic et al. as enriched in osteocytes and by Mantila Roosa et al. as downregulated in the loaded ulna. Kelly et al. also observed that *Wnt16*, *Wnt7b*, and *Sost* were highly expressed in unloaded cortical bone compared to unloaded cancellous bone. High expression of *Wnt16* in cortical bone is consistent with the cortical bone phenotype in mice lacking *Wnt16*.[72] Other genes highly expressed in unloaded cortical bone include bone metabolism related genes *Postn*, *Aspn*, *Mepe*, *Ostn*, and *Ptn* while genes including *Grem1*, *Kcnj5*, and *Slc24a5* showed high expression in unloaded cancellous bone. This study highlights the importance of WNT signaling in load induced bone formation and provides novel insights into differential response of cortical and cancellous bone to mechanical loading. Further investigation into the downregulation of muscle-related genes in cancellous bone is required to understand the functions of these genes in bone.

Tissues derived from an organism are highly heterogeneous and the transcriptional profile represents a comprehensive sum of multiple cell-type outputs. A highly specialized signal that comes exclusively from one cell type may be diluted in tissue samples if the surrounding tissues may exhibit the opposite transcriptional effect. Wasserman et al.[21] purified osteocytes from loaded bone in an attempt to understand the changes specific to this cell type and identified several differentially regulated genes. However, they failed to recapitulate several known load induced changes in osteocyte transcriptome including downregulation of *Sost*. Studies by Mantila Roosa et al.[20] and Kelly et al.[22] highlighted the importance of studying loaded induced changes as a function of time; they observed significant differences in the loaded bone transcriptome at different time points. Future studies will have to rely on purifying homogenous populations of cells, similar to the study described in the first section by Paic et al.,[15] from different time points in order to distinguish cell autonomous from noncell autonomous effects and to understand temporal changes.

1.4 Profiling Gene Expression Changes Occurring as a Function of Altered Bone Metabolism

1.4.1 Profiling Bone in Animal Models With Impaired Bone Metabolism

In this section we will discuss recent work that describes global gene expression changes that occur as a function of altered bone metabolism (resulting in net gain or loss of bone mass) in animal models. OP has been linked to age-related postmenopausal hormonal changes in women, and is strongly correlated with decreases in estrogen-related bone signaling therefore, ovariectomized (OVX) mice and rats represent an established animal model for postmenopausal bone loss.[73] Xiao et al.[23] used this OVX animal model to compare the genomic

profile between OP, non-OP, aged, and juvenile rats.[23] They applied microarrays with 34,000 known genes to examine gene expression in bone marrow mesenchymal stromal cells isolated from the bone marrow of the four different treatment groups. Comparisons between OP (7-month-old OVX) and non-OP (7-month-old) identified 195 up- and 109 downregulated transcripts; non-OP versus aged rats (>2-years old) identified 62 up- and 86 downregulated transcripts; and young (7-weeks old) versus older(7-month-old), non-OP rats identified 120 up- and 80 downregulated genes. OP caused an increase in the expression of cell adhesion-related gene *Spon1*, adipogenic differentiation genes (*Alox5*, *Baat*, *Sult4a1*, *Lpl*), and genes involved in cell growth and maintenance (*Mmp8*, *Cyp3a9*, *A2m*, *Alpl*, *Crabp2*, *Slc26a1*, *Cdkn2b*). Many genes were also found to be downregulated in OP, such as *Npy* (neuropeptide Y, involved in bone growth), *Cd24* (promotes proliferation and differentiation), *Ramp3* (osteoclast regulator), *Marcksl1* (involved in calcium channel function), *Wnt4*, *Plpcb* (prolactin-like protein C beta; reported to have inhibitory effects on osteoblast formation), and *Adrb3* (glucose and lipid metabolism). In addition, this paper compared genes that were upregulated in OP versus aged tissue, and found that there were 14 genes upregulated in OP and downregulated in aged rats (*Mmp8*, *Sponf1*, *Csrp2*, *Ivl*, *Folrl*, *Crabp2*, *Loc64305*, *Nac1*, *Gludins*, *Braf*, *Inhbp*, *Pgr*, *Slc26a1*, *Sp1*) and 6 genes downregulated in OP but upregulated in aged rats (*Prlpb*, *Iilrn*, *Plpcb*, *Loc171569*, *Ramp3*, *Mip*).

Runx2 has been shown to play a key role during skeletogenesis.[74] In *Runx2* knockout mice both intramembranous and endochondral bone formation is blocked. These mice lack mature osteoblasts and have a skeleton made of cartilage.[74] To identify *Runx2* target genes, Vaes et al.[24] compared the gene expression of skeletal tissues (calvaria, forelimbs, and hindlimbs) in *Runx2* knockout mouse embryos at 14.5 dpc to wild-type controls. The authors found 1277/22,625 transcripts (531 downregulated in KO), 606 (296 downregulated in KO), and 492 (172 downregulated in KO) to be differentially expressed in calvaria, forelimb, and hindlimb, respectively. These data suggested that loss of the *Runx2* transcription factor had both positive and negative effects on gene expression in skeletal tissue.[24] To identify potential *Runx2* targets, the authors searched for transcripts that were modulated similarly in all three tissues. They found 41 transcripts (35 known genes and 6 ESTs) to be upregulated and 25 transcripts (22 genes and 3 ESTs) to be downregulated in all three datasets including: *Ibsp*, *Spp1*, *Akp2*, *Runx2*, *Dlx5*, *Matn4*, *Mmp9*, *Col9a1*, *Scgf*, *Agc1*, as well as 15 genes previously unknown to be *Runx2* targets or to function during bone formation: *Pim1*, *Satb2*, *Snf1lk*, *Cfh*, *Gtpbp2*, *Tubb5*, *Hck*, *H2-T10*, *Tce1*, *Ppp2r5d*, *Ndufb10*, *Fdps*. The other three novel transcripts were ESTs or Riken cDNA clones.[24]

Two recently published papers have taken a novel approach for studying global gene expression changes.[25,26] They used genes identified from human linkage studies, eQTL analysis, high-density SNP maps, causality modeling, and genome-wide association studies and integrated them with genetic variants, gene expression profiling, and skeletal phenotypes in inbred mice to help identify candidate genes for bone phenotypes.[25,26] These approaches are very complex and should be read in detail; however a number of important genes were identified as being strongly correlated with OP. Genes highlighted by Farber et al.[26] include *Grem2*, *Twist2*, *Ccdc28b*, *Timd4*, *and Smad4* with additional emphasis on *Rasd1* and *Wnt9a* (the two most significantly related genes and thus the two strongest candidates for OP delineated in this paper). RAS, dexamethasone-induced 1 (*Rasd1*) is a Ras family GTPase thought to be involved in circadian rhythm.[75] *Wnt9a*, on the other hand, is a member of the canonical WNT signaling pathway, and is involved in joint formation and maintenance in addition to being linked to skeletal formation and growth.[76] Using a similar integration approach, Hsu et al.[25] identified 16 candidate genes, *Ppap2b*, *Gpr177*, *Hecw2*, *Casr*, *Mmrn1*, *Irx2*, *Pdzd2*, *Tgfb1*, *Cacnb2*, *Dock1*, *Sox6*, *Pdgfd*, *Rad51L1*, *Sall1*, *Fbxo31*, and *Cdh2*. Of note, *Ppap2b* and *Gpr177* have both been previously shown to be involved in the regulation of the WNT receptor-signaling pathway; *Ppap2b* via a glycerolipid and glycerophospholipid metabolism pathway and *Gpr177* through regulation of I-kappB kinase/NF-kappaB cascade pathway.[25,77] In addition, *Sox6* and *Cdh2* have also been linked to the canonical WNT/β-catenin signaling pathway.[78,79] Furthermore, *Casr*, the gene encoding the calcium-sensing receptor, is known to interact with *Vdr/Rxr* activation and is important in the mineralization of bone.[80] *Tgfβ1* and *Cacnb2* have also both been linked to endochondral bone formation in cartilage and calcium ion transportation, respectively, indicating their importance in bone ossification.[81,82]

Mutations in WNT coreceptor low-density lipoprotein receptor-related protein 5 (LRP5) cause high or LBM phenotypes depending on the nature of mutation. Ayturk et al.[27] profiled the transcriptome of *Lrp5* wild type ($Lrp5^{+/+}$), *Lrp5* knockout ($Lrp5^{-/-}$), and HBM-causing ($Lrp5^{p.A214V/+}$) knock-in alleles to identify genes and molecular mechanisms altered in these genotypes. Using RNAseq they identified 302 genes differentially expressed between $Lrp5^{-/-}$ and $Lrp5^{+/+}$, 166 genes differentially expressed between $Lrp5^{-/-}$ and $Lrp5^{p.A214V/+}$, and 28 genes differentially expressed between $Lrp5^{p.A214V/+}$ and $Lrp5^{+/+}$ in mouse diaphyseal bone. A large number of genes downregulated in $Lrp5^{-/-}$ compared to $Lrp5^{+/+}$ mice, including *Col1a1*, *Col1a2*, *Bglap*, *Mt1*, *Mt2*, *Cyr61*, *Cgref1*, and *Gata1*, overlapped with genes downregulated in $Lrp5^{-/-}$ compared to $Lrp5^{p.A214V/+}$ mice. Interestingly, two positive regulators of WNT pathway, *Wnt10b*

and *Fzd4*, exhibited significantly increased expression in $Lrp5^{-/-}$ compared to $Lrp5^{p.A214V/+}$ and $Lrp5^{+/+}$ mice. Other genes upregulated in $Lrp5^{-/-}$ compared to $Lrp5^{p.A214V/+}$ and $Lrp5^{+/+}$ included *Postn*, *Thbs2*, and *Mdm4*. Another interesting finding was the upregulation of *Wnt16*, a positive regulator of bone mass, in $Lrp5^{-/-}$ compared to $Lrp5^{+/+}$. Genes differentially expressed in $Lrp5^{p.A214V/+}$ compared to $Lrp5^{+/+}$ included *Kera*, *Myoc*, *Angptl7*, *Serpina1a*, *Serpina1d*, *Serpina1b*, *Serpina1e* (upregulated), *Igkv9-123*, *Igkv1-88*, *Igkv8-27*, and *Ighv7-1* (downregulated). Further studies are required to understand the roles of these genes in LRP5-mediated regulation of bone mass.

Inhibition of WNT pathway inhibitor Sost with Sost antibody (Scl-Ab) has been shown to promote bone formation and decrease bone resorption, ultimately leading to an increase in bone mass in both human and animals. Nioi et al.,[28] using Affymetrix microarrays, profiled transcriptional response associated with Scl-Ab administration (single dose, 100 mg/kg) in mature osteoblast subpopulations [osteoblasts (OB), lining cells (LC), and osteocytes (OCy)] at several time points (6, 24, 72, and 168 h postdose), after enrichment with laser capture microdissection. The number of probe sets changed in response to Scl-Ab in any cell type or time point ranged from 0 to 514. Transcriptional changes caused by Scl-Ab were very similar across all three cell types. Majority of well-known canonical WNT signaling genes did not show significant change in their expression, in response to Scl-Ab; however, this study identified several WNT targets (*Wisp1*, *Twist1*, *Bglap*, *Gja1*, *Tcf7*, *Enpp2*, *Mmp2*) as Scl-Ab-responsive genes. Four genes, *Wisp1*, *Twist1*, *Bglap*, and *Mmp2* showed progressive upregulation across the time course and a similar pattern in all three cell populations after Scl-Ab administration. This study also identified several genes involved in synthesis and mineralization of bone matrix (*Omd*, *Bgn*, *Dcn*, *Sparc*, *Lepre*, *Lox*, *Bmp1*, *Alpl*) as differentially regulated in response to Scl-Ab. Other key genes regulated by Scl-Ab included *Tmem119*, *Pdgfa*, *Cxcl12*, *Cxcl14*, *Dlx5*, sphingolipid signaling genes (*Smpd*, *Sgms2*, *S1pr3*, *Spns2m*), and cell cycle genes (*Cdkn1a*, *Cgref1*, *Aurka*, *Bub1*, *Ccnd1*).

In another study, Taylor et al.[29] profiled time dependent transcriptional changes in OB, OCy, and LC in response to long-term Scl-Ab treatment (3 or 50 mg/kg/week) for up to 26 weeks (183 days), followed by a treatment-free period (TFP). The gene expression analysis was mainly focused on 50 mg/kg group where they profiled gene expression changes at days 8, 29, 85, 183, 237, and 309. This study identified several genes differentially regulated in response to chronic Scl-Ab administration, with greatest number of gene expression changes occurring in OCy and least changes in LC. Similar to Nioi et al., Taylor et al. also found that OB, LC, and OCy had very similar changes in their gene expression profiles at day 8, with an upregulation of a number of extra-cellular proteins and few canonical WNT targets including *Wisp1* and *Twist1*. However, on day 29, the WNT target gene expression pattern significantly changed in OCy with *Twist1* returning to vehicle levels and upregulation of a different set of WNT targets [*Cd44*, *Id2*, *Irx3*, *Vegfa*, *Tcf7l2* (*Tcf4*)] that remained elevated throughout the time course. Another set of WNT targets including *Birc5*, *Ccnd1*, and *Mmp9* showed a decrease in expression in response to Scl-Ab beginning on day 29. Changes in WNT signaling pathway were limited to upregulation of *Wnt5b* and WNT inhibitor *Sfrp4* in OCy. Scl-Ab treatment also upregulated cell cycle genes *Cdkn1a* and *Mdm2* in OCy at day 29 which remained elevated throughout the time course. Several other cell cycle genes including *Aurka*, *Bub1b*, *Chek1*, *Kif23*, *Kifc1*, *Knstrn*, and *Plk1* were downregulated beginning on day 29. Other important Scl-Ab induced genes included *Dmp1*, *Mepe*, *Phex*, *Postn*, *Tgfb3*, and *Bmp7* in OCy and *Col1a1*, *Alpl*, and *Mgp* in OB. Apart from the Scl-Ab responsive genes identified with microarrays, Taylor et al. also identified *Dkk1* and *Sost* as Scl-Ab inducible genes using TaqMan analysis.

Here we discussed some key findings from genomic profiling in animal models of OP; however, it is important to note that numerous other studies have also used microarrays or RNAseq to profile gene expression changes in animal models with altered bone metabolism.[83,84] Comprehensively, these animal studies have identified signaling pathways and groups of genes that act concordantly (many with previously unknown functions), suggesting that these cohorts of genes are functionally related during bone regulation. These results highlight the utility of animal models for delineating relevant biological pathways. However, animal models cannot fully replicate the complex genetic and environmental interactions that contribute to the development of OP and other bone-related diseases, in humans. Therefore, it is necessary to complement these animal models with studies of human tissues.

1.4.2 Profiling Osteoporosis in Humans

OP is actually a family of metabolic bone diseases defined using bone densitometry by a >2.5 standard of deviations below the average BMD value of a healthy, young person. OP can result in cortical bone thinning and porosity, fragility, and increased fracture risk.[85] Since adult bone mass homeostasis is achieved through a balance between bone formation and bone resorption, either an increase in bone resorption and/or a decrease in bone formation could lead to bone loss. Age, diet, physical activity, along with genetic predisposition, all contribute to these processes. Although there has been extensive progress in the use of genomics to identify genetic loci and variants that contribute to susceptibility to OP,[86–92] these polymorphisms account for very little of the overall variation in BMD. Therefore, many more

genes and genetic variants involved in the regulation of bone mass and susceptibility to skeletal disease await discovery. This section will address the current use of genomic expression profiling and its importance in understanding how genomic regulation results in complex bone disease.

Lei et al. compared circulating monocytes in premenopausal subjects ranging from extremely low peak bone mass (PBM) to high PBM.[30] Forty nine genes (37 upregulated and 12 downregulated) were differentially expressed between the two groups. Gene ontology biological process classification found 17 major categories including cytokine–cytokine receptor interaction, toll-like receptor signaling pathways, and Jak-STAT signaling pathways, all of which are significantly involved in bone metabolism and osteoclast differentiation. Following false-discovery rate adjustments, 3 of the 49 genes were found to be significant (*Stat1*, *Gbp1*, and *Cxcl10*). All three of these genes are known to be involved in osteoclastogenesis.[30,93,94] In a more recent study, Liu et al.[31] performed microarray analysis of monocytes in 42 (16 pre- and 26 postmenopausal) high hip BMD and 31 (15 pre- and 16 postmenopausal) low hip BMD Caucasian females. Their analysis identified several apoptosis genes including *DAXX*, *PLK3*, *PDCD5*, and *VDAC1* downregulated in low BMD females. Five genes associated with cell cycle arrest, *HBP1*, *CDKN2D*, *GAS2L1*, *PKD1*, and *PPP1R15A* were also down in low versus high BMD subjects. A metaanalysis of seven GWAS studies identified association of three of these genes, *VDAC1*, *DAXX*, and *PLK3*, with hip BMD. Two of the apoptosis induction genes *DAXX* and *PLK3*, both downregulated in the low BMD subjects, overlapped with previous studies from this group.[30,87] These findings suggest that decreased apoptosis of monocytes might be a contributing factor to low BMD.

Trost et al.[32] explored another approach for identifying OP-related genes by examining the transcriptional profile of cultured osteoblasts isolated from 55 unrelated patients undergoing hip arthroplasty due to osteoarthritis (non-OP) or femoral neck fracture (OP).[32] Eight postmenopausal (four with normal and four with low BMD) were also included in the study. Following data acquisition, microarray intensity values were compared to a predetermined set of genes thought to be characteristic of osteoblasts: *ALPl*, *BGLAP*, *BMP2*, *COL1A1*, *CSF1*, *LRP5*, *MGP*, *RUNX2*, *TNFRSF11b*, and *VDR*. Of these genes, bone matrix genes, such as *COL1A1, MGP*, and the *osteoprotegerin* gene, *TNFRSF11b*, had the highest expression levels in OP samples. In contrast bone differentiation factors *BMP2* and *RUNX2*, a matrix mineralization factor, *ALPL*, and the differentiation cytokine factor, *CSF1*, were dramatically reduced in the OP samples. In total, the microarray analysis detected 1606 genes differentially expressed, where 352 transcripts (144 upregulated; 208 downregulated) were changed by greater than 2.0-fold in the OP relative to the non-OP tissues. This paper indicated a large list of genes involved in OP, such as upregulated genes *CXCL2*, *ADRA2A*, *TSPAN8*, *SLC7A11*, *CNND2*, *PSG11*, and *COL15A1* and downregulated genes *PTN*, *IBSB*, *PRPF19*, *COL10A1*, *NGEF*, *CCNB2*, *CDC2*, and *PBK*.

Sorting the differentially expressed genes into KEGG canonical pathways identified ribosomal proteins (*Rpl13a*, *21*, *26*, etc.) and proteins involved in the cell cycle (*CCND2*, *CDKN1a*, *CDC2*, *CDNB2*, *CCNA2*, *CDK2*, etc.) as important pathways, suggesting that osteoblasts during OP differ both in their rate of proliferation and protein synthesis. Confirming this observation, Giner and coworkers[95] previously reported that osteoblasts from OP patients do in fact have decreased proliferative potential.[95] Other interesting pathways found included: cytokine–cytokine receptor interaction (*CCL2*, *CXCL2*, *CSF1*, *TNFRSF19*, etc.), regulation of actin cytoskeleton (*ARPC1A*, *ARPC1B*, *PPP1R12A*, *ACTN1*, *THOA*, *ARPC5*, etc.), and WNT signaling (*SFRP2*, *CCND2*, *CSNK2A2*, *PPP2CA*, *CTBP2*, *TCF7*, *PRICKl1*, *RHOA*, and *FZD5*). Therefore, this study showed the strength of microarrays in genomic profiling. Not only did the authors find that osteoporotic osteoblasts had upregulation of cytokine signaling and downregulation of the growth factor *PTN*, but this study also identified a list of potential candidate osteoporotic-genes previously uncharacterized in bone disease. It is also important to note that the *PTN* gene was also identified by Paic et al.[15] as an osteoblast gene that is dramatically repressed in osteocytes, while Wasserman et al.[21] and Kelly et al.[22] found *PTN* to be dramatically upregulated upon biomechanical stimulation. These results suggest that *PTN* deserves additional attention as a contributor to bone formation, mass maintenance, and biomechanical response. Further characterization of some of the genes highlighted by various microarray experiments may reveal them as potent therapeutic targets for the treatment of OP-related bone disorders.

Due to the difficulties of obtaining human tissue samples and the complexities of designing human experiments (identifying large cohorts matched for age, ethnicity, gender, etc.), very few microarray studies have used human bone. Hopwood et al.[33] used microarray analysis to identify candidate OP genes in trabecular bone from the intertrochanteric region of the proximal femur from 10 women undergoing hip arthroplasty for a fractured neck of the femur (OP), and 10 women undergoing hip arthroplasty for primary OA (non-OP) in addition to 10 women at autopsy (control). They found 150 transcript levels were changed in OP bone, of which 75 corresponded to genes known to condition bone metabolism. In particular OP bone had elevated levels of genes known to promote myelomonocytic/osteoclast precursor differentiation and osteoclast function

(*TREM2*, *ANXA2*, *SCARB2*, *CCL2/3*, *CD14*, *ST14*, *CCR1*, *ADAM9*, and *PTK9)* and a few downregulated genes that encode inhibitors of monocyte numbers/activity (*MNDA*, *PSTP1P1*, and *ADORA2A*). These transcriptional changes are consistent with the physiological events during bone metabolism of OP patients characterized by an increase in: (1) the number of osteoclast precursors and mature osteoclasts; (2) osteoclast activity; and (3) bone resorption.[33] A second group of upregulated genes normally function to inhibit osteoblastogenesis (*CD14*, *ANXA2*, *ST14*, *SGK1*, *CTSB*, *FST*, *LGALS1*, *SPP1*, *SPARC*), consistent with decreased bone formation in OP. A third group of differentially expressed genes is involved in: (1) regulating adipogenesis, such as genes with proadipogenic functions (*SPARC*, *ANXA2*, *IL10*, *MARCO*, *CD14*, *PPP2cb*, *AEBP1*, *FST*, *CCL2*); (2) lipid metabolism (*SCARB2*, *MARCO*, *ADFP*, *FABP5*, *CD14*, *PPP2cb*, *PLA2G7*, *CAV2*, *MGLL*), and (3) glucose metabolism/glucose transport/insulin signaling/IGF1 signaling (*PEA15*, *ANXA2*, *SGK1*, *IGFBP7*, *PPP2CB*, *HSD11B1*, *CCL2*, *DOK4*). These findings were all consistent with the frequent occurrence of insulin resistance, type 2 diabetes, and obesity in OP.[33]

The expression of several genes previously identified as contributors to OP pathogenesis, such as *TREM2*, *IL10*, *CD14*, *COL4A1*, *FST*, *SPARC*, *SHIP1*, and *SPP1*, were strongly differentiated by OP bone.[33] In addition, *IL1B*, *CALCRL*, *IL6*, *PLOD2*, and *RANK* were also significantly altered, but to a slightly lesser extent. Ten genes previously linked to OP through gene expression and animal models were not identified as genes differentially expressed by microarray analysis in this study (*RUNX2*, *LEP*, *VDR*, *ESR1*, *CALCA*, *CALCR*, *PTH*, *PTHR1*, *IGF1*, *LRP5*).[33] Even though these candidate genes were not differentially expressed, many genes were differentially expressed that are known to interact with and/or modify some of these well characterized genes and pathways. For instance, differentially expressed *SHOX2*, *PDLIM4*, *HDAC4*, and *TAZ* have all been shown to interact with *RUNX2* and regulate its activity, suggesting that the *RUNX2* transcriptional regulatory balance could be compromised in OP via these factors.[33] These findings suggest the presence of a very complex interplay between the osteogenic, adipogenic, and haematopoietic cell populations of the bone microenvironment that might account for these differences among experiments.

A follow up study performed by Reppe et al.[34] examined a larger population of OP patients, to reduce the possible variation errors that may have occurred with the small sample size studied by Hopwood et al.[33,34] Reppe et al.[34] compared *trans*-iliac bone biopsies from 84 postmenopausal women with BMD variations [37 with OP, 11 with "osteopenia," and 36 with normal or high BMD scores as determined by Dual-Energy X-ray Absorptiometry (DXA)], and correlated gene expression with BMD in each woman patient. They found ~1600 genes among three sites (L1-L4, total hip, and femoral neck) to be differentially expressed in the OP patients. Of these, 142 differentially expressed genes were found to be strongly correlated with BMD, 4 of which showed strong inverse correlation to BMD (*ACSL3*, *NIPS-NAP3B*, *ABCA8*, and *DLEU2*), while 4 showed strong positive correlations with BMD (*DKK1*, *SOST*, *C10RF61*, and a probe for the human 28S ribosomal RNA gene).[34]

Other interesting upregulated genes included *SEC61B*, thought to interact with *RAMP4* (regulator of osteoclasts), and *WIF1*, a WNT inhibitory factor similar to *SOST* in its regulatory role in bone differentiation.[96,97] Only 1 of these 142 differentially expressed genes overlapped with the Hopwood et al.[33] findings, *PDK4* (involved in glucose metabolism). Possible reasons for this discrepancy include the difference in sample size (10 vs. 37, respectively) and the differences in the comparison groups. Hopwood et al.[33] compared OP women to osteoarthritic or autopsy material, while Reppe et al.[34] compared patients with varying BMD and correlated that information with microarray chips that contained 3 times as many probes. In addition, the ethnic background of the patients should also be taken into account; Hopwood and coworkers' cohorts were Australian while Reppe and coworkers' biopsies were Norwegians.[33,34]

In a different study, Jemtland et al.[35] examined gene expression profiles of 84 postmenopausal women with distinct BMD values (27 OP T-score < 2.5; 18 with intermediate BMD values, and 39 healthy controls).[35] Of the 609 differently expressed genes, 439 were significantly upregulated and 170 were significantly downregulated in the OP patients; bioinformatics analyses defined 302 as disease-related, 47 as age-related, and 40 as bone mass index-related transcriptional changes.[35] Of the genes associated with OP, 256 were unique for being OP-related without being influenced by either age or bone mass index, indicating these particular genes as OP-specific candidate genes. Correlation analyses between these 256 candidate genes and BMD at 3 skeletal sites (hip, lumbar spine, and femoral neck) found that all 256 genes significantly correlated with total-hip BMD, 93% correlated with lumbar spine BMD, and 87% correlated with femoral neck BMD. This confirmed that the majority of OP genes are correlated with BMD. Some interesting genes found to be positively correlated with BMD in all three BMD phenotypes included *SOST* and *DKK1*, (both inhibitors of the canonical WNT signaling pathway; also shown to be upregulated in Reppe et al.[34]), *PGGF1* (which maintains the transcriptionally repressive state of *BCL6* and *CDKN1A*, both of which are involved in cell cycling and found to be differentially expressed in the Trost et al.[32] publication), and *PPME1*

[a protein phosphatase known to demethylate *PP2CB* (found by Hopwood et al.[33] to be differently expressed in OP patients[33])]. In addition, both *BCL2* and *SOX4* (thought to mediate *PTH* and *PTHRP* related bone development) were positively correlated with BMD at the hip and femoral neck but not at the lumbar spine. Finally, *KTN1*, *PTP4A1*, *RTN4*, *SLC16A1*, and *COPS4* were among the top 20 genes negatively correlated with BMD in all three phenotypes and all of which were also significantly decreased in Reppe et al.,[34] indicating their importance in OP.

1.5 Profiling Noncoding RNA Expression in Bone

MicroRNAs (miRNAs) are short (~20–25 nt long), single-stranded noncoding RNAs that play a major role in posttranscriptional gene regulation. Recent studies have shown that miRNAs play a role in regulating skeletal development and bone metabolism. For example, cartilage cell-specific knockdown of Dicer, an essential component of miRNA biogenesis, in mice, resulted in severe skeletal defects during development.[98] Inhibition of miR-92a enhanced fracture healing via promoting angiogenesis.[99] Transgenic mice overexpressing miR-206 in osteoblasts developed a LBM phenotype due to impaired osteoblast differentiation.[100]

Several in vitro[22,101–108] and in vivo gene expression profiling studies[36–38] have been conducted to identify miRNAs involved in the regulation of bone metabolism and bone diseases. In a recent study, using miRNA PCR Arrays, Seeliger et al. identified 11 miRNAs (miR-21-5p, miR-23-3p, miR-24-3p, miR-25-3p, miR-27a-3p, miR-100-5p, miR-122a-5p, miR-124-3p, miR-125b-5p, miR-148a-3p, miR-223-3p) significantly upregulated in the serum of osteoporotic patients compared with non-osteoporotic patients.[38] Five of these miRNAs (miR-21, miR-23a, miR-24, miR-100, miR-125b) were also found to be upregulated in the bone of osteoporotic patients. In another study, An et al.[36] investigated the changes in miRNA profiles in OVX mice and identified 9 miRNAs significantly differentially regulated between OVX and sham-operated mice. miRNAs miR-127, miR-133a, miR-133a*, miR-133b, miR-136, miR-206, miR-378, and miR-378* were identified as upregulated in OVX compared to sham-operated controls mice while, miR-204 was downregulated. Subsequently, they studied the role two of these miRNAs (miR-127; miR-136) have in osteoblast and osteoclast differentiation, as well as in osteocytes. Their results suggest that both miR-127 and miR-136 may contribute to bone loss by suppressing osteoblast differentiation and osteocyte survival, while promoting osteoclast differentiation.

Waki et al.[37] studied the differential regulation of miRNAs in healing femoral shaft fractures compared to unhealing fractures, in rats. This study identified 317 miRNAs with high expression in standard healing fractures compared to unhealing fractures. Waki et al. further filtered the genes based on fold upregulation and high expression and identified eight miRNAs (miR-140-3p, miR-140-5p, miR-181a-5p, miR-181d-5p, miR-208b-3p, miR-451a, miR-743b-5p, miR-879-3p) highly expressed in healing fractures compared to unhealing fractures. Five of these miRNAs (miR-140-3p, miR-140-5p, miR-181a-5p, miR-181d-5p, and miR-451a) were conserved between human and rat. Subsequently, they validated the expression of these miRNAs using reverse-transcription PCR and confirmed that all five miRNAs are significantly higher in standard healing fractures compared with unhealing fractures. Four of these miRNAs (miR-140-5p, miR-181a-5p, miR-181d-5p, miR-451a) have been reported to be involved in the regulation of skeletal development. Three miRNAs (miR-140-3p, miR-181a-5p, miR-451a) have been shown to regulate inflammatory responses.

Long noncoding RNAs (lncRNAs) belong to a class of noncoding RNAs, with transcript length ranging from 200 nt to ~100 kb. LncRNAs play a major role in regulating gene expression during development and disease. In recent years, a number of studies have been performed to identify novel lncRNAs in different cell types and diseases and to understand their function. However, very little work has been done in exploring the role of lncRNAs in regulating skeletal development and diseases, and much of this has been done in vitro. In a recent study, Wang et al.[39] profiled lncRNA expression during osteogenic differentiation of human bone marrow MSCs. Compared to day 0 (undifferentiated MSC), 1206 lncRNAs were significantly differentially expressed (687 upregulated and 519 downregulated) at day 14. Five of these lncRNAs (H19, uc022axw.1, XLOC_008374, LINC00707 and ENST00000436742.1) were further validated using qRT-PCR. A recent study by Huang et al.[109] showed that H19 promotes osteogenesis via TGF-β1/Smad3/HDAC signaling pathway, highlighting its role in the osteogenic differentiation process. Zuo et al.[40] profiled lncRNA expression during BMP2-induced osteoblast differentiation of C3H10T1/2 cells. At 1 day posttreatment, they identified 886 upregulated and 825 downregulated lncRNAs in the BMP2 treated group. 595 upregulated and 548 downregulated lncRNAs were identified at day 4 posttreatment. 59 upregulated and 57 downregulated lncRNAs were common to both time points. These studies have identified several miRNAs and lncRNAs with potential role in bone metabolism, OP and fracture healing; however, functions of majority of these noncoding RNAs remain unclear. Further in vivo studies are required to define the precise role of each of these miRNAs and lncRNAs in bone development and diseases.

2 CONCLUSIONS

In this report, we highlighted a few key publications spanning the last decade that cover key topics in bone biology that have greatly benefited from gene expression profiling. The summary of the genes discussed is also presented in Table 5.1. There are many more in the literature, and by no means have we exhausted the published data. The microarray and RNAseq experiments we have outlined earlier clearly emphasize that it is no easy task to explain, based on genomic profiling how bones respond to loading or maintain their integrity. Skeletal tissue is highly complex both molecularly and physiologically. And while variations in transcript levels for a small combination of genes have the potential to lead to altered bone metabolism, and may ultimately result in bone loss phenotypes, these gene expression experiments clearly identify larger cohorts of transcripts, some of which may not be the obvious candidates for the job, according to their previously described functions. There are limitations on how we can design and generate large datasets based on in vivo experiments. As of now, we can only obtain static glimpses of the bone microenvironment, quantifying the transcriptome incrementally as a function of treatment or disease. As we learn how to measure these events dynamically in humans and animal models, we will be able to determine how the disease emerges or progresses. These genome-wide expression studies undoubtedly will help identify multiple new candidate genes in an unbiased approach but, as for now, these putative candidates still require significant validation through traditional experimental approaches, which will continue to be the bottleneck of scientific discoveries. While the field of bone biology is still in its infancy exploring the available genome-wide technologies, it can greatly benefit from the existing body of work and can move forward with unique and creative approaches that will ultimately lead to well designed and successful gene expression experiments.

CHAPTER

6

Functional Genomics

Michael Mannstadt, Marc N. Wein

Massachusetts General Hospital, Boston, MA, United States

1 WHAT IS FUNCTIONAL GENOMICS?

The publication of the first draft sequence of the human genome marked a milestone in our global understanding of human biology.[1,2] It provided a comprehensive catalog of the 3 billion nucleotide sequence. One of the mysteries was that the roughly 20,000 protein-coding genes occupy only a small fraction (about 1%–2%) of the whole genome. What are the roles of the remaining 98%–99% of the genome, which were once regarded as "junk"? Functional genomics can be defined as studies designed to assign function to this wealth of genomic information. Large international efforts, such as ENCODE and the Epigenomics Roadmap have since revealed hundreds of thousands of regulatory elements throughout the genome that reflect the complexity of gene regulation, and these elements are often located in these intergenic regions. Functional domains in the genome include protein-coding genes with their promoters, exons, and introns, in addition to enhancers, insulators, and imprinting control regions. Many of these regulatory elements are enhancers, which interact with promoters of genes and regulate both spatial and temporary patterns of gene expression.

Another layer of complexity was added with the discovery of the three-dimensional organization of the genome. The genome is organized into so-called topological domains, which are megabase-sized local chromatin interaction domains separated from each other by the insulator protein CTCF.[3] These domains, which are highly conserved between mice and men, separate different transcriptional control processes. Surprisingly, these domains are relatively similar between different cells. Disruption of the barriers between topological domains has been shown to be a mechanism in certain malignancies.[4]

Cell-specific maps of the regulatory elements in our genome can be layered onto the DNA sequence information, bringing life to the "simple" DNA map of sequences and providing a look into the inner workings of a given cell. However, novel approaches are needed to integrate and better understand the function of genomic and epigenomic information. In addition to a better understanding of the physiology of the bone cells, these advances are already providing help in our search for the basis of skeletal diseases and bone cancer.

This chapter addresses methods and recent advances in functional genomics. We describe the identification of functional elements throughout the genome and provide examples with relevance to the field of bone and mineral metabolism. We then highlight examples of methods to assess their cellular function. As this chapter can only mention a small part of the rich published literature, the reader is referred to other chapters in this book and recent reviews.

2 ANNOTATING THE GENOME—AN EMERGING PICTURE

2.1 Encode and Roadmap: An Overview

ENCODE, the Encyclopedia of DNA Elements, is a massive NIH-sponsored public research project launched in 2003 as a follow up of the Human Genome Project. Its goal is to better understand the vast majority of noncoding genomic DNA and to comprehensively catalog functional elements in the human genome. The primary methods used were DNase-seq, RNA-seq, ChIP-seq, and assays for DNA methylation. After an initial pilot phase using 1% of the human genome, the consortium applied their methods to the entire genome in the production phase. The initial results were published in 2012 comprising 30 papers in *Nature*, *Genome Research*, and *Genome Biology*.[5] Taken the results from all 147 investigated cell types, more than 80% of the genome is involved in at least one chromatin or RNA-associated event. More than 70,000 promoters and 400,000 enhancers were assigned.

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00006-X

Intriguingly, single-nucleotide polymorphisms found in genome-wide association studies (GWAS) to be associated with complex traits are enriched in noncoding regions that contain ENCODE-annotated functional elements. This has created opportunities to understand GWAS findings and has already resulted in some spectacular findings.[6] ENCODE also determined that much of our genome is transcribed into noncoding RNA molecules, and some of them are now known to belong to the large group of noncoding RNA of regulatory elements.[7] The ENCODE findings also contribute to our understanding of the evolution of regulatory elements. Contrary to previous assumptions, many enhancers are located in regions that are not the most evolutionarily conserved ones, pointing to their relatively recent development. The current phase of the ENCODE project is providing an even deeper characterization of our genome.

The complementary efforts of the NIH Roadmap Epigenomics Mapping Consortium generated high-quality, genome-wide epigenomic data (histone modification, DNase hypersensitivity sites, DNA methylation, and RNA expression) across 100 different human cell types and human tissues.[8] The current dataset of ENCODE and Roadmap contain limited data from bone cells, namely only partial datasets for primary human osteoblasts (ENCODE uses the name E129). They include genome-wide methylation profiles, histone modifications (such as H2A.Z, H3K27ac, and H3K4me1), and CTCF insulator sites (http://www.encode-roadmap.org). ENCODE and Roadmap data can be easily visualized or downloaded using genome browsers, such as the UCSC genome browser.

2.2 DNase-seq

DNase-seq is a powerful technique that produces a global view of open chromatin, and allows for the prediction of specific transcription factor (TF) binding sites. DNase-seq is based on the well-established observation that within the genome, active DNA elements (promoters and enhancers) exist in an "open" (i.e., nucleosome-free) chromatin configuration making the binding of TFs to DNA possible (Fig. 6.1).[9]

In contrast to "closed" chromatin, these "open" sites can be digested with DNase I; the location of these DNase hypersensitivity sites (DHS) can then be mapped to the genome, revealing active regulatory elements.[10] Recently, next generation sequencing of the DHS was shown to allow for a surprising and unexpected resolution of TF binding sites down to the base-pair level. This resolution is based on the fact that within "open" DHS (median size 300 bp), individual base pairs bound by their specific TF are protected from digestion by DNase I, and, as a result, very specific "footprints" are left behind.[11–14] Putative binding sites for specific TFs are identified among these footprints by computational means using the consensus DNA-binding sequences of the TF of interest.[15] Data from DNase-seq has been demonstrated to have striking concordance with ChIP-seq and crystallography data, for instance across 41 diverse cell and tissue types by ENCODE.[16]

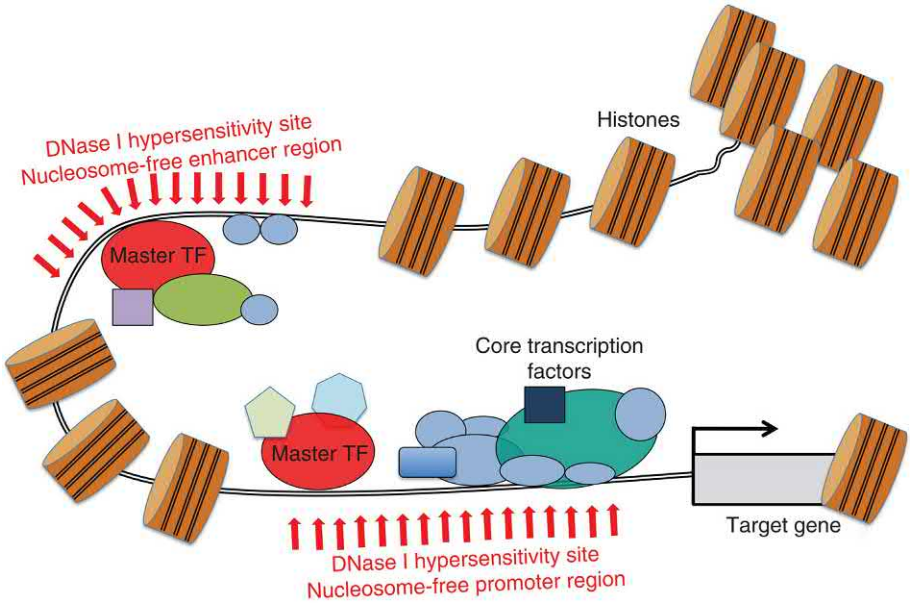

FIGURE 6.1 **Schematic depiction of the general genomic organization with gene body, proximal promoter, and distal element (enhancer).** DNA is wrapped around histone proteins. Inactive regions of the genome are tightly bound by histones and condensed, and inaccessible to DNase I digestion. In the open configuration, DNA is exposed and susceptible to digestion with DNase (so-called DNase-I hypersensitivity sites). DNase hypersensitivity sites (DHS) are typically related to functional activity with various proteins and transcription factors (TFs) binding to these sites.

2.3 ChIP-seq and Chromatin Profiling

All sites of chromatin modifications or TFs binding can be mapped using chromatin immunoprecipitation combined with massively parallel sequencing (ChIP-seq). This powerful method makes it possible to understand differences between both tissues and cells, and between different cell differentiation states. For example, the changing epigenomic landscape can be addressed when osteoblasts differentiate into osteocytes. By determining the chromatin marks associated with active promoters (H3K4me3 and H3K9ac), active enhancers (H3K4me1 and H3K27ac), or active repressors (H3K27me3 and H3K9me9), a deep view into the changing usage of promoters and enhancers down to several base-pair levels can be obtained. This example is further discussed later.

In brief, to carry out ChIP-seq, cultured cells, or minced fresh or frozen tissue, are treated with formaldehyde, which crosslink TFs that are bound to their cognate DNA. Nuclear extracts are prepared, and genomic DNA is sheared using sonication. The resulting DNA–protein complexes are immunoprecipitated using a histone mark or TF-specific antibody. The immunoprecipitated chromatin is collected and crosslinks are reversed. Purified DNA is sequenced using next generation sequencing. DNA that was bound by the TF of interest is enriched in the sample and identified through direct sequencing. A positive control antibody and a negative control (e.g., preimmune serum) are used.

Several examples of epigenetic profiling of skeletal cells are given. These publications give an insight into the kind of data that can be generated using genome-wide epigenetic profiling.

2.3.1 SP7/Osterix is Restricted to Bone-Forming Vertebrates Where it Acts as a Dlx Cofactor in Osteoblast Specification

An example of the power of chromatin profiling combined with ChIP-seq data is the recent comprehensive analysis of osterix targets in osteoblasts.[17] Osterix (SP7), together with RUNX2, is one of the key TFs in the development of bone cells.[18] During skeletal development, mesenchymal progenitors develop into RUNX2-positive preosteoblasts, then become RUNX2/osterix-double positive osteoblast precursors and later mature osteoblasts. The critical importance of osterix for the development of precursors into osteoblasts was demonstrated by the failure of osterix-null mice to develop mature osteoblasts.[19] Therefore, a better understanding of the molecular targets of osterix is fundamental for our understanding of osteoblast development.

Hojo et al. sought to identify targets of osterix, using primary osteoblasts from mice as opposed to a cell line to more faithfully represent the in vivo condition. To facilitate chromatin immunoprecipitation, they first generated a knocking mouse to add two tags (a biotinylated sequence and a 3xFLAG tag) to osterix expressed from the endogenous locus. Antibodies against the FLAG tag and streptavidin for biotinylated proteins are well suited for immunoprecipitation.

The analysis revealed key insights into the role of osterix. Genome wide, the investigators identified 2,112 osterix-binding peaks. Based on conservation scores, osteoblast expression of the nearest gene, and strength of the ChIP-seq peaks, 194 putative enhancer regions were identified. For a subset of them, enhancer activity was confirmed in cell-based luciferase reporter assays, and bone-specific expression confirmed using transgenic reporter mice. An example of the power of this approach to identify targets of osterix was provided by focusing on osteoblast-expressed genes with strong association with osterix, which included Notch2, FGFR2, COL1a2, Gli2, and Kremmen1. Notch2, which is expressed in all skeletal cell types, and of known importance for osteoblast differentiation, contains an osterix ChIP peak in intron 2 located in a conserved block of DNA. An enhancer-driven reporter containing DNA from this intronic region demonstrated higher activity in preosteoblastic MC3T3E1 cells compared with 3T3 cells. The activity of this enhancer increased several folds during osteogenic induction and was suppressed by osterix knockdown, consistent with an osteoblast-specific regulation through the regulatory region in intron 2 of Notch2 (Fig. 6.2).

Surprisingly, most osterix peaks did not map to a consensus GC box that is used by other members of the Sp family of TFs to bind DNA. However, in EMSA assays, osterix does not consistently bind to the AT-rich motif it was observed to associate with by ChIP-seq. This paradox was supported by evidence that suggests that osterix binds most targets indirectly by binding to homeodomain-containing TFs of the Dlx family, which then directly bind to DNA target

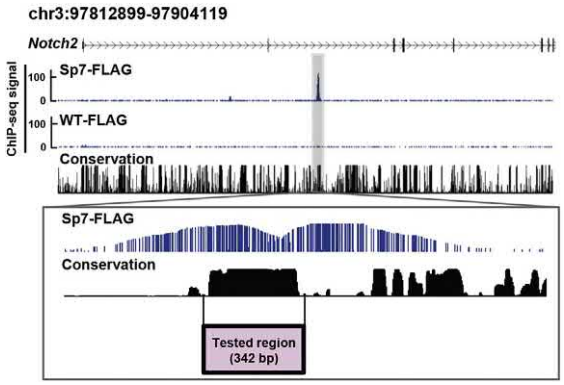

FIGURE 6.2 Osterix ChIP-peak identified in intron 2 of Notch2 in a conserved region. A 342-bp piece was tested in an enhancer–reporter assay, which showed strong correlation to osteogenic induction.[17]

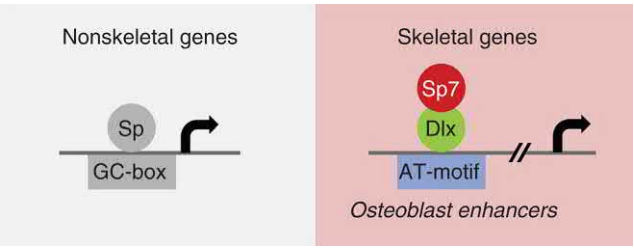

FIGURE 6.3 Model of Sp7 (osterix) binding to osteoblast enhancers of skeletal genes, as opposed to the typical mode of action of other members of the Sp family of TFs for nonskeletal genes.[17]

sequences. Furthermore, the identification of an N-terminal transcriptional activation domain in osterix led the authors to predict that osterix acts as a transcriptional coactivator for Dlx in osteoblast development. Paralogs to osterix were identified in all bone-forming vertebrates. The emergence of osterix (Sp7) within the Sp family, and its ability to enhance the evolutionary older transcriptional activity of Dlx factors might therefore have been a key factor in the development of bone-forming cells during evolution. This study provides an unprecedented insight into the osteoblast regulatory program, and novel mechanistic understanding of how osterix binds its targets (Fig. 6.3).

2.3.2 *Distinct Transcriptional Programs Underlie Sox9 Regulation of the Mammalian Chondrocyte*

Sox9 is an essential TF for chondrocyte specification and differentiation. Sox9 is expressed in cells of mesenchymal condensation and is essential for their initial differentiation into chondrocytes and osteoblasts.[20] After the initial differentiation, Sox9 is exclusively expressed in chondrocytes. In the growth plate, its expression is high in proliferating chondrocytes, but Sox9 expression is lost as chondrocytes differentiate into hypertrophic chondrocytes. The genome-wide identification of Sox9 targets has been an important step in our understanding of this key skeletal TF.[21] Using an in vivo approach, investigators subjected mouse rib chondrocytes to Sox9 ChIP-seq experiments. 27,656 peaks were identified genome wide and further analysis revealed two distinct types of Sox9 binding in the chondrocytes' genome. There were two classes of osterix target sites. About 25% of peaks were found around the transcription start site of genes, were associated with key components of the transcriptional complex, and included nonskeleton-specific genes, such as house-keeping genes. These so-called class I peaks showed relatively weak Sox9 binding, and importantly, did not show enrichment for Sox9 DNA binding motifs. The remaining peaks form class II targets, which showed typical enhancer signatures, as they were enriched in the histone marks (H3K27ac and H3K4me2). In contrast to class I peaks, Sox9 binding

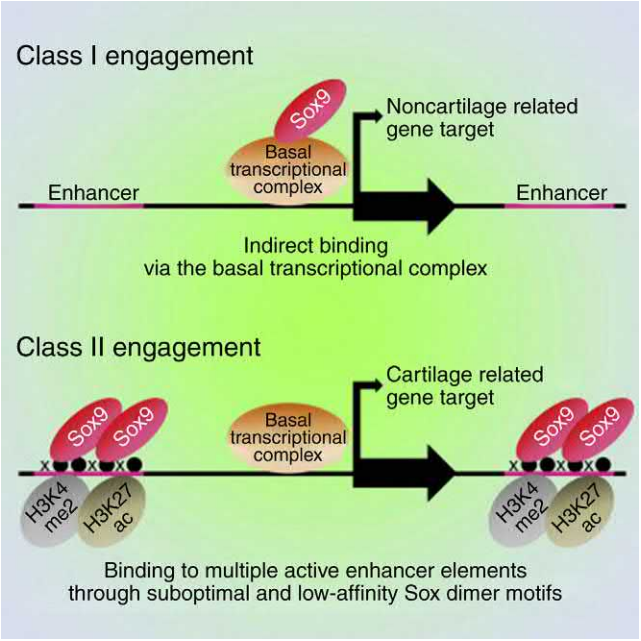

FIGURE 6.4 ChIP-seq using mouse chondrocytes revealed two different classes of Sox9 engagement: class I sites are located at or near the transcription start site (TSS) of house-keeping genes and part of the basal transcriptional complex; class II sites are enhancers of cartilage-specific genes.[21]

motifs were highly enriched in so-called class II peaks, and the associated genes were enriched in cartilage-related genes (Fig. 6.4).

In addition, 502 superenhancers around 422 genes were identified. These are special enhancers that lead to high levels of expression of their associated genes, and are often found near genes that code for cell-type-specific master TFs. Therefore, genome-wide mapping of Sox9 binding sites further clarified the mechanism through which it controls chondrocyte development.

2.3.3 *The Osteoblast-to-Osteocyte Transition: Epigenetic Changes and Response to the Vitamin D3 Hormone*

Osteocytes are derived from osteoblasts and possess unique characteristics. They are by far the most abundant cell type in the adult bone, and while they are embedded in mineral matrix, they maintain multiple connections to other cells in the bone and orchestrate bone remodeling. They produce factors, such as sclerostin and FGF23, play a role in bone resorption, and function as mechanosensors.[22]

A fundamental question in the understanding of osteocytes is the characterization of the changes that cells undergo during the transition from osteoblasts to osteocytes. Using the conditionally immortalized osteocyte cell line IDG-SW3, which has osteoblast-like characteristics at 33°C and develops into osteocytes at

37°C in osteogenic media, investigators profiled these cells in an attempt to obtain insights into the transition to osteocytes. Extensive ChIP-seq analysis of key histone marks across the genome at day 3 and day 35 of differentiation from osteoblasts into osteocytes were performed and compared with global changes of the transcriptome. Most changes of RNA abundance were reflected by the expected quantitative changes of histone modifications for gene elongation and gene enhancer activities. However, a limited number of histone modifications were either removed or added, for example, in the gene locus for PTH1 receptor and osterix (Sp7).[23]

2.3.4 The Binding of Runx2 During Osteoblastogenesis

Runx2 is a master regulator of osteoblastogenesis and mice missing Runx2 have no osteoblasts, and abnormalities in chondrocytes.[20,24] The genome-wide identification of target genes would therefore provide an important step for a better understanding of its transcriptional program. Using ChIP-seq, investigators recently profiled Runx2 binding using MC3T3-E1 preosteoblasts during proliferating, matrix deposition, and mineralization.[25] Binding of Runx2 to promoter regions, and to presumed enhancers were identified, with significant changes during differentiation. Runx2 binding was found in genes known to be regulated by Runx2, and also in genes of broad general cellular processes. These investigations led to the identification of new Runx2-regulated genes and extend our understanding of Runx2-regulated gene network.

2.3.5 Chromatin Profiling of Parathyroid Glands

The methods in functional genomics described earlier can be applied to other cells and tissues that play a role in skeletal and mineral homeostasis. For example, there is a lack of knowledge of the specific transcriptional program that governs parathyroid cells. It is not known, what epigenetic changes are characteristic of adenoma of primary hyperparathyroidism, and a comprehensive understanding of target genes of the parathyroid-specific master TF GCM2 is missing. We have therefore undertaken DNase-seq and chromatin profiling of human parathyroid glands, as well as ChiP-seq experiments using antibodies against GCM2. Together with transcriptome data these approaches will annotate parathyroid-specific active elements in the genome as a first step toward further insights into the transcriptional regulation of parathyroids cells (Fig. 6.5).

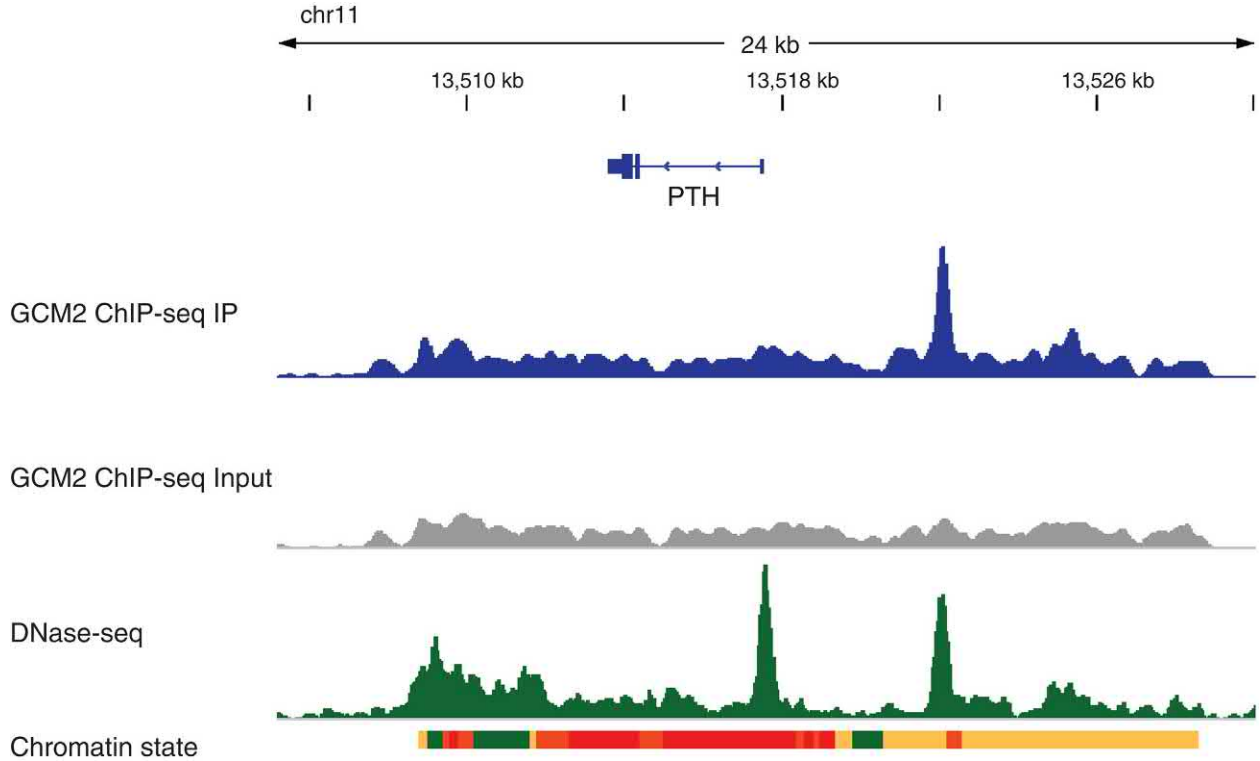

FIGURE 6.5 **DNase-seq data, GCM2 ChIP-seq, and chromatin states obtained from human parathyroid tissue (unpublished data).** Browser view showing broad peaks of DNase hypersensitivity at the proximal PTH promoter, over the gene body, as well as 5 kb upstream of the TSS, and GCM2 engagement 5 kb upstream of the TSS.

3 FROM ANNOTATED SEQUENCES TO FUNCTION

Fifteen years ago, a draft of the human genome was first reported.[1] Since then, biomedical research has been revolutionized by rapidly increasing knowledge regarding the genetic basis of disease and variation across individuals.[26] In contrast, our understanding of the functional consequences of such variation has lagged far behind the accelerated rate of gene and locus discovery afforded by the genomic revolution.[27] Broadly speaking, functional genomics refers to studies designed to assign function to this wealth of genomic information.

Well-powered GWAS have been performed to understand how common genetic variants contribute to many traits pertinent to mineral metabolism[28,29] and skeletal biology.[30,31] While these studies identified variants in genes previously known to regulate these traits, functional characterization of novel genes identified has been lacking. As such, a major unmet need is to comprehensively use the clues provided from human genetics to obtain a better understanding of the molecular circuitry controlling the cells crucial for mineral metabolism and skeletal homeostasis. Here, we will review recent technical advances in the area of functional genomics that will allow comprehensive characterization of such variants.

As discussed earlier, the ENCODE project[32] was launched in 2003, and sought to identify all functional elements in the human genome. This included a mammoth effort to map epigenomic modifications at the genomic level. Currently, information regarding nucleosome accessibility, histone tail modifications, TF binding sites, long-range intra- and interchromosomal interactions, and expression (transcriptomic) profiling is available across a range of human cell and tissue types.

Facilitated by advances in next generation sequencing technology, these efforts have rapidly led to the development of annotated maps that can be layered on top of genomic sequences. This work has led to an explosion in ideas, fueled by bioinformatics, about the functions of the noncoding genome. The majority of GWAS-identified trait and disease variants do not affect protein-coding DNA sequences[33]; therefore, a likely possibility is that noncoding variants linked to disease affect the function of regulatory elements present in the noncoding genome. Importantly, cell and tissue types crucial for mineral metabolism and skeletal development are under represented in current ENCODE databases.

In addition, information provided by ENCODE only provides a snapshot of the epigenomic state of the genome in whatever cell or tissue type is analyzed at a given developmental stage. This information generates hypotheses about the function of noncoding sequences and an embedded disease-associated variant, but functional data remains needed to truly understand how noncoding nucleotide changes affect cellular phenotypes. Here, we will review current efforts outside the field of skeletal biology to approach this daunting problem, and discuss how these conceptual approaches might be applied to bone biology and mineral metabolism research.

As the majority of GWAS variants associated with disease risk and trait variation lie outside of protein-coding DNA sequences, novel techniques are needed to better understand how sequence variation affects cellular and organismal phenotypes. One approach to this challenge has been to crossreference ENCODE annotation to disease-associated noncoding variants. However, several caveats apply to this approach.

First, the cell type(s) responsible for the phenotypic effects of a given variant are not necessarily known. Furthermore, epigenomic datasets from ENCODE are incomplete in that many cell types of particular importance in skeletal biology and mineral metabolism are not represented. Therefore, optimal annotation in the correct cellular context may be absent. For example, a distinct possibility is that common variants associated with differences in height[30] modulate the pathways underlying chondrocyte hypertrophy in the growth plate.[20] As growth plate chondrocytes have not been extensively profiled in ENCODE, cell type specific epigenomic marks linked to common sequence variation may be missed.

Second, ENCODE annotation can provide information about the broader regulatory state of a given region of noncoding DNA. However, the function of individual nucleotides within such regions cannot be determined. Therefore, higher-resolution maps of the function of the noncoding genome are required.

Third, epigenomic mapping of noncoding sequences provides hypotheses about the potential function of these sequences, many of which have borne out to be correct when tested in tradition, "low-throughput" experimental systems.[34–36] However, these predictions have not been extensively tested; therefore, at the present time functional data are needed to fully understand how a sequence variant might affect the function of a noncoding regulatory DNA element.

Here, we will summarize two recently described approaches that begin to address this important challenge.

3.1 In Situ Saturating Mutagenesis With CRISPR/Cas9

As outlined earlier, sequence variants associated with disease risk and phenotypic variation are enriched in noncoding enhancers. However, fine resolution functional understanding of sequence elements across lengthy stretches of enhancer DNA has been difficult to achieve. The advent of genome editing with CRISPR/Cas9[37] has

revolutionized our ability to experimentally interrogate the function of the noncoding genome.[38]

Bauer et al. recently reported the use of in situ saturating mutagenesis to dissect disease-associated enhancer function.[39] Hemoglobinopathies, such as sickle cell anemia are due to mutations in the beta-globin gene. Persistent expression of the fetal hemoglobin (HbF) variant is known to be protective for sickle cell disease. Genetic studies have implicated a crucial role for the transcriptional repressor BCL11A as a regulator of HbF expression.[40] BCL11A itself is transcriptionally regulated by an erythroid-specific enhancer, which is subject to noncoding genetic variation in humans.[41]

However, it had been difficult to precisely map the functions of multiple potential BCL11A enhancers with traditional methods. For this reason, a saturating mutagenesis screen was performed. To do this, Canver et al.[39] designed *all* possible sgRNAs targeting the putative human and murine BCL11A enhancers and introduced these sgRNAs along with active Cas9 into erythroid lineage cells via lentiviral-mediated transduction. The typical outcome following Cas9-mediated double stranded DNA breaks is repair via the imprecise nonhomologous end joining pathway; therefore, a panel of insertions/deletions will be generated by this in situ mutagenesis approach. Phenotypic effects of these noncoding mutations were assessed based on HbF expression. Cells were then analyzed for HbF expression by flow cytometry, and cells HbF^{hi} cells were recovered by cell sorting. Genomic DNA isolated from these cells was purified, and sgRNA sequences present (due to lentiviral integration into the host cell genome) characterized by next generation sequencing and their abundance compared to the input population of sgRNAs tested. This approach allowed quantification of the effects of all 1973 sgRNAs on regulation of HbF expression.

Two interesting and unexpected results were noted. First, in each species a single subelement of BCL11A enhancer DNA was observed to have a dominant effect in regulating BCL11A (and therefore HbF) expression. In humans, ~4 kb of putative enhancer DNA was tested, and yet mutation of only ~350 bp of this sequence led to appreciable effects. Therefore, only a subset of DNase-hypersensitive enhancer sequence is "essential" for BCL11A expression as defined by this technique. Second, although both human and murine BCL11A share conserved intronic enhancer elements, the subelement deemed to be most important for BCL11A expression differed across species. Therefore, species-specific studies should be conducted when assessing effects of noncoding elements in the future, as apparent sequence conservation appears to mask underlying functional divergence.

This powerful approach of saturating mutagenesis via CRISPR/Cas9 can be broadly applied to dissect noncoding DNA function across genes and cell types. In bone, for example, a number of polymorphisms near the SOST gene (encoding the osteoporosis drug target sclerostin) have been linked to bone mineral density and fracture risk.[31] However, our understanding of the regulatory elements controlling SOST expression in murine and human cells remains incomplete.[42,43] Applying a similar in situ saturating mutagenesis screen to better understand the functional impact of elements controlling SOST would significantly improve our understanding of how this gene is regulated at the transcriptional level, and how human genetic variation linked to skeletal phenotypes intersects with the circuitry controlling SOST expression.

3.2 Multiplexed Reporter Assays (MPRA) to Assess Function of Expression-Modulating Variants

The in situ saturating mutagenesis approach outlined earlier powerfully assesses function of enhancers at the single-nucleotide resolution. However, this method currently focuses on a relatively small stretch of noncoding DNA (4–5 kb per species), and pays no attention to the impact of common genetic variants.

Recently, two groups have described an alternative and complementary method to assess functional effects of single nucleotide variants through parallel large-scale episomal reporter assays.[44,45] Here, large numbers of sequences encompassing variants linked to different phenotypic traits (red blood cell parameters, inflammatory bowel disease, BMI, coronary artery disease, among others) were cloned into barcoded reporter vectors. For each putative disease-associated variant, both common alleles are tested in parallel. Next, bulk populations of these reporter constructs were introduced into cells of interest, and reporter activity was determined by next generation sequencing. This workflow allows for systematic interrogation of whether disease- or trait-associated variants influence reporter activity.

This approach provides a vital framework for future studies to better understand the function of sequence variants linked to disease. Further study of all variants identified as functionally important from this approach is required. Merging multiplexed reporter assays (MPRA) data with ENCODE annotation and expression data appears to highlight variants of particular functional importance.[45] Overall, it is quite clear that MPRA represents a powerful addition to the current toolset of GWAS follow-up techniques. Again, one can imagine how this framework could be applied to efforts to better understand how variants associated with skeletal and mineral metabolism traits exert their functional effects. For example, a MPRA library could be generated to include all bone mineral density-associated variants, and

subsequently this bone-focused library could be profiled in osteoblastic and osteoclastic cells.

4 INTERROGATION OF CELLULAR FUNCTION: GENOME-WIDE GAIN- AND LOSS-OF-FUNCTION SCREENING IN MAMMALIAN CELLS

Without a doubt, a better understanding of how common human genetic variants linked to disease function is a major priority in the rapidly developing field of functional genomics. However, the magnitude of phenotypes caused by most GWAS "hits" is rather modest. Furthermore, common variants (and thus GWAS hits) are limited in effect size due to absence of evolutionary selection. Therefore, complementary approaches to interrogate cellular function at the genome-wide level are needed.

For decades, investigators in our field have employed powerful cell culture models to interrogate mechanisms of chondrocyte,[46] osteoblast,[47] osteoclast,[48] and osteocyte[49] functions in vitro in transformed cell lines. While all these models do have limitations, they have yielded crucial bona fide insights into cellular function. In addition, recent advances in induced pluripotent stem cell technologies have led to derivation of osteoblasts[50] and chondrocytes[51] from these sources. Therefore, a wide variety of options are now available to explore molecular mechanisms in bone cell function in vitro.

The vast majority of mechanistic studies pursued to date in such systems have involved detailed characterization of candidate genes of interest. Such studies are inherently limited by existing knowledge. Historically, genetic screens have been performed in model organisms, such as baker's yeast, worms, and fruit flies.[52–54] These unbiased approaches have yielded important new insights into a wide variety of biologic processes. More recently, multiple methodologies have been developed to perform functional genetic screening in cultured mammalian cells. Here, we will review genome-wide functional screening methodologies, including RNA interference (RNAi), ORFeomics, and CRISPR/Cas9, and discuss applications to probe mechanisms of bone cell function.

4.1 RNAi-Based Functional Genomics

RNAi refers to sequence-specific posttranscriptional gene silencing. This is initiated by a double-stranded RNA species homologous to the sequence of the silenced gene. Over 15 years ago, it was demonstrated that RNAi is mediated by sequence-specific 21-nucleotide siRNA duplexes, which could easily be delivered to mammalian cells.[55] Since then, RNAi has proved to be an invaluable tool for experimental loss-of-function studies in a wide variety of mammalian cell lines and primary cells. Given the refractory nature of some primary cells to transfect with RNAi duplexes, alternative delivery methods, such as lentiviral-mediated shRNA expression, have been developed.[56] In skeletal biology, lentiviral-mediated shRNA has been described for selected target gene silencing in a variety of cells, including primary calvarial osteoblasts.[57] Shortly after its introduction as a tool to disrupt target gene expression for focused candidate gene studies, large-scale RNAi libraries were developed to facilitate genome-wide functional screens.[56,58] In such studies, libraries of RNAi or shRNA constructs are generated, introduced into target cells, and then phenotypic consequences assessed.

While the majority of large-scale screens have been performed in cancer cells and neurons, to date two screens in bone cells have been reported, both in human bone marrow derived mesenchymal stromal cells capable of osteoblast differentiation.

Zhao and Ding[59] screened a synthetic siRNA library targeting 5000 human genes to identify repressors of osteoblast differentiation. Mesenchymal stromal cells were transfected with this library in high-throughput conditions, and cells were subsequently assayed for alkaline phosphatase (ALP) expression as an early marker of osteoblast differentiation. Importantly, cells were grown under conditions not designed to promote robust osteoblast differentiation. The authors reported 53 confirmed "hits" that gave rise to a significant increase in ALP expression. Twelve of these genes were selected for further studies in vitro. Interestingly, this approach identified GNAS as a gene that regulates osteoblast differentiation, a result corroborated by extensive in vivo human and mouse genetics.[60,61]

More recently, Zou et al.[62] reported a similar strategy in which the same human mesenchymal stromal cells were screened with a lentiviral-based shRNA library targeting ~1500 human kinases, phosphatases, and receptors. Importantly, this library contains four to five distinct shRNAs for each gene targeted, allowing for confirmation that multiple (at least two) independent shRNAs cause the same phenotype. While systematic results of all genes whose knockdown causes increased ALP was not reported, DCAMKL1 emerged as a robust "hit" from this screen. The authors went on to demonstrate that DCAMKL1 knockout mice show increased bone mass and osteoblast activity, as predicted from the shRNA screening results. Furthermore, DCAMKL1 controls activity of the TF RUNX2 in vitro, and a genetic interaction between DCAMKL1 and RUNX2 was demonstrated in vivo.

Comparing these two similar screens side by side is challenging. Zhao and Ding did not report DCAMKL1 as a "hit" from their RNAi screen, but it is not clear if DCAMKL1 was present in the library of RNAi duplexes

tested. Zou et al. did not comment on whether any of the 53 "hits" from the Zhao and Ding study were detected in their screen, and did not report a full list of genes whose knockdown increased ALP in their study. These shortcomings illustrate some of the challenges associated with RNAi/shRNA screening, systematic data analysis and sharing tools would greatly facilitate efforts to clarify the rigor and reproducibility of "hits" identified. To the great credit of Zou et al.,[62] the shRNA screen reported represented a starting point for detailed functional studies on a new gene, DCAMKL1, and its role in bone biology.

Recently, it has become clear that major caveats associated with RNAi screening exist. Many potential drug targets identified through this technology in academic laboratories have not been confirmed by independent studies in industrial laboratories.[63] In addition, an inherent weakness in RNAi-based screening is that the introduced small RNA enters the microRNA processing pathway, and therefore affects expression of many mRNAs that have a complementary "seed" (first 9 nucleotides) rather than the full 21 nucleotides of complementarity.[64] The pervasiveness of such "off-target" effects in the setting of RNAi screening is now well-appreciated.[65] These findings have led experts in the field to conclude that the "honeymoon" is over with respect to current RNAi screening technologies.[66] Certainly, relying on a single RNAi sequence as a surrogate for a gene's function may lead to erroneous conclusions. Proper interpretation of RNAi screening experiments therefore requires robust computational approaches, including assurance that multiple independent RNAi sequences targeting a single gene all leads to the same phenotype. Therefore, novel modalities are needed for robust functional genomic screening in mammalian cells.

4.2 The Orfeome: A Tool for Gain-of-Function Screening

While generally loss-of-function approaches are thought to be ideal to define gene function, complementary gain-of-function studies are also useful in certain instances. Large-scale libraries of cloned cDNAs for overexpression studies have been developed to facilitate such efforts.[67,68] Yang et al. have reported the largest collection of cloned open reading frames (ORFs) to date, that is, >16,000 cDNAs inserted into a versatile epitope-tagged lentiviral expression vector. This collection also benefits from a barcoded tag to easily facilitate identification of cDNAs leading to cellular phenotypes from genomic DNA of infected cells by next generation sequencing. Gain-of-function screens have been reported with this library, mainly focusing on identifying kinases that when overexpressed lead to resistance to chemotherapy effects in cancer cell lines.[69]

To date, no such "ORFeomic" screens have been performed relevant to skeletal biology. Incomplete knowledge exists regarding the regulatory mechanisms controlling expression of several bone-specific genes. Therefore, one could envision that a gain-of-function screen designed to identify new genes sufficient to induce high expression of FGF23, for example, could lead to important and novel insights into the mechanisms controlling phosphate homeostasis by bone cells.

4.3 Genetic Screens Using CRISPR/Cas9: The Next Frontier

The past 3 years have witnessed a revolution in genome editing afforded by CRISPR/Cas9. This bacterial immune system consists of an RNA-guided DNA nuclease (Cas9), whose activity can easily be programmed to target specific host DNA sites by sequence embedded within a 20 nucleotide "guide" RNA species. The term "sgRNA" refers to an engineered single guide RNA commonly used for experimental purposes.[37] Expression of two components, Cas9 and sgRNA, is necessary and sufficient to this technology to a wide variety of mammalian cellular targets.

While multiple potential applications for CRISPR/Cas9 in experimental sciences have been described, here we will focus on its potential utility for functional genomic screening.[70] To date, several large-scale sgRNA libraries have been designed containing multiple sgRNA sequences targeting all human or mouse-coding genes in lentiviral expression delivery systems. A popular experimental workflow (Fig. 6.6) has been designed to produce populations of heterogeneous lentiviralparticles containing all possible perturbations.

Therefore, large numbers of cells can be infected in a "bulk" (rather than arrayed) format, and cells possessing rare phenotypes of interest isolated by positive selection. This screening workflow significantly reduces complexity and cost of screening efforts. Genomic DNA can be isolated from cells possessing the phenotype of interest, and sgRNA sequences present in the host cell genome determined by next generation sequencing.

The experimental approach was first applied to identify genes whose absence confers resistance to chemotherapeutic agents in cancer cells.[71,72] More recently, reports have emerged using loss-of-function CRISPR screening to identify genes required for toxin-induced cell death, and in vivo in models of hematologic malignancies.[73–75] Considerable excitement exists in the functional genomic community regarding the superiority of CRISPR-based loss-of-function screening modalities above traditional RNAi approaches. However, concerns regarding possible off-target activity (DNA cleavage at sites not perfectly targeted by the 20 nucleotide sgRNA sequence) and variable on-target activity (variable mutagenic activity across

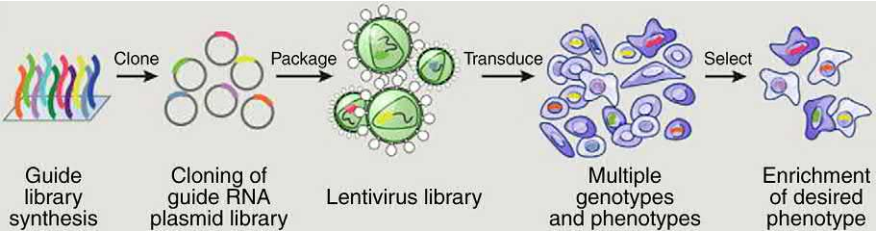

FIGURE 6.6 Workflow for functional genomic screening using CRISPR/Cas9. *Source: Hsu PD, Lander ES, Zhang F. Development and applications of CRISPR-Cas9 for genome engineering.* Cell *2014;***157***(6):1262–78.*

multiple sgRNAs) remain. Current efforts to minimize off-target[76,77] and maximize on-target cleavage[78] are likely to further improve the performance of this exciting functional genomic screening approach.

The use of a modified, catalytically inactive Cas9 to modulate gene expression is an additional possibility afforded by CRISPR/Cas9. Here, a nuclease-dead form of Cas9 can be fused to a potent activating or inhibitory domain. This artificial TF can then be recruited to target gene promoter sequences by complementary sgRNAs.[79,80] To date, genome-wide screening efforts using this approach have been limited, but this represents an exciting complement to existing RNAi and cDNA-based approaches to modulate (rather than eliminate) target gene expression.

5 OUTLOOK

Understanding the landscape of regulatory elements of cells important for bone and mineral homeostasis is still in its infancy. More comprehensive genome-wide maps of histone modifications and TF binding sites are needed. For example, although "master regulator" TFs that control chondrocyte, osteoblast, and osteoclast differentiation are known, osteocyte-specific TFs responsible for osteocytogenesis are unknown. Understanding the epigenetic changes that dictate cell stage transitions and differentiation will further contribute to knowledge that is applicable to both physiology and disease states.

To date, no genome-wide CRISPR screens have been reported in bone cells. As reviewed earlier, powerful in vitro models of osteoblast, osteoclast, and osteocyte functions exist. Combining these models to genome-wide screens carefully designed to interrogate cellular phenotypes of interest will undoubtedly lead to discovery of novel genes crucial for bone cell function.

6 SUMMARY

The current postgenomic era represents an exciting time in biomedical research. Information abounds, and rapidly new tools are being developed to discover new genes and probe their function. Combining these tools with powerful in vitro and in vivo models commonly used in skeletal biology research will lead to new discoveries and new drug targets.

Mouse Models: Approaches to Generate In Vivo Models for Hereditary Disorders of Mineral and Skeletal Homeostasis

Siân E. Piret, Rajesh V. Thakker

University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism (OCDEM), Churchill Hospital, Headington, Oxford, United Kingdom

1 INTRODUCTION

In vivo models may facilitate the investigation of the pathophysiological mechanisms that underlie inherited bone disorders, as well as preclinical translational studies to assess new treatments.[1] In addition, in vivo models are of particular importance for the study of multisystem disorders, such as skeletal diseases that may affect multiple cell types or multiple tissues, and thus have advantages over in vitro cell culture methods, which are important for functional and molecular investigations, but are nevertheless isolated systems that are outside the context of the whole organism.[1] In recent years, the mouse has increasingly become the species of choice for developing such in vivo mammalian models, as it has many similar physiological systems to man.[1] The small size of mice, coupled with their ability to reproduce rapidly with a short-generation time, yields many practical advantages for studying genetic disorders, as well as the effects of different diets and environments.[1] In addition, the coding regions of mouse and human genomes share ~85% nucleotide sequence identity[2] and development of gene targeting methods in the mouse has facilitated the generation of mouse models for human disorders by using mutagenic, transgenic, and targeted approaches.[3] Finally, the availability of inbred mouse strains for these models offers two advantages: first, they help to minimize the variations in phenotype that may occur from genetic modifiers; and second, generating the same disease model in different strains conversely enables interstrain differences in phenotype to be studied, as well as identifying the influence of genetic modifiers, which may also contribute to differential phenotypes in man.

Inherited bone disorders may be associated with abnormal mineral metabolism, which may result in alterations of plasma or urine calcium or phosphate concentrations; or skeletal dysplasia that may be due to defects in structural proteins. This chapter will review the main strategies that have been used for generating mouse models (Tables 7.1 and 7.2), and illustrate their utility with some examples of mouse models that have been generated for inherited disorders of calcium metabolism and parathyroid hormone (PTH) signaling (Tables 7.3–7.5). Also summarized are details of other mouse models that have been generated for disorders of phosphate homeostasis, vitamin D metabolism, and the pathways of fibroblast growth factor 23 (FGF23) signaling (Tables 7.6 and 7.7); and skeletal dysplasias due to abnormalities of FGF receptors (FGFRs), collagens, transcription factors, and bone-specific proteins (Tables 7.8–7.10).

2 METHODS FOR GENERATING MOUSE MODELS

2.1 Nontargeted Strategies

Spontaneous mutations in mice may result in benign phenotypes, such as variable coat colors, or in disorders that have similarities to diseases in man, for example, the hyperphosphatemia (*Hyp*) mouse, which is representative of X-linked hyperphosphatemia in man.[59] Such *spontaneous mutations* occur at very-low frequencies, thus several techniques that increase the rate of mutation induction in the mouse genome by either nontargeted (random) or targeted strategies have been

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00007-1

TABLE 7.1 Methods Resulting in Mutations

Methods	Examples	References
Spontaneous	Hypophosphatemic rickets (*Hyp*) mouse due to mutation of *Phex*[a]	4,6
Radiation	Gyro (*Gy*) mouse, which has hypophosphatemic rickets and hypercalciuria, due to deletion of *Phex* and spermine synthase genes on the X chromosome	6–8
Chemical	*Nuf* mouse, which has autosomal dominant hypocalcemia with cataracts due to an activating CaSR mutation, induced by an alkylating agent, isopropyl methane sulfonate (iPMS), which is mutagenic to testicular and epididymal sperm DNA[b]	9
Molecular biological	Deletion of an allele (knock out), for example, *Gcm2*[c]; introduction of point mutation (knock in), for example, *Pthr1*[d]; transgenic that overexpresses a gene, for example, *Fgf23*[e]	10–13

[a] *Phex*—Phosphate-regulating gene with homology to endopeptidases on the X chromosome.
[b] N-ethyl-N-nitrosourea (ENU) is another alkylating agent that can be used.

TABLE 7.2 Some Methods, With Their Advantages and Disadvantages, That Are Used for Generating Mouse Models

Strategies	Methods	Types of mutations	Advantages	Disadvantages
Nontargeted (random)	Spontaneous	Point mutations, small deletions, chromosomal rearrangements	Visible phenotype, no manipulation of genome	Very-low frequency
	Radiation	Deletions, inversions, translocations, complex rearrangements	Easier mapping due to large rearrangements	Multiple genes may be affected
	Chemical (e.g., ENU)	Primarily point mutations, some small deletions; hypo- and hypermorphs	Most potent mutagen in mice; can be used for high throughput	More complex mapping, may be multiple mutations
	Molecular biological—gene trap	Knock out	Easy to map disrupted gene; can include reporter gene	Unpredictable phenotypes
Targeted[a]	"Targeted trapping"	Knock out	High-targeting frequency	Gene must be expressed in ES cells
	Knock out	Loss of function		
	Conventional	Disruption of endogenous gene	Can include reporter gene	Gene lost in every tissue; homozygotes often embryonic lethal
	Tissue specific (conditional)	Disruption of gene in tissue(s) of interest	Can mimic somatic loss of function; can overcome embryonic lethality of knock out	Requires breeding with second mouse line; some promoters have "leaky" expression in other tissues
	Inducible	Disruption of gene at time of choice	Can mimic somatic loss of function; can overcome embryonic lethality of knock out	Less than 100% knock out
	Knock in	Mutation of choice including toxic gain of function	Introduction of specific mutation	Labor intensive; expensive
	Transgenic	Activating or dominant mutations; can also inject shRNA for RNAi	Introduction of specific mutation or shRNA of interest	Random insertion into genome; transgenes often overexpressed
	Genome editing	Loss of function or mutation of choice including toxic gain of function	More efficient than conventional knock out and can introduce specific mutation	Potential for off-target effects

[a] *All the targeted methods use molecular biological mutagenesis (Table 7.1). Table compiled from Refs. 3,14–21.*

TABLE 7.3 Some In Vivo Mouse Models for Inherited Hypoparathyroid Disorders Associated With Hypocalcemia

Diseases (OMIM)	Gene defects	Proteins	Mouse models	Heterozygous mouse phenotypes	Homozygous mouse phenotypes	References
DiGeorge syndrome type 1 (188400)	*TBX1* loss of function	T-box 1	Conventional *Tbx1* knock out	Cardiac outflow tract abnormalities	Thymic, parathyroid hypoplasia; abnormal facial structures and cleft palate; cardiac OFT abnormalities; absent hyoid bone; delayed cranial bone ossification, clavicular hypoplasia	22–25
			Pharyngeal endoderm specific *Tbx1* knock out	No phenotype	Neonatal death; absent middle and outer ear; craniofacial abnormalities; absent thymus and parathyroid; thyroid hypoplasia; cardiac OFT abnormalities	26,27
			Otic vesicle specific *Tbx1* knock out	ND	Abnormal inner ear development (complete absence in 75%)	27
			Mesoderm specific *Tbx1* knock out	ND	Malformation of inner ear; proximal mandible defects; thyroid hypoplasia; cardiovascular defects; delayed cranial bone ossification	25,28–31
			Osteoprogenitor specific *Tbx1* knock out	ND	Perinatal death; failure of hyoid bone ossification; small parietal bones; hypoplastic clavicle	25
			Neural crest specific *Tbx1* knock out	ND	Perinatal death; failure of hyoid bone ossification	25
FIH (146200)	*PTH* loss of function	Parathyroid hormone	Conventional *Pth* knock out	Normal serum biochemistry	Hypocalcemia, hyperphosphatemia, enlarged parathyroids; bone abnormalities	32,33
FIH (146200)	*GCMB* loss of function	Glial cells missing homologue B	Conventional *Gcm2* knock out	No phenotype	Hypocalcemia, hypophosphatemia; absent parathyroids; high bone mass	10

ND, Not determined; OFT, outflow tract.

TABLE 7.4 Some In Vivo Mouse Models for Inherited Disorders of PTH Signaling

Diseases (OMIM)	Gene defects	Proteins	Mouse models	Phenotypes	References
Blomstrand's chondro-dysplasia (215045)	*PTHR1* loss of function	PTH receptor 1	Conventional knock out (*Pthr1*$^{-/-}$)	Embryonic lethal; skeletal abnormalities; excessive mineralization; delayed chondrocyte differentiation	34–36
			Chondrocyte-specific *Pthr1* knock out	Accelerated chondrocyte differentiation	37
			Inducible chondrocyte-specific *Pthr1* knock out	Shortening of long bones, chondrocyte apoptosis	38
			Inducible osteocyte-specific *Pthr1* knock out	Mild osteopenia; reduced trabecular bone; reduced BMD	39
			Constitutive osteocyte-specific *Pthr1* knock out	Normal serum calcium, phosphate and PTH; increased BMD; blunted anabolic and catabolic responses to intermittent and chronic PTH administration	40

(*Continued*)

TABLE 7.4 Some In Vivo Mouse Models for Inherited Disorders of PTH Signaling (*cont.*)

Diseases (OMIM)	Gene defects	Proteins	Mouse models	Phenotypes	References
Jansen's disease (156400)	*PTHR1* gain of function	PTH receptor 1	Transgenic chondrocyte-specific mutant His223Arg PTHR1	Reduced mineralization; shortened limbs, delayed chondrocyte differentiation	41
			Transgenic osteoblast-specific mutant His223Arg PTHR1	Increased osteoblasts, osteoclasts, increased trabecular bone volume, decreased cortical bone	42
			Transgenic osteocyte-specific mutant His223Arg PTHR1	Increased bone mass; increased bone remodeling; increased osteoblasts and osteoclasts	43
			Phosphorylation deficient PTHR1 knock in	Normocalcemia with low plasma PTH; reduced BMC in females and bone volume on low-calcium diet; normal increases in BMD after intermittent PTH	11,12,44
PHPIa (103580) and PPHP (612463)	*GNAS1* loss of function	$G_s\alpha$	Conventional knock out (*Gnas*$^{-/-}$)	Maternally inherited null allele: PTH resistance; all mice: subcutaneous ossifications	45–47
			Chondrocyte-specific *Gnas* knock out	Short limbs; domed skulls; epiphyseal and growth plate defects; ectopic cartilage	48
			Osteoblast/osteocyte-specific *Gnas* knock out	Shortened long bones, reduced trabecular bone; increased cortical bone; craniofacial abnormalities	49
			ENU-induced *Gnas* Val159Glu mutation	Maternal inheritance: hypocalcemia, hyperphosphatemia, elevated PTH; osseous heteroplasia	50,51
PHPIb (603233)	Loss of *GNAS1* imprinting		Conventional knock out of *Stx16* exons 4–6	No phenotypic abnormalities	52
			Conventional knock out of *Nesp55* DMR	Maternal inheritance: hypocalcemia, hyperphosphatemia, secondary hyperparathyroidism	53

BMC, Bone mineral content; BMD, bone mineral density; DMR, differentially methylated region; NESP55, neuroendocrine protein 55; PHPIa, pseudohypoparathyroidism type Ia; PHPIb, pseudohypoparathyroidism type Ib; PPHP, pseudopseudohypoparathyroidism; PTH; parathyroid hormone; STX16: syntaxin-16.

developed (Tables 7.1 and 7.2). An early example of non-targeted mutagenesis is provided by *irradiation*, which generated the *Gy* mouse, a second model for X-linked hypophosphatemia.[59] More recently, *chemical mutagens* have been used in large-scale mutagenesis programs. Successful agents include isopropyl methane sulfonate (iPMS) used to generate the *Nuf* mouse model with an activating calcium-sensing receptor (CaSR) mutation, and *N*-ethyl-*N*-nitrosourea (ENU) used to generate a mouse model for osteogenesis imperfecta with a collagen 1 alpha 1 (COL1A1) mutation. ENU, which is an alkylating agent that primarily introduces point mutations via transfer of the ENU alkyl group to the DNA base followed by mispairing and subsequent basepair substitution during the next round of DNA replication (Fig. 7.1A), is the most potent mutagen in mice.[14] Intraperitoneal injections of ENU to male mice generate approximately one mutation per 1–1.5 Mbp of sperm DNA,[14] which allows the mutations to be inherited (Fig. 7.1B). ENU mutagenesis programs utilize two complementary approaches, which are *phenotype-driven* and *genotype-driven* screens. In phenotype-driven screens, the offspring of mutagenized mice are assessed for phenotypic variances, using a panel of morphological, biochemical, or behavioral tests, in a "hypothesis-generating" strategy, which aims to elucidate new genes, pathways, and mechanisms for a disease phenotype[14] (Fig. 7.1B). By establishing appropriate matings, phenotype-driven screens can be used to identify dominant or recessive phenotypes. Genotype-driven screens, in which mutations in a gene of interest are sought, are "hypothesis driven" and are feasible by using available parallel archives of DNA and

TABLE 7.5 Mouse Models for Hypercalcemic and Hypocalcemic Disorders Due to CaSR Mutations

Model types	Heterozygous phenotypes	Homozygous phenotypes	References
Loss-of-function			
• Conventional knock out (*Casr*$^{-/-}$)	Hypercalcemia, hypocalciuria, elevated serum PTH	Severe hypercalcemia, high serum PTH, parathyroid hyperplasia, bone abnormalities, neonatal death	54–56
• Parathyroid-specific knock out (PT-KO)	Hypercalciuria, hypercalcemia, mild hyperparathyroidism	Severe hyperparathyroidism, hypercalcemia, hypercalciuria, skeletal undermineralization, neonatal death	57
• Osteoblast-specific knock out (COL-KO)	No phenotype	Undermineralization of bone, multiple fractures	57
• Inducible chondrocyte-specific knock out (Tam-Cart-KO)	ND	Short bones	57
Gain-of-function			
• iPMS mutant (*Nuf*), Leu723Gln	Hypocalcemia, hyperphosphatemia, low plasma PTH, some renal ectopic calcification	Hypocalcemia, hyperphosphatemia, low plasma PTH, widespread ectopic calcification	9
• Knock-in models: Cys129Ser, Ala843Glu	Hypocalcemia, hyperphosphatemia, low plasma PTH, low plasma 1,25$(OH)_2D_3$, hypercalciuria, renal calcification	ND	58

iPMS, Isopropyl methane sulfonate; ND, not determined; PTH, parathyroid hormone.

TABLE 7.6 Some In Vivo Mouse Models for Inherited Bone Disorders With Abnormalities of Phosphate, Vitamin D, and FGF23

Diseases (OMIM)	Gene defects	Proteins	Mouse models	Phenotypes	References
HHRH (241530)	*NPT2C* loss of function	Sodium-dependent phosphate transporter 2c	Conventional *Npt2c* knock out	Hypercalcemia, hypercalciuria, high 1,25$(OH)_2D$, no phosphate or bone phenotype	[a]
			Inducible renal epithelia-specific *Npt2c* knock out	Normal serum calcium, phosphate, PTH, FGF23, and 1,25$(OH)_2D$; normal urinary calcium excretion	[b]
			Conventional *Npt2a* knock out	Hypophosphatemia, hypercalcemia, hypercalciuria, no rickets	[c]
			Double *Npt2c*/*Npt2a* knock out	Severe hypophosphatemia, hypercalcemia, high 1,25$(OH)_2D$, rickets	[d]
VDDR1A (264700)	*CYP27B1* loss of function	25(OH)D 1-α-hydroxylase	Conventional *Cyp271b* knock out	Hypophosphatemia, hypocalcemia, secondary hyperparathyroidism, rickets, defective cartilage mineralization	[e,f]
			Chondrocyte-specific *Cyp27b1* knock out	Widened growth plate hypertrophic zones, reduced osteoclastogenesis, increased bone volume	[g]
VDDR2A (277440)	*VDR* loss of function	Vitamin D receptor	Conventional *Vdr* knock out	Hypophosphatemia, hypocalcemia, secondary hyperparathyroidism, rickets, defective growth plates	[h,i]
			Intestine-specific *Vdr* knock out	Normocalcemia, normo-phosphatemia, elevated serum PTH and 1,25$(OH)_2D$, normal bone growth but reduced postweaning bone mass accrual, spontaneous fractures	[j]
			Osteoblast-specific *Vdr* knock out	Normal serum calcium, phosphate, PTH, 1,25$(OH)_2D$, FGF23; increased BMD and trabecular bone volume; decreased bone resorption	[k]

TABLE 7.7 Some Compound Mouse Mutants With Disruption of Phosphate, Vitamin D and FGF23 Signaling

Mouse models	Phenotypes	References
Hyp/Dmp1$^{-/-}$	Phenotypes of growth retardation, increased serum FGF23, increased serum PTH, hypophosphatemia, and reduced BMD no more severe than single mutants	[a]
Hyp/Galnt3$^{-/-}$	Phenotypes of growth retardation, hypophosphatemia less severe than in *Phex* mice	[b]
Fgf23$^{-/-}$*/hyp*	Dominance of *Fgf23*$^{-/-}$ phenotype over hyp phenotype: hyperphosphatemia, skeletal deformities similar to *Fgf23*$^{-/-}$ mice	[c,d]
Fgf23$^{-/-}$*/Dmp1*$^{-/-}$	Dominance of Fgf23 null phenotype over Dmp1 null phenotype: hyperphosphatemia, elevated 1,25$(OH)_2$D levels, growth plate abnormalities, no rickets	[e]
Fgf23$^{-/-}$*/Npt2a*$^{-/-}$	Hypophosphatemia, high 1,25$(OH)_2$D, skeletal phenotype similar to *Fgf23*$^{-/-}$ mice	[f]
Fgf23$^{-/-}$*/Cyp27b1*$^{-/-}$	Hypophosphatemia, secondary hyperparathyroidism, decreased BMC and BMD, reversal of soft tissue mineralization in *Fgf23*$^{-/-}$ mice, rickets	[g]
Fgf23$^{-/-}$*/Vdr*$^{-/-}$	Normophosphatemia, bone phenotype identical to that in *Vdr*$^{-/-}$ mice, no soft tissue mineralization	[h]
Fgf23$^{-/-}$*/Kl*$^{-/-}$	Similar to *Kl*$^{-/-}$ alone: hyperphosphatemia, elevated 1,25$(OH)_2$D (similar levels to *Fgf23*$^{-/-}$ and *Kl*$^{-/-}$ mice), soft tissue and vascular calcification	[i]
Fgf23$^{-/-}$*/Pth*$^{-/-}$	Further increase in serum phosphate compared to *Fgf23*$^{-/-}$ alone and *Pth*$^{-/-}$ alone; normocalcemia; lower 1,25$(OH)_2$D than *Fgf23*$^{-/-}$ alone; partially rescued bone phenotypes compared to *Fgf23*$^{-/-}$ alone	[j]
Kl$^{-/-}$*/Fgf23*^{R176Q}	Dominance of *Kl*$^{-/-}$ phenotype over FGF23 gain of function: hyperphosphatemia, elevated 1,25$(OH)_2$D, increased skeletal mineralization, soft tissue mineralization	[k]
Kl$^{-/-}$*/hyp*	Hyperphosphatemia, elevated 1,25$(OH)_2$D (similar level to *Kl*$^{-/-}$ mice), dense bone mineralization, soft tissue and vascular calcification	[l,m]
Kl$^{-/-}$*/Dmp1*$^{-/-}$	Growth retardation and survival improved compared to *Kl*$^{-/-}$ alone; osteomalacia and rickets improved, and bone remodeling defect corrected compared to *Dmp1*$^{-/-}$ alone; similar serum biochemistry to *Kl*$^{-/-}$ alone, except for FGF23 level between *Dmp1*$^{-/-}$ and *Kl*$^{-/-}$ alone	[n]
Kl$^{-/-}$*/Npt2a*$^{-/-}$	Mild hypophosphatemia, elevated 1,25$(OH)_2$D, reduction of soft tissue calcification usually found in *Kl*$^{-/-}$ mice	[o]
Kl$^{-/-}$*/Cyp27b1*$^{-/-}$	Dominance of *Cyp27b1*$^{-/-}$ phenotype over *Kl*$^{-/-}$ phenotype: hypophosphatemia, secondary hyperparathyroidism, absence of ectopic calcification	[p]
Kl$^{-/-}$*/Pth*$^{-/-}$	Normocalcemia; further elevation in serum phosphate compared to *Kl*$^{-/-}$ and *Pth*$^{-/-}$ alone; soft tissue calcification similar to *Kl*$^{-/-}$ alone; slightly reduced serum 1,25$(OH)_2$D and FGF23 levels compared to *Kl*$^{-/-}$ alone; bone phenotypes of *Kl*$^{-/-}$ mice rescued	[q]
Kl$^{-/-}$*/Vdr*$^{-/-}$	Normocalcemia, normophosphatemia; bone phenotypes of *Kl*$^{-/-}$ mice rescued	[r]
Hyp/Fgfr1$^{Dmp\text{-}cKO}$	Growth retardation, rickets and increased serum FGF23 less severe than in *Hyp*; hypophosphatemia, elevated PTH, and elevated 1,25$(OH)_2$D in *Hyp* restored to normal	[s]
Hyp/Fgfr3$^{-/-}$	Growth retardation; kyphosis; elevated FGF23 (twice that in *Hyp* mice); hypophosphatemia; normal 1,25$(OH)_2$D; bowing of long bones; rickets; osteomalacia; bone mineralization defect, that is, no rescue of *Hyp* phenotype	[t]
Hyp/Fgfr4$^{-/-}$	Growth retardation; kyphosis; elevated FGF23 (twice that in *Hyp* mice); hypophosphatemia; normal 1,25$(OH)_2$D; bowing of long bones; rickets; osteomalacia; bone mineralization defect, that is, no rescue of *Hyp* phenotype	[t]
Fgfr1^{MM}*/Fgfr4*$^{-/-}$	Hyperphosphatemia, elevated serum FGF23 and 1,25$(OH)_2$D, decreased serum PTH, incomplete suppression of serum FGF23 levels on low-phosphate diet	[u]
Fgfr3$^{-/-}$*/Fgfr4*$^{-/-}$	Small size; early death; elevated 1,25$(OH)_2$D; elevated FGF23; no reduction in 1,25$(OH)_2$D after administration of FGF23, but decreased serum PTH and increased serum phosphorous	[v,w]

TABLE 7.7 Some Compound Mouse Mutants With Disruption of Phosphate, Vitamin D and FGF23 Signaling (*cont.*)

Mouse models	Phenotypes	References
Hyp/*Fgfr3*$^{-/-}$/*Fgfr4*$^{-/-}$	Small size; kyphosis; partial correction of *Hyp* rickets and low serum phosphate. Overcorrection of *Hyp* phenotype with respect to 1,25(OH)$_2$D. Further increase in *Hyp* elevated serum FGF23	[x]

BMD, Bone mineral density; Dmp1, dentin matrix protein 1; FGFR, FGF receptor; *Fgfr1*^{MM}, metanephric mesenchyme-specific *Fgfr1* knock out; *Fgfr1*$^{Dmp1\text{-}cKO}$, osteocyte-specific *Fgfr1* knock out; Fgf23, fibroblast growth factor 23; Kl, klotho; Npt2a, sodium-dependent phosphate transporter 2a; PTH, parathyroid hormone; Vdr, vitamin D receptor; 1,25(OH)$_2$D, 1,25-dihydroxyvitamin D.

TABLE 7.8 Some In Vivo Mouse Models for Inherited Bone Disorders With Abnormalities of FGF Receptors 1-3 (FGFR1-3)

Genes	Mouse models	Phenotypes	References
Fgfr1	Osteochondro-specific *Fgfr1* knock out	Delayed osteoblast differentiation, increased bone mass	[c]
	Osteoblast-specific *Fgfr1* knock out	Accelerated osteoblast differentiation, increased bone mass	[c]
	Osteocyte-specific *Fgfr1* knock out	No bone phenotype, increased serum FGF23, normal serum calcium, phosphorus, PTH or 1,25(OH)$_2$D	[d]
	Bone-marrow monocyte/osteoclast-specific *Fgfr1* knock out	Increased BMD, increased trabecular bone thickness, defective osteoclast differentiation	[e]
	Fgfr1 Pro250Arg knock in (Pfeiffer syndrome mutation)	Postnatal craniofacial malformations due to premature fusion and mineralization of sutures; enhanced osteoblast proliferation and differentiation	[f]
	Various hypomorphic *Fgfr1* models	Loss of anterior digits; delayed ossification in distal phalanges; syndactyly; vertebral malformations	[g]

(*Continued*)

TABLE 7.8 Some In Vivo Mouse Models for Inherited Bone Disorders With Abnormalities of FGF Receptors 1-3 (FGFR1-3) (*cont.*)

Genes	Mouse models	Phenotypes	References
	Metanephric mesenchyme-specific *Fgfr1* knock out	Elevated serum FGF23; decrease in serum $1,25(OH)_2$ but not in serum phosphate after FGF23 administration	h
Fgfr2	Conventional *Fgfr2* splice variant IIIc knock out	Short and dome-shaped skull; abnormal suture fusion; delayed ossification of skeleton	i
	Osteoblast/chondrocyte-specific *Fgfr2* knock out	Growth retardation; dwarfism; dome-shaped skull; vertebral abnormalities; reduced BMD	j
	ENU-induced *Fgfr2* Trp290Arg mutation (Crouzon syndrome mutation)	Heterozygotes: short snout; dome-shaped skull; premature fusion of coronal sutures; defective endochondral ossification. Homozygotes: perinatal death; delayed ossification of coronal sutures; absent limbs; defective endochondral ossification	k
	Fgfr2 Ser252Trp knock in (Apert syndrome mutation)	Neonatal death; shortened and dome-shaped skull; premature fusion of coronal suture; ectopic cartilage at sutures; disorganized growth plates; reduced BMD and trabecular number; short long bones and vertebrae	l,m,nl–n
	Inducible mesoderm-specific *Fgfr2* Ser252Trp knock in	Premature fusion of coronal sutures; ectopic cartilage at sutures; normal parietal bone development; facial shortening	o
	Fgfr2 Pro253Arg knock in (Apert syndrome mutation)	Shortened and dome-shaped skull; premature fusion of coronal suture; shortened limbs	p
	Fgfr2 Cys342Tyr knock in (Crouzon/Pfeiffer syndrome mutation)	Heterozygotes: shortened and dome-shaped skull; premature fusion of coronal sutures. Homozygotes: shortened and dome-shaped skull; cleft palate; excessive bone formation	q
	Loss of *Fgfr2* exon 9 (activating mutation)	Shortened and dome-shaped skull; accelerated ossification and fusion of sutures	r
Fgfr3	Conventional *Fgfr3* knock out	Postnatal death in ~50%; kyphosis; scoliosis; curvature, overgrowth and increased thickness of femur and humerus; osteopenia; arthritis	s–w
	Fgfr3 Pro244Arg knock in (equivalent to Muenke syndrome mutation Pro250Arg)	Heterozygotes: small rounded skull in minority of males; reduced BMD; reduced cortical bone thickness. Homozygotes: small rounded skull in all males and minority of females; twisted snout in some; reduced BMD; reduced cortical bone thickness	x
	Fgfr3 Gly369Cys knock in (equivalent to ACH mutation Gly375Cys)	Heterozygotes: postnatal dwarfism; dome-shaped skull; reduced trabecular bone; reduced BMD; defects in bone matrix mineralization. Homozygotes: similar to heterozygotes but more severe	y,z
	Fgfr3 Gly374Arg knock in (equivalent to ACH mutation Gly380Arg)	Heterozygotes: small size; rounded and distorted skull; kyphosis; dwarfism; disorganized growth plates; premature synchondrosis closure	aa,bb
	Fgfr3 Ser365Cys knock in (equivalent to TD-I mutation Ser371Cys)	Heterozygotes: small dome-shaped skull; severe dwarfism; shortened long bones; disorganized growth plates; high-postnatal death	cc
	Fgfr3 Tyr367Cys knock in (equivalent to TD-I mutation Tyr373Cys)	Heterozygotes: narrow trunk; bowed and shortened long bones; macrocephaly; dwarfism; delayed ossification; defective chondrocyte proliferation and differentiation; reduced cortical thickness, trabecular thickness and trabecular number	dd–ff
	Chondrocyte-specific *Fgfr3* Tyr367Cys knock in	Dwarfism, short limbs; moderately dome-shaped skull; delayed secondary ossification; disorganized growth plates; reduced cortical thickness, trabecular thickness and trabecular number	ff
	Osteoblast-specific *Fgfr1* Tyr367Cys knock in	No dwarfism; normal limb length, skull shape, ossification, growth plates, cortical thickness, trabecular thickness and trabecular number	ff
	Fgfr3 Lys644Glu knock in[a] (equivalent to TD-II mutation Lys650Glu)	Heterozygotes: small size; short tail. Homozygotes: postnatal dwarfism; shortened long bones; shortened tail vertebrae; macrocephaly	gg

TABLE 7.8 Some In Vivo Mouse Models for Inherited Bone Disorders With Abnormalities of FGF Receptors 1-3 (FGFR1-3) (*cont.*)

Genes	Mouse models	Phenotypes	References
	Fgfr3 Lys644Glu knock in[b] (equivalent to TD-II mutation Lys650Glu)	Heterozygotes: neonatal death; decreased ossification; rounded skull; shortened, widened and bowed long bones with disorganized growth plates	[hh]
	Fgfr3 Lys644Met knock in (equivalent to SADDAN mutation Lys650Met)	Heterozygotes: death within 4 weeks in ~50%; shortened long bones; delayed secondary ossification. Homozygotes: embryonic lethal	[ii]
	Transgenic mutant Gly380Arg FGFR3	Short snout; dwarfism; shortened and bowed long bones; defective chondrocyte proliferation	[jj]

TABLE 7.9 Some In Vivo Mouse Models for Inherited Osteochondrodysplasias Due to Loss of Function of Collagens

Diseases	Gene defects	Mouse models	Phenotypes	References
Osteogenesis imperfecta	Collagen type I, alpha 1 (COL1A1)	ENU-induced *Col1a1* mutation	Heterozygotes: high-postnatal lethality; severe bone deformitites; long bone and pelvic fractures; low BMD and BMC. Homozygotes: embryonic lethal	[a]
		Viral insertion causing *Col1a1* knock out	Heterozygotes: brittle bones; abnormal cortical bone. Homozygotes: embryonic lethal	[b,c]
		Col1a1 Gly349Cys knock in	Heterozygotes: perinatal lethality in ~50%; small size; bowed and thin limbs; undermineralization of skeleton	[d]
		Transgenic expressing *Col1a1* with large deletion	Perinatal death in some; extensive fractures of long bones and ribs; undermineralization of skull; short femurs	[e,f]
	Collagen type I, alpha 2 (COL1A2)	Spontaneous *Col1a2* single nucleotide deletion	Heterozygotes: decreased bone strength; Homozygotes: small size; multiple fractures; long bone deformities; osteopenia; reduced cortical bone; decreased BMC, BMD	[g–i]
Type II collagenopathies	Collagen type II, alpha I (COL2A1)	Radiation-induced *Col2a1* insertion–deletion	Heterozygotes: mild postnatal dwarfism; reduced ECM; osteoarthritis. Homozygotes: cleft palate; short skull; severe dwarfism; shortened long bones; disorganized growth plates; reduced ECM	[j–l]
		Spontaneous *Col2a1* missense mutation Arg1417Cys	Homozygotes: shortened trunk and long bones; short skull; disorganized growth plates; decreased bone volume and trabecular thickness	[m]
		ENU-induced *Col2a1* missense mutation Asp1469Ala	Heterozygotes: mild dwarfism; short limbs. Homozygotes: perinatal death; severe dwarfism; short limbs; pelvic hypoplasia; reduced ECM	[n]
		ENU-induced *Col2a1* missense mutation Ser1386Pro	Heterozygotes: short fore and hind limbs; decreased BMD; disorganized growth plates; delayed endochondral ossification. Homozygotes: perinatal lethality, cleft palate; short and wide long bones	[o]
		ENU-induced *Col2a1* splicing defect	Homozygotes at embryonic day 18.5: microcephaly; short mandible; short and wide long bones	[p]
		Conventional *Col2a1* knock out	Heterozygotes: minor skeletal changes. Homozygotes: perinatal lethality; no palate; small size; shortened and thickened long bones; disorganized growth plates	[q]
		Col2a1 Arg519Cys knock in	Mild dysplasia of long bones; mild osteoarthritis; short bones	[r]
		Col2a1 Gly1170Ser knock in	Heterozygotes: normal size and long bone lengths. Homozygotes: perinatal lethality; severely dwarfed; short trunk and limbs; truncated facial bones; cleft palate; delayed endochondral ossification; disorganized growth plates	[s]
		Transgenic expressing *COL2A1* with large deletion	High-perinatal death; cleft palate; cranial bulge; short and thick long bones; delayed bone mineralization; osteoarthritis	[t,u]
		Transgenic expressing *Col2a1* with exon 7 deletion	Small size; shortened long bones; reduced cartilaginous ECM; defective ossification; disorganized growth plates; disorganized collagen fibrils; cranial defects	[v,w]
		Inducible transgenic expressing *Col2a1* with Arg1192Cys mutation	Short trunk; short and wide long bones and vertebrae; disorganized growth plates; altered chondrocyte polarity; decreased chondrocyte proliferation	[x]
		Transgenic mutant Arg789Cys *Col2a1*	Neonatal death; severe dwarfism; shortened long bones; short snout; cleft palate; delayed ossification; disorganized cartilage; reduced collagen	[y]
Schmid metaphyseal chondrodysplasia	Collagen type X, alpha 1 (COL10A1)	*Col10a1* Asn617Lys knock in	Homozygotes: small size; shortened long bones; small and distorted pelvis; expanded hypertrophic zones; disrupted chondrocyte differentiation	[z]

TABLE 7.9 Some In Vivo Mouse Models for Inherited Osteochondrodysplasias Due to Loss of Function of Collagens (*cont.*)

Diseases	Gene defects	Mouse models	Phenotypes	References
		Transgenic expressing *Col10a1* with frame-shift mutation	Shortened long bones; *coxa vara*; thickened growth plate hypertrophic zones; disrupted chondrocyte differentiation	[aa]
		Conventional *Col10a1* knock out	Perinatal lethality in ~10%; dwarfism; kyphosis; small growth plates; small trabeculae; reduced BMC	[bb,cc]
Type XI collagen-opathies	Collagen type XI, alpha 1 (COL11A1)	Spontaneous *Col11a1* single nucleotide deletion	Heterozygotes: osteoarthritis after 3 months. Homozygotes: short snout; cleft palate; shortened limbs; disorganized chondrocytes;	[dd,ee]
	Collagen type XI, alpha 2 (COL11A2)	Conventional *Col11a2* knock out	Homozygotes: small size; short snout; facial defects; disorganized growth plates; thin articular cartilage	[ff]

TABLE 7.10 Some In Vivo Mouse Models for Inherited Osteochondrodysplasias Due to Transcription Factors and Bone-Specific Proteins

Diseases	Gene defects	Mouse models	Phenotypes	References
Paget's disease of bone	RANK (*TNFRSF11A*) loss of function	Conventional *Rank* knock out	Severe osteopetrosis; shortened and club shaped long bones; defective bone resorption; lack of osteoclasts	[a,b]
		Spontaneous *Rank* 8bp deletion	Homozygotes: retarded growth; craniofacial defects; increased BMD; progressive kyphosis; enlarged epiphyseal growth plates; lack of osteoclasts	[c]
	Sequestosome 1 (SQSTM1) mutations	*Sqstm1* Pro394Leu knock in	Age-related osteolytic lesions in long bones; increased bone turnover; abnormal osteoclast morphology	[d]
Juvenile Paget's disease	Osteoprotegerin (OPG/*TNFRSF11B*) loss of function	Conventional *Opg* knock out	Homozygotes: postnatal death in some; spontaneous fractures; severe osteoporosis; kyphosis	[e,f]
Hereditary multiple exostoses	Exostosin 1 (EXT1) loss of function	Conventional *Ext1* knock out	Heterozygotes: increased chondrocyte proliferation. Homozygotes: embryonic lethal	[g,h]
		Chimeric chondrocyte-specific *Ext1* knock out	Multiple osteochondromas with 100% penetrance on most endochondral bones; bowing of radius	[i,j]
		Limb bud mesenchyme-specific *Ext1* knock out	Heterozygotes: no phenotype. Homozygotes: perinatal death; short and wide long bones; fused forelimb bones	[k]
		Inducible cartilage-specific *Ext1* knock out	Growth retardation; disorganized growth plates; delayed secondary ossification; increased osteoclast numbers; exostotic outgrowths	[l]
	Exostosin 2 (EXT2) loss of function	Conventional *Ext2* knock out	Heterozygotes: occasional exostoses on ribs. Homozygotes: early embryonic lethality	[m]
Hypophosphatasia	Tissue nonspecific alkaline phosphatase (ALPL) loss of function	Conventional *Alpl* knock out	Homozygotes: early postnatal death; small size; epileptic seizures in ~50%; osteopenia; spontaneous fractures; short growth plates; defective secondary ossification; craniofacial defects; craniosynostosis	[n–r]
		ENU-induced *Alpl* splice site mutation	Age-related accumulation of uncalcified osteoid in subchondral bone; ossification of joint capsules	[s]
Fibrodysplasia ossificans progressiva (FOP)	Activin A receptor, type 1 (ACVR1) gain of function	Inducible muscle-specific *Acvr1* Gln207Asp knock in	Within 20 days of induction: severely decreased mobility; loss of joint flexion; bony calluses fusing with bones; heterotopic ossification	[t]
		Chimeric *Acvr1* Arg206His knock in	Short first metatarsal; extraskeletal bone formation; heterotopic ossification in skeletal muscle and progressive immobility after injury	[u]
Diastrophic dysplasia (DTD)	DTD sulfate transporter (DTDST/SLC26A2) loss of function	*Dtdst* Ala286Val knock in	Homozygotes: reduced postnatal growth; kyphosis; early death in ~50%; shortened long bones; bite overclosure; hip dysplasia	[v]
Multiple epiphyseal dysplasia	Cartilage oligo-meric matrix protein (COMP) dominant negative mutations	*Comp* Thr583Met knock in	Disorganized growth plates; enlarged proliferative zone. After 9 weeks of age: small size; shortened long bones; hip dysplasia. At 16 months of age: articular degeneration.	[w]
		Comp Asp469Del knock in	Homozygotes: progressive short-limb dwarfism and hip dysplasia after 9 weeks of age; disorganized growth plates with hypocellularity and mislocalization of cartilage structural proteins	[x]
Chondro-dysplasia punctate (X-linked dominant)	Delta(8)-delta(7) sterol isomerase emopamil-binding protein (EBP) loss of function	Radiation induced *Ebp* Arg107Gly mutation	Heterozygous females: small size; domed skull; short snout. Hemizygous males: small size; domed skull; short limbs; cleft palate; embryonic death	[y]

TABLE 7.10 Some In Vivo Mouse Models for Inherited Osteochondrodysplasias Due to Transcription Factors and Bone-Specific Proteins (*cont.*)

Diseases	Gene defects	Mouse models	Phenotypes	References
Trichorhino-phalangeal syndrome type 1 (TRPS1)	TRPS1 loss of function	Targeted deletion of *Trps1* zinc finger domain	Heterozygotes: arched palate; kyphoscoliosis; reduced bone volume. Homozygotes: perinatal death; scoliosis; delayed ossification	z
		Conventional *Trps1* knock out	Homozygotes: perinatal death due to respiratory distress; growth retardation; shortened limb long bones; abnormal sternum and rib cage; shortened maxillary and mandibular bones; reduced chondrocyte numbers in growth plates; abnormal temporomandibular joints	aa,bb
Grebe chondrodysplasia	GDF5 loss of function	Five spontaneous *Gdf5* frame-shift deletions	Homozygotes: slightly shortened long bones; severely shortened digits; altered digit patterning	cc–ee
Cleidocranial dysplasia	Runt-related transcription factor 2 (RUNX2) loss of function	Conventional *Runx2* knock out	Heterozygotes: hypoplastic clavicles and nasal bones; reduced ossification Homozygotes: immediate perinatal death; dwarfism; short limbs; very little or no ossification.	ff,gg
		Runx2 Phe377Stop knock in	Heterozygotes: missing clavicles. Homozygotes: late embryonic death; complete loss of endochondral and intramembraneous ossification	hh
		Hypomorphic *Runx2* mutant	Heterozygotes (79%–84% expression): no phenotype. Homozygotes (55%–70% expression): reduced calvarial ossification; cranial defects; hypoplastic clavicles	ii
		Runx2-II isoform-specific knock out	Heterozygotes: osteopenia. Homozygotes: normal intramembraneous ossification; absence of endochondral ossification	jj
		Runx2-I isoform-specific hypomorph	Homozygotes: perinatal death within 24 h; diminished bone formation; absent clavicle and occipital bone; decreased trabecular number and increased trabecular separation.	kk
		Chondrocyte-specific deletion of *Runx2* exon 8	Immediate postnatal death due to respiratory failure; absent vertebrae, pelvic, scapula and metacarpal/metatarsal bones; short ribs and limb bones; craniofacial bones poorly developed or absent	ll
		Chondrocyte-specific deletion of *Runx2* exon 8	Perinatal death; domed skull, short snout, small limbs; reduced ossification; disorganized growth plates.	mm
		Osteoblast-specific deletion of *Runx2* exon 8	Comparable size and weight to wild-type mice; normal skeletal patterning; normal long bone length; normal growth plates; decreased calcification of long bones, digits and vertebrae; impaired cranial development; retarded postnatal growth; decreased bone stiffness; decreased trabecular volume, number and thickness.	nn
Campomelic dysplasia	SRY-box 9 (SOX9) loss of function	Conventional *Sox9* knock out	Heterozygotes: perinatal death; cleft palate; bent long bones and pelvic bones; defective endochondral ossification; hypoplastic scapulae	oo
		Chondrocyte-specific *Sox9* knock out	Late embryonic death; round head; short snout; short trunk and limbs; reduced endochondral ossification	pp

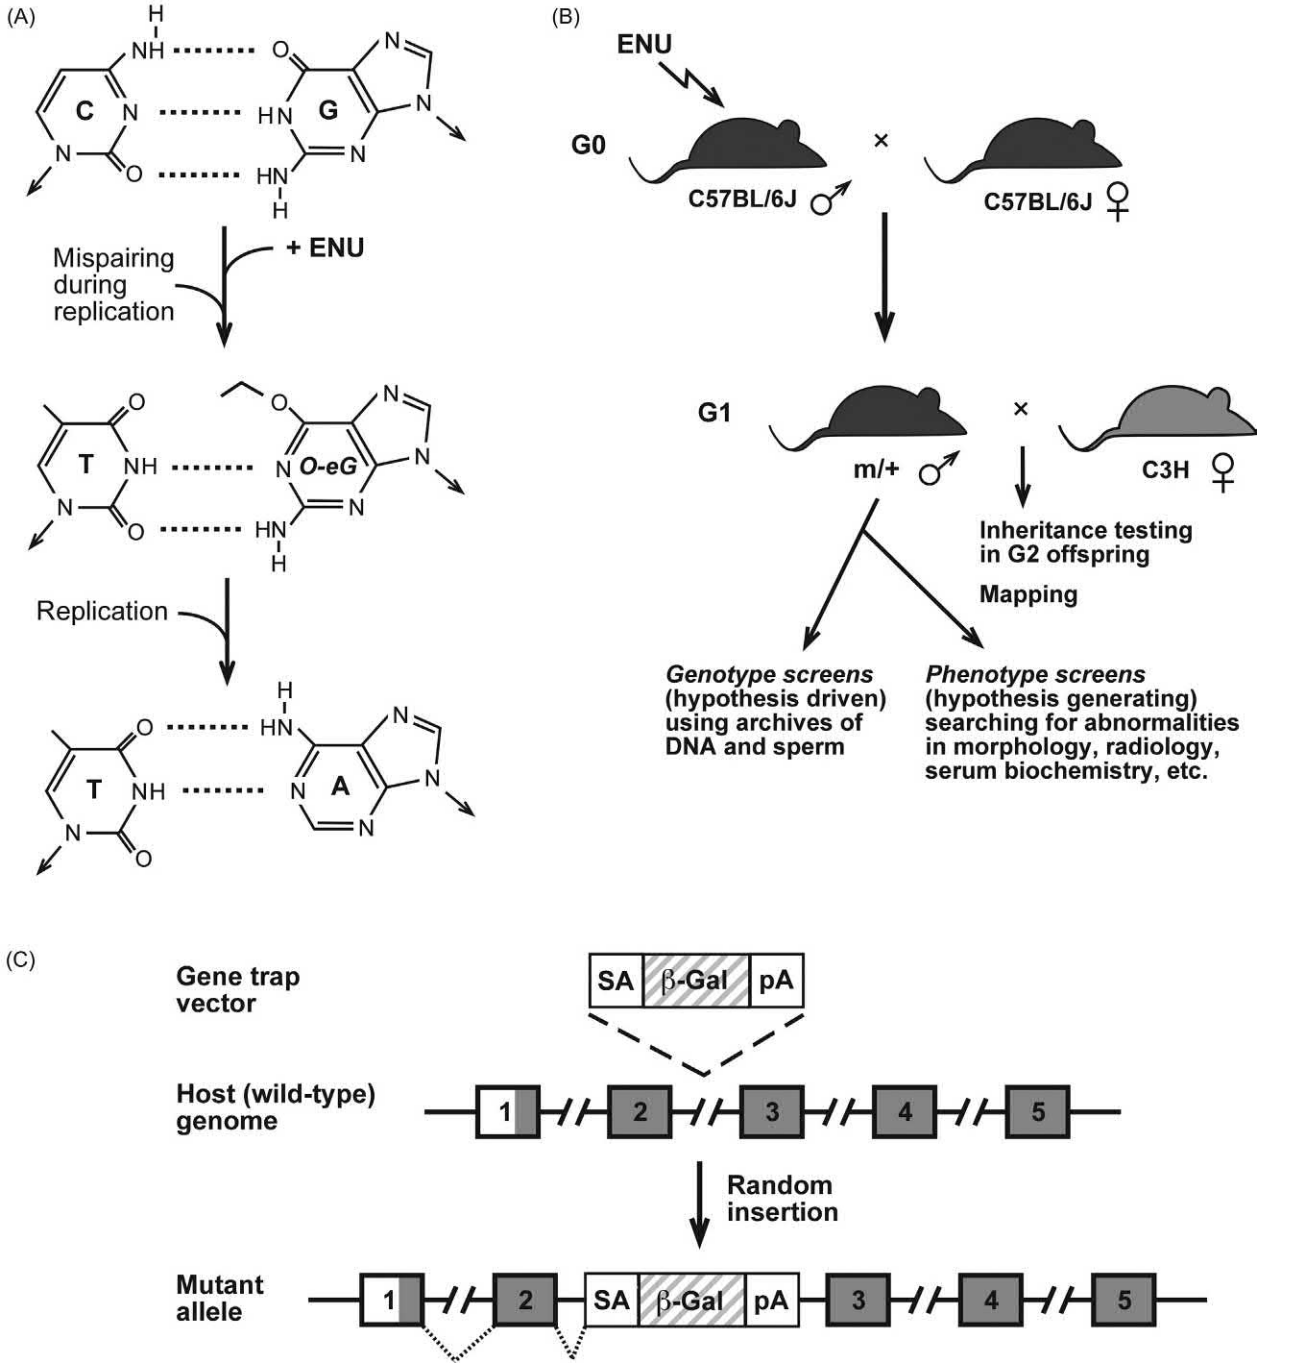

FIGURE 7.1 Methods for nontargeted (random) mutagenesis. (A) Chemical mutagenesis using *N*-ethyl-*N*-nitrosourea (ENU). ENU is an alkylating agent that transfers its ethyl group to one of a number of reactive sites on DNA nucleotides, including the O6 of guanine as shown. Modification of guanine with the ethyl group to produce O^6-ethylGuanine (O-eG), causes mispairing during DNA replication, for example, at spermatogenesis, and during subsequent replication a mutation is introduced. (B) ENU-mutagenized G0 male mice, harboring induced mutations in their sperm DNA, are mated with wild-type females of the same strain to generate G1 mice. G1 males are examined for phenotypic abnormalities (i.e., the phenotype-driven screens). Males with phenotypic abnormalities of interest are then mated with wild-type females to facilitate inheritance testing and genetic mapping in affected offspring (G2) to identify the mutation causing the phenotypic abnormality. DNA and sperm from all the G1 males are also archived to facilitate genotype-driven screens. m, Mutant allele; +, wild-type allele. (C) Insertion mutagenesis using gene trap vectors. Gene trap vectors consist of a strong splice acceptor (*SA*), a reporter gene, such as β-galactosidase (β-gal) and a polyadenine tract (pA). The gene trap randomly inserts into the host genome (dashed lines), and during splicing, the SA is used in preference to the normal genomic splice sites (splicing pattern shown by dotted lines). Filled/striped boxes denote coding sequences and open boxes denote noncoding sequences. *Source: Reproduced from Piret SE, Thakker RV. Mouse models for inherited endocrine and metabolic disorders.* J Endocrinol *2011;***211***:211–30.*[1]

sperm samples from mutagenized male mice (Fig. 7.1B). Archived DNA samples from the mutagenized male mice are used to search for mutations in the gene of interest, and once mutations are identified in the mouse DNA, then the corresponding sperm sample for the male mouse harboring the mutation is used to establish progeny carrying the mutation by in vitro fertilization.[14] It is estimated that the probability of finding three or more mutant alleles in an archive of >5000 DNA samples is >90%.[60] Thus, the gene-driven approach can be used to generate an "allelic series" of mutations within one gene, which may yield insights into genotype–phenotype correlations in the gene and disease of interest.[61]

ENU mutations most frequently result in missense mutations (>80%) that may generate hypo- and hypermorphs, although occasionally nonsense or frame-shift mutations (<10%) generating knock-out models may be obtained.[62] However, a more recent and reliable method for generating nontargeted knock-out models on a large scale is by the use of insertional mutagenesis, utilizing *gene-trap* strategies.[63,64] Gene-trap vectors usually consist of a reporter gene, either with or without a promoter, and a strong splice acceptor (SA) site, which causes any upstream exons to splice directly to the gene trap[15] (Fig. 7.1C). The vector is either electroporated or retrovirally infected into embryonic stem (ES) cells, after which it randomly inserts into the genome. Mutagenized ES cells are then reintroduced into developing blastocysts to generate chimeric mice, from which germline mutant mice can be bred (Fig. 7.2). A recent refinement of the gene-trap strategy is *targeted trapping*, in which the vector also contains regions homologous to the targeted gene, thereby facilitating the deletion of a specific gene.[16,63]

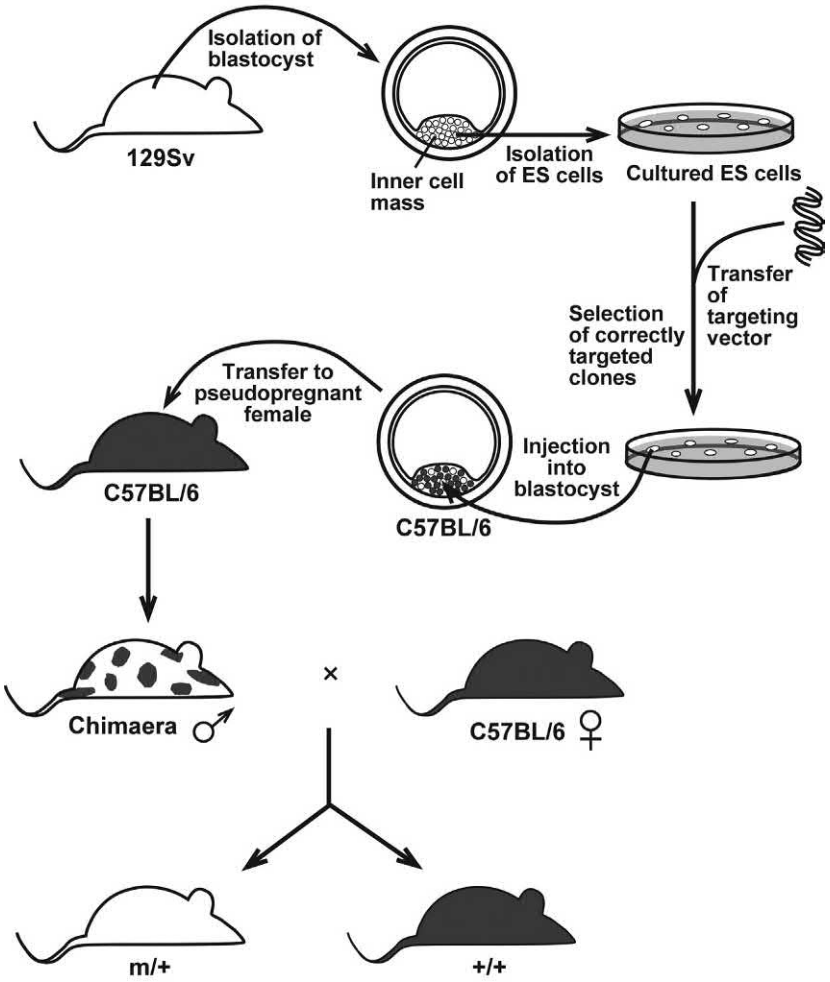

FIGURE 7.2 Gene targeting by modification of embryonic stem (ES) cells. Totipotent ES cells are isolated from the inner cell mass of a blastocyst [e.g., from a 129Sv embryo (shown)] and cultured. The targeting vector is transferred to the ES cells, and those in which homologous recombination or integration has been successful are selected. These are injected into the inner cell mass of a blastocyst from a different mouse strain [e.g., C57BL/6 (shown)], which is transferred to the uterus of a pseudopregnant female. The resulting chimeric offspring (usually males are selected) are bred with wild type, for example, C57BL/6 mice (usually females are selected) to achieve germline transmission. m, Mutant allele; +, wild-type allele. *Source: Reproduced from Piret SE, Thakker RV. Mouse models for inherited endocrine and metabolic disorders.* J Endocrinol *2011*;**211**:*211–30.*[1]

2.2 Targeted Knock-Out Strategies

A specific loss of function (i.e., knock out) of a gene of interest in the germline can be generated to yield *conventional targeted knock-out* models, as follows. A targeting construct is assembled, which contains two "arms" of sequence homologous to the gene of interest and that flank a positive selection cassette, such as the *Escherichia coli* neomycin phosphotransferase (Neo^R) gene (Fig. 7.3A). Integration of the Neo^R gene (and therefore the targeting construct) into the ES cell genome allows these ES cells to survive normally toxic amounts of antibiotic treatment, thereby allowing selection of ES cells that have been successfully targeted by homologous recombination. Furthermore, replacement of an exon (or exons) by the Neo^R cassette results in gene disruption, that is, "knock out"[17] (Fig. 7.3A). To further facilitate the selection of ES cells that have undergone successful targeting by homologous recombination, a negative selection cassette, such as the *Herpes Simplex* virus thymidine kinase (TK) gene, may also be used. The TK gene cassette is inserted at one end of the homologous region of the targeting construct, such that the TK cassette is lost if homologous recombination has occurred (Fig. 7.3A), but retained if nonhomologous recombination has occurred. In the presence of a thymidine analog in the growth medium, ES cells containing the TK cassette (i.e., following nonhomologous recombination) will not undergo cell division, as the thymidine analog will undergo phosphorylation and will be incorporated into the DNA by the TK, and thereby disrupt cell division, hence selecting out these ES cells. In contrast, those ES cells that do not have the TK cassette (i.e., following homologous recombination) will not have disrupted cell division due to incorporation of the thymidine analogue, and as a result will proliferate.[17] Correctly targeted ES cells are used to generate chimeric mice (Fig. 7.2), which are then bred with wild-type mice to yield mice with germline transmission of the disrupted allele, that is, "knock-out" mice, that have one copy of the disrupted allele in all of their cells. Cross-breeding of these heterozygous knock-out mice can then yield homozygous knock-out mice, which will have a disruption of both alleles of the gene in all of their cells. These "conventional" knock-out models have proved to be very useful in studies of human diseases, although their use may be limited if the disruption of the gene in a critical organ results in early death, for example, at any embryonic stage. To overcome such limitations, it may be useful to generate tissue-specific (i.e., *conditional knock out*) or time-specific (i.e., *inducible knock out*) models. This can be achieved by refining the gene-trap and "conventional" knock-out strategies by the addition of either LoxP or flippase (FLP) recombinase target (FRT) sites in the targeting vector (Fig. 7.3B). LoxP and FRT sites are short-DNA sequences, which are recognized and acted upon by the enzymes Cre (*C*auses *re*combination) recombinase or FLP recombinase enzymes, respectively, and when inserted to flank the genomic region of interest, will result in either excision or inversion of the DNA flanked by the LoxP or FRT sequences, depending on whether the two sequences are in the same orientation (Fig. 7.3B), or opposite orientations, respectively. Thus, insertion of the LoxP and FRT sequences allows several variations on the knock-out mouse, including either tissue-specific (conditional) or time-specific (inducible) knock outs (Table 7.2). Thus, if mice containing alleles in which the exon containing the start codon is flanked by LoxP sites (floxed) or FRT sites (flirted) are crossed with transgenic mice expressing Cre or FLP under the control of tissue-specific promoters (e.g., the PTH gene promoter for parathyroid-specific expression), the gene of interest can be knocked out in a specific tissue (Fig. 7.3B). The inducible models utilize a fusion protein, such as a modified ligand-binding domain of the estrogen receptor fused to the Cre (Cre^{ER}) or FLP gene, which on administration of an estrogen receptor antagonist (tamoxifen), translocates to the nucleus to excise the floxed allele(s), thereby allowing the gene to be permanently knocked out at the desired time, which may be either during embryonic or neonatal development, or in adult life.[18] These conditional and inducible knock-out mouse models have proved particularly useful to overcome embryonic or early postnatal lethality, for example, in studies of Blomstrand's chondrodysplasia due to PTHR1 loss of function (Table 7.4), or to understand the role of a protein in one particular tissue.

2.3 Targeted Knock-In Strategies

Knock-out mice have been very valuable for the study of physiological functions of proteins and the elucidation of disease mechanisms. However, knock-out models are not always the most appropriate, particularly when the human disease being studied is not due to a loss-of-function or null allele for the gene. Indeed, the majority of human diseases are unlikely to be due to null alleles, but are instead associated with point mutations, which may result in a constitutively active protein, or a toxic gain of function, as illustrated by PTHR1 mutations in Jansen's disease (Table 7.4), or dominant negative effects. Thus, to generate appropriate murine models for these diseases, the specific mutation needs to be introduced into the mouse genome, and this may be achieved by targeted knock-in or transgenic approaches (Tables 7.1 and 7.2). The generation of *targeted knock-in* models utilizes a similar approach to that described earlier for targeted knock-out models, except that a targeting vector which carries the desired mutation must be specifically generated (Fig. 7.3C). In addition, the positive selection cassette is normally placed in an intron and floxed so that it can be excised and cause minimal effects on gene expression.[19] The generation of *transgenic* models utilizes a targeting construct that usually contains the cDNA carrying the mutation, together with an appropriate promoter and poly(A) sequence, which is injected into the pronucleus

of fertilized mouse eggs.[20,21] The transgene undergoes random insertion into the genome, and several copies are often inserted together, which therefore generates an overexpression model. Newly developed techniques for generating knock-in mouse models utilize genome editing. The general approach relies on the ability to target nucleases to specific DNA sequences. Thus, rather than relying on low-frequency spontaneous double-strand breaks followed by repair, as in the targeted knock-out and knock-in strategies described earlier, DNA strand breaks are induced at specific locations, followed by either nonhomologous repair or homologous repair if a template is also added (Fig. 7.4). To date, two main systems have been successfully used in vivo and these are: transcription activator-like effector nucleases (TALENs) and clustered regularly interspaced short-palindromic repeats (CRISPR)-CRISPR–associated (Cas) proteins.[65,66] TALENs utilizes the DNA-binding domain of a TALE conjugated to an endonuclease, such as Fok1 (Fig. 7.4A). TALEs consist of 7–34 repeats of 33–35 amino acids, with each repeat able to bind to one DNA nucleotide. Amino acids 12 and 13 within each repeat, known as the repeat variable diresidue (RVD), determine which DNA nucleotide the repeat binds to, and since the nucleotide-RVD "code" is known, TALEs can be designed which bind to any nucleotide sequence.[65] Since Fok1 operates as a dimer, a pair of TALEs is required, which recognize adjacent target sites, in order to introduce double strand breaks (Fig. 7.4A). Thus, ES cells can be transfected with a plasmid encoding the designed TALEs conjugated to Fok1, along with a template for homologous repair if desired, and a mutation introduced.[65] By contrast, Cas proteins are themselves endonucleases, and require a separate guide RNA to target them to the DNA sequence of interest (Fig. 7.4B). Furthermore, a single Cas protein introduces double strand breaks, and hence only one Cas protein is needed for each target site. Thus, the CRISPR–Cas system has major advantages over TALENs, as the same Cas protein is used regardless of the target, and the specificity is achieved by small RNA molecules, rather than having to design new TALENs for each target site.[66,67] Modifications of CRISPR–Cas genome editing, such as gene silencing or activation have also recently been developed, making the CRISPR–Cas system a powerful tool for multiple genetic manipulations.[67] These newly developed genome editing techniques have been utilized to generate models for diseases, such as autoimmune disorders and immune deficiencies, but not yet for bone and mineral disorders. As reviewed later, these different strategies for generating mouse models of human diseases have greatly facilitated studies of inherited bone and mineral disorders that have investigated mechanisms and treatments, which would not be easily feasible in patients.

3 GENETIC BONE DISEASES ASSOCIATED WITH DEFECTIVE CALCIUM HOMEOSTASIS

Heritable disorders of calcium homeostasis are most often caused by altered parathyroid gland function or PTH signaling, and/or altered renal calcium handling. These abnormalities of calcium homeostasis may be associated with hypocalcemia (Tables 7.3–7.5) or hypercalcemia (Tables 7.4 and 7.5), as well as skeletal dysplasias and disorders of bone undermineralization (Tables 7.3–7.5). The studies of some mouse models for disorders of parathyroid gland development, PTH signaling and the CaSR are reviewed as they provide examples for the variety of methods that have been utilized for generating different types of models, as well as important advances in our understanding of the genetic and physiological mechanisms of calcium homeostasis.

3.1 Disorders of Parathyroid Development

Defects in parathyroid gland development result in primary hypoparathyroidism, which may occur as an idiopathic endocrinopathy, or as part of a syndrome, such as the DiGeorge syndrome (DGS). Forms of familial isolated hypoparathyroidism (FIH) with autosomal dominant, autosomal recessive, and X-linked recessive

◀ **FIGURE 7.3 Strategies for targeted mutagenesis in ES cells.** Targeting vectors (dotted lines/striped boxes) typically consist of two "arms" of sequence homologous to the target gene flanking a positive selection cassette, such as the neomycin phosphotranserase (Neo^R) gene, and with a negative selection cassette, such as the thymidine kinase (TK) gene at one end of the construct. The Neo^R cassette is usually flanked by two LoxP sites (open triangles) so that it may be removed by expression of Cre recombinase after homologous recombination (dashed lines) with the host (wild-type) genome (solid lines). When homologous recombination occurs, the negative selection cassette is lost. Thick lines denote sequences derived from genomic DNA, with filled/striped boxes representing coding exons and open boxes representing noncoding exons; thin lines denote sequences derived from vectors. (A) Conventional knock out. In a typical conventional knock-out targeting vector, the Neo^R cassette replaces one or more exons, and is then excised by Cre recombinase after homologous recombination. (B) Conditional or inducible knock out. The Neo^R cassette may be flanked by flippase (FLP) recombinase target (FRT) sites (filled triangles) to allow removal by expression of FLP. Part of the coding region of the gene is also flanked by LoxP sites (open triangles). Thus, when homozygote mutant mice are crossed with mice expressing Cre in a tissue-specific manner, or mice expressing an inducible Cre, the gene is knocked-out within the tissue or upon administration of the inducer. (C) Knock in. A specific mutation is introduced into the targeting vector (*asterisk*), usually by site-directed mutagenesis. The Neo^R cassette is placed in an intron close to the mutation and excised after homologous recombination, either by introduction of Cre recombinase into the ES cells, or by breeding mutant mice with mice with ubiquitous Cre expression. *Source: Adapted from Piret SE, Thakker RV. FIGURE 7.4 Gene editing using TALENs and CRISPR–Cas. (A) TALENs require transfection of two expression plasmids encoding two sequence-specific TALEs designed to bind to the DNA region of interest, conjugated to an endonuclease, for example, Fok1. The sequence specific TALEs bind to the sequences of interest, and bring together the two Fok1 monomers, which combine to introduce a double-strand break into the DNA. (B) CRISPR–Cas requires transfection of two plasmids encoding a guide RNA and the Cas endonuclease. The guide RNA binds to the sequence of interest and recruits the Cas protein, which introduces a double strand break into the DNA. (C) If a repair template is not included, the double strand break is repaired by nonhomologous repair, which usually introduces insertions/deletions into the DNA, and predominantly results in knock-out models via frameshifts, deletions, and/or premature stop codons. If a repair template is included, homologous repair can be achieved, which may be used to introduce any mutation of interest and generate a knock-in model.

modes of inheritance have been described. Hypoparathyroidism is associated with hypocalcemia and hyperphosphatemia.

3.2 Models for the DiGeorge Syndrome Type 1 Due to TBX1 Mutations

DGS is an autosomal dominant disorder characterized by the occurrence of hypoparathyroidism, immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth. It arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches, with resulting absence or hypoplasia of the parathyroids and thymus. DGS was reported during the 1980s to be associated with unbalanced translocations and deletions involving chromosome 22q11.2, and this is referred to as DGS type 1 (DGS1). Further studies in 2003 identified mutations of the transcription factor, T-box 1 (TBX1) gene in patients with DGS1.[68,69] Mice that are deleted for *Tbx1* have developmental abnormalities of the pharyngeal arches (Table 7.3). Thus, heterozygous ($Tbx1^{+/-}$) mice have cardiac outflow tract abnormalities, which are defects of the fourth branchial pouch.[22–24] However, only homozygous knock-out ($Tbx1^{-/-}$) mice have all the developmental anomalies of DGS1 due to third and fourth branchial defects which include: thymic and parathyroid hypoplasia, abnormal facial structures and cleft palate, skeletal defects, and cardiac outflow tract abnormalities.[22–24] The basis of the phenotypic differences between DGS1 patients, who are heterozygous, and the $Tbx1^{+/-}$ mice remain to be elucidated. TBX1 dosage, together with downstream genes that are regulated by TBX1, could provide an explanation, but the roles of these putative genes in DGS1 remain to be elucidated. Several tissue-specific murine knock-out models of Tbx1 have also been generated (Table 7.3). Knock out of *Tbx1* in the pharyngeal endoderm led to neonatal death with malformations identical to $Tbx1^{-/-}$ mice, likely due to failure of pharyngeal pouch outgrowth.[26] Selective inactivation of Tbx1 in the otic vesicle led to an absence of the inner ear.[27] Mesoderm-specific knock out of *Tbx1* led to multiple phenotypes that included malformation of the inner ear, defective pharyngeal patterning, cardiovascular defects, defective development of the proximal mandible, thyroid hypoplasia, and delayed ossification of the cranial bones.[25,28–31] An "allelic series" of Tbx1 expression showed tissue-specific dosage effects, demonstrating that cardiac outflow tract development is more susceptible to loss of TBX1 than craniofacial development.[70] Recent studies have shown that TBX1 may have a direct role in bone. Thus, mice with osteoprogenitor-specific knock out of *Tbx1* exhibited reduced ossification of the hyoid bone, significantly smaller parietal bones, and hypoplastic clavicles.[25] This was likely due to impairment of osteoblast differentiation, as the expression of markers of osteoblast differentiation, such as RUNX2 and bone sialoprotein was decreased in bones of $Tbx1^{-/-}$ mice; indeed TBX1 was shown to directly regulate RUNX2 expression.[25] These different mouse models have helped to elucidate the roles of TBX1 in organogenesis and DGS, and some of the transcriptional cascades required for development of these structures.

3.3 Models for Familial Isolated Hypoparathyroidism Due to PTH and GCMB Mutations

Both autosomal dominant and autosomal recessive forms of FIH have been found to be due to mutations in PTH itself and glial cell missing homolog B (GCMB), which is a member of a small family of GCM transcription factors whose expression appears to be restricted to the developing and adult parathyroid glands in mice.[71] FIH-associated PTH and GCMB mutations likely lead to a loss of function, and knock-out mice for Pth and the mouse GCMB homologue Gcm2, develop hypoparathyroidism (Table 7.3). *Pth* heterozygous ($Pth^{+/-}$) mice were viable with no apparent phenotypic abnormalities.[32] However, PTH null ($Pth^{-/-}$) mice had enlarged parathyroid glands with an absence of PTH expression, but with substantial CaSR expression. $Pth^{-/-}$ mice also had abnormal skull formation with enhanced mineralization, shortening of the long bones and other skeletal abnormalities.[33] When maintained on a normal calcium diet, $Pth^{-/-}$ mice developed hypocalcemia and hyperphosphatemia, consistent with hypoparathyroidism, that was associated with an decreased serum $1,25(OH)_2D_3$ concentration.[32] However, when given a low-calcium diet, serum $1,25(OH)_2D_3$ concentrations increased in the $Pth^{-/-}$ mice, and this led to increased bone resorption and stabilization of the low serum calcium at the expense of osteopenia.[32]

Mice lacking a copy of Gcm2 ($Gcm2^{+/-}$) appear normal, viable, and fertile. However, $Gcm2^{-/-}$ mice have no parathyroid glands, resulting in hypocalcemia and hyperphosphatemia, consistent with hypoparathyroidism. $Gcm2^{-/-}$ mice also have a mild bone phenotype, consisting of a low number of osteoclasts and osteoblasts, and increased bone volume. Yet, in contrast to $Pth^{-/-}$ mice, PTH was detected in their serum, and this PTH was produced by a cluster of cells in the thymus.[10] A detailed analysis of $Gcm2^{-/-}$ embryos showed that a presumptive parathyroid domain was initially formed, with transient expression of CaSR, before being lost by embryonic day 12.5 (E12.5) due to apoptotic cell death of the parathyroid precursor cells.[72]

3.4 Disorders of PTH Signaling

Abnormalities of PTH signaling in target tissues may result in disorders that include several types of pseudohypoparathyroidism (PHP), Blomstrand's

chondrodysplasia, and Jansen's disease (see Chapters 35 and 36). Blomstrand's chondrodysplasia and Jansen's disease are due to loss-of-function or gain-of-function mutations in the type 1 PTH receptor (PTHR1), respectively, while PHP is due to loss-of-function mutations in a G-protein ($G_s\alpha$) associated with the downstream signaling pathways of PTHR1.

3.5 Blomstrand's Chondrodysplasia

Blomstrand's chondrodysplasia is an autosomal recessive disorder, characterized by accelerated chondrocyte differentiation, dramatically advanced skeletal maturation, high bone density, short and poorly modeled long bones, and early death.[73] Blomstrand's chondrodysplasia is caused by homozygous loss-of-function mutations in PTHR1, resulting in a loss of PTH signaling. As PTHR1 also responds to PTH-related protein (PTHrP), loss of PTHrP signaling accounts for the additional features of abnormal breast development and tooth impaction in Blomstrand's chondrodysplasia.[74] Most homozygous PTHR1 knock-out (*Pthr1*$^{-/-}$) mice typically died in midgestation due to abrupt cardiomyocyte death, possibly as a result of defective intracellular calcium ion (Ca^{2+}) homeostasis.[34,35] Analysis of E18.5 embryos showed abnormalities throughout the skeleton, including reduced skeletal size, skull and mandible defects, excessive mineralization and lack of unmineralized cartilage, and shortened long bones.[34] Further analysis of embryos showed delayed chondrocyte differentiation at E15.5, and increased numbers of osteoblasts, increased cortical bone, and decreased trabecular bone at E18.5.[36] Generation of chimeric *Pthr1* knock-out mice containing different numbers of *Pthr1*$^{-/-}$ cells, in which the cells lacking *Pthr1* also contained the β-galactosidase gene, allowed the *Pthr1*$^{-/-}$ cells to be identified. This revealed abnormal ectopic differentiation of chondrocytes, and these differentiated *Pthr1*$^{-/-}$ chondrocytes were found to activate the Indian hedgehog (Ihh)/PTHrP signaling loop, which slowed differentiation of wild-type chondrocytes and led to defective mineralization of cartilaginous matrix, thereby demonstrating the importance of cell nonautonomous regulation of coordinated chondrocyte differentiation.[75] In contrast, chondrocyte-specific *Pthr1* knock out and *Pthr1* knock-down mice showed accelerated chondorocyte differentiation, thereby suggesting significant effects of loss of PTHR1 in other tissues on the conventional *Pthr1*$^{-/-}$ phenotype.[37] Postnatal ablation of *Pthr1* in chondrocytes in inducible chondrocyte–specific knock-out mice resulted in shortening of the long bones due to loss of growth plate chondrocytes, cartilage matrix and secondary ossification centers. This was associated with reduced proliferation and increased apoptosis of chondrocytes, thus indicating a requirement for PTHR1 signaling for the survival of chondrocytes.[38] Postnatal ablation of *Pthr1* selectively in osteocytes in adult mice led to mild osteopenia, reductions in trabecular bone and bone mineral density (BMD). Interestingly, during dietary calcium restriction, these osteocyte-specific *Pthr1*$^{-/-}$ mice were not able to compensate by increasing PTH production, and developed hypocalcemia, raising the possibility that osteocytes may play a role in adult extracellular calcium homeostasis.[39] In contrast, a knock-in model expressing mutant PTHR1 which retained the ability to signal via adenylyl cyclase but specifically inhibited phospholipase C (PLC) signaling (i.e., a "partial" knock out), unlike *Pthr1* knock-out mice, had increased proliferation, but delayed differentiation, of chondrocytes, along with defective ossification.[76] This phenotype was similar to overexpression of PTHR1, thereby indicating that PLC signaling in chondrocytes may normally act to suppress PTHR1 signaling.[76]

3.6 Jansen's Disease

Jansen's disease is an autosomal dominant disorder characterized by hypercalcemia, hypophosphatemia, normal or undetectable serum PTH levels, and short-limbed dwarfism.[73] Jansen's disease is due to heterozygous activating mutations in PTHR1, which cause PTHR1 to remain active even in the absence of PTH. One such activating mutation is His223Arg, and transgenic mice expressing human PTHR1 with this 223Arg mutation in growth plates had reduced mineralization due to delayed endochondral bone formation, resulting in short and deformed hindlimbs. Chondrocytes showed increased proliferation, but markedly delayed maturation, that is, the opposite phenotype to chondrocyte-specific knock out of PTHR1.[41] Furthermore, when the mice expressing the Jansen transgene were crossed with *Pthr1*$^{-/-}$ mice, the cranial defects, early mineralization, shortened long bones, and abnormal chondrocyte differentiation of the *Pthr1*$^{-/-}$ mice were rescued.[77] Selective expression of the His223Arg transgene in osteoblasts in vivo caused an increase in both osteoblast and osteoclast numbers, resulting in increased trabecular bone volume and decreased cortical bone thickness;[42] and selective expression of the same transgene in osteocytes resulted in increased bone mass and bone remodeling due to increased numbers of osteoblasts and osteoclasts.[43] Many hormone receptors, including PTHR1, are desensitized by internalization. In vitro work showed that phosphorylation of PTHR1 is required for its internalization, and knock-in mice with mutant PTHR1 in which serine phosphorylation sites were changed to alanine residues, had normal plasma calcium with very-low plasma PTH levels, that is, an activation of PTHR1, thereby demonstrating the importance of desensitization by internalization of the PTHR1 in vivo.[11] When placed on a low-calcium diet, phosphorylation deficient PTHR1 mice also had reduced bone volume and trabecular number compared to wild-type mice.[12]

3.7 Pseudohypoparathyroidism

PHP is characterized by hypocalcemia and hyperphosphatemia; however, in contrast to primary hypoparathyroidism, serum PTH is raised, consistent with normal parathyroid gland function and instead peripheral PTH resistance. PHP occurring in association with Albright hereditary osteodystrophy (AHO), which is characterized by short stature, obesity, round face, subcutaneous and ectopic soft tissue ossification, brachydactyly, and other skeletal abnormalities, is referred to as PHP type Ia (PHPIa) (see Chapter 35). The occurrence of hypocalcemia and hyperphosphatemia, due to PTH resistance, in the absence of AHO is referred to as PHP type Ib (PHPIb), while the sole occurrence of AHO (i.e., without hypocalcemia and hyperphosphatemia) is referred to as pseuopseudohypoparathyroidism (PPHP).[78] PHPIa and PPHP are caused by heterozygous loss-of-function mutations in the *GNAS1* gene, which encodes the alpha subunit of the G-protein Gs ($G_s\alpha$) that is coupled to PTHR1, and activates intracellular signaling in response to PTH or PTHrP stimulation. PHPIb is caused by disruption of imprinting control elements at the *GNAS1* locus, including intragenic deletion of exons of the syntaxin-16 (*STX16*) gene, and deletions of the whole neuroendocrine protein 55 (NESP55) differentially methylated region (DMR).[78]

PHPIa and PPHP may occur within the same family, and studies have shown that PPHP occurs in children of a father with PPHP or PHPIa, whereas children of a mother with PPHP or PHPIa develop PHPIa.[78] This is because of imprinting of the *GNAS1* gene. Thus, PHPIa is only manifested if the mutated allele is inherited from the mother, since *GNAS1* is predominantly expressed from the maternal allele in several endocrine tissues, that is, *GNAS1* is an imprinted gene.[78] Studies of heterozygous mice lacking *Gnas1* have further revealed the basis for PHPIa and PPHP. Heterozygous knock-out mice lacking exon 1 or exon 2 of *Gnas1* have decreased postnatal survival. However, PTH resistance was seen in surviving mice with a maternally inherited null allele (−m/+), but not mice with a paternally inherited null allele (+/−p).[45,46] $G_s\alpha$ expression was reduced in −m/+ mice compared to +/−p mice in some tissues, for example, renal cortex and thyroid, but not in other tissues, for example, renal medulla and heart, demonstrating tissue-specific imprinting of *Gnas1*.[45,46] Exon 1 heterozygous mice developed subcutaneous ossifications, starting with rare lesions at 3 months, and affecting all mice by the age of 12 months.[47] However, fewer and less severe lesions were detected in females than in males, regardless of maternal or paternal inheritance of the null allele, suggesting that ossification is a consequence of haploinsufficiency of $G_s\alpha$ and gender, rather than parental imprinting. These ossifications consisted of mineralized bone, which expressed osteoblast markers, such as osteopontin and osteonectin.[47] Heterozygous mice lacking a copy of the putative imprinting control region (ICR) for *Gnas1* were generated, and when mated with mice carrying an ENU-induced mutation in exon 6 of *Gnas1*, double heterozygotes in which the exon 6 mutant *Gnas1* allele was maternally inherited, had a partially restored response to PTH due to restoration of expression of $G_s\alpha$ from the paternal allele, demonstrating the importance of the ICR for *Gnas1* expression.[50] Chondrocyte-specific $G_s\alpha$ knock-out mice had short limbs, domed skulls, and epiphyseal and growth plate defects. The tibial epiphyses were shortened due to a reduced number of proliferating chondrocytes, which also had accelerated hypertrophic differentiation, similar to the chondrocyte-specific PTHR1 knock-out mice.[48] In addition, tibiae developed ectopic cartilage in the metaphyseal region, which contained mature chondrocytes.[48] In osteoblast/osteocyte-specific $G_s\alpha$ knock-out mice, early bone development (pre-E14.5) was normal; however, these mice had shortening of the long bones, and defects in bone formation, with reduced trabecular bone volume due to defective osteoblast maturation.[49] In contrast, cortical bone was thickened, likely due to reduced osteoclasts resulting in decreased bone resorption. Newborn mice also had craniofacial abnormalities due to premature ossification of cartilage.[49] Ablation of $G_s\alpha$ earlier in the osteoblast lineage substantially reduced bone formation, causing severe osteoporosis and multiple fractures at birth, likely due to premature maturation of osteoblasts to osteocytes, thus depleting osteoblast numbers.[79]

Several unrelated families with PHPIb have a 3 kb deletion which encompasses exons 4–6 of the *STX16* gene.[52] However, mice with deletion of exons 4–6 of *Stx16* had normal serum calcium and PTH concentrations regardless of maternal or paternal inheritance, and no epigenetic abnormalities were detected when compared to wild-type mice.[52] In contrast, targeted deletion of the *Nesp55* DMR resulted in hypocalcemia, hyperphosphatemia, and secondary hyperparathyroidism when inherited on the maternal allele but not when inherited on the paternal allele, thereby generating a model for PHPIb.[53] These *Gnas* mouse models are thus important tools to understand both the mechanisms of normal and ectopic ossification, and the regulation of gene expression by parental imprinting.

3.8 Disorders of the Calcium-Sensing Receptor (CaSR)

The CaSR is a 1078 amino acid G-protein coupled receptor with 7 transmembrane domains and a large 612 amino acid extracellular domain, and is predominantly expressed in the parathyroid glands and kidneys.[80,81] The CaSR is pivotal in extracellular calcium homeostasis

by mediating alterations in the release of PTH from the parathyroid glands in response to changes in extracellular Ca^{2+} concentrations.[80,81] CaSR mutations resulting in loss-of-function are associated with two hypercalcemic disorders, which are familial benign hypercalcemia, also referred to as familial hypocalciuric hypercalcemia (FHH), and neonatal severe hyperparathyroidism (NSHPT)[82]; while gain-of-function CaSR mutations result in two hypocalcemic disorders, which are autosomal dominant hypocalcemia with hypercalciuria (ADHH),[83,84] and a form of the Bartter syndrome.[85,86]

3.9 FHH and NSHPT Due to Loss-of-Function CaSR Mutations

FHH is an autosomal dominant disorder caused by heterozygous loss-of-function CaSR mutations. NSHPT is a life-threatening disorder characterized by severe neonatal hypercalcemia and undermineralization of bones and multiple fractures, which may be caused by homozygous, compound heterozygous, or de novo or paternally transmitted heterozygous loss-of-function CaSR mutations.[80,81] These loss-of-function CaSR mutations consist of nonsense mutations, frameshifting insertions and deletions, and missense mutations that result in an alteration of the CaSR such that the extracellular calcium concentration at which the defective CaSR produces a half-maximal response (EC_{50}) is significantly raised. To provide models for FHH and NSHPT, *Casr* knock-out mice were therefore generated[54] (Table 7.4). *Casr* heterozygous knock-out ($Casr^{+/-}$) mice had modest hypercalcemia with relative hypocalciuria and inappropriately elevated serum PTH, consistent with the features observed in FHH patients[54] (Table 7.4). $Casr^{-/-}$ homozygote knock-out mice had early onset of severe hypercalcemia in association with increased serum PTH concentrations, parathyroid hyperplasia, and bone demineralization. Moreover, $Casr^{-/-}$ mice died between 3 and 30 days after birth.[54–56] These findings in the $Casr^{-/-}$ mice are representative of the features found in patients with NSHPT.[80]

Further insights into the physiological role of the CaSR in extracellular calcium homeostasis have been gained by breeding *Casr* knock-out mice with *Pth*, *Gcm2*, and *Cyp27b1* (vitamin D 1-α-hydroxylase) knock-out mice. Thus, $Casr^{-/-}$ $Pth^{-/-}$ mice did not have increased neonatal lethality or skeletal abnormalities.[87] Furthermore, the overall mean values for serum Ca^{2+} concentrations and urinary Ca^{2+} excretion were similar in $Casr^{-/-}$ $Pth^{-/-}$ mice and wild-type control mice; however the fine control of calcium homeostasis was lost in the $Casr^{-/-}$ $Pth^{-/-}$ mice, which had a much larger range of serum Ca^{2+} concentrations. These findings demonstrate that the CaSR has PTH-independent roles in calcium homeostasis, since normal Ca^{2+} excretion did not require PTH.[87] Furthermore, a hypercalcemic challenge, induced by increased oral calcium intake, PTH infusion, or dietary phosphate deficiency, resulted in a greater elevation of serum Ca^{2+} in the $Casr^{-/-}$ $Pth^{-/-}$ mice, which had a reduced renal calcium clearance and failed to increase serum calcitonin, when compared to $Casr^{+/+}$ $Pth^{-/-}$ and $Casr^{+/-}$ $Pth^{-/-}$ mice.[88] However, infusion of PTH in $Casr^{-/-}$ $Pth^{-/-}$ mice further reduced the renal calcium clearance, thereby demonstrating that PTH can increase the CaSR-independent Ca^{2+} reabsorption by the kidney. Thus, it appears that PTH is necessary for the maintenance of normal serum calcium concentrations when facing a hypocalcemic challenge, but that PTH-independent mechanisms, such as CaSR-stimulated CT-secretion and increased renal Ca^{2+} excretion, are involved in maintaining normal serum calcium concentrations in response to hypercalcemic challenges.[88]

$Casr^{-/-}$ $Gcm2^{-/-}$ mice, which lack parathyroid glands, also do not have the increased neonatal lethality, skeletal abnormalities, or hypercalcemia observed in $Casr^{-/-}$ $Gcm2^{+/+}$ mice.[89] Interestingly, $Casr^{-/-}$ $Gcm2^{-/-}$ mice did not appear to demonstrate the large variability in serum Ca^{2+} levels that was observed in $Casr^{-/-}$ $Pth^{-/-}$ mice, and this may be due to the residual PTH production by the thymus.

$Casr^{-/-}$ $Cyp27b1^{-/-}$ mice had improved survival rates and body size compared to $Casr^{-/-}$ mice, and normocalcemia. However, $Casr^{-/-}$ $Cyp27b1^{-/-}$ mice had more severe hypophosphatemia and more marked PTH elevations, in association with significant parathyroid hyperplasia, compared to $Casr^{-/-}$ mice, indicating a role for $1,25(OH)_2D$ in suppression of PTH secretion.[90] The reduced bone mineralization detected in $Casr^{-/-}$ mice was partially ameliorated in $Casr^{-/-}$ $Cyp27b1^{-/-}$ mice; however, the $Casr^{-/-}$ $Cyp27b1^{-/-}$ mice still had reduced bone mineralization compared to wild-type mice, likely due to the elevated PTH levels in the $Casr^{-/-}$ $Cyp27b1^{-/-}$ mice.[90]

The absence of bone abnormalities in either $Casr^{-/-}$ $Gcm2^{-/-}$ or $Casr^{-/-}$ $Pth^{-/-}$ mice, which respectively have no parathyroid glands or do not make PTH, suggested that the bone abnormalities in the $Casr^{-/-}$ $Gcm2^{+/+}$ and $Casr^{-/-}$ $Pth^{+/+}$ mice and in NSHPT patients are largely due to the primary hyperparathyroidism.[89] However, the expression of the CaSR in bone and cartilage also suggests a role for the CaSR in the skeleton and in contributing to the bone abnormalities observed in the $Casr^{-/-}$ $Gcm2^{+/+}$ and $Casr^{-/-}$ $Pth^{+/+}$ mice. An additional complicating factor is the presence of an alternative CaSR splice variant in the *Casr* knock-out mice, which were generated by insertion of the Neo^R cassette into exon 5 so as to disrupt the gene. However, this results in an incomplete knock out of the CaSR receptor because of alternate splicing of the *Casr* gene. The alternative spliced CaSR lacks the amino acid sequence encoded by exon 5, which encodes 77 amino acid residues of the extracellular

domain. This spliced receptor lacking the protein from exon 5 ($^{Exon5(-)}$Casr) is shorter, but retains the majority of the extracellular domain, all of the seven transmembrane domains and the cytoplasmic domain, and is able to compensate for the absence of full length CaSRs in bone and cartilage.[91] Thus, the $^{Exon5(-)}$*Casr* knock out is incomplete.[91] In order to explore further the skeletal role of the CaSR, tissue-specific knock outs of the *Casr* which lacked exon 7 (that encodes the 501 amino acids which form the 7 transmembrane domains and 4 intracellular loops) were generated in the parathyroid glands, bone, and cartilage (Table 7.4). Parathyroid gland–specific homozygous *Casr* knock-out (PT-KO) mice died ~2 weeks after birth and were much smaller than wild types. The *Casr* PT-KO mice had severe marked hypercalcemia with elevated serum PTH concentrations, and increased urinary Ca^{2+} excretion, which is different compared to the conventional $Casr^{-/-}$ mice, due to the presence of functional CaSR in the kidney.[57] *Casr* PT-KO mice also had severe undermineralization of the skeleton, consistent with NSHPT. Heterozygous (PT-Het) mice had mild hyperparathyroidism.[57] Selective knock out of the *Casr* in osteoblasts by utilizing a Collagen I-Cre to generate heterozygous (COL-Het) and homozygous (COL-KO) knock-out mice, revealed COL-KO mice to have a similar skeletal phenotype to the PT-KO mice, with multiple factures and profound undermineralization, due to a lack of differentiation, and increased apoptosis, of osteoblasts.[57] Homozygous knock out of the *Casr* in growth plate cells caused embryonic lethality at ~E12–E13. To overcome this, an inducible growth plate–specific knock out was generated via the use of an ER-Cre. The *Casr* was electively knocked out in growth plates before birth, and this also resulted in bone defects, such as short bones, as well as a decrease in mature and terminally differentiated chondrocytes.[57] Further evidence for the role of CaSR in bone responses to PTH comes from studies in which $Pth^{-/-}$ mice and $Casr^{-/-}$ $Pth^{-/-}$ mice were infused with PTH. Continuous infusion of PTH into $Pth^{-/-}$ mice resulted in the expected increases in cortical bone turnover and decreases in cortical bone volume, bone mineral content and BMD, but these responses were blunted in $Casr^{-/-}$ $Pth^{-/-}$ mice, indicating an important role for the CaSR in modulating the effects of PTH on cortical bone.[92] Thus, these tissue-specific and double knock-out models demonstrate a role for the CaSR in bone and calcium homeostasis, and indicated that the skeletal abnormalities seen in patients with NSHPT may not be solely due to the primary hyperparathyroidism.

3.10 ADHH Due to Gain-of-Function CaSR Mutations

Gain-of-function CaSR mutations are associated with the disorder of autosomal dominant hypocalcemia type 1 (ADH1). The hypocalcemia is usually mild and asymptomatic, but may sometimes be associated with tetany and seizures. Hyperphosphatemia and hypomagnesemia are also notable features, and the circulating PTH concentrations are usually in the low–normal range.[83] The CaSR mutations resulting in ADH1 are invariably heterozygous missense mutations that result in a lower EC_{50}. To generate a mouse model for ADH1 and such an activating CaSR mutation, two possible strategies could have been utilized, which were a knock-in approach or searching for a chemical induced mutation (Table 7.2, Figs. 7.1 and 7.3). Indeed, in 2004, a search of mice derived from use of the chemical iPMS to produce mutants, identified a mouse model for ADH1 (Table 7.4). This mouse model, which was first noted to feature opaque flecks of the lens and designated *Nuf* (nuclear flecks),[9] has hypocalcemia and hyperphosphatemia in association with inappropriately low plasma PTH concentrations. In addition, mutant mice may also have widespread ectopic calcification and suffer from sudden death.[9] These phenotypic features in the mutant *Nuf* mice are due to a CaSR missense mutation, Leu723Gln, which results in a reduced EC_{50}, consistent with an activating CaSR mutation.[9] *Nuf* mice have also been used in preclinical studies of a CaSR negative allosteric modulator (known as a calcilytic), NPS 2143. When administered by i.p. injection, NPS 2143 elicited a rise in plasma Ca^{2+} and PTH in both heterozygous and homozygous *Nuf* mice.[93] Two knock-in models for ADH1 have recently been generated, in which the endogenous mouse *Casr* gene was replaced with the human *CaSR* gene harboring either the Cys129Ser or Ala843Glu ADH1 mutations. Both of these models developed hypocalcemia and hyperphosphatemia with inappropriately low plasma PTH levels, and were also hypomagnesemic and hypercalciuric with reduced plasma $1,25(OH)_2D_3$ levels, and when fed a high-Ca^{2+} diet to correct the hypocalcemia, developed renal calcification.[58] Treatment of both Cys129Ser and Ala843Glu knock-in mice with the calcilytic JTT-305/MK-5442 resulted in increased plasma Ca^{2+} and PTH levels, reduced plasma phosphate levels, and reduced urinary Ca^{2+} excretion, in contrast to treatment with PTH(1-34), which did not suppress urinary Ca^{2+} excretion.[58] Thus, the *Nuf* and Cys129Ser and Ala843Glu knock-in mouse models for ADH1 due to activating mutations of the CaSR have been utilized for preclinical studies, and may also be an important tool to understand the mechanisms of ectopic calcification and the contribution of the CaSR to renal Ca^{2+} handling.

4 CONCLUSIONS

Mouse models for inherited disorders of mineral and skeletal homeostasis have been generated by a variety of strategies, and investigations of these have provided

new and valuable insights into the pathogenesis of these often-complex conditions. These murine models have also helped to increase our understanding of the relationships between different signaling components involved in skeletal biology, and calcium and phosphate homeostasis. Mouse models as preclinical models also provide opportunities for assessing future novel therapies for bone and skeletal disorders.

1 INTRODUCTION

Gene therapy refers to the strategy by which nucleic acids, such as genes, microRNAs (miRNAs) and short-interfering RNAs (siRNAs), are delivered to target tissues using naked oligonucleotides, viral vectors or nonviral vectors to prevent, treat, or cure disease. In its infancy, the gene therapy field focused on use of viral vectors to deliver genes encoding wild-type proteins for the purposes of replacing absent or aberrant proteins produced due to genetic mutations. However, as time has progressed, gene therapy has been adopted to address more complex disease states, including nonhealing fractures (termed "nonunion fractures") and arthritis, where pathogenesis is typically not caused by a single mutation but by complex interactions between genetics and the environment. In this regard, the approach is typically used to introduce factors to overcome barriers to healing, such as inflammation, while enhancing tissue regeneration.

The foundations for gene therapy were first laid with the discovery that DNA encoded genetic information and could be transferred from cell to cell by conjugation, transformation, or transduction.[1] In the 1970s, following the discovery of the genetic code, Friedmann proposed gene therapy as a means with which to replace mutated genes and cure disease.[2] Almost 2 decades later, the first gene therapy trial was approved by the FDA and used white blood cells transduced ex vivo with the adenosine deaminase gene to treat two patients suffering from adenosine deaminase deficiency. Though a temporary response was observed in one patient, continued enzyme replacement therapy was ultimately required.[3] Despite this setback, modifications to viral vectors and transduction protocols would be met with success in future trials. Unfortunately, in 1999, progress and achievements celebrated by the field were overshadowed by the passing of Jesse Gelsinger—the first death directly related to a gene therapy vector.[4] This tragedy was soon followed by discovery of acute T-cell lymphoblastic leukemia or preleukemic myelodysplastic syndrome in patients with immune disorders, such as X-linked severe combined immunodeficiency, treated with gene therapies utilizing integrating viral vectors.[5,6] Together, these and other events highlighted the need for a deeper understanding of human immunology, and for improved vectors and approaches for gene therapy.

Despite the clinical setbacks seen in the 1990s and early 2000s, the field of gene therapy has celebrated some great successes in recent years. In particular, efficacious applications in human patients have been obtained in clinical trials for previously intractable inherited diseases, such as certain forms of immunodeficiency, neurologic disorders, blindness, hemoglobinopathy, and coagulation disorders.[7] Considering these successes and the number of ongoing clinical trials, there is renewed hope that gene therapy may still be a viable treatment option for monogenetic and multifactorial diseases.

In all cases, the success of any gene therapy is tightly linked to its ability to efficiently deliver genes to target cells and maintain gene expression over an extended period of time. As mentioned earlier, gene therapy vectors can be viral or nonviral in origin. Viruses have naturally evolved to efficiently transduce host cells, but safety issues surrounding their immunogenic profile and potential for integration mutagenesis remain a concern. While

nonviral vectors are perceived to be a safer alternative, transduction efficiencies are far below what can be achieved with viral vector systems.

Gene therapies are designed and delivered using either an in vivo or ex vivo approach. The former involves administration of the vector directly into the organism, whereas the latter requires extraction of target cells, transduction with a vector and reintroduction of those manipulated cells into the organism. An overview of gene therapy approaches is illustrated in Fig. 8.1 and discussed below.

2 VECTORS IN SKELETAL GENE THERAPY

The choice of optimal vector is one key to successful gene therapy. Many vectors—viral and nonviral—exist, of which the most commonly used are discussed below. Key features of the various vectors are listed in Table 8.1.

2.1 Adenovirus

Adenoviruses (AdVs) belong to the family of Adenoviridae and consist of at least 55 immunologically distinct serotypes divided into 7 different species (A–G).[8,9] These nonenveloped viruses possess a linear double-stranded DNA (dsDNA) genome surrounded by a 100-nm icosahedral capsid formed of hexon and penton subunits with protruding fiber proteins that assist with binding of the virus to target cells.[10,11] For the widely used serotype 5 AdV (AdV5) vectors, the knob domain of the viral capsid's fiber protein binds to the coxsackievirus and adenovirus receptor (CAR) expressed on the target cell surface. This is followed by interactions with cell surface α_v integrins that lead to internalization via clathrin-mediated endocytosis.[12] Upon entry into the cytosol, the viral particle escapes the endosome and is disassembled, allowing the viral genome to translocate and replicate within the nucleus in an episomal state.[10,11]

The AdV genome is approximately 36 kb in size and consists of early (E1–E4) and late genes (L1–L5), which are transcribed before and after viral DNA replication, respectively.[11] To deliver therapeutic genes (TGs) using AdV vectors, the virus must be rendered replication-deficient by removal of genes required for its lytic life cycle. In first-generation AdV vectors, E1 was replaced with the TG of interest, and the E1 proteins required for virus production were provided in trans by a special cell line. The subsequent second-generation AdV vectors were generated by deletion of E2, E3, or E4 in various combinations. Despite absence of E1, the remaining viral genes are expressed at low levels in transduced cells, which is directly cytotoxic and can lead to long-term, chronic toxicity.[13] Further, expression of viral proteins can provoke an adaptive immune response against transduced cells, leading to loss of TG expression after short periods of time.[14]

TABLE 8.1 Commonly Used Gene Transfer Vectors and Their Key Features

Vectors	Particle size (nm)	Genome	Maximum transgene capacity (kb)	Transduced cell types
AdV	80–100	dsDNA	36	MSCs, synoviocytes, ligament cells, tendon cells
AAV	20	ssDNA	5	Chondrocytes, tendon cells, MSCs
RV/LV	80–100	ssRNA	12	MSCs, chondrocytes, periosteal cells
Naked DNA (biolistics, sonication, electroporation)	Depending on plasmid size	dsDNA	—	Muscle cells
Liposomes	Wide range	dsDNA	—	Perichondrial cells, chondrocytes, ligament cells, tendon cells
Nanoparticles (chitosan)	100–300	dsDNA	—	Chondrocytes

AAV, Adeno-associated virus; AdV, adenovirus; dsDNA, double-stranded DNA; LV, lentivirus; MSCs, mesenchymal stem cells; RV, retrovirus; ssDNA, single-stranded DNA; ssRNA, single-stranded RNA; —, unlimited size.

To overcome these issues, helper-dependent AdVs [also known as gutless, gutted, or high-capacity vectors (HDVs)] were developed, in which all viral coding sequences excluding the inverted terminal repeats and packaging signal are removed, and replaced with the TG of interest. To package the HDV for gene therapy, a helper virus is used to provide in trans all proteins necessary for viral particle assembly.[15] In addition to having a remarkable cloning capacity of up to 36 kb, the HDV vectors are safer and more efficacious compared to their first-generation predecessors. In fact, it has been shown that HDVs can mediate gene expression for up to 7 years in the liver of nonhuman primates.[16] Although HDVs were designed to minimize the host immune response, these too can activate an innate and adaptive immune response directed against the viral capsid or TG components.[17,18]

Overall, the features that make AdVs useful as gene therapy vehicles are their large genetic payload and their ability to efficiently infect dividing and quiescent cells in a wide range of tissues. Other advantages include the low risk for insertional mutagenesis due to infrequent integration into the host cell genome and relatively easy manipulation of the virus genome.

2.2 Adeno-Associated Virus

A member of the Parvoviridae family, adeno-associated virus (AAV) was discovered in 1965 as a contaminant in AdV preparations.[19] AAVs are naturally replication-deficient and require the assistance of a helper virus, such as AdV or herpes virus, to replicate. The virions are nonenveloped with an icosahedral capsid measuring about 20-nm in diameter surrounding a linear, single-stranded DNA (ssDNA) genome.[11,20] Similar to AdVs, AAVs enter target cells through receptor-mediated endocytosis; however, variability in sequence identity within the capsid coding region leads to differences in tissue tropism amongst the serotypes.[21,22] Once in the endosome, the virus escapes into the cytosol where its single-stranded DNA genome is released and transported to the nucleus to be converted to dsDNA.[10,11]

The AAV genome is approximately 4.7 kb in size, and consists of 145-base inverted terminal repeats flanking two open reading frames (ORFs): the 5′-*rep* ORF (replication) and the 3′-*cap* ORF (capsid). Through alternative splicing, the 5′-*rep* ORF encodes for four distinct proteins essential for genome replication, encapsidation, and integration, whereas the three proteins that form the viral capsid are encoded by the 3′-*cap* ORF.[11,20] Though the AAV genome can specifically integrate into the human host cell genome at the AAVS1 locus on chromosome 19, the majority of AAV vectors exist in an episomal state.[23] Still, random integration can occur within genes as well as at regulatory, ribosomal, and palindromic DNA sequences.[24]

The major advantage of AAV is its low immunogenicity, which enables long-term gene expression in a variety of tissues.[25] AAV gene therapy vectors are generated by replacing the 5′-*Rep* and 3′-*Cap* genes with an expression cassette for the TG of interest. However, the utility of these vectors is limited to small transgenes owing to its small cloning capacity (maximum 4.7 kb). For TGs >4.7 kb in size, efforts have been made in recent years to increase cloning capacity of AAVs. In addition to limiting expression elements,[26] dual-vector systems have been developed in which the TG of interest is split between two distinct constructs and reconstituted by homologous recombination of overlapping sequences following transduction.[10] Unfortunately, this system yields relatively low expression when compared with a single vector approach. In addition to its limited cloning capacity, the single-stranded DNA genome of AAVs must be transformed into dsDNA before transcription can occur, resulting in delayed onset of gene expression.

This problem has been solved by packaging dsDNA into AAV capsids generating so-called self-complementary AAVs; however, the transgene capacity of these vectors is limited to approximately 2.5 kb.[27]

2.3 Retrovirus and Lentivirus

Members of the Retroviridae family can be divided into simple or complex viruses. Among the simple retroviruses [(RVs) oncogenic retroviruses], the murine leukemia virus is most commonly used as a vector in gene therapy, while the most commonly used vector among the complex RVs is lentivirus (LV).[28] Retroviridae are enveloped viruses with a diameter of 80–100-nm. The envelope is a lipid bilayer derived from the host cell membrane that also contains viral-encoded glycoproteins. The genome is a diploid (+) linear, single-stranded RNA (ssRNA) molecule approximately 7–12 kb in length. Simple RVs have a genome containing three major coding segments (*gag*, *pol*, and *env*) and one small coding domain (*pro*). The structural proteins of RVs are encoded by *gag*, whereas *pol* encodes enzymes including reverse transcriptase, integrase, and proteases that accompany the single-stranded RNA genome.[28,29] In addition to these genes, complex RVs carry six accessory genes responsible for regulating viral gene expression, replication, and packaging.[30]

In general, viral glycoproteins of RVs bind the cluster of differentiation 4 (CD4) receptor and deliver the viral core to the cytosol through fusion with the plasma membrane or receptor-mediated endocytosis.[31] Upon entry into the cell, viral reverse transcriptase converts the ssRNA genome into dsDNA. Since the DNA strand derived from simple RVs is not able to pass through the nuclear membrane, integration can only occur in mitotically active cells. In contrast, the LV genome encodes the viral matrix protein gag and accessory viral protein vpr that permit nuclear entry of viral nucleic acids in the absence of mitosis;[28,32] as such, LVs can be used to infect both dividing and nondividing cells. Following reverse transcription, the DNA strand of the RV is integrated into the host cell genome through interactions between long terminal repeat-localized integrase attachment sites and the viral integrase.

For gene therapy purposes, all viral genes of the RV genome are deleted to render the vectors replication-deficient and provide space for insertion of the TG of interest. Compared to AdV and AAV, RV-based vectors show relatively low transduction efficiency and restricted tropism to CD4(+) cells in vivo. As such, investigation has focused on altering the retroviral capsid proteins (termed pseudotyping) to increase the number of cell types susceptible to transduction. For instance, the vesicular stomatitis virus glycoprotein has been used to target cells expressing low density lipoprotein receptor, glycoproteins from the measles virus have been employed to target lymphocytes and other immune cells,[33] and envelope proteins from Sendai virus permit transduction of epithelial cells.[34,35] Perhaps the most advantageous property of retroviral vectors is their ability to stably integrate and confer long-term transgene expression in rapidly dividing tissues. Further, use of tissue-specific promoters together with regulatory elements, such as the woodchuck hepatitis virus posttranscriptional regulatory element, have been employed to improve expression levels of the transgene while limiting promoter inactivation.[10] Though use of retroviral gene therapy has shown potential for treatment of human diseases, the risk of insertional mutagenesis is still a concern.

2.4 Nonviral Vectors

Apart from the viral vectors described earlier, a number of nonviral gene transfer mechanisms exist. Genes can be simply transferred into target cells as naked DNA; however, naked DNA has shown significant transfection efficiency only in skeletal muscle tissue, whereas in most other musculoskeletal tissues gene transfer was not sufficient. To increase transfection efficiency, a gene gun (biolistic particle delivery system), sonication, or electroporation can be used. While these methods are useful for in vitro gene transfer, their application in vivo is difficult except in the case of skeletal muscle and skin.

The transduction efficiency of naked DNA is generally low due to its negative charge and susceptibility to decay via actions of DNA degrading enzymes. To overcome these hurdles, DNA can be incorporated in or attached to liposomes or nanoparticles. Liposomes are spherical vesicles composed of a lipid bilayer that have been shown to transduce certain cell types in vitro and in vivo, while chitosan, a polysaccharide and naturally occurring biopolymer, is widely used to make biodegradable nanoparticles that encapsulate DNA. Transfection efficiency in vitro was further improved using hyaluronic acid/chitosan hybrid nanoparticles.[36]

2.5 Conclusions

Every vector type has its advantages and disadvantages. As such, a number of factors, including transduction efficiency, gene expression duration, transgene capacity, and method of delivery, need to be considered when choosing vectors for a particular therapeutic application. Furthermore, potential risks and ethical aspects with regard to integrating vectors need to be considered.

3 METHODS OF GENE DELIVERY

In addition to the selection of an appropriate viral vector, researchers must decide which method of delivery best suits their experimental or therapeutic needs.

In vivo gene therapy refers to direct administration of the viral vector into the organism, whereas ex vivo gene therapy requires extraction of cells from the patient, transduction with a vector and reintroduction of those manipulated cells back to the target site. Below the advantages and disadvantages of these two approaches are reviewed.

3.1 In Vivo Delivery

Of the two delivery strategies, in vivo approaches are simpler and less expensive. However, given that vectors are delivered directly into the systemic circulation or target tissue, immune responses to viral antigens are a significant clinical concern as they can limit transgene expression and produce a variety of adverse immunological reactions that, in severe cases, could result in death (Section 4). Additionally, as successful expression of TGs is predicated on the existence of a healthy cell population to be transduced, the lack of such cells in many disease or injury states can potentially limit this method's effectiveness.[37]

3.2 Ex Vivo Delivery

In a typical ex vivo approach, cells are isolated from either the patient (autologous) or a healthy donor (allogenic), expanded in culture, and transduced with the TG of interest before being implanted back into the patient. Though this method reduces exposure of the patient's immune system to viral antigens, a number of other concerns exist including rejection (in allogenic transfers), the need for multiple surgeries (in autologous transfers), gene transfer efficiency, stability of transgene expression, and the question of whether the genetically modified cells will engraft into the tissue.[38] Additionally, many primary cell types do not expand or transduce well in culture, making it difficult to obtain the quantity necessary for successful treatment.

Cell types commonly used in ex vivo approaches include mesenchymal stem cells (MSCs),[39] fibroblasts,[40] and native tissue cell types, such as chondrocytes.[41] With regards to usage of MSCs, it is the known that these cells release antiinflammatory and tissue remodeling factors at the site of delivery.[42] Though this could be beneficial in most instances of tissue injury or disease, lack of proper controls can make it difficult to determine what additional benefit the TG itself provides.

In addition to simply injecting transduced cells, many groups utilize natural or synthetic scaffolds—a concept borrowed from more traditional tissue engineering, in which cells are cultured onto the scaffolds and the entire scaffold/cell complex is added to the defect.[43] Use of gene-activated scaffolds, in which the vector is embedded within the matrix and transduces cells as they migrate in from the tissue, are also becoming more popular.[44]

4 THE IMMUNE RESPONSE TO GENE THERAPY VECTORS

The immune response to viral vectors (and even nonviral vectors) represents a significant challenge to the use of gene therapy in human patients. The immediate inflammation triggered by viral capsid proteins and nucleic acids is mediated largely by the innate immune system, whereas later phases of the immune response involve cellular and humoral aspects of the adaptive immune system. For simplicity, immune responses against AdV5 are described as an example given their prominence in gene therapy clinical trials.[45] For information on immune reactions to AAV, RV, and other AdV vectors, refer to the following excellent reviews.[46,47]

4.1 The Innate Immune Response

The innate immune response, which is responsible for the immediate recognition of and in vivo toxicity to viral vectors, can be divided into intrinsic and extrinsic components. The components of intrinsic innate immunity preexist within host cells and block viral replication directly,[48] whereas extrinsic mechanisms limit infection indirectly through receptor-mediated signaling and subsequent upregulation of chemokines and cytokines including interferons (IFNs) and interleukin-1 (IL-1).[49]

Before reaching the target cell, viruses are typically sequestered and destroyed by binding of various factors to the viral capsid, including clotting factors, immunoglobulins, and components of the complement system.[49,50] Once at the target cell, binding of the AdV capsid to CAR and α_v integrins initiates intracellular signaling that activates expression of nuclear factor-κB (NF-κB) target genes, such as IL-1 and tumor necrosis factor-α (TNF-α). Following internalization, the viral DNA is unpackaged and released into the endosomal lumen where it is recognized by Toll-like receptor 9, leading to upregulation of NF-κB-regulated chemokines and cytokines, and induction of type I IFNs.[49,50] Viral DNA that escapes the endosome and reaches the cytosol is detected by DNA-dependent activator of IFN-regulatory factors or nucleotide oligomerization domain-like receptors, which culminates in induction of an IFN or IL-1 response, respectively.[51,52] In general, IFNs, such as IFN-α, function in an autocrine and paracrine manner to inhibit viral replication and packaging, whereas IL-1 acts to upregulate chemokines and cytokines required for apoptotic induction of infected cells and recruitment of proinflammatory cell types.[49]

4.2 The Adaptive Immune Response

Within 3–7 days following viral infection, transduced cells process and present viral-derived peptides on major histocompatibility complex (MHC)-I to cytotoxic T-lymphocytes, which release factors that perforate the cell membrane to induce apoptosis. At the same time, virally transduced antigen presenting cells, such as dendritic cells, present viral proteins on MHC-II to CD4(+) and CD8(+) T-lymphocytes. These T-lymphocytes in turn activate B cells within lymph nodes, which differentiate into plasma cells and produce neutralizing antibodies against viral capsid antigens.[53]

One of the major limitations with viral vectors for gene therapy lies in the widespread global immunity to AdVs and AAVs. In addition to neutralizing the virus upon administration, neutralizing antibodies can activate complement and induce an inflammatory state.[54] The prevalence of neutralizing antibodies against either AdVs or AAVs varies depending on the serotype. For instance, 96% of individuals tested by Chirmule and coworkers were positive for antibodies against AdV capsid proteins; interestingly, serum from only 55% of these subjects was capable of neutralizing AdV5 infection in vitro .[55] In addition to AdVs, 35%–80% of individuals have humoral immunity for AAV2, whereas the less commonly used AAV7-9 exhibit only a 15%–30% seroprevalence.[46,56] Interestingly, seroprevalence to AAVs is also geographically dependent. For instance, more individuals in Africa and China have neutralizing antibodies to AAV1 compared to those in the USA.[57]

4.3 Strategies to Limit Immune Reactions to Gene Therapy Vectors

The various strategies used to circumvent the immune response to viral vectors have focused on altering the viral capsid to avoid an innate and/or humoral response or immune suppression to enhance transduction of target tissues.[46,53] With regards to the former, one approach has been to pseudotype viral vectors with capsid proteins from virions with little-to-no preexisting immunity in the human population. An alternative has been to disrupt specific epitopes within the viral capsid, but this is problematic owing to a lack of knowledge with regards to the characteristics of serotype-specific viral epitopes. To overcome this, error-prone PCR has been employed to generate capsid variant libraries that can be screened for resistance to serum neutralization.[58] Conjugation of the vector with polyethylene glycol (PEG), a synthetic polymer that exhibits low toxicity and immunogenicity, has also been utilized to mask the immunogenic epitopes in lieu of directly altering viral capsid proteins. In this regard, PEGylation has been shown to decrease the immune response to AdV5 compared to native virus alone.[59,60]

An alternative approach to modifying or masking viral antigens is to indirectly prevent an immune response to them. This could be achieved by pharmacological inhibition of the immune system during transduction, prevention of transgene expression in antigen-presenting cells using tissue-specific promoters or through ex vivo infection of cells followed by their reintroduction into the patient.[46,53]

5 GENE THERAPY FOR PATHOLOGIES OF THE SKELETAL SYSTEM

While gene therapy has been used to address diseases caused by a single genetic mutation, it is more commonly studied in the skeletal field for its potential to treat complex pathologies including nonunion fractures and arthritis. Regardless of pathogenesis, most approaches used to date target anabolic, catabolic, or inflammatory pathways to promote healing and cure disease. In the past, the field focused investigation on secretable proteins, such as growth factors and cytokines; however, investigators have more recently begun to target intracellular mediators such signaling pathway components and transcription factors.

5.1 Bone

The extracellular matrix of bone consists of an organic component composed of type I collagen (COL1) as well as other noncollagenous proteins and a mineral component consisting largely of hydroxyapatite.[61] The synthesis and remodeling of bone is achieved by its three resident cell types: the bone-forming osteoblast, the bone-resorbing osteoclast, and the mechanosensing osteocyte. Under physiological conditions within the adult skeleton, the actions of the osteoblast and osteoclast are tightly coupled, and perturbations to this balance lead to bone loss or gain in diseases such as osteoporosis and osteopetrosis, respectively.[62]

5.1.1 Bone Healing and Osteogenesis

Issues surrounding bone loss and repair have immense clinical and economical importance. Bone fractures occur at an incidence of 6 million/year in the United States alone, and roughly 10% are nonunion requiring an orthopedic graft.[63] Though the gold standard for skeletal grafting therapies is the autograft, this procedure has been hindered by problems with inadequate tissue supply and donor site morbidity.[64] A solution for tissue availability has been to use allografts; however, these display reduced biological activity and mechanical properties with a potential for disease transmission.[65]

Fracture (or bone) healing is a highly complex process governed by an intricate network of mechanical and cellular factors. Primary fracture healing resembles normal bone remodeling and occurs when the fracture gap is minimized with sufficient stabilization. However, most fractures seen clinically do not stabilize completely and repair via secondary bone healing—a multistage process involving formation of a hematoma, inflammatory cell infiltration, and generation of a fibrocartilage callus that mineralizes and is subsequently remodeled until the bone is completely repaired.[66] To assess efficacy for bone healing within the preclinical milieu, investigators have utilized in vivo and ex vivo approaches to evaluate TGs for their potential to form ectopic bone and heal critical-sized defects of the calvaria and femur. More relevant to patients, models of nonunion fracture are also employed to assess the role of these factors in repair.

Of the anabolic strategies tested for bone healing, bone morphogenetic protein (BMP) family members remain at the forefront given their central role in osteoblast differentiation as well as skeletal development, remodeling, and repair.[67,68] Using nonviral and viral vectors, convincing evidence exists demonstrating that BMP-2 is capable of enhancing osteogenesis, vascularization and bone repair in calvarial, femoral, and fibular defect models. Studies utilizing nonviral vector approaches have shown that combining untransfected MSCs with BMP-2 plasmid (pBMP-2) DNA in scaffolds has positive but marginal effects on osteoblast differentiation and ectopic mineralization in vivo,[69,70] and is comparable to the effects of recombinant BMP-2 protein.[71] In addition, MSCs transfected with pBMP-2 DNA undergo osteoblast differentiation in vitro and produce ectopic bone when implanted on apatite-coated silk scaffolds in immunodeficient mice.[72]

AdV has been the most common viral vector for BMP-2-mediated gene therapy of skeletal pathologies. Direct injection of AdVs expressing BMP-2 has been shown to increase bone formation in critical-sized bone defects in rats and rabbits.[73] In another study, intramuscular injection of BMP-2-expressing AdV induced ectopic bone formation in mice, with more robust osteogenic responses observed in immunodeficient animals.[74] However, despite evidence for success of in vivo BMP-2 gene therapy, most investigations employ ex vivo approaches using MSCs and other cell types with or without scaffolds. In this regard, BMP2-expressing MSCs transduced using viral vectors significantly accelerate bone healing in various animal models.[75–78] Further, genetically modified MSCs and adipose-derived stem cells (ADSCs) expressing BMP-2 loaded onto scaffolds composed of materials, such as calcium phosphates,[79,80] devitalized bone matrix[81,82] or collagen[83,84] have been used to promote bone healing in vivo with varying degrees of success.

Stem cells are an attractive cell source for bone repair as they have the potential to directly contribute to healing. Though studies have indicated that MSCs transduced with BMP-2 transgenes may directly participate in bone repair, work done by Pensak et al. suggests that BMP-2-expressing MSCs also promote healing by recruiting resident progenitors to the defect site.[77] This finding suggests that cellular identity and differentiation potential may not be critical for ex vivo BMP-2 gene therapy. In this regard, fibroblasts transduced with BMP-2 using AdV promote healing when compared to control cells both in femoral and fibular critical-sized defect models.[85,86] Moreover, autologous muscle and adipose grafts activated to express BMP-2 by AdV transduction promote osteogenesis and bone repair in vivo.[87–89] It is important to consider that BMP-2 may drive osteogenic differentiation even in these terminal cell types and tissues as has been shown previously for fibroblasts.[90,91] On the other hand, Zwingenberger et al. demonstrated that fat tissue grafts expressing BMP-2 mediate repair through recruitment of endogenous MSC populations.[92] In either case, the use of tissues, such as muscle for delivery of TGs is advantageous given that expansion of isolated cells can be avoided and autologous tissue can be utilized.

In addition to BMP-2, a number of studies have evaluated the potency of other BMPs in mediating bone repair following injury. BMP-4-expressing MSCs healed critical-sized defects in rats,[93] with evidence suggesting that adipose-derived MSCs rather than bone marrow-derived MSCs produce more extracellular matrix in response to BMPs.[94] Muscle-derived MSCs expressing BMP-9 also promoted bone healing in a segmental bone defect model,[95] and use of scaffolds have been reported to enhance the osteogenic effect.[96] Though Betz et al. showed only a marginal effect of muscle fragments transduced with BMP-7 on femoral defects in rats,[97] an independent study using mesoporous bioglass/silk fibrin scaffolds loaded with AdV expressing BMP-7 enhanced bone formation in an ovariectomized femoral defect model.[98] In a direct comparison of BMP-2 and BMP-6, Mizrahi et al. demonstrated that both adipose- and bone marrow-derived MSCs transfected with pBMP-6 DNA generated more bone at an accelerated rate compared to BMP-2.[99] Further, plugs of protease-solubilized collagen (termed atelocollagen) loaded with pBMP-12 led to better repair of femoral bone defects than either pBMP-2 or plug alone.[100] Future comparisons of different BMPs and their effects on osteogenesis and bone healing in vivo may provide important insights for future clinical trials.

The osteogenic potential of a number of other growth factors and morphogens have also been investigated in the context of bone healing. The canonical Wnt/β-catenin pathway is essential for skeletal development and bone remodeling.[67,101] In this regard, Gao et al. found

that RV-mediated Wnt10b overexpression increased cell proliferation, BMP-2 expression, and bone mineral density leading to complete repair in a nonunion atrophic fracture model.[102] Fibroblast growth factor 2 (FGF-2) has also demonstrated efficacy in calvarial defect models, where pFGF-2 transfected bone marrow-derived MSCs embedded on a hydroxyapatite scaffold accelerated healing compared to controls.[103] In an independent study, genetically modified MSCs overexpressing FGF-2 by AAV transduction enhanced blood vessel and bone formation in calvarial defects.[104]

Vascularization of the fibrocartilage callus is critical for bone formation and fracture healing. As such, a number of studies have used the potent angio- and vasculogenic inducer vascular endothelial growth factor (VEGF) to enhance bone repair; however, use of VEGF alone as a gene therapy has been met with mixed results. For instance, genetically modified BMSCs expressing VEGF loaded onto collagen-modified PLGA/TCP scaffold promoted vascularization and new bone formation in a critical-size defect model of the distal radius.[105] On the other hand, though RV delivery of VEGF cDNA to human MSCs on silicate-substituted apatite granules increased vascularization of grafts, they showed less bone compared to untransduced controls.[106] Despite the conflicting evidence for VEGF monotherapy, combined expression of VEGF with BMP-6 enhances osteogenesis compared to BMP-6 alone, and treatment with VEGF and BMP-2 promotes vascularization without negatively affecting BMP-2-induced bone formation in vivo.[76,107]

Cyclooxygenase-2 (COX-2) regulates synthesis of prostaglandins and is required for chondrogenesis and cartilage formation during fracture healing.[108,109] As a therapeutic target for gene therapy, in vivo delivery of COX-2 via RV to periosteal cells following fracture led to increased MSC recruitment to the fracture callus, decreased cartilage formation, and enhanced angiogenesis and remodeling of the cartilage fracture callus.[110] This study was followed by a second that used microarray to reveal that direct delivery of RV expressing COX-2 to the fracture site results in downregulation of inflammatory genes and upregulation of transcriptional regulators of hematopoiesis and erythropoiesis.[111] A previous study from the same group had demonstrated that COX-2 gene transfer suppressed repair of calvarial defects;[112] however, calvarial bones heal without the cartilaginous callus seen in the long bones. Therefore, given that COX-2 regulates fracture healing by modulating chondrogenesis and vascular remodeling, its use as a gene therapy may only be suitable for repair of long bone defects.

In addition to targeting extracellular mediators, recent studies have focused on directly modulating intracellular signaling pathways. For instance, overexpression of the osteoblast master regulator runt-related transcription factor 2 (Runx2) in ADSCs delivered to radial bone defects or sites of mandibular distraction promotes osteogenesis and bone healing in vivo.[113,114] Furthermore, combinatorial expression of Runx2 with BMP-2 in ADSCs using a bicistronic vector enhanced in vitro osteoblast differentiation and ectopic bone formation in athymic rats compared to cells transduced with BMP-2 alone.[115] In addition to transcription factors, miRNAs have been adopted for use in gene therapy for bone repair. For instance, delivery of miR-26a mimics using transfected BMSCs led to complete repair in a calvarial defect model.[116] Additionally, a separate study found that RV-mediated delivery of miR-148b together with BMP-2 to ADSCs promotes repair of calvarial defects in mice.[117] In other studies, knockdown of miR-214 promotes repair of femoral defects in ovariectomized (OVX)-rats where BMP-2 alone failed.[118] Further, use of antisense sequences to knockdown miR-31 in BMSCs loaded onto bioglass scaffolds promotes osteoblast differentiation and healing of calvarial critical-sized defects.[119]

5.1.2 *Implant Stability and Aseptic Loosening*

Successful hip arthroplasty or dental implant placement requires that the implant surface integrates with the bone (referred to as osteointegration). Aseptic loosening typically precedes failure of the implant, which is characterized by the generation of tiny particles at the interface between bone and the implant surface. This debris may provoke granuloma formation, bone resorption, or inflammatory cell infiltration leading ultimately to osteolysis and loss of the prosthesis.[120]

The molecular mechanisms that contribute to failed osteointegration and aseptic loosening remain unclear. As aseptic loosening progresses, the appearance of the implant/bone interface shares some histological characteristics with rheumatoid arthritis (RA) and a foreign body reaction.[121] In particular, IL-1 and TNFα have been implicated as potent mediators to implant failure as both these chemokines can trigger downstream immune responses and osteoclastogenesis. Specifically, osteoclastic modulatory factors osteoprotegerin (OPG) and receptor activator of nuclear factor-κB ligand (RANKL) are upregulated around failing implants and the increased RANKL:OPG ratio favors bone resorption.[120]

Retroviral vectors encoding human IL-1 receptor antagonist (IL-1Ra) and soluble human tumor necrosis factor receptor (sTNF-R) have been evaluated using an air pouch model, in which articulate wear debris was coimplanted with bone substrate into the subcutaneous space.[122] In this study, IL-1Ra gene transfer decreased inflammation and pouch fluid accumulation while simultaneously lowering macrophage infiltration. In vivo gene transfer of OPG using either AdV or AAV has also been employed to target osteoclasts directly. In this regard, AAV expressing OPG exhibited protective effects against orthopedic wear in two different murine models of osteolysis,[123] and the expression of

OPG reduced bone calcium release by approximately 40% compared to placebo-injected groups. In addition, overexpression of OPG by AdV at the bone defect site prior to placement of titanium implant was found to reduce osteoclast number, increase osteointegration and improve implant stability.[124] A combinatorial approach in which OPG and IL-1Ra were delivered to the peri-implant site by AAV and RV, respectively also decreased wear-induced osteoclastogenesis and increased the force required for implant extraction.[125]

5.1.3 Osteoporosis

Osteoporosis remains the most prevalent low bone mass disease both in the United States and worldwide.[126] In osteoporotic patients, bone mass is decreased leading to bone fragility and increased fracture risk. At the cellular level, this disease is caused by an imbalance in bone remodeling resulting from decreased bone formation and excessive bone resorption. The most prevalent therapeutic strategies utilize pharmacological agents that inhibit osteoclastogenesis and bone resorption. Teriparatide is a recombinant form of parathyroid hormone (PTH) 1–34 and remains the only FDA-approved anabolic agent for treatment of osteoporosis, though other biologics targeting Wnt signaling are in various stages of clinical trials.[127]

In the past 5 years, investigators have begun to use gene therapy to increase bone mass either in wild-type mice or preclinical models of osteoporosis. Using an in vivo nonviral approach, one study demonstrated that systemic hydrodynamic injection of insulin-like growth factor 1 (IGF-1) cDNA into the tail vein of OVX-mice increased serum and histomorphometric markers of bone formation and bone mineral density.[128] An alternative approach has been to use stem cell antigen-1-positive (Sca-1+) hematopoietic progenitors to deliver TGs to the bone microenvironment. These cells are particularly useful for systemic as well as local injection given their ability to migrate and engraft to the bone marrow niche. In this regard, Hall et al. in 2007 demonstrated that retro-orbital delivery of genetically modified Sca-1(+) cells expressing a modified FGF-2 transgene into sublethally irradiated mice lead to increased serum levels of FGF-2 and bone formation markers associated with extensive endosteal bone formation.[129] However, a number of adverse effects were also observed, including partial or complete loss of the bone marrow space, osteomalacia, and hyperparathyroidism. A follow-up study by the same group utilized the erythroid-specific promoter β-globin in place of a ubiquitous viral promoter to express the modified FGF-2 transgene in Sca-1(+) cells. In this context, the authors saw extensive bone formation in the endosteum of injected mice with no evidence of osteomalacia and less pronounced hyperparathyroidism.[130] Similar results have also been observed with platelet-derived growth factor subunit B (PDGFB).[131] In a separate approach, intramedullary injection of a RV-siRNA targeting the adipocyte critical transcription factor peroxisome proliferator-activated receptor γ (PPARγ) increased bone mass, osteoblast number while decreasing the number of osteoclasts.[132] Taken together, these recent advances suggest that gene therapies may one day exist for the treatment of systemic bone diseases, such as osteoporosis.

5.1.4 Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a genetic connective tissue disease that occurs with an incidence of one in every 10,000–20,000 live births.[133] While poor bone quality is the predominant feature of OI, other tissues rich in COL1 including tendons, ligaments, and teeth can also be affected. The disease shows significant clinical variability with dominant and recessive inheritance being linked to mutations in *COL1* or its posttranslational modification machinery, respectively. Strategies to limit fracture and increase bone mass in patients typically employ pharmacological agents, such as bisphosphonates to inhibit osteoclastic activity. At the same time, emerging evidence suggests that increasing Wnt signaling or inhibiting transforming growth factor β (TGF-β) may improve bone mass and strength in mouse models of dominant and recessive OI.[134,135]

It has been suggested that OI patients with gain-of-function mutations in *COL1* could benefit from ex vivo gene therapy designed to reduce COL1 levels. Certainly, in an in vitro context, Millington-Ward et al. have shown that using the hammerhead ribozyme Rzpo1a1, which targets a common *COL1A1* polymorphism, they could downregulate *COL1A1* transcripts at a ribozyme to transcript ratio of 1:1 in human MSCs;[136] however, it is unclear whether this strategy would work in vivo. A second approach might be to transplant MSCs transduced with wild-type *COL1* into OI patients with the hopes of replacing aberrant COL1 with the wild-type protein. In this regard, it has been shown that *Col1a1* from wild-type MSCs infused into transgenic OI mice expressing a human mini-COL1A1 could be detected in various tissues including marrow, cartilage, and bone.[137] Further, at 1-month postinfusion, humeri from OI-transgenic mice that received wild-type MSCs displayed modest increases in collagen and mineral content.[137] That being said, gene therapies targeting dysregulated cell signaling caused by extracellular matrix disruptions (as opposed to the extracellular matrix itself) may be more advantageous and widely applicable given recent successes using anti-TGF-β antibody therapy.[135]

In recent years, mutations in genes other than *COL1A1* or *COL1A2* have been identified as causing recessive forms of OI. For instance, mutations in *SERPINF1*, a gene that encodes pigment epithelium-derived factor (PEDF), have been identified in patients with OI type VI.[138,139] Given that PEDF is a secreted glycoprotein

protein, Rajagopal et al. investigated whether restoration of circulating PEDF in the blood could rescue the low bone mass phenotype seen in *Serpinf1*$^{-/-}$ mice.[140] Surprisingly, though HDV-mediated overexpression of PEDF within the liver restored serum levels of the protein, it failed to correct the bone phenotype in this mouse model. At the same time, overexpression of PEDF in vitro did increase osteoblast differentiation and matrix mineralization of an LV-transduced osteoblast-like cell line,[140] suggesting that PEDF may need to be produced locally within bone itself.

5.2 Cartilage

Most gene therapies for cartilage have focused on treatment of either osteoarthritis (OA) or RA—the two major diseases of articular joints. Articular joints consist of a diverse array of tissues including cartilage, synovium and synovial fluid, subchondral bone, menisci, ligaments, muscles, and nerves. The extracellular matrix of articular cartilage, which is both avascular and aneural, is composed primarily of type II collagen (COL2) and proteoglycans, and is produced and maintained by resident chondrocytes. During movement, articular cartilage functions to reduce friction between articulating skeletal elements and protect the subchondral bone from mechanical stress.[141] Though changes to articular cartilage play a significant role in pathogenesis of joint degeneration, the synovium, subchondral bone, and menisci must also be considered when developing therapies for these multifactorial diseases.

In contrast to conventional recombinant protein therapies for joint disease, gene therapy has the potential to deliver appropriate concentrations of a therapeutic agent in a localized and sustained manner. A number of vectors and transgenes have been evaluated and shown to have varying degrees of efficacy in different animal models of OA and RA. Although the first clinical trials were performed with RVs, researchers have shifted preference more recently to the safer and easier-to-produce AdVs and AAVs. In this regard, HDV transduces chondrocytes at a higher efficiency compared to AAVs, and expression of genes delivered using HDV can be sustained for over a year following intraarticular delivery.[142]

Of the cell types present in synovial joints, synoviocytes are preferentially targeted by most viral vectors including HDVs. When dealing with secreted factors that act extracellularly on joint tissues, transduction of synoviocytes may be sufficient; however, their high rate of turnover in OA and RA can lead to reduced TG expression overtime. Given that chondrocytes exhibit slower turnover during OA pathogenesis (particularly in early stages of disease), they may be a more relevant target for gene therapy when using nonintegrating viral vectors. However, chondrocytes do not express CAR, the major AdV receptor, and while transduction using these vectors can be achieved, it requires much higher doses than other tissues. To overcome this obstacle, Ruan and colleagues conjugated a monoclonal antibody against α-10 integrin (a10mab) to a HDV with biotin acceptor peptide-modified fibers. α-10 integrin is the surface receptor forCOL2 and is expressed by chondrocytes of the joint. In this study, the authors demonstrated that these fiber-modified vectors could successfully retarget the TG of interest to chondrocytes leading to 10-fold reduction in effective dosage[143] (further details later).

5.2.1 Osteoarthritis

OA is a major cause of disability and one of the most common musculoskeletal disorders, with its economic burden on the US health care system alone estimated to exceed $100 billion annually.[144] This degenerative disease of the joint is characterized by loss of articular cartilage, periarticular and subchondral bone remodeling, intraarticular inflammation with synovitis, and pain.[145] To date, no medical therapies are available that markedly alter OA pathogenesis. Instead, current interventions are limited to symptomatic relief of pain, physical therapy and, in end-stage disease, joint replacement.

Articular cartilage displays a limited potential for self-regeneration. As such, anabolic agents such as TGF-β,[146–148] IGF-1,[149–151] FGFs,[151–153] and BMPs (most recently BMP-2 and BMP-4)[147,154–156] have been attractive therapeutic targets. For instance, Mi et al. injected an AdV encoding human IGF-I into arthritic rabbit knee joints and found it was able to maintain a healthy hyaline cartilage phenotype by promoting matrix synthesis without evidence of chondrocyte hypertrophy.[157] However, the joint is composed of other tissues apart from articular cartilage that may be adversely affected by growth factor gene therapy. In this regard, though TGF-β1 acts on chondrocytes to drive cartilage matrix synthesis, its overexpression within the joint causes fibrosis and formation of cartilaginous nodules within the synovial membrane.[158] Taken together, careful dosage tests will be necessary for any anabolic growth factor before clinical trials can proceed, and the effects of various therapeutic interventions on all tissues in the joint must be considered.

Recent work in this field has also focused on using transcription factors, such as the RUNX2,[44] and the cartilage master transcription factors sex-determining region Y (SRY)-box 5 (SOX-5), SOX-6, and SOX-9 (SOX trio)[159,160] as anabolic agents for gene therapy. In this regard, Needham et al. generated gene-activated bilayered scaffolds with an upper layer impregnated with vectors carrying the SOX trio to activate chondrogenesis and a lower layer carrying vectors of RUNX2 to stimulate osteogenesis. The study showed that, contrary to previous studies in which cells were simply cotransfected with the transcription factors, the spatially-distributed combination led to

greater tissue ingrowth and implant degradation.[44] Sieker et al. also utilized implants of autologous bone marrow coagulates transduced with indian hedgehog (IHH), a transcription factor critical for chondrocyte proliferation and maturation, in an osteochondral defect model in rabbit knees. Interestingly, this study showed superior histological repair compared to BMP-2- and green fluorescent protein (GFP)-transduced groups, including improvements in COL2 staining, tissue morphology, and surface integrity.[155]

In addition to deficits in anabolism and tissue regeneration, OA is marked by progressive inflammation and tissue degradation. To address this issue, a plethora of anti-inflammatory and anticatabolic targets have been tested in recent years. While previous work focused primarily on blockade of the IL-1 pathway through use of IL-1Ra,[152] alternative targets and approaches have become more widely investigated. One exciting new trend is the use of siRNA to silence catabolic and/or inflammatory genes.[161,162] Hypoxia-inducible factor-2α (Hif-2α) controls the hypoxic response and has been shown to directly induce the chondrocytes to express a wide variety of catabolic factors. It is also upregulated in OA cartilage where it is thought to play a central role in articular cartilage destruction. Using a chondrocyte-targeting peptide carrying anti-Hif-2α siRNA to knockdown Hif-2α, Pi et al. observed that a multitude of catabolic genes were downregulated, including matrix metalloproteinases (MMPs-13 and -9), aggrecanse-1, as well as other markers of cartilage degradation, such as type X collagen (COL10) and VEGF. When injected into knee joints of mice with surgically induced OA, anti-Hif-2α siRNA improved cartilage protection as demonstrated by decreased Mankin scores, reduced synovitis, and reduced IL-1β.[163]

Components of the extracellular matrix and synovial fluid have also received attention in OA-related gene therapy in recent years. For instance, Ruan et al. showed that both genetic and HDV-mediated overexpression of lubricin (PRG4) in the knee joint significantly delayed disease progression in posttraumatic and age-related models of OA.[142] PRG4, a protein secreted by superficial zone chondrocytes and synovial lining cells, was first described as a chondroprotective factor that provided synovial fluid with the ability to dissipate strain energy produced by loading.[164] In addition to its reported role in joint lubrication, Ruan and coworkers found that PRG4 overexpression could inhibit expression of cartilage catabolic and hypertrophic genes through upregulation of Hif-3α.[142] Moreover, the therapeutic efficacy of PRG4 gene therapy could be enhanced using a fiber-modified HDV that retargeted viral vectors to chondrocytes.[143]

Though many of the approaches described earlier have led to promising therapeutic outcomes in animal models of OA, it is unlikely that this complex disease will respond long term to a single TG; as such, combinatorial therapies have become a focus in this field. While some investigators have focused efforts on testing different growth factor pairs,[153] others have explored combinations of anabolic, anticatabolic, and/or antiinflammatory targets[149,152] with varying degrees of success. For instance, Madry et al. used alginate to deliver NIH-3T3 cells transfected with expression plasmids for either IGF-1 alone or IGF-1 and FGF-2 into osteochondral defects in rabbits, and saw improved articular cartilage repair and enhanced subchondral osteogenesis at the defect site when IGF-1 and FGF-2 were used in combination.[153] Taken together, a combinatorial approach (together with advances in tissue engineering) is likely to have the best chance at effectively treating disease.

5.2.2 Rheumatoid Arthritis

RA affects approximately 1.3 million people in the United States alone; however, despite its economic burden, effective treatment options remain limited and no cure is available. Unlike OA, RA is an autoimmune disorder characterized by a chronic inflammatory state within the joint that leads to cartilage degradation, bone damage, pain, and disability that often present with or are followed by other chronic systemic health conditions, such as cardiopulmonary disorders.[165] Though a complete understanding of the pathogenicity of RA is yet to be elucidated, it is known that there is an interplay of genetic susceptibility and environmental factors leading to a loss of self-tolerance, the development of autoantibodies, and ultimately joint destruction.[166]

There is a greater diversity of targets being investigated clinically for RA gene therapy compared to OA. The first clinical trials for RA gene therapy began in 1996, and others have followed.[167] Still, despite the variability in therapeutic targets, a large percentage of the focus continues to be on antiinflammatory factors, such as IL-10,[168–171] binding immunoglobulin protein,[172] and tumor necrosis factor receptor type II (TNFR-II). Inhibition of TNF-α has shown promising results, which led to FDA approval of TNF-α monoclonal antibodies (infliximab and adalimumab) and a TNF-α soluble receptor antagonist (etanercept). Unfortunately, these TNF-α inhibitors must be administered frequently to maintain therapeutic concentrations within the joint—a need that could be easily met using a gene therapy approach. In this regard, a number of studies have demonstrated the feasibility of anti-TNF-α gene therapy strategy using AdV, RV, and AAV.[173,174] For instance, Chan et al. demonstrated in a streptococcal cell wall rat arthritis model that local (intraarticular) as well as systemic (intramuscular) AAV-mediated expression of TNFR-II fused to the Fc domain of immunoglobulin IgG_1 (TNFR:Fc) decreased inflammatory cell infiltration, pannus formation, cartilage and bone destruction. Furthermore, studies with an AAV expressing TNFR:Fc under the control of the

inflammation-inducible NF-κB promoter demonstrated the possibility of having TG expression specifically during disease flare-ups. This approach is particularly advantageous as it would avoid unwanted expression of immune suppressive agents during disease regression in RA patients. Unfortunately, a 2008 clinical trial of AAV2-TNFR:FC (termed tgAAC94) was halted early when a 36-year-old female trial enrollee succumbed to an infectious disease shortly after receiving her second dose. Postmortem analysis determined that the patient had died from a *Histoplasma capsulatum* fungal infection, a known complication for patients taking TNF antagonists. Since the patient was also taking adalimumab concurrently with the study, it is difficult to determine the specific role, if any, tgAAC94 played in her death. Patient-reported outcome measures showed improvement in 42% of AAV2-TNFR:Fc cases versus 19% in the placebo group. Though the FDA has since cleared the study organizers of wrong doing and allowed the trial to continue, no phase III trial has been scheduled as of yet; in addition, the developing company has changed its name and removed tgAAC94 from the list of pipeline candidates.[175] Another key proinflammatory cytokine induced during RA pathogenesis is Il-1β. The endogenous Il-1Ra can inhibit the effects of Il-1β in inflammatory conditions and has displayed efficacy in various RA models. Consequently, recombinant Il-1Ra has been developed and was approved by the FDA in 2001 for treatment of RA. Given the short in vivo half-life of recombinant IL-1Ra (~4 h), several investigators have begun to test the efficacy of various viral vectors for sustained delivery of IL-1Ra to the joint. For instance, synoviocytes transduced ex vivo with RV-expressing Il-1Ra prevented disease progression in mouse and rabbit RA models.[176,177] Also, direct intraarticular injection of an Il-1Ra-expressing AdV abrogated disease activity in an autoimmune arthritis mouse model. Finally, other groups have attempted to directly modulate the immune response by targeting Th-17 cells[178–180]

While inflammation is a logical target for treatment of RA, some groups are attempting to address other aspects of disease pathogenesis. The aggressive, tumor-like proliferation of fibroblast-like synoviocytes during RA progression has led to testing of tumor-suppressive agents. Specifically, the rapid expansion of fibroblast-like synoviocytes is known to be triggered by activation of phosphatidylinositol 3-kinase (PI3K)/AKT and Ras/extracellular signal-regulated kinase (ERK) signaling pathways, which results in massive upregulation of inflammatory cytokines and MMPs. Zhang et al. attempted to alter this proliferative and catabolic phenotype by overexpressing Sprouty2 (SPRY2), a known inhibitor of the PI3K/AKT and Ras/ERK cascades.[181] In these experiments, rats were treated with AdV-SPRY2 (or AdV-GFP) 7 days following induction of adjuvant-induced arthritis. The authors observed that joint swelling and rigidity were reduced in mice treated with AdV-SPRY2 compared to the controls; further, proinflammatory cytokine production, synovial hyperplasia, and cartilage degradation were diminished.[181]

In addition to synovitis, RA is marked by extensive bone loss owing to overactivation of osteoclasts. As such, a number of recent investigations have looked at modifying disease progression by suppressing osteoclast activity through overexpression of OPG.[182,183] In this regard, Zhang et al. injected collagen-induced arthritis rats with an AdV-OPG at both early and established arthritis time points. The authors determined that cartilage degradation enzymes, proteoglycan loss, and chondrocyte apoptosis were inhibited by the treatment; however, overall cartilage destruction was only improved in the early treatment group. Additionally they found, in alignment with previous studies, that the treatment had no impact on swelling or inflammation.[182] Thus, similar to findings for OA, this study further emphasizes the importance of combinatorial treatments for modification of joint disease pathogenesis.

5.3 Tendon

Tendons are viscoelastic tissues that function to transmit force from muscular contractions to the skeleton.[184,185] The extracellular matrix of tendon is composed primarily of COL1 as well as smaller quantities of other collagens, elastin, and proteoglycans.[186] Following injury, tendons heal incompletely leading to formation of scar tissue and inferior biomechanical properties compared to uninjured tissue. In addition to partial and complete tears, tendons often rupture at their insertion into bone (termed the enthesis). Further, tendons can develop adhesions, which interferes with gliding leading to compromised function.

Similar to strategies for bone healing, the gene therapy field has targeted a variety of growth factors and intracellular signaling mediators to improve tendon repair. BMP-12 has been found to induce transformation of soft tissue into ligament- or tendon-like tissue,[187] and transduction of primary chicken tendon in vitro with AdV expressing BMP-12 induced Col1 synthesis.[188] Moreover, in an in vivo model of complete flexor digitorum profundus laceration, injection of an AdV expressing BMP-12 led to significantly greater ultimate failure force and stiffness compared to controls. Similar to BMP-12, BMP-13 overexpression has been shown to drive ligamentous differentiation in MSC cultures.[189] Moreover, in vivo BMP-13 gene therapy promoted tendon healing more effectively compared to platelet-rich plasma (contains growth factors, such as TGF-β) and control AdV in an injured rat supraspinatus model.[190] In addition to BMPs, delivery of pIGF-1 DNA to wounded rat Achilles

tendon improved histological and biomechanical properties during healing compared to controls, suggesting that IGF-1 may be an interesting candidate for healing of midtendon injury.[191]

Apart from midtendon damage, failure following excessive or repetitive loading often occurs at the enthesis. Interestingly, osteogenic factors with proven efficacy in bone healing following fracture also enhance repair at this site. For instance, a rat cell line transfected with pBMP-2 mixed with calcium alginate gel and implanted within the tunnel formed during tendon grafting improved osteointegration and vascularization compared to control.[192] With respect to intracellular targets, application of RV-expressing COX-2 during surgical repair of the tendon enthesis enhanced angiogenesis, osteointegration, and pull-out strength of the tendon graft.[193] Further, two separate studies examining in vivo Sox9 and ex vivo Scx (tendon master transcription factor) gene therapies demonstrated improved biomechanical strength at the enthesis with minimal alterations to histological appearance compared to controls.[194,195]

While gene therapy approaches to improve healing of tendon injuries have shown promising results, only very few TGs in a limited number of studies have been evaluated. With increased understanding of the underlying molecular biology of tendon development and disease, it is the hope that more gene therapy targets for ligament and tendon healing might be identified in the future.

5.4 Intervertebral Disc

Intervertebral discs (IVD) are elastic structures found between vertebrae composed of the annulus fibrosis on the exterior and the nucleus pulposus (NP), its inner gel-like center. The NP is avascular with its extracellular matrix composed primarily of proteoglycans and COL2, and serves as a pressure distribution pad for the spinal column. During IVD degeneration, the size of the NP decreases leading to increased strain on the annulus fibrosis, which increases in size to compensate. The extracellular matrix of the NP condenses and is slowly replaced with a more fibrous tissue. All of these changes serve to alter the biomechanical properties of the disc and is one of the leading causes of lower back pain.[196]

As in OA, much attention has been paid to targeting growth factors to improve regeneration, including the TGF-β superfamily,[197] growth and differentiation factor 5 (GDF-5),[198] and IGF-1.[199] The goal of treatment with growth factors is to induce proliferation of NP resident cells, reduce apoptosis, and induce extracellular matrix production (proteoglycans, COL2, and aggrecan).[200] The BMP family is also a common target, with labs investigating BMP-2[201] and BMP-7.[202]

Similar to gene therapy approaches for OA and RA, combinatorial trials using anabolic and anticatabolic targets are becoming more common in this field. Liu et al. tested the in vitro combination of connective tissue growth factor (CTGF) as an anabolic agent and tissue inhibitor of metalloprotease-1 (TIMP-1) as an anticatabolic. CTGF promotes the expression of matrix components and inhibits apoptosis, while TIMP-1 inhibits MMP production. They found that the combination of the two factors increased production of proteoglycans and COL2 over either monotherapy.[203] Yue et al. tested in vivo the combination of survivin, TGF-β3, and TIMP-1 in a rabbit model of IVD disease and found that the combinatorial injection slowed progression of degeneration compared to their empty vector treatment groups. It should be noted though that they did not include any single therapy controls to determine if the combination is empirically better than any single target alone.[204] It is likely that survivin was included in the combination as it is upregulated in cells of patients with degenerative disc disease and knockdown via siRNA in vitro reduced NP cell proliferation and sensitized them to apoptotic stimuli in vitro;[205] however, other groups have shown that overexpression of survivin had no impact in vitro on cell survival.[206]

One target under investigation in this field that is unique from targets being actively investigated for arthritis is the telomerase reverse transcriptase (TERT). TERT is found in stem cells, and was initially used to prolong the activity and expansion of NP cells grown in culture to permit greater production of NP cells for transplantation.[207] Shi et al. have shown that these transduced hTERT-NP cells are also superior to nontransduced NP cells in a dog model as they delay degeneration and preserve structural integrity, matrix composition, and mechanical stability.[208] It will be interesting to see if combinatorial therapy using hTERT-NP cells together with other targets, such as GDF-5 or TIMP-1 can improve upon these results.

6 CONCLUSIONS

Gene therapy has many characteristics that could contribute to improvements in current treatments of skeletal diseases. Importantly, gene therapy confers stable, long-term expression of a therapeutic protein, which otherwise would have to be frequently administered. Many gene therapy approaches have been evaluated in vitro and in vivo in small and large animal models, and a few have been tested in human clinical trials. Due to the wealth of preclinical data, researchers have insight about which TGs might be most useful for certain conditions. Moreover, given the immense evaluation and optimization of various vectors in both in vivo and ex vivo contexts, researchers can now choose the most suitable gene transfer approach for their therapeutic needs. Although the number of clinical trials is still limited, data show that gene therapy for skeletal diseases is safe especially when

ex vivo or local in vivo gene therapies are used. No gene therapy agents have so far been approved by regulatory agencies in the United States; however, Glybera (a treatment for lipoprotein lipase deficiency) was approved in Europe in 2012 and two gene therapy drugs for cancer are on the market in China. More recently, Strimvelis, the first ex vivo stem cell gene therapy for treatment of adenosine deaminase severe combined immunodeficiency, was approved by the European Commission in May 2016. At present, the gene therapy treatments that are the most likely to receive approval treat rare life-threatening diseases, whereas treatments for complex, less life-threatening diseases, such as those discussed here may take more time to gain approval as the regulatory agencies become more comfortable with the concept. The development of safer vectors with long-term expression, such as HDVs and AAVs, and improvements in technologies, such as gene-activated scaffolds, should facilitate the next wave of clinical trials in both ex vivo and in vivo contexts.

Osteoporosis and its consequence of fragility are recognized as a major skeletal disorder, because they are associated with increased risk of mortality and major healthcare costs. The disease affects up to 40% postmenopausal women and 15% elderly men of Caucasian background.[1] From the age of 50, approximately 44% of women and 25% of men will sustain a fracture during their remaining lifetime.[2] Although any bone can sustain a fracture, the residual lifetime risk of hip fracture, often considered the most serious fracture is 8.5% for women and 4% for men.[2] Hip fracture, along with most osteoporotic fractures, is associated with increased risks of subsequent fractures,[3] premature mortality,[4,5] and incurs significant health care cost.[6,7] Moreover, up to 24% women and 38% men will die within the first 3 months after experiencing a hip fracture.[8,9] All types of fragility fracture are associated with loss of independence, loss of quality of life, and premature mortality.[10–12] Survivors after fragility fractures often develop chronic pain, decreased independence, and/or reduced quality of life. Taken together, fragility fracture is a common and serious bone disorder that is expected to increase in magnitude over the next few decades as populations are rapidly aging.

In osteoporosis care, a much anticipated application of the Human Genome Project (HGP) is the translation of genetic discoveries for early identification of high-risk individuals and selection of appropriate therapies for an individual. Osteoporosis offers an interesting case for the application of genetics in risk prediction, because the susceptibility to the disease is determined by genetic and environmental factors. Moreover, osteoporosis is a condition characterized by multiple phenotypes, including worsened bone strength and architecture, and ultimately fragility fracture. Currently, there are multiple treatments and combination of treatments available for reducing bone loss and reducing fracture risk. These are effective in some, but not all individuals. The efficacy and clinical outcome of current therapies are highly variable among patients. How to assess the risk of fracture for an individual (i.e., individualized prognosis), and which treatment is appropriate for an individual (e.g., individualized treatment decision) are among the most pressing questions in osteoporosis research. Pharmacogenetics and pharmacogenomics offer the possibility to individualize fracture prognosis and therapy.

Pharmacogenetics refers to the science of how genetic factors affect the interindividual variation in drug efficacy and safety.[13] A goal of pharmacogenomics is to identify for all human genes, their products, interindividual variation, intraindividual expression, and function over time.[14] The ultimate aim of pharmacogenomics is to select the right treatment for an individual patient and to design new drugs. In reality, most pharmacogenetic studies focus on single genes and their associations with interindividual differences in drug behaviors, while pharmacogenomics is concerned with the genomic interactions among genes in the overall variation in drug metabolism and response. Both pharmacogenetics and pharmacogenomics have important applications in studies of the pathogenesis and treatment of osteoporosis.[15–17]

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00009-5

1 COMPLEXITY OF PHENOTYPES

Osteoporosis has multiple phenotypes, and this presents a challenge for the genetic dissection of the disease. Fracture is a direct consequence of bone fragility and is therefore a key component of an osteoporosis phenotype. However, fracture is a dichotomous event, resulted from cumulative deterioration in multiple tissues, which are in turn linked to genetic and nongenetic factors. Moreover, fracture is age-dependent such that the risk of fracture increases exponentially with advancing age. Theoretically, if the life expectancy of a population were infinite, then the lifetime risk of fracture would be 100%. Therefore, a genetic analysis of fracture as a single phenotype will not adequately capture the dynamics of osteoporosis.

Fracture itself is associated with multiple risk factors, some of which may be causal factors. These factors include advancing age, low bone mineral density (BMD), a personal history of fracture, fall, low body mass index, and interestingly genetic factors.[18] Recent data have shown that the 10-year probability of fracture at the forearm, humerus, spine, or hip increases between ages 45 and 85 as much as eightfold for women and fivefold for men.[19] A prior fragility fracture signals substantially elevated risk of future fracture.[4,20–22] The elevated risk is 1.5- to 9.5-fold depending on age at assessment, number of prior fractures and the site of the incident fracture. Pooling the results from all studies (women and men) and for all fracture sites, the risk of subsequent fracture among those with a prior fracture at any site is 2.2 times that of those without a prior fragility fracture.[22]

BMD, as a phenotype of osteoporosis, is causally related to fracture risk, such that there is a strong, continuous, and consistent relationship between BMD and fracture risk. Each standard deviation (SD) lower BMD is associated with a 1.6-fold increase in fracture risk in both men and women.[23] The magnitude of association between BMD and hip fracture risk (with relative risk being 2.2[24]–3.6[25]) is equivalent to or even stronger than the association between serum cholesterol and cardiovascular disease. Moreover, therapies that increase BMD reduce fracture risk.[26] Given the strong association between BMD and fracture risk, in 1994 the World Health Organization (WHO) expert panel proposed an operational definition of osteoporosis, by which a postmenopausal woman is considered to have osteoporosis if her femoral neck BMD is at least 2.5 SD lower than the mean value in young adults.[27] Nevertheless, in the same way that "hypertension" relates to cut-off value for blood pressure measurements, there is no threshold of BMD that discriminates absolutely between those who will or will not have a clinical event. Hence, a nonosteoporotic BMD does not guarantee that fracture will not occur; only that the risk is relatively lower. Conversely, if BMD is in the osteoporotic range, then fractures are more likely, but still may not occur. Low BMD alone does not completely account for the incidence of fragility fracture. More than 50% of women and 70% of men with a fragility fracture do not have "osteoporotic" BMD.[28] This suggests that factors other than BMD play important roles in the determination of fracture liability.

Biochemical markers of bone remodeling can also be considered phenotypes of osteoporosis. Bone mass is the net result of two counteracting processes of bone resorption and bone formation, often referred to as bone remodeling. Bone remodeling is a normal, natural process that maintains skeletal strength, enables repair of bone damage, and is essential for calcium homeostasis. During the remodeling process, osteoblasts produce a number of cytokines, peptides, and growth factors that are released locally and into the circulation. Their concentration thus reflects the rate of bone formation. Osteoclasts produce bone degradation products that are also released into the circulation; most of these are cleared via the kidney. These include both enzymes and nonenzymatic peptides derived from cellular and noncellular compartments of bone. It has been proposed to estimate bone formation and bone resorption by serum or urinary biochemical markers.[29] These markers include osteocalcin, bone-specific alkaline phosphatase and procollagen I N-terminal telopeptide (PINP) and collagen C-terminal propeptide of type 1 collagen (PICP) for formation and for resorption, urinary excretion of hydroxyproline, pyridinoline (PYR), deoxypyridinoline (D-PYR), collagen type I cross-linked N telopeptide (NTX) and collagen type I cross-linked C telopeptide (CTX). Markers of bone formation and resorption have been shown to be related to bone loss, with higher rates of bone resorption being associated with more rapid bone loss and importantly, with fracture risk.[30–32] However, few genetic studies of osteoporosis have analyzed bone turnover markers as phenotypes.[33,34]

Fragility fracture is also a function of nonskeletal factors, such as fall propensity that is affected by neuromuscular function, muscle strength, and postural sway.[35] Many of these nonskeletal traits are also determined by genetic factors. The liability to fracture is therefore a complex phenotype, in the sense that it is a constellation of bone strength and nonskeletal factors, and each of these factors may be determined by specific genes or sets of genes.[36]

2 GENETICS OF OSTEOPOROSIS

Through several twin and family studies, it is now clear that all osteoporosis phenotypes aggregate in families. A key measure of genetic influence on a trait is the index of heritability, which is defined as the extent to

which genetic differences contribute to individual differences in an observed trait. In a Finnish twin study, approximately 35% of the variance in the liability to fracture (in both males and females) was attributable to genetic factors.[37] In a recent family study, approximately 25% of the liability to one fracture type, that is, Colles' fracture of the wrist, was attributable to genetic factors.[38] Familial analysis within the Study of Osteoporotic Fracture[39] suggests that women, whose mother had had a hip fracture, had a twofold increase in risk of hip fracture compared with controls. The risk of hip or other fractures was threefold higher with a paternal history of wrist fracture. In two small studies of osteoporotic women with vertebral or hip fractures, their daughters had bone density deficits intermediate between their mothers and "expected" at the site of their mothers' fracture, that is, lumbar spine or proximal femur.[40,41] Similar observations have been made in both elderly men and women.[42] In summary, these biometric studies have consistently shown that the liability to fracture is partly determined by genetic factors.

BMD is one of the more heritable traits in human. Indeed, variation in BMD among individuals is largely determined by genetic factors. It has been estimated from twin studies that 70%–80% of variance of BMD measured at the lumbar spine and femoral neck is attributable to genetic factors.[43–45] The heritability of forearm BMD appears to be lower than in the femoral neck or lumbar spine.[46,47] There is also evidence for pleiotropic effects, in which BMD in various skeletal sites is determined by both common and site-specific sets of genes.[36,48] Genetic factors have been shown to contribute significantly to the interindividual variance of bone formation markers (both osteocalcin and collagen C-terminal propeptide of type 1 collagen) in premenopausal twins.[33,34,48]

The involvement of multiple genetic and nongenetic factors suggests that osteoporosis is indeed a complex phenotype. As for many other multifactorial diseases, osteoporosis is also determined by environmental factors, and possibly by the interaction between environmental and genetic factors. Genetic variations do not necessarily cause osteoporosis or fracture, but rather influence an individual's susceptibility to specific environmental factors and so modify the disease risk. The dissection of gene–environmental interaction effects on bone phenotypes is still a major challenge in genetic research.

2.1 Candidate Genes

During the past 2 decades, intensive searches for specific genes linked to osteoporosis phenotypes have been attempted with significant success. Gene-search studies have been based on the two major approaches, initially candidate gene and more recently genome-wide studies.[49] The candidate gene approach has been used within the context of association studies, in which specific DNA variants are analyzed in cases and unrelated controls. This straightforward design has been used extensively in the field of osteoporosis, but it suffers from a number of shortcomings. The selection of appropriate controls can be a challenge, particularly for fractures that occur mainly in later life. The arbitrary classification of BMD into a dichotomous variable (e.g., osteoporosis vs. nonosteoporosis) does not exclude the possibility that a nonosteoporotic individual will develop "osteoporosis" in the future. Any statistically significant association between a specific gene variant and fracture may not necessarily indicate a causative relationship, because such an association can have arisen from population stratification and, even when a gene is associated with the fracture outcome, it may not be the gene studied but due to linkage disequilibrium with a causative gene that can be considerably distant along the chromosome.[50]

Nevertheless, based on this commonly used approach, several gene polymorphisms (including vitamin D receptor, collagen type Iα1, osteocalcin, IL-1 receptor antagonist, calcium-sensing receptor, α2HS glycoprotein, osteopontin, osteonectin, estrogen receptor α, interleukin-6, calcitonin receptor, collagen type Iα2, parathyroid hormone, and transforming growth factor α1 polymorphisms) have been proposed[51] (Table 9.1). However, the decade in which candidate gene association studies blossomed was also accompanied by frustration with conflicting findings and a lack of independent replication, mainly due to, among other factors, lack of statistical power[52] and/or to false positives.[53]

2.2 Genome-Wide Studies

Instead of focusing on a biologically plausible candidate gene, the genome-wide study scans the entire genome to identify chromosomal regions harboring genes likely to influence a trait. Two analytic strategies can be used in genome-wide study: linkage analysis and association analysis. Genome-wide studies, using either linkage or association analysis, are essentially a hypothesis-free approach, because they make no assumptions about the location and functional significance of associated loci or their products, only that there is some locus associated with a phenotype.[85] Genome-wide studies can examine the linkage or association between representative tagging-single-nucleotide polymorphisms (SNPs) spread throughout the genome and the susceptibility of diseases. As such, genome-wide studies can overcome weaknesses of the candidate gene design[86,87] by providing a holistic picture of genes that are likely to contribute to the susceptibility of disease. However, genome-wide studies have the major challenge of multiplicity of hypothesis tests. Since genome-wide

TABLE 9.1 Genes for Osteoporosis [Bone Mineral Density (BMD)] From Candidate Association Analyses

Genes	Gene names	Location	References
ARHGEF3	Rho guanine nucleotide exchange factor 3	3p14-p21	54
COLI1A1	Collagen type I alpha 1	17q21.33	55,56

ZBTB40	Zinc finger and BTB domain-containing protein 40	1p36	66

studies test the hypothesis of association for thousands of alleles, a statistically significant linkage or association is not necessarily a real phenomenon.[86]

Genome-wide linkage studies: Aim at identifying anonymous markers that cosegregate in families with multiply affected members. Linkage analysis is based on the principle that alleles at loci close together will tend to be inherited jointly; therefore, if a marker allele and a locus for a specific trait are close together on the same chromosome they are unlikely to be separated by crossovers during meiosis. A common metric of linkage is the log-of-the-odds (LOD) score, which measures the likelihood of linkage compared with no linkage. A linkage with a LOD score of >3.6 is considered significant at the genome-wide level, while a LOD score >2.2 is usually taken to indicate "suggestive" linkage.[88]

Linkage analysis has been successfully used to map causative genes linked to BMD and fracture. Genome-wide linkage analysis has identified several regions that are linked to variation in BMD (Table 9.2). Linkage analysis of data from a family with osteoporosis-pseudoglioma syndrome (OPPG), a disorder characterized by severely low bone mass and eye abnormalities, was able to localize the OPPG locus to chromosomal region 11q12-13.[89] At the same time, a genome-wide linkage analysis of an extended family with 22 members, among whom 12 had very high bone mass (HBM), suggested that the HBM locus also located within the 30 cM of the same locus.[90] In follow-up studies using the positional candidate approach, both research groups found that a gene encoding the low-density lipoprotein receptor-related protein 5 (LRP5) was linked to both OPPG and HBM.[91–93] The finding that the LRP5 gene is linked to

TABLE 9.2 Linkage Studies of Quantitative Trait Loci for BMD

Studies	Phenotype	Locus/marker	LOD score
Devoto et al.[95]	Hip BMD	1p36 (D1S540)	3.51

	Wrist BMD	4q32 (D4S413)	2.53
Koller et al.[100]	Spinal BMD	1q21-23 (D1S484) 6p11-12 (D6S462) 11q12-13 (D11S987) 22q12-13 (D22S423)	3.11 1.94 1.97 2.13
	Hip BMD	5q33-35 (D5S422)	1.87

HBM was confirmed in a family study that included individuals with exceptionally high BMD but who were otherwise phenotypically normal.[92] This study showed that a missense mutation (G171V) was found in individuals with high BMD.[93] Another family-based study identified 6 novel mutations in the LRP5 gene among 13 confirmed polymorphisms that were associated with different conditions characterized by increased BMD.[94] The conditions included endosteal hyperostosis, van Buchem disease, autosomal dominant osteosclerosis, and osteopetrosis type I. The discovery of the LRP5 gene has opened up a new chapter of research in the genetics of osteoporosis.

Genome-wide association studies (GWAS): Are a powerful approach for searching for genes that are associated with a trait. GWAS can be seen as a hypothesis-free approach that scans hundreds of thousands of common SNPs (minor allele frequency usually greater than 5%) in the entire genome for single SNP associations in an unbiased manner. The basic idea is to test for differences in allelic frequency of anonymous genetic variants between cases and controls, unadjusted for any current understanding of disease etiology. The underlying idea of GWAS is linkage disequilibrium (i.e., association between genetic variants). That is, identified variants may be associated with other variants of potential interest more frequently than expected by chance. The SNP variants may also lie many hundreds of kilobases upstream or downstream from a known putative gene.

Statistically, in the presence of hundreds of thousands of tests, there is the real possibility of false-positive finding in GWAS. Just as with the evaluation of a diagnostic test, where one needs to know specificity, sensitivity, and positive predictive value, the reliability of a statistical association can also be evaluated by three analogous parameters: the observed *P* value, the observed power (sensitivity) given an effect size, and the prior probability of a true association.[101] The *P* value may be viewed as equivalent to the false-positive rate of a diagnostic test; it is the probability of observing the current data (or more extreme data) given that there is no true association. Power is the probability that a study will identify a true association if it exists, which is equivalent to the concept of sensitivity of a diagnostic test. Prior probability is a subjective probability of a true association. Based on these three parameters and by using the Bayesian approach, it is possible to determine the probability of no true association given a statistically significant finding or the false-positive report probability (FPRP).[102] Of the three parameters for evaluating FPRP, the prior probability is the most difficult parameter for which to assign a weight. This probability is dependent on the number of gene variants that affect fracture

susceptibility, which is unknown. Indeed, we do not know how many genes are involved in the regulation of, or are relevant to, the underlying susceptibility to osteoporotic fracture. However, we do know that in the human genome, there are about 3 billion base pairs,[103] and that on average, more than 90% of the differences between any two individuals is due to common variants where both alleles are present in at least 1% of the population.[104] Therefore, it has been hypothesized that the susceptibility to common diseases, such as osteoporosis is caused by relatively few common genetic variants with low effect size (i.e., the "common gene–common variant" hypothesis).[105] Under this hypothesis, it has been estimated that the number of genetic variants that are associated with a common disease is about 100 or less.[106] It has also been estimated that the number of common variants in the human population is about 10 million.[107] Therefore, it may be reasonable to assume that the probability that a randomly selected common variant is associated with the risk of fracture is 1/100,000 or 0.000001. Based on these assumptions, it has been suggested that a claim of association from a GWAS can be made if P value (less than 5×10^{-5})[108] or more stringently, 5×10^{-8}.[109]

Recent GWAS have identified many susceptibility loci for BMD and fracture risk. The earliest GWAS study in osteoporosis examined the association between 71K genetic variants and BMD measured at different skeleton sites, and found evidence of association for 40 SNPs. Although the study was then considered to be underpowered, several SNPs identified in this study were located in potential osteoporosis-associated genes, such as *MTHFR*, *ESR1*, *LRP5*, vitamin D receptor *(VDR*), and *COL1A1* genes.[110] Another GWAS screened 300K variants in an Icelandic population, and found that variants in the *ZBTB40*, *ESR1*, *OPG*, *RANKL* genes, and those in a novel region 6p21 were significantly associated with BMD at genome-wide threshold ($P < 5\times10^{-8}$).[70] This study also suggested some loci associated with fracture risk, including variants in the 1p36, 2p16, *OPG*, *MHC*, *LRP4*, and *RANK.* In the meantime, a GWAS in United Kingdom and Rotterdam cohorts found that variants in the *TNFRSF11B* and *LRP5* genes were associated with BMD, and the *LRP5* gene was also associated with fracture risk.[111]

Two metaanalyses of GWAS showed that variants in the *ZBTB40*, *ESR1*, *LRP4*, *LRP5*, *TNFSF11*, *SOST,* and *TNFRSF11A* genes were associated with BMD,[66,112] and that variants in the *LRP5*, *SOST*, and *TNFSF11A* were associated with fracture risk.[66] The latest metaanalysis involving 81,949 cases and 102,444 controls, identified 56 loci that are associated with BMD and 13 of these 56 loci were associated with fracture.[113] Overall, 60 loci have been found to be associated with BMD, and 15 loci associated with fracture.[114]

Whole genome sequencing (WGS): The search for genes associated with osteoporosis has been driven by two competing hypotheses: common disease–common variant hypothesis and common disease–rare variant hypothesis. The common disease–common variant hypothesis postulates that the susceptibility to common disease is determined by multiple common genetic variants (e.g., more than 5% minor allele frequency), each with low penetrance (or low magnitude of association). On the other hand, the common disease–rare variant argues that the susceptibility to disease is caused by multiple rare variants, each with high penetrance. The common disease–common variant hypothesis really underlies the GWAS approach. In recent years, remarkable progress in genome-sequencing technologies has facilitated a more thorough examination of exonic regions of the chromosome, which code for functional proteins, to identify potentially causative genes. Sequencing determines every nucleotide in a DNA sequence, including rare mutations that GWAS cannot identify. Therefore, in theory, these approaches, termed whole exome sequencing and WGS, are more likely to identify rare genetic variants that have a greater effect size. It has been proposed that between 80% and 90% of inherited disease-causing mutations are located within protein coding regions. If this was the case then, by analyzing just 1% of the genome using whole exome sequencing, it would be possible to identify almost 90% of disease-causing mutations.

Using WGS approach with extensive data from the UK10 Project, a genetic variant near the EN1 gene was discovered to have strong effect on BMD and fracture risk. This variant (rs11692564, located in noncoding regions) has a minor allele frequency of 1.6%, but the allele was associated with 0.2 SD higher lumbar spine BMD, and a 15% lower odds of fracture.[115]

Another successful application of WGS is the recognition of variants of the LGR4 gene associated with BMD and fracture risk. LGR4 is a member of the G protein-coupled receptor (GPCR) superfamily, which has various roles in development. Using WGS approach, a rare nonsense mutation in the LGR4 gene was found to be associated with BMD and fracture risk[116]; as previously identified in GWAS.[68] A recent study also making use of the WGS technology found two rare missense mutations (p.Gly496Ala and p.Gly703Ser) in the COLIA2 gene, a gene that is known to be associated with osteogenesis imperfecta.[117] Both variants were associated with 0.5–0.9 SD lower BMD and increased fracture risk (odds ratio = 4.4 for p.Gly496Ala and 7.0 for p.Gly703Ser).

2.3 Pathways

The genes identified by GWAS and WGS so far are involved in four main pathways: the RANK-RANKL-OPG

pathway (*TNFRSF11B*, *TNFRSF11A*, and *TNFSF11* genes); the Wnt-β-catenin pathway (*LRP5*, *LRP4,* and *SOST* genes); the estrogen endocrine pathway (*ESR1* gene); and the 1p36 region (*ZBTB40* gene) (Table 9.3).

The RANK-RANKL-OPG system was independently discovered by four groups in the 1990s,[128–131] and has since led to major advances in the understanding of the pathogenesis of osteoporosis. The system is involved in the regulation of bone modeling and remodeling, such that RANK/RANKL signaling controls the formation of osteoclasts from their precursors, whereas OPG by binding to RANKL protects the bone from excessive bone resorption.[132] The genes in the RANK-RANKL-OPG pathway include *TNFRSF11A* and *TNFSF11* genes encoding RANK and RANKL, respectively. The genes are members of the TNF superfamily. Binding of RANKL to RANK stimulates the formation and differentiation of osteoclasts, which in turn increase bone resorption.[133] OPG is an inhibitor of this pathway that binds to RANKL and prevents the interaction between RANKL and RANK. Genetic variants within the *TNFRSF11A* gene[134] and *TNFRSF11*[134] and *OPG*[79,134] were found to be associated with BMD and fracture in both candidate gene association studies and GWAS.[68,70]

The Wnt-β-catenin signaling pathway: Wnts are secreted glycoproteins that bind to receptors of the Frizzled and LRP families on the cell surface. Wnt proteins constitute a family of secreted signaling molecules that control cell–cell interactions during development. The Wnt signal is transduced to β-catenin, which enters the nucleus and forms a complex with TCF to activate transcription

TABLE 9.3 Some Key BMD-Associated Genes From Genome-Wide Association Studies (GWAS)

Genes	Gene names	Location and SNP	References
ADAMTS18	A disintegrin and metalloproteinase with thrombospondin motifs 18	16q23; Rs16945612	118
ALDH7A1	Aldehyde dehydrogenase 7 family	5q31; Rs13182402	119
CTNNB1	Catenin (cadherin-associated protein), beta 1	3p21; Rs7935346	70
CRHR1	Corticotropin releasing hormone receptor 1	17q12-q22	112
DCDC5	Doublecortin domain containing 5	11p14.1	112
FAM3C	Interleukin-like EMT inducer; predicted osteoblast protein	7q31; Rs7776725	120
FLJ42280	Putative uncharacterized protein FLJ42280	7q21.3	112
GPR177	Wntless homolog (*Drosophila*)	Chr 3; Rs2306033	70
IL21R	IL-21 receptor	16p11; Rs8057551 Rs8061992 Rs7199138	121
JAG1	Protein jagged-1	20p12.1-p11.23; Rs2273061	122
MARK3	Microtubule affinity-regulating kinase 3	Chr 12; Rs2010281	70,112
MEF2C	Myocyte enhancer factor 2C	13 45.0 cM	112
MHC	Major histocompatibility complex	6p21; Rs3130340	70
OSBPL1A	Oxysterol binding protein-like 1A	18q11.1; Rs7227401	123
PLCL1	Phospholipase C-like 1	2q33; Rs2278729	124
RAP1A	RAP1A, member of RAS oncogene family	1p13.3; Rs494453	123
RTP3	Receptor (chemosensory) transporter protein 3	3p21.3; Rs7430431	125
SFRP4	Secreted frizzled-related protein 4	7p14.1; Rs1721400	120
SOX6	SRY-box containing gene 6; transcription factor SOX-6	11p15.3; Rs297325, Rs4756846	126
SP7	Transcription factor 7	Chr 15	68
STARD3NL	STARD3 N-terminal like	7p14-p13	112
TBC1D8	TBC1 domain family, member 8	2q11.2; Rs2278729	123
TGFBR3	TGF-beta receptor type 3	1p33-p32; Rs7524102	68,70,126,127

of Wnt target genes.[135] Mutations in Wnt-signaling pathway result in birth defects, cancer, and other diseases. In bone metabolism, the Wnt pathway contributes to the process of bone formation by regulating the differentiation and proliferation of osteoblasts, and bone mineralization. Expression of the *LRP5* gene, which is an element of this pathway, signals into the nucleus to activate bone formation. The *LRP5* gene was identified as a candidate gene of BMD[136] and fracture risk.[111,137] Although several polymorphisms in the *LRP5* gene have been studied, variants in exon 9 (V776M) and exon 18 (A1330V) are the two most widely investigated.[138] An inhibitor of the Wnt-pathway, SOST, was also a candidate gene of osteoporosis. Expression of *SOST* was found to inhibit bone formation by preventing the binding of Wnt to LRP5.[139] Polymorphisms of the *SOST* gene were associated with BMD variation in both a candidate gene study[76] and GWAS.[68]

The estrogen pathway: The estrogen endocrine pathway has long been known to play a key role in the formation and maintenance of bone mass.[140] The *ESR1* gene has been shown to be a candidate gene for the genetic effect on BMD[141] and fracture risk[141–143] in several populations. Moreover, polymorphisms of the *ESR1* gene were found to be associated with bone loss.[144] Although the mechanism of effect of these genetic variants on BMD is unclear, intronic variants in this gene are thought to exert an effect on the efficiency of gene transcription.[145]

The 1p36 region: The chromosomal region 1p36 has been implicated in the regulation of bone mass by linkage analysis.[95,146] The *ZBTB40* gene situated in this region was identified as a candidate gene for BMD variation in some recent GWAS[68,70] and in metaanalysis.[112] However, any function of the *ZBTB40* in bone homeostasis is still largely unknown.

Apart from the aforementioned pathways, genes in the endochondral ossification pathway have also been shown to be associated with BMD or fracture. Endochondral ossification is a major embryonic process of bone formation,[147] in which osteoblasts deposit collagen and noncollagenous proteins on a cartilaginous template, which subsequently mineralizes. GWAS have identified several genes in this pathway, including genes involved in the development of cartilage, cartilage ossification, and osteoblast differentiation: *IBSP, PTHLH, RUNX2, SOX6, SOX9, SPP1*, and *SP7*.

3 GENE–GENE INTERACTION AND "MISSING HERITABILITY"

Genetic variants identified so far from candidate gene and GWAS studies explain only a modest proportion (less than 3%) of the variance in fracture liability[112] raising the question of "missing heritability." This "missing heritability"[148,149] has also been observed in other heritable conditions, such as cancer[150] and cardiovascular diseases.[151]

In most genetic studies of fracture, the association between putative loci and fracture risk has been analyzed in a one-by-one SNP strategy, where the effect of each SNP on fracture risk is assumed to be independent from the effect of other SNPs. If a SNP itself is sufficient to confer an increased risk of fracture, it can be detected by comparing the frequency of the variant in fracture and nonfracture group. However, if a SNP confers an increased risk of fracture only in the presence of other SNPs, then they can only be detected when these variants are analyzed simultaneously by modeling their gene–gene interactions. At the individual level, gene–gene interaction predicts that two individuals can have different fracture risk even if they share the same genotype at one locus. At the population level, epistasis suggests that heterogeneity and incomplete penetrance of fracture is expected. Therefore, the "missing heritability" may be explained by the presence of gene–gene interaction effects that have not been taken into account in previous studies.

Gene–gene interaction is defined as the effect of a genetic variant being modulated by a variant or variants of other genes on the same or different chromosomes.[152] Gene–gene interaction can result in differences in genetic penetrance, and mask the effect of putative genes. Thus, a SNP may not be associated with a phenotype in a single analysis, but it is associated with the phenotype in the presence or absence of another SNP. Although gene–gene interaction is recognized as a ubiquitous phenomenon in the genome,[153] it is difficult to detect the effect due to the lack of powerful methodology and generally insufficient sample size.[154] Current linear statistical genetic methods used for analyzing and detecting gene—phenotype association in human populations are not sensitive enough to detect nonlinear interacting effects due to the combinatorial complexity of gene–gene and gene–environment interactions. The complexity is even more formidable if one considers data from multiple genes (rather than two genes), with higher dimensional values leading to very large number of comparisons, resulting in an increase in type I errors. In linkage scans in humans, testing 400 markers for pairwise epistasis involves testing 79,800 combinations. In GWAS, more than 10^{11} two-marker combinations may need to be studied; for three-marker interactions more than 10^{16} possible combinations are involved. As linkage studies in common human diseases in particular have low power to identify the genetic effects from single loci, it is easy to understand why the power to detect epistasis is very low, and why few reported interactions have been confirmed in subsequent studies.

4 PHARMACOGENETICS OF THERAPEUTIC RESPONSE

During the past 2 decades, several major advances in the treatment of osteoporosis have been made with many therapeutic options available. Antifracture therapies can be broadly divided into two groups: antiresorptive and bone-forming (anabolic) agents.[26] The former decreases bone turnover, while the latter increases bone formation. The antiresorptive agents include bisphosphonates (e.g., alendronate, risedronate, clodronate, etidronate, ibandronate, zoledronic acid, raloxifene, and calcitonin), while anabolic agents include teriparatide (recombinant human parathyroid hormone)[1–34] and possibly strontium ranelate. Both types of agents have been shown to reduce fracture risk for some, although not necessarily all, fragility fractures.[155] In most clinical trials, the relative risk reduction in fracture incidence has been 25%–60% with significant variability in response across individuals and across fracture sites.

The variation in individual clinical response to osteoporosis treatment is also present in BMD. Indeed, the SD of change in BMD induced by antiresorptive drugs is up to twice the mean rate of change. As a result, while the majority of patients experience an increase in (or stabilization of) BMD, a small proportion (perhaps up to 10%) of patients apparently still lose bone.[156] Thus, although few patients experience absolutely no therapeutic effects following typical antiresorptive treatment, no treatment completely prevents bone loss and none prevents all fractures.

While patients' characteristics, such as age, gender, ethnicity, and concomitant disease may affect drug response, genetic factors may also determine an individual's response to pharmacological therapy for each specific drug.[157] Indeed, there is considerable evidence suggesting that genetic factors affect the variability in drug response.[158] For example, in studies of twins, identical twins were more similar than nonidentical twins with regard to the plasma half-life of numerous drugs, providing the best experimental indication of strong genetic components in drug elimination.[159] Genetic information can, thus, potentially be used to identify patients who are likely to respond (or not respond) to pharmacological therapy.[160]

Some drugs used in osteoporosis therapy, bisphosphonates, for example, are not subject to metabolism, but absorption, which is poor for oral bisphosphonates could be affected. Other therapies are metabolized to active components or as part of their elimination pathways. During the past 2 decades, there have been at least 20 studies on the association between genetic polymorphisms and response to antiresorptive therapies. Almost all studies have focused on genes identified from the candidate gene association analysis (e.g., VDR, COLIA1, LRP5), and used BMD change as an endpoint. All these studies were based on small sample sizes, thus "significant" associations observed may not be good evidence for a true association. On the other hand, a statistically nonsignificant association is more likely inconclusive rather than reliable evidence of no association. Some key findings of pharmacogenetic studies are summarized in Table 9.4, and can be highlighted as follows:

Response to hormone replacement therapy (HRT): HRT has been used in the treatment of osteoporotic patients, and can effectively increase BMD[173] and reduce fracture risk. Results of a metaanalysis of randomized controlled trials (RCT) suggested that postmenopausal women on HRT had lower risk of nonvertebral fracture (relative risk: 0.74; 95% confidence interval: 0.56–0.94), and the effect was particularly pronounced in women younger than 60 years.[174] However, it was estimated that 8% of women on HRT were nonresponders.[175]

Recent studies have attempted to elucidate the differential effects of HRT on BMD, and results suggested that polymorphisms of the estrogen receptor alpha (ERα), VDR, and MTHFR genes might be involved in the determination of responders versus nonresponders. Short TA repeat alleles at the promoter of the ERα gene (rs3138774) have been reported to be associated with reduced BMD and increased risk of fracture.[142,176] A study on 79 postmenopausal women on HRT for 3 years, carriers of *PP* and *XX* genotypes of the ER gene responded with higher increases in BMD at the lumbar spine and femoral neck.[177] This finding had also been previously noted in a Thai study on 124 women, among whom those with the *P* allele had greater increases in BMD.[178] Furthermore, among postmenopausal women on equine estrogen alone or in combination with medroxyprogesterone, those with short TA alleles responded with greater increases in BMD at the lumbar spine.[179] However, this interesting finding was not replicated by others.[144,180–186]

A series of studies by Palomba and coworkers[134–136] suggested that among postmenopausal women who were on HRT treatment, the *b* allele of the VDR Bsm-I polymorphisms was associated with a greater increase in BMD than those carriers of the *B* allele. Moreover, Deng[127] and Kurabayashi[129] observed that postmenopausal women treated with equine estrogen for at least 3 years, women with TT genotype (which is in high linkage disequilibrium with the BsmI bb genotype) responded with greater increases in lumbar spine BMD. There was no significant effect of Sp1 genotypes within the COLIA1 gene on BMD changes among women treated with estradiol.[187]

Response to selective estrogen receptor modulators (SERMs): SERMs are FDA-approved for the treatment

TABLE 9.4 Studies on Association Between Candidate Genes and Response to Treatment

Genes	Drug studied	Phenotype	Main findings
VDR	Raloxifene	BMD changes	GG genotype was associated with higher increase in lumbar spine BMD[161]
VDR	Etidronate	BMD changes	GG genotype was associated with higher increase in lumbar spine BMD[162]
VDR	Alendronate + HRT, Alendronate + Raloxifene, Alendronate or Teriparatide	BMD changes	Patients with AG and GG genotypes had greater increase in BMD[163,164]
ER	Raloxifene	BMD changes	Patients with PvuII PP genotype were associated with higher increase in BMD[165]
ER	Etidronate	BMD changes	No significant association[166]
COLIA1	Etidronate	BMD changes	GG genotype was associated with greater increase in femoral neck BMD[167]
COLIA1	HRT	BMD changes	GG genotype was associated with greater increase in femoral neck BMD[168]
FDPS	Alendronate or Ibandronate	BMD changes	Patients homozygous CC genotype for rs2297480 had a decreased response of bone turnover markers[169]
FDPS	Alendronate or Risedronate	BMD changes	Suggestive association between GGPS1 −8188A ins/del polymorphism and femoral neck change in Korean women[170]
LRP5	Risedronate	BMD changes	No statistical association between polymorphism within the gene and response to treatment[171]
OPG	Alendronate	BMD changes	BMD change at the intertrocher was higher in women with AA genotype, but at site T245G, the change was higher in women with the TT genotype[172]

of osteoporosis, with a significant efficacy.[188] Among patients on raloxifene, carriage of the *B* allele (of the VDR) was associated with a greater increase in BMD than the *b* allele carriers.[161] Among those on combined alendronate and raloxifene there was no significant association between VDR polymorphisms and BMD change. These results illustrate the potential for interaction between VDR polymorphisms and various antiresorptive drug therapies in BMD change.[164]

Response to bisphosphonates: Oral bisphosphonates are considered first-line treatment for osteoporotic patients. RCT have consistently shown that bisphosphonates can increase BMD or prevent bone loss and reduce fracture risk,[189,190] including hip fracture risk.[191] However, as in the case of estrogen and HRT, not all patients respond to bisphosphonate therapy, and it is hypothesized that genetic factors partially account for the variation between responders and nonresponders. Studies by Palomba and coworkers[161,163,164] suggested that among postmenopausal women on alendronate, carriers of the *b* allele of the VDR Bsm-I polymorphisms had greater increase in BMD than those carriers of the *B* allele.

The response to bisphosphonate therapy may also be associated with the collagen I alpha 1 (COLIA1) gene which has been shown to be associated with variation in BMD and fracture risk.[192] In a study on 108 perimenopausal women with osteopenia who were randomized to receive cyclical etidronate (a bisphosphonate) or placebo, femoral neck BMD increased in carriers of the Sp1 (dbSNP rs1800012) SS genotype (~64% in the population) but decreased in those carrying the *s* allele (Ss and ss genotypes).[167] It should be noted that this Sp1 polymorphism has also been reported to be associated with the response to human growth hormone in men and women with growth hormone deficiency:[193] Individuals with the SS genotype required a higher subcutaneous dose than those with the ss genotype.[193] However, because these studies were based on relatively small sample sizes and the confidence intervals of effect size were wide, no definite conclusion on the association between the Sp1 polymorphism and drug response can be reliably inferred.

There is evidence that genetic variants in the *VDR* gene influence intestinal absorption of calcium leading to an effect on bone mass.[194,195] In a longitudinal study of calcium supplementation in the elderly, participants with *VDR Bsm*I variant carrying BB genotype had a higher proportion of bone loss at lumbar spine than those with Bb and bb genotypes.[196,197] Women with BB genotype were also found to have reduced efficiency of calcium absorption on a regimen of low calcium intake.[198] Looked at another way, these results imply that people with BB genotype might be more likely to respond to a calcium-rich diet.

Osteonecrosis of the jaw (ONJ): Apart from antifracture efficacy, bisphosphonates are commonly used in the management of patients with advanced cancers that have metastasized to the bone, who are at high risk of bone pain and fractures. Several cancers can involve or metastasize to the bone, including lung, breast, prostate, multiple myeloma, and others. In cancer chemotherapy, bisphosphonates are given intravenously, and usually in more frequent and much higher cumulative doses than used in osteoporosis treatment. In these patients with cancers, there is a risk of ONJ. The risk of ONJ in osteoporosis treatment is much lower than in the cancer therapy situation and arguably even if it occurs is much less clinically severe. During the past 20 years, there have been 368 cases of ONJ reported to be associated with bisphosphonates treatment; among whom ~95% occurred in patients with myeloma or breast cancer.[199] In a study on more than 260,000 patients with cancers of the breast, lung, and prostate and who had been on bisphosphonates, the investigators found 224 ONJ cases; an incidence of 0.3%.[200]

The risk of bisphosphonates-related ONJ is associated with genetic factors. In a genome-wide association study on 22 cases of ONJ and 65 age-matched controls, by screening >500,000 SNPs, the investigators reported 4 SNPs (rs1934951, rs1934980, rs1341162, and rs17110453) mapped within the Cytochrome P450-2C gene (CYP2C8) to be associated with the risk of ONJ.[201] The relative risk of ONJ associated with each of the SNPs ranged between 10 and 13.[201] However, in a subsequent study,[202] the association between rs1934951 and ONJ risk was not confirmed. In another recent GWAS study on 30 cases of ONJ and 60 genetically matched controls, it was found that the SNP rs17024608 within the RBMS3 gene was associated with ONJ risk ($P < 7 \times 10^{-8}$). Individuals positive for the SNP rs17024608 were almost 6 times more likely to develop bisphosphonates-induced ONJ.[202] However, further studies using case control and cohort design found no clear association between the risk of ONJ and variants in the RBMS3, as well as IGFBP7, ABCC4 genes,[203] CYP2C8,[201] COLIA1, RANK, MMP, OPG,[204] FDPS,[205] or MMP2 gene [206] (Table 9.5).

In summary, most studies of genetics of therapeutic response have been largely based on the candidate gene approach, with limited sample size. Experience in the candidate gene association studies of fracture suggest that this type of design has often yielded conflicting findings and poor replication, mainly due to lack of statistical power[52] and false positive.[207] Therefore, all of the reviewed findings are somewhat mixed, and yet to be replicated in independent samples. Moreover, cost-effectiveness studies are needed to optimize the selection of therapies.

TABLE 9.5 Summary of Findings From Genetic Analysis of Bisphosphonates-Induced Osteonecrosis of the Jaw (ONJ)

Author	Design and participants	Genes	Main findings
Sarasquete et al.[201]	Case-control; multiple myeloma, 22 cases and 65 matched controls	CYP2C8	Three SNPs within the CYP2C8 gene (rs 1934951, rs1934980, rs1341162, and rs17110453) associated with increased risk of ONJ
Nicoletti et al.[203]	35 cases and 18 controls	RBMS3, IGFBP7, and ABCC4	Suggestive association
Such et al.[202]	Case-control; multiple myeloma, 9 cases, and 79 matched controls	CYP2C8	No statistically association between SNP rs1934951 and ONJ
Katz et al.[204]	Cohort study, patients with multiple myeloma on intravenous bisphosphonate	COLIA1, RANK, MMP, OPG, OPN	Trend of statistical significance
Marini et al.[205]	Case control study. 68 patients with multiple myeloma or metastatic cancers receiving bisphosphonates	FDPS	SNP rs2297480 significantly associated with risk of ONJ
Lehrer et al.[206]	Case series, 7 patients with ONJ and were on bisphosphonates.	MMP2	No data, only hypothesis of association

5 TOWARD INDIVIDUALIZED ASSESSMENT AND INDIVIDUALIZED TREATMENT DECISIONS

Osteoporosis research is entering an exciting phase of translation of highly promising research findings into clinical applications. Within the translational domain, models for predicting individuals at high risk of fracture have been developed. Given the availability of multiple treatments and their associated, albeit uncommon, adverse events, there is also clearly a pressing need for research to guide treatment decisions and predict patient responses to drugs. Pharmacogenetics and pharmacogenomics can be applied to address these needs.

Using established clinical risk factors, a number of predictive models have recently been developed and implemented.[208–210] The predictive accuracy of these models have been less than perfect, with the area under the receiver operating characteristic curve ranging between 0.70 and 0.80.[209,210] Most predictive models have low sensitivity and high specificity. Thus, there is room for further improvement of prognostic accuracy of the current models by incorporating genetic markers.

There are potentially major advantages of using genetic markers as a prognostic factor of fracture risk. First, since an individual's genotype is time-invariant, it is easier to estimate its effect size and to incorporate its information into a prognostic model. Furthermore, the time-invariant nature of genotypes can be used in the prediction of fracture at a younger age well before the conventional risk factors, such as BMD become informative. Second, as the association between a genetic variant and fracture risk appears to be independent of clinical risk factors, the use of such a genetic marker can potentially improve predictive value. Third, although there is no "genetic" therapy for individuals at high risk of fracture, the use of genetic markers could help segregate individuals at high risk from those with low risk of fracture, and thus help manage the burden of osteoporosis in the community.

The translation of genetic research into clinical applications faces challenges, particularly in relation to the effect size of genetic variants. Two common features of the genes identified so far are that their allelic frequency in the general population is highly variable (ranging from 1% to 61%), and the effect size is very small, with relative risk ranging between 1.05 and 1.5. In the presence of such small effect sizes, it can be anticipated that the contribution of any single genetic variant to fracture prediction is minimal. Even for a gene conferring a relative risk of 3, the AUC attributable to this gene is barely 0.51 (in the absence of clinical risk factors). Even with five genes, each conferring a relative risk of between 2 and 3, the AUC is still 0.60, which is not useful for predicting fracture. These findings are in part driven by the fact that genes variants of larger effect size are inherently (mathematically) more rare. This finding suggests that the contribution of any single gene to fracture prediction, no matter how large the effect size, is likely limited and may be of limited use in the clinical setting. However these analyses do not exclude the likely combination of common gene variants of small effect size with less common variants of larger effects size. Since the currently identified risk-associated allele of the genes related to fracture risk have low penetrance, the combination of multiple genes could be used to develop clinically useful tests. Our recent work suggests that the integration of genetic profiling, either in the form of a genetic risk score or individual genes, into the current prognostic models could significantly improve the predictive accuracy of fracture risk for an individual. Our recent simulation study suggested that a profile of up to 25 genes (each with relative risk of 1.1 to 1.35 and gene frequency ranging from 0.25 to 0.60) in the presence of clinical risk factors—with or without BMD—could achieve an AUC of 0.80, indicative of clinical usefulness.[211] Until now, very few genes have been implicated in the determination of fracture risk. A recent metaanalysis of 150 SNPs found that only 5 SNPs from 4 genes were consistently associated with fracture risk with RR ranging from 1.1 to 1.4.[66] Although a single gene may not help, a genetic profile of multiple genetic variants could help improve the assessment of fracture risk. Indeed, 2 empirical studies in postmenopausal women of Korean background reported that the genetic profile of 39 SNPs in 30 human genomic loci could increase the precision of nonvertebral fracture prediction and help to define the risk threshold[212] while 35 risk alleles were significantly associated with the risk of vertebral fracture[212,213] in patients on bisphosphonate. Taken together, these results suggest that genetic profiling may be useful in the identification of high-risk individuals.

The aim of individualized prognosis is to provide an accurate and reliable prognosis of fracture for an individual, and to help improve the management of the individual's predisposition to fracture. At present, individuals with low BMD (i.e., *T*-scores less than −2.5) and/or with a history of prior low trauma fracture are recommended for therapeutic intervention.[214,215] This recommendation is logical and appropriate, since these individuals have higher risk of fracture,[24,216] and treatment can reduce their risk of fracture.[191,217,218] However, because fracture is a multifactorial event, there is more than one way that an individual can attain the risk conferred by either low BMD or a prior fracture.[219] Moreover, each individual is a unique case, because no "average individual" exists in the population. The uniqueness of an individual can be defined in terms of the individual's environmental and genetic profile. Thus, the knowledge of genetics, in combination of clinical risk factors, could shift the current risk stratification (i.e., "one-size-fits-all") approaches to

a more individualized evaluation and treatment of osteoporosis.

An important application of pharmacogenetics is the optimization of treatment outcome and minimization of adverse effects from therapies. There is a paradox in clinical osteoporosis in that, while RCT are the gold standard for evaluating efficacy of a therapy in a population, they are suboptimal for evaluating efficacy for an individual. Indeed, results of RCT provide the best evidence for a group of individuals, but individual patients often differ in their response to drug therapies. Thus, there is reasonable uncertainty whether the drug that works for a group of individual is optimal for an individual. Moreover, while the variability in treatment efficacy is a reality, but there is also a large variability in adverse drug reactions associated with drug treatment. Therefore, the goal of pharmacogenetics and pharmacogenomics is to optimize the selection of therapy for an individual.

Recent pharmacogenetic studies have suggested a number of genes (e.g., VDR, COLIA1, ERα) that may be implicated in diverse physiological pathway, such as calcium metabolism and changes in BMD. However, these findings have poor replication, and consistent data remain rather elusive. These genes require further studies, as well as careful functional genomics working to identify any specific molecular events that may produce clinical effects in order to contribute to future drug development strategies. In osteoporosis, pharmacogenetic studies have focused on one major phenotype: changes in BMD. There is considerable variation in the phenotype, which reduces the power of small studies to distinguish real association from stochastic noise.

Finding genes that are associated with drug response is a challenging task. It is not clear how many genes are involved in the regulation of, or relevant to, the underlying drug response (e.g., efficacy and safety). Under the hypothesis that the variability in drug response is determined by multiple genes, each with low effect size, and given that the estimated number of common variants is ~10 million,[34] the probability of a randomly selected common variant being associated with drug response is very low, probably in the order of 1/100,000 or 0.000001. Even if there is a priori biologic justification, this probability may be around 0.001. Since the a priori is generally low, the probability of a true association between a genetic variant and drug response is also low. Using the Bayesian approach[102] and a prior probability of association set at 0.001 and 0.000001 (corresponding to that expected for a candidate gene and for a random SNP in a genome-wide association/analysis, respectively), most reported associations between the genetic variants and BMD changes had FPRP of greater than 0.20, which means that most of these associations are probably not "true." Genetic profiling, by combining the effects of many small effect loci, may be a better approach to define the association between genetic variation and response to antiosteoporotic therapies.

6 CONCLUSIONS

It is established that genetic factors play an important role in the regulation of BMD variation and fracture risk. There is now evidence that genetic factors may be involved in the determination of interindividual variation in response to osteoporosis therapies. It is highly likely that both fracture risk and drug response are modified by multiple genes (and perhaps interactions among genes), but it is not known how many genes are involved nor the mode of inheritance. In fact, with current methodology, it is unlikely that we will completely understand the causes of fracture, and why some individuals respond to drug therapies and others do not. However, it is possible to identify risk factors that identify a substantial proportion of individuals at risk and who would be amenable to intervention. Newly identified genetic variants in combination with clinical risk factors may help improve the accuracy of prognosis of fracture for an individual, and segregate individuals at high risk of fracture from those with lower risk and hence, lead to better management of the burden of osteoporosis in the general community.

This chapter has reviewed the polymorphisms or genes that have been shown to be associated with BMD, fracture risk, or response to therapies. In clinical practice, patients are highly heterogeneous with respect to risk profile, and the identification of genetic variants that contribute to the identification of high-risk individuals, as well as the response to therapies will be the next important step to replace the current general protocols with specific and individualized decision tools.

To date, no gene test has been developed for predicting the risk of fracture or the response to osteoporosis therapies. This is largely due to the lack of clarity about which genes are definitely associated with fracture risk or response to therapies. It is also not clear whether the two traits (e.g. fracture risk and drug response) have common or trait-specific genes. Although genetic tests for making treatment decision are not yet available, knowledge of the underlying mechanisms of adverse drug reactions will inform drug development process and enable better prediction of the potential toxicity of new drugs. Recent advances in genetic technologies, such as the sequencing of the entire human genome, the international HapMap project, and new genotyping technologies, and GWAS have created an opportunity to identify genes that are truly associated with fracture risk and drug response.[152] These molecular and bioinformatic approaches can potentially help guide future drug discovery and development, and enhance the possibility of personalized prevention and treatment of osteoporosis.

1 GENETIC TESTING

There are several ways that an individual's genome can vary from "normal." Specific molecular techniques have been developed to test for the different types of variants. Here we discuss the different types of variants associated with genetic disorders, and the types of genetic testing available now and in the future in molecular diagnostic laboratories.

1.1 Small-Scale Variants

Base-pair substitutions, the replacement of one nucleotide base by another, are the most abundant variant type in the human genome. Single-nucleotide polymorphisms (SNPs) are base-pair substitutions that are common in the population; by definition two or more versions of a sequence must be present in at least 1% of the general population to be classified as an SNP. SNPs make up about 90% of all human genetic variation, and occur every 100–300 bases along with the 3 billion base human genome. This variation in the DNA sequence can have an impact on how humans respond to disease, environmental factors, and therapies.[1] As of June 2016, the SNP database listed about 150 million SNPs in humans (NCBI SNP database build 148 for human, https://www.ncbi.nlm.nih.gov/projects/SNP/snp_summary.cgi). The vast majority of SNPs are located in noncoding regions, including intergenic regions (stretches of DNA that contain few or no genes) and intronic regions (stretches of DNA within a gene that is removed by RNA splicing). This is not surprising given that although the haploid human genome contains about 3 billion base pairs,[2] only about 1.5% of the genome codes for proteins. The rest of the genome consists of noncoding RNA genes, regulatory sequences, introns, and noncoding DNA[3] and this is where most SNPs are found.

However, not all single-nucleotide changes are polymorphisms. Unlike SNPs, specific disease-causing variants are not common (occur in <1% of the population) and often occur within a gene's coding or regulatory regions, affecting the function of the protein encoded by the gene.[4] Single nucleotide variants, whether an SNP or a disease-causing variant, that are located in the coding regions (exons) can be further classified based on their effect on the amino acid sequence of the protein. Synonymous variants, also called "silent variants," do not change the amino acid, or protein product, because of the "degeneracy" of the genetic code. Although, in most cases, synonymous variants are not thought to have any consequences, there is increasing evidence that they can alter a phenotype due to effects on transcription, splicing, or translation.[5] Thus, the consequences of these variants may be hard to predict. Nonsynonymous variants change the amino acid coded for. When the nucleotide change results in the replacement of one amino acid for another it is called a missense variant; when the nucleotide change results in the gain of a stop codon it is called a nonsense variant. Sometimes a nucleotide change results in the loss of a stop codon (i.e., a stop codon changes to a codon that inserts an amino acid). Nonsynonymous variants that have a significant impact on protein structure may impact the phenotype.

Splicing variants are single nucleotide variants that occur in the regions of an intron that are required for removal of the introns and joining of the exons to form the

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00010-1

final mRNA. Variants in the 3′ or 5′ invariant splice sites most commonly result in exon skipping, although they can also lead to activation of a cryptic splice site or intron retention.[6] Amino acids are deleted (exon skipping) or added (intron retention) to the protein. In addition, if the deleted or added DNA sequence is not a multiple of three, a frameshift occurs leading to a change in the amino acid sequence and very often a new stop codon downstream, truncating the protein. Clearly, splicing variants have significant impact on the protein and usually on the phenotype.

Indels are the insertion or deletion of one or several nucleotides within a sequence.[7–10] When the number of nucleotides inserted or deleted is a multiple of three, an in-frame insertion or deletion of one or more amino acids could occur, the reading frame downstream is not shifted, and the normal protein sequence resumes after the insertion or deletion. When the number of nucleotides is not a multiple of three, a frameshift occurs, the downstream amino acid sequence changes, and very often a new stop codon occurs downstream, truncating the protein. Thus, out-of-frame indels usually have a greater impact on protein structure and function than in-frame indels, and often impact the phenotype.

Repeat expansions occur in areas within the genome that contain trinucleotide repeating sequences; an increase, or expansion, in the number of these repeating sequences can occur in both coding and noncoding regions.[11] "Trinucleotide (or triplet) repeat disorders" are disorders that occur when there is an abnormal expansion of these DNA-triplets (trinucleotides). This type of insertion variant is known to be associated with a limited number of disease-causing genes, but constitutes an important category of variant and disease mechanism. Examples include Huntington disease and fragile X syndrome.[12]

Epigenetic modifications, finally, some disorders are caused by changes in the epigenetic modification pattern, such as DNA methylation.[13] There are regions in the human genome where the two alleles are differentially methylated and expressed depending on parent of origin (the imprinting phenomenon). Changes in the methylation pattern at these loci may disrupt the imprinting pattern and lead to imprinting disorders. Examples include Prader–Willi/Angelman syndrome (https://www.ncbi.nlm.nih.gov/books/NBK1330), as well as Albright hereditary osteodystrophy and pseudohypoparathyroidism.[14]

1.2 Large-Scale Variants

Large-scale variants affect at least one exon of a gene or a larger genomic segment. Copy number variants (CNVs) are imbalanced structure variants. Genomic DNA copy number gain or loss have been known for many years, but a renewed interest in CNVs is due to the finding that not only CNVs are much more abundant in the human genome than previously appreciated, but also they are now known to have a large impact on genome structure and function.[15] Furthermore, many CNVs, especially large ones, have significant clinical relevance. CNVs constitute the second most frequent variant type associated with genetic disorders.

Balanced structural variants, including chromosomal translocations and inversions, represent another type of large-scale variant. They can lead to disease if a gene is disrupted.

Another large-scale variant is referred to as copy neutral loss of heterozygosity (cn-LOH). LOH refers to the deletion of one allele of a gene. cn-LOH occurs when there is LOH but with no net change in the copy number. When both alleles originate from one parent, cn-LOH is referred to as uniparental disomy (UPD). In UPD, both copies of a chromosome, or part of a chromosome, are inherited from one parent and no copies from the other parent.[16] cn-LOH can also occur within a family due to identity by descent whereby family members inherit identical copies of the same ancestral allele. Identity by descent may be due to distant relatedness between two individuals or consanguinity indicating recent relatedness.[17]

Traditionally, microsatellite marker based genotyping methods have been used to detect UPD. Recent microarray platforms are able to detect large segments of cn-LOH and UPD in a genome-wide manner.

1.3 Evolving Approaches to DNA-Based Genetic Testing

The most-effective method for detecting most small-scale variants has been Sanger sequencing of DNA fragments amplified using the polymerase chain reaction (PCR).[18] To assess the number of repeats in the case of repeat expansions, PCR-based assays, and occasionally Southern-blot based assays, are necessary.

A fairly common technique used in a variety of circumstances is multiplex ligation dependent probe amplification (MLPA).[19] MLPA is a form of multiplex PCR in which multiple genomic targets are amplified using a common primer pair located at the outside ends of the multiple oligonucleotide probe pairs specific to the genomic targets. Thus, the strength of amplification signal reflects the amount of genomic target (inferred as copy number). Methylation-specific MLPA can be used to assess the methylation status of disease-related genes in the case of epigenetic variants. In methylation-specific MLPA specific probes are selected at the methylation loci and the genomic DNA is treated with methylation sensitive restriction enzymes that disrupt the methylated DNA preventing the ligation, hence reducing the amplification signal. The strength of the amplification signal at the methylated sites compared to the signal generated from DNA that has not been treated with enzyme reflects

the methylation level. MLPA is used to detect variants and gene deletions/duplications. In fact, for disorders in which deletions or duplications are common, MLPA is performed first as it is much easier and faster than sequencing. MLPA is also used to complement Sanger sequencing, in which case Sanger sequencing is performed first and, if the result is normal, MLPA is then performed to detect possible exonic deletions; sometimes, the two tests are performed simultaneously.

For more than 10 years now, microarray-based genomic profiling technologies have enabled the effective analysis of large variants, which cannot be reliably detected by conventional PCR and Sanger sequencing-based assays, with much improved sensitivity, resolution, and reproducibility. There are two basic microarray-based genomic profiling types.[20] Comparative genomic hybridization (CGH) detects copy number changes (unbalanced rearrangements). DNA from a patient and a normal control are labeled with different fluorescent tags, mixed, and then hybridized to normal chromosomes. Differences in the ratio of fluorescent labeling with the patient versus the control DNA can identify abnormal regions in the patient's genome. Currently, oligo-based CGH arrays are most often used and offer a resolution of 50 kBp. The subsequent addition of SNP probes onto CGH arrays have enabled detection of both CNV and LOH by CGH array. A second array platform is derived from SNP genotyping arrays. The addition of probes onto genotyping arrays that identify CNVs significantly enhances the sensitivity of detecting CNVs by genotyping array. The two array types show a functional convergence. Microarray platforms are able to detect large segments of cn-LOH and UPD, traditionally detected using microsatellite marker-based genotyping methods.[21] The one type of large-scale variant that is not detected using microarray techniques is balanced variants, and thus these variants can only be detected by conventional cytogenetic approaches. Due to the limited resolution of cytogenetic approaches, the balanced genomic variants are believed to be underdetected. It should be noted that many apparently balanced rearrangements ascertained by cytogenetic approaches are later found to harbor cryptic imbalances when high resolution microarray-based genomic profiling techniques are used.[22]

The advent of next generation sequencing (NGS) technologies has change the way genetic testing is performed and consequently brought a paradigm shift in genetic testing.[23] NGS-based whole exome sequencing (WES) or whole genome sequencing (WGS) generates DNA sequence data by massive parallel sequencing of clonally amplified or single DNA molecules.[24] Recent advances in NGS technologies are making an NGS-based diagnostic approach more cost-effective with a reasonable turnaround time.[25] Currently, gene panel testing for conditions with genetic heterogeneity or overlapping phenotype, and exome sequencing for conditions with complex presentation or uncertain clinical diagnosis, have become increasingly utilized as part of the genetic evaluation and even as first-tier test.[26] The premise for using WES instead of WGS for Mendalian disorders is that protein-coding sequences constitute about 1% of the human genome but harbor about 85% of the known variants that cause human diseases. However, given that large-scale variants, such as CNVs can be detected by a WGS, but not easily by WES, it is predicted that when the cost for WGS becomes acceptable for routine testing, it will become the method of choice for clinical diagnostics. Many challenges lie ahead, particularly in the area of data interpretation (informatics), which often involves database searching, segregation analysis, bioinformatic prediction, and functional demonstration.

NGS not only is effective for small-scale variants, but also it may eventually replace array-based technologies for interrogating CNV, as well as for many other types of large-scale variants. NGS data can provide a much more complete picture of cn-LOH in the whole genome.[27] NGS-based approaches are poised to solve effectively the technical difficulty of detecting balanced rearrangements; it will become the method of choice for genome-wide detections of both balanced and imbalanced genomic variants. One of the major hurdles in the application of NGS to genetic testing is informatics; how to understand and make sense of the vast amount of data generated. Finally, it should be noted that even though NGS will eventually replace many current genetic testing methods, conventional sequencing, genotyping, and CNV detecting technologies will continue to be useful for validating and confirming variants detected by NGS.

The nature of the variant dictates what method should be used for genetic testing. The clinician makes a clinical diagnosis and orders the gene test that is most likely to explain the patient's clinical condition. Conventional approaches to genetic testing in the clinical setting involve interrogating one gene or one variant at a time in one patient. The molecular diagnostic laboratory may use Sanger sequencing to test for small-scale variants, and whole gene or gene-panel based tests are currently the most commonly used approaches in genetic testing. As sequencing can only detect small-scale variants, it is often complemented by CNV testing using MLPA or quantitative PCR to detect potential exonic deletion or duplication. If a large-scale variant, such as a CNV is suspected, targeted methods for the detection may be performed using quantitative PCR or MLPA. Whole genome chromosomal microarray (CMA) analysis for CNVs and LOH is a useful scanning tool for genome-wide detection of possible genomic defects associated with many genetic conditions. In fact, the much enhanced clinical utility of CMA over conventional cytogenetic techniques justifies its use as the first tier test for patients with complex or

unknown genetic conditions, and microarray-based genomic profiling techniques have been recommended as the first tier genetic test in many clinical scenarios.

2 GENETIC TESTING FOR SKELETAL DISORDERS

2.1 Genetic Tests Available

As knowledge about genetic disorders of bone has expanded greatly over the past few years, the number of disorders for which genetic testing is commercially available has also increased (https://www.ncbi.nlm.nih.gov/gtr/). Although there has always been a lag between the research discovery of causative genes and the availability of commercial diagnostic testing,[28] genetic testing is available for a large number of skeletal diseases, including metabolic bone disorders and skeletal dysplasias.

Genetic testing for metabolic disorders of bone can be useful in the clinical setting for diagnostic purposes. There are a number of genetic causes of metabolic bone disease for which there is genetic testing available, including familial hypophosphatemic rickets, autosomal dominant hypophosphatemic rickets, two forms of autosomal recessive hypophosphatemic rickets , X-linked recessive hypophosphatemic rickets, and hereditary hypophosphatemic rickets with hypercalciuria. While X-linked recessive hypophosphatemic rickets is by far the most common, genetic testing for all of the forms is available (although genetic testing for hypercalciuria is currently only available clinically in Europe; see http://www.genetests.org) and can be used to differentiate between the forms when it is not clear from an inheritance pattern.[29] Genetic testing is available for most inherited vitamin D-related disorders, including vitamin D-dependent rickets type I (VDDR-IA) also known as 1-α-hydroxylase deficiency, and vitamin D-dependent rickets type II (VDDR-II) also called vitamin D-resistant rickets (http://www.genetests.org). Finally, genetic testing is available for hypophosphatasia, due to variants in ALPL, the gene encoding the alkaline phosphatase, tissue nonspecific isozyme. For many of these conditions, the diagnosis is made clinically and can be confirmed by genetic testing.

Genetic testing for skeletal dysplasias can be used to confirm a clinical diagnosis, as well as for cases where a clinical diagnosis is not immediately clear but several different disorders are under consideration. All patients with a suspected skeletal dysplasia should have a thorough physical exam documenting any dysmorphic features, as well as a full radiographic skeletal survey in cases where the diagnosis is not suggested by history and physical exam alone. There are hundreds of skeletal dysplasias and many genes that are affected. Here, we highlight some of the more common skeletal dysplasias for which there is genetic testing available.

2.2 When to Order Genetic Testing

Once a preliminary diagnosis of a genetic condition is made, the decision to order genetic testing is influenced by several factors, including the diagnostic and treatment necessity, the need for reproductive counseling, patient and family desire for testing, and cost and payment issues. Prior to ordering any genetic test, the provider needs to determine if the desired test is clinically available. In the USA, all genetic testing must be performed in a CLIA-certified clinical laboratory for both legal and reimbursement reasons.[30] The website http://www.genetests.org is an excellent source for determining which CLIA-certified clinical laboratories offer the desired testing. Any testing sent on a research basis must be done under the supervision of an institutional review board and often the results cannot be legally revealed to the patient until the testing is repeated and the results are verified in a CLIA-certified laboratory.[31] Fortunately, genetic testing tends to move rather quickly in most cases from the research setting to clinical testing.

The most common clinical situation where genetic testing is ordered is when the genetic testing is required to make a diagnosis or to confirm the diagnosis. Genetic testing is especially useful if a course of treatment is available and dependent on the diagnosis. In these cases, genetic testing will provide a clear benefit for the care of the affected patient. A clear example of this is osteogenesis imperfecta, in which bisphosphonates may be beneficial.

Often, if the diagnosis is unclear, a staged approach to testing, while perhaps prolonging the time to final diagnosis, can potentially conserve resources. This involves requesting one genetic test at a time and moving on to other genetic testing only if the initial tests are negative. Frequently, one blood sample can almost always provide enough DNA for a laboratory to carry out multiple sequencing analyses, thus preventing repetitive blood draws. This staged testing approach is also useful for disorders with genetic heterogeneity. Testing can begin with the most commonly affected gene and then proceed to subsequent genes only if the first test is negative. However, in cases where diagnosis will affect treatment and delaying therapy is not optimal, ordering multiple tests at once or gene panels may benefit the patient.

Reproductive counseling is another reason that genetic testing may be useful in a clinical setting. It is not uncommon for skeletal disorders to be diagnosed clinically based on family history, physical exam, and radiographic evidence. While the diagnosis may not be in question, knowledge of the specific variant causing the phenotype may be useful for future reproductive decisions. In the

pediatric setting, parents of an affected child may desire prenatal or preimplantation genetic testing with future pregnancies. In this situation, the patient's exact variant needs to be known to determine if the parents are carriers (or affected themselves if the variant is dominant) and to allow for prenatal testing with future pregnancies. In the case of recessive disorders, carrier testing is appropriate for adult family members but should not be performed on minor children until they reach maturity and can consent to their own testing.[32–35]

Patients or family members may request or refuse genetic testing for various reasons. In cases where genetic testing is needed for initial diagnosis or to confirm a clinical diagnosis, a full discussion of the risks and benefits should be undertaken with the patient (or parents if the patient is a minor). This discussion should include the reason(s) why genetic testing is needed, how are the results, whether a variant is found or not, will affect the patient's immediate after treatment, and how the results may affect the patient's care in the future. Discussion of these issues can help alleviate many misunderstandings and anxieties about genetic testing.[36] In the USA, the 2008 Genetic Information Nondiscrimination Act (GINA) bars discrimination by health insurance providers and employers due to genetic testing results, although GINA does not protect from genetic discrimination in other areas, such as long-term care or life insurance.[37] Finally, the discussion should include the limits of genetic testing, particularly when a negative test will not exclude a clinical diagnosis, which is often the case. Available genetic tests may only detect variants in a small number of clinically diagnosed patients depending on the disorder. Patients and families may consider a negative test result "the final answer" and need to understand that a negative genetic test does not always exclude a given clinical diagnosis.

The cost of genetic testing can affect the ability to order genetic tests in different settings. Genetic tests can be among the most expensive laboratory-based tests available, ranging from hundreds to tens of thousands of dollars. Third-party payers are becoming increasingly reluctant to pay for the costs of genetic testing, particularly in the absence of documented clinical necessity. In the pediatric population, single gene and panel testing for diagnostic purposes are often covered by private insurance companies, as long as the patient's pertinent history and physical findings are well documented. However, families with high-deductible plans should be warned that the cost of one genetic test may be greater than the entire deductible, requiring a single large payment. Carrier testing may not be covered by insurance companies, except when done for prenatal testing purposes. As genetic tests are ordered more frequently, institutions, such as hospitals may limit the number of tests that can be ordered or require that tests be ordered only from laboratories that bill the patients' insurance company directly. This can effectively put testing for some disorders out of the reach of patients and providers. These increasing costs place a responsibility on providers to ensure that genetic tests are only ordered under appropriate circumstances where there is a clear benefit for the patient.

The increasing availability of genetic testing for all types of skeletal disorders can be of great benefit to patients and providers. Genetic testing can be useful for diagnosis and subsequent treatment, as well as for reproductive counseling for patients and families. However, as with all medical testing, genetic testing has risks and benefits and may not be appropriate for every clinical situation.

3 GENETIC COUNSELING

There has been an "explosion" of new discoveries in the fields of genetics and genomics in the last decade that has resulted in the incorporation of new genetic tests, such as CMA analysis, gene panel testing, and whole exome/genome sequencing, into mainstream clinical practice. As much of the current research in genetics and genomics is focused on the study of complex trait versus single-gene disorders, the possibility that there will soon be numerous additional clinical tests available is not out of the question. Given the advances in genetic and genomic medicine, subspecialists, as well as primary care physicians have been increasingly being called upon to utilize genetic information, including risk assessment and testing in their practice[38,39] and help to determine which patients may be appropriate for genetic testing and counseling.

The diagnosis of a genetic disorder is likely to bring up numerous questions for patients and their families. Families must grapple with the many facets of the diagnosis, including the natural history, prognosis, and treatment options. "What caused this to happen?" and "Could this happen again?" are common questions asked in the setting of a new diagnosis as patients come to terms not only with their own diagnosis but also with the potential impact on other family members, both medically and psychosocially. Genetics professionals can help individuals to navigate these issues by providing the factual information required, as well as engaging patients and their families in a discussion of the potential psychological, social, and health impacts of the disorder. This affords the genetics provider the opportunity to better assess the patient's understanding of the information given and their ability to process that information to make autonomous decisions.

While primary care providers and subspecialists offer education concerning the clinical features, treatment, and prognosis of bone disease, genetics professionals are

often needed to ensure that patients and their families are receiving comprehensive information regarding the testing, therapeutic, and reproductive options available to them, as well as psychosocial support. As such, it becomes incumbent upon primary care clinicians, genetics professionals, and other clinical specialists to partner to provide optimal genetics care, including counseling, to their patients.

3.1 History

The field of genetic counseling is fairly young compared to other healthcare professions, albeit one that continues to grow rapidly. The term "genetic counseling" was coined in 1947 by Sheldon Reed, who subsequently authored the book *Counseling in Medical Genetics*.[40,41] At the time of his publication in 1955, there were approximately 12 genetics clinics in North America providing services to families.[42] Reed proposed providing genetic information to families while remaining attune to their psychological needs.[40,43] However, the history of the field of genetics shows the limited scope of information that could be provided to patients during the 1940s and 1950s. In fact, the structure of DNA remained unknown until 1953, while the diploid number of chromosomes was not discovered until the publication by Tjio and Levan in 1956.[44] In addition, it would be another decade before the successful use of amniocentesis for genetic diagnosis was demonstrated. Therefore, in the early years of genetic counseling, families could only be provided with medical information and predictions of recurrence risk. Over the ensuing decades, the identification of cytogenetic abnormalities and single gene disorder variants, as well as the development of prenatal diagnostic procedures greatly expanded the need for skilled professionals to provide genetic counseling to patients and families.

Genetic counseling is carried out by genetics professionals, generally clinical geneticists and genetic counselors. Genetic nurses credentialed through nurse genetics programs (http://www.isong.org/ISONG_genetic_nurse.php) may also provide genetic counseling. In the USA, clinical geneticists are physicians who have completed a minimum of 1 year, full-time training that includes at least 12 months of direct patient care experience in an American Council of Graduate Medical Education accredited residency, and then at least 24 months of training in an American Council of Graduate Medical Education-accredited Clinical Genetics and Genomics training program. Alternatively, physicians can complete a 4–5 year training residency programs that combines Clinical Genetics and Genomics with Internal Medicine, Maternal Fetal Medicine, Reproductive Endocrinology and Infertility, or Pediatrics. Clinical geneticists are trained to provide "comprehensive genetic diagnostic, management, therapeutic, and counseling services" (http://www.abmgg.org/) and are certified by the American Board of Medical Genetics.

Genetic counselors are trained in Master's-level genetic counseling training programs[45] accredited by the Accreditation Council for Genetic Counseling (http://www.gceducation.org) and are currently certified by the American Board of Genetic Counseling (http://www.abgc.net). At present, 19 states within the USA also require licensure of genetic counselors, a number that is growing steadily. Graduates of these genetic counseling programs are trained to provide services to patients and their families, and receive instruction in human, medical, and clinical genetics, as well as counseling theory and techniques. The training of all genetics professionals also includes exploration of the relevant social, ethical, and legal issues inherent in the field.

As noted earlier, practitioners of genetic counseling or "genetics professionals" include genetic counselors, clinical geneticists, genetic nurses, and other clinicians with specialized training in the field. While genetics providers have traditionally worked in academic medical institutions, genetics professionals also provide services within the primary care, diagnostic laboratory, and public health sectors, as well as in specialized areas, including assisted reproductive technologies, cardiology, and oncology. As such, genetics providers serve patients at all stages from preconception through pregnancy to pediatrics through adulthood.[46]

3.2 The Genetic Counseling Process

Genetic counseling, as defined by the National Society of Genetic Counselors,[47] "… is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates the following:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence.
- Education about inheritance, testing, management, prevention, resources, and research.
- Counseling to promote informed choices and adaptation to the risk or condition."[47]

The technique of "nondirectiveness" has been intertwined with genetic counseling since its inception. However, this approach has been questioned, both in terms of its definition, as well as its role in the genetic counseling session.[48,49] Kessler states that nondirectiveness "describes procedures aimed at promoting the autonomy and self-directedness of the client." With this in mind, professionals engaged in genetic counseling strive to provide information to patients in a noncoercive and empathetic manner to facilitate autonomous decision making. Whenever possible, information is given in a

way that is unbiased. However, there may be situations when this may not be appropriate, such as discussing a particular diagnosis that has a well-established treatment strategy (e.g., calcitriol for vitamin D-dependent rickets, type I) or a surveillance program (e.g., tumor screening through imaging and biochemical testing in the setting of MEN1).[50] Genetics providers have a responsibility to provide professional guidance and should be comfortable advising their patients to consider the treatment or surveillance program once the benefits, risks, and limitations have been fully described. This does not mean that a counseling session will be devoid of advice given in a noncoercive manner, if that is what is required based upon the patient's needs and circumstances.[48,51] Ultimately, the counseling provided should be skills-based, and remain flexible to be effective in any given session.[48,49,51]

Regardless of the setting, the key components of a genetic counseling session remain largely the same—information gathering, establishing or verifying diagnosis, risk assessment, information giving, psychological assessment and counseling, help with decision making, and ongoing client support.[51,52] The genetic counseling session is specific to each patient in terms of providing information in a culturally sensitive manner by being attuned to a patient's educational and socioeconomic background. Techniques to achieve this include the use of layman's terms, avoidance of words that are emotionally charged, such as "abnormal" or "variant," and the preferred use of person-centered language (e.g., child with achondroplasia vs. achondroplastic child) to emphasize the individual person not the disorder. Visual aids are often useful to better illustrate the information provided. It is of the utmost importance that the counseling be consistent with the patient's perception and needs, to ensure that the patient's ability to successfully utilize the information for informed decision making is not impaired.

3.3 The Genetic Counseling Session

Genetic counseling is indicated once the diagnosis or presumed diagnosis of a genetic condition is made, either by a clinical geneticist, primary care physician, or subspecialist. A patient may be referred to the genetics professional with a diagnosis that needs to be confirmed, or the patient may be referred to a clinical geneticist to make a genetic diagnosis. Regardless of the setting, the components of the genetic counseling session are similar. The session begins with the genetics professional contracting with the patient, including solicitation of the patient's understanding of the reason for referral and expectations/desired outcomes of the session. This allows the genetics provider to dispel any initial misconceptions regarding the purpose and potential outcomes of the genetic counseling session including genetic testing.

3.3.1 Family History

Eliciting the family and medical history information and constructing the pedigree using standard nomenclature is central to the genetic counseling session.[46,53] While the pedigree is necessary for determining the pattern of inheritance and assessing recurrence risks, it can also be helpful in determining family dynamics through exploration of the patient's psychosocial history. Indeed, the patient's family history should engage in a discussion of the personal, family, and community values to help to appreciate the patient's support network and coping skills while identifying areas of concern. The "pedigree process" also allows one to correct any misapprehensions the patient may have about the degree of heritability in a family for any given diagnosis. Families may have long-held beliefs regarding the causes of certain disorders within the family. For example, family members may falsely attribute birth trauma as the cause of a disorder, or believe that a certain disorder affects only males since all of the females in their family are unaffected. Therefore, it is important that the genetics provider initially determines how the family has come to such beliefs to address any misconceptions in a sensitive yet effective manner.

The duty to warn relatives with respect to their genetic risk is an ethical issue that often needs to be addressed during this portion of the genetic counseling session. This duty may bring up a multitude of concerns, including patient confidentiality and the autonomy of relatives in being able to choose not to know of their risk status.[54] Given the current status of privacy and confidentiality legislation, genetics professionals cannot directly contact other family members deemed at risk. However, as the discussion of the family history includes the possible identification of at risk family members not present in the session, the potential impact the disorder may have on the medical management of those family members cannot be ignored. While the focus of the counseling session should remain on the patient and the family members present, genetic counseling needs to include guidance as to why and how to discuss the diagnosis and potential impact with other family members, and to guide them to appropriate resources.

3.3.2 Genetic Testing

The genetic counseling session often includes a discussion of the availability of genetic testing or lack thereof. One of the core tenets of genetic counseling is the belief that the decision of whether or not to proceed with genetic testing is voluntary. As such, patients must be counseled as to the real and potential risks, benefits, and alternatives to testing, and also be given the assistance needed to make an informed decision regarding their testing options. It is worth noting that patients may actually put more weight on their perceived risk and

emotions as opposed to the factual risks.[55] Given this, and the fact that genetic test results may impact not only the patient but other family members, it is preferred that a patient receive genetic counseling prior to genetic testing. Pretest genetic counseling also allows for a discussion of the potential for unclear or unexpected findings, such as variants of unknown significance, incidental/secondary findings, and nonpaternity.

Genetic testing in the setting of childhood and adolescence is an issue that continues to be debated in the genetics field. Multiple professional societies have taken the stance that testing of minors should only be done when the disorder in question has a childhood onset and effective treatment or surveillance in childhood is available.[33,35,54,56,57] Although recently the American College of Medical Genetics and Genomics released a policy statement stating that incidental findings including those of adult onset identified in pediatric patients be disclosed to families in the setting of clinical exome and genome sequencing.[58,59] This was not without controversy.[60,61] However, there remains a lack of consensus as to the definitive steps to take in the setting of a disorder without preventative or therapeutic options.[62,63] There are some instances in which the appropriateness of genetic testing in childhood and adolescence seems quite clear. For example, genetic testing for MEN Type II via RET variant analysis for minors with a substantial risk (50%) is an accepted practice as thyroidectomy to prevent medullary thyroid carcinoma should be performed during childhood.[64] On the other hand, although diagnostic testing for an autosomal recessive skeletal dysplasia in a child is considered appropriate for surveillance purposes and for assessing recurrence risks in the parent, carrier testing of siblings may not be appropriate given the lack of empiric evidence regarding the effect that presymptomatic or carrier testing may have on children.[65]

When offering genetic testing to minors, it is important for parents and their children to be fully informed of the potential benefits, risks, and limitations of genetic testing, including a discussion of the child's autonomy and privacy issues. The potential benefits, such as elimination or reduction of uncertainty, or the initiation or elimination of surveillance techniques, must be weighed against the potential harms, such as increased anxiety or effects on familial relationships. If the patient is not of the age and/or level of maturity to assent to carrier or presymptomatic testing, parents should be engaged in a discussion of when and how they will inform their child of the test results (whether they are negative, positive, or inconclusive) and their reasons for pursuing testing at that time in their child's life.

Another issue that has been highlighted with regard to genetic testing is the "duty to recontact." It is not unimaginable for a patient to receive genetic counseling at a time when genetic testing for their specific disorder is not yet possible, but several months or years later the causative variant is identified and clinical testing becomes available. Patients may also need to be recontacted in the setting of previously identified variant of unknown significance being reclassified as a causal or "normal" variant. Legal and ethical arguments have been raised for and against the duty to recontact when new information is discovered regarding a genetic test or diagnosis.[66–68] Some have advocated that it is the treating clinician's responsibility to initiate recontact whereas others have suggested that the responsibility lies, at least partially, with the patient. The issue of practicality also comes into play. Does a genetics clinic have the appropriate infrastructure and resources required to recontact all relevant patients with new testing options? How will the primary care provider keep current information on the development of new genetic tests? Currently, as outlined by the American College of Medical Genetics and Genomics policy statement, the genetics provider should initiate the recontact in cases where there is an ongoing relationship with the patient, whereas in cases lacking this ongoing relationship, the primary care provider should shoulder the responsibility.[67] The policy further recognizes the importance of encouraging patients to contact their primary care or genetics provider if, or when, changes pertinent to their diagnosis arise.

The importance of a client's confidentiality and privacy, including testing results, has been acknowledged within the field of medicine for some time. Genetic testing poses unique challenges as the disclosure of genetic information, whether voluntary or involuntary, has the potential to lead to social and economical consequences. The passage of GINA was landmark legislation for the field of genetics, as it affords protection from workplace and health insurance discrimination. However, as noted previously, it does not speak to the possibility of genetic discrimination with regard to life, disability, or long-term care insurance. As such, the potential for insurance discrimination based on one's genetic background is a topic, which is still discussed during the genetic counseling session, particularly when patients are contemplating presymptomatic genetic testing.

3.3.3 *Communicating the Facts*

Patient education and disclosure of information go hand in hand. Genetics providers operate under the belief of complete disclosure; families should be given all relevant information as it pertains to the diagnosis.[51] Complete disclosure, however, is subjective; as what is deemed relevant information by a given practitioner or a family may well differ from another. In addition, it may not be appropriate or feasible to disclose every piece of information regarding a disorder, genetic test, or treatment as the provision of too much information during a single session may lead to confusion and negatively

impact decision making. For example, when providing prenatal genetic counseling to a couple who already have a child with a skeletal dysplasia, a detailed explanation of prenatal testing options may be more appropriate than a lengthy discussion of the prognosis of the disorder. Alternatively, in the pediatric setting, an extensive description of prenatal diagnostic testing may not be appropriate when the family is primarily interested in confirming the diagnosis and obtaining prognostic information for their child. Indeed, genetic counseling aims to provide patients with the information they will need to make the most informed and autonomous decision possible at that time.

Dissemination of information also includes a discussion of "risks," whether it is recurrence, genetic testing, or prenatal diagnostic procedures risk. In genetic counseling practice, as the term "risk" may be seen as a negative term, the terms "chance" or "likelihood" are often preferred.[51,69] However, people have difficulty quantifying their own risks accurately, which has been well-documented, including the trend toward overestimation.[70] Whether the use of the word "risk," when one actually means "probability," has lent itself to oversimplifying patients' risk perception and their subsequent decision making has also been questioned. The ability of a patient to recall the quantitative risk figure they were given may not provide insight into how they perceive that risk, nor the steps they may take to mitigate the risk. Thus, genetic counseling should focus on understanding how the risk is internalized by the patient rather than the regurgitation of the risk figure.

People process risk figures differently. Therefore, risks should be provided using a variety of techniques, including fractions, percentages, and scales. A patient with a 1% risk for recurrence in their offspring may be counseled that, "You have a 1% chance for this to occur in any future pregnancy which means you also have a 99% chance that it will not occur." Illustrating both sides of the risk (the chance something will happen and the chance it will not) may help patients to better understand the degree of risk. In addition, the use of more than one method of risk framing (e.g., using percentages and fractions) to describe the same risk figure may be beneficial. For example, a genetics provider may counsel a patient that "A 1% chance means that 1 out of 100 people will develop the disorder while 99 out of 100 people will not."

Patients take many factors into account when assessing their risks, including their personal experiences with the condition, environmental factors, occupation, and diet, to name a few.[70] One's physical resemblance to an affected family member may also influence an individual's personal risk assessment.[70] Additionally, a patient's perception of risk can also change over time as one's life experiences change.[71] As people's perception of risk influences their future actions, genetics providers need to ensure that this perception is not skewed in a particular manner and also provide support as patients internalize and manage their risk. Following the risk dissemination, patients should be asked questions, such as "Is this a number you expected?" and "Does this seem like a high, low or average chance?" One cannot make assumptions, as a 2% risk may be deemed a high risk by one individual while another may perceive it as negligible. By asking such questions, the genetics professional can ascertain whether the patient has understood the risk and how it is personally perceived. This helps to illuminate the patient's understanding of the information provided and allow for adjustment of counseling as needed.

3.3.4 Counseling and Support

During the counseling session, a focused assessment of the patient's psychosocial needs must be performed. In fact, it has been suggested that in some cases the emotional support provided during the counseling session may be more beneficial to clients than the factual information presented.[72] Patients may express a variety of emotions during the genetic counseling session, including anger, grief, denial, guilt, shame, helplessness, and fear of social discrimination.[51–53] Genetics providers need to determine how the patient will cope with the information to foster independent decision making. Again, it is important for genetics providers to remember that how a patient views risks, makes decisions, adapts to situations, and communicates within a family depends largely on life experiences and cultural background.

As previously stated, patients must often make decisions based on the factual information provided to them during the genetic counseling session. Such decisions may involve choosing a course of treatment, pursuing or declining genetic testing, making reproductive choices, or informing others of the diagnosis and its implications. The genetics provider must strive to empower patients in their decision making. Potential obstacles to autonomy should be identified and assistance provided to reduce or eliminate those barriers. To help patients determine the best course of action for their family at that time, patients should be encouraged to explore various scenarios envisioning how different decisions may affect their family socially, economically, and emotionally. The patient's thoughts and feelings about the diagnosis should be addressed, not only to assess comprehension, but also to determine if or how this may affect their ability to inform other family members, friends, coworkers, etc. of the situation. Patients should also be engaged in a discussion of the potential responses, both verbal and nonverbal, they may encounter when informing others of the diagnosis and their decisions surrounding it. The patient's potential reactions to such responses should also be explored along with their coping strategies to effectively handle such responses.

Providing assistance and support to the patient is vital to information processing and independent decision making. As such, genetics providers need to identify the additional resources that patients and their families may require as they process and incorporate the information given. A patient may benefit from participation in a formal support group or a one-on-one interaction with another patient with the same diagnosis. In the prenatal setting, it may be helpful for a patient to speak to other individuals who had been given a similar prenatal diagnosis and grappled with their reproductive options. Genetic counseling must also include the facilitation of referrals to other healthcare providers for further information regarding treatment, prognosis, and other medical information as needed. Additionally, genetic providers often offer information regarding disorder specific foundations and/or genetic organizations (e.g., Osteogenesis Imperfecta Foundation, Paget Foundation, Genetic Alliance), which can provide supplemental information and support to patients and their families. Furthermore, genetics professionals must recognize when a patient may require additional psychological support outside of the genetic counseling session and refer patients when appropriate.

Significant advances continue to be made in genetics and genomics including the increased availability of clinical testing. As such, the field of genetic counseling has had to keep pace with this progression, oftentimes resulting in more challenging genetic counseling sessions. Genetics professionals remain at the forefront of this genetics and genomics revolution, ensuring that patients are adequately counseled as to the many facets of their particular genetic diagnosis while also providing the support needed for successful information processing and autonomous decision making.

SECTION 2

GENERAL BACKGROUND TO BONE BIOLOGY

CHAPTER

11

Biology of Bone and Cartilage

Brendan F. Boyce, Michael J. Zuscik, Lianping Xing

University of Rochester Medical Center, Rochester, NY, United States

1 INTRODUCTION

Bones are formed during embryonic development through endochondral and intramembranous ossification. Long bones are formed by endochondral ossification from limb buds that extend from the embryonic torso and form cartilaginous molds (known as anlagen), which are shaped roughly in the form the bones will have when they are more fully formed. The chondroblasts that give rise to these anlagen are derived from mesenchymal stem cells (MSCs), which also give rise to osteoblasts (OBs), fibroblasts, adipocytes, striated muscle, and endothelial cells, which comprise most of the tissues in limbs.[1,2] Cells in the central parts of the anlagen differentiate from small prehypertrophic into large hypertrophic chondrocytes, and the matrix around these cells calcifies by means of a process that remains poorly understood.[1] This calcified cartilage is invaded by blood vessels, associated with matrix dissolution by metalloproteinases and chondrocyte apoptosis. As the calcified cartilage is removed, it is replaced by new bone laid down as plate-shaped structures called trabeculae by teams of OBs derived from precursors, some of which appear to circulate in the blood.[3] Some of the OBs on the surface of the new trabeculae become embedded in the unmineralized matrix (osteoid) and remain there as osteocytes as the matrix calcifies and until the bone is subsequently remodeled. Osteocytes have numerous functions within and outside of bone, some anticipated and others unexpected.[4]

Radial growth of long bones and growth of flat bones, such as some of the bones of the skull, are accomplished by intramembranous ossification in which bones are formed directly by OBs without being preformed in cartilage. As bone growth and the formation of a bone marrow (BM) cavity within each long bone occurs very rapidly during embryonic development, new bone has to be removed quickly by osteoclasts (OCs) to prevent the cavity being filled with unresorbed bone. Failure of OC formation or function during skeletogenesis results in buildup of bone in BM cavities, called osteopetrosis,[5,6] which can limit movement of hematopoietic precursors formed in the liver to the BM and the transition from extra- to intramedullary hematopoiesis. Removal of calcified hypertrophic cartilage in anlagen may involve OCs, but these cells are not required, since it occurs in the absence of OCs in osteopetrotic humans and other mammals[2,7] and the mechanisms involved are poorly understood. The matrix may be dissolved by metalloproteinases secreted possibly by the chondrocytes themselves or by endothelial cells in nearby vessels or by chondroclasts, poorly characterized cells that may be in the mononuclear/phagocyte lineage.[2] OCs are often mistakenly assumed to be chondroclasts because they resorb at the osteochondral junction in growth plates. However, chondroclasts are not multinucleated and do not express tartrate-resistant acid phosphatase (TRAP) in sections of bones from osteopetrotic mice, such as NF-κB double knockout (dKO) and $RANK^{-/-}$ mice that do not form OCs or $TRAP^{+}$ mononuclear cells in bone. These KO mice still have vascular invasion of anlagen, removal of cartilage, and formation of bone, but this bone does not get resorbed.[2,7]

There is continuous modeling and remodeling of the shape and thickness of bones during childhood and adolescence in response to patterning and mechanical stimuli. After skeletal maturity is attained, bone integrity is maintained by continuous, highly regulated, bone remodeling, during which OCs excavate trenches on bone surfaces and tunnels through cortical bone that are subsequently filled by new bone laid down by OBs. New bone consists of layers (lamellae) of extracellular matrix of primarily type I collagen upon which a crystalline inorganic component (predominantly calcium hydroxyapatite) is laid down during mineralization. Sites of bone remodeling have been defined as basic multicellular units or bone remodeling units. Many metabolic, inflammatory, and neoplastic conditions affect bones

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00011-3

and joints. They impact the remodeling cycle and can positively or negatively affect turnover rates and thus bone volume and shape. Bone modeling and remodeling are regulated locally by interactions between cells, by factors released from cells that influence functions of cells around them, and systemically by hormones and growth factors released by other organs, as well as by the central and peripheral nervous and intestinal systems. Given this complexity, it is not surprising that there are numerous congenital disorders of skeletal development.

In this chapter, we review current understanding of how bone cells are formed and perform their functions, interact with one another to form and maintain bones, and how deficiency, mutation, aberrant, or overexpression of the genes that encode the proteins involved in these functions can lead to common and rare bone diseases.

2 OSTEOCLASTS

OCs are multinucleated cells formed by cytoplasmic, but not nuclear, fusion of committed precursors derived from myeloid lineage hematopoietic cells that also give rise to macrophages.[2] Differentiation of the progenitor cells requires their expression of cytokine receptors and numerous transcription factors and signaling molecules that regulate osteoclastogenesis. Macrophage-colony stimulating factor (M-CSF) and RANKL are the two most important cytokines required for OC formation under basal and pathologic conditions,[2,7] but costimulatory signaling through other receptors also mediates osteoclastogenesis, particularly in response to inflammation[8] OCs have long been considered to be merely bone-degrading cells whose formation and functions were under the control of osteoblastic, stromal, and immune cells in the marrow. However, OCs and their precursors (OCPs) interact with and positively and negatively regulate the formation and functions of these and other cell types, and they can behave as immune cells.[9] These findings and reports of OCs having regulatory roles in autoimmune and inflammatory diseases affecting the skeleton spawned the field of osteoimmunology.[8] Murine and human genetic studies have identified several genetically inherited diseases that result from mutations in genes that regulate the formation and activation of OCs. This chapter will focus on current knowledge of the genes and proteins that regulate these processes and how defects in them affect the skeleton.

2.1 Regulation of Osteoclast Formation: The RANKL–RANK–OPG Pathway

The RANKL/RANK/NF-κB signaling system and osteoprotegerin (OPG), which positively and negatively regulate the mid-to-later stages of osteoclastogenesis were discovered >20 years ago.[2,10] These seminal studies revealed that RANKL$^{-/-}$ and transgenic mice overexpressing OPG had marked osteopetrosis because they lacked OCs, while OPG$^{-/-}$ mice had severe osteoporosis due the unopposed OC-inducing effects of RANKL. Mice deficient in NF-κB1 and 2, two major components of the NF-κB signaling pathways that regulate immune responses, were reported earlier to have marked osteopetrosis due to a lack of OCs.[2] Later, it became clear that NF-κB signals downstream from RANK, and is required for RANKL-induced OC formation.[2,10]

RANKL is a member of the TNF superfamily of proteins and is typically expressed on the surface of osteoblastic cells in response to most of the factors known to stimulate bone resorption. However, like M-CSF, it is also secreted by osteoblastic cells and by numerous other cell types, including activated T cells,[2,10] B cells, and synovial cells in joints of patients with rheumatoid arthritis (RA) where, along with other cytokines, it contributes to joint destruction,[2,10] and where synoviocytes appear to be the major source of RANKL.[11] Chondrocytes in growth plates express RANKL, RANK, and OPG.[2] 1,25-dihydroxyvitamin D, bone morphogenetic protein 2 (BMP2) and Wnt/β-catenin signaling regulate chondrocyte expression of RANKL to attract OCPs to growth plates for removal of newly formed bone.[2] RANKL$^{-/-}$ and RANK$^{-/-}$ mice, like NF-κB1/2 dKO mice, also have impaired B-cell development, and failure of lymph node formation[2] and mammary lobular hyperplasia during pregnancy leaving them unable to feed their offspring.[12] RANKL centrally controls fever and body temperature in females[12] and promotes mammary cell proliferation,[12] carcinogenesis, and breast cancer metastasis to bone.[12] It also has antiinflammatory and neuroprotective effects in a mouse model of ischemic stroke in which it limits infarct volume.[12] Mutations in RANKL occur rarely in humans associated with osteopetrosis, but affected individuals do not appear to have obvious immunological defects.[13]

RANK, a TNF receptor superfamily member, is expressed by OCPs in response to PU.1, microphthalmia-induced transcription factor (MITF), M-CSF, TNF[2], Il-34,[14] and Wnt5a,[15] thus priming them for terminal differentiation when they encounter RANKL. RANK is also expressed by dendritic cells, normal breast epithelial cells,[12] and in some cancers, including breast and prostate.[12] Inactivating mutations of *rank* are rare in humans and are associated with OC-poor osteopetrosis.[13,16] Activating *rank* mutations are more common[13] and account for the increased OC formation, activity, and osteolysis seen in some patients with early-onset (juvenile) Paget's disease, expansile skeletal hyperphosphatasia, and familial expansile osteolysis.[5,6]

OPG binds to RANKL and prevents its interaction with RANK and downstream signaling through TNF receptor-associated factor 6 (TRAF6) (Fig. 11.1). It is

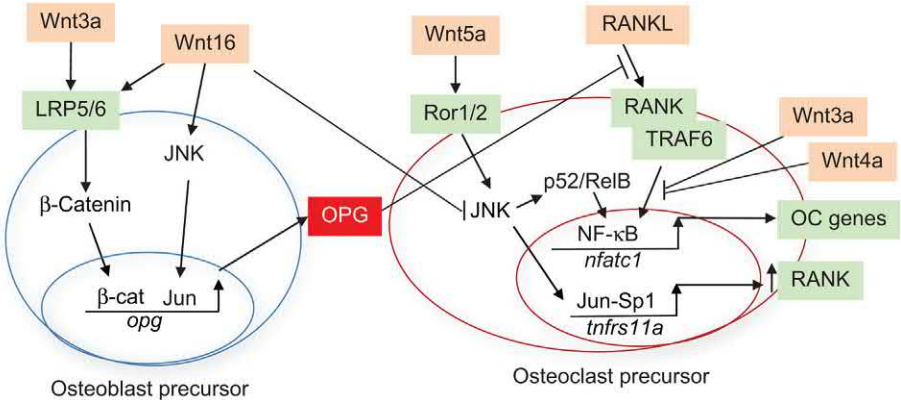

FIGURE 11.1 Wnt regulation of osteoclastogenesis through direct and indirect mechanisms. Wnt3a and Wnt16 inhibit osteoclast (*OC*) formation by upregulating *opg* expression in osteoblastic cells via β-catenin in the Wnt canonical pathway. Wnt16 also upregulates *opg* expression through Jun kinase/Jun signaling in the noncanonical pathway; in addition, Wnt16 expressed by osteoblastic cells also limits OC formation and activation directly by inhibiting RANKL-induced JNK/NF-κB-mediated *nfatc1* expression. In contrast, Wnt5a, also expressed by osteoblastic cells, increases *tnfrs11a* (*rank*) expression via Ror2/JNK signaling in the noncanonical pathway, leading to enhanced OC formation. Wnt4 inhibits RANK/TRAF6-induced expression of NF-κB-mediated *nfatc1*, which Wnt3a also inhibits.

secreted by OBs in response to most of the factors that also upregulate RANKL expression and in this way it limits OC formation, activity and survival.[12] Cells in numerous other organs express OPG, including the liver, heart, spleen, and kidney, where it has other regulatory functions. Some patients with juvenile Paget's disease, an autosomal recessive disorder,[17] have homozygous partial deletions of *opg* resulting in osteopenia and fractures. Some children with idiopathic hyperphosphatasia, an autosomal recessive disease associated with increased bone turnover and deformities of long bones, acetabular protrusion, and kyphosis, have an inactivating deletion in exon 3 of *opg*.

Major pathways that regulate OB formation and differentiation of MSCs to OBs also affect RANKL/RANK and/or OPG expression and OC formation. For example, Wnt3a- and Wnt16-induced canonical signaling through β-catenin upregulates OPG expression in OBs[18] (Fig. 11.1). Wnt16, Wnt3a,[19] and Wnt4a[20] expressed by osteoblastic cells also limit OC formation noncanonically by inhibiting RANKL-mediated noncanonical NF-κB-induced NFATc1 expression (Fig. 11.1). Wnt5a, also expressed by osteoblastic cells, positively regulates OC formation noncanonically through receptor tyrosine kinase (TK)-like orphan receptor (Ror) proteins expressed on OCPs that leads c-Jun N-terminal kinase (JNK)-mediated increased expression of RANK[15] (Fig. 11.1). Importantly, a soluble form of Ror2 acted as a decoy receptor of Wnt5a and abrogated bone destruction in mouse models of arthritis.[15] Activation of β-catenin signaling in early OCPs promotes their differentiation into OCs, but activation of this pathway in more differentiated precursors inhibits OC formation[21] Thus, Wnts can have positive and negative regulatory roles in osteoclastogenesis. In addition, Jagged1/Notch1 signaling, which also regulates MSC numbers and OB differentiation, negatively regulates OC formation indirectly by affecting the OPG/RANKL ratio in stromal cells.[2,22,23] However, the effects of Notch ligands and receptor signaling on osteoclastogenesis are complex and may be time- and context-dependent.[24]

OPG$^{-/-}$ mice also have aortic and renal artery medial calcification,[12] which complicates atherosclerotic plaques on the intimal surfaces of arteries, particularly in patients with diabetes mellitus and/or chronic renal failure. OPG has been implicated in calcification because OPG/apoE dKO mice have more accelerated calcific atherosclerosis than apoE$^{-/-}$ mice.[2,12] Aberrant OPG and RANKL expression have been implicated in cardiovascular disease,[25] diabetes, hypertension, and numerous other diseases, suggesting that OPG or RANKL inhibitors could be used to limit calcification of arteries in these common diseases.

2.2 Transcription Factor Regulation of Osteoclastogenesis

Transcription factors with essential functions in hematopoiesis, including PU.1, Pax5, and NF-κB, also regulate multiple stages of OCP differentiation. PU.1$^{-/-}$ and Pax5$^{-/-}$ mice, like NF-κB1/2 dKO mice, do not form OCs and develop marked osteopetrosis.[2,16] PU.1 along with MITF regulates expression of c-fms, the M-CSF receptor in OCPs, and M-CSF induces RANK expression in OCPs by upregulating c-Fos expression. However, M-CSF alone is unable to drive complete progenitor cell differentiation into OCs, which requires exposure to RANKL and activation of c-Fos and NFATc1 through NF-κB[2] (Fig. 11.2). NF-κB1/2 dKO mice have increased numbers of CD11b + /RANK + OCPs[2], similar to RANKL$^{-/-}$ mice; if treatment with Denosumab,

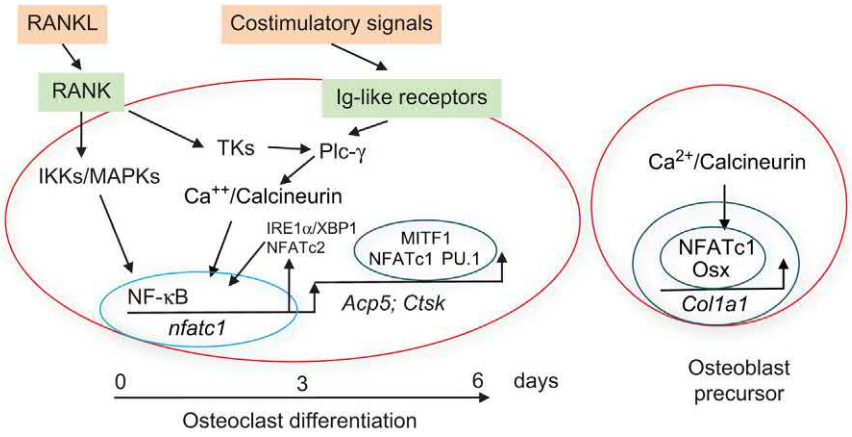

FIGURE 11.2 Activation of NFATc1 in osteoclastic and osteoblastic cells. RANKL/RANK signaling activates NF-κB to induce very early expression of NFATc1, which transiently autoamplifies its own expression through NFATc2 and IRE1α/XBP1 and induces OCP differentiation. NFATc1 is also activated by costimulatory signaling and by RANK through Brouton and Tec tyrosine kinases (*TKs*), which activate Plcγ. This leads to intracellular Ca^{2+} fluxes, which activate calcineurin-mediated NFATc1 dephosphorylation and NFATc1 nuclear translocation. In the later phases of OC formation, NFATc1 binds to the promoters of TRAP (*Acp5*) and cathepsin K (*Ctsk*) in a complex with MITF and PU.1 to promote their expression and bone resorption. NFATc1 also induces expression of genes involved in OCP fusion, including DC-STAMP, OC-STAMP, and Atp6v0d2, as well as intergrin β3 and MMP9. NFATc1 is also involved in osteoblast (*OB*) differentiation by binding to and synergizing with osterix on the *Col1a1* promoter to enhance its expression.

a RANKL monoclonal antibody, increases CD11b+/RANK + OCP numbers in humans, rapid differentiation of these cells into OCs with accelerated resorption could potentially explain the increased resorption marker and fracture rates that have been reported following cessation of therapy in some osteoporotic patients.[26] NFATc1 is activated by RANK and costimulatory signaling following its dephosphorylation through a calcium-dependent mechanism involving PLCγ and calcineurin[12] (Fig. 11.2) and regulator of G-protein signaling 10 (RGS10), which interacts with Ca^{2+}/calmodulin and phosphatidylinositol (3,4,5)-triphosphate (PIP_3) to mediate PLCγ activation and $[Ca^{2+}]_i$ oscillations in OCPs.[27] Ca^{2+}/PLCγ signaling can also be activated by adenosine, which is generated from the catabolism of adenine nucleotides in response to oxidative stress and hypoxia. Blockade or deletion of adenosine receptor A_1R reduced bone resorption in mice, resulted in osteopetrosis, while $A_{2A}R^{-/-}$ mice have increased bone resorption and reduced bone mass. An $A_{2A}R$ agonist reduced wear debris-induced bone resorption and inflammation in mice, suggesting that stimulation of $A_{2A}R$ signaling specifically might diminish orthopedic prosthesis loosening.[28]

Ca^{2+} oscillations occur through Ca^{2+} release from mitochondria and are regulated by transmembrane protein 64 (Tmem64), which interacts with sarcoplasmic endoplasmic reticulum Ca^{2+} ATPase 2 (SERCA2).[29] This leads to increased Ca^{2+}/calmodulin-dependent protein kinase (CaMK) IV activity and mitochondrial release of reactive oxygen species, both of which are required for osteoclastogenesis. $Tmem64^{-/-}$ mice have increased bone mass due to decreased OC formation, associated with suppression of CREB activation and c-Fos and NFATc1 induction. However, they also have increased bone formation, associated with increased osteoblastic expression of Runx2, osterix and β-catenin, and reduced adipogenesis.[29] Thus, Tmem64 appears to positively regulate bone resorption and limit bone formation. Limiting its expression or enhancing its degradation could increase bone mass.

Additional factors that activate NFATc1 include myostatin, which is a TGFβ superfamily member expressed by myocytes that negatively regulates muscle growth and regeneration after injury. Myostatin is also secreted by synovial fibroblasts in inflamed RA joints and by osteoblastic and osteoclastic cells. It increases osteoclastogenesis and bone resorption by paracrine and autocrine actions through SMAD2-enhanced NFATc1 nuclear translocation and activation (Fig. 11.3) resulting in increased expression of integrin αv, integrin β3, DC-STAMP, and calcitonin receptor, and in OC numbers and size.[30] Myostatin deficiency or inhibition reduced the severity of arthritis in TNF-transgenic mice, mainly through decreased bone erosion.[30] In response to RANKL, the transcription factor, c-myc, directly binds to the NFATc1 promoter[31] in association with bromodomain and extraterminal (BET) proteins to promote NFATc1 expression (Fig. 11.3). BET proteins bind to acetylated histones (H-Ac) on chromatin via their bromodomains and epigenetically regulate gene transcription by recruiting additional chromatin regulators. A small molecule BET inhibitor prevented c-myc binding to NFATc1 and reduced OC formation and OVX-induced and inflammatory bone loss.[31] NFATc1 is also activated transiently in association with Ca^{2+} oscillations and ER stress in OCPs by the inositol-requiring protein-1α/X-box–binding protein1 (IRE1α/XBP1)-mediated branch of

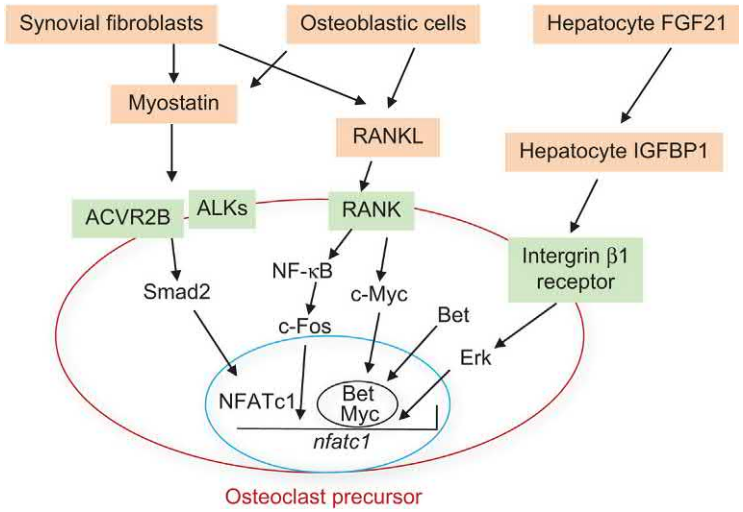

FIGURE 11.3 Regulation of NFATc1 expression in osteoclastic cells by cells outside of bone. OB precursors, osteocytes and synovial fibroblasts express RANKL, which induces NFATc1 nuclear translocation and increases *nfatc1* expression through RANK/NF-κB/c-Fos signaling. RANK signaling also induces nuclear translocation of c-Myc, which binds to the *nfatc1* promoter along with bromodomain and extra-terminal (*BET*) proteins, which function epigenetically to induce *nfatc1* expression. OB precursors and synovial fibroblasts also express myostatin, which binds to and activates a heterodimeric complex of activin receptor 2B (ACVR2B) and ALK4 (also called ACVR1B) or ALK5 (also called TGFBR1) leading to Smad2-mediated NFATc1 nuclear translocation. OCs and OCPs express myostatin, which promotes OC formation by an autocrine mechanism that is less potent than the OB paracrine effect. In response to FGF21, hepatocytes express IGFBP1, which binds to the intergrin β1 receptor on OCPs and induces ERK phosphorylation and *nfatc1* expression.

the unfolded protein response, a cellular adaptive mechanism activated in response to accumulation of unfolded proteins in the ER.[32] This temporary induction of XBP1 may trigger the transient NF-κB/NFATc2-induced autoamplification of NFATc1 (Fig. 11.2) that occurs early in response to RANKL and suggests that the UPR has a limited role in the resorptive activity of mature OCs, which NFATc1 also regulates.[12] Basal and RANKL-induced NFATc1 expression is increased by insulin-like growth factor binding protein IGFBP1, a hormone released from the liver in response to FGF21, which is also produced by the liver and regulates glucose and lipid metabolism, but also induces bone loss.[33] IGFBP1 binds to the integrin β1 receptor on OCPs leading to increased ERK phosphorylation and NFATc1 activation during the later phase of OC differentiation, consistent with NFATc1's effects to induce expression of genes involved in OC activation (Fig. 11.3). IGFBP1 blockade prevented FGF21-induced bone resorption without affecting FGF21's positive insulin-mediated effects on metabolism, suggesting that IGFBP1 inhibitors could be used to prevent FGF21-induced bone loss.[33]

Nuclear receptors comprise a superfamily of transcription factors that also regulate OC formation (reviewed in Ref. 34). They are activated by numerous factors, including steroid hormones, retinoic acid, and lipid metabolites, but there are many with no known ligands, called orphan receptors. Nuclear receptors can activate or repress gene expression by recruiting coactivators or corepressors. They include estrogen, androgen, glucocorticosteroid, and vitamin D receptors, peroxisome proliferator-activated receptors (PPARs), estrogen-related receptors, liver X receptors, and retinoic acid receptors. Estrogen and androgen inhibit OC formation and promote their apoptosis, and glucocorticosteroids and vitamin D promote OC formation. However, their effects are complex, and there are conflicting data on the molecular mechanisms involved.[35] PPARs suppress differentiation of OBs from precursors and promote adipocyte differentiation, but they also promote OC formation. For example, PPARγ directly increases c-Fos expression in OCPs and PPARγ agonists, such as rosiglitazone, which are used to treat type-2 diabetes mellitus, induce bone loss, and increase fractures in patients after long-term use due to increased bone resorption and decreased bone formation. In contrast, liver X receptors inhibit OC formation by suppressing NF-κB and c-Fos activity, while retinoic acid receptors inhibit OC activation by binding to v-maf musculoaponeurotic fibrosarcoma oncogene family protein B (MafB) in mature OCs and impairing normal ruffled border formation.[36]

2.3 Costimulatory Signaling-Mediated Osteoclastogenesis

Costimulatory signaling is another important mechanism for inducing OC formation during inflammatory and immune responses by activating PLCγ/calcineurin-Ca^{2+} fluxes[8] (Fig. 11.2). It is activated in pathologic immune responses by immune complexes (ICs, which consist predominantly of polymerized IgGs) and ligand

binding to immunoglobulin-like receptors, such as triggering receptor expressed in myeloid cells-2 (TREM-2), OC-associated receptor (OSCAR), and PIR-A (Fc receptor common γ subunit; FcRγ).[8] Adaptor molecules, including DNAX-activating protein 12 (DAP12) and FcRγ are recruited to these receptors. Phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) within these adaptor proteins activates downstream signaling. Four FcγRs are expressed in mice, and of these FcγRIIB and FcγRIII are highly expressed in OCPs. In basal conditions in which IgG levels are low, FcγRIII binds to and sequesters FcγRIIB in OCPS, and it thus inhibits OSCAR- and FcRγ-mediated osteoclastogenesis. In bone destructive autoimmune diseases IC levels increase leading to down regulation of FcgRIII expression and an increase in the FcγRIIb/FcγRIII ratio, which favors osteoclastogenesis.[37] DAP12/FcRγ dKO mice are severely osteopetrotic because they do not form OCs due to impaired RANKL-induced NFATc1 activation, but DAP12$^{-/-}$ and FcRγ$^{-/-}$ mice have only mildly impaired OC formation.[8] Mice doubly deficient in Dap12 and αvβ3 integrin have moderate osteopetrosis, associated with normal osteoclastogenesis, but deficient attachment to bone matrix and thus reduced function.[38] Despite the essential function of DAP12/FcRγ, this signaling pathway cannot induce OC formation on its own.

The ligands for most costimulatory receptors have still to be identified, but OSCAR is activated in OCPs by specific motifs within collagen fibers in bone matrix that become exposed in resorption lacunae.[39] RANK- and costimulatory signaling-mediated PLCγ activation are linked directly in OCPs through Bruton and Tec TKs[40] (Fig. 11.2). These are members of the largest family of receptor-associated Tks, mutations of which are associated with immunodeficiencies, including Bruton's agammaglobulinemia, and with malignant lymphomas.[41] Costimulatory signaling likely enhances OC formation in inflammation-induced bone resorption to mediate what can be devastating effects on joints of patients with RA. T and B lymphocytes also regulate osteoclastogenesis in inflammatory arthritis by secreting RANKL. Th17 T cells, particularly those derived from Foxp3-Tcells, are the major subset of T cells responsible for osteoclastogenesis in RA.[42] IL-17 upregulates RANKL expression in synoviocytes and induces expression of TNF, IL-6, and IL-1 from immune cells, and these cytokines in turn upregulate RANKL expression by synoviocytes. TNF expression is also increased in OCPs in response to autoantibodies against citrullinated proteins, particularly citrullinated vimentin, which are raised in the serum of RA patients, bind to OC surfaces and increase osteoclastogenesis in vitro and bone resorption when injected into mice.[43] Thus, high levels of these autoantibodies in the serum of RA patients may predict more aggressive bone resorption.

2.4 RANKL/RANK Downstream Signaling

TNF superfamily receptors, including RANK, lack intrinsic protein kinase activity, and recruit adapter proteins, called TRAFs, to their cytoplasmic tails to mediate downstream signaling. RANK recruits TRAFs 1, 2, 3, 5, and 6 in OCPs[2,12] in response to RANKL, but of these only TRAF6 appears to have essential functions in OCPs. Two sets of TRAF6$^{-/-}$ mice have been generated; both are osteopetrotic, but interestingly one lacks OCs and the other is OC rich.[2,12] The difference in the OC phenotype remains to be explained definitively and may be related to different knockout strategies, but the findings indicate essential functions for TRAF6 in both OC formation and function. RANK/TRAF-mediated protein kinase signaling activates several pathways. Four of them mediate OC formation: NF-κB-inducing kinase/inhibitor of NF-κB kinase/NF-κB, JNK/activator protein-1 (AP-1)/c-Fos, c-myc, and PLCγ/calcineurin/NFATc1[2,12] (Figs. 11.2 and 11.3). Others mediate OC activation (Src and mitogen-activated protein kinase kinase 6 (MKK6)/p38/MITF) and survival (Src and ERK).[2,12] Several other adapter molecules bind to the intracytoplasmic domain of RANK to mediate signaling, including Grb-2-associated binder (Gab) protein 2, which recruits signaling molecules that contain Src homology-2 domains and mediates RANKL-induced OC differentiation.[44]

2.5 Regulation of Osteoclast Activation

OCPs are attracted to bone surfaces from the bloodstream by a variety of factors, including CXCL-12 and sphingosine-1 phosphate.[2] Once formed, OCs form tight, roughly circular, ring-like organelle-poor sealing zones onto the bone surface, which is exposed after lining cells covering quiescent bone surfaces retract their cytoplasm. These rings have actin filament-rich podosomes, which are surrounded by adhesion, adaptor, and signaling molecules.[45] Inside these attachment zones, secretory lysosomes fuse with the cytoplasmic membrane to form the finger-like processes of the ruffled border membrane in a process regulated by autophagy.[46] Attachment initiates OC activation mainly through the vitronectin receptor αVβ3 integrin[45] and requires expression of kindlin-3.[47] Kindlin-3$^{-/-}$ mice have severe osteopetrosis due to an OC adhesion defect,[47] and patients with kindlin-3 gene mutations also have osteopetrosis,[48] which is rescued by BM transplantation, consistent with an OC defect. However, studies using MSCs from these patients suggested that enhanced OB differentiation may also have contributed to the increased bone mass, a feature not seen in the kindlin-3$^{-/-}$ mice.[48]

β3 integrin- and Src-mediated signaling is essential for ruffled border and normal actin ring formation, and thus for bone resorption. β3 integrin recruits numerous

signaling proteins, including the TKs, Src, and Syk, and the guanine nucleotide exchange factor, Vav3, resulting in activation of the small GTPase, Rac1.[45] Src recruits a number of proteins to the vitronectin and other receptors and phosphorylates tyrosine residues on them. These include Pyk2, Syk, cortactin, and the ubiquitin ligase, c-Cbl.[49] Although Src mediates RANKL-induced survival signaling in vitro, OCs survive normally in $src^{-/-}$ mice in vivo, presumably because other members of the Src family substitute for it.

The ruffled border increases the cell surface area for the passage of H^+ and Cl^- ions, which form HCl outside the cell to dissolve the mineral, and proteolytic enzymes, particularly cathepsin K, to degrade the matrix.[2,45] H^+ ions are secreted through the V-type H^+ ATP6i proton pump complex and Cl^- flows through a chloride channel encoded by *ClCN7*. The brain-type cytoplasmic creatine kinase (Ckb) regulates ATP distribution and supply in OCs to mediate actin ring formation, RhoA GTPase activity, vacuolar ATPase function and thus osteoclastic resorption. Ckb siRNA or cyclocreatine, a Ckb inhibitor, suppress bone resorption in vitro, and $Ckb^{-/-}$mice are protected against Ovx-, LPS-, and IL-1-mediated bone resorption, suggesting that Ckb is a target for prevention of pathologic bone loss.[50] The organic and inorganic breakdown components of bone pass through the cytoplasm of OCs in vesicles and are secreted from the cytoplasm facing the BM cavity into the bloodstream in a process that also involves small GTPases.[2,45]

Most cases of osteopetrosis in humans occur because of mutations in genes involved in matrix demineralization and dissolution. These include: chloride channel 7 (ClCN7); T-cell, immune regulator 1 (TCIRG1), which encodes the α3 subunit of the H^+ ATPase; carbonic anhydrase II, which catalyzes hydration of CO_2 to H_2CO_3 to provide a source of H^+, cathepsin K, mutations of which result in pycnodysostosis; and Pleckstrin homology domain-containing family M member 1 (Plekhm1), which encodes for a vesicle-associated protein linked to small GTPase signaling.[2,45,51]

OCP fusion is an important component of OC activation, because high OC nuclear numbers correlate with more aggressive resorption. Cytoplasmic fusion occurs in resorption lacunae under the influence of a number of factors, including DC-STAMP,[52] OC-STAMP, CD9, Atp6v0d2, SHP2[53] protocadherin-7, vitamin E, strawberry notch homologue 2,[2,45] and Fra-2 through leukemia inhibitory factor (LIF)/LIF receptor signaling and hypoxia.[2,45] Atp6v0d2 is a subunit of V-ATPase, a component of the V-type H^+ ATP6i proton pump complex.[2,45] NFATc1 in conjunction with MITF and PU.1 regulates expression of a number of genes encoding some of these and other genes involved in several key OC functions, including NFATc1 itself, TRAP, cathepsin K, VATPase-d2, DC-STAMP, and OSCAR[2,16,45] (Fig. 11.2). Mutations in MITF result in reduced OC formation and fusion and osteopetrosis of varying severity.[2,45] MITF also has essential functions in melanocytes, and $MITF^{-/-}$ (gray lethal) mice have not only a "malignant" form of osteopetrosis, but also gray, rather than black hair because they have defective melanin production. MMP13 secreted by myeloma cells in BM promotes OCP fusion and bone resorption independent of its proteolytic activity.[54] NFATc1 also positively regulates expression of type 1 collagen (*Col1a1*) in conjunction with osterix (Fig. 11.2), a transcription factor which functions downstream of Runx2 to mediate OB differentiation.[2,45] Thus, it may be challenging to develop a bone resorption inhibitor whose function is based on preventing PLCγ/calcineurin activation of NFATc1 that does not also have detrimental effects on bone formation.[55]

2.6 Negative Regulation of Osteoclast Formation and Function

Calcitonin, a hormone released from C cells in the thyroid, was identified many decades ago as the first negative regulator of OC activity. Since then, many others have been identified and point to the high importance of negative regulation to limit both physiologic and pathologic bone resorption. For example, there are several transcriptional repressors expressed constitutively in OCPs to limit osteoclastogenesis that are downregulated by RANK signaling. These include Eos, MafB, inhibitors of differentiation/DNA binding (ids), which are induced by CCAAT-enhancer-binding protein β (C/EBPβ), Bcl6, B lymphocyte–induced maturation protein 1 (Blimp-1) and interferon regulatory factor-8.[56]

In unstimulated OCPs, Bcl6 is recruited to NFATc1, cathepsin K, and DC-STAMP promoters to inhibit OC formation and activation. RANK signaling induces loss of Bcl6 from these promoters and NFATc1 replaces it, suggesting that these factors have a reciprocal relationship in osteoclastogenesis.[57] Consistent with this, $Bcl6^{-/-}$ mice have accelerated osteoclastogenesis and severe osteoporosis. Bcl6 is a direct target of Blimp1, *Irf8*, and *Mafb*. Blimp1 deletion in OCs resulted in impaired osteoclastogenesis and osteopetrosis due to upregulation of Bcl6.[57] Signaling through CD11b and β2 integrins in OCPs treated with M-CSF limits osteoclastogenesis by suppressing RANK expression and inducing BCL6 binding to *NFATC1* and repressing its transcription. RANKL downregulates CD11b expression, but inflammatory mediators, including fibrinogen and complement split products also enhance CD11b signaling to limit inflammation-induced osteoclastogenesis.[58] Thus, RANKL/RANK induction of NFATc1 in OCPs not only promotes osteoclastogenesis directly, but also indirectly by repressing negative regulators.

RANKL also downregulates expression of inhibitory microRNAs in OCPs to induce OC formation.

These include miR-34a, which directly targets transforming growth factor-β-induced factor 2 (Tgif2). Tgif2 induces expression of NFATc1 and AP-1, and these in turn promote Tgif2 expression in an autocrine loop. Nanoparticle-delivered miR-34a prevented OVX-induced bone loss, while transgenic mice overexpressing miR-34a in OCs have reduced bone resorption and increased bone mass, similar to Tgif2$^{-/-}$ mice.[59] These findings suggest that miR-34a is a key OC suppressor and that its administration could reduce pathologic bone resorption. Several other miRNAs have been shown to regulate OC formation both positively and negatively.[59]

RANKL induction of osteoclastogenesis is associated with a shift to oxidative metabolism in OCPs and epigenetic regulation of gene expression, including methylation and histone modification. For example, increased oxidative metabolism results in production of S-adenosylmethionine from methionine and ATP in OCPs and increased expression of the de novo DNA methyltransferase, Dnmt3a, which stably silences gene expression in numerous cell types. Dnmt3a promotes OCP differentiation by methylating CpG motifs on *Irf8* and thus stably represses its expression. OC-specific *Dnmt3a*-deficient mice are osteopetrotic and protected from Ovx-induced bone loss. In addition, a Dnmt3a inhibitor reduced OC formation and bone loss after OVX, suggesting that Dnmt3a is a new therapeutic target for osteoporosis.[60]

Other negative regulatory factors include Leucine-rich-repeat containing G-protein-coupled receptor 4 (LGR4), a recently identified additional receptor for RANKL.[61] It competes with RANK and limits OC formation by activating $G\alpha_q$ and GSK3-β signaling, which suppresses expression and activity of NFATc1. Mice with global or OC-specific loss of *Lgr4* have increased OC numbers and size and osteoporosis. Soluble LGR4 extracellular domain inhibited OC formation in mice in vivo because it bound to RANKL, similar to OPG, and it reduced RANKL-induced bone loss in three mouse models of osteoporosis. Developmental endothelial locus-1 is a protein expressed by OCs that limits their formation and resorptive activity by inhibiting NFATc1 expression through a Mac-1 integrin-dependent mechanism. Locally injected human developmental endothelial locus-1 reduced bone resorption and bone loss in a nonhuman primate model of periodontal disease.[62] Discoidin domain receptor 2 (DDR2) is a receptor TK, which promotes OB differentiation. It also limits OC formation by facilitating binding of the coreceptors, Neuropilin-1 and PlexinA1, to form a DDR2-Nrp1-PlexinA1 complex, which blocks PlexinA1-mediated osteoclastogenesis. DDR2 also prevents PlexinA1 from interacting with TREM2 and DAP12.[63] Transmembrane protein 178 (Tmem178), a downstream target of PLCγ2, localizes to the ER and negatively regulates RANKL-induced Ca^{2+} fluxes to limit NFATc1 activation and OC formation particularly in inflammation-induced bone resorption.[64] In addition, Stat5 negatively regulates bone resorption in response to IL-3-induced activation of RANKL by limiting ERK signaling. This promotes expression of the MAPK phosphatases, dual specificity phosphatase 1 (Dusp1) and Dusp2, and promotes a cell-autonomous negative feedback loop in OCs.[65]

WNT16 is an OB-derived protein linked to low cortical bone mass in humans; it inhibits osteoclastogenesis directly by limiting OCP differentiation and indirectly by increasing OPG expression in OBs (Fig. 11.1). Wnt16$^{-/-}$ mice have low-cortical thickness associated with increased endosteal OC activity, but normal trabecular bone volume. Consequently the mice develop spontaneous tibial fractures, identifying Wnt16 as an important regulator of osteoclastogenesis and fracture susceptibility.[66] Wnt4a also limits OC formation by inhibiting TRAF6/Tak1/TAK1-binding protein 2–mediated NF-κB activation in OCPs (Fig. 11.1), and transgenic mice overexpressing Wnt4a in OBs are resistant to age- and TNF-induced inflammatory bone resorption, associated with increased bone formation in vivo, while recombinant Wnt4a prevented Ovx-induced bone loss, suggesting that positive targeting of Wnt4a signaling could prevent postmenopausal and age-related bone loss.[20]

Charged multivesicular body protein 5 (CHMP5), which regulates late endosomal trafficking and multivesicular body formation, cooperates with the Paget's disease genetic risk factor, valosin-containing protein (VCP/p97), to limit OC formation by downregulating ubiquitination of IκBα downstream of RANK in association with the deubiquitinating enzyme, USP15.[67] CHMP5 in OCs also negatively regulates bone formation by limiting expression of a number of OB stimulating factors from OCs. CHMP5$^{-/-}$ mice have increased bone remodeling and a Paget's disease-like bone phenotype.

There are other mechanisms to limit the effects of RANKL and TNF on OCs, particularly in inflammatory bone diseases. For example, in rheumatoid joints, T cells and synoviocytes express RANKL, which induces c-Fos activation in OCPs.[2,8,45] c-Fos not only induces OC formation, but also limits it by inducing expression of INFβ by OCPs.[68] T cells also secrete INFγ, which degrades TRAF6 in OCPs to enhance this inhibitory activity.[8] Although TNF induces osteoclastogenesis predominantly by inducing RANKL expression by accessory cells, it can also induce osteoclastogenesis directly.[69] Furthermore, it limits osteoclastogenesis directly in OCPs.[69] RANKL and TNF activate NF-κB RelA and p50 directly in the canonical NF-κB pathway in OCPs to promote osteoclastogenesis; they also induce expression of NF-κB p100, which acts as an inhibitory κB by binding to other NF-κB proteins.[69] Unlike RANKL, TNF does not efficiently process NF-κB p100 to p52 in the noncanonical NF-κB pathway and consequently p100 levels increase in the OCPs and

limit RANKL- and TNF-induced osteoclastogenesis.[69] This buildup of p100 is associated with a concomitant increase in TRAF3, which promotes degradation of NF-κB-inducing kinase to limit OCP differentiation. RANKL-induced TRAF3 degradation can be prevented by chloroquine, a drug still used in some parts of the world to reduce inflammation in RA and SLE. Chloroquine administration to mice prevented ovariectomy-induced bone loss, suggesting that it could be used as an antiresorptive drug.[70] This buildup of p100 and TRAF3 in OCPs in part explains why TNF does not induce OC formation when administered to either $RANKL^{-/-}$ or $RANK^{-/-}$ mice, but does in these mice when they are also deficient in p100.[69] TNF can also limit OC formation by inducing expression of interferon regulatory factor-8 and the Notch-induced RPB-Jκ.[56] TNF induces bone resorption by additional mechanisms. For example, it increases OCP proliferation in and egress from the BM into the bloodstream, making more of them available to be attracted by chemokines, such as SDF-1, expression of which TNF induces in inflamed joints.[2] Thus, there are several potential strategies that could be developed to limit TNF-induced bone destruction in RA.

Toll-like receptors are activated in monocytes at sites of inflammation by microbial products and this enhances their immune response functions. Toll-like receptors signaling in OCPs, as well as GM-CSF and IL-4 inhibit osteoclastogenesis at sites of inflammation by inducing the cells to shed the extracellular domain of c-fms.[56] IL-10 is an antiinflammatory cytokine, which helps to resolve inflammation in a variety of clinical settings. It inhibits expression of NFATc1, c-Fos, c-Jun, and TREM-2 in OCPs.[56] During costimulatory signaling, ITAM-bearing proteins typically interact with partnering proteins that contain an immunoreceptor tyrosine-based inhibitory motif,[56] some of which can promote and others limit immune responses and osteoclastogenesis. For example, the human inhibitory immunoglobulin-like receptor, LILRB, and the murine paired Ig-like receptor, PIR-B, recruit the SH2 domain-containing tyrosine phosphatase 1 (SHP-1) to negatively regulate osteoclastogenesis, while Ly49Q promotes it by competing with PIR-B for association with SHP-1).[71] CD80/86 complexes, which are expressed by antigen-presenting cells and bind to CD28 on T cells during costimulation, also negatively regulate OC formation through cytotoxic T-lymphocyte-associated protein 4 (CTLA-4)–mediated activation of indoleamine 2,3-dioxygenase in OCPs, which degrades tryptophan and thus promotes OCP apoptosis.[72] CD80/86 dKO and $Ido^{-/-}$ mice are osteopenic due to increased osteoclastogenesis. Abatacept, a CTLA-4–immunoglobulin fusion protein, targets CD80/86 and inhibits osteoclastogenesis in humans.[72] Finally, interaction between ephrin B2, a protein expressed by OCPs, and its receptor, Eph 4, on OB precursors prevents c-Fos activation of NFATc1 to inhibit OCP differentiation[56] (Fig. 11.4).

2.7 Osteoclast Apoptosis

OCs are short-lived cells that die predominantly in the central and deeper parts of resorption lacunae as new OCs form at the cutting edges of the lacunae by addition of new mononuclear cells.[2] Cytokines, such as RANKL, M-CSF, TNF, IL-1, and VEGF-A, which induce OC formation and/or activation, also prevent their apoptosis through Rho family small G-protein Ras/Rac1/Erk and PI3 kinase/mTOR/S6K signaling.[2,45] Indeed, withdrawal of these cytokines from cultures leads to rapid induction

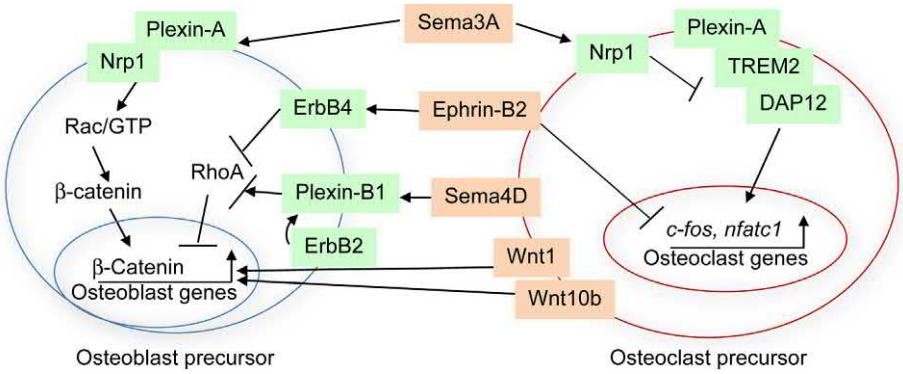

FIGURE 11.4 Signaling pathways regulated by OB–OC interacts. Sema3A is produced by OBs; its receptor, Plexin-A, is expressed on OB precursors and OCPs. Sema3A binds to Nrp1 on OB precursors and promotes β-catenin nuclear translocation via Rac/GTP to stimulate OB differentiation. Sema3A/Nrp1 signaling on OCPs disrupts Plexin 1/TREM2/DAP12-mediated (costimulatory) OC formation. Ephrin-B2 expressed on OCPs forward signals through its receptor, ErbB4, on OBs to enhance OB differentiation by causing Rho A inactivation. At the same time, ErbB4/Ephrin-B2-mediated reverse signaling into OCPs decreases OC formation by inhibiting *c-fos* and *nfactc1* transcription. Sema4D produced by OCs binds to its receptor, Plexin-B1, on OB precursors resulting in activation of ErbB2, which phosphorylates Plexin-B1. Sema4D binding to a Plexin-B1–ErbB2 receptor complex promotes bone formation by enhancing OB migration and differentiation. Wnts 1 and 10b are secreted by OCPs to promote OB precursor differentiation.

of OC apoptosis, in part mediated by reduced expression of Bcl-2, the principal member of the Bcl-2 family of antiapoptotic proteins.[73] Bcl-xL promotes OC survival in response to TNF, but not to RANKL.[2]

Mice with conditional deletion of Bcl-xL in OCs have increased OC apoptosis, but surprisingly they also have increased bone resorption apparently due to increased c-Src activity and expression of vitronectin and fibronectin by OCs, which increased integrin-mediated resorptive activity.[2,74] These findings suggest that Bcl-xL also inhibits OC resorptive activity. Bim is a proapoptotic BH3 homology-containing Bcl-2 family member whose expression is downregulated at the transcriptional level by IL-3-mediated Raf/Erk and/or PI3K/mTOR signaling. Bim is constitutively ubiquitylated and degraded on withdrawal of M-CSF, apparently by c-Cbl, an ubiquitin ligase, and $Bim^{-/-}$ mice have decreased OC activity, despite increased OC survival.[73] Thus, although in general, enhanced OC survival is associated with increased resorption and vice versa, these two activities can be uncoupled.

The earliest report of OC apoptosis was its induction by estrogen and tamoxifen in vitro through expression of TGFβ by BM cells cultured with 1,25 $(OH)_2$ Vitamin D_3.[75] Estrogen also increased OC apoptosis in vivo in mice suggesting that sex steroids limit bone resorption in part at least by limiting OC survival. More recent studies have reported that estrogen induces OC apoptosis by inducing Fas-ligand expression in OCs and OBs,[76] and that TGFβ can actually support OC survival directly through TAK1/MEK/AKT-mediated activation of NF-κB in RANKL/M-CSF-treated BM-derived OCs.[77] Thus, the effects of estrogen and TGFβ on OCs are complex. Nevertheless, administration of estrogen to sex-steroid-deficient rodents and women inhibits bone loss, in part by inducing OC apoptosis, which is also induced by high extracellular calcium concentrations that result from bone resorption.[78]

Bisphosphonates are the most widely prescribed anti-resorptive drugs. The mechanisms whereby they inhibit bone resorption have become much clearer in the past decade, but one of the earliest mechanisms identified was induction of OC apoptosis in vitro and in vivo[79] in part by caspase cleavage of Mst1 kinase. This effect is attenuated by TNF through upregulation of Bcl-xL in OCPs and OCs[80] and by glucocorticosteroids[81] by a mechanism that remains to be determined. Other studies suggest that for some nitrogen-containing bisphosphonates inhibition of OC activity, rather than promotion of apoptosis is the predominant inhibitory mechanism.[82] OPG can also induce OC apoptosis by binding to RANKL and preventing it from interacting with RANK to mediate survival and other signaling. However, OPG can also bind to TNF-related apoptosis-induced ligand, which induces OC apoptosis; one study has reported that OPG can reduce human OC apoptosis in vitro by inhibiting this mechanism.[83] Further studies are required to determine if this mechanism has a functional role in vivo.

3 OSTEOBLASTS

The term OB tends to be used rather loosely to describe a variety of cells in the lineage from committed precursors derived from MSCs to plump cells seen on bone surfaces laying down osteoid, but typically does not include osteocytes, which help to regulate and maintain bone homeostasis. OBs not only play critical roles in the skeleton, but they also influence a number of diverse processes, including hematopoiesis, cancer development and bone metastasis, and glucose and phosphate metabolism. OBs are controlled by numerous mechanisms, including key transcription factors and signaling pathways, epigenetic modification, and cell–cell communication, particularly with osteoclastic cells. Mutations related to some of these factors cause genetic disorders involving the skeleton. In this section, we describe the major factors and pathways that regulate OB formation and cellular communication under physiological conditions.

3.1 Transcription Factors and Signal Pathways

OB formation from MSCs is a two-step process involving lineage commitment of MSCs to osteogenic precursors followed by differentiation of pre-OBs and their maturation into OBs. Several critical signaling pathways and transcription factors are involved, including BMPs/Runx2, Wingless (Wnt)-β-catenin, and Notch. Mutations in these genes have been identified in human diseases associated with skeletal abnormalities, including craniofacial dysplasia, limb or joint deformities, and high and low bone mass. Given the important roles of these genes, it is not surprising that only patients with haploinsufficiency can survive, and that mutations are all autosomal-dominant.

3.1.1 BMP/RUNX2 Signaling

BMP signaling involves numerous ligands, receptors, and intracellular cascades. BMPs bind to their transmembrane serine-threonine kinase receptors to active canonical Smad dependent and noncanonical p38 mitogen-activated protein kinase signaling, resulting in expression of Runx2, an essential transcription factor for OB differentiation. The BMPs often have redundant roles in OB development. For example, BMP2, -4, and -7 regulate all stages of limb development, but single knockout mice have normal limb development.[84]

RUNX2 plays essential roles in bone formation by transactivating many genes required for OB differentiation. Runx2 is initially expressed in mesenchymal

condensations at E10.5, well before the appearance of chondroblasts or OBs at the very earliest stages of endochondral ossification.[85] It is essential for vascular invasion of the calcified hypertrophic cartilage anlagen by directly regulating transcription of VEGF-A.[86] RUNX2 levels are tightly controlled by multiple processes, including transcriptional regulation and protein modification, such as phosphorylation and ubiquitination. RUNX2 can directly link to the RNA polymerase II machinery via MED23, a member of the Mediator transcription complex. Mice deficient in Med23 in MSCs or OB precursors have a bone phenotype similar to that observed in *Runx2*$^{+/-}$ mice.[87] RUNX2 stabilizes *N*-α-acetyltransferase 10 (NAA10), a yeast protein whose function is poorly understood in mammals, which in turn inhibits OB differentiation by causing RUNX2 acetylation,[88] which also participates in RUNX2 regulation.

OB differentiation and maturation is associated with increased energy requirement, involving glucose metabolism and protein synthesis, both of which are regulated by key OB-positive regulators.[89,90,91] Glucose enters OBs through the glucose transporter (Glut1) whose expression in pre-OBs requires RUNX2. Crosstalk between Glut1 and RUNX2 determines the onset of OB differentiation and the extent of bone formation.[92] Furthermore, Wnt stimulates glutamine catabolism in pre-OBs, resulting in reduced intracellular glutamine levels, which activate a general control nonderepressible 2 (GCN2)-mediated integrated stress response to increase the translational capacity necessary for bone formation. Increased glutamine levels or depletion of GCN2 rescue the high bone mass phenotype of mice with increased Wnt signaling.[93] Manipulation of glutamine/GCN2 signaling may provide a valuable approach for normalizing deranged protein anabolism associated with human diseases.

Some of the genes encoding regulators of Runx2 are mutated in humans. For example, twist-1, a homeobox transcription factor, blocks Runx2 binding to DNA and individuals with *twist-1* haploinsufficiency suffer from Saethre–Chotzen syndrome,[94] an autosomal-dominant craniosynostosis with brachydactyly, soft tissue syndactyly and facial dysmorphism. Muscle segment homeobox homolog-2 (MSX2) is an upstream transcriptional activator of Runx2, and a single amino acid substitution in the *MSX2* gene causes Boston-type craniosynostosis,[94] a common developmental anomaly that causes abnormal skull shape due to premature closure of calvarial sutures. Moreover a genome-wide association study in 6000 Latin Americans implicated Runx2 in human facial variation.[95]

3.1.2 *Wingless (Wnt)-β-Catenin*

The Wnt family consists of a large number of secreted glycoproteins, which function by either paracrine or autocrine mechanisms. Wnt ligands bind to the 7-transmembrane domain-spanning Frizzled (Fzd) receptor and LRP5/6 coreceptors to stabilize β-catenin by preventing its phosphorylation. Unphosphorylated β-catenin translocates to nuclei, forms complexes with members of the LEF/TCF family of DNA-binding proteins, and regulates target gene expression. In the absence of a Wnt ligand, β-catenin forms a nonfunctional complex with adenomatous polyposis coli (APC), axin, glycogen synthase kinase 3, and casein kinase 1, which facilitate phosphorylation of β-catenin. Phosphorylated β-catenin undergoes ubiquitination and proteasomal degradation through its interaction with the F-box-containing E3-ligase, β-TrCP.[96]

Multiple Wnt ligands are expressed in bone during mouse limb development, including Wnts 2, 2b, 5b, 6, 7b, 9, 10a, 10b, 11, and 16.[97] Wnts 3a, 4, 5a, 7b, 10b, and 16 have been shown to bind to osteoblastic cells to regulate bone formation or osteoblastic control of osteoclastogenesis.[98,99] Interestingly, osteoclastic cells also secrete Wnt ligands, which regulate OB formation or function as a new mechanism for coupling bone formation to sites of new bone resorption. For example, mice with OC-specific deletion of TGF-β receptor (*Tgfbr2*$^{f/f}$*;cathepsin K-Cre*) develop osteoporosis due to reduced OB numbers without affects on OC numbers or activity. Wnt1 is secreted by OCs in response to TGF-β released from bone in resorption lacunae and stimulates OB precursor differentiation[100] (Fig. 11.4). In addition, TGF-β stimulates OCs to secrete Wnt10b, which promotes OB mineralization by a mechanism dependent on Smad2/3 activation and independent of TGF-β stimulation of protein kinase B or MAPK kinase[99] (Fig. 11.4). Wnt signaling also directly affects the cellular metabolism of OB-lineage cells by regulating aerobic glycolysis, glutamine catabolism, and fatty acid oxidation, which links bone anabolic signals and cellular bioenergetics.[101]

Frizzleds (Fzds) are G protein-coupled receptors to which Wnts bind and activate signaling.[102] Secreted Fzd-related proteins bind to and prevent Wnt signaling. Cell surface numbers of Fzds are controlled by a balance between E3 ligase ring finger protein 43- and zinc and ring finger 3-mediated ubiquitination[103] and deubiquitylase ubiquitin-specific protease-6-mediated deubiquitylation.[104] Roles for Fzds and their related proteins in bone came from analyses of several human skeletal disorders. Mutations in *Fzd4* are linked to familial exudative vitreo-retinopathy, an autosomal dominant disease characterized by progressive vision loss, reduced BMD and increased fracture risk in some patients.[105]

A critical role for LRP5 in bone was discovered following clinical reports that children with the autosomal recessive disorder, osteoporosis pseudoglioma, have a loss of function mutation in *Lrp5*, while patients with *Lrp5* gain of function mutations develop high bone mass associated with very strong, fracture-resistant bones.[106] These

clinical reports were confirmed in global *Lrp5*$^{-/-}$ mice, which have low bone mass associated with decreased Wnt signaling in OBs.[106] Mice deficient in Lrp5 specifically in OBs (*Lrp5*$^{f/f}$;*osteocalcin-Cre*) have reduced postnatal bone mass with increased body fat and decreased energy expenditure. Conversely, mice expressing a high bone mass mutant Lrp5 (G171V) allele are leaner with reduced plasma triglyceride and free fatty acid levels. Wnt-initiated signaling downstream of Lrp5, but not Lrp6, regulate expression of key enzymes required for fatty acid β-oxidation, suggesting that Wnt-Lrp5 signaling in OBs also regulates global energy homeostasis.[107] Mice carrying osteocyte-specific Lrp5 depletion (*Lrp5*$^{f/f}$;*DMP-1-Cre*) have smaller skeletons with reduced BMD, mineral apposition and bone formation rates in response to mechanical loading, indicating that Lrp5-mediated Wnt signaling in osteocytes significantly contributes to maintenance of biomechanical properties and bone mass.[108] Mice in which both Lrp5 and Lrp6 are conditionally deleted in chondrocytes and OBs (*Lrp5*$^{f/f}$;*Lrp6*$^{f/f}$;*collagen 2a1-Cre*) are embryonic-lethal with severe skeletal defects, while adult mice carrying Col2-cre-mediated deletions of Lrp5 and/or Lrp6 have low bone mass. These findings suggest that Lrp5 and Lrp6 have redundant functions in both embryonic skeletal development and regulation of adult bone mass.[109] These new findings emphasize the importance of LRP5 signaling in skeletal health and diseases associated with low bone mass.

LRP4 and LRP6 share a structure similar to the extracellular domain of Lrp5. *Lrp4*$^{-/-}$ mice die at birth because they can't breathe. OB-specific Lrp4 knockout (*Lrp4*$^{f/f}$;*osteocalcin-Cre*) mice develop high bone mass as they mature; by 8-months-old, they have increased bone formation, reduced bone resorption, and increased serum sclerostin levels. Loss of Lrp4 in OBs abolishes the inhibitory effect of sclerostin on Wnt/β-catenin signaling and OB differentiation because sclerostin requires Lrp4 to inhibit bone formation and impairs sclerostin induction of RANKL, leading to a lower RANKL/OPG ratio.[110] *Lrp4* mutations occur in patients with Cenani–Lenz syndrome (CLS), an autosomal-recessive disorder affecting distal limb development, associated with syndactyly and/or oligodactyly and kidney anomalies.[111] The CLS1 locus is mapped to chromosome 11p11.2-q13.1. Most CLS patients have splicing and missense mutations. Truncating mutations in *Lrp4* lead to a prenatal lethal form of CLS.[112] A novel splicing mutation in *APC* on chromosome 5q22 was reported in a CLS family with typical CLS features in addition to severe scoliosis. Thus, reduction of the negative regulator, APC, may increase availability of β-catenin by affecting its degradation, leading to a phenotypic similar to Lrp4 mutation.[113]

Lrp6$^{-/-}$ mice are perinatal lethal due to developmental abnormalities, including truncations of the axial skeleton, limb defects, and loss of the paraxial mesoderm.[114] OB-specific *Lrp6* knockout (*Lrp6*$^{f/f}$;*osteocalcin-Cre*) mice have significantly reduced bone mass, OBs and bone formation rates, but no change in OC and OB precursor numbers. They have more apoptotic OBs on bone surfaces and do not respond to the anabolic and anti-apoptotic effects of PTH.[115] Patients with a putative partial loss-of-function mutation in *Lrp6* are predisposed to early cardiovascular-related death, associated with high levels of plasma LDL and triglycerides, hypertension, diabetes, and osteoporosis.[116] Mutations, including missense, frame-shift, and splice-site mutation in *Lrp6* have also been detected in patients with tooth agenesis and/or orofacial clefting.[117,118]

Sclerostin is secreted by osteocytes and blocks Wnt signaling in part by binding to LRP5 and LRP6. Genetic deletion of sclerostin results in high bone mass due to increased bone formation in mice and humans.[119] Loss of function mutations and deletion of enhancer regions have been identified within the *SOST* gene encoding sclerostin in patients with sclerosteosis and Van Buchem disease.[120] Patients have generalized osteosclerosis, most prominent in the skull base, mandible, and long bones. Sclerosteosis is more severe than Van Buchem disease, and patients show additional features, including tall stature, syndactyly, and neurological complications due to cranial nerve compression. The difference in severity between these conditions may be explained by low levels of sclerostin in Van Buchem disease patients and undetectable serum sclerostin in sclerosteosis patients.[121]

3.1.3 Notch

In mammals, Notch comprises 4 (1–4) single-pass transmembrane receptors consisting of extracellular, transmembrane, and intracellular domains that determine cell fate following activation by 5 ligands (Jagged (Jag1) and Jag2, and Delta-like 1(Dll1), Dll3, and Dll4. Upon ligand binding, the Notch intracellular domain (NICD) is cleaved by γ-secretase and translocates to nuclei via its nuclear localization signal where it associates with and mediates removal of the RBP-Jκ transcriptional repressor to regulate expression of target genes, including Hes1 and Hey1, in the canonical pathway.[44] The C-terminus of the NICD contains a proline/glutamic acid/serine/threonine (PEST)-rich motif, which mediates its proteasomal degradation. Ubiquitination and deubiquitination regulate NICD stability through this PEST motif, contributing to tight regulation of Notch signaling in a spatial-temporal manner.[122]

Genetically modified mice with depletion of Notch[22] or γ-secretase[23] in the limb mesenchyme or OB precursors have markedly increased bone mass in adolescence followed by severe osteopenia as they aged. This led to a model that Notch signaling acts normally to maintain a pool of mesenchymal progenitors and inhibit OB precursor differentiation. Over-expression of NICD in

Col3.2-CreERT2 mice, in which the expression of the 3.2 kb *Col1a1* promoter is restricted to mature OBs and osteocytes, leads to increased bone mass and bone healing.[123] Conditional Notch activation in osteocytes increased bone formation in mice. Haploinsufficiency of the gamma-secretase, presenilin-1, which inhibits downstream Notch activation, inhibits terminal OB differentiation. Pharmacologic or genetic disruption of Notch or Jag 1 inhibits bone formation.[124] These studies suggest that Notch signaling is anabolic in mature OBs and osteocytes. However, RBP-Jκ depletion in mature OBs or chondrocytes did not affect fracture repair,[125] while depletion of RBP-Jκ in BM stromal cells resulted in fracture nonunion. These conflicting findings may reflect utilization of different Cre lines and the timing of Notch manipulation. In inflammation-induced bone loss, TNF activates Notch in MSCs, limiting OB differentiation.[126]

Mutations in *Jag1* are responsible for Alagille syndrome, an autosomal dominant disorder with defective development of the liver, heart, eyes, and bones. Skeletal abnormalities include "butterfly" vertebrae, narrower lumbar spine interpedicular spaces, and craniofacial deformities.[127] Mutations in *Notch 2* were identified by whole-exon sequencing of DNA from patients with Hajdu–Cheney syndrome[128] in which there is progressive focal bone destruction and osteoporosis, craniofacial anomalies, and renal cysts.[129] These generated a mature form of Notch 2 protein that contains a disrupted or absent proteolytic PEST sequence endowing it with an increased half-life and persistence of Notch intracellular signaling.[130] Exon sequencing revealed a compound heterozygous *Jag1/Notch 2* mutation in a patient with Alagille syndrome.[131]

OB lineage cells affect the homing and long-term repopulating of hematopoietic stem cells (HSCs), HSC mobilization, and lineage determination[132] and in the induction of leukaemogenesis. Mice carrying an activating mutation of β-catenin in OBs ($Catnb^{+/lox(ex3)}$;$\alpha_1(I)Col\text{-}Cre$) develop acute myeloid leukemia. β-catenin stimulates expression of Jag1 in OBs, which activates Notch signaling in HSCs to induce the leukemia. Increased β-catenin and Notch signaling was reported in OBs and hematopoietic cells, respectively, in 38% of patients with myelodysplastic syndromes or acute myeloid leukemia.[133] These new findings suggest that targeting Notch could increase bone mass in osteoporotic patients or at sites of osteolytic bone metastases. However, this likely will be challenging, given that the effects of Notch vary depending upon the stage of OB differentiation. Thus, Notch inhibitors might be most effective with fewer side-effects in patients with activated Notch signaling.

3.2 Epigenetic Modifications

Epigenetic regulation refers to functionally relevant modifications to the genome that do not involve changes in nucleotide sequence and act by modifying the accessibility of genes to transcription factors and other modulators. Epigenetic mechanisms play a central role in the promotion of appropriate transcriptional signaling during skeletal development and homeostasis. Epigenetic modifications include DNA methylation, histone modifications and micro-RNA and are carried out by complicated networks of epigenetic modifiers.

3.2.1 DNA Methylation

DNA methylation alters cytosines in DNA without changing the genomic DNA sequence and is modified by environmental factors and gene polymorphisms, linking environmental influences to disease pathogenesis. Most major signaling pathways in OBs are affected by DNA methylation of promoter regions of osteogenic genes.[134] OB differentiation from MSCs or precursor cells is associated with decreased DNA methylation in the promoters of homeobox 5 *(Dlx5)* and Osterix (*Osx)*, and increased expression of alkaline phosphatase, DLX5, OSX, and RUNX2.[135] BMP-2 causes hypomethylation of the *Dlx5* promoter, thereby inducing *Dlx5* expression and OB differentiation.[136] DNA methylation of the *SOST* promoter occurs close to binding sites for osteogenic transcription factors, including RUNX2 and promotes OB differentiation.[137,138] *SOST* proximal promoter DNA methylation is inversely associated with *SOST* levels in iliac bone samples.[139] MSCs cultured under mechanical loading conditions or in OB-inducing medium have decreased methylation at the *osteopontin* promoter as well as increased Osteopontin expression.[140]

3.2.2 Histone Modification

Histones are the major protein components of chromatin and act as coils around which DNA winds. There are five major histone families: H1/H5, H2A, H2B, H3, and H4. Histone modification includes methylation, acetylation, phosphorylation, ubiquitination, SUMOylation, citrullination, polyadenylation, and glycosylation, of which histone acetylation and methylation have been studied most. Histone modifications typically promote OB differentiation. For example, acetylation of histones H3 and H4 increases accessibility of the *osteocalcin* promoter to Runx2 and other osteo-inductive transcription factors. Histone acetylation is carried out by histone acetyltransferases and deacetylases (HDACs), while histone methylation requires methyltransferases and demethylase.[141] Among these, the most widely studied in bone are the HDACs, which affect OB commitment and differentiation by regulating bone-related genes[142] and modifying intracellular signaling pathways.[143] Drugs targeting epigenetic modulators have been tested in various disease models, and Vorinostat, an FDA-approved histone deacetylase inhibitor, is used to treat cancer patients. However, nonspecificity of epigenetic-targeted drugs

and potential adverse effects will likely limit their use in chronic diseases, such as osteoporosis. Thus, understanding of which epigenetic modulators are expressed and function in bone cells may help to design more bone-specific inhibitors.

Oculo-facial-cardio-dental syndrome (OFCD), an X-linked dominant disorder that mainly affects development of the eyes, facial features, heart, and teeth, occasionally includes syndactyly of toes 2–3. OFCD is due to mutations of the BCL-6 corepressor, which normally catalyzes demethylation of Histone H3 lysine 36, but fails to do so when mutated. The resultant methylation reduces binding of BCL-6 to the *AP-2α* promoter, leading to uncontrolled AP-2α expression and osteo/dentinogenic differentiation of MSCs in OFCD.[144]

3.2.3 Micro-RNA

Micro-RNAs (miRNAs) are small, 16-25bp, noncoding RNA sequences that silence RNA and regulate post-transcriptional gene expression by binding to the 3′- untranslated regions of target mRNA. Hundreds of miRNAs are involved in bone regeneration and many regulate the expression of key OB regulators.[145] For example, MR-204, miR-23a, miR-30c, and miR-34c target Runx2[146] and miR-214, miR-145, and miR-31 target *Osx*.[147] miR-135 attenuates *Smad5* expression.[148] miR-335 enhances osteogenesis indirectly by decreasing expression of *dkk1*, a specific inhibitor of Wnt/β-catenin signaling.[149] MiR-210 and miR-34c regulate TGF-β/activin[150] and Notch signaling.[151] Elevated miR-214 levels correlate negatively with the degree of bone formation in fracture specimens from aged patients. Blockade of osteoblastic miR-214 by miR-214 antagomir prevents ovariectomy- or hindlimb unloading-induced bone loss, suggesting that miR-214 may be a therapeutic target for treating osteoporosis.[152] miR-188 is highly expressed in BM MSCs from aged mice and humans. Overexpression of miR-188 in Osx-expressing osteoprogenitors reduces OB differentiation and promotes adipogenesis by directly targeting HDAC9 and mTOR signaling, suggesting that miR-188 may be a key regulator of age-related switching from osteogenesis to adipogenesis.[153]

3.3 Regulation of Osteoblast/Osteoclast Communication

Normal bone remodeling is maintained by close communication between osteoclastic and osteoblastic cells. It is initiated by OC-mediated bone resorption, releasing coupling factors from bone matrix, including TGFβ and IGF-1, which recruit OBs to bone resorption sites. TGFβ is activated by the acidic environment generated by OCs in resorption lacunae and appears to induce migration of OB precursors to resorbing surfaces,[154] a role that also has been attributed to S1P and BMP6 expressed by OCs.[155] Ephrins and Semaphorins are other "OC–OB communicating factors" that regulate bone formation (Fig. 11.4). These were first identified as axon-guidance molecules that regulate communication between neurons and axons during development of the nervous system.[156] They are also expressed in endothelial and T cells and outside the nervous system where they control cell migration, immune responses, tissue development, and angiogenesis.[157,158]

3.3.1 Ephrins

Ephs (erythropoietin-producing hepatocyte kinases) receptors and their interacting ligands, ephrins (Eph receptor-interacting proteins) are cell surface molecules that mediate both forward and reverse (thus, bidirectional) cellular responses. Fourteen Eph receptors and eight ephrin ligands have been identified in humans. OCs express ephrinsB1 and B2, and OBs express EphB receptors, particularly EphB4. Interaction of ephrinB2 on OCs with EphB4 on OBs leads to ephrinB2-mediated reverse signaling in OCPs to decrease c-Fos and NFATc1 expression and inhibit osteoclastogenesis, and forward signaling to enhance OB differentiation through EphB4-mediated Rho A inactivation[159] (Fig. 11.4). OBs also express ephrin ligands, and their expression is increased by PTH or PTHrP, which may in part mediate the bone anabolic effects of these hormones.[160] Mice carrying OB specific *EfnB2* deletion (*Efnb2$^{f/f}$;Osx1-Cre*) have delayed bone mineralization and a 50% reduction in OB differentiation in response to PTH administration. These defects are associated with significantly lower mRNA levels of late OB differentiation markers and greater levels of OB and osteocyte apoptosis, indicating an antiapoptotic role of ephrinB2 signaling in maintaining OB differentiation and bone strength.[161]

Mutations in *ephrinB1* have been reported in patients with craniofrontonasal syndrome, an X-linked developmental disorder in which affected females have multiple skeletal malformations, including asymmetry of craniofacial structures and abnormalities of the thorax.[162] Ephrin-Eph receptor signaling also appears to be involved in cancer-induced bone loss. For example, ephrinA1 and Eph A1 mRNA expression is decreased in bones from patients with metastatic prostate cancer[163] and giant cell tumor of bone.[163] Myeloma cells appear to downregulate Eph4 expression in osteoprogenitors, which could account in part for the reduced bone formation seen typically at involved sites.[163] Thus, strategies to enhance ephrin and Eph4 signaling in osteoclastic and osteoblastic cells, respectively, could enhance bone formation and inhibit bone resorption.

3.3.2 Semaphorins

Semaphorins are axonal guidance repellents that induce growth cone collapse during neuronal development and comprise a large family of secreted and

membrane-bound glycoproteins characterized by a conserved amino-terminal "Sema" domain. Semaphorins are implicated in communication between different bone cell types by relaying autocrine or paracrine signals.[164] Semaphorin 4D (Sema4D) is selectively expressed by OCs and binds to its receptor, Plexin-B1, on OBs, resulting in activation and autophosphorylation of ErbB2, which phosphorylates Plexin-B1 (Fig. 11.4). RhoA associates with Plexin-B1, and binding of Sema4D to the Plexin-B1–ErbB2 receptor complex alters the activity of RhoA-associated protein kinase, affecting two aspects of OB functions: RhoA/cadherin-11-mediated spontaneous migration and IRS-1/IGF-1-mediated differentiation.[165] *Sema4d*$^{-/-}$ mice have high bone mass associated with increased OB numbers and bone formation, but normal OC numbers.[165] Bone scaffolds loaded with siRNA for Sema4D enhances bone fracture repair in ovariectomized rats.[166]

Sema3A is predominantly expressed by OBs, while its receptor, Plexin-A1, is expressed both on OCPs and OB lineage cells. Plexin-A1 promotes OC differentiation by activating ITAM signaling via formation of a Plexin-A1–TREM-2–DAP12 complex.[167] Binding of Sema3A to Neuropilin-1 (Nrp1) reduces OCP differentiation by sequestering Plexin-A1 from TREM2 and suppressing ITAM signaling (Fig. 11.4). Sema3A also inhibits OCP migration by suppressing RhoA activation. In contrast, Sema3A stimulates OB differentiation through activation of the canonical Wnt/β-catenin pathway. Binding of Sema3A to Nrp1 results in activation of Rac1 through a Rac-specific GEF FARP2, which enhances nuclear accumulation of β-catenin (Fig. 11.4). *Sema3a*$^{-/-}$ mice are osteoporotic due to increased bone resorption accompanied by decreased bone formation. Thus, bone mass is controlled by semaphorin signaling between OBs and OCs.

Given the roles of Ephrin and Semaphorin signaling in bone cells, it will be very important to determine if they interact with one another and if there are defects in them that lead to bone diseases in humans. Interestingly, a pathway-based genome-wide association analysis in a cohort of 1000 unrelated US Caucasians revealed that among 76 pathways studied EphrinA-EphR associated most significantly with variability in femoral neck bone geometry and biomechanical strength.[168]

The importance of these new findings may go beyond OC/OB interactions. Ephrins and semaphorins are expressed by other cells, including vascular endothelial cells, T cells, and certain cancer cells; interactions between these and bone cells could contribute to changes in bone mass in pathological conditions where the functions of these cell types are altered. Interruption of the interactions between ephrins or semaphorins and their receptors might be a new target for the development of therapies to induce anabolic responses in bone in a variety of conditions.

4 CARTILAGE

Cartilage is comprised primarily of matrix (collagens and proteoglycans) that encases sparse populations of chondrocytes, which generate and maintain the matrix. There are various types of cartilage, which include the least abundant elastic cartilage (found in the pinna of the ear, trachea, epiglottis), fibrocartilage (primarily forms as a response to injury), and the most abundant, hyaline cartilage. Hyaline cartilage is also found in the trachea and bronchial tubes, in the articular surfaces of diarthrodial joints, and during development in craniofacial structures and growth plates, which drive limb lengthening and bone growth pre- and postnatally. Chondrogenesis and endochondral bone formation are not restricted to the developing skeleton; indeed, chondrocyte proliferation, maturation, hypertrophy, and terminal differentiation are reinitiated at sites of fracture repair. Additionally, diseases of cartilage, such as osteoarthritis (OA) also have significant effects on the differentiation of chondrocytes and maintenance of articular cartilage. Consequently, the cellular and molecular mechanisms that regulate chondrogenesis and chondrocyte differentiation have been studied intensively. This section describes the processes of chondrogenesis and chondrocyte differentiation and highlights some of the critical regulators and molecular targets.

4.1 Chondrocyte Formation

Chondrogenesis is required for the formation of the mineralized skeleton in vertebrates. This process begins with the aggregation and condensation of loose mesenchymal tissue to form anlagen comprised of cells that actively express various extracellular matrix (ECM) and cell adhesion molecules, importantly aggrecan (Agc1) and the IIa splice form of the α1 chain of type 2 collagen (Col2α1-IIa).[169,170] Regulation of temporal and spatial ECM secretion and the coordinated parallel steps of differentiation rely on the action of numerous morphogens/growth factors, receptors, and transcription factors. The earliest events in the mesenchyme and sclerotome that participate in anlagen formation are initially driven by the morphogen Sonic Hedgehog (Shh) via its transmembrane receptors Patched-1 and -2 (Ptch1,2), leading to recruitment of another transmembrane protein Smoothened (Smo) and activation of Gli transcription factors.[171] Activation of this signaling system leads to the induction of various targets, including the master regulator of chondrogenesis, Sox9,[172] and Nkx3-2, which maintains Sox9 expression in condensing cells.[173]

Once the early developmental signals downstream of Shh initiate Sox9 upregulation, a series of other signaling pathways contribute to its tight regulation and thus the progression of chondrogenesis. Deceleration of

chondroprogenitor entry into the chondrocyte lineage is in part restricted by Notch inhibition of Sox9 via the transcription factor, RBP-Jκ, and the downstream activation of HES1 and HES5, with chondrogenesis ensuing only following reduced signaling in this pathway.[174,175] Once Notch repression is overcome, several key pathways further drive Sox9 upregulation, expansion of chondrogenesis and entry into the chondrocyte hypertrophic program. These include FGFs,[176–178] hypoxic conditions and the concomitant upregulation of Hypoxia-inducible factor 1α (HIF-1α),[179] and TGFβ.[180] BMPs also possess potent chondrogenic activity, and consistent with this, blockade of signaling by the decoy receptor, Noggin, inhibits cartilage formation.[181] Overall, these signaling pathways and others work in concert with each other to modulate progenitor commitment to the chondrocyte lineage. The full integration of signaling modulators that drive chondrogenesis, and the subsequent maturation of chondrocytes during endochondral ossification summarized below was reviewed recently.[169]

4.2 Endochondral Ossification

As anlagen elongate during endochondral ossification, growth plates form near each end of the element, and periarticular chondrocytes near the distal ends develop a spherical shape, continue to show Sox9 upregulation, and progressively upregulate chondrocyte lineage markers, including the IIb splice form of Col2a1 and Agc1,[169,170] as well as specific downstream targets of the Indian hedgehog (Ihh) signaling pathway.[182] As chondrocytes proliferate in the centers of anlagen and undergo the early steps of maturation, they flatten and form columns parallel to the axis of longitudinal growth. Flat columnar chondrocytes, the most proliferative cells in the growing cartilage elements, express low levels of Runx2 and Osterix (Osx) and high levels of Fgfr3, Nkx3.2, and Ptc1.[169] Prehypertrophic chondrocytes enlarge slightly and initiate expression of Ihh,[183] PTHrP and its receptor (Pth1r),[184,185] and other cooperative transcription factors/cofactors, including Mef2c/2d,[186] Foxa2,[187] HDACs,[188] and Zfp521.[189] Overall, interactions among these signaling pathways dictate the pace of cell proliferation and entry into hypertrophy. Ultimately, due to progressive domination of Ihh signaling and the influence of other factors that drive chondrocyte maturation, including FGFs, BMPs, and Wnt activators of β-catenin signaling,[169] these columnar cells begin the process of hypertrophy and withdraw from the cell cycle.

As hypertrophy ensues, chondrocytes increase expression of Osx[190,191] and the master transcriptional regulator of skeletal mineralization, Runx2,[192–194] which drive enlargement of the cells and expression of molecules that facilitate matrix mineralization, including Col10a1, alkaline phosphatase, MMP9&13, osteopontin (Spp1), and osteocalcin.[169,170] Terminal maturation is triggered by IGF-1,[195] and mature chondrocytes located in the center of the anlagen produce high levels of VEGFA, which is thought to promote vascularization of the cartilage as these cells undergo apoptosis.[196] Only the most terminal hypertrophic chondrocytes express MMP13, an enzyme that controls cartilage matrix degradation, facilitates vascular invasion, and is required for creation of the marrow space.[191]

During early postnatal development, epiphyseal chondrocytes (immature chondrocytes in the epiphyseal centers at the ends of long bones) undergo maturation similar to the chondrocyte differentiation that occurs in the middle of anlagen. These cells differentiate, hypertrophy, undergo apoptosis, and are replaced by invading vasculature and OBs creating a secondary ossification center, which separates the only two areas of remaining cartilage within individual long bones of the growing skeleton: articular and mature growth plate cartilage.[197] When chondrogenesis occurs in adults, such as during fracture repair, secondary centers, or novel limbs are not formed, but repair progresses essentially the same way and hypertrophic chondrocytes are ultimately required for analogous purposes (initiation of mineralization and induction of vascular invasion).

Disruption of this orderly process of chondrogenesis and chondrocyte maturation has a significant impact on formation and growth of the skeleton. More than 380 conditions are associated with gene mutations in key signaling pathways that modulate the chondrogenic lineage and differentiation. For example, heterozygous mutations in Runx2 in humans cause cleidocranial dysplasia ,[198] consistent with this factor's central role in skeletal mineralization. Either inhibition or overactivation of signaling in the PTHrP pathway leads to disruption of orderly chondrocyte hypertrophy and dwarfism.[199,200] In fact, activating or inactivating PTHrP receptor mutations lead to a series of growth disorders, including Blomstrand's lethal chondrodysplasia, enchondromatosis, and Jansen metaphyseal chondrodysplasia.[201] An inactivating mutation in intestinal cell kinase (ICK) impairs chondrocyte Ihh signaling and causes short rib-polydactyly syndrome,[202] and inactivating mutations of FGF receptors in humans cause multiple growth defects, including Pfeiffer syndrome (FGFR1[203]), Apert Syndrome (FGFR2[204]) and craniosynostosis, achondroplasia, and hypochondroplasia (FGFR3[205–207]). Multiple hereditary exostoses is associated with an inactivating mutation of EXT1 and EXT2, leading to defective heparin sulfate production by chondroprogenitors and chondrocytes leading to cartilage-capped bony outgrowths.[208] Finally, metachondromatosis, an autosomal dominant tumor syndrome featuring multiple exostoses and enchondromas,[209,210] is associated with activation mutations of PTPN11[211,212] and downstream activation of Ihh

and PTHrP signaling in chondroprogenitors.[213] A comprehensive list of other less common genetic diseases in humans that are associated with disrupted chondrocyte function, signaling, or metabolism has been compiled and described.[214]

4.3 Endochondral Ossification in the Adult Skeleton

Healing of unstabilized skeletal fractures is supported by chondrogenesis and endochondral ossification, which is initiated by an early inflammatory response to injury.[215] Following cortical bone fracture or osteotomy, local progenitor cells residing in the periosteum, BM or other niches are sensitized, enabling them to respond to biological or biophysical stimuli produced within the local injury milieu.[216] In contrast, stabilized fractures heal by intramembranous bone formation with virtually no cartilage formation and direct osteogenic responses in the periosteal layer.[217] While the source of cells that contribute to cortical bone repair generally arise from multiple pools, in either endochondral or intramembranous healing, the periosteum is a major source of either chondro- or osteo-progenitors[218]). Data suggest that periosteum-initiated bone repair might be analogous to fetal limb bud development,[219] including reliance of the process on activation of essential pathways in limb development discussed above, including BMPs/TGFβ, PTHrP, Ihh, and Wnt signaling. Thus skeletal dysplasias that result from defects in these signaling networks likely have critical implications in successful fracture repair. Moreover, given the role of these pathways in the healing process, therapeutics to address delayed healing or fracture nonunions have been or are under development. These include targeting of the Pth1r with teriparatide,[220,221] activation of the Wnt/β-catenin pathway with antibodies that inhibit the decoy receptor-binding activities of Sclerostin[222] and Dickkopf (DKK) family members,[223] and BMP receptor agonists.[224]

4.4 Formation of Articular Cartilage

Articular cartilage development begins during embryogenesis at sites of synovial joint formation through a sequential series of steps that include patterning of the joint site, interzone formation, cavitation, and morphogenesis.[225,226] Articular chondrocytes are formed from interzone cells and, unlike human growth plate chondrocytes, which are removed completely following adolescent growth, they persist; although the mechanisms that maintain them are largely unknown. Adult articular cartilage is maintained as four distinct cellular zones from the surface to the underlying bone: superficial, intermediate, radial, and calcified cartilage. The superficial zone consists of 1–2 cell layers of flattened chondrocytes expressing Proteoglycan 4 (Prg4) (also known as superficial zone protein or lubricin), Sox9, Col2a1(IIb), Agc1, Tnc and low levels of cartilage intermediate layer protein (Cilp).[226] Chondrocytes of the intermediate zone are round and express many of the same molecules as the superficial zone except for Prg4, although they have higher levels of Cilp. Radial and calcified cartilage zone chondrocytes express markers of chondrocyte differentiation and hypertrophy, including Col10a1.[226] Each zone is maintained throughout adulthood unless stress-related injury, inflammation, or genetic defects lead to loss of the signals required to maintain or inhibit excessive differentiation of chondrocytes. These pathways that decelerate or prevent chondrocyte hypertrophy are disrupted or impaired in OA,[227] leading to progressive loss of biomechanically appropriate articular cartilage matrix.

4.5 Cartilage Degeneration

OA is the most common form of arthritis, characterized by dysfunction of articular chondrocytes, articular cartilage and meniscal degradation, periarticular bone formation (osteophytes) and often enhanced bone density below the articular cartilage surface (subchondral sclerosis).[227] While the etiology of OA is not fully understood, it is generally held that biochemical, metabolic, genetic, and trauma-related factors participate in the progression of overall joint degeneration.[227] In the early stages of disease, synovial cells produce catabolic cytokines that initially induce transient articular chondrocyte proliferation and increased matrix synthesis (Col2a1, Agc1).[228,229] However, chronic low level production of these cytokines, which include TNF, IL-1, IL-17, and -18, and PGE_2 lead to enhanced synthesis of collagenases (MMP-1, -8, -9, -13) and aggrecanases (ADAMTS4 and 5), which drive matrix degradation, and progressively erode the articular surface.[230,231] This is considered to be an initiating step in the disease process and is associated with inappropriate expression of genetic and morphologic markers of endochondral ossification by articular chondrocytes, including Runx2, Col10a1, and increased apoptosis.[232]

Several pathogenic mechanisms have been associated with the initiation and progression of OA and matrix catabolism characterized by decreased collagen networking, proteoglycan loss and reduced cartilage stiffness. These include mechanical overloading of cartilage, such as high intensity exercise, abnormally large static or sudden loading, and injury to cartilage or surrounding structures (such as the shock-absorbing meniscus in the knee), all of which increase the risk of developing OA between 6- and 20-fold in humans[233] and are associated with increased cytokine production. Specifically, IL-1 and TNF induce expression of catabolic proteins, such as MMPs and aggrecanases, and prostaglandin and nitric

oxide, which promote chondrocyte injury and apoptosis.[231,234] Articular chondrocytes in degenerating cartilage also have more reactive oxygen species, including superoxide anion and hydrogen peroxide, which also likely contribute to the pathogenesis of OA by enhancing production of MMPs and cytokines.[235]

While there are several transgenic/knockout mouse models of OA that identify important roles for key matrix molecules, signaling networks, enzymes and cytokines in the disease process, perturbation of genes involved with the regulation of chondrocyte maturation are particularly pathogenic, based on their influence over the hypertrophic program in articular chondrocytes.[236] In other words, with a singular focus on the chondrocyte, the genetic basis of disease progression may be related to defects that are specific to signaling pathways involved with controlling articular chondrocyte maturation. For example, one early study established that increased β-catenin signaling, caused by an inactivating polymorphism of the Wnt decoy receptor, FrzB, is associated with increased incidence of hip OA in women.[237] This study has prompted growth of the field's focus on the genetic basis of OA, with work over the past fifteen years identifying other OA-associated polymorphisms, with a pool of more than 50 disease-associated SNPs identified.[238] Included are various IGF signaling modifiers, VEGF, interleukins 6, 8, 16, and 17, Insulin Receptor, TGFβ1 and associated Smad signaling molecules, and COX2. Some of these mutations have been validated in studies using mouse genetics, and development of cartilage-targeted therapeutic strategies may hinge directly on our understanding of these signaling network contributions to disease.

5 CONCLUSIONS

Understanding of the mechanisms that regulate skeletal development and bone remodeling and repair has improved considerably over the past 25 years as a result of advances in molecular biology and genetics and development of techniques that permit deletion or overexpression of genes in animals. Many inherited skeletal diseases, such as osteopetrosis, juvenile osteoporosis, sclerosteosis, and cleidocranial dysplasia, have been attributed to mutations identified in specific genes that regulate OC or OB formation or functions or cartilage mineralization following seminal studies in knockout mice and human genetics. Initial studies identifying an essential role for RANKL expressed by osteoblastic stromal cells in OC formation and activation have been followed many others showing that chondrocytes, osteocytes, lymphocytes and synoviocytes are also involved and that RANKL also activates many negative pathways to limit bone destruction. There are complicated interactions between osteoclastic and osteoblastic cells that positively and negatively influence one another's formation and functions involving Wnt, Notch, and networking pathways that have given more insights into how bone remodeling is regulated locally. However, these findings have also raised many questions about how systemic hormones, growth factors, and cytokines influence these pathways and cellular interactions locally along with mechanical forces to regulate bone mass in normal and disease states. Future studies are required to determine precisely which osteoclastic and osteoblastic cells interact in remodeling units to ensure that they are filled completely during normal remodeling and how these interactions are disrupted in pathologic processes that lead to pathologic bone loss.

1 INTRODUCTION

Fracture associated with osteoporosis represent an immense and increasing public health issue. Based on current demographic trends, the number of fractures and their associated costs are projected to double or triple in the near future.[1] Indeed, by 2025, annual costs attributable to osteoporosis and fractures are expected to exceed USD 25 billion in the United States alone.[2] Most importantly, the consequences of these fractures are enormous, as those who suffer fractures experience increased mortality rates, chronic pain and disability, and a decreased quality of life.[3]

Strategies designed to prevent fractures require a sound understanding of their etiology. From an engineering viewpoint, fractures of any type are due to a structural failure of the bone. This failure occurs when the forces applied to the bone exceed its load-bearing capacity. Engineering principles dictate that the load-bearing capacity of a bone depends on the bone's morphology (e.g., its size, shape, distribution of bone mass, and microarchitecture), the intrinsic mechanical properties of the bone matrix, and the rate and direction of loads applied to the bone. Thus it is clear that factors related both to the forces applied to the bone, as well as to its load-bearing capacity are important determinants of fracture risk. Thus, identification of the genetic determinants of fracture risk are not only complicated by the unpredictable role played by skeletal loading (e.g., falls), but also by the fact that several factors contribute to bone strength. Whereas areal bone mineral density (BMD) is associated with whole-bone strength and strongly associated with fracture risk. Newer imaging modalities may allow further investigation of the genetic contributions to bone morphology and microarchitecture.[4–6]

In this chapter clinical and laboratory studies demonstrating age-related differences in bone morphology and the contribution of bone structure to bone strength are reviewed. First, the basic concepts related to the biomechanics of bone, including a summary of the factors that determine the material and structural behavior of bone, are presented, and second, the specific age-related changes in bone structure and their impact on skeletal fragility are discussed.

2 BONE BIOMECHANICS AND THE DETERMINANTS OF WHOLE-BONE STRENGTH

The ability of a bone to resist fracture (or whole-bone strength) depends on the amount of bone (i.e., mass), the spatial distribution of the bone mass (i.e., shape, ratio of cortical to trabecular bone, and microarchitecture), and the intrinsic properties of the bone matrix (Fig. 12.1). Bone remodeling, specifically the *balance* between formation and resorption, is the biologic process that mediates changes in the traits that influence bone strength. Thus, diseases, conditions, and drugs that impact bone remodeling will influence a bone's resistance to fracture.

In thinking about the determinants of bone strength and how bone strength changes with age, one must consider several important concepts. First, unlike most engineering materials, the bone is continually adapting to changes in its mechanical and hormonal environment, and is capable of self-renewal and repair. Thus, in

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00012-5

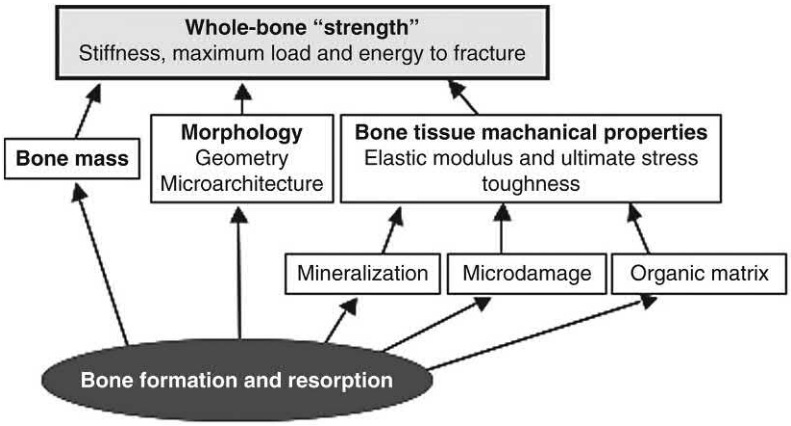

FIGURE 12.1 Determinants of whole-bone strength. Bone mass, morphology, and tissue-level material properties contribute to whole-bone strength. The balance between bone formation and resorption is the biologic process that mediates changes in bone mass, morphology, and matrix properties.

response to increased mechanical loading, a bone may adapt by altering its size, shape, and/or matrix properties. This type of adaptation is readily seen by the greater size of the bones in the dominant versus nondominant arm of tennis players[7] and of throwing athletes.[8] In addition, favorable changes in bone geometry may occur in response to deleterious changes in bone matrix properties.[9] Thus, the age-related changes in bone strength reflect continual skeletal response to altered biochemical and mechanical environments.

A second important concept concerns the hierarchical nature of the factors that influence whole-bone strength (Fig. 12.2). Alterations at the cellular, matrix, microarchitectural, and macroarchitectural levels may all impact bone mechanical properties, though not all to the same degree. In addition, the various factors are interrelated, and therefore changes in a single trait are unlikely to be the only predictor of changes in whole-bone mechanical behavior. Thus, the challenge is to identify (and measure) the factors that have the greatest impact on whole-bone strength and fracture risk.

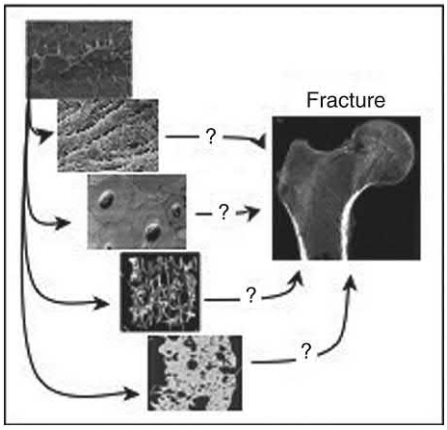

FIGURE 12.2 Hierarchical structure of bone. Changes in bone cellular activity influence the matrix, lamellar, and microarchitecture of bones. Alterations at all these different levels of structure may influence bone mechanical properties. Importantly though, the various factors are interrelated, and therefore a change at a single structural level is unlikely be the *only* predictor of changes in whole-bone mechanical behavior. The challenge is to identify and measure the factors that have the strongest association with whole-bone strength and fracture risk.

2.1 Structural Versus Material Properties of Bone

In discussing bone strength, it is important to distinguish between the material and structural properties of the bone. During any activity, a complex distribution of forces (or loads) is applied to the skeleton. With the imposition of these forces, bones undergo deformations. The relationship between the forces applied to the bone and the resulting deformations characterize the *structural behavior*, *or structural properties*, of the whole bone. Thus, the size and shape of the bone, as well as the properties of the bone tissue influence structural properties. In contrast to the structural behavior, the *material behavior*, *or material properties*, of bone tissue is independent of the specimen geometry. The material properties reflect the intrinsic biomechanical characteristics of cortical and trabecular bone. Although the biomechanical properties of the whole bone are functionally the most important outcome, assessing bone microarchitecture and tissue-level material properties may be helpful for understanding the mechanisms that underlie changes in whole-bone properties.

Importantly, in a heterogeneous material, such as bone, the definition of "material properties" is not altogether straightforward. In describing the material properties of bone, one could consider the mechanical properties of a single trabeculae, of the calcified bone matrix, or of small specimens of cortical or trabecular bone. For

purposes of this review, we consider bone "material" to include the calcified bone matrix, the marrow spaces in trabecular bone, and Haversian and Volkmann's canals in cortical bone. With this approach, we take a continuum mechanics view of bone, in that the specimen is small enough to be homogeneous (uniform), but large enough to include a sufficient number of trabeculae or osteons to characterize the overall material behavior.

2.2 Mechanical Properties of Bone Tissue Depend on Loading Direction

The elastic properties of *isotropic* materials, such as steel or rubber, are the same in all directions. The elastic properties of bone, however, depend on the orientation of the material with respect to the loading direction. Materials whose elastic properties are sensitive to loading direction are referred to as *anisotropic* materials. For example, cortical bone from the femoral diaphysis has a higher modulus and is stronger when loaded in the longitudinal direction than when loaded in the transverse direction.[10,11] The anisotropic nature of bone reflects its function as a load-bearing structure, as it is generally strongest in the primary loading direction. Hence, the degree of anisotropy in bone varies with anatomical site and functional loading.[12,13] For instance, trabecular bone from the vertebral body is highly anisotropic, being much stronger in the vertical direction than in the transverse direction,[14–16] yet trabecular bone from the iliac crest and central femoral head are nearly isotropic.[17,18]

2.3 Determinants of Biomechanical Properties of Trabecular and Cortical Bone

There is extensive literature describing the factors that influence the intrinsic (i.e., material) properties of trabecular and cortical bone, including the response not only to slow, monotonic loads, but also to high-rate impact loading, as well as to cyclic loading. The material properties of trabecular bone are influenced by many factors; however, the strongest determinants are apparent density (or volume fraction) and the microstructural arrangement of the trabecular network. Sampled over a wide range of densities, the stiffness and strength of trabecular bone are related to density in a nonlinear fashion, such that the change in strength is disproportionate (i.e., greater) than the change in density.[19–22] For example, a 25% decrease in density, approximately equivalent to 15 years of age-related bone loss, would be predicted to cause a 44% decrease in the stiffness and strength of trabecular bone. However, given the heterogeneous nature of trabecular bone, it is clear that density alone cannot explain all of the variation in trabecular bone mechanical properties. Both empirical observations and theoretical analyses indicate that trabecular microarchitecture contributes to bone mechanical properties. In particular, the degree of alignment of trabeculae with the axis of loading is a key contributor to bone mechanical behavior.[23,24]

The primary determinants of the biomechanical properties of cortical bone include porosity and the mineralization of the bone matrix. Indeed, over 80% of the variation in cortical bone stiffness and strength is explained by a power law relationship with mineralization and porosity as explanatory variables.[25–28] Some studies show that with increasing age, the degree of mineralization of the matrix increases, leading to stiffer, but more brittle material behavior,[29,30] although other studies indicate no age-related changes in the degree of mineralization.[31] McCalden et al. report that cortical porosity alone explains over 75% of the variability in the ultimate stress of cortical bone.[28] Other properties that influence cortical bone mechanical behavior include, but are not limited to, its histologic structure (primary, lamellar vs. osteonal bone), the collagen content and orientation of collagen fibers, extent and nature of collagen crosslinking, the number and composition of cement lines, and the presence of fatigue-induced microdamage.[32–37]

3 CONTRIBUTION OF BONE GEOMETRY TO BONE STRENGTH

With regard to whole-bone biomechanical behavior, the overall size of the bone (i.e., mass), as well as its morphology (i.e., ratio and distribution of cortical and trabecular bone mass) play important roles. Consistently, laboratory testing of the strength of human cadaveric vertebra, distal radii, and proximal femora has shown, not surprisingly, that larger bones are stronger than smaller bones.[38–42]

The loads applied to the skeleton generally are a combination of compression or tension forces with bending or torsional moments. The resistance to bending and torsional loading is particularly important, as the highest stresses in the appendicular skeletal are due to these loading modes. The most efficient design for resisting bending and torsional loads involves distributing the bone material far from the neutral axis of bending or torsion (generally this neutral axis is near the center of the bone). The distribution of mass about the neutral bending axis is quantitatively described by a geometric property termed the *area moment of inertia*. Importantly, the area moment of inertia of a solid circular bar is proportional to its diameter to the fourth power (i.e., moment of inertia α diameter).[4] Thus, small increases in the external diameter of a long bone can markedly improve its resistance to bending and torsional loading. The structure of the femoral neck is a good example demonstrating that the geometry of a bone reflects the forces that are applied to it. For example, the region of the femoral neck

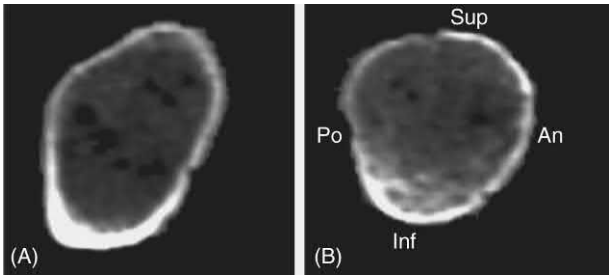

FIGURE 12.3 Cross-sectional computed tomography (CT) images of the femoral neck of a cadaveric hip. (A) Cross-section of the femoral neck adjacent to the shaft is elliptical, with the longer diameter in the superior-inferior (*Sup–Inf*) direction and with thicke cortical bone inferiorly to minimize bending stresses. (B) Cross-section of the femoral neck near the femoral head, showing a more circular shape [more area in the posterior-anterior direction (*Po–An*) than (A)] and largely trabecular bone, with uniform cortical thickness around the perimeter to withstand compressive stresses.

adjacent to the shaft is elliptical, with the longer diameter in the superior–inferior direction and with thicker cortical bone inferiorly to minimize *bending* of the femoral neck during the stance phase of walking (Fig. 12.3). In comparison, near the femoral head, where the stresses are mainly compressive, the femoral neck cross-section is largely circular and comprises trabecular bone, with uniform cortical thickness around its perimeter (Fig. 12.3).

3.1 Age-Related Changes in Bone Size and Shape

It is interesting to consider how age-related changes in bone geometry in part preserve whole-bone strength. Considerable evidence indicates that age-related declines in the material properties of bone tissue are accompanied by a redistribution of cortical and trabecular bone. Specifically, in the appendicular skeleton these changes involve endosteal and intracortical resorption along with periosteal apposition, leading to an age-related increase in the diameter of long bones but a decrease in cortical thickness.[43–45] This increase in the outer diameter helps to maintain the resistance to bending and torsional loads. It is generally thought that men undergo this pattern of favorable geometric adaptation mentioned previously to a greater extent than women, and that this may contribute to lower fracture rates in elderly men than women[43,44,46–50]; however, data employing three-dimensional (3D) quantitative computed tomography (QCT) challenge this paradigm.[51,52] A cross-sectional study by Riggs et al.[51] examined 373 women and 323 men aged 20–97 years and showed that whereas women have greater declines in volumetric bone density, both men and women show similar age-related increases in bone area and moments of inertia at the femoral neck and vertebral body, demonstrating that the extent to which bone geometry exhibits favorable geometric changes with aging is similar in men and women. A similar finding was reported in a cross-sectional study in men and women from Iceland, where femoral neck cross-sectional area increased by about 2% per decade in both sexes.[52] In contrast, longitudinal studies using QCT have been unable to detect changes in femoral neck dimensions.[53,54] To be able to detect such small increases in bone geometry with advancing age likely requires long-duration follow-up. For example, prospective studies of forearm geometry in women at menopause and with regular measurements up to 28 years afterward report that periosteal expansion is present in the first postmenopausal decade but not at later ages.[55,56] Moreover, a longitudinal study using single-energy X-ray absorptiometry measurements of the forearm in postmenopausal women over approximately 7 years found that, although periosteal expansion occurs, it does not compensate fully for endosteal resorption, leading to an age-related decline in estimated bone strength.[57] It is clear that carefully conducted longitudinal studies over several years duration, including both men and women, are needed to sort out the ability of different skeletal sites to increase their size to compensate for declines in bone density.

In sum, the sex-specific nature of age-related changes in bone geometry, particularly periosteal expansion, remain controversial. The discrepancies in findings related to sex-specific age-related changes in bone geometry may be attributed to several factors. Most importantly, many of these studies use a cross-sectional design, thereby possibly introducing secular changes that confound the data and eliminate the possibility of demonstrating a causal relationship with age. In addition, differences in methodology (direct vs. in vivo measurements), subject populations (archaeological vs. modern human specimens vs. in vivo studies), and measurement site (femur vs. radius vs. tibia) likely contribute to the conflicting findings.

4 AGE-RELATED CHANGES IN TRABECULAR AND CORTICAL BONE MICROARCHITECTURE

With aging, the coupled process of bone remodeling where bone formation equals resorption becomes unbalanced, with bone resorption exceeding formation. This imbalance in remodeling leads to a decline in bone mass overall. In particular, trabecular bone density declines profoundly with increasing age: by 45%–56% in the lumbar spine and femoral neck from age 20–90.[51] Perhaps more important than the decline in bone mass is the deterioration of trabecular and cortical microstructure that results from this net imbalance in remodeling.

In trabecular bone, the imbalance in bone remodeling leads to decreased trabecular thickness, trabecular perforation, and loss of individual trabecular elements. In

particular, whereas trabeculae aligned with the primary loading direction are maintained longer, those that are not aligned with the primary loading direction are preferentially resorbed, leading to greater structural anisotropy with increasing age. This phenomenon is especially prominent in the vertebrae, where horizontally oriented trabeculae are resorbed first, leaving behind vertically oriented trabecular struts that are unsupported horizontally and thus susceptible to failure by buckling[58–60] (Fig. 12.4). In addition, more bone resorption cavities weaken trabecular architecture, leading to declines in bone strength beyond what would be predicted simply by the decline in bone volume.[61,62]

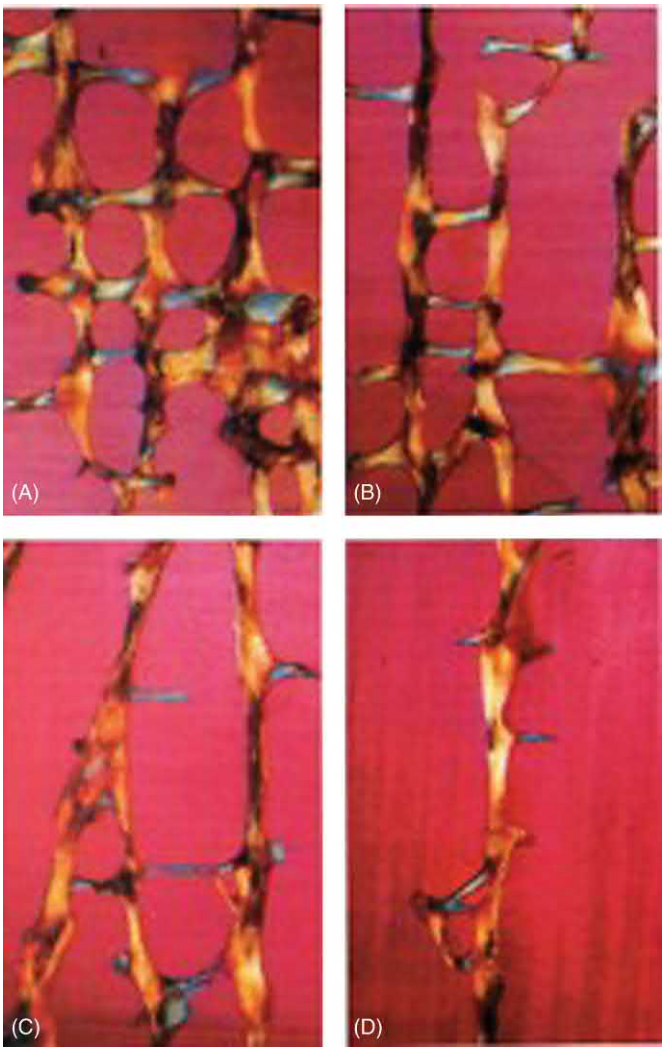

FIGURE 12.4 Age-related changes in vertebral trabecular architecture. Polarized light image of human vertebral trabecular bone in (A) 50-year-old man, (B) 58-year-old man, (C) 76-year-old man, and (D) 87-year-old woman. Note the progressive loss of horizontally oriented trabeculae, leading to a wider separation of trabecular elements, and unsupported vertically oriented trabeculae. Original magnification 8×. *Source: From Mosekilde L. Age-related changes in vertebral trabecular bone architecture—assessed by a new method.* Bone *1988;***9***:247–50, with permission.*[58]

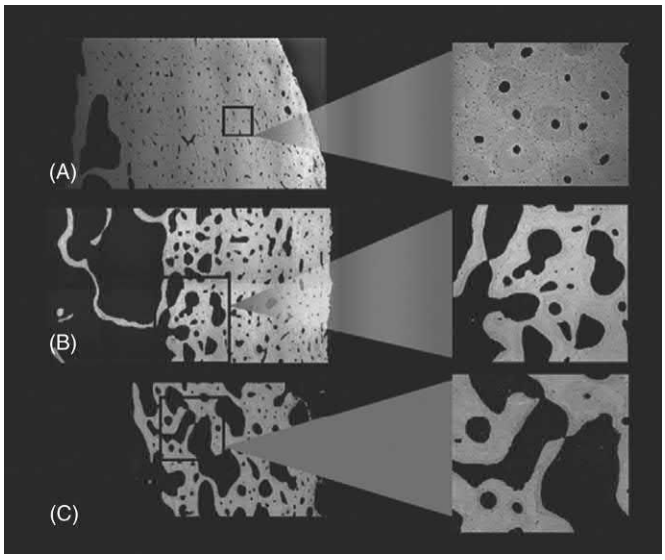

FIGURE 12.5 Age-related changes in femoral cortical structure. Micrograph of femoral subtrochanteric region in women aged (A) 29 years, (B) 67 years, and (C) 90 years. Note the small, regularly shaped pores in the young woman compared to large, irregular pores located toward the endocortical surface, leaving "trabecularized" remnants of the former cortical bone. *Source: From Zebaze RM, Ghasem-Zadeh A, Bohte A, et al. Intracortical remodeling and porosity in the distal radius and post-mortem femurs of women: a cross-sectional study.* Lancet *2010;***375***(9727):1729–36, with permission.*[66]

In cortical bone, the remodeling imbalance favoring resorption leads to a marked age-related increase in cortical porosity, particularly on the inner third of the cortex of long bones and in the femoral neck.[28,63–65] Intracortical remodeling near the endocortical surface appears to result in a "trabecularization" of the cortex as cortical pores coalesce, leaving remnants of cortical bone that resemble trabeculae[66] (Fig. 12.5). Both endocortical resorption and this trabecularization of the cortex lead to thinning of the cortex.

Trabecular bone loss begins early in life[67] and may slow with increasing age, as there are fewer and fewer trabecular surfaces for resorption to take place, and fewer remaining trabeculae to be resorbed. In contrast, cortical bone loss may begin later in life, but the process of intracortical resorption actually creates more surfaces for resorption, thereby allowing further resorptive activity. The consequence of this pattern is that much of the bone loss later in life is cortical bone.[66] Importantly, reflecting the importance of loading on the skeletal, the patterns of bone loss are not uniform neither between skeletal sites nor even within a given bone. For example, representative proximal femur images from two women, a 40-year old and a 77-year old (Fig. 12.6), show that at by age 40 there has clearly been trabecular bone loss in the trochanter and superiorly in the femoral neck, but the cortical bone is still preserved. In comparison, in the 77-year old there has been profound trabecular bone loss

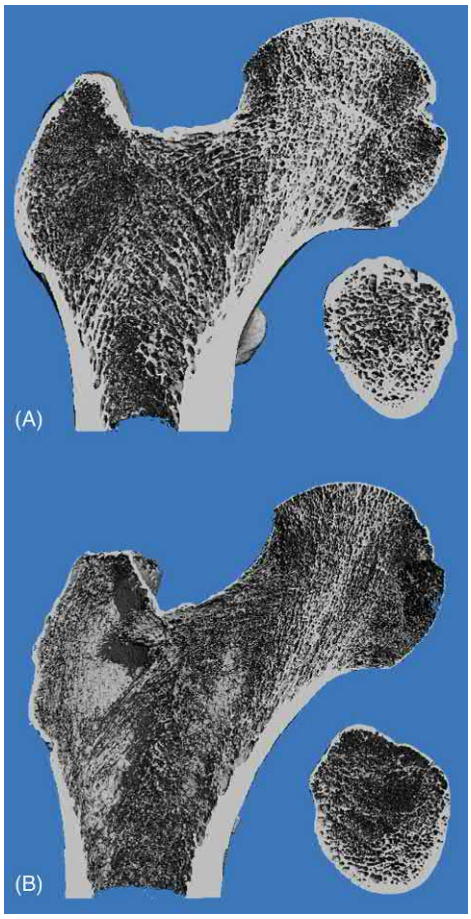

FIGURE 12.6 Age-related changes in trabecular and cortical bone structure in human proximal femur. These 3D models of cadaveric hips were made using high-resolution micro-CT. Midcoronal cross-section and cross-section through femoral neck of (A) a 40-year-old woman and (B) a 77-year-old woman, respectively. Note the extensive trabecular and cortical bone changes with increasing age.

and distinct cortical bone loss. However, in the weight-bearing inferior femoral neck both trabecular and cortical bone are preserved.

Longitudinal studies using in vivo high-resolution peripheral quantitative computed tomography (HR-pQCT) imaging of the distal radius and distal tibia have confirmed that trabecular bone loss begins in young adults and continues throughout life, whereas cortical bone loss begins later in life.[67,68] Further, rates of bone architecture decline were greater in women than in men.[68] These in vivo studies provide insight into the compartment-specific changes in bone microarchitecture that may contribute to fracture risk. To date, all studies have been conducted in Caucasian populations, and new data are needed to delineate longitudinal changes in bone microarchitecture in other race and ethnic groups, as several cross-sectional studies indicate that differences in bone microarchitecture may contribute to variation in fracture rates seen among different race/ethnic groups.[69–71]

5 CONTRIBUTION OF BONE MICROARCHITECTURE TO BONE STRENGTH

5.1 Trabecular Microarchitecture

Although bone volume fraction is among the strongest predictors of the mechanical behavior of trabecular bone, both empirical observations and theoretical analyses show that trabecular microarchitecture influences trabecular bone strength as well.[21,22,72] Trabecular architecture can be described by the shape of the basic structural elements and their orientation. The trabecular structure is generally characterized by the number of trabeculae in a given volume, their average thickness, the average distance between adjacent trabeculae, and the degree to which trabeculae are connected to each other. Previously, assessment of trabecular microarchitecture was possible only by 2D histomorphometry. However, newer high-resolution micro-CT and magnetic resonance imaging allow for 3D assessment of trabecular structure on excised bone specimens and in vivo.[5]

Laboratory studies have demonstrated moderate-to-strong correlations between trabecular bone architecture and biomechanical properties of trabecular bone.[12,73–76] Generally, however, trabecular bone microarchitecture is strongly correlated with trabecular bone volume[73,74,77] and therefore discerning the independent effects of specific architectural features on bone mechanical properties is challenging. Nonetheless, Ulrich et al. reported that including indices of trabecular architecture assessed by 3D micro-CT enhanced prediction of the biomechanical properties of human trabecular bone.[12] To further address this issue, analytical studies have been used to investigated how specific changes in trabecular architecture may influence trabecular bone mechanical behavior.[78–80] For example, Silva and Gibson employed an analytical model of vertebral trabecular bone, and reported that for the same decline in bone mass, loss of trabecular elements was 2–5 times more deleterious to trabecular bone strength than thinning of the trabecular struts, implying that maintaining connectivity of the trabecular network is critical.[78]

5.2 Age-Related Changes in Cortical and Trabecular Bone Material Properties

The age-related changes in cortical and trabecular bone microstructure lead to significant declines in elastic moduli and ultimate strength of cortical[28,29,81–84] and cancellous bone[15,60,85–88] in both men and women. In human cortical bone from the femoral middiaphysis, the tensile and compressive strengths and elastic moduli decrease approximately 2% per decade after age 20.[81] In addition, the incurred deformation and energy absorbed before fracture decrease approximately 5%–12% per decade,

suggesting the bone becomes more brittle and less tough with increasing age.[28,81,84] Moreover, the energy required to fracture a cortical bone specimen under *impact* loading decreases threefold between the ages of 3 and 90.[89]

Human cancellous bone exhibits an even more profound age-related decline in material properties.[15,85–88] For example, the elastic modulus, ultimate strength, and toughness of vertebral trabecular bone decline approximately 12%–15% per decade.[86] Aging is characterized by a marked decline in trabecular bone volume at all skeletal sites. This loss of trabecular bone volume is likely responsible for much of the decline in trabecular material properties, as there is a nonlinear relationship between bone density and strength,[19–21,86,90,91] such that a given change in bone density leads to relatively greater change in trabecular bone biomechanical properties. For example, the vertebral trabecular bone volume declines approximately 50% from ages 20–80, while vertebral trabecular biomechanical properties (compressive elastic modulus, ultimate stress, and energy to failure) decrease by approximately 75%–90%.[86]

5.3 Contribution of Bone Structure to Vertebral Strength

The vertebral body is characterized by a central core of cancellous bone surrounded by a thin covering of condensed trabecular bone (often referred to as a *cortical shell*). In the spine, compressive and bending loads are transferred from the intervertebral discs to adjacent vertebral bodies. Therefore, age-related changes in the properties of the intervertebral disc, the vertebral centrum, and the vertebral shell can each influence the load-bearing capacity of the vertebrae. In addition to a profound decline in trabecular bone volume, the thickness of the outer shell decreases from approximately 400–500 μm (age 20–40), to 200–300 μm (age 70–80), and to 120–150 μm in osteoporotic individuals.[92] This change in vertebral morphology likely influences the way that loads are transmitted throughout the spine. For instance, whereas the relative contributions of the vertebral centrum and shell to overall vertebral strength remain controversial, it is suggested that the vertebral cortical shell may account for 10%–30% of vertebral strength in healthy individuals, and due to decreased bone mass in the trabecular centrum, from 50%–90% in osteoporotic persons.[92–95] Yet, high-resolution finite element analyses indicate that the cortical shell has very little structural integrity when the vertebral trabecular centrum is absent, suggesting that the trabecular and cortical bone function together to determine vertebral strength.[96]

Several studies report that specific features of vertebral trabecular microarchtiecture contribute to whole-vertebral strength. Accordingly, addition of trabecular microarchitecture to bone mass improves the predicted vertebral strength,[23,97,98] and the bone volume fraction of *vertically oriented* trabeculae explained substantially more of the variation of whole-vertebral strength than does the total trabecular bone volume fraction (r^2 = 0.83 vs. r^2 = 0.59).[24] Furthermore, local variations in microstructure have also been associated with failure patterns in the vertebra, and accounting for the heterogeneous distribution of bone tissue throughout the centrum improves the prediction of strength compared to that based on mean density alone (r^2 = 0.75 vs. r^2 = 0.61).[99]

5.4 Contribution of Bone Structure to Proximal Femoral Strength

In addition to age,[100] loading rate,[101] and loading direction,[102–104] femoral geometry also influences the load-bearing capacity of the proximal femur. The relationship between femoral geometry and load-bearing capacity is not unexpected. As the load-bearing capacity is a *structural* property, it is influenced by the size of the specimen. Therefore, larger femurs have a greater load-bearing capacity. In fact, femoral neck area, neck width, and neck axis length are all positively correlated (r^2 = 0.21–0.79) with femoral failure loads.[100,102,105,106] The positive correlation between femoral neck length and femoral strength appears to contradict findings from clinical studies, where a longer hip axis length is associated with a greater risk of hip fracture.[107]

Cortical and trabecular bone properties both contribute to mechanical behavior of the human proximal femur. Evidence for an important role of trabecular bone in femoral strength is provided by a study of the microstructural failure mechanisms of the human proximal femur during a sideways fall impact, which showed that tissue-level failure starts in the trabecular bone.[108] Also, indices of trabecular architecture contribute independently of bone density to the prediction of femoral strength in vitro.[109] High-resolution finite element modeling of the elderly human femoral neck found that, while cortical bone supported up to 90% of the overall load in stance, it supported only about 60% of the load in a sideways fall, indicating that cortical and trabecular bone work in synergy to provide strength of the femur.[110] Additional studies are required to understand the complex relationship between hip geometry, the distribution of cortical and trabecular bone, and fracture risk.

6 CONTRIBUTION OF BONE STRUCTURE TO FRACTURE RISK IN HUMANS

Clinical studies support the importance of both bone size and microarchitecture as predictors of fracture risk. For example, lower cross-sectional area of the radius is

a risk factor for wrist fracture among both young girls[111] and postmenopausal women.[112] In addition, individuals with smaller vertebral bodies have an increased risk of vertebral fracture,[113–115] and a smaller femoral neck cross-section and lower cortical bone volume increase the risk of hip fracture in men even after adjusting for femoral neck BMD.[116]

The importance of bone microarchitecture has also been supported by clinical studies showing altered trabecular and cortical microarchitecture in subjects with fragility fractures compared to age-matched controls with no fractures.[117–120] For example, Ciarelli et al.[117] compared trabecular bone specimens from the femoral head of individuals who had suffered a hip fracture to age-matched cadaveric controls and showed that, after controlling for bone volume, trabecular bone from individuals who suffered hip fracture was more oriented in a single direction than bone from unfractured individuals. One interpretation of this finding is that the femoral trabecular bone from individuals with hip fracture was able to withstand unusual loading conditions to a lesser degree, such as would be expected during a sideways fall. Other studies have also shown altered trabecular microarchitecture among those with vertebral fracture,[118,120] and that the extent of microarchitectural deterioration is related to vertebral fracture severity.[121]

Furthermore, several cross-sectional studies have shown that in vivo measurements of trabecular or cortical bone microarchitecture at the distal radius and tibia are worse in women and men with a prior fragility fracture.[122–130] For example, Boutroy et al. were the first to demonstrate that, although osteopenic women with a history of fragility fracture had similar hip and spine BMD as other women with no prior fracture, they had worse trabecular bone architecture than those without prior fractures.[122] Similarly, premenopausal women with a recent distal radius fracture had worse trabecular bone microarchitecture than controls with no fracture, even after adjusting for forearm BMD.[131] A recent multicenter study including nearly 1400 postmenopausal women found that deficits in trabecular volumetric BMD and microarchitecture were associated with a history of fragility fracture, independent of hip BMD *t*-score.[130] Cortical porosity in the appendicular skeleton may also contribute to fracture risk, and in particular may be helpful in distinguishing women, who are at higher risk for fracture, with osteopenia by dual-energy X-ray absorptiometry areal bone mineral density (DXA-aBMD) measurements.[132,133] Cortical bone deficits at the proximal femur are also important, as specific changes in femoral neck cortical thickness, particularly a decline in thickness of the superoanterior region, are associated with hip fracture more strongly than BMD alone.[134] Furthermore, a study applying voxel-based morphometry to QCT images of the proximal femur found that compared to nonfractured controls, postmenopausal women who fractured their hips had relative deficits along the endocortical margin at both the superior and inferior aspects of the femoral neck, as well as in the intertrochanteric region.[135] Interestingly, the regions at the hip that are fracture related are similar to where age-related declines are most prominent as well, except the inferior femoral neck, which is largely preserved in normally aging women.[54]

7 CONCLUSIONS

Although fractures are associated with low BMD, many individuals who fracture do not have BMD in the osteoporotic range.[136,137] These observations indicate that a better understanding of the bone and nonbone factors that influence fracture risk may improve identification of those at the highest risk for fracture. This chapter outlined the key determinants of bone strength, focusing on the key role of bone morphology and microarchitecture. While it is clear that bone morphology and microarchitecture contribute to bone strength and fracture risk independently of BMD, it is only relatively recently that bone microstructure could be measured noninvasively. While initial cross-sectional studies support an important role for trabecular and cortical bone architecture in skeletal fragility, additional prospective studies are needed to clarify the clinical utility of bone structure measurements in vivo. There is marked heterogeneity in bone structure, even at a single skeletal site, and research is needed to determine the underlying contributors to this wide range in bone size, shape, and structure. In particular, there are few studies examining the genetic determinants of bone structure[138]; although this is likely to be an area of great interest with the growing availability of noninvasive imaging modalities to assess bone structure.

CHAPTER

13

Overview of Joint and Cartilage Biology

Rik J. Lories, Frank P. Luyten

University Hospitals Leuven and Skeletal Biology and Engineering Research Center, Leuven, Belgium

1 INTRODUCTION

The joints are specialized structures that connect the bones of the skeleton and support movement while at the same time restricting the range of motion between its different elements. The joints in the body are structurally and functionally divided into three different groups. The *synarthroses* or fibrous joints, such as the sutures between the bones of skull, allow very little or no movement. *Amphiarthroses*, typically found in the spine, have only limited mobility and are characterized by a fibrocartilaginous cap between the articulating bones. From the perspective of mobility, *diarthroses* or synovial joints are most important (Fig. 13.1). In these specialized organ-like structures, the bony bearings are capped with a thin layer of hyaline or articular cartilage while the joint cavity is lined by the *synovium* or synovial membrane. The joint capsule further encloses the joints. Intra- and extraarticular ligaments provide additional stability. Together, these different tissues allow smooth movement with very low friction and sufficient lubrication between joint surfaces while preventing dislocation. The shape of the synovial joints varies greatly from site to site. For instance, the glenohumeral joint in the shoulder and the acetabulofemoral joint in the hip typically have a ball-in-socket shape that allows rotation movements. Condyloid joints have a concave side articulating with a convex surface allowing flexion, extension, adduction, and abduction, for example, in the tibiofemoral joints of the knee and the radiocarpal joint of the wrists. Small joints in the hands and feet typically have a saddle form and allow similar directions of movement as the condyloid joints.

In this chapter, we discuss the development, anatomy, and function of the synovial joints; the main diseases affecting the joints; and give some insights into the rapidly developing aspects of joint-repair strategies.

2 JOINT DEVELOPMENT

Great progress has been made in understanding the basics of skeletal and joint development. Most data available provide insights into the developmental processes of the different skeletal elements and the molecular aspects of chondrogenesis and osteogenesis.[1,2] Less is currently known about the factors that specifically control joint development. This knowledge is particularly relevant as it provides a basis to better understand the molecular background of common joint disorders and diseases, as well as genetic syndromes associated with joint malformations.[3,4] Insights into mechanisms of joint development are also important for regenerative medicine and tissue engineering, which try to mimic nature's own mechanisms to restore a damaged tissue, a concept described as a biomimetic or developmental engineering approach.[5]

Joint development consists of different phases and events which all contribute to the future functional synovial joint.[1,6–9] These include patterning and joint specification, cell commitment, cell differentiation, joint cavitation, and integration of the joint with the rest of the skeletal elements. Part of joint development in particular the formation of the joint surface, the articular cartilage, and subchondral bone, is a postnatal and not a fetal event (Table 13.1).

2.1 Joint Development as a Part of Skeletal Development

To understand the specifics of synovial joint formation, these processes cannot be uncoupled from the general plan for the outline of the skeleton in vertebrate organisms.[1,2]

The primary skeleton is almost entirely cartilaginous and most of the cartilaginous template will be progressively replaced by bone during development

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00013-7

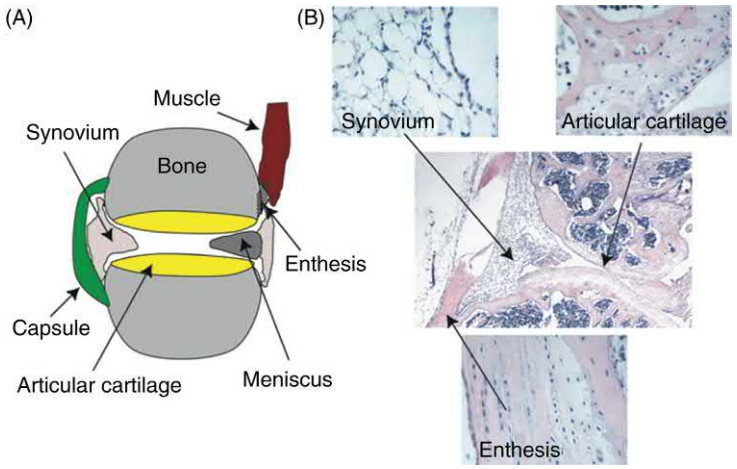

FIGURE 13.1 The anatomy of the synovial joint. (A) Schematic drawing of a synovial joint. The articular surfaces are connected by the synovium that consists of a thin pseudoepitheloid lining layer and a loose connective tissue sublining zone. In some joints a fibrocartilagenous meniscus is found. The joint is encapsulated. The enthesis is an anatomic region referring to the insertion of tendons and ligaments in the underlying bone. (B) Microscopic image of a knee joint in the mouse. Images of the synovium, the articular cartilage and the enthesis are further enlarged. *Source: Lories RJU, Luyten FP. Bone morphogenetic protein signaling in joint homeostasis and disease.* Cytokine Growth Factor Rev *2005;***16***(3):287–98.*[18]

and growth. This process is called endochondral bone formation (Fig. 13.2). Joints and additional bones will be formed concomitantly during fetal life and postnatal growth. The skeletal elements and the joints are derived from cell populations denominated as osteochondroprogenitor cells. However, as these cells also contribute to the development of other tissues, such as the *synovium*, the ligaments, and tendons; it was proposed to call them skeletogenic cells.[1]

During skeletogenesis, two different processes play an essential role: skeletal patterning which defines the position of the different skeletal elements and tissue specification. The skeletogenic cells are mainly derived from the embryonic mesoderm (lateral plate for the appendicular skeleton and paraxial mesoderm for the axial skeleton) although ectodermal neural crest cells contribute to the development of the cranial bones (Fig. 13.3). Patterning genes, such as the *Hox* (Homeobox) cluster define the position of the different skeletal elements[10,11] and master switch transcription factors, such as *Sox9* (SRY-box containing gene 9) and *Runx2* (runt related transcription factor 2) steer chondrogenesis and osteogenesis, respectively.[2,12] *Sox9* acts in a complex with functionally redundant *Sox5* and *Sox6*, whereas *Osx* (Osterix) is an essential transcription factor in osteogenic differentiation.[13]

Bone and cartilage are different tissues with distinct properties and function. Cartilage has a collagen type II, aggrecan, and other proteoglycan-rich extracellular matrix (ECM) giving it resilient properties.[14] In bone, type I collagen is prevalent and the matrix is mineralized, a process to which macromolecules, such as osteocalcin and bone sialoprotein contribute.[15] The skeletal elements form through well-defined branching of cell condensations (anlagen) in which chondrogenesis starts (Fig. 13.2). Growth of the differentiating anlagen occurs through shaping of the growth plate in the small diaphysis and later on in the epiphyses. The central diaphysis contains the primary ossification center whereas the epiphyses become the secondary ossification centers. During endochondral bone formation, progenitor or skeletogenic cells differentiate into chondrocytes and go through different phases of maturation to hypertrophy, finally becoming terminally differentiated cells undergoing apoptosis and being replaced by a calcified matrix and bone. As outlined later, the development of the articular cartilage does not follow this path and many aspects of its development and functional integration with the other skeletal tissues remains unknown.

2.2 Joint Site Determination

The first apparent sign of joint specification is the demarcation of the joint interzone, a region with more compact and tightly associated cells that forms between the branching cartilaginous elements[1,6,9] (Fig. 13.4). Gap junctions, specialized intercellular communication pores that allow the transport of inorganic ions and small hydrophilic molecules directly from cell to cell, connect the interzone cells. It is not clear whether the anlagen first develops as a continuous element in which the joint interzones are later defined or whether these zones are prespecified and never enter the sequence of skeletal element formation. Data looking at specific isoforms of the type II collagen gene transcript suggest that cartilage-associated collagen type IIB is never expressed in the joint interzone supporting the concept that the skeletal elements appear as entities different from the future joints.[8] The specification of the joint interzones may be

TABLE 13.1 Genetic Disorders in Mice and Men Linked to Genes Involved in Joint Development

Genes of interest	Mutations in mouse	Human genetic disorders	OMIM accession no. (www.omim.org)
Wnt4	Homozygous mutants exhibit impaired development of the kidney, pituitary gland, and female reproductive system. Mutants die within 24 h of birth.	Mullerian aplasia and hyperandrogenism Serkal syndrome	603490
Wnt9a	Neonatal lethality, altered chondrocyte maturation, cranial defects, and skeletal abnormalities including shortened appendicular long bones, partial joint fusions of carpal and tarsal elements, and chondroid metaplasia in synovial and fibrous joints.	None identified	602863
Wnt16	No data available.	None identified	606267
β-Catenin	Homozygous null embryos show anterior-posterior axis formation anomalies, but develop to E7. Multiple conditional mutations have shown defects in distinct stem cell types that result in proliferation defects, such as intestinal polyps, brain, and spinal cord size anomalies, etc.	Colorectal cancer Hepatoblastoma Hepatocellular carcinoma Ovarian cancer Pilomatricoma	116806
Gdf5	Homozygotes for null mutations exhibit slightly shortened long bones of the limbs, and drastically shortened bones of the feet, with some complete or partial fusions.	Acromesomelic dysplasia Hunter–Thompson type Brachydactyly, type C Chrondrodysplasia, Grebe type Fibular hypoplasia and complex brachydactyly Symphalangism, proximal Multiple synostoses syndrome 2 Osteoarthritis	601146
Gdf6	Homozygous null mice show multiple joint and skeletal patterning defects affecting the extremities, inner ear, and skull.	Klippel–Feil syndrome 1, autosomal dominant Microphthalmia, isolated 4	601147
Noggin	Homozygotes for a targeted null mutation exhibit failed closure of neural tube, exencephaly, wide club-shaped limbs, loss of tail vertebrae, shortened body axis, abnormal cartilage condensations, and lethality at birth.	Brachydactyly, type B2 Multiple synostosis syndrome 1 Stapes ankylosis with broad thumb and toes Symphalangism, proximal Tarsal–carpal coalition syndrome	602991
Chordin	Homozygotes for a targeted null mutation show some death prior to embryonic day 8.5, but most die perinatally with abnormalities of the skull, malformations of cervical, and thoracic vertebrae, cardiovascular defects, and absence of parathyroid and thymus.	None identified	603475
Sox5	Homozygous null mice fail to breathe and die at birth exhibiting a narrow thoracic cage, irregularly mineralized sternum, cleft secondary palate, and delayed bone mineralization.	None identified	604975
Sox6	Homozygotes for null mutations exhibit cardioskeletal myopathy, cardiac blockage, delayed growth, and early postnatal lethality.	None identified	607257
Sox9	Null mutant heterozygotes and conditional knockout mutants display perinatal lethality with cleft palate, hypoplasia, and distortion of numerous cartilage-derived skeletal structures, and premature mineralization in many bones. Specific conditional knockout mutations are sex reversed.	Acampomelic campomelic dysplasia Campomelic dysplasia Campomelic dysplasia with abnormal sex reversal	608160

determined by the expression of a number of genes that are associated with skeletal patterning, such as the *Hox* gene cluster. For instance, *Hoxa* genes appear to determine skeletal elements along with the proximodistal axis whereas *Hoxd* genes define the place along with the anteroposterior axis in the limb.[10,11] Boundaries or gradients between the expression of the different Hox genes could determine the position of the joint interzones.[7] From the molecular perspective, joint interzone cells are characterized by the expression of specific markers, including different Wnts [*Wnt4*, *Wnt9a* (formerly *Wnt14*), and *Wnt16*],[9,16,17] bone morphogenetic proteins (BMPs), and

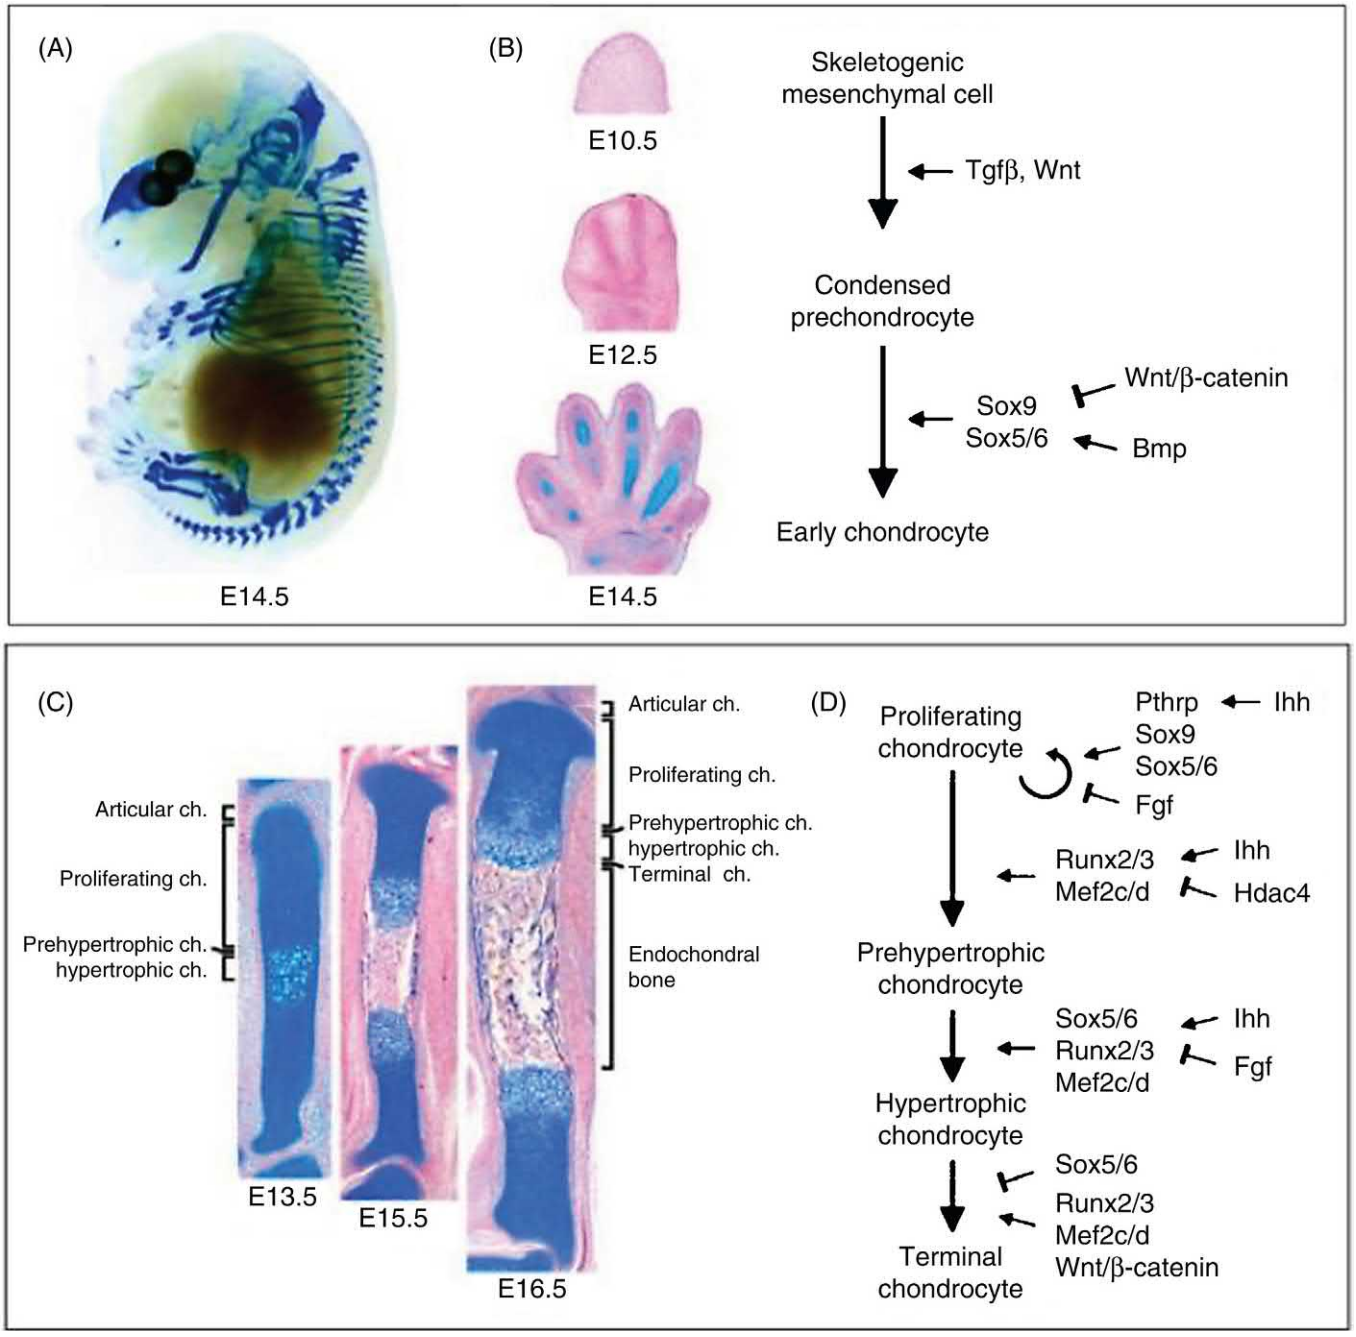

FIGURE 13.2 **Endochondral bone formation.** (A) Alcian blue staining of a mouse embryo at E14.5 demonstrates that chondrocyte differentiation of skeletogenic cells leads to the formation of a primary skeleton that is entirely cartilaginous. (B) Sections through the developing paws of mouse embryos illustrate the major steps of early chondrogenesis. At E10.5, the limb bud is filled with skeletogenic cells. By E12.5, some of these cells have formed precartilaginous condensations that prefigure the future digits. By E14.5, condensed prechondrocytes have undergone chondrocyte early differentiation. The sections are stained with alcian blue and nuclear fast red. (C) Sections through a mouse embryo tibia illustrate the development of growth plates and endochondral bone. At E13.5, early chondrocytes in the center of cartilage primordia undergo prehypertrophic and hypertrophic maturation. They reach terminal maturation and are replaced by endochondral bone by E15.5. Later on, growth plates maintain themselves and elongate developing bones. Chondrocytes keep proliferating and give rise, layer by layer, to maturing chondrocytes. These cells which eventually die and are replaced by bone. The sections are stained with alcian blue and nuclear fast red. (D) Schematic presentation of the molecular control of growth plate chondrocytes. *Source: Reproduced from Lefebvre V, Bhattaram P. Vertebrate skeletogenesis*. FIGURE 13.3 Origin of skeletal cells in the vertebrate embryo. (A) Schematic of a cross section through a mouse embryo soon after gastrulation at day 8 of development (equivalent to gestation day 17 in humans). The three germ layers are seen: ectoderm, endoderm, and mesoderm. Ectoderm-derived neural folds are rising. The mesoderm has formed the notochord and is starting to form lateral plate and paraxial derivatives on either sides of the midline. (B) Schematic showing the delamination of neural crest cells from the neural folds at the time of neural tube closure. These cells are starting to migrate inside the embryo [(*small arrows* (blue arrows in the web version)], where they will participate in the formation of various structures. (C) Schematic showing the contribution of the neural crest, lateral plate mesoderm, paraxial mesoderm, and notochord to the three major parts of the skeleton. (D) Mid-sagittal sections through the notochord of mouse embryos at the gestation days 12.5 (E12.5, top) and E15.5 (bottom). The E12.5 notochord is a rod-like structure that becomes surrounded by the mesenchymal cell condensations of the prospective vertebral bodies (VB) and intervertebral discs (IVD). E15.5 vertebral bodies are cartilaginous and notochord cells have migrated into the intervertebral disc spaces, where they have formed nuclei pulposi (NP). Sections are stained with nuclear fast red and with alcian blue, which is specific of the notochord and cartilage extracellular matrix (ECM). *Source: Lefebvre V, Bhattaram P. Vertebrate skeletogenesis.* Curr Top Dev Biol *2010;***90***:291–317.*[1]

related growth and differentiation factors (GDFs; *Gdf 5* and *6*), BMP antagonists (Noggin and Chordin),[6,18] the type II transforming growth factor beta receptor[19] *Sox5*, *6*, and *9*,[20] as well as type II collagen but not matrilin-1,[21] supporting differences between the stable articular chondrocytes and developing, transient chondrocytes in the growth plate.

2.3 What Happens in the Joint Interzone?

The joint interzone contains different populations of cells that contribute to the development of the synovial joints (Fig. 13.4). Articular progenitor cells are likely derived from the skeletogenic precursors but take a different path when present in the joint interzone.[6–8] The three-layered interzone consists of two chondrogenic layers and the densely packed cells in between where cavitation will occur.[22] Specific dissection of joint interzone cells has demonstrated the chondrogenic activities of the outer layers, which are in continuity in vivo with the epiphyseal ends with which they may integrate. The inner layer is more likely to be the source of the articular chondrocytes. Less is known about the source of the cells that will form the other tissues of the joint, such as the *synovium* and the ligaments.[8,23]

Gdf5 was one of the first genes associated with the joint interzone and its essential role in the development of the synovial joint is demonstrated by the severe skeletal phenotypes, including multiple joint fusions in mice and human, associated with loss-of-function mutations in this gene.[24–27] There is substantial functional overlap with redundancy between GDF5 and GDF6, and the phenotype of the double knockout mice is more severe than that of each single knockout model.[28] However, GDF5 is not the joint-inducing factor as in vitro and in vivo experiments have rather supported its chondrogenic properties.[3,29] Moreover, GDF5 is dynamically expressed during skeletal development, first in the developing anlagen where it appears to stimulate chondrogenesis and later in the joint interzones where it

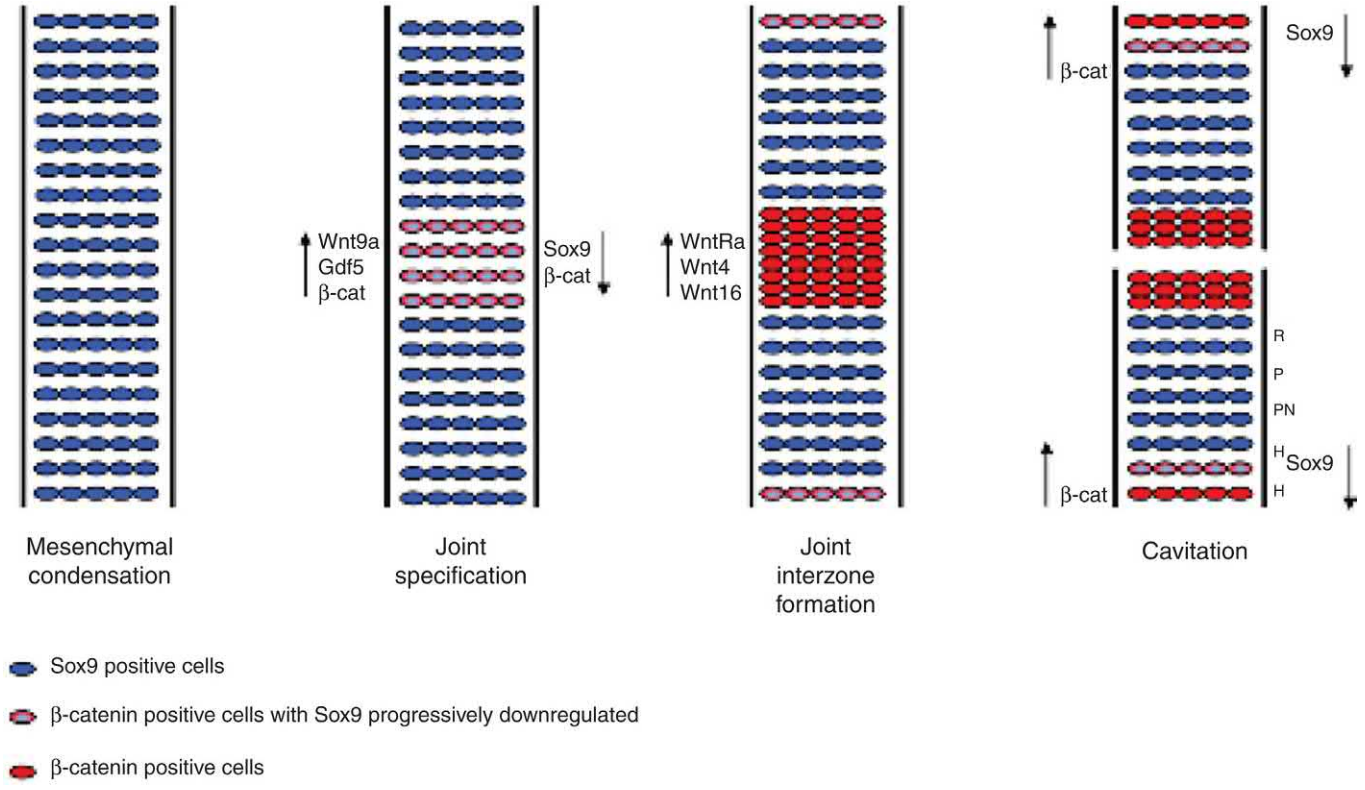

FIGURE 13.4 A model of joint formation. A mesenchymal condensation expresses *Sox9* [black (blue in the web version) ovals]. Upon *Wnt9a* signaling, transcription of β-catenin and *Gdf5* is induced while *Sox9* and collagen II repressed [*light gray* (red/blue in the web version) ovals]. Next, cells in the joint interzone cease expressing *Sox9* and maintain the expression of β-catenin [*gray* (red in the web version) *ovals*]. Finally, the cavitation process takes place with physical separation of the cartilaginous element. Concomitant with that process, *Sox9* is repressed and β-catenin induced in hypotrophic chondrocytes. *Arrows up*, induction; *arrows down*, repression; *black* (blue in the web version) *ovals*, *Sox9* positive cells; *light gray* (blue/red in web version) *ovals*, *Sox9* and β-catenin positive cells; *gray* (red in the web version) *ovals*, β-catenin positive cells. Wnt signaling and osteoarthritis.* Bone *2009;***44***(4):522–27.*[4]

may affect differentiation processes downstream of factors that initiates joint development. BMP antagonists and GDF5 processing enzymes may play a specific role in defining boundaries or gradients of BMP signaling. Of interest, the skeletal and joint consequences of loss of function in the noggin gene are far more severe than that of the chordin gene suggesting that these different BMP antagonists are not functionally redundant.[30,31]

Wnt9a is another gene that is specifically expressed within the joint interzone.[16,17] Viral overexpression in the developing chick limb induces local changes resembling the definition of a joint interzone. Moreover, *Wnt9a* is a factor that negatively affects chondrogenesis. Loss of *Wnt9a* in mice does not affect joint induction, but results in synovial chondroid metaplasia in some joints.[9,32] Other Wnts appear are also involved, in particular Wnt4 and Wnt16.[17] Conditional ablation of the canonical Wnt signaling master switch β-catenin leads to abnormal joints.[33] The current dataset therefore suggests that Wnts are required but are not sufficient for a full joint to develop.

Indian hedgehog (IHH) signaling is another pathway of interest as *Ihh* ablation leads to joint defects, mainly in the distal elements.[34] This suggests that IHH could be a critical mediator not only in the growth plate where it determines the speed of proliferation and differentiation,[1,2] but also in the communications between the joint interzone and the secondary ossification centers in the epiphyses. Another molecule of interest is α5β1 integrin.[35] Both gain- and loss-of-function approaches in developing limb models have suggested that blocking this integrin results in the formation of joint interzone-like structures whereas misexpression leads to joint fusions. However, these data still need to be corroborated in in vivo systems to fully define the extent of the role of these integrins.

2.4 Joint Cavitation

The process of cavitation that gives rise to the synovial space remains poorly understood. Cell death was thought for a long time as an essential factor but this hypothesis has not been convincingly demonstrated as

signs of cell death and apoptosis are only found in small and limited areas in the developing joints.[8,22,36,37] Current concepts therefore rather suggest that rearrangement of the ECM and production of hyaluronan are the essential factors in the cavitation process.[8] However, evidence from developmental models also provides support for the long-standing hypothesis that biomechanical factors (movement) are essential[38] whereas initial cell death in a time- and place-restricted manner may contribute to the specific initiation of events.[7] Picnotic dark cells previously associated with cell death and apoptosis are now considered to be precursors cells of the superficial layer of the articular cartilage.[22] The changes in hyaluron synthesis have been linked to activation of the mitogen activated protein kinases[39] and to upstream fibroblast-like growth factor signaling.[40,41]

2.5 The Differentiation of the Articular Cartilage and Other Joint Structures

The articular cartilage mainly develops postnatally and the chondrocytes that are found within this tissue have specific properties as compared to the developing chondrocytes in the anlagen and growth plates.[7] In contrast to the latter cells, articular chondrocytes do not undergo terminal differentiation toward hypertrophic cells. Despite articular cartilage being extremely important from a clinical and functional perspective, surprisingly little is known about the specific factors and processes that steer its formation. Current evidence suggests that chondrogenic transcription factors *Sox5* and *Sox6* are required.[20] *Sox9* likely also plays a role but it is not clear whether it is really essential.[1] Other molecules suggested to play a role include notch signaling[42] and the transcription factor ERG (v-ets erythroblastosis virus E26 oncogene homolog).[43] Further evidence suggests that the latter acts as a factor that maintains a pool of chondrogenic cells. Similarly, Wnt–β-catenin signaling may have a role in preventing chondrocyte differentiation and contribute to the differentiation of progenitors that will not become articular chondrocytes.[44] Some observations suggest that most of the cartilage present at birth in the epiphyses bordering the joint will be replaced by bone and that the articular cartilage itself is formed in the first 3 months of postnatal life.[45] The articular cartilage therefore appears to be formed by appositional growth. Of interest, both the superficial zone of adult cartilage and the synovium contain cell populations that fit the definition of mesenchymal stem cells (MSCs), which could play a role in cartilage formation.[46–48] More recently, in lineage tracing experiments, it was reported that in mice *Prg4*-expressing cells may include both multipotent articular stem cells and lubricin-producing cells.[49] These findings further contribute to our understanding of the articular joint surface development, and illustrate the need for further research to more fully dissect the lineage and functional relationships between joint surface cells and the underlying articular chondrocytes.

Even less is known about the factors contributing to the development of ligaments and *synovium*. Of interest, mice with a naturally occurring loss-of-function mutation in *Gdf5* [brachypodism (bp) mice] lack different ligaments supporting a role for GDF5 in their development.[24,50] The synovium is lined by the synovial fibroblasts, which specifically express cadherin-11.[51] Genetic deletion of cadherin-11 affects the anatomy of the synovium. In the absence of the adhesion molecule a clearly defined lining layer is not found.

2.6 Integration of the Joints with the Skeleton and Joint Shape Morphogenesis

Skeletal development clearly entails more than the definition and patterning of the different elements and subsequent specification of the skeletal tissues. Joint development and integration with the skeletal elements is essential to build the skeleton and to make it functional. In this concept both the primary, secondary ossification centers, and the developing joint are likely to act as signaling centers that define each other's boundaries. The interaction between the developing joint with the articular cartilage and the secondary ossification center that will become the subchondral bone is critically important. Within the secondary ossification center a zone of new bone is formed between the growth plate and the articular cartilage. MMP14 is a critical factor in establishing this zone[52] and interestingly it is also involved in the remodeling of the enthesis, the anatomical zone in which tendons and ligaments insert into the bone.[53] The boundary between the articular cartilage and the subchondral bone appears to be dependent on an IHH/parathormone related peptide loop which may confer the resistance of the articular chondrocytes toward hypertrophy.[54]

3 JOINT ANATOMY

The synovial joint is composed of different tissues that function together as a complex organ. Among these, the articular cartilage and the *synovium* are the structures that provide the potential to move. Other parts of the joints include ligaments, capsule, menisci, and tendons and all play a role in supporting or limiting movement.

3.1 The Articular Cartilage

The articular cartilage is a nonvascular connective tissue comprising the articular chondrocytes as a unique cell population that are producing a specific ECM in which they are embedded (Fig. 13.5). This ECM is essential for

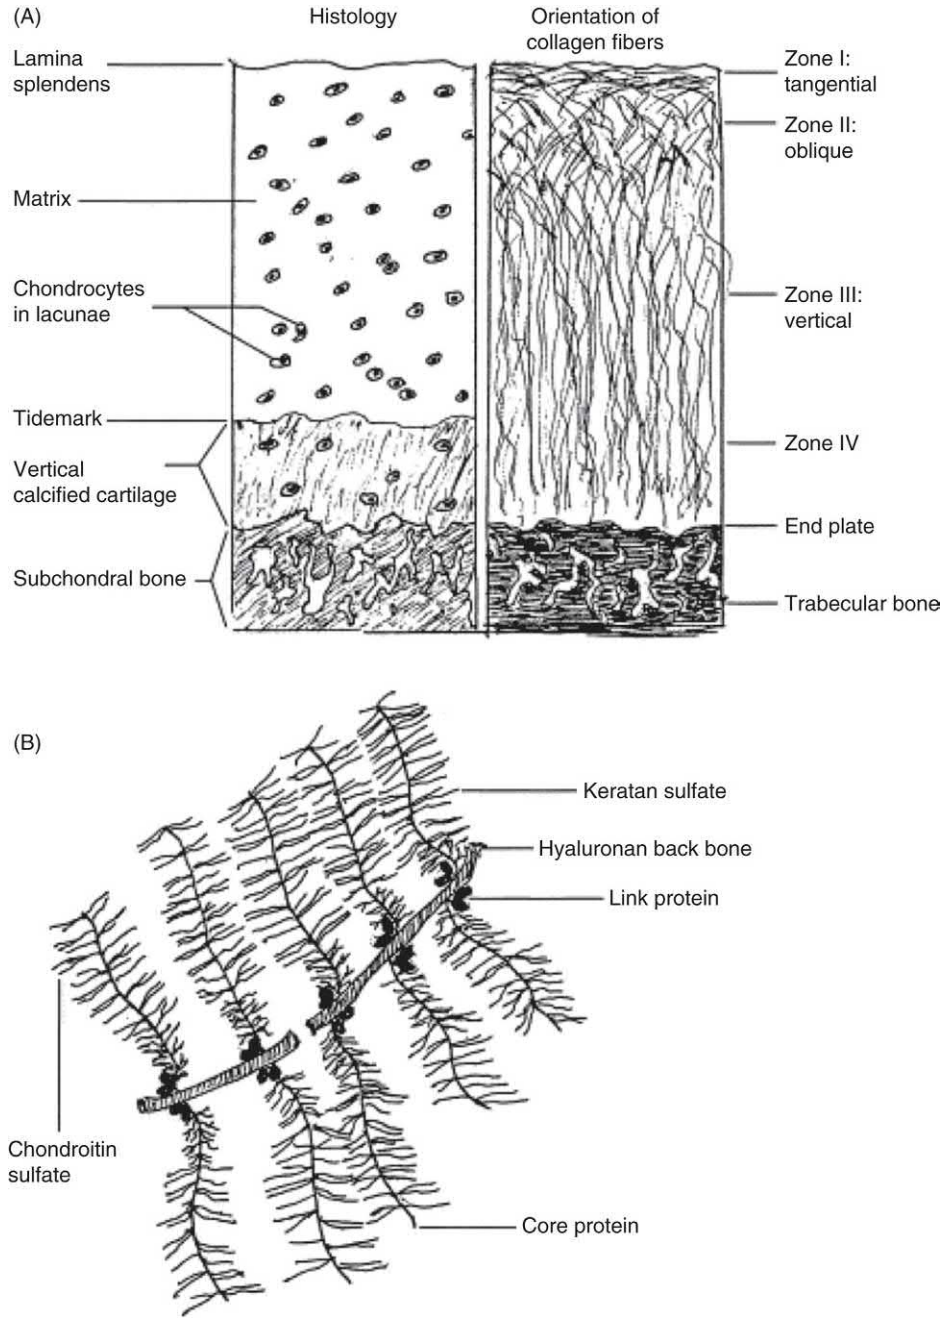

FIGURE 13.5 (A) The composition of articular cartilage includes chondrocytes and several ECM molecules. Chondrocytes only make up about 1% of the total volume of cartilage. The ECM contains two major types of molecules: collagen and proteoglycans. Over 90% of the collagen found in articular cartilage consists of type II collagen. This matrix protein provides much of the mechanical integrity of cartilage and comprises 60% of the total dry weight of cartilage. It is organized into fibers that compose four zones: Zone I or tangential, Zone II or oblique, Zone III or vertical, and Zone IV. Below Zone IV lie the end plate and the trabecular bone. Proteoglycans, on the other hand, compose 25%–35% of cartilage dry weight. (B) Aggrecans contain large amounts of chondroitin sulfate and keratan sulfate. Chondroitin sulfate and keratan sulfate, called glycosaminoglycans (GAGs), are modified with negatively charged sulfate groups and are highly polar. When many of these GAGs associate with a core protein to form a proteoglycan, the polar nature of the proteoglycans allows the molecules to interact strongly with water. *Source: Seal BL, Otero TC, Panitch A. Polymeric biomaterials for tissue and organ regeneration.* Mater Sci Eng *2001;***34***:147–230.*[96]

joint function and composed of three main components, such as collagens, proteoglycans, and other noncollagen proteins.[14,55] The articular cartilage is considered a low-turnover homeostatic tissue in which the chondrocytes support extracellular matrix synthesis and do not appear to proliferate in steady state conditions. The responses of the cells under pathological circumstances not only support the view that they can react to different stimuli including biochemical factors but also mechanical stress.[56] Maintenance of the ECM is necessary in particular in

response to changes in mechanical loading. Moreover, the network-like construction of the ECM molecules and the contact between its different components support the concept that the ECM is also a means of communication.[14,55]

3.1.1 Collagens

The major protein within the articular cartilage is collagen type II which forms the basis of a fibrillar network in association with other collagen fibrils, in particular collagen type XI[14,57] (Fig. 13.6). Collagens are trimeric molecules composed of three polypeptide chains. Collagen type II is a homotrimer with three α-1 chains that form the fibrils. The trimeric molecule is organized into a helix structure with every third amino acid being a glycine. The other amino acids are frequently prolines and hydroxyprolines and more specifically hydroxylysine in collagen type II. These specific residues are critical for the formation of oxidative crosslinks between the α-chains within one and between different collagen molecules. Crosslinking of different collagen molecules increases the resistance of the network against degradation by proteases. This protection is already established at a lower level by the helical structure and further increases with its complexity. Type II collagen also has nonhelical domains at its amino and C-terminal ends and these parts of the polypeptides play a critical role in its assembly process.

Type XI collagen in contrast is a heterodimer which forms fibrils in association with type II collagen. The combined fibrillar structure associates with type IX collagen at its fibrillar surface. Type IX collagen is a FACIT

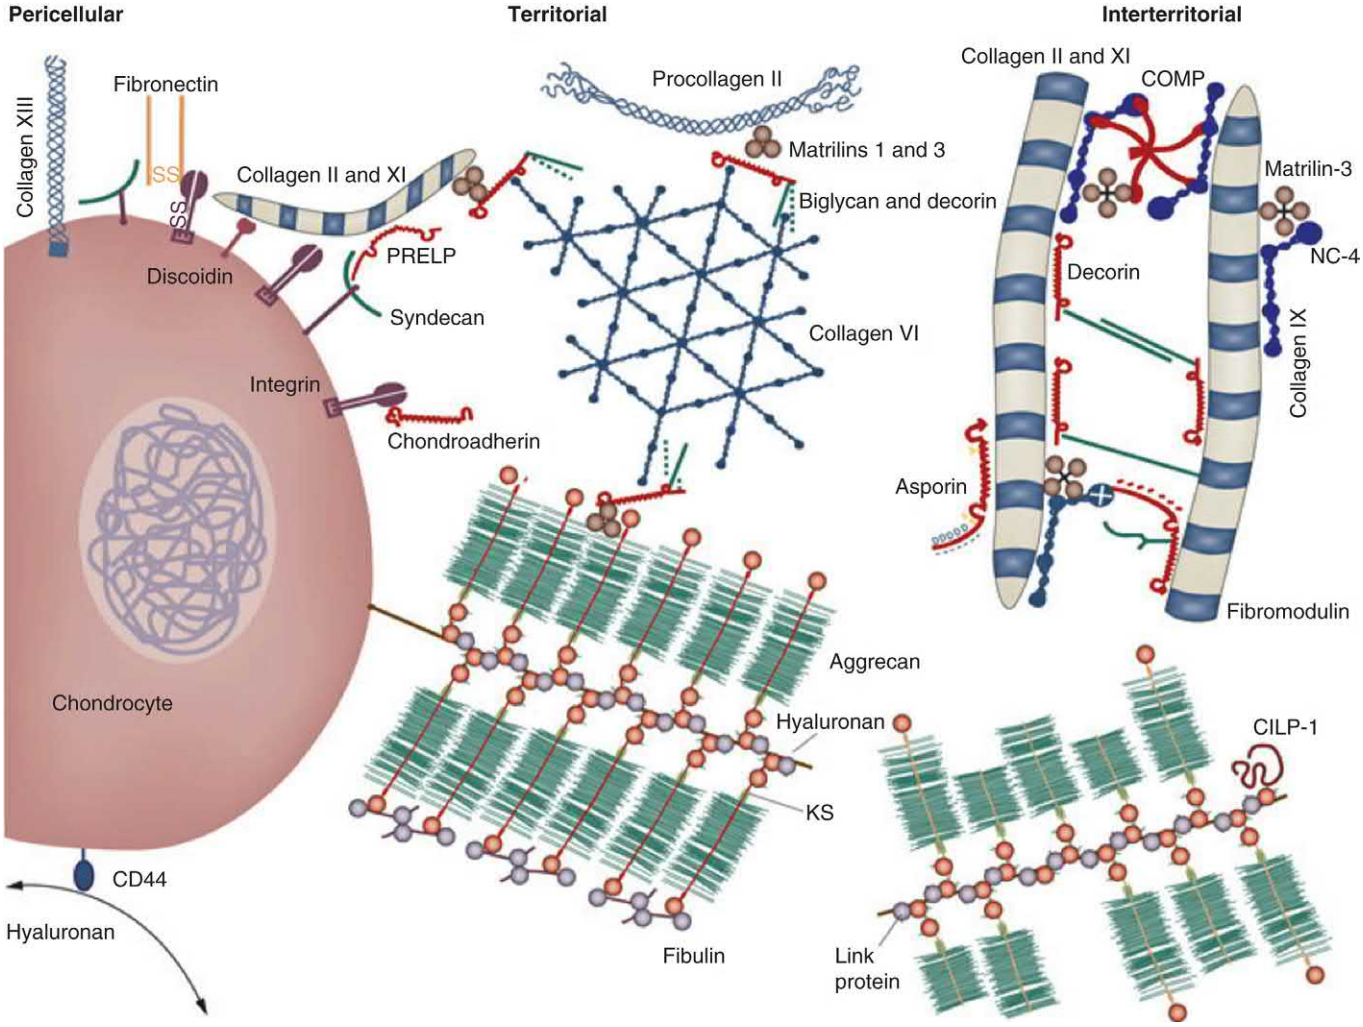

FIGURE 13.6 The cartilage matrix surrounding chondrocytes in healthy articular cartilage is arranged into zones defined by their distance from the cell. The pericellular matrix lies immediately around the cell and is the zone where molecules that interact with cell surface receptors are located; for example, hyaluronan binds the receptor CD44. Next to the pericellular matrix, slightly further from the cell, lies the territorial matrix. At largest distance from the cell is the interterritorial matrix. The types of collagens and the collagen-binding proteins that form the matrices are different in each zone. Abbreviations: CILP-1, cartilage intermediate layer protein 1; COMP, cartilage oligomeric matrix protein; CS, chondroitin sulfate; KS, keratan sulfate; PRELP, proline-arginine-rich end leucine-rich repeat protein. *Source: Seal BL, Otero TC, Panitch A. Polymeric biomaterials for tissue and organ regeneration.* Mater Sci Eng *2001*;**34**:*147–30.*[96]

collagen (fibril associated with interrupted triple helices). It consists of two collagen helix domains separated from a third helix by a noncollagenous domain. The third helix extends into the interfibrillar space together with a highly charged N-terminal domain allowing its interactions with other matrix proteins. The collagen network established by type II, type XI, and type IX collagens defines the interterritorial matrix within the articular cartilage.[57] This is the area found in between but not in the immediate proximity of the chondrocytes. Closer to the cells, the so-called territorial or pericellular matrix is different in its composition with the presence of a smaller network defined by type VI collagens.[58] Fibril formation is a complex process to which other ECM molecules contribute. These noncollagen proteins, discussed more extensively later, frequently remain attached to the collagen fibrils and further define the complexity of and potential interactions and communications within the matrix.

3.1.2 Proteoglycans

Proteoglycans are glycosylated proteins typically found in the ECM of connective tissues.[14,57,59] They can be distinguished from other glycoproteins by the presence of sulfated glycosaminoglycans (GAGs) bound to the core protein of the proteoglycan molecules. These sulfated GAGs are polysaccharides composed of disaccharide units characteristically containing repeats of a hexosamine and a hexuronic acid residue (Figs. 13.5 and 13.6). Three different types of sulfated GAGs can be distinguished, such as chondroitin sulphates, keratan sulphates and heparan sulfates. They are usually covalently linked to the core protein of the proteoglycan through O-glycosidase bonds.

Through their association with a large number of sulfated GAG side chains, proteoglycans are a rich source of negative charges within the ECM thereby attracting water molecules. These contribute to the articular cartilage's resilience and its reaction toward compressive forces. Under compression, water molecules are able to shift within the cartilage making the tissue softer and more flexible as compared to the subchondral mineralized bone. The proteoglycans are trapped in the earlier described collagen network which contributes to the specific structure and strength of the articular cartilage. The most abundant proteoglycan within the articular cartilage is aggrecan.

Hyaluronan is another macromolecule that belongs to the family of the GAGs but it is very different in its biological behavior.[60] It is not associated with the proteoglycan core as side chains, but forms a very large polymer and is not sulfated. Moreover, hyaluronan is synthesized outside the cell and is not assembled in the Golgi apparatus as other GAGs. Hyaluronan and aggrecan form very large aggregates making up the major molecular complex within the articular cartilage. The complex structure is built on the aggrecan molecules which contain three globular domains. The GAG side chains are found in between the second and third globular domain. The latter can associate with molecules, such as fibrillins, fibulins, and tenascin but its presence in the core protein is variable as different splice variants of aggrecan exist. The first globular domain is associated with hyaluronan and link protein in a ternary complex leading to the formation of macromolecules that together with the collagen network make up the most important part of the ECM.

3.1.3 Noncollagenous Matrix Proteins

The noncollagenous matrix proteins have important functions in the assembly of the matrix macromolecules, contribute to the complex network and thereby define properties and functions of the ECM.[14] Matrilin-3 is part of the matrilin family and a multimeric protein that can bind to triple helix collagens, biglycan, and decorin. It plays a role as a linker molecule in the network of the articular cartilage.[14]

The small leucine-rich proteins all have repeats of around 25 amino acids with leucine residues at conserved locations.[14] Decorin, biglycan, and asporin are typical examples of this group that bind collagens during fibril formation and thereby determine the rate and end of the process. They can also bind to the beaded head of collagen type VI molecules in the interfibrillar space. Fibromodulins, such as lumican bind to fibrillar collagens.[14] They are rich in sulfated tyrosine residues and acidic amino acids thereby forming a polyanionic domain that can also bind growth factors and cytokines and may determine local concentrations and effects of these signaling molecules.

Thrombospondins are a family of molecules of which cartilage oligomeric protein (COMP) is the best known.[14] COMP is a modular protein with a globular C-terminal domain with five subunits binding to collagen. It serves as a catalyst to bring collagen fibers together during their assembly. The balance between COMP and collagen fibrils may be very important for proper maintenance of the ECM. Detection of COMP in the serum of patients has been proposed as a biomarker for cartilage breakdown in joint diseases.

3.1.4 Organization of the Articular Cartilage

Within the human articular cartilage, a four-layered pattern can be distinguished[54,61,62] (Fig. 13.5). The cells of the superficial zone are lining the joint cavity. On top, the lamina splendens contains only fibrils and no cells. The cells underneath appear small and flattened with a relatively low amount of ECM surrounding them. Here, the ECM is rich in collagen but relatively poor in proteoglycans. These cells express lubricin and parathormone related peptide, which may play a role to keep them in their specific differentiation status. The organization of the ECM in the superficial layer confers its specific ability

to resist shear stresses and to serve as a guiding surface for joint movement. It may also limit the passage of molecules from the synovial fluid to the deeper layers of the cartilage. Cells in the middle zone or transitional layer appear more rounded and are usually dispersed as single cells throughout the ECM. These cells and matrix are involved in the transition between the shear forces found in the surface layer to the compression forces in the deeper cartilage layers. In the deeper radial layer, large cells are found in clusters and display a columnar organization in mammalian species. These cells typically express *Ihh* and *Runx2*. Below this zone, the articular cartilage becomes calcified. This transition can be recognized on histology by the tidemark, a basophilic transition line between both zones that is easily visible on microcopy sections.

3.1.4.1 Soft Tissues of the Joint

The *synovium* is a loose connective tissue that connects the opposing bones and lines the synovial cavity. The lining layer is, under normal circumstances, an epithelial-like structure without basement membrane. Two types of cells are found within the lining layer: type A synoviocytes belongs to the macrophage lineage and type B synoviocytes also described as synovial fibroblasts.[63] The architecture of the lining layer appears to be dependent on adhesion molecule cadherin-11.[51] The cells of the lining layer produce major components of the synovial fluid, such as lubricin and hyaluronan. Lubricin attracts an additional layer of water molecules on the edges of the articular cartilage smoothening the movement of the opposing sides against each other. Hyaluronan protects the synovium from being locked and pinched in between the cartilage. The synovial sublining zone is a loose connective tissue with blood and lymphatic vessels, some fibroblasts, pericytes, and a small amount of cells belonging to the immune system. The vessels are very important to bring nutrients to the synovium and the joint cavity as the nourishment by diffusion of the articular cartilage is largely dependent upon it. The synovium has the potential to attract massive amounts of cells under inflammatory circumstances and plays a key role in chronic arthritis. There is a large heterogeneity in the sublining zone, such as characteristic loose connective tissue, more dense fibrous zones, and also fat pads. The latter may be specifically involved in inflammation in joint diseases.[64]

Some joints, such as the knee joints contain additional fibrocartilaginous structures, such as menisci. These are important to support motion in the specific joints. Ligaments, capsules, and tendons are composed of dense connective tissue and particularly rich in type I collagen fibers which confer their tensile strength.

3.1.4.2 The *Enthesis*

Ligaments, capsules, and tendons insert into the underlying bone in a specific anatomical zone called the *enthesis*.[65] The *enthesis* is a multilayered structure important in translating mechanical stress triggered by movement from the tendons or ligaments toward the underlying bone. It consists of an uncalcified fibrocartilage layer through which the collagen fibers of tendon or ligaments are passing, followed by a calcified fibrocartilage layer and then inserting onto the bone. The tidemark between the uncalcified and calcified cartilage is relatively straight. The transition between fibrocartilage and underlying bone is irregular thereby increasing the surface of the interaction and providing additional strength. Like the articular cartilage, the *enthesis* is largely nonvascular and resistant to cell invasion. Tissue responses toward entheseal overload or damage are therefore hypothesized to accrue cells into the adjacent synovium and bone marrow with which the *enthesis* is connected through small channels in the bone. This so-called synovio–entheseal complex is hypothesized to play key roles in some chronic joint diseases, such as ankylosing spondylitis and psoriatic arthritis.[66]

4 JOINT HOMEOSTASIS

Proper joint function is critically dependent on the complex maintenance of homeostasis in all joint tissues.[67] The articular cartilage needs to maintain its resilience and relative softness, with the synovium providing nutrients and lubrication. From the biomechanical perspective, the cartilage–bone interface appears of particular importance.[56] Both the chondrocytes as well as the bone cells found in the subchondral zone perceive strain and load and will react to these stimuli. Maintenance of homeostasis is likely based on a specific balance between the resistance of the mineralized tissues and the flexibility of the softer articular cartilage. Moreover, the interface between cartilage and subchondral bone has recently been associated with intense molecular crosstalk between the tissues. The existence of vascular communication channels and the irregular border between the tissues form a junction over which diffusion of small molecules can occur. Not only is the border between the deeper calcified layers of the articular cartilage and the bone irregular but also patches of uncalcified cartilage can come into contact with the bone facilitating molecular interactions. Changes in this system likely contribute to the onset and progression of joint diseases.[56]

5 JOINT DISEASE

Chronic joint diseases are among the most frequent health problems and have a high burden on society due to morbidity, disability, and high-socioeconomic costs.[68] The most common joint diseases are osteoarthritis (OA),

rheumatoid arthritis (RA), and spondyloarthritis. The latter two are chronic inflammatory diseases linked to autoimmunity and autoinflammation respectively. OA is too often considered as a simple degenerative disease or a natural consequence of aging but should be considered as a more complex disorder to which both genetic and acquired factors contribute ultimately leading to joint failure.

5.1 Rheumatoid Arthritis

RA is a chronic inflammatory systemic disease mainly affecting the synovial joints and associated with autoimmune phenomena, such as autoantibodies including the so-called rheumatoid factor and anticitrullinated protein antibodies.[69] The key role of these autoantibodies in onset and course of the disease support the view that RA is an autoimmune disease. RA affects more women than men and usually occurs between the third and fifth decade of life. The disease susceptibility is determined by genetic factors but environmental factors, such as smoking also play an important role in the onset of disease. Patients experience joint paint, swelling, and loss of function. RA typically symmetrically not only affects the small joints of hands and feet but may also involve larger joints of the peripheral skeleton. Involvement of the spine is very rare with the exception of the articulation between the dens and axis, the first two cervical vertebrae. The clinical picture of arthritis is caused by synovial inflammation and joint effusion. The inflammatory process leads to progressive cartilage and bone destruction (Fig. 13.7). The synovium undergoes a dramatic transformation with the synovial fibroblasts proliferating and acquiring an "aggressive" phenotype.[63] They produce tissue destructive enzymes, such as matrix metalloproteinases and other proteases breaking down the ECM of the articular cartilage. Activation of synovial fibroblasts and T cells triggers the RANKL–RANK cascade and stimulates the differentiation, maturation, and activation of osteoclasts leading to juxtaarticular bone erosions.[70]

A number of therapeutic options are available.[69] The introduction of targeted biological therapies directed against cytokines, such as tumor necrosis factor or interleukin-6, or against immune cell populations, such as T and B cells, has greatly improved the outcome of the disease in a large number of patients. Strategies are aimed at controlling inflammation and preventing structural damage, and in RA both these processes are linked to each other. Therefore early disease detection becomes a major point of attention.[71] Successful treatment of the disease with either potent immune modulators and increasingly with targeted biological therapies is capable of controlling symptoms as well as preventing damage to the joints.

5.1.1 Spondyloarthritis

The spondyloarthritis concept groups different diagnostic entities that share clinical, genetic, and pathological characteristics.[72] Within this concept ankylosing spondylitis, psoriatic arthritis, reactive arthritis, and arthritis associated with inflammatory bowel disease are the best-known subforms. In addition undifferentiated and juvenile spondyloarthritis are also recognized. The clinical presentation of spondyloarthritis can therefore be very different between patients. In contrast to RA which is characterized by a symmetrical peripheral polyarthritis, spondyloarthritis affects the sacroiliac joints and the spine. Peripheral joint involvement, if present, is mainly nonsymmetrical and affects the lower limbs. However, polyarticular forms do exist. New concepts integrating evidence from magnetic resonance imaging, distinguish a mainly axial pattern of disease, in which the spine and

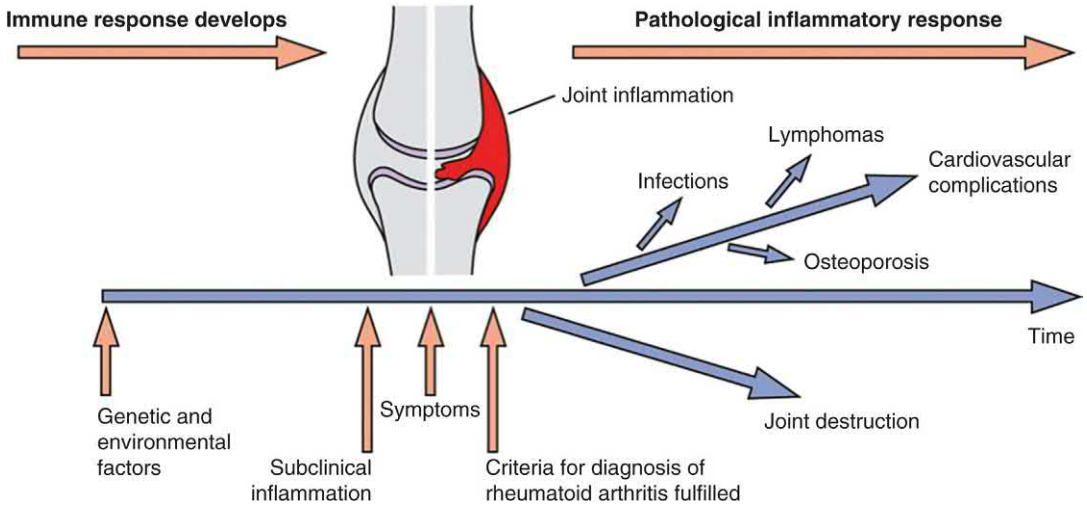

FIGURE 13.7 Longitudinal course of rheumatoid arthritis from preclinical stages to joint damage and systemic manifestations of the chronic inflammatory joint disease. *Source: Klareskog L, Catrina AI, Paget S. Rheumatoid arthritis.* Lancet *2009;***372***(9664):659–72.*[69]

sacroiliac joints are affected, from a predominantly peripheral disease.[73] In spondyloarthritis patients, inflammation as manifested by osteitis, enthesitis, and synovitis, triggers pain and loss of function. There is a strong genetic association with the HLA-B27 gene and novel genetic factors have recently been identified.[74] There is a little evidence that acquired immune responses play any role in the pathogenesis.[75] Moreover, tissue damage and structural progression of disease are characterized by new bone formation leading to spine or joint ankylosis instead of joint destruction.[75] Treatment strategies for spondyloarthritis are limited but the introduction of anti-tumor necrosis factor drugs has greatly changed the perspective and prognosis of the patients. Many challenges in spondyloarthritis remain, in particular the prevention of long-term structural damage caused by progressive ankylosis, a process that appears molecularly uncoupled from inflammation and for which current drug strategies do not have a short-term benefit.

5.1.2 Osteoarthritis

The osteoarthritic diseases cause the most common chronic joint problems. OA may affect not only single or multiple joints, including large joints, such as the hip or knee, but also the small joints of the hands and the spine. Although most commonly found in the elderly, the disease process is complex and both genetic and acquired factors may contribute to its onset, course ,and outcome.[76,77] Abnormal loads on a normal joint as well as normal loads on a structurally abnormal joint may contribute to the prevalence and progression. OA is characterized by progressive degradation of the articular cartilage, thickening of the subchondral bone, and the appearance of bone outgrowths on the edges of the joint called osteophytes (Fig. 13.8). Progression of disease is also associated with synovial inflammation and increasing pain.

OA is an interesting case study on failure of joint homeostasis. In patients that develop OA, homeostatic and repair mechanisms do not match the catabolic events that are the consequence of stress and strain in the chondrocytes and the subchondral bone.[56] In response to these stresses, not only chondrocytes increase their metabolism and ECM synthesis but also matrix turnover with a rise in tissue destructive enzymes, such as matrix metalloproteinases and aggrecanases. When the catabolic cascades outweigh the anabolic potential, cartilage destruction is the net result. In parallel, subchondral bone cells are activated and increase their matrix synthesis. This results in apparent thickening or sclerosis of the subchondral bone. Increased bone anabolism is paralleled by increased osteoclast activation resulting in bone breakdown. As the mineralization process cannot match the speed of matrix synthesis, the net result here is a thicker but weaker and less structured bone also contributing to progressive joint failure. Therapeutic pharmaceutical opportunities in OA are limited to painkillers and anti-inflammatory drugs and at the end stage of the disease prosthesis or joint-corrective surgery is often required.[76]

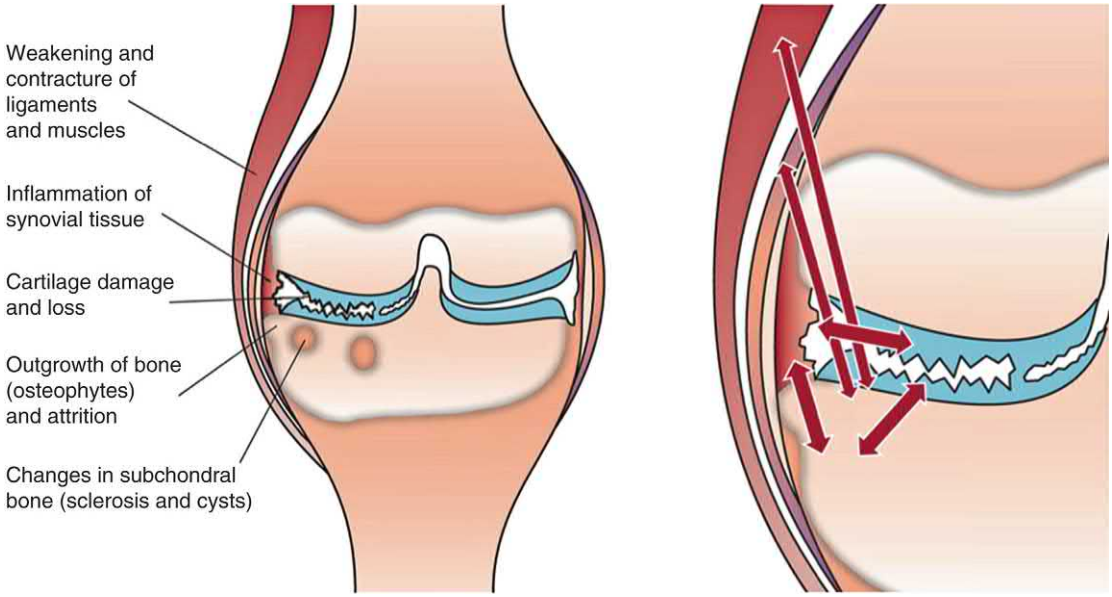

FIGURE 13.8 Schematic drawing of an osteoarthritic joint. The different tissues involved in clinical and structural changes of the disease are shown on the left. Note that cartilage is the only tissue not innervated. On the right the bidirectional interplay between cartilage, bone, and synovial tissue involved in osteoarthritis is shown, and the two-way interaction between this interplay and the ligaments, and muscles. In the interplay between cartilage, bone, and synovial tissue one of the tissues might dominate the disease, and as such should be targeted for treatment. *Source: Bijlsma JWJ, Berenbaum F, Lafeber PJG. Osteoarthritis: an update with relevance for clinical practice.* Lancet *2011;***377***(9783):2115–26.*[76]

6 JOINT REPAIR

As the lifespan of prosthetic devices is limited, new treatment approaches to repair skeletal structures, such as the joints need to be devised for the young- and middle-aged individuals with joint damage caused by congenital, traumatic, or inflammatory conditions. It is believed that joint repair through regenerative medicine and more specifically tissue engineering approaches may fill this void to some extent.[78]

6.1 Tissue Repair by Enhancing the Endogenous Healing Response

For interventional tissue repair, two mechanistic approaches are possible: enhancing intrinsic repair mechanisms including stimulation of cell proliferation, differentiation, and metabolic activity of the tissue, and the recruitment of endogenous progenitor populations into the damaged tissue. Extrinsic repair is the alternative if insufficient intrinsic repair leads to clinical symptoms and signs, with loss of function. This includes tissue engineering approaches using cell populations and combination products of cells, matrices, and scaffolds that can contribute mostly locally to the tissue repair processes. Some of these targeted anabolic and tissue repair approaches to stimulate intrinsic repair have been translated into the clinics with, for example, OP1/BMP7[79] and fibroblast-like growth factor[80] being explored in early phase clinical trials for OA and joint surface defects.

6.2 Joint Resurfacing by Tissue Engineering

Cell-based therapies and tissue engineering for joint repair are starting to enter the clinical arena, and thus becoming of relevance to the clinicians today. Many preclinical and early clinical applications appear promising. This relates particularly to the use of autologous and allogenic adult MSCs in musculoskeletal tissue repair and regeneration in general, and joint disorders/disease and OA more in particular.[78] MSCs are defined by their self-renewal capacity and their ability to differentiate in vitro into chondrocytes, osteoblasts, or adipocytes.[81] The mechanisms through which the cellular therapies and combination products in vivo can contribute to tissue repair and interfere with disease processes are multiple and involve not only the direct engraftment into damaged tissue, proliferation, and differentiation to tissue specific cell types, but also include paracrine actions, such as the secretion of growth and differentiation factors that enhance the local tissue responses toward the damage that has occurred. Indeed, cellular products can be considered multisignal delivery systems and interact with the microenvironment.[82] This is obviously a strength of the approach but it also highlights the complexity of developing a cell therapy and the need for control over quality, consistency, and safety of such products. Indeed, cellular products are now subjected to regulatory review and approval before they can enter clinical practice. Cell-based products belong to the new class of Advanced Therapy Medicinal Products regulated by the European Medical Agency.

Some tissue engineering applications have reached the clinic and aim to restore the integrity and function of the joint and in particular the joint surface. Among them and most prominently, are treatments for the repair of articular cartilage and osteochondral defects in otherwise healthy joint or (early) OA. Marrow stimulation techniques were described for the first time by Pridie in 1959. A cartilage lesion was debrided back to stable borders and the subchondral plate was perforated with a drill.[83] The microfracture method developed out of this tradition and is most widely used and is still considered a first-line treatment for small focal cartilage defects in joints, primarily in the knee.[84] It is technically an easy procedure that can be performed via arthroscopy. Although the repair tissue is a mixture of fibrous and cartilaginous tissue with the presence of some collagen type II and proteoglycans, this tissue tends to degenerate over time into fibrous tissue resulting in recurrence of clinical symptoms and signs.[85,86] Marrow stimulation techniques may however be less suitable, or at least may be more complex for the treatment of OA, as the subchondral bone and bone marrow characteristics are profoundly affected in this disease, and thus the biology will be quite different and to be explored.[56]

Regeneration or repair of symptomatic articular cartilage defects has been on the forefront of regenerative medicine ever since Brittberg et al. reported in 1994 a remarkably good clinical and structural outcome using a procedure called autologous chondrocyte transplantation/implantation (ACI).[87] Briefly, cell populations were prepared by enzymatic release from a biopsy of articular cartilage taken from an unloaded area in the symptomatic joint during arthroscopy. The chondrocytes were subsequently expanded in vitro, and reimplanted through arthrotomy in the joint surface defect under a periosteal flap, taken from the tibia from the same patient. This was then followed by a rehabilitation to reach its optimal outcome at 18–24 months. Since then, progress has been made by improving and standardizing the preparation of the autologous chondrocytes, the development of other delivery systems for the chondrocytes and the replacement of the periosteal flap by a membrane of diverse composition, and a series of prospective multicenter clinical studies. Recent trials strongly suggest that ACI with a well-defined cell product and an applied rehabilitation protocol may be superior in the long term to microfracture.[88,89] Although still open for debate with respect to long-term clinical durability, there is a broad

consensus that ACI can be considered as a regenerative treatment with good structural and clinical outcome. Importantly, the data indicate that the outcome may be superior to standard care if the "proper" patients are treated. Positive predictors of good outcome include early intervention (less than 3 years symptomatic), good quality of chondrocytes, well-trained surgeons, adherence to rehabilitation protocols, and no signs of OA (as defined by Kellgren II). Cost-effectiveness will certainly improve if the treatment is also shown to prevent the progression toward OA, but these data are not yet available.

The so-called "second generation" ACI, cells cultured in/on a matrix might have some distinct advantages over the "classical" cell suspensions implanted under a periosteal flap. Culturing the cells in 2D-plus (in multilayer on a membrane) or 3D-conditions (distributed in a matrix) seems to favor the phenotypic stability of the chondrocyte.[90,91] Due to the fact that suturing is not always required, the surgery becomes easier and can be performed through a mini-open or even arthroscopic procedure.[92] Recent data report superiority of this approach after 2 years over microfracture in a prospective randomized trial.[93] At this moment, several matrices are in use in a clinical setting, but it is unclear which is the ideal matrix at this time. The new wave of developments within this field relate to the use of autologous and/or allogenic progenitor cell populations for the repair of joint surface defects in combination with new biomaterials, and the application of gene therapy.[94] Recent evolutions also study the use of noncellular approaches including nano-scale scaffold structures. Although some data in preclinical models appear of interest, applications in human are still in their first steps.

In conclusion, tissue repair approaches so far have mostly been investigated in damaged posttraumatic joints. No or very limited data have been reported with these tissue engineering approaches in established OA. Indeed, as the microenvironment in OA is very different when compared to damaged joints without signs of definite OA, we cannot extrapolate the data to (osteo)arthritic disease. Recent developments identify the potential of MSCs and their secretory vesicles in the treatment of OA, with promising results in preclinical animal models of OA and early phase clinical trials in men (for review).[95]

1 INTRODUCTION

Osteocytes are the most abundant cells in bone and play a central role in the execution of the functions of the skeleton. At one time thought as inactive quiescent cells buried in the mineralized tissue, osteocytes coordinate bone acquisition during growth and are critical for the maintenance of a strong and healthy skeleton able to accomplish the functions of locomotion and protection of essential organs. Osteocytes regulate the genesis and activity of osteoblasts and osteoclasts through factors produced and secreted in response to mechanical and hormonal stimuli, thus adapting the skeleton to changes in environmental cues. In addition, osteocytes contribute to the endocrine functions of bone by secreting hormones that affect other tissues; and they also regulate mineral homeostasis and hematopoiesis, which are essential for organismal life. The central role of osteocytes was long foreseen by pioneers in the field, who predicted that these cells contribute to skeletal homeostasis. Booming research on the biology of osteocytes of the last 2 decades unraveled some of the mechanisms underlying the functions attributed to osteocytes, recently reviewed.[1–3] It is envisioned that the intense current research will continue to increase our knowledge of osteocyte biology and pathophysiology.

2 THE FUNDAMENTAL ROLE OF OSTEOCYTES IN SKELETAL HOMEOSTASIS

2.1 The Osteocyte Network

The intricate network that connect osteocytes with each other and with cells on the bone surface and the vasculature has fascinated bone biologists for long time. The studies by Marotti and coworkers using microscopy of human bones showed that osteocytes within lacunae extend multiple cytoplasmic projections reaching neighboring osteocytes and cells on bone surfaces.[4] Based on these morphological features, these investigators hypothesized that osteocytes are central players in a cellular network in which cells are connected via gap junctions and are able to sense mechanical and biochemical signals.[5] Knowledge accumulated during the last few years supports the important role of the osteocyte network for skeletal homeostasis and has identified mechanisms and messengers by which osteocytes control not only bone formation, but also resorption. Recent evidence now supports a role for the osteocyte network in the distribution of molecules, such as sclerostin, osteoprotegerin (OPG), and fibroblast growth factor 23 (FGF23), which reach cells on the bone surface, the bone marrow (BM), and even the general circulation (Fig. 14.1). Premature death of osteocytes and disruption of the osteocyte network is likely to negatively impact the skeletal response to environmental cues (as will be discussed later in Section 6).

2.2 Osteocytes as Mechanosensory Cells

The skeleton adapts to meet mechanical needs by changing its mass, shape, and microarchitecture.[6–8] Frost developed the mechanostat theory that proposes that the magnitude of the mechanical stimulation applied to bone dictates whether bone will be increased (by increasing bone formation) or reduced (by increasing bone resorption).[9] In this model, osteocytes sense the load imposed to bone and respond by signaling to osteoblasts and osteoclasts to adapt to mechanical changes.[10] Osteocytes are proposed to act as mechanosensors.[11] Whereas bone-forming osteoblasts and bone-resorbing osteoclasts

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00014-9

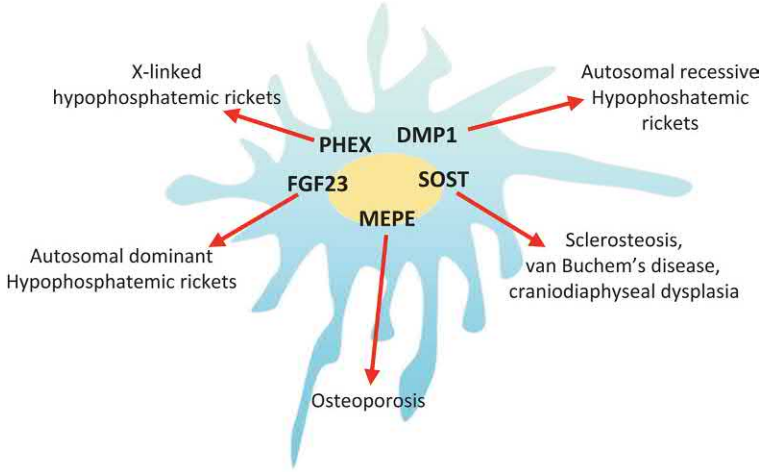

FIGURE 14.1 In addition to normal physiological functions, osteocyte factors can also play a role in bone and kidney disease. Mutations in the early osteocyte factors PHEX and DMP1 can play a role in hypophosphatemic rickets as does FGF23. The mature osteocyte factor MEPE plays a role in osteoporosis and the mature osteocyte factor, sclerostin, coded by the gene SOST, plays a role in high bone mass genetic disease.

are present on bone surfaces for relatively short periods of time and in low numbers, osteocytes are by far the most abundant resident cells and are present throughout the entire bone tissue. Their abundance and strategic location in the core of the lacuna–canalicular network make these cells the most suitable candidates for detecting variations in the level of strain and for distributing signals leading to adaptive responses.[12] However, the molecular mediator(s) had remained elusive until it was demonstrated that mechanical loading decreases the expression of Sost/sclerostin in osteocytes, and that conversely, unloading increases it. Moreover, areas of cortical bone receiving greater strain stimuli and higher bone formation exhibit a greater reduction in both the number of sclerostin-positive osteocytes and the intensity of sclerostin staining per osteocyte.[13] These findings support the notion that osteocytes coordinate the osteogenic response to mechanical force by downregulating sclerostin, thereby locally unleashing the powerful Wnt anabolic signaling.

Indeed, the osteogenic response to mechanical stimulation is disrupted in mice overexpressing in osteocytes a human SOST transgene that cannot be downregulated by loading (DMP1-SOST).[14] Thus, WT mice showed the expected decrease in sclerostin expression in osteocytes and a robust and dose-dependent increased bone formation upon ulnae loading, DMP1-SOST mice exhibited an overall reduced sensitivity to mechanical stimulation. Moreover, loading increased the expression of several genes associated with activation of Wnt signaling in wild type (WT) mice, whereas this effect was absent in DMP1-SOST mice.[14,15] Thus, Sost/sclerostin downregulation is an obligatory step for mechanotransduction, and for activation of the Wnt pathway and the increase in bone formation induced by mechanical force. Furthermore, other osteocyte-derived molecules, including RANKL and the Wnt target gene OPG and are also involved in bone adaptation to mechanical stimuli.[11]

2.3 Osteocytes and the Skeletal Response to PTH

Parfitt proposed in the 1970s that osteocytes were involved in the response of the skeleton to parathyroid hormone (PTH).[16] Based on the rapid timing of hypercalcemic responses to PTH, the fact that new protein synthesis is not required, and that calcium is released into the circulation at two different rates, Parfitt concluded that osteocytes control the rapid release of calcium, whereas osteoclastic resorption determines the later phase of calcium released from bone to the circulation induced by PTH. Studies using genetically modified mice have recently demonstrated profound skeletal effects of activation of the PTH receptor in osteocytes[17–20] and defective response to PTH of mice lacking this receptor in osteocytes.[21,21a] These studies support and extend Parfitt's concept that indeed osteocytes are target cells of PTH action. Further, mice lacking the PTH receptor in osteocytes lose less bone with lactation, a condition in which calcium release from the skeleton to the blood induced by PTHrP (the other ligand of the PTH receptor) is required for milk production in the mammary glands.[22] In addition, the characteristic increase in osteocyte lacunar size observed in lactating wild-type mice is not found in mice, lacking the PTH receptor in osteocytes, suggesting that removal of perilacunar bone by osteocytes as a source of calcium contributes to the bone loss. The process of perilacunar remodeling, named earlier by Belanger osteocytic osteolysis,[23] is achieved by the expression in osteocytes of gene usually expressed by osteoclasts during bone resorption. These genes encode for proteins that decrease extracellular pH, such as carbonic anhydrases and ATPases, that degrade

the extracellular matrix, such as MMP13 and cathepsin K, and that dissolve the mineral, such as TRAPase.

3 MOLECULAR AND FUNCTIONAL SIGNATURE OF OSTEOCYTES

Between 5% and 20% of the osteoblasts present on the bone surface become surrounded by matrix proteins that they produce and differentiate into osteocytes,[8,24] by mechanisms that are still uncertain. This transition is characterized by alterations in gene expression and it is accompanied by morphological and functional changes. Osteoblasts are highly secretory cells characterized by cuboidal shape, large nucleus located close to the cell basal membrane, enlarged Golgi apparatus on the nuclear apical surface, and extensive endoplasmic reticulum. During osteocytogenesis, the number of cellular organelles markedly reduces and the ratio between nuclear and cytoplasm volume increases as the cell acquires a star-like morphology. The long osteocytic cytoplasmic processes run through canaliculi, "dug" in mineralized bone, and touch neighboring osteocytes, bone surface cells, and endothelial cells of the blood vessels. This extensive lacunar–canalicular system is maintained by the ability of osteocytes themselves to remodel their surrounding space, as demonstrated by calcification of the lacuna and reduced numbers of canaliculi when osteocytes are lost by apoptosis.

3.1 Formation and Maintenance of the Osteocytic Network

The transition from osteoblasts to osteocytes occurs while the cells become surrounded first by unmineralized matrix or osteoid, and later, by mineralized bone matrix. Several molecules might mediate the development of dendrites by dictating the formation of osteocytic projections or, indirectly, by controlling mineralization and matrix degradation and thus the formation of the lacunar–canaliculi system.

E11 (also called OTS-8, podoplanin, gp38, or T1α), originally described in osteoblastic cells and subsequently cloned from other tissues,[25,26] is expressed in dendritic cells of the kidney, lung, brain, and skin.[27,28] In bone, E11 is expressed in newly embedded osteocytes, but not in more mature osteocytes surrounded by mineralized bone matrix or in osteoblasts on the bone surface, indicating that is a marker of early osteocyte differentiation.[29] E11 expression is required for dendrite elongation induced by loading in vitro and it is increased by mechanical stimulation in vitro and in vivo, suggesting that mechanical signals might control osteocytogenesis. E11 binds to CD44, a molecule also expressed in neuronal dendrites,[30] and expression of either molecule has been associated with osteocytic dendrite branching.[31,32] Osteocytic dendrites also contain α-actinin and fimbrin, actin-bundling proteins required for the cytoskeletal organization of osteocytes isolated from chicken.[33,34] Mutations of PLS3, the human homolog of fimbrin that encodes for the protein Plastin 3, causes X-linked osteoporosis with fractures,[35] suggesting an association of deficient dendrite formation with bone fragility.

Dentin matrix protein 1 (DMP1) is expressed in mature osteoblasts and its expression increases as osteoblasts differentiate toward osteocytes.[36] DMP1 expression is required for proper osteocyte maturation, as evidenced by abnormally elevated expression of osteoblastic and early osteocytic genes (such as alkaline phosphatase, collagen type 1 and E11) and low expression of sclerostin (a marker of mature osteocytes) in deeply embedded osteocytes in mice lacking the DMP1 gene.[37] Mineralization is also defective in DMP1 knockout mice likely causing the incomplete differentiation of osteocytes and the disorganized osteocytic lacunar–canalicular system. Interestingly this can be corrected by normalizing phosphate levels using anti-FGF23 antibodies[38] or by improving bone mineralization with antisclerostin antibodies.[39] As for DMP1, the expression of matrix metalloproteinases (MMPs) also increases as osteoblasts differentiate into osteocytes. The function of MMPs in osteocytogenesis might be related to their ability to cleave collagen in the matrix surrounding osteocytes, allowing the formation of canaliculi through which osteocytes extend cytoplasmic projections. Consistent with this notion, mice lacking MMP14, a member of the MMP family of proteins, exhibit reduced or absent osteocytic processes.[40] Further, the ability of collagen to be degraded by MMP13 is required to maintain osteocyte viability, as demonstrated by increased osteocyte apoptosis in mice expressing a mutated nondegradable collagen 1.[41]

A molecule crucial for the functionality of the osteocyte network is connexin 43 (Cx43), the most abundant member of the connexin family of proteins expressed in osteocytes.[42] Cx43 forms gap junction channels between cells participating in cell-to-cell communication within the osteocyte network; and it also forms hemichannels connecting cells with the extracellular milieu. Deletion of the Cx43 gene from osteocytes in mice decreases osteocyte viability and induces changes in the geometry of long bones, which present the features of bones from old mice or humans.[43–45] Apoptotic osteocytes and empty lacunae are increased, the BM cavity is enlarged by exaggerated endosteal resorption, and the diameter of the bones is larger due to increased periosteal bone apposition. These effects of Cx43 deletion are intrinsic to osteocytes, as knockdown of the gene in vitro result in cells that die spontaneously and exhibit increased RANKL/OPG ratio and increased ability to support osteoclast formation.[45,46] Further, osteoclasts are found on surfaces

adjacent to areas where apoptotic osteocytes accumulate in Cx43 knockout mice, suggesting that signals released by dying osteocytes are required to target osteoclast recruitment. Cx43 expression in osteoblasts/osteocytes is also required for cell survival induced by bisphosphonates or PTH, as well as for a full bone anabolic response to PTH.[47–50] Cx43 is also involved in the response of osteocytes to mechanical signals. However, PGE_2 release induced by in vitro mechanical stimulation requires Cx43 expression in osteocytes, paradoxically Cx43 restrains the response of bone to mechanical stimulation in vivo as deletion of the Cx43 gene from osteocytes enhances the anabolic response of bone to loading.[51–53] This suggests that Cx43 does more than regulate PGE_2 release in vivo. Future research is warranted to explain the mechanisms underlying this phenomenon.

3.2 Regulation of Bone Formation by Osteocytes

One of the most important events of the last 2 decades that advanced our understanding of skeletal biology was the discovery of the role of Wnt/βcatenin signaling in bone.[54] The so-called canonical Wnt-signaling pathway controls fate of mesenchymal stem cells and their differentiation into the various cell lineages. Canonical Wnt signaling restrains chondrogenic and adipogenic differentiation while enhancing osteoblastic differentiation from mesenchymal stem cells. In addition, Wnt/βcatenin signaling promotes osteoblast maturation and survival of osteoblasts and osteocytes. At the same time, it inhibits osteoclastogenesis, although indirectly by increasing the expression of OPG in osteoblasts and osteocytes.

Osteocytes are critical players in the regulation of this signaling pathway both as targets of the Wnt ligands and as producers of molecules that modulate their action. Wnt/βcatenin signaling is activated by binding of Wnt proteins to a receptor complex composed of frizzled receptors and coreceptors of the low density lipoprotein receptor–related protein (LRP) family, LRP5 and 6. This event stabilizes βcatenin, induces its translocation to the nucleus, and activates gene transcription. Activation of this pathway is critical for bone acquisition and maintenance through increased bone formation and decreased resorption.

Dickkopf-related protein 1 (Dkk1) is a Wnt antagonist expressed in osteoblasts and at higher levels in osteocytes.[55] Dkk1 binds to LRP5/6 preventing the binding of Wnt ligands. Mice overexpressing Dkk1 in osteoblastic cells exhibit decreased bone formation and low bone mass, consistent with the stimulatory role of the Wnt/βcatenin pathway on bone formation.[56] Another Wnt inhibitor, secreted frizzle-related protein 1 (sFRP1) is expressed in early osteocytes and its levels decrease as osteocytes mature.[57] Consistent with the role of sFRP1 as an inhibitor of anabolic Wnt/βcatenin signaling, its deletion from the mouse genome results in increased bone mass.[54]

Another antagonist of Wnt signaling is sclerostin, a protein encoded by the Sost gene, which is primarily expressed by mature osteocytes but not by early osteocytes or osteoblasts.[58] Sclerostin binds to the Wnt coreceptors LRP5/6 antagonizing downstream signaling.[59] Sclerostin also binds to LRP4, another member of the LRP family of proteins, which acts as a chaperone and is required for the inhibitory action of sclerostin on Wnt/βcatenin signaling.[60] Absence of sclerostin expression or secretion in humans causes sclerosteosis, van Buchem disease, or craniodiaphyseal dysplasia, inherited high bone mass (HBM) conditions characterized by exaggerated bone formation.[54] Further, inactivating mutations of the Wnt coreceptor LRP5 result in low bone mass (osteoporosis pseudoglioma); and, conversely, activating LRP5 mutations lead to HBM partially due to decreased binding affinity of the mutated LRP5 for sclerostin.[54] Consistent with the requirement of LRP4 for the inhibitory function of sclerostin, individuals with LRP4 inactivating mutations exhibit HBM. Moreover, deletion of the Sost or LRP4 genes in mice or neutralizing antibodies for sclerostin or LRP4 reproduces the HBM phenotype found in humans lacking SOST or LRP4 activity,[61–65] whereas overexpression of Sost/sclerostin decreases bone mass.[14,18,66,67] Remarkably, osteocyte-targeted deletion of LRP5 or overexpression of HBM LRP5 mutants only in osteocytes reproduces the low or HBM, respectively, exhibited by mice or humans with the genetic modifications in all cells, suggesting that activation of the pathway in osteocytes is sufficient to elicit bone formation downstream of LRP5.[68,69] This conclusion is consistent with recent findings demonstrating that osteocytes mediate the anabolic actions of canonical Wnt/βcatenin signaling in bone.[70]

3.3 Regulation of Bone Resorption by Osteocytes and the Role of Osteocyte Apoptosis in Targeted Remodeling

Osteocytes produce cytokines that regulate osteoclast formation and survival. Deletion of the RANKL gene from osteocytes renders an osteopetrotic phenotype, due to reduced number of osteoclasts, decreased resorption, and progressive increase in bone mass,[71,72] suggesting that, postnatally, osteocytes are an important source of RANKL in bone. M-CSF, produced by bone cells including osteocytes,[55] promotes osteoclast precursor proliferation and survival and is required for osteoclast formation.[73] Similar to mice lacking M-CSF in all tissues,[74] mice lacking M-CSF only from osteocytes exhibit reduced osteoclast number and osteopetrosis demonstrating the osteocytes are an important source of the cytokine in bone.[75] Osteocytes also express receptors for M-CSF,[55] and mice lacking osteocytic M-CSF have osteocytes with abnormal morphology, high prevalence

of apoptosis, increased production of reactive oxygen species, and reduced gap junction communication,[75] suggesting that osteocytes are also a target cell for this cytokine.

The antiosteoclastogenic cytokine OPG is expressed in both osteoblasts and osteocytes, although its mRNA expression is higher in the latter cells.[76] OPG is a target gene of canonical Wnt signaling and mice lacking βcatenin from osteoblasts/osteocytes or only from osteocytes, exhibit similar reduced OPG expression, increased osteoclasts, and low bone mass.[76–78] These findings suggest that the regulation of osteocytic OPG by Wnt/βcatenin signaling plays an important role in the control of bone resorption.

Osteocyte viability is an important component of the cascade of events that directs osteoclasts to particular bone surfaces, so-called targeted bone remodeling.[3,79,80] Accumulation of apoptotic osteocytes in certain areas of bone promotes preosteoclast recruitment, local osteoclast differentiation, and increased resorption. Although the mechanisms underlying this phenomenon are still unclear, it is recognized that osteocyte apoptosis precedes temporally and spatially osteoclastic resorption. Induction of osteocyte apoptosis by injecting diphtheria toxin to transgenic mice expressing the diphtheria toxin receptor in osteocytes is sufficient to increase osteoclasts and trigger resorption in the vicinity of dead osteocytes.[81] Moreover, osteocyte death is accompanied by increased osteoclasts in nearby bone in rodent models of unloading, excessive mechanical forces, or ovariectomy, opening the possibility that increased osteocyte apoptosis is a generalized mechanism to induce localized bone resorption.

One of the potential mechanisms by which increased osteocyte apoptosis could trigger local bone resorption is by increasing RANKL expression in osteocytes located close to the dying cells. This notion is supported by the fact that inhibition of apoptosis by administering bisphosphonates that prevent osteocyte apoptosis but do not act directly on osteoclasts or caspase inhibitors blocks the increase in osteocytic RANKL found in the aforementioned animal models.[3,79,80,82,83] Further, deletion of RANKL from osteocytes and mature osteoblasts prevents the decrease in bone mass and the increase in osteoclast number in tail-suspended mice.[71] Moreover, inhibition of osteocyte/osteoblast apoptosis with a bisphosphonate that does not affect osteoclasts or with a pan caspase inhibitor prevented the increase in osteocytic RANKL induced by unloading. However, the bisphosphonate did not prevent the increase in circulating bone resorption markers or the loss of bone,[82] whereas the caspase inhibitor did. In this latter case, however, resorption was evaluated only at the local level in cortical bone, and systemic effects on circulating CTX or bone mass throughout the skeleton were not reported, potentially explaining the apparent discrepancy between the studies. Nevertheless, taken together these findings demonstrate a cause–effect relationship between osteocyte apoptosis and osteocytic RANKL and suggest that, under certain unloading conditions, osteocytic RANKL is central for osteoclast formation and bone resorption.

In addition to osteocytic genes or pathways that regulate either bone formation or bone resorption, genetic manipulations targeting osteocytes can simultaneously control both arms of remodeling. For example, activation of βcatenin in osteocytes increases bone mass in the context of elevated bone formation and bone resorption, leading to high bone remodeling with bone gain.[70] This effect contrasts with the findings that activation of βcatenin in osteoblasts/osteocytes increases bone mass due to reduced bone resorption, without affecting osteoblast function.[78]

4 GENE DELETION AND MUTATIONS AFFECTING OSTEOCYTES

Osteocytes were elevated to their role of master regulators of bone metabolism after genetic studies linked two distinct pathologies, sclerosteosis and van Buchem disease to a protein, sclerostin, made predominantly, if not exclusively, by mature osteocytes. Over the years, the list of osteocyte specific genes linked to disorders of skeletal or mineral metabolism has grown steadily and now it is known that these "unique" cells synthetize hormones, cytokines, and proteins required for phosphate homeostasis and bone integrity. Genome-wide association studies (GWAS) have analyzed hundreds of thousands of single nucleotide polymorphisms and correlate them with skeletal phenotypes. GWAS identified more than 500 genes linked to osteoporosis and 3 predominant pathways that are critical for skeletal biology: Wnt, Notch, and Indian Hedgehog (for review, see Ref. 84). Genes and loci that highly correlate with osteoporosis include, among others, MEPE, Lrp4, Mef2C, HDAC5, all abundantly expressed in osteocytes. Moreover, osteocytes are also important regulators of the Wnt pathway, so we will review genetic disorders affecting bone or mineral metabolism that are primarily related to osteocyte defects.

Canonical Wnt signaling plays an important role in the development and maintenance of many organs, including bone, as described earlier. Several rare genetic disorders affecting the Wnt-signaling pathway have provided strong evidence for its role in skeletal homeostasis. Genetic mutations of various components of the Wnt pathway are associated with skeletal disorders (see following).

4.1 Sclerostin, Sclerosteosis, and van Buchem's Disease

Sclerosteosis was first described by Hansen in 1967 as a skeletal disorder characterized by generalized osteosclerosis with hyperostosis of the calvarium, clavicles, and sternum, and abnormalities of the digits (syndactyly). The disease was distinct from osteopetrosis due to the lack of skeletal fragility or of disturbance of dentition or anemia. In patients with sclerosteosis, the skeletal deformities are not present at birth but they became noticeable in early childhood and progress steadily thereafter. The disease is quite rare and cases have been reported in South Africa,[85] Netherland, Spain,[86] Japan,[87] Brazil,[88] and Egypt.[89] Clinical features of sclerosteosis closely resemble that of van Buchem disease, with the exception of gigantism and hand abnormalities that are not present in the latter. Both diseases were found to be autosomal recessive and they remained of unknown etiology until 1999 when the gene responsible for sclerosteosis and van Buchem disease was localized on chromosome 17g12-q21.[62,90,91] Two years later, changes in sclerostin, the product of the gene SOST, were identified as the cause. Sclerostin, a cysteine rich protein with homology to gremlin, is a potent inhibitor of bone formation and acts by binding and inactivating the canonical Wnt-signaling pathway. Patients with sclerosteosis carry a point mutation in the SOST gene whereas patients with van Buchem disease are characterized by a 52 kb deletion downstream of the gene.[92] Although osteoclasts were initially thought to be the main source of sclerostin[93] soon it became clear that this protein is secreted predominantly, if not exclusively, by osteocytes.[94,95] Sclerostin binds to low-density lipoprotein (LDL)–related protein 5, 6, and 4 (LRP5, 6, and 4) receptors expressed on osteoblasts and osteocytes and inhibits Wnt/βcatenin pathway.[96] Whereas LRP5 and 6 are needed for Wnt-signaling transduction, LRP4 works as an anchor for Sclerostin binding. The pathological role of sclerostin has been further validated in knockout and transgenic animal models that recapitulate the high bone mass phenotype of sclerosteosis and van Buchem patients.[63,97] Recently, craniodiaphyseal dysplasia, a rare and severe bone dysplasia characterized by sclerosis of the skull and facial bones has also been linked to a "de novo" mutation in the SOST gene[61]

4.2 LRP Mutations

The role of canonical Wnt-signaling in bone was first described when loss-of-function mutation of LRP5, a coreceptor for Wnts, were found to cause, in humans, osteoporosis-pseudoglioma syndrome (OPPG), an autosomal recessive disorder characterized by osteopenia and low bone mass.[98] Similarly, heterozygous missense mutation in LRP5 (gain-of-function mutations) leads to the high bone mass phenotype in both humans[69,99] and in mice. Mutation in LRP4 and 6 have also been identified and correlated with genetic disorders. Once again, genetically modified animals have helped to unravel the pathophysiology of LRPs and Wnt/βcatenin mutations and to characterize their underlying mechanisms of action. LRP5-null mice recapitulate the osteoporosis-pseudoglioma phenotype seen in humans, and the low bone mass phenotype in these animals appears to be driven by severely compromised bone formation. Interestingly, when LRP5 is ablated from specific cells of the osteoblastic lineage, the phenotype becomes more complex, suggesting additional mechanisms might be involved. Deletion of LRP5 or βcatenin in osteoblast, using the collagen 1 promoter, or in osteocytes, using the DMP1 promoter, induce marked osteopenia and increased bone resorption.[67,68,78]

The exact underlying genetic mutations and pathophysiology of LRPs and Wnts are discussed in more details elsewhere in this book.

4.3 Mutations Leading to Disturbance of Phosphate Homeostasis

Besides their role on bone mineral metabolism, osteocytes (and possibly late mature osteoblasts) function as an endocrine organ by secreting hormones and factors required for controlling serum phosphate levels. Several phosphate regulating hormones and enzymes, namely, FGF23, PHEX, and MEPE, are synthesized predominantly by osteocytes and, to a lesser extent, by mature osteoblasts. FGF23 was identified in 2000 by White et al. (ADHR Consortium[100]) as the long sought-after phosphate-regulating hormones (phosphatonins) causing autosomal dominant hypophosphatemic rickets (ADHR). Soon after this initial report, FGF23 was shown to cause phosphate wasting in tumor-induced-osteomalacia and X-linked hypophosphatemia (XLH). A few years later, two groups independently demonstrated that autosomal recessive hypophoshatemic rickets (ARHR) was caused by a mutation in dentin matrix protein 1 (DMP1) that affected FGF23 circulating levels.[37,101] Mice lacking DMP1 have skeletal abnormalities (including a disrupted osteocyte-network), are hypophosphatemic and have increased FGF23 levels, faithfully mimicking the mineral and skeletal abnormalities of ARHR patients. Once again the main culprits in this disease are osteocytes. DMP1 is produced by osteocytes and late mature osteoblasts, and it is a negative regulator of FGF23 synthesis and secretion, through unclear mechanisms. Osteocytes are also, together with mature osteoblasts, the main source of FGF23 and recent work demonstrated that targeted ablation of this hormone in bone cells, indeed recapitulate the hyperhosphatemia present in FGF23 null mice.[102] Whereas the role of osteocytes in skeletal metabolisms has been quite well

validated, their role in phosphate homeostasis still has some unanswered questions. When osteocytes are temporarily ablated in mice, using a mouse model in which the diphtheria toxin receptor is targeted to these cells[37] by the DMP1-promoter, the animals, as expected, develop severe osteopenia but their mineral homeostasis remains unchanged. Moreover, FGF23 and phosphate levels are normal, despite the lack of more than 80% of these cells, suggesting the presence of other sources. These findings have puzzled the scientific community and it has been proposed that other cells in the skeleton (maybe endosteal osteoblasts) might be the source of FGF23. Recent work from Clinkenbeard[102,103] used a floxed FGF23 mouse model to demonstrate the role of bone-derived FGF23. By targeting FGF23 deletion in Col2.3- or DMP1-expressing cells the authors demonstrated that both osteoblasts and osteocytes contribute to FGF23 circulating levels and partially explain absence of changes in mineral homeostasis in osteocyte-less mice.

In summary, over the last decade, several genetic mutations and human diseases have been ascribed to osteocyte defects and GWAS has identified osteoporosis "candidate genes" that are highly expressed in these unique cells. Future studies and better understanding of the role of these cells will unravel more functions of the unique bone cells.

5 CROSS TALK OF BONE WITH OTHER ORGANS/TISSUES

Osteocytes are endocrine cells that can secrete factors with the potential to have effects on distant organs. Bone as a mineralized tissue is thought to be more of a support structure and not as an endocrine organ similar to the pituitary or adrenal glands. However, as bone is highly vascularized and secretes factors into the bloodstream to affect distant targets, it must be defined as an endocrine organ.[2] The vascular system has a close, connecting association with the osteocyte lacuna–canalicular system. A bone fluid with a molecular weight cutoff of around 70 kDa flows through this system with the potential to provide autocrine and paracrine factors to neighboring osteocytes and in association with the vascular system, endocrine factors to other organs. As described earlier these osteocytes produce circulating factors, such as FGF23 and sclerostin and, most likely, other as yet unknown factors. Potentially osteoblasts have the capacity to release factors into the circulation, but they compose approximately 5% of bone cells compared to 1% being osteoclasts, whereas 90%–95% of bone cells are osteocytes. Considering the total mass of osteocytes and their dendritic processes in bone that are equivalent to the mass of the brain,[104] these cells are likely a major source of circulating factors from the adult skeleton.

Clearly bone is a source of osteogenic growth factors, such as the bone morphogenetic proteins, the TGF-β, and the insulin-like growth factors. It is thought that these factors are deposited in matrix by osteoblasts and released by osteoclasts during resorption to initiate coupling.[105] One factor produced uniquely by bone is osteocalcin which has been shown to target numerous tissues and is therefore considered a hormone.[106] Osteocalcin is produced by the late osteoblast before embedding into osteoid and also by embedded osteocytes. Like growth factors, it is thought that osteocalcin is mainly deposited into the bone matrix during bone formation and is hypothesized to be released by osteoclasts during resorption.[107] Osteocalcin has high affinity for hydroxyapatite, but with removal of carboxylation potentially by acid, it becomes a circulating factor. Osteocalcin has effects on glucose metabolism, energy metabolism, fertility, ectopic calcification,[108] and on muscle activity.[109] As osteocytes can remove their perilacunar matrix,[22] this matrix is also a potential source of endocrine factors and growth factors.

Osteocytes are mechanosensors and their secreted factors are also regulated by loading or unloading of the skeleton. One major example is the decrease in sclerostin with loading[13] and increase with unloading.[14,110] This response is most likely mediated through the Wnt/βcatenin pathway which serves as an important regulator of bone mass and is important in osteocyte transmission of mechanical loading signals to cells on the bone surface.[76] The pathway is triggered by cross talk with the prostaglandin pathway in response to loading resulting in a decrease in negative regulators of bone formation, such as sclerostin and Dkk1.[11] It has recently been shown that two factors, prostaglandin E_2 and Wnt3a, both produced by osteocytes in response to shear stress support myogenesis and muscle function.[111–114] Therefore, mechanical loading of the skeleton especially in the form of exercise is important to ensure healthy osteocyte function.

5.1 Cross Talk of Bone With Kidney and Heart

Osteocytes regulate mineral homeostasis especially phosphate through factor production, such as phosphate regulating neutral endopeptidase on chromosome X (Phex), dentin matrix protein 1 (Dmp1), and FGF23.[115] Since its identification in 2000, FGF23 has become recognized as one of the most important osteocyte-secreted endocrine factors due to negative effects on kidney and heart.[37,116–118] Under normal physiological conditions, both Dmp1 and Phex downregulate FGF23 in osteocytes allowing reabsorption of phosphate by the kidney to maintain sufficient circulating phosphate to maintain normal bone mineral content. In the absence of either Dmp1 or Phex, FGF23 is elevated in the osteocyte and systemically, leading to phosphate excretion by the

kidney resulting in osteomalacia and rickets.[37] Interestingly, FGF23 is also able to act on the parathyroid gland to decrease PTH secretion, identifying the parathyroid gland as another endocrine target of osteocyte signaling.[119,120]

FGF23 also plays a pathological role in chronic kidney disease (CKD). It was first shown by Pereira and coworkers in 2009 that FGF23 is elevated in osteocytes in CKD.[121] In CKD, serum levels of FGF23 are increased, particularly in the later stages of the disease.[122,123] FGF23 levels predict cardiovascular events before but not after dialysis for CKD and FGF23 is a risk factor for adverse outcomes in patients with CKD and End Stage Renal Disease (for review, see Ref. 124). Therefore, regulation of systemic FGF23 levels has become a significant clinical target.

High circulating levels of FGF23 have negative effects on cardiac muscle (for review, see Ref. 125). Studies have linked elevated levels of circulating FGF23 to increased risk of heart disease and independently associated with left ventricular hypertrophy in human population studies.[126,127] Increased serum FGF23 has also been linked with impaired vascular function,[126] vascular calcification,[128] and increased fat mass.[129] Clearly osteocyte-regulated proteins play an important role not only in normal physiology but also in disease.

5.2 Cross Talk of Bone With Muscle

Bone–muscle cross talk is of interest because of the realization of the implications of this emerging field of research for the diseases of osteoporosis and sarcopenia and potentially others.[125] It is not clear if the two diseases are concurrent or if one precedes the other. With life expectancy increasing, the consequences of aging on the musculoskeletal system will place a greater burden on public health and the economy. It is projected that 20% of the world population will be in their 60s or older by 2050 and over 30% by 2150.[130,131]

Bivariate GWAS has been used to identify pleiotropic candidate genes/single nucleotide polymorphisms/regions associated with traits in both bone and muscle.[132–137] One of the genes identified was *MEF2C*, that encodes a transcription factor (myocyte enhancer factor 2C) known to be involved in cardiac and skeletal muscle development.[138] A mouse model where *Mef2C* was specifically deleted in osteocytes has increased bone density through downregulation of Sost and increased OPG resulting in reduced osteoclastogenesis.[139] Another gene identified was *METTL21C*. Downregulation of this gene in C2C12 muscle cells led to reduced myogenic differentiation, a decrease in myotube cell area, and reduced calcium release from the sarcoplasmic reticulum, while downregulation in MLO-Y4 osteocytic cells resulted in cells more prone to dexamethasone-induced cell death. These effects were linked to the alteration of common signaling pathway, the NF-kB pathway.[140] *METTL21C* is part of the METTL21family of the methyltransferase superfamily with protein-lysine *N*-methyltransferase activity,[141] and methylates valosin-containing protein chaperones. These proteins can harbor specific mutations that are causal for inclusion body myositis (muscle) with early onset of Paget's disease.[142] These studies suggest important roles for MEF2C and METTL21C in both bone and muscle.

Dogma has been the main interaction between muscle and bone in the mechanical loading of bone through muscle contraction. However, not only the bone is an endocrine organ, but also the muscle.[143] Myostatin, is a potent inhibitor of skeletal muscle cell proliferation and growth,[144,145] and in 2007 Pedersen coined the term "myokines," for muscle secreted factors which includes IL-8,[146] brain-derived neutrophic factor,[147] irisin, a potent regulator of the conversion of white fat into brown fat,[148] and IL-15, a muscle factor that reduces adiposity.[149] Secreted factors from C2C12 myotubes but not from C2C12 myoblasts increased the viability of MLO-Y4 osteocyte-like cells treated with dexamethasone[150] and intact skeletal muscles electrically stimulated ex vivo also protect osteocytes against cell death.[150]

Conversely, osteocytes secrete factors that regulate muscle mass and function. MLO-Y4 osteocyte-like cells and primary osteocytes secrete factors that induce muscle myogenesis and activate the Wnt/βcatenin pathway in C2C12 pluripotent cells.[112,113] These findings suggest that this pathway not only plays a role in muscle development but also in muscle repair and myogenesis. Two factors produced by osteocytes in response to shear stress, PGE_2 and Wnt3a, were found to enhance myogenesis and ex vivo primary muscle function. The first in vivo data to suggest that bone regulates muscle mass and function was in 2015 showing that osteocalcin partially restored muscle mass in a model of deletion of Cx43 in osteocytes[151] and these effects of osteocalcin on muscle have been repeated and extended by the Karsenty laboratory in 2016.[109] Also in 2015, Waning and coworkers[152] showed that cancer induced release of TGF-β from bone was responsible for muscle cachexia and Gorski and coworkers[153] showed that deletion of a protease, MBTPS1, in osteocytes resulted in little effects on bone but significant increases in muscle mass and function with aging. Therefore, several lines of in vitro and in vivo evidence are emerging to support the hypothesis that bone can regulate muscle mass and function through secreted factors.

5.3 Cross Talk of Bone and Hematopoietic Cells

Under physiological conditions, the BM is the primary site for hematopoiesis, a process highly orchestrated

by the interactions between the hematopoietic stem cells (HSC) and their niches. Seminal work of two groups,[154,155] identified endosteal osteoblasts as key component of the HSC niche. Over the last decade, the complexity and composition of the HSC niche has been recognized to be much more complicated than expected. Osteoclasts,[156] CXCL12-abundant cells (CAR Cell),[157] perivascular Nestin + cell,[158,159] endothelial and adipose cells[160] have all been shown to be a critical component on the niche (for review, see Ref. 161). Considering the physical proximity and the secretory capability of osteocytes, it is not surprising that these cells also participate in maintaining the HSC niche. Studies from Fulzele et al.[162] showed that osteocytes and GPCR signaling were important in controlling myeloid cells proliferation and mice lacking osteocytes (osteocyte-less animals) were shown to have defective HSC mobilization and lymphopenia.[163,164] Whether osteocytes control the HSC niche directly, through their cytoplasmic extensions, or indirectly, via secreted factors, still awaits further clarification.

5.4 Cross Talk of Bone and Fat

Using a mouse model in which osteocytes can be ablated by use of diphtheria toxin (DT), Sato et al.[164] demonstrated that these cells might also regulate adipose tissue. Upon DT-injections, Osteocyte-less mice had a marked reduction in white adipose tissue including subcutaneous, mesenteric, and retroperitoneal fat. Although in this model the lean phenotype could not be rescued by parabiotic experiments, further studies have demonstrated a role for sclerostin in inducing adipocyte differentiation.[165] Similarly, mice lacking Gs-α signaling in osteocytes and/or osteoblasts also develop a lean phenotype characterized by reduced white adipose tissue and increased brown adipose tissue (Divieti Pajevic et al., unpublished data).

6 THE DYING AND AGING OSTEOCYTE

As described earlier, osteocyte cell death is important to repair damaged bone.[166–168] This cell death acts as a beacon to direct osteoclasts to microdamaged bone for removal as the cells sacrifice themselves to target bone repair. This death is highly programmed to release factors, such as RANKL to direct osteoclasts to damaged sites for repair. Therefore, it is important to maintain the health of the osteocyte. However, it appears that oxidative stress caused by disuse, estrogen deficiency, corticosterone, and aging may be responsible for bone cell death and therefore bone fragility.[169] Osteocyte viability is crucial for the normal functioning of the skeleton and the normal function of other organs, such as kidney and muscle. As osteocytes have multiple functions, outlined earlier, it is important to maintain normal viability and function of these cells.[2] A number of factors and cytokines have been shown to induce osteocyte cell death including glucocorticoids, IL-1 and TNF-α and a number of molecules have been shown to protect osteocytes from cell death, such as estrogen, bisphosphonates (for review, see Refs. 170–172) and PTH. Recently, it has been shown that secreted muscle factors could protect osteocytes from glucocorticoid-induced cell death and that this effect was mediated through the βcatenin pathway.[111] The large number of factors that can induce osteocyte cell death and the large number of protective mechanisms imply the importance of regulating osteocyte cell death and viability.

The osteocyte is an aging, senescent cell. As osteocytes reside in human bone for decades while osteoblasts and osteoclasts live for only days or weeks, the osteocyte is very susceptible to the effects of aging. The osteocyte cannot be replaced except by bone remodeling, therefore the osteocyte should be considered the senescent cell in bone. Osteocyte cell death can result in micropetrosis where mineral fills the lacuna resulting in a cell that becomes a "living fossil."[173] Fewer numbers of osteocyte lacunae were found in patients suffering from fractures compared to controls[174] and an age-dependent decrease occurs in osteocyte lacunar density with an increased amount of hypermineralized calcium phosphate occlusions.[43] Infilling of osteocyte lacunae and canaliculi has important implications for the flow of bone canalicular fluid, that may determine the capacity of the osteocyte to sense mechanical loading and to sense microdamage. The aging osteocyte in a compromised lacuno–canalicular system is less likely to produce secretory factors. Therefore, it is important to maintain osteocyte viability with age.

7 CONCLUSIONS

Whereas the majority of genetic mutations responsible for bone disease are important in embryogenesis, growth, and development, such as collagen mutations, clearly a number of genetic mutations have been found in genes either relatively specific or highly expressed in osteocytes, such as sclerostin, Phex, Dmp1, and FGF23. The number of osteocytes is relatively low in the embryo and increases in number during the growth so that in the mature adult the number of osteocytes outnumber osteoblasts 10–1 and osteoclasts 100–1. When thinking of bone genetic diseases, it will be important to consider these two categories before proposing specific cellular and molecular mechanisms. The osteocyte clearly regulates bone function postnatally and most likely has a progressively greater role in the health of the skeleton with aging.

CHAPTER

15

Skeletal Stem Cells/Bone Marrow Stromal Cells

Pamela G. Robey

National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD, United States

1 HISTORY AND DEFINITIONS OF POSTNATAL STEM CELLS

The notion that postnatal tissues self-renew, and do so by means of a local tissue-specific stem/progenitor cell is not a new one, and is based on observations around the turn of the 19th century by classical histologists (e.g., Regaud working on spermatogenesis[1,2]) and hematologists (e.g., Weidenreich, Dantschakoff, Maximow, Ferrata, and Pappenheim, reviewed in Ref. 3). This concept was originally based on studies of tissues with high proliferative capacity and rate of turnover (blood, gastrointestinal track, epidermis).[4] However, findings since 1990s have demonstrated that virtually all postnatal tissues have some form of a tissue-specific stem/progenitor cell, capable of local regeneration, albeit with different rates of turnover and structural design, depending on the demands imposed upon them (e.g., intestine, mammary gland, and muscle, reviewed in Ref. 5).

1.1 Definitions

While much has been learned through the use of lineage tracing in mice,[6,7] the distinction between a stem cell and a progenitor cell is still somewhat blurry in many cases. However, it is now generally agreed upon that a stem cell is able to: (1) proliferate upon demand to generate progeny that differentiate and reform a tissue (potency), and (2) self-renew (it has the ability to maintain itself as a stem cell in a sea of more committed and differentiated progeny). On the other hand, a progenitor cell, while able to transiently proliferate, is thought to be more committed to a phenotype. Yet, this definition may be somewhat rigid in that there are examples of progenitor cells switching their fate based on changes in the microenvironment (e.g., bone marrow stromal cells, and even committed osteogenic cells being able to form adipocytes indicating their flexibility). However, that is not to say that progenitor cells are able to differentiate into a cell type outside of the lineage of their tissue of origin (so-called "transdifferentiation") without extreme chemical (e.g., treatment with DNA methylation inhibitors) or molecular [e.g., reprogramming with the specific transcription factors to create induced pluripotent stem cells (iPSCs)] modifications. In this context, bone and its stroma represent a unique organ system for the study of stem/progenitor cell kinetics, regulation, and the maintenance of tissue hemostasis.

1.2 Identification of Skeletal Stem/Progenitor Cells

Perhaps the first evidence of the presence of stem/progenitor cells in a connective tissue emanated from the pioneering studies of Alexander Friedenstein in the late 1960s. He demonstrated that when single cell suspensions of murine bone marrow, free of fragments of trabecular bone, were plated at low density, rapidly adherent fibroblastic cells appeared, and proliferated to form a colony composed of bone marrow stromal cells (BMSCs). When individual colonies, established by these colony-forming unit-fibroblasts (CFU-Fs) were transplanted in a closed system, impenetrable by the vasculature (diffusion chamber), a number of them formed bone on the exterior of the chamber (an aerobic environment), and cartilage in the interior (an anaerobic environment). When transplanted in a collagen sponge into an open system that could be vascularized (under the kidney capsule), a number of single colonies were able to reform a bone/marrow organ, composed of bone, hematopoiesis-supportive stroma (a defining feature of these cells) and marrow adipocytes of donor origin, and

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00015-0

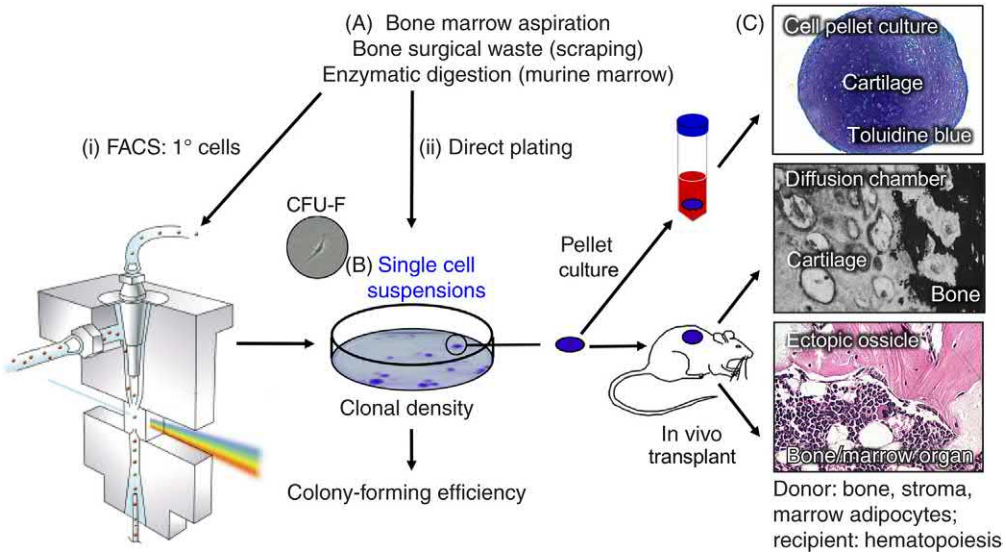

FIGURE 15.1 Isolation and characterization of SSCs/BMSCs. A. SSCs/BMSCs are can be obtained from bone marrow (BM) aspirates or scrapings of marrow from surgical waste, or by enzymatic digestion of marrow, which is used primarily for murine bone marrow. A(i). The freshly isolated single cell suspensions thus generated can be used for FACS sorting based on a variety of cell surface markers, or A(ii), used for direct plating. B. Colony-forming efficiency (CFE) is determined by plating the single cell suspension at clonal density (see text) in order to determine the number of colonies initiated by colony-forming units-fibroblasts *(CFU-Fs)*. This is the closest approximation of the number of SSCs available to date. C. After ex vivo expansion of individual colonies, aliquots are used to generate cell pellet cultures for evidence of chondrogenic differentiation, or transplanted in vivo into immunocompromised mice in conjunction within a diffusion chamber (cartilage and bone), or with an appropriate scaffold. The constructions form an ectopic ossicle (BM/organ), with bone, stroma, marrow adipocytes of donor origin, and hematopoiesis of recipient origin. Support of hematopoiesis is a defining feature of SSCs/BMSCs.

hematopoiesis of recipient origin[8] [Fig. 15.1A(ii)–C]. He, along with his collaborator, Maureen Owen, later called these cells "multipotent bone marrow stromal stem cells," (reviewed in Refs. 9,10). More recently, the term "skeletal stem cell" (SSC) was coined by Paolo Bianco and coworkers based on the ability of individual CFU-Fs to recreate skeletal tissue.[11] He also determined, for the first time, the anatomic location of this elusive cell, and its ability to self-renew,[12] making SSCs bona fide stem cells.

1.3 From SSCs/BMSCs to "Mesenchymal Stem Cells"—A Source for all Mesodermal Derivatives?

The original concept of a tissue-specific skeletal stem/progenitor cell put forward by Friedenstein and Owen was based on rigorous evidence of the inherent properties of BMSCs and its subpopulation of SSCs, and was limited to the skeletal system. As such, these findings were largely unnoticed, except by some, interested in the osteogenic differentiation process (from uncommitted precursor to a fully mature osteocyte), and in harnessing their potential to reconstruct a bone/marrow organ. However, as studies on the bone regenerative properties of SSCs/BMSCs expanded, the original concept was altered. Based on their predominantly mesodermal origin, it was envisioned that SSCs/BMSCs would not only regenerate nonhematopoietic cell types found in the bone/marrow organ, but also other mesodermal derivatives, such as muscle, tendon, ligament, etc. This so-called "mesengenic process" was originally modeled on BMSCs, which were then renamed "mesenchymal stem cells" (MSCs).[13] On the surface, this change in concept was appealing to some, but defied basic principles of developmental biology. "Mesenchyme" is an embryonic connective tissue with broader differentiation properties (able to form not only connective tissues, but also blood and blood vessels).[14] No postnatal stem cell to date (other than iPSCs) has been found to form all three of these types of tissues by rigorous criteria. Furthermore, not even mesodermal derivatives that form bone derive from a common precursor. Somites, derived from paraxial mesoderm, segregate into axial bone-forming tissue (the sclerotome), tendon-forming tissue (syndotome), and muscle- and dermis-forming tissue (dermomyotome); splanchnic lateral plate mesoderm forms bone of the appendicular skeleton[15]; neural crest, derived from ectoderm, forms the facial bones,[16] and lastly, the dorsal root of the aorta gives rise to mesoangioblats that contribute to bone formation.[17,18] During development, there is no common mesodermal (or "mesenchymal") cell for even bone formation, let alone for tendon, muscle, dermis, or other connective tissues.[15]

Although not based in solid science, the thought that "MSCs" derived from bone marrow stroma could

differentiate into mesodermal cell types outside of their normal lineage sparked numerous studies to characterize the biological nature of these cells. Reports emerged suggesting that BMSCs have the ability to differentiation into skeletal muscle, tendon, cardiomyocytes, and so forth, but usually based on extensive chemical modification of culture conditions or genetic engineering, expression of a few markers of the "differentiated" phenotype, and less than rigorous assays to demonstrate their functional capacity (reviewed in Refs. 19–21).

Because of the purported ability to differentiate into cell types outside of their lineage, markers that could effectively isolate multipotent bone marrow (BM)–derived "MSCs" based on their cell surface were intensively investigated. Stro1 emerged as the first such marker, capable of effectively isolating all of the CFU-Fs from BM prospectively.[22] Subsequently, ex vivo–expanded BM-derived "MSCs" were further described as being CD29, CD44, CD71, CD90, CD106, CD120a, and CD124 positive.[23] However, none of these markers are specific for BMSCs, or for the SSC subset within the BMSC population. The majority of these markers is found on many connective tissue cells, and cannot predict a stem cell character (the ability of a single cell to reform a tissue and to self-renew) based on rigorous assays. Furthermore, these markers have most often been used to characterize cells after ex vivo expansion, but it is well known that the pattern of expression of many of these markers change, depending on the culture conditions and length of time in culture, and the value of FACS relates to the use of freshly isolated cells (reviewed in Refs. 20,21) [Fig. 15.1A(i)].

1.4 From Bone Marrow–Derived "MSCs" to Ubiquitous "MSCs"?

Because of the lack of specificity of the reported markers, studies rapidly appeared describing the isolation of "MSCs" from nonskeletal connective tissues. In addition, it became a mainstay to compare the differentiation potential of these nonskeletal "MSCs" to that of BMSCs by using in vitro assays and expression of mRNAs representative of differentiated cell types (as described in Ref. 23), instead of in vivo transplantation (as reported in Refs. 8,24 and by many others). However, current in vitro assays are prone to artifact and misinterpretation, and do not reliably predict the inherent osteogenic, adipogenic, and chondrogenic potential of a cell population (as will be described further, reviewed in Refs. 25,26). These two issues combined to generate a great deal of confusion as to actually what is an "MSC". In an attempt to clarify the nature of these cells, a "recommendation" was made that the name "mesenchymal *stromal* cell" be used (due to the lack of convincing data of stemness in many cases) for cells that are: (1) adherent in culture; (2) express CD105, CD73, and CD90, but lack expression of CD45, CD34, CD14, CD11b, CD79a, and HLA-DR markers; and (3) able to differentiate into osteoblastic, adipogenic, and chondrogenic cells in vitro.[27] However, this new term is also inappropriate for postnatal stem/progenitor cells, which are not embryonic, and are not necessarily stromal in nature (e.g., cord blood "MSCs"). Unfortunately, due to its widespread adoption, this recommendation has contributed greatly to the confusion about the what "MSCs" are, as opposed to highlighting the need to determine the nature of connective tissue–specific stem/progenitor cells, to the extent that it is now commonly thought that "MSCs" are ubiquitous and are equivalent in their differentiation properties,[28] in spite of the lack of rigorous analyses (reviewed in Ref. 20). In essence, making a nonskeletal "MSC" behave like a BMSC is like trying to stick the proverbial square peg into a round hole, and the overemphasis on artificial assays overshadows efforts to reveal the inherent differentiation potential of nonskeletal connective tissue stem/progenitor cells.

1.5 "MSCs" are Pluripotent?

Along with the explosion in studies aimed to characterize the nature of BMSCs, and subsequently nonskeletal "MSCs," the thought emerged that BMSCs and "MSCs" are pluripotent. This new twist was based on early studies that aimed to treat generalized disorders of the skeleton, and other mesodermal tissues by direct orthotopic injection or systemic infusion of BMSCs. What followed were suggestions that BMSCs were able to "transdifferentiate" into cell types outside of the mesodermal lineage, such as neuronal cell types, hepatocytes, insulin-producing cells, and so forth [reviewed in Ref. 19). The vast majority of these studies and others related to nonskeletal "MSCs" relied on the expression of a few markers, and did not convincingly demonstrate functionality of these "transdifferentiated" cells. In some cases, formation of a differentiated cell of donor origin could be attributed to cell fusion, which is a natural process in some tissues.[29,30] Based on more recent studies, it is now apparent that "transdifferentiation" of SSCs/BMSCs is a rare event, if it occurs at all (reviewed in Ref. 20). Yet a read of current literature indicates that this concept is still widely held by many scientists; for not only BMSCs, but also for nonskeletal "MSCs." However, the lack of transdifferentiation does not mean that tissue-specific stem/progenitor cell populations are not useful in molecular reprogramming into iPSCs using current methods (transduction with specific transcription factors, modification with mRNAs or small molecules).[31] Rather, it is important to highlight that reprogramming is not equivalent to "transdifferentiation" as originally reported.

2 ORIGINS OF SKELETAL STEM CELLS/ BONE MARROW STROMAL CELLS

The identity of local stem/progenitors has long been sought, but the lack of specific markers of a stem/progenitor cell in any connective tissue has made this a challenging task. However, recent studies suggest that pericytes, cells located on the extravascular surface of blood vessels, may be the source of tissue-specific stem/progenitors that emerge through what might be a common developmental process in many connective tissues.[12,15,20]

During development of BM, blood vessels gain access to what will become the medullary cavity by invading through a layer of committed osteogenic cells.[32,33] Due to an association of the osteogenic cells with endothelial cells, they change not only their morphology, but also cease to synthesize and deposit bone matrix, and proliferate along with the developing blood vessel.[33,34] These former osteogenic cells, now pericytic cells, further proliferate to establish the BM stroma upon which hematopoiesis occurs[33,34] (Fig. 15.2B). In this regard, CD146 (Muc18/MCAM) was demonstrated to mark pericytes on BM sinusoids, and to be a useful marker in isolating pericytes from human BM,[12] providing the first evidence that pericytes are CFU-Fs (Fig. 15.3A–B). Prospective cell sorting for $CD45^-/CD34^-/CD146^+$ cells isolated all of the CFU-Fs in human BM, and after clonal expansion and in vivo transplantation, ~10%–20% of these prospectively isolated CFU-Fs were determined to be multipotent: able to form bone, hematopoiesis-supporting stroma, marrow adipocytes and pericytes of donor origin upon in vivo transplantation (Fig. 15.3B). Of note, these cells were positive for all of the other markers that have been associated with "MSCs," but making them tissue-specific stem/progenitor cells of a different type: $CD146^+$ pericytes. Confirmation of the osteogenic origin of BM sinusoidal pericytes has been reported by lineage tracing using the bone-specific transcription factor, Osterix.[35]

Studies of murine BM using nestin,[36] Mx1,[37] and leptin receptor[38] have also eluded to the pericytic nature of skeletal stem/progenitor cells. Interestingly, pericytes have been identified in other connective tissues as the source of local/stem progenitor cells, such as in dental pulp and in adipose tissue based on Stro1 and CD146 expression, respectively[39,40] and in muscle based on alkaline phosphatase expression.[41] But then,

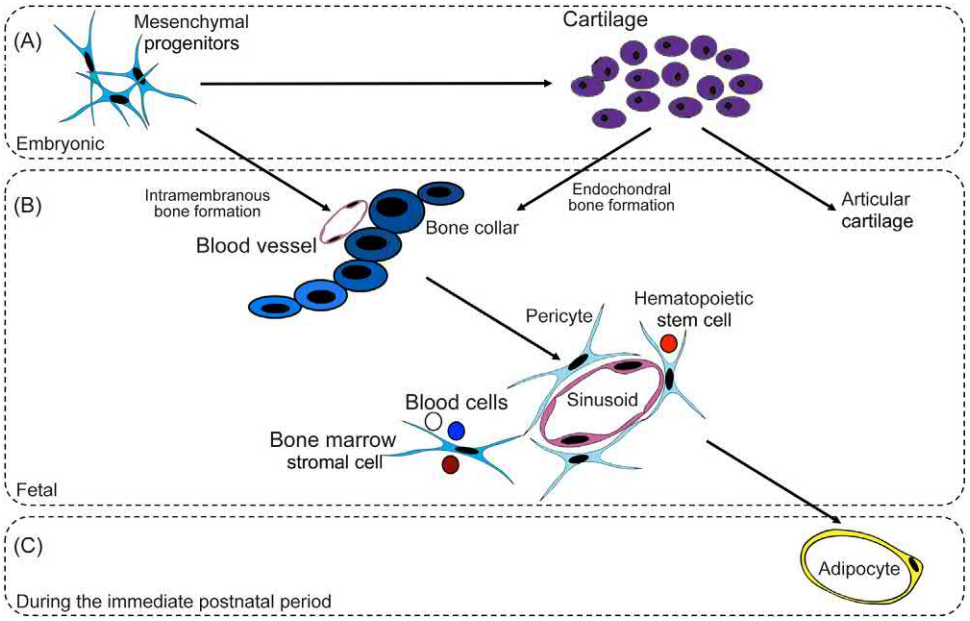

FIGURE 15.2 **Prenatal development of bone and its marrow.** A. At early stages of development, embryonic mesenchyme condenses and forms provisionary cartilage. B. As fetal development continues, the vast majority of the cartilage anlagen undergoes hypertrophy and is replaced by bone, while it remains as articular cartilage in certain sites. In long bones, bone formation begins with the formation of the bone collar by an intramembranous process. Blood vessels associate with committed osteogenic cells in the bone collar and incorporate them as pericytes on the abluminal wall of sinusoids as vascular invasion of the hypertrophic cartilage proceeds. These pericytes further elaborate the prehematopoietic bone marrow stroma. Subsequently, hematopoietic stem cells migrate from the fetal thymus, liver, and spleen to establish hematopoiesis in the newly formed medullary cavity. C. After birth, when hematopoiesis has been established at the level necessary to sustain the organism, bone marrow stromal cells transition into marrow adipocytes. *Source: Modified from Bianco P, Robey PG. Skeletal stem cells.* Development *2015;***142***(6):1023–7.*[15]

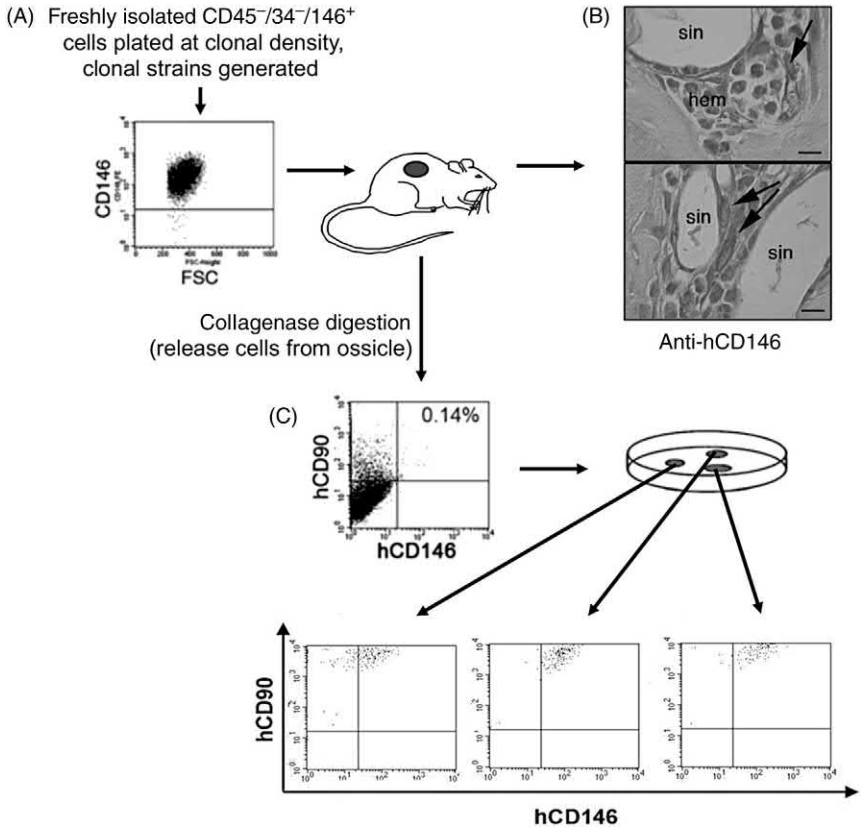

FIGURE 15.3 Identification of SSCs as self-renewing CD146⁺ pericytes. A. In searching for a cell surface marker that would enrich for SSCs, CD146 emerged as an appropriate candidate. Ex vivo–expanded CD146⁺ cells were used to generate in vivo transplants. B. Histological analysis revealed that these cells formed a complete bone/marrow organ, but in addition, reformed CD146⁺ pericytes on BM sinusoids. C. After collagenase digestion of the ectopic bone/marrow organ to liberate cells, human CD146⁺ cells (also hCD90⁺) were isolated and found to be clonogenic, and maintained CD146 expression, indicative of their ability to self-renew. *Source: Modified from Sacchetti B, Funari A, Michienzi S, et al. Self-renewing osteoprogenitors in bone marrow sinusoids can organize a hematopoietic microenvironment.* Cell *2007;***131***:324–36.*[12]

another twist, based on the fact that "MSCs" share a common cell surface phenotype, and that some "MSCs" are also CD146⁺ pericytes, it was reported that pericytes from all tissues are the true "MSCs." However, this assertion, that pericytes from all tissues are osteogenic, adipogenic, and chondrogenic, was overly dependent on in vitro differentiation assays.[42] This study suffered from all of the issues noted previously with regards to the reliability of in vitro differentiation assays and expression of markers, and did not provide solid evidence to support the claims. However, a recent study using CD45⁻/CD34⁻/CD146⁺ cells from BM, muscle, and umbilical cord blood have shown that they have the ability to form pericytes using an in vivo angiopoiesis assay,[43] providing proof of principle. More tissue-specific stem/progenitor cells need to be analyzed in this fashion to determine if this is really a shared paradigm operating in different connective tissues. However, it must be noted that the developmental origin of pericytes varies from tissue to tissue (they are not a lineage, just as "MSCs" are not a lineage), and their biology is complex and not well understood to date (reviewed in Refs. 44–46). Nonetheless, it can be envisioned that as nascent blood vessels (which are pericyte-free) grow into a developing tissue composed of cells that are at early stages of commitment to a particular lineage, endothelial cells capture the local cells with certain cell surface characteristic to form pericytes, thereby giving the blood vessel stability.[47] As tissue and blood vessel development are completed, these hijacked cells remain quiescent until they are liberated from the blood vessel wall during tissue turnover, or due to injury, at which point they reveal their inherent differentiation capacity[20,43] (e.g., SSCs, Fig. 15.4). In support of the thought that pericytes are committed to a particular lineage, it can be noted that transcriptome analysis of "MSCs" isolated from different tissues do in fact display their inherent differentiation preference; for example, undifferentiated SSCs/BMSCs express low levels of osteogenic, chondrogenic, and adipogenic transcription factors and matrix proteins,[12] while muscle-derived cells express myogenic transcription factors.[43]

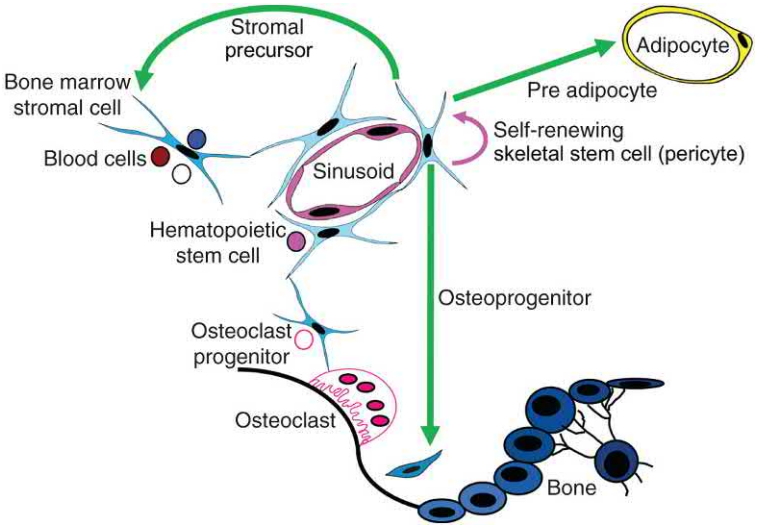

FIGURE 15.4 The role of SSCs/BMSCs in skeletal homeostasis (bone turnover and remodeling). By virtue of their role in hematopoiesis, SSCs/BMSCs support the formation of osteoclastic progenitors, and based on their expression of RANKL, they play a role in osteoclast formation. The pericytic SSC, residing on the abluminal side of marrow sinusoids is quiescent until activated by the need for bone turnover or extrinsic changes in the BM microenvironment, at which point, it is driven to an osteogenic, adipogenic, or stromal cell fate [*dark gray* (*green* in the web version) *arrows*].

3 PRACTICAL CONSIDERATIONS—PREPARATION AND ASSESSMENT OF SSCs/BMSCs

3.1 Isolation

Many different methods have been published for the isolation of SSCs/BMSCs, but generally two techniques are utilized: (1) BM aspiration or lavage of bone fragments containing marrow and direct plating, and (2) FACS sorting of freshly isolated BM using a combination of negative and positive markers (e.g., for human, $CD45^-/CD34^-/CD146^+$ cells, other sorting strategies have been used as well) (reviewed in Refs. 25,26) [Fig. 15.1A(i–ii)]. The volume of an aspirate should be small (~2–5 mL) with several repositionings of the aspiration needle in order to avoid dilution of the marrow with peripheral blood, which can have a negative impact on growth of SSCs/BMSCs.[48] When using human BM, isolation of BMSCs generally does not require the use of enzymatic digestion; however, enzymatic digestion has been found to be necessary for optimal isolation of murine BMSCs.[49,50]

3.2 Culture Conditions

Both murine and human BMSCs are extremely sensitive to culture conditions, and the quality of ex vivo–expanded cells depends on optimization of culture conditions. In particular, fetal bovine serum (FBS) must be lot-selected and used at a level of 20%.[24] Furthermore, it has been shown that heat-inactivation has a negative effect on BMSC growth.[51] In addition to the medium composition, atmospheric conditions also impact cell growth. It has been suggested that hypoxia (2% O_2) is more effective in maintaining stem cells within the SSC/BMSC population than atmospheric conditions (20% O_2).[52] While it is clear that low oxygen increases the rate of proliferation, preliminary results of in vivo transplantation indicated that cells grown in low oxygen do not seem to support hematopoiesis to the same extent as cells grown in atmospheric oxygen (Balakumaran and Robey, unpublished results). More in vivo testing is necessary. Furthermore, addition of certain growth factors can alter the potency of the SSC/BMSC population. For example, bFGF has been demonstrated to increase BMSC proliferation; however, upon in vivo transplantation, the cells made copious amounts of bone, but failed to support the formation of marrow, which is where the SSC resides.[12] This indicates that bFGF treatment does not support self-renewal of SSCs and directs them into an osteogenic fate[12] (or increases chondrogenesis[53]). It also should be noted that optimal ex vivo expansion conditions for murine BMSCs are very different compared with human BMSCs,[54] a fact that is often not recognized.

3.3 Characterization of the Biological Nature of SSCs/BMSCs

Characterization of the SSC/BMSC population after ex vivo expansion is a critical step not only for using them in in vitro experiments, but also for devising processes for their use in tissue engineering (TE) (as described later). Scaling up to generate the numbers of cells

needed for clinical applications do not always recapitulate what is done in the laboratory, or generate populations of cells with equivalent biological activities.

3.3.1 Cell Surface Markers

Cell sorting is essential to define the character of freshly isolated cells, but FACS does not yield sufficient numbers of cells for use in extensive ex vivo experiments, and for bone regeneration studies and clinical applications, so the cells must be expanded in culture. Although the cell surface markers used are not specific, assessment of the cell surface profile after cell expansion does provide some important information on the nature of the cell population. Due to the fact that cell surface markers can change in vitro, loss of certain markers that play important roles can be indicative of less than optimal culture conditions, and overexpansion and senescence. In addition to being negative for hematopoietic markers, they are also negative for endothelial markers [CD31 (PECAM-1), CD62E (E-Selectin)]. In humans, SSCs/BMSCs cells are generally positive for CD13 (aminopeptidase N), CD29 (β1 integrin subunit), CD44 (hyaluronan receptor), CD49α (α1 integrin subunit, VLA), CD63 (lysosomal membrane-associated glycoprotein 3, LAMP3), CD 73 (ecto-5′-nucleotidase), CD90 (Thy-1), CD105 (endoglin), and CD106 (VCAM-1, α4β1 integrin ligand) (reviewed in Ref. 55). Some of these markers are involved in cell–matrix interactions (CD29, CD44, CD49a), while others may be critically important in the biological function of SSCs/BMSCs, such as CD105 (endoglin), which is the regulatory subunit of the TGF-β receptor that modulates responses to TGF-β. Furthermore, based on the potential pericytic nature of SSCs/BMSCs, it is also important to assess the expression of CD106 (Vcam1, murine cells[50]) and CD146 in human cells,[12] which are suggested to regulate interactions with endothelial cells. Other pericyte markers of note are NG2, a cell surface chondroitin sulfate proteoglycan that is expressed by pericytes.[56]

3.3.2 Colony-Forming Efficiency

To date, the colony-forming efficiency (CFE) assay is the closest approximation of the number of SSCs present in freshly prepared single cell suspensions of BM (Fig. 15.1B). However, it must be kept in mind that while all SSCs are CFU-Fs, not all CFU-Fs are SSCs, based upon in vivo transplants of single colony-derived strains. Currently, simple plastic adherence is the most effective way to separate human SSCs/BMSCs from hematopoietic cells, although this is not the case with murine SSCs/BMSCs, which are heavily contaminated with macrophages. In this assay, single cell suspensions are plated at low density ($0.14–14.0 \times 10^3$ nucleated cells/cm^2 for BM aspirates, $0.007–3.5 \times 10^3$ nucleated cells/cm^2 core biopsies). The most accurate determination of CFE is obtained using bone fragments with marrow, based on variable dilution of BM aspirates with peripheral blood.[26,55] When this assay is performed using freshly sorted cells to eliminate hematopoietic cells (e.g., $CD45^-/CD34^-/CD146^+$ cells), clonal density is 1.63–163.0 cells/cm^2. Single CFU-Fs rapidly adhere (2–3 h), and within 24–48 h, begin proliferating to form colonies, demonstrating density-independent growth.[57] Interestingly, to date, sorting with different combinations of cell surface markers and applying appropriate calculations to account for removal of hematopoietic cells results in a similar CFE as that obtained by simple plastic adherence.[12] CFE for human SSCs/BMSCs ranges from 10 to 50 per 10^5 nucleated cells, and does not change dramatically with aging,[58] (Fig. 15.5B, left panel), although the number of population doublings is reduced in BMSCs from aged compared with young donors.[59,60] Substantial differences in CFE can signify either inadequate culture conditions, or a potential skeletal pathology[61] (Fig. 15.5B, middle and left panels). Secondary CFE can be interrogated after ex vivo expansion, but it must be noted that in the secondary assay, transiently amplifying cells (cells that are more committed or differentiated than SSCs, but still proliferative) are also enumerated. CFE may appear to increase, but that does not signify an increase in the number of SSCs without assessment of potency by in vivo transplantation. On the other hand, a significant decrease or loss of colonies would again signify an inefficient ex vivo expansion or pathology.

3.3.3 Demonstration of Bona Fide Stem Cell Characteristics

Differentiation assays are most often performed on BMSC populations as a whole, and as such, are useful in ensuring that SSCs within the population have not been lost during ex vivo expansion. However, clonal analysis and subsequent assays that rigorously demonstrate differentiation potential and self-renewal are essential to support the claims that SSCs reside within the population (Fig. 15.3A–C).

3.3.3.1 Differentiation Potential—In Vitro

Unfortunately, in vitro assays that are widely used to demonstrate osteogenic and adipogenic differentiation potential are highly prone to artifact, and have become (poor) substitutes for in vivo transplantation. Treatment of cells at high density with high levels of β-glycerolphosphate often induces dystrophic calcification formed by dying and dead cells rather than matrix mineralization,[63] yet both forms of mineralization stain positively with Alizarin Red S and von Kossa. In addition, treatment of cells with BMPs is not an appropriate assessment of inherent osteogenic capacity, due to the fact that BMPs will transiently convert virtually any fibroblastic cell into an osteoblast-like cell type as has long been known from the pioneering work of Marshall Urist.[64]

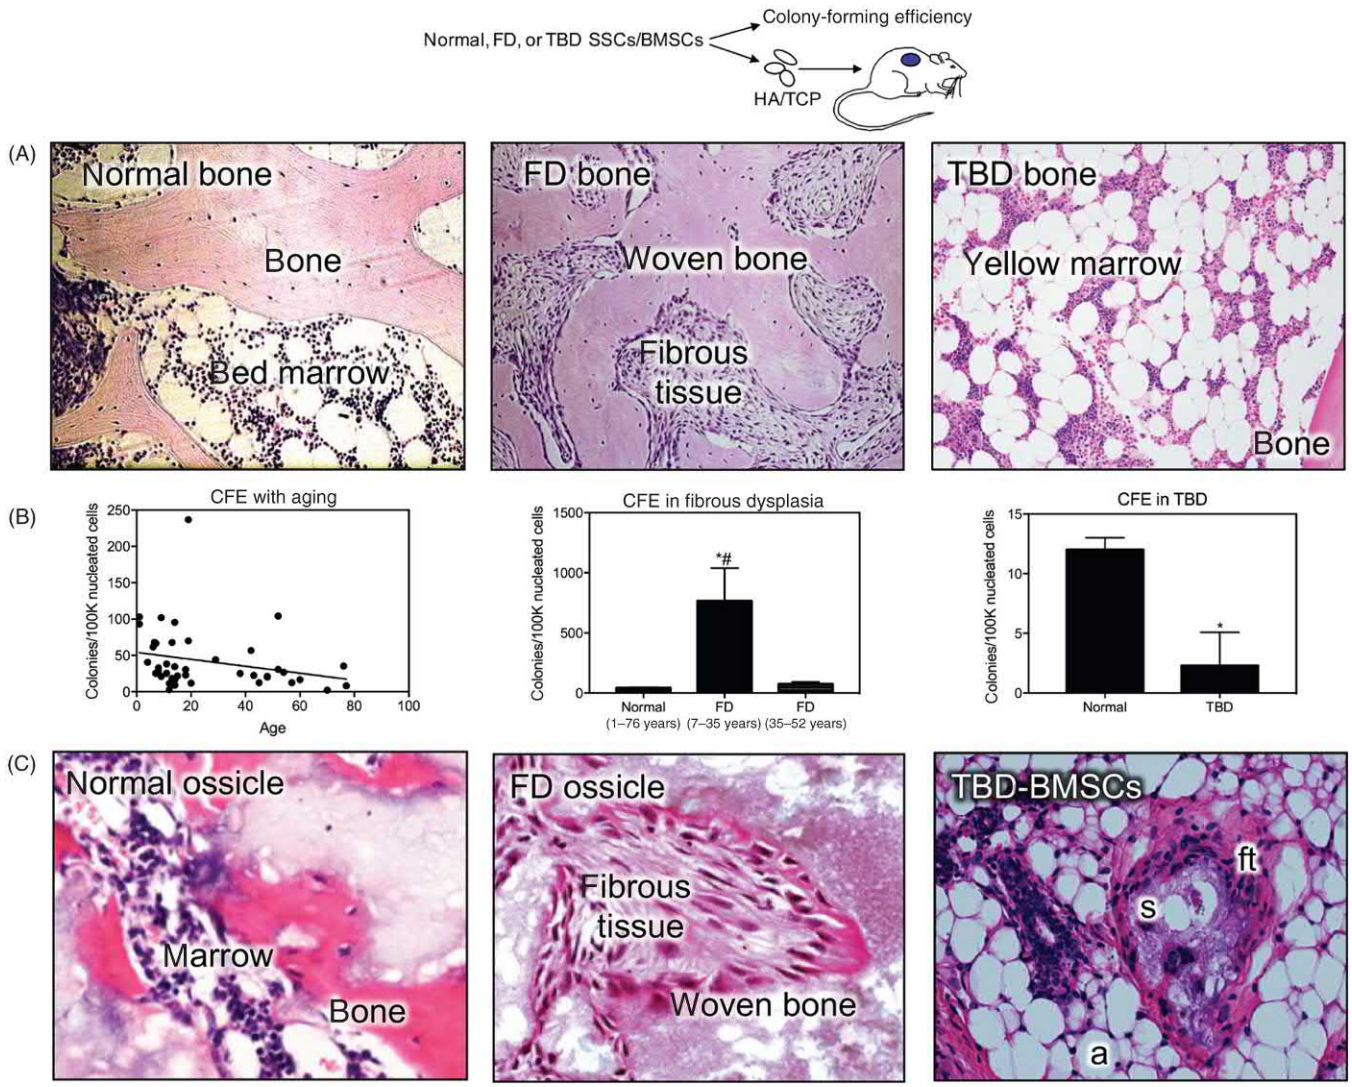

FIGURE 15.5 The role of SSCs/BMSCs in skeletal and hematological diseases. Normal and pathological specimens of BM are used to determine the CFE, the closest approximation of the number of SSCs currently available, and to create ectopic bone/marrow organs upon transplantation into immunocompromised mice. A. Compared to normal marrow (left panel), marrow from patients with the somatic mosaic disease, fibrous dysplasia of bone (FD), is characterized by poorly mineralized woven bone, and replacement of marrow with a fibrotic tissue devoid of hematopoiesis and marrow adipocytes (middle panel). In patients with a telomere biology disease (TBD), hematopoietic red marrow is replaced with yellow marrow (right panel). B. CFE of normal marrow is ~50 colonies/10^{-5} marrow nucleated cells. While there is a gradual decrease with aging, the change is not statistically significant (left panel). In FD, there is a marked increase in CFE in patients under the age of 35 years, but CFE normalizes with age ($P > 0.05$, * in comparison with normal CFE, # in comparison with CFE from patients over 35 years in age) (middle panel). CFE was dramatically decreased in patients with TBD ($P > 0.05$, * in comparison with normal CFE) (right panel). C. Transplantation of normal SSCs/BMSCs reformed a complete bone/marrow organ (left panel). FD SSCs/BMSCs from young patients recapitulated the formation of an FD lesion (middle panel), whereas cells from old patients formed a normal bone/marrow organ (data not shown, presented in Ref. 62). Taken together with the CFE data from young and old patients, it was surmised that the mutated SSCs did not self-renew, whereas the nonmutated SSCs were able to survive and reform a BM organ.[62] SSCs/BMSCs from patients with TBD established a transplant devoid of hematopoiesis, and filled with yellow marrow (right panel).

For adipogenic assays, cells sometimes accumulate lipids from serum rather than synthesize them de novo.[65]

Unlike for osteogenesis and adipogenesis, for chondrogenesis, the gold standard is the in vitro cell pellet culture, although cartilage is also formed in diffusion chambers along with bone (Fig. 15.1C). In the cartilage pellet, one can histologically analyze the tissue formed, and can see bona fide chondrocytes lying in lacuna, surrounded by matrix that stains purple with toluidine blue (metachromasia).[66] The metachromatic staining by toluidine is more specific than staining with alcian blue (which will also lightly stain osteoid), or staining with safranin O (which is also a nuclear stain in addition to a cartilage matrix stain). In many cases, faint staining of micromass cultures or pellet cultures with alcian blue or safranin O has not convincingly demonstrated chondrogenic

differentiation. Of note, chondrogenic differentiation of SSCs/BMSCs is not enduring. Pellet cultures undergo hypertrophy in vitro[67] and in vivo,[68] or remodel directly into a BM organ in vivo.[69] The fact that postnatal SSCs/BMSCs have chondrogenic potential may lie in the fact that before vascularization of hypertrophic cartilage in a developing bone rudiment, some "borderline" chondrocytes do not undergo apoptosis, and become osteoblastic cells.[70] These cells can just as easily be captured by invading blood vessels (like committed osteogenic cells) to form a pericyte, but with a distant memory of its previous life as a chondrocyte.

It is the overutilization and/or misinterpretation of these in vitro assays that has led to the flawed notion, that virtually any fibroblastic population ("MSCs" from nonskeletal tissues) has the inherent capability to form bone, fat, and cartilage. There are very few studies that have performed in vivo transplantation assays on cells derived from nonskeletal connective tissues (without treatment with BMPs or molecularly engineered) to show that mineralized matrix (rather than dystrophic calcification) is formed, with osteocytes, osteoblasts, hematopoiesis-supportive stroma, and marrow adipocytes of donor origin. Furthermore, mRNA expression of a few markers is often used as evidence for osteogenic, adipogenic, and chondrogenic phenotype. However, in most cases their level of expression is not compared to a positive control in order to show the magnitude of expression, and the pattern of expression often does not match the pattern exhibited by SSCs/BMSCs during differentiation. Consequently, expression of markers is not sufficient in the absence of showing differentiation into a functional tissue (reviewed in Refs. 26,71).

3.3.3.2 Differentiation Potential—In Vivo

Based on in vivo transplantation with an appropriate scaffold,[24] there is substantial evidence by using single colony-derived strains that a subset of cells within the BMSC population are multipotent (Fig. 15.1B–C). In this regard, the choice of a scaffold for in vivo analyses must be carefully evaluated. Generally speaking, murine BMSCs are able to recreate a bone/marrow organ in both collagen sponges and high-quality ceramic particles, whereas human BMSCs show a strong preference for ceramics. Of note, most commercially available ceramics are sold as "bone fillers" and are not necessarily osteoconductive.[25] In vivo transplantation assays have shown that some of them support a limited amount of bone formation, but do not support the formation of a hematopoietic marrow, and some do not even support bone formation (Kuznetsov and Robey, unpublished results). Using optimized culture conditions and scaffolds, ~10%–20% of the single cell-derived strains were found to recreate a bone/marrow organ.[8,72–74] This highlights the fact that SSCs are a fraction of the population, and that not all BMSCs are multipotent. Thus, one does not establish a culture of stem cells, as is often stated in the literature; one establishes a culture in which a subset of cells is comprised of stem cells. That is not to say that BMSC populations as a whole are less useful than single colony-derived strains, it is only to say that it is necessary to document the existence of multipotent (or unipotent) stem cells within the population via clonal analysis and appropriate differentiation assays, which primarily rely on in vivo transplantation, although in some cases, in vitro assays are required (cartilage pellet culture).

3.3.3.3 Self-Renewal

The ability to proliferate extensively, in vitro has often been used as evidence of self-renewal. However, extensive proliferation does not indicate that the ex vivo–expanded SSCs/BMSCs (or any other "MSC" population) have maintained: (1) their differentiation capacity or (2) their ability to self-renew (maintained a subset of SSCs). Assays of SSC self-renewal are challenging due to the solid, rather than fluid, nature of bone, and its marrow. The serial repopulation assay of the hematopoietic system is the most rigorous assay of self-renewal available, which serves as a model for developing assays of self-renewal in other tissues. Based on this model, it was reported that SSCs do indeed self-renew.[12] In this study, prospectively isolated human $CD146^+$ cells were used to generate clones that were then transplanted in vivo. Human $CD146^+$ cells were again identified on the surface of sinusoids, and human cells were isolated after enzymatic release from the transplants and found to be $CD146^+$. When plated at clonal density, individual clones were isolated and again found to be $CD146^+$. This study clearly demonstrated that the progeny of a single CFU-F with the same cell surface phenotype as the original explanted cell could be retrieved from the transplant, indicative of self-renewal[12] (Fig. 15.3).

4 THE ROLE OF SSCs/BMSCs IN POSTNATAL BONE TURNOVER

Bone turnover is initiated in response to release of parathyroid hormone (PTH) from the parathyroid gland when the calcium-sensing receptor senses a decrease in serum calcium, and when there is a need to replace bone that has become microdamaged. Formation of osteoclasts from monocyte precursors bearing RANK occurs in the vicinity of the bone surface that is destined to be remodeled. The formation of osteoclast precursors in the monocyte/macrophage series (Fig. 15.4), as well as T cells that impact on osteoclast formation,[75] are supported by SSCs/BMSCs by providing a "bed" [στρώμα (Greek)—*strṓma*] upon which they are formed. SSCs/BMSCs express a long list of hematopoiesis-associated

cytokines and growth factors [Gene Ontology categories (GEO GSE64789) "hematological system development and function" and "hematopoiesis" are highly over-represented in multipotent SSC/BMSC clonal lines[74]]. SSCs/BMSCs also express high levels of M-CSF and RANKL, both of which are essential for osteoclast formation, and osteoprotegerin (OPG), which serves as a decoy receptor for RANKL preventing osteoclast formation. Osteoclast formation and bone resorption is dependent on the balance of RANKL and OPG expressed by BMSCs and more mature osteoblastic cells, and BMSCs have long been thought to play a major role in osteoclast formation.[76] Recently, based on mouse models with conditional or cell/tissue-specific deletion of RANKL, it has been proposed that osteocytes also control osteoclast formation based on their expression of RANKL. However, it appears that the RANKL$^+$ cell type that controls osteoclastogenesis may be site specific. For example, mice with RANKL deletion in mature osteoblasts and osteocytes using a DMP1-Cre driver maintain tooth eruption, which requires bone resorption to occur, whereas the long bones exhibit an osteopetrotic-like phenotype (reviewed in Refs. 77,78). Further studies are needed to determine the contribution of SSCs/BMSCs, more mature osteoblastic cells and osteocytes to initiating osteoclast formation throughout the skeleton.

Subsequent to the formation of osteoclasts and dissolution of mineralized matrix, a plethora of growth factors, buried within bone due to their affinity for carbonate-rich apatite, are liberated, including BMPs, PDGF, IGF-I and IGF-II, and TGFβs. Consequently, PTH, the released factors, as well as those synthesized by local cells (Wnt10b by CD8$^+$ cells, FGF and VEGF by BMSCs), mediate the reversal stage, which is marked by a cessation in bone resorption and creation of a microenvironment conducive for bone formation, thereby coupling bone resorption with bone formation (reviewed in Refs. 78,79). It is currently thought that through osteoclastic action, active TGFβ is released and establishes a gradient between the resorption sites through the marrow to the pericytes located on a nearby blood vessel. This gradient has two effects. Due to the high concentration of TGFβ at the site of resorption, it inhibits migration of osteoclastic precursors into the area; however, the gradient initiates migration of SSCs/BMSCs into the area in need of restoration (Fig. 15.4), but does not induce differentiation.[80] Upon arrival in the resorption bay, BMSCs are induced to osteogenic differentiation by the interplay of the TGFβ/BMP, Wnt, and IGF-I signaling pathways. Interestingly, PTH, in addition to initiating bone resorption, also plays a role in bone formation. PTH bound to its receptor, PTHR1, complexes with Lrp6 (Wnt coreceptor), which leads to the stabilization of β-catenin and pSmad1 signaling, along with stimulating cAMP-mediated signaling. The PTH–PTHR1 complex can also bind to the TGFβRII receptor, leading to pSmad2/3 signaling (reviewed in Ref. 79). IGF-1 signaling activates mTOR via the PI3K-Akt pathway and induces osteogenic differentiation of BMSCs. Alterations in any of these pathways due to mutation, or alterations in levels of expression due to changes in the microenvironment, can have significant consequences on the balance of bone resorption and formation necessary for skeletal homeostasis (reviewed in Refs. 78,79).

5 THE ROLE OF SSCs/BMSCs IN DISEASE

SSCs/BMSCs are central mediators of skeletal homeostasis not only because of their role in bone formation, but also in control of bone resorption due to their expression of RANKL, which controls the formation of osteoclasts through interactions with RANK on osteoclastic precursors. Thus, it was hypothesized that any intrinsic change (mutation) would result in a skeletal disease or disorder. Proof of principle of this concept came from studies of fibrous dysplasia of bone (FD) and the McCune–Albright syndrome (MAS). FD/MAS is a somatic-mosaic disease caused by activating missense mutations of *GNAS*, which encodes for Gsα, leading to overproduction of cAMP. The impact of this mutation on the activity of the SSC/BMSC population (which express Gsα) is profound, leading to the formation of osteomalacic woven bone and replacement of marrow with a fibrotic stroma[81–83] (Fig. 15.5A, middle panel). Although CFE appeared to increase in this disease (Fig. 15.5B, middle panel), the mutated cells were found to be transiently amplifying BMSCs, and were devoid of SSCs.[62] When the cells were transplanted in vivo into immunocompromised mice, they recapitulated the formation of an abnormal bone and fibrotic tissue (devoid of marrow), completely reminiscent of native FD lesions[84] (Fig. 15.5C, middle panel). These studies demonstrated that independent activation of Gsα leads to extensive proliferation of SSCs/BMSCs (transiently amplifying cells), some of which differentiate into misfunctioning osteoblasts that are not able to mineralize osteoid due to their overproduction of the phosphate-regulating hormone, FGF23.[85] Furthermore, it was shown that the mutation prevented self-renewal of SSCs based on the disappearance of mutated SSCs from FD lesions as a function of aging.[62]

Based on their known ability to support hematopoiesis, and the presence of the SSC in the hematopoietic stem cell niche,[86] it was hypothesized that SSCs/BMSCs may also play a role in hematological disorders. One study utilized SSCs/BMSCs from patients with an inherited form of aplastic anemia (Fig. 15.5A, right panel) caused by mutations in genes controlling telomere length [telomere biology disorders (TBD)], such as *TERT*, *TERC*, and a number of other genes (reviewed in

Ref. 87). Dyskeratosis congenital is an example of a TBD characterized by oral leukoplakia, nail dystrophy, abnormal skin pigmentation, high rates of BM failure, growth retardation, and osteopenia. It was determined by performing the CFE assay that the number of SSCs from patients with a TBD was dramatically reduced compared to normal controls (Fig. 15.5B, right panel), and that upon in vivo transplantation into immunocompromised mice, they failed to form bone, but instead formed extensive areas of yellow marrow, devoid of hematopoiesis (Fig. 15.5C, right panel), a replica of misfunctioning marrow in these patients.[88] While it is also known that hematopoietic stem cells are abnormal in TBD, this study suggests that SSCs/BMSCs are a potential therapeutic target for certain types of hematological diseases and disorders.

These two studies provide examples of the power of in vivo transplantation of mutated human SSCs/BMSCs into immunocompromised mice; that is, the ability to make a piece of abnormal human bone and marrow in a small animal model. This model is amenable to the development of new therapies for treatment of skeletal diseases, either by treatment with factors or small molecules to reverse the effects of the mutation, or by the development of gene correction methodologies either in vitro for generation of corrected cells that could be used in TE, or even of gene correction in vivo,[89] based on rapidly evolving gene editing methods, such as CRISPR/Cas9.[90]

Along the same vein, iPSCs derived from patients with genetic skeletal diseases, driven to osteogenic differentiation, could also be used in the in vivo transplantation model to study pathogenetic mechanisms and potential treatments. In this regard, there are two possible approaches: one would be in which iPSCs are derived from $CD34^+$ peripheral blood cells of patients with inherited forms of skeletal disease,[91] and then gene edited; or that a specific mutation be created by gene editing in normal iPSCs. The point of these two approaches is that the normal and the mutated lines would be isogeneic, and free of the potential confounding variable of genetic background. This feature may also allow for the determination of the contribution of a specific gene in polygenic diseases, characterized by the contribution of independent genes on generation of the phenotype. While a number of studies have been published showing osteogenic differentiation by in vivo transplantation, most are not robust, and more work is needed.[92] In addition, to date, none of the studies have shown that the osteogenic cells derived from iPSCs are able to support the formation of marrow, but this is not surprising based on the fact that bone comes before BM stroma during development. It may be that one would have to "educate" osteogenically differentiated IPSCs by coculture with endothelial cells to form an SSC/BMSC-like phenotype.

6 REGULATION OF SSC/BMSC FATE

As described previously, embryonic mesenchyme, which contains the most primitive SSC, forms cartilage, bone, bone marrow stroma, and marrow adipocytes in a sequential fashion in time and space (Fig. 15.2). Thus, during fetal development, chondrocytes, osteoblasts, SSCs/BMSCs, and marrow adipocytes can be seen as different stages of maturation rather than separate lineages.[15] In postnatal life, SSCs are quiescent due to their association with blood vessels until liberated by the need for bone turnover (Fig. 15.4). During fetal and postnatal life, chondrogenesis, osteogenesis, adipogenesis are controlled by three master transcription factors: Sox 9 (chondrogenic),[93] Runx2 (osteogenic and chondrogenic, but to a lesser extent),[94] and PPARγ2 (adipogenic) (reviewed in Ref. 95). While postnatal SSCs/BMSCs do form cartilage in vitro, it is extremely rare that they form cartilage in vivo (except in pathological conditions), or following injury. Fracture repair is mediated primarily by periosteal cells that are similar to, but not identical with SSCs/BMSCs[43] (reviewed in Ref. 96). For this reason, a chondrogenic cell fate of postnatal SSCs/BMSCs will not be discussed later.

Upon liberation from blood vessel walls, SSCs have the possibility to form osteogenic cells, adipogenic cells or to form more hematopoiesis-supportive stroma (Fig. 15.4). The balance between osteogenic and adipogenic differentiation has received a large amount of attention due to its relevance to bone fragility and osteoporosis.[97–101] On the other hand, there is little information on how the SSC is directed into becoming a hematopoiesis-supporting stromal cell that is not a stem/progenitor cell. There are clear examples of the expansion of the hematopoiesis, which relies on the presence of stroma, such as in hemolytic diseases where bone is lost to accommodate increased blood formation. However, it has rarely been determined if the increase in hematopoiesis-supportive BMSCs is matched by an increase in SSCs.

Regulation of cell fate is complex, and is controlled by many factors, including hormones, cytokines, growth factors, and their downstream signaling pathways, all of which impact on the epigenetic pattern of the genome and subsequent transcriptional activity. Further control arises from posttranscriptional modifications (splice variants and isoforms), translational variation (small noncoding RNAs), and posttranslational modifications (reviewed in Ref. 99). Mechanical forces, cell–matrix and cell–cell interactions also are influential. Lastly, there are a number of iatrogenic (illness caused by medical examination or treatment) and distantly related causes of fate switching. What follows in subsequent sections is a brief summary (while most certainly not complete, appropriate articles, and reviews are cited). However, it must be noted that in sorting through the information that is available concerning

regulation of fate choices, there is much confusion based on the fact that it is considered by many that adipocytes from white or brown fat are equivalent to those in marrow, but they are not. Furthermore, it is assumed that factors that induce osteogenic differentiation of SSCs/BMSCs will induce osteogenic differentiation of adipose-derived "MSCs," and they are not, primarily because adipose-derived "MSCs" are not inherently osteogenic.

6.1 Hormonal Regulation

SSCs/BMSCs express receptors for many of the hormones that control skeletal growth and homeostasis, such as the PTH receptor, vitamin D receptor, glucocorticoid receptors, sex hormone receptors, thyroid hormone receptor, and so on. If and how the corresponding ligands of these receptors control SSC/BMSC cell fate has not been closely examined in many cases. However, there are a few instances in which hormonal control or changes in their downstream signaling pathways (briefly described later) do impact on the fate of SSCs/BMSCs. For example, in hyperparathyroidism, it is thought that the ensuing endosteal fibrosis is due to the enhanced proliferation of stromal progenitor cells that accumulate and partially differentiate into osteoblastic cells.[102] Along this same line, excess PTH signaling due to a constitutively activating mutation in the PTH/PTHrP receptor (H223R), expressed specifically in mature osteoblasts in mice, led to the formation of excessive medullary bone due to the proliferation and maturation of SSCs/BMSCs, at the expense of marrow stromal cells and adipocytes.[103] Interestingly, this phenotype resolved with age with the removal of excess bone and establishment of a marrow cavity composed of stromal cells that were not SSCs based on in vivo transplantation assays. On the other side of the coin, it has long been known that estrogen deficiency leads to expansion of adipocytes at the expense of hematopoiesis-supportive stroma (and bone), especially in females,[104] which is thought to reflect a commitment of SSCs/BMSCs to adipogenesis.[105] However, it is also possible that direct conversion of stromal cells into adipocytes contributes to this phenomenon. Likewise, glucocorticoid treatment in vivo leads to conversion of red marrow to yellow marrow, again thought to be due to a switch in fate of SSCs/BMSCs.[106] Paradoxically, a glucocorticoid, dexamethasone, is commonly used in medium used to osteogenically differentiate SSCs/BMSCs,[26] implying that other factors are at play in vivo that drive glucocorticoid-mediated adipogenic differentiation of SSCs/BMSCs.

6.2 Signaling Pathways and Transcription Factors

The levels of expression of Runx2, the master regulator of osteogenesis, and PPARγ, the master regulator of adipogenesis, are controlled by a number of signaling pathways activated by Wnts, members of the TGFβ/BMP superfamily, Notch, Hedgehogs, FGFs (and others), with extensive crosstalk between these pathways (reviewed in Refs. 99,107–109). Generally speaking these pathways increase Runx2 expression with a concomitant decrease in PPARγ, or vice versa, during commitment and differentiation of SSCs/BMSCs. Runx2 is the first upregulated gene during osteogenic commitment, and in turn, upregulates Osterix, which along with Runx2, is essential for osteogenesis. Adipogenesis is initiated by upregulation of C/EBPβ and δ, which in turn induces PPARγ2. PPARγ2 upregulates C/EBPα, which maintains PPARγ2 expression via a positive feedback loop (reviewed in Ref. 107).

Perhaps one of the most important signaling pathways that promotes osteogenesis of SSCs/BMSCs at the expense of adipogenesis is the Wnt/β−catenin pathway, which stimulates Runx2 expression, and inhibits C/EBPα, thereby inhibiting adipogenesis[110,111] (reviewed in Ref. 107). Members of the TGFβ superfamily also exert major influences mediated by pSmads 2/3, and have multiple effects on differentiation of SSCs/BMSCs. While TGFβs stimulate proliferation, they inhibit osteogenic differentiation[112] and adipogenic differentiation.[113] Additionally, BMPs play a major role in osteogenic commitment via pSmads 1/5/8 and Msx/Dlx homeoproteins to increase expression of Runx2 (reviewed in Ref. 107). However, BMPs also appear to play a role in early adipogenic commitment, although the mechanisms are not clear. Adipogenic differentiation may be related to the type of BMP and its concentration, and/or the type of receptors that are present on the cells at different stages of commitment (reviewed in Refs. 99,108). It is generally reported that Notch signaling mediated by Delta/Jagged suppresses osteogenic differentiation,[114] and maintains SSCs/BMSCs in a primordial state,[115,116] however, positive effects on osteoblastogenesis have been reported (reviewed in Refs. 108,109). Notch signaling also appears to have negative and positive effects during adipogenic commitment and differentiation (reviewed in Ref. 95). Indian hedgehog signaling, mediated by the Kinesin family protein, Kif7, and the main intracellular Hedgehog pathway regulator, SUFU, is typically thought of in the context of growth plate dynamics, where it promotes osteogenic differentiation.[117] However, in the context of the BM microenvironment, Hedgehog signaling decreases with adipogenic differentiation of SSCs/BMSCs, suggesting that it is a negative regulator of adipogenesis.[118] Hedgehogs may also interact with BMP signaling to promote osteogenic commitment (reviewed in Ref. 99). FGFs can also be osteogenic (FGF2, FGF4, FGF3, FGF9, and FGF19) and adipogenic (FGF1, FGF2, and FGF10), and signal via a number of pathways that include ERK1/2, p38 MAPK, JNK, PKC, and PI3K[119,120] (reviewed in Ref. 99).

As briefly listed previously, these are the major players that have implicated in controlling the fate of SSCs/BMSCs, but there are other pathways initiated by factors, such as IGF-1 and PDGF (liberated from bone matrix during bone resorption), EGF, and the transcription factor, YAZ (reviewed in Refs. 99,107–109). There are likely to be more regulators identified in the future.

6.3 Epigenetic Controls

It is currently thought that epigenetic changes induced by signaling pathways operating in SSCs/BMSCs play a major role in fate decisions and stabilization of the osteogenic or adipogenic phenotype.[97] Modification of the conformation of chromatin (defined as DNA with bound protein) impacts on transcription, with open chromatin (euchromatin) being accessible, and condensed chromatin (heterochromatin) being inaccessible to transcriptional machinery, transcription factors, and other cofactors. Changes in chromatin architecture are brought about by DNA and histone modification, reviewed very succinctly in the following website: http://www.sabiosciences.com/pathwaymagazine/pathways8/epigenetic-modifications-regulate-gene-expression.php.

DNA methylation at CpG dinucleotides and CpG islands by methyltransferases (DNMTs), are usually suppressive in nature. It has been reported that "MSCs" from different tissues have similar DNA methylation patterns,[98] but this is most likely due, in part, to the fact they share fibroblastic and/or pericytic features, and expression of common extracellular matrix proteins. More recently, it has been determined that "MSCs" from different tissues, including SSCs/BMSCs, can be distinguished from each based on an "Epi-Tissue Score" at two CpG sites.[121]

In addition to DNA methylation, chromatin structure is also influenced by modifications made to histones bound to DNA, such as methylation and acetylation (and there are others) that occur posttranslationally. Histones 3 and 4 are commonly methylated at specific sites by histone methyltransferases (HMTs). H3K4me3 is usually associated with euchromatin and gene activation, whereas H3K9me3 and H3K27me3 are usually associated with heterochromatin and gene repression. These methyl groups can be removed by histone demethylases (HDMs), and the changes in methylation are very dynamic, promoting flexibility. As an example, it has been demonstrated that formation of H3K27me3 by the HMT, EZH2, promotes adipogenesis of SSCs/BMSCs, whereas its removal by the HDM, KDM6A, promotes osteogenesis.[122] Histone acetylation by histone acetyltransferases (HATs) and deacetylation by deacetylases (HDACs) is also dynamic. H3K9ac and HRK16ac are generally found in euchromatin and are indicative of transcriptional activation, whereas deacetylation leads to gene inactivation. While use of the HDAC inhibitor, trichostatin A, was thought to improve osteogenic differentiation of SSCs/BMSCs, it was determined that it profoundly decreased cell proliferation, and did not improve their osteogenic capacity upon in vivo transplantation.[123] Further work is needed to demonstrate what role histone acetylation and deacetylation plays in SSC/BMSC cell fate.

6.4 MicroRNAs

There are three forms of small noncoding RNAs: shorthairpin RNAs (shRNAs), microRNAs (miRs), and piwi RNAs. shRNAs are generally synthetic, and introduced exogenously (or created by processing of foreign dsRNAs), and piwi RNAs are primarily expressed in germline cells (reviewed in Refs. 124,125), consequently, the role of miRs in controlling cell fate will be briefly summarized. miRs represent a way in which protein expression can be rapidly modified by either blocking translation or inducing the degradation of target mRNAs (reviewed recently in Ref. 126). Interestingly, regulators of skeletal homeostasis, such as BMPs and TGFβs are known regulators of miR expression and processing (reviewed in Ref. 127). Numerous studies have been published indicating that miRs can control cell fate by downregulating the protein level of Runx2 or PPARγ, thereby enhancing adipogenesis or osteogenesis, respectively. Members of the miR-320 family were found to increase during adipogenic differentiation of SSCs/BMSCs by decreasing levels of Runx2 (among other genes).[128] Conversely, mir-20a promotes osteogenesis by targeting PPARγ, as well as inhibitors of the BMP signaling pathway.[129] In addition, mir26a was found to decrease in SSCs/BMSCs during rapid bone loss in mice induced by ovariectomy. Overexpression of mir26a was found to increase osteogenesis by SSCs/BMSCs by reducing levels of Tob1, which is a negative regulator of the BMP/Smad signaling pathway.[130] These are just few examples, and others can be found in a recent review.[131]

6.5 Cell–Cell and Cell–Substrate Interactions, Cell Shape, and Mechanical Forces

SSCs/BMSCs are not alone in the bone/marrow organ, and interaction with other cell types undoubtedly influences fate. As already described previously, interaction with endothelial cells keeps them in a primordial state, and a study has shown that this is due to repression of Osterix.[132] They also interact with hematopoietic stem cells; however, how HSCs and other hematopoietic cells influence SSC fate is not well known at this time, owing to the rather recent recognition by hematologists that SSCs are members of the HSC niche (reviewed in Ref. 133).

Cell–matrix interactions occur primarily through: (1) integrins (which bind to many of the extracellular matrix components of bone), (2) discoidin domain receptors (DDRs) and urokinase plasminogen activator receptors (uPARAP), which bind to collagens, and (3) other cell surface molecules, such as CD44, which binds to Osteopontin (a major component of bone matrix), and hyaluronan. Of note, BM is characterized by a preponderance of cell–cell interactions rather than cell–matrix interactions. Marrow contains thin reticular fibers composed primarily of type III collagen, and high levels of hyaluronan, which is gel-like in nature (reviewed in Ref. 134). However, there is no doubt that, after isolation from marrow, substrate has a profound influence on cell fate. For example, binding of αvβ1 to Osteopontin inhibited adipogenic differentiation and stimulated osteogenic differentiation of murine SSCs/BMSCs, via downregulation of C/EBP expression.[135] Modulation of cell shape also impacts on fate. In a study where cell shape was controlled by plating at different densities, it was found that if cells were plated at low density and allowed to spread, the cells were directed toward osteogenesis, whereas plating at high densities, such that the cells remained rounded, induced adipogenesis. These phenomena were found to be mediated by the small GTPase, RhoA, which is a regulator of the cytoskeleton.[136] Currently there are a number of different methods by which substrates can be patterned, not only in shape, but in their surface character.[137] Patterns that promoted cytoskeletal contraction via JNK and ERK1/2 activity induced osteogenic differentiation, whereas when cytoskeletal contraction was not supported by a particular pattern, adipogenesis predominated.[138] Substrate elasticity and stiffness, and the resulting mechanical forces sensed by SSCs/BMSCs control fate as well, with stiffer substrates generally favoring osteogenesis, and softer substrates favoring adipogenesis. How substrate interactions control cell fate is extensively reviewed in Ref. 139. However, again the reader is cautioned that many of these studies purport differentiation of SSCs/BMSCs into nonskeletal phenotypes based on morphology and expression of a few markers, without demonstration of functionality. Lastly, matrix remodeling has a profound effect on the fate of SSCs/BMSCs. A dramatic example is found in the global deletion of the membrane type matrix metalloproteinase, MT1-MMP (which is a true collagenase), in mice. Although mice appear normal at birth, there is a rapid decrease in growth and by 40 days they exhibit severe dwarfism and multiple skeletal defects. Transplantation of SSCs/BMSCs from the mutant mice revealed an almost complete inability to reform a bone/marrow organ, indicating that MT1-MMP activity is essential for SSC self-renewal.[140] This mouse model is a direct phenocopy of the human vanishing bone disease, Winchester syndrome, now known to be caused by an inactivating mutation in MT1-MMP.[141]

6.6 Iatrogenic Effects

In addition to all the aforementioned, iatrogenic effects (i.e., caused by medication or other forms of therapy) and seemingly unrelated diseases can impact on SSC/BMSC fate. Chemotherapy and radiation therapy are well known to induce marrow adiposity (reviewed in Ref. 105). In addition, there is a conversion of red marrow to yellow marrow in extreme cases of starvation, as in anorexia nervosa.[142] Of interest, there is a striking conversion of yellow marrow to red marrow in many patients with congestive heart failure.[143]

7 SSCs/BMSCs IN TISSUE ENGINEERING AND REGENERATIVE MEDICINE

7.1 Regeneration of the Bone/Marrow Organ

Generation of sufficient numbers of SSCs/BMSCs to reconstruct a critical size bone defect that will never heal on its own is an area of intense research (Fig. 15.6A), along with development of optimal scaffolds and surgical approaches. As aforementioned, it has been shown that the SSCs reside in marrow on the abluminal side of marrow sinusoids.[12] Consequently, if a population of BMSCs is found to form only bone upon in vivo transplantation, it is indicative of the fact that the SSCs within the population have been lost. Thus, the presence of marrow in in vivo transplants of BMSCs is a surrogate marker of presence of the SSCs, and of the ability of that bone/marrow organ to undergo bone turnover and remodeling.

However, one may ask why is it necessary to maintain SSCs in the BMSC population; would more committed osteogenic cells not suffice? The answer most likely is that sometimes they would and sometimes they would not, depending on the rate of bone turnover. In areas of the skeleton that turnover very slowly and are not weight bearing (e.g., the skull vault), the use of more mature populations of cells may be sufficient. In addition, regeneration of bone with mature osteogenic cells that have lost the ability to self-renew may be efficacious in older recipients in nonweight-bearing bones. However, in cases where higher levels of bone formation and remodeling are required (e.g., in weight-bearing bones), SSCs are a necessary ingredient in any type of construct for long-term efficacy. In younger recipients, the ability to turn over throughout life is essential to maintain bone strength, and the engineered tissue construct must contain a stem/progenitor cell.

In protocols for bone regeneration, there are additional considerations: (1) autologous (self) versus allogeneic (nonself); and (2) embryonic origin of the bone. It is thought that SSCs/BMSCs are immune privileged; that is, that they can escape rejection when used in an allogeneic setting. This may be the case when allogeneic

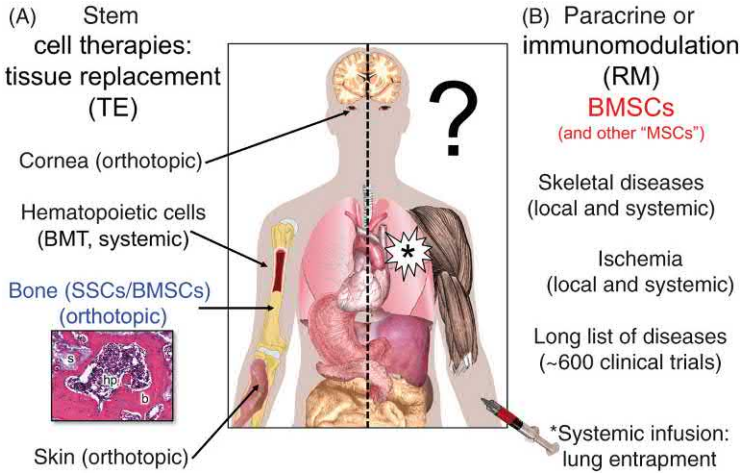

FIGURE 15.6 The role of SSCs/BMSCs in tissue engineering (TE) and regenerative medicine (RM). A. There are a very limited number of cases in which tissue-specific stem/progenitor cells themselves have been successfully used to regenerate a tissue (limbal stem cells to regenerate cornea, hematopoietic stem cells in BM transplantation, and epidermal stem cells for skin regeneration. SSCs/BMSCs have been demonstrated to regenerate functional bone in small number of case reports,[144] and efforts are continuing to the development of direct orthotopic procedures with appropriate scaffolds. B. On the other hand, there is a great deal of effort to use SSCs/BMSCs (and other types of "mesenchymal stem/stromal cells") for generalized skeletal diseases and a long list of other diseases and disorders by systemic infusion or direct injection without a carrier (over 600 clinical trials, see clinicaltrials.gov). This is based on their putative paracrine and immunomodulatory effects, whereby they encourage local stem/progenitor cells to begin the repair process. However, these cells are rapidly trapped in the lungs and disappear, and it is not clear what the mechanism of actions is for these types of treatments.

or xenogeneic BMSCs are introduced into developing embryos prior to establishment of the immune system.[145] However, there are studies that show that allogeneic and xenogeneic BMSCs are indeed rejected when infused systemically into immune-competent recipients.[146] They are even more likely to be rejected when they are induced to differentiate, based on their expression of histocompatibility antigens. Consequently, for bone TE, cells will most likely have to be autologous in order to avoid the need for immunosuppression of the recipient. In addition, the source of SSCs/BMSCs may need to be considered. As aforementioned, bones in the facial region of the skull derive from neuroectoderm, while those in the axial and appendicular skeleton derive from mesoderm (reviewed in Ref. 16). There are studies indicating that cells from these two different embryonic sources are not identical.[147] Oral surgeons have long noted that transplantation of iliac crest (mesodermally derived) into the jawbones (neuroectodermally derived) is not enduring,[148] suggesting some sort of incompatibility. Far less is known about differences between bone formed by paraxial mesoderm (axial skeleton) and by somatic lateral plate mesoderm (appendicular skeleton), and it is not clear if this impacts on their use in sites outside of their developmental origin.

7.2 SSCs/BMSCs in Another Form of Regenerative Medicine

While not directly related to the topic of this book, it cannot be ignored that SSCs/BMSCs are being used in a different form of regenerative medicine (RM) that does not utilize SSCs/BMSCs in conjunction with appropriate scaffolds to reform bone (TE). BMSCs (as well as other types of "MSCs") are being used in a large number of clinical trials around the world (see clinicaltrials.gov) for treatment of a variety of skeletal and nonskeletal diseases and disorders (Fig. 15.6B) caused by systemic infusion or direct injection. What has become apparent in preclinical animal studies is that upon systemic infusion, these cells are rapidly cleared from the circulation by entrapment in the lungs. Even upon direct orthotopic injection (without a scaffold), the cells do not readily engraft and rapidly disappear. Nonetheless, animal studies suggest that there may be a beneficial effect for treatment of skeletal diseases and disorders, perhaps due to the production of cytokines and growth factors secreted by the donor cells that encourage local stem/progenitor cells to begin a repair process (albeit at a distance when the cells are trapped in the lungs); the so-called paracrine, immunomodulatory, and immunosuppression effects.[19,149,150] It is also thought that locally administered cells may stabilize blood vessels (again, going back to their pericytic nature). Whatever the potential mechanisms of action are, it is clear that this is a form of RM that is not stem cell based. Rather, it relies on the activity of the BMSC population as a whole, not on the subset of SSCs within it, which is relatively rare. Furthermore, it may be that all cells of fibroblastic habit (MSCs) have similar effects,[151] although their effects may be a variation on a theme based on their tissue source. To date, it is not

clear whether this type of cell-based therapy will prove to be efficacious.

8 CONCLUSIONS

The bone/marrow organ is a complex system that includes not only hard tissue proper, but also a population of bona fide SSCs and more committed BMSC progenitor cells. These cells are quite unique in their ability to not only form the specialized mineralized matrix of bone, but also in their support of hematopoiesis, a property that is not found anywhere else in the normal postnatal organism. These cells are not like other types of "MSCs" based on these exclusive properties. Likewise, nonskeletal "MSCs" are not like SSCs/BMSCs, and for these reasons, the terminology should be abandoned in favor of names of cells that reflect their tissue of origin, and their status as a stem or progenitor cells, based on rigorous assays.

SSCs/BMSCs arise from different specifications of neural crest and mesoderm, and during development, they are formed by the incorporation of osteogenically committed cells into blood vessel walls as pericytes. SSCs/BMSCs remain quiescent until stimulated by factors signaling for a bone turnover event, in which SSCs/BMSCs control, at least in part, the formation and activity of osteoclasts, and replace resorbed bone. SSCs/BMSCs also respond to changes in the microenvironment, and can adopt an osteogenic, adipogenic, or stromal cell fate. SSC/BMSC cell fate is controlled by many extrinsic factors (hormones, growth factors, cytokines), mediated by a multitude of signaling pathways, but also intrinsic factors (mutations, epigenetics) that alter the biological activity of SSCs/BMSCs. Taken together, one could consider SSCs/BMSCs to be the "units" of skeletal diseases, akin to Koch's postulates to identify the causative agent of a particular disease: (1) the microorganism or pathogen (the mutated cell, in this case) must be present in all cases of the disease, (2) the pathogen (mutated cell) can be isolated from the diseased host and grown in pure culture, (3) the pathogen from the pure culture must cause the disease when inoculated into a healthy, susceptible laboratory animal (in vivo transplantation into mice to recapitulate the formation of an abnormal bone/marrow organ), (4) the pathogen must be reisolated from the new host and shown to be the same as the originally inoculated pathogen (self-renewal of the phenotype, or of the stem cell). Thus, generating ectopic ossicles with populations of normal and mutated SSC/BMSC populations offers a unique model system for the study and treatment of genetic diseases of the skeleton. While mouse models of disease are of interest, there are cases in which a known mutation in man does not create a phenocopy when introduced into mice.

In addition to serving as a model system for study skeletal homeostasis and disease, the remarkable ability of SSCs/BMSCs to recreate a bone/marrow organ themselves (when transplanted with an appropriate scaffold) makes them a leading candidate for bona fide TE. However, there are many hurdles yet ahead in terms of appropriate delivery and stabilization strategies, based on the time required to generate functional weight-bearing bone. While many have hoped that these cells would be useful for treatment of systemic skeletal diseases and disorders by systemic infusion or direct injection due to paracrine, immunomodulatory, and immunosuppressive effects of the cells, this is not a stem cell therapy. Nor are there clear mechanisms of action based on the fact that the cells rapidly disappear. More preclinical studies that identify rigorous outcome parameters to be measured and establishment of efficacy are needed. These are not only exciting times in the area of stem cell research, but also a time in which clinical applications should proceed with caution. There is much to be learned about tissue-specific stem/progenitor cells; what they are, and what they are not, and what they can and cannot do. Nonetheless, SSCs/BMSCs offer a unique model system for study of genetic and acquired diseases of the skeleton, and development of novel therapeutic strategies.

Acknowledgments

This chapter is dedicated to the memory of Prof. Paolo Bianco, who made numerous seminal contributions to the bone biology field, in particular in the area of SSC biology. He will be sorely missed. The author would also like to acknowledge all past and present fellows in the Craniofacial and Skeletal Diseases Branch, NIDCR, NIH, DHHS. This work was supported, in part, by the DIR, NIDCR, a part of the IRP, NIH, DHHS.

CHAPTER

16

Osteoimmunology

Kazuo Okamoto, Hiroshi Takayanagi

The University of Tokyo, Tokyo, Japan

1 INTRODUCTION

Bone is a key component of the skeletal-locomotor system and serves as a calcium reservoir regulated by the endocrine system in vertebrates.[1] Bone also functions as the "primary lymphoid organ" in that it harbors hematopoietic stem cells (HSCs), immune progenitor cells, and mature immune cells, including B cells. The immune cells and bone cells share not only the same microenvironments in the bone marrow, but also a number of regulatory molecules, including cytokines, receptors, signaling molecules, and transcription factors. The systems interact with each other to cooperatively carry out the functions of bone. "Osteoimmunology" was created as an interdisciplinary field to investigate the shared mechanisms and inseparable link between the bone and immune systems.

The immune system first emerged in primitive animals and plants, subsequently developing into the complex system of innate and adaptive immunities in vertebrates. The highly sophisticated immune system in vertebrates requires functionally specialized immune cells, as well as the tissues in which these cells develop and activate, such as the thymus, lymph nodes, and bone marrow. The fact that bone and the acquired immune system appeared at the same stage of vertebrate evolution makes us speculate that the immune system included the bone as a part of its essential units during the course of evolution.[2] The cells in the bone marrow are largely divided into two types, cells engaged in bone metabolism and hematopoietic cells. By interacting with each other, these cell types cooperatively carry out the required functions of the bone, such as body support, control of mineral metabolism, and hematopoiesis.[3] Now the situation is such that it has become necessary to keep this "osteoimmune system" in mind whenever we think about anything related to either system.

The close relationship between the immune and bone systems has been appreciated since the pioneering studies on immune cell-derived osteoclast-activating factors in the 1970s.[4,5] The term osteoimmunology was coined in 2000 to highlight the reciprocal interplay between these two systems.[6,7] Subsequently, studies on the bone destruction associated with rheumatoid arthritis (RA), as well as the identification of the various bone phenotypes found in genetically modified, immunocompromised animals have further unveiled the physiological and pathological significance of the shared mechanisms and cross talk between the two systems. It is now well known that numerous immune cytokines influence bone cell activity and bone mass. Among them, receptor activator of NF-κB ligand (RANKL) is one of the most important molecules that explicitly link the two systems. RANKL was first cloned as a member of the TNF superfamily expressed by T cells in order to stimulate dendritic cells (DCs),[8,9] and was rediscovered as an essential factor for osteoclast differentiation.[10,11] RANKL has been shown to serve multiple immune functions. Moreover, the immune regulation of osteoclasts is closely associated with the pathogenesis of RA, which is characterized by a progressive destruction of multiple joints. The bone destruction in RA is the result of the enhanced osteoclast activity due to the inflammatory responses triggered by the activation of a unique helper T cell subset, Th17 cells.[12,13] As evidenced by the clinical benefits conferred by anti-TNF and anti-IL-6 therapy on inflammation and osteoclast differentiation in RA, the osteoimmunological approach is now of growing importance in clinical applications. Furthermore, with the intense global competition in the research field of the hematopoietic stem cell niche, the physiological significance of bone as a "primary lymphoid organ" has been underscored. This chapter provides an overview of recent progress in the field, as well as an overview that frames a context for the basic and clinical investigation of the skeletal and immune systems.

2 THE RANKL/RANK SYSTEM IN BONE METABOLISM

2.1 RANKL is Essential for Osteoclastogenesis

A relationship between the immune and bone systems has been suggested since the original pioneering studies on the osteoclast biology in the 1970s. Soluble factors produced by antigen-stimulated immune cells, such as interleukin (IL)-1, were shown to stimulate osteoclastic bone resorption.[4,14,15] In the 1980s, studies using in vitro culture systems for osteoclast formation indicated that the osteoblast lineage cells or the bone marrow stromal cells of the mesenchymal lineage are involved in the induction of osteoclastogenesis. Burger et al. showed in vitro osteoclast formation using a coculture of murine hematopoietic cells and embryonic bone rudiments containing osteoblasts, chondrocytes and osteocytes.[16] Takahashi et al. established another in vitro coculture system for osteoclastogenesis that has come into general use. This coculture system required cell-to-cell contact between the bone marrow-derived cells of monocyte/macrophage lineage and the osteoblast lineage cells derived from calvaria.[17] It was thus suggested that osteoclastogenesis-supporting cells must provide an osteoclast differentiation factor (ODF).[18] Analysis of *op/op* mice with osteopetrosis revealed macrophage colony-stimulating factor (M-CSF) to be one of the factors essential for osteoclastogenesis. However, M-CSF alone does not induce the differentiation of osteoclasts. One year after the cloning of the inhibitor of osteoclastogenesis, osteoprotegerin (OPG; encoded by the *Tnfrsf11b* gene),[19,20] Yasuda et al. and Lacey et al. independently identified ODF and OPG ligand, respectively, as the long-sought ligand for osteoclast differentiation.[10,11] Interestingly, this cytokine, which belongs to the tumor necrosis factor (TNF) family, was shown to be identical to RANKL (encoded by the *Tnfsf11* gene) and TNF-related activation-induced cytokine (TRANCE), both of which had been cloned as T cell cytokines in the field of immunology.[8,21] The receptor for RANKL is RANK (encoded by the *Tnfrsf11a* gene), a type I transmembrane protein.[8,22] OPG acts as a soluble decoy receptor that blocks RANK signaling by binding to RANKL with a higher affinity.[10,11] Mice with a disruption of either the *Tnfsf11* or *Tnfrsf11a* gene exhibit severe osteopetrosis accompanied by a tooth eruption defect owing to a complete lack of osteoclasts.[23–25] Mice lacking the *Tnfrsf11b* gene exhibit a severe form of osteoporosis due to an increase in both the osteoclast number and bone resorption.[26–28] In humans, mutations in *TNFRSF11A*, *TNFSF11*, and *TNFRSF11B* cause bone disorders, such as familial expansile osteolysis, autosomal recessive osteopetrosis, and juvenile Paget's disease, respectively.[29–33] These genetic findings provide clear evidence that the RANKL/RANK signaling is essential for osteoclast differentiation.

RANKL is expressed as two forms: a membrane-anchored and a secreted protein form. The soluble form arises from proteolytic processing of the membrane form, by metalloproteinases, such as matrix metalloproteinase (MMP)-14.[34,35] Although both forms function as agonistic ligands for RANK, the membrane-bound RANKL is more efficient.[34–36] In bone, RANKL is expressed by several different mesenchymal cells, including osteoblasts, chondrocytes, and osteocytes in response to certain osteoclastogenic factors, such as 1,25-dihydroxyvitamin D_3, prostaglandin E_2, parathyroid hormone (PTH), IL-1, IL-6, and IL-17.[34,37]

Certain reports have suggested that osteoclasts can differentiate independently of RANKL.[38–41] TNF-α), APRIL, BAFF, NGF, IGF I, IGF II, LIGHT, TGF-β, IL-6, IL-11, and SOFAT have been proposed as RANKL-independent osteoclastogenic factors. However, most of these reports lack clear experimental evidence showing that RANKL can be replaced by other molecules, even under RANKL- or RANK-deficient conditions. Kim et al. showed that TNF-α plus TGF-β induces osteoclastogenesis in RANK or RANKL-deficient cells in vitro, but the in vivo effects were not evaluated.[39] Administration of high dose TNF-α into RANKL-deficient mice leads to a minimal local formation of tartrate-resistant acid phosphatase (TRAP)-positive cells, but not functional osteoclasts.[25] It has been recently reported that lysyl oxidase (LOX)-induced osteoclastogenesis in vitro without any addition of recombinant RANKL.[40] However, LOX failed to rescue the in vitro osteoclastogenesis or osteopetrotic phenotype of RANKL-deficient mice.[42,43] Therefore, RANKL-independent osteoclastogenesis has never been demonstrated thus far in vivo and there is no molecule that substitutes for RANKL in osteoclastogenesis. RANKL-independent osteoclastogenesis should properly be judged using RANKL/RANK-deficient conditions in order to unambiguously exclude the involvement of permissive levels of RANKL.

2.2 The Cellular Source of RANKL in Bone Remodeling

RANKL is expressed by various types of mesenchymal cells, including osteoblasts, osteocytes, and hypertrophic chondrocytes.[44–47] Although osteoblasts and bone marrow stromal cells (BMSCs) have been considered the major source of RANKL in vivo,[7,18] recent studies using RANKL conditional knockout mice has further revealed the physiological relevance of each cell type-derived RANKL on bone metabolism. In addition, the development of a method for isolating highly pure osteocytes from bone tissue using osteocyte-specific reporter mice has further advanced our knowledge of the characteristics of osteocytes.[47] Isolated osteocytes were found to express the *Tnfsf11* mRNA at a higher level and have a greater capacity to induce osteoclastogenesis

in vitro than isolated osteoblasts.[47] Osteocyte-specific RANKL-deficient mice, which were generated by crossing *Tnfsf11*-floxed mice with *Dmp1-Cre* mice, were born without any obvious skeletal defect, but became osteopetrotic postnatally due to a severe reduction in osteoclast number.[47] The age-dependent osteopetrotic phenotype observed in osteocyte-specific RANKL-deficient mice indicates that osteocyte-derived RANKL plays a key role in bone remodeling after birth, but not skeletal development in the embryo. Osteocytes are embedded in the bone matrix and are thought to act as mechanosensory cells. In a mechanical stress experiment using osteocyte cell line MLO-Y4 cells, RANKL expression was significantly induced by mechanical loading.[47] In addition, unloading-induced bone loss was prevented in osteocyte-specific RANKL-deficient mice (generated with *Dmp1-Cre*).[48] Thus, osteocytes are suggested to sense mechanical stress and regulate the expression level of RANKL.

The importance of osteoblasts as a source of RANKL in bone remodeling after birth has been evaluated using inducible deletion systems of osteoblasts in adult mice.[48] Inducible ablation of cells expressing a thymidine-kinase transgene under the control of osteocalcin promoter by gancyclovir administration led to a defect in bone formation but exerted no effect on osteoclastic bone resorption.[49] A similar approach using type I collagen promoter-thymidine-kinase transgenic mice also showed that the deletion of osteoblasts did not affect RANKL expression in bone tissue.[50] Furthermore, inducible deletion of *Sp7* (encoding Osterix)-expressing cells, which are considered to be committed osteoblast progenitors, did not reduce the number of osteoclasts. Therefore, it is unlikely that the RANKL on osteoblasts in adults contributes much to bone remodeling. On the other hand, in *Tnfsf11*-floxed mice crossed with *Prx1*-Cre mice, which express *Cre* recombinase in mesenchymal progenitors in the developing limbs, including all chondrocytes, osteoblasts, and osteocytes, exhibit severe limb bone osteopetrosis at birth.[48] Conditional deletion of RANKL in chondrocytes using type X collagen Cre mice resulted in a severe osteopetrotic phenotype at birth.[48] A similar bone phenotype was observed in *Tnfsf11*-floxed mice crossed with *Sp7*- or *Bglap*-Cre mice. Therefore, the RANKL expressed by osteoblasts and chondrocytes contributes to the osteoclastogenesis that occurs in fetal skeletal development.[48]

Several Cre transgenic mouse lines were generated in order to specifically target and analyze osteocytes. On the basis of the specific expression of Dmp1 in osteocytes, 10 kb-*Dmp1-Cre*, 8 kb-*Dmp1-Cre* mice, and mice expressing tamoxifen-inducible Cre under the control of the 10 kb *Dmp1* promoter were generated as osteocyte-specific Cre mice.[51–53] Although 10 kb-*Dmp1-Cre* mice have been widely used in osteocyte-specific deletion, Cre recombination was reported to be observed in unexpected cell types when the 10 kb-*Dmp1* Cre mice were crossed with the reporter mice, such as mature osteoblasts, CXC chemokine ligand (CXCL) 12-abundant reticular (CAR) cells, and muscle cells.[54,55] It should be noted that Dmp1 expression was also reported in brain, pancreas, and kidney.[56] *Sost-Cre* transgenic mice are also accepted as being specific for osteocytes, but not bone-forming osteoblasts, among bone cells.[57] Mice lacking RANKL in osteocytes using *Sost-Cre* mice also exhibit a severe osteopetrotic phenotype similar to that of the RANKL conditional knockout mice generated using *Dmp1-Cre* mice.[57]

Although RANKL was originally identified in activated T cells, the role of RANKL on T cells has been highlighted mainly in the context of autoimmune arthritis.[7] T-cell specific expression of RANKL partially rescued the osteopetrotic phenotype of RANKL-deficient mice,[58] implying that the RANKL on T cells has the capacity to regulate bone remodeling under physiological conditions. However, neither T cell-specific nor B-cell specific *Tnfsf11*-deficient mice exhibit any discernible osteopetrotic phenotype.[47,59] Furthermore, transplantation of HSCs from a healthy donor did not improve the osteopetrotic phenotype of humans with a mutation in the *TNFSF11A* gene.[29] Thus, overall, the RANKL expressed on T cells does not contribute to the physiological regulation of osteoclastogenesis.

2.3 The Role of RANKL in the Mammary Gland and Cancer

Mice lacking the *Tnfrsf11a* or *Tnfsf11* gene fail to form lactating mammary glands, resulting in the death of newborn pups. RANKL and RANK on mammary epithelial cells are essential for development of the lobulo-alveolar mammary structures during pregnancy.[60] The RANKL signaling in mammary epithelium is also involved in progesterone derivative-driven mammary cancers.[61,62] Mammary stem cell activation by RANKL signaling is crucial for the oncogenic activity of both estrogen and progesterone.[63,64] Moreover, recent studies have shown a key role of the RANKL/RANK axis in *BRCA1*-associated breast cancer and also the therapeutic potential value of RANKL inhibition.[65,66] The RANKL provided by tumor-infiltrating regulatory T (Treg) cells stimulates the metastatic progression of RANK-expressing mammary carcinoma cells.[67]

Bone is a common metastasis site for certain cancers, including breast, prostate, and lung cancers.[68] Bone metastases result in pain, fracture, spinal cord compression, and hypercalcemia, but the mechanism underlying the preferential metastasis to bone is not well elucidated. RANKL is important for cancer progression in bone through its effect in activating osteoclastic bone

resorption. The anti-RANKL neutralizing antibody Denosumab has attracted attention because it helps prevent skeletal-related events in breast cancer patients more efficiently than bisphosphonates.[69] RANKL has been reported to act as a chemotactic factor, recruiting certain epithelial tumor cells and melanoma cells that express RANK to bone.[70] The metastasis of prostate cancer to bone is also related to the RANKL/RANK system. Tumor-infiltrating RANKL-expressing inflammatory cells promote prostate cancer metastasis by inhibiting the expression of Maspin, a metastasis suppressor.[71] These findings show that the RANKL/RANK system plays a critical role in the metastatic behavior of cancer cells.

3 IMMUNOLOGICAL ROLE OF THE RANKL/RANK SYSTEM

The TNF superfamily of cytokines is known to be involved in a diverse range of immunological responses and immune organ development.[72] The RANKL/RANK system is not limited to the regulation of bone remodeling. As mentioned earlier, RANKL was originally identified as a T cell–derived cytokine. RANK is now known to be expressed at high levels in lymphoid tissues, breast epithelium, hematopoietic cells, and epithelial cells.[11,23,73] The RANKL/RANK system is essential for the development of mammalian immune organs, such as the thymic medulla and lymph node.[23,74,75] Considering that the bone marrow space is created by osteoclastic bone resorption, it can be said that RANKL is a cytokine critical for immune organ development in vertebrates (Fig. 16.1). Animals with hard bones received benefit of extended mobility while also incurring the increased risk associated with an exposure to a much more diverse array of pathogens, which one would expect to be an important driver in the emergence of a highly organized immune system. The immune organs can be divided into primary and secondary lymphoid tissues. The primary lymphoid tissues, where lymphocytes develop from progenitor cells and mature, are the bone marrow and thymus. The secondary lymphoid tissues are sites of lymphocyte activation and proliferation, and are comprised of the lymph nodes, spleen, and other gut-associated lymphoid tissue (GALT) in mammals. From analyses of mice lacking the *Tnfrsf11a* or *Tnfsf11* gene, the RANKL/RANK system has been shown to be essential for the development of mammalian immune organs, such as the thymus and lymph nodes.[23,74,75]

The thymus provides a specialized microenvironment that is maintained by cortical thymic epithelial cells (cTECs) and medullary thymic epithelial cells (mTECs), for regulation of the selection of a functional and self-tolerant T-cell repertoire.[76,77] In the thymic cortex, $CD4^+CD8^+$ (double positive) thymocytes expressing T-cell antigen receptors (TCRs) are selected for survival or death depending on the avidity of the interaction between the TCR and the self-peptide/MHC (pMHC) complexes presented by cTECs. A weak avidity pMHC–TCR interaction induces the survival and differentiation into $CD4^+CD8^-$ or $CD4^-CD8^+$ single-positive (SP) thymocytes. After their migration into the thymic medulla, positively selected SP thymocytes are further screened for self-reactivity via interactions with mTECs.[78] mTECs express a variety of peripheral tissue-specific antigens, a process which is controlled by the unique nuclear proteins autoimmune regulator (Aire) and forebrain-expressed zinc finger 2 (Fezf2).[79–82] SP thymocytes that recognize the pMHC expressed by mTECs are destined to die. Thus, mTECs are essential for the deletion of the self-reactive T cells that initiate autoimmune diseases. RANK is highly expressed in mTECs and is required for Aire-expressing mTEC development.[74,83] In mice deficient

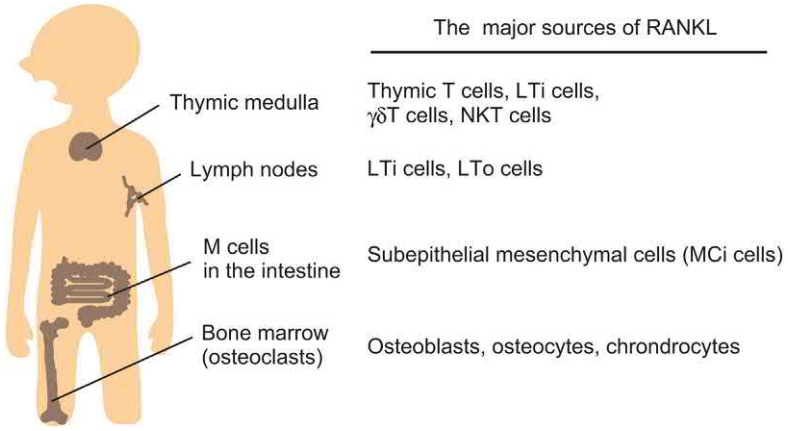

FIGURE 16.1 The RANKL-RANK system in the development of the immune organs. RANKL is a cytokine essential for the differentiation of osteoclasts, the activity of which causes the formation of the bone marrow cavity. In this sense, RANKL plays an essential role in the development of the immune organs in vertebrates, including the bone marrow, thymus, lymph node, and GALT.

in either RANK or RANKL, Aire-expressing mTECs are markedly reduced.[74,75,83] Moreover, the transplantation of RANK-deficient thymic stroma into nude mice induces signs of autoimmunity.[74,75] Various cell types in the thymus produce RANKL so as to promote the development of the mTECs that express RANK. Positively selected SP thymocytes are the most prominent source of RANKL in the postnatal thymus.[83–85] In addition, LTi cells,[74,83,85] γδT cells,[83,86] and natural killer T (NKT) cells[87] express RANKL and cooperate to maintain the thymic medullary microenvironment during ontogeny. The OPG expressed by mTECs acts as a negative feedback regulator of RANKL-RANK signaling in the thymus.[83,88] mTEC development is also controlled by the interaction between CD40L by CD4 SP thymocytes and CD40 on mTECs.[83] Mice doubly deficient for CD40 and RANKL exhibit an almost complete loss in Aire-expressing mTECs, whereas CD40-deficeint mice display only a mild defect.[75] Collectively, the RANKL-RANK signal cooperates with the CD40L-CD40 signal in playing a critical role in mTEC development and the establishment of self-tolerance of T cells in the thymus.

Mice lacking the *Tnfrsf11a* or *Tnfsf11* gene lack lymph nodes. The development of the secondary lymphoid organs is initiated during embryogenesis by the recruitment of lymphoid tissue inducer (LTi) cells to the lymphoid organ primordium.[89] This recruitment process is especially controlled by the chemokines produced by the anlage-resident stromal cell, lymphoid tissue organizer (LTo) cells. Both LTi and LTo cells express RANKL and RANK in the lymph node anlage during embryogenesis, suggesting that RANKL/RANK signaling is required for the interplay between LTi and LTo cells. Nevertheless, the formation of GALT, such as isolated lymphoid follicles and Peyer's patches are undisturbed in RANKL or RANK-deficient mice.[23,90] TNF receptor-associated factor (TRAF) 6, a crucial signal transducer of RANK signaling, is required for the development of lymph node development, but not for that of GALT,[90] indicating tissue-specific requirements of RANKL/RANK/TRAF6 signaling for lymph node organogenesis.

The microfold cell (M cell), located in the follicle-associated epithelium of GALT, is a kind of epithelial cell specialized for antigen sampling and important for the induction of efficient immune responses to mucosal antigens.[91,92] M cell differentiation requires the RANKL signal,[93] but the major source of RANKL in the gut remained unknown. Recently, a distinct type of subepithelial mesenchymal cells that highly expresses RANKL has been identified as an essential inducer for M cell differentiation [called M cell inducer (MCi) cells], which maintains the diversification of the gut microbiota by controlling IgA production.[94] Intestinal epithelium-specific deletion of the *Tnfrsf11a* gene results in the absence of the M cell, leading to defects of germinal center maturation in Peyer's patches and IgA production.[95] Thus, the RANKL/RANK signal is also important for the humoral acquired immune response in mucosal tissues.

As described earlier, RANKL was originally identified as a T-cell cytokine regulating DC function. Indeed, DC survival is supported by the TNF receptor superfamily members, such as RANK, CD40, and LTβR, that are expressed on DCs.[8,9,96] However, RANKL has no capacity to induce the expression of MHC class II and CD80/86 in DCs. Mice lacking the *Tnfrsf11a* or *Tnfsf11* gene exhibit no apparent defects in DC number and function,[97] suggesting that the CD40L/CD40 axis compensates for the loss of RANKL signaling. In support of this view, inhibition of RANKL signaling by treatment with the RANK-Fc fusion protein potently prevented T cell-dependent immune responses against viruses and parasites in CD40-deicient mice. Furthermore, a high expression of RANKL in T cells enhanced the survival of colonic $CD11c^+$ DCs in *Il2*-deficent mice, resulting in bone loss and a spontaneous form of colitis.[98] Adoptive transfer of RANKL-stimulated DCs exacerbated autoimmunity in MRL/lpr recipients.[99] Thus, the proinflammatory effect of RANKL on DCs was especially emphasized under certain experimental conditions. On the other hand, immunosuppressive roles of RANKL were also reported. RANKL on dermal keratinocytes has the ability to inhibit experimental autoimmune and allergic responses by increasing the number of Treg cells via epidermal DCs.[100] Moreover, administration of a neutralizing antibody against RANKL inhibits Treg-mediated suppression of colitis.[101] Inhibition of RANKL was shown to result in a rapid progression to diabetes due to a decrease in the Treg cell number.[102] However, there are no reports of severe immunodeficiencies in patients treated with the anti-RANKL antibody denosumab.[103] Again, it is possible that functional redundancy with the CD40 signal compensates for the defect of the RANKL/RANK signal in DCs.

In addition to DC regulation, the RANKL on T cells has been highlighted especially as a pathogenic effector of experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis. T cell-specific inactivation of RANKL inhibited infiltration of T cells into the central nervous system (CNS) and the development of EAE. The RANKL on T cells stimulates the production of CCL20 by astrocytes that express RANK, leading to the infiltration of T cells into the CNS. Interestingly, studies using single-cell transcriptomics demonstrated that RANKL is one of the key signatures of pathogenic effector T cells infiltrated into the CNS during EAE.[104] As pharmacological inhibition of RANKL prevented the onset and progression of EAE, RANKL inhibition might be a promising therapeutic strategy for multiple sclerosis.[105]

B cell–development was impaired in mice lacking the *Tnfrsf11a* or *Tnfsf11* gene. Also, in humans, *TNFSF11A*

mutations result in low levels of immunoglobulin-secreting B cells. Inhibition of the systemic RANKL/RANK system clearly leads to loss of the microenvironment for B cell–development due to severe osteopetrosis. The impaired development of bone marrow B cells was also observed in *Rag1*-deficient mice reconstituted with fetal liver cells from *Tnfsf11*-deficient mice, indicating that the RANKL expressed by hematopoietic lineage cells is essential for B cell–development. The number of pre-B cells was moderately but significantly decreased in B cell-specific RNAKL-deficient mice, indicating that the RANKL on B cells is involved in B cell–development. On the other hand, B cell-specific deletion of the *Tnfrsf11a* gene had no obvious effects on B cell–development, secretion of immunoglobulins, class switch recombination, or somatic hypermutation.[106] Further studies are needed to elucidate the detailed mechanisms by which the RANKL on hematopoietic cells regulates B cell–development.

4 INTRACELLULAR SIGNALING FOR OSTEOCLASTOGENESIS

Osteoclasts are large, multinucleated cells formed by the fusion of precursor cells of monocyte/macrophage lineage that originate from HSCs. Mature osteoclasts decalcify the inorganic components of bone by releasing hydrochloric acid, and degrade bone matrix proteins by secreting proteolytic enzymes, such as cathepsin K and MMPs. Studies on osteoclast biology have made a critical contribution to the development of osteoimmunology by providing information on the shared molecular mechanisms and interaction between immune and bone cells.

Before the identification of RANKL as an ODF, studies on naturally occurring or genetically modified mutant mice exhibiting osteopetrosis provided important clues for understanding the molecular mechanisms underlying osteoclast differentiation and function. For example, *op/op*, *gl/gl*, *oc/oc*, and *mi/mi* mice, which respectively carry a spontaneous mutation in the *Csf1*, *Ostm1*, *Mitf*, and *Tcirg1* genes, all develop osteopetrosis. Genetically modified mice deficient in PU.1, c-Fos, TRAF6, NF-κB p50/p52, c-Src, or TRAP also develop osteopetrosis.[107] The cloning of RANKL enabled further investigation of the signaling pathways for osteoclast differentiation in a sophisticated culture system using recombinant RANKL and M-CSF.

4.1 RANKL Signaling for Osteoclast Differentiation

RANKL binds to a type I transmembrane protein on the monocyte/macrophage linage cells called RANK to initiate osteoclast differentiation. RANK has no intrinsic enzymatic domain in its cytoplasmic domain, but does contain three putative TRAF-binding domains. Although RANK interacts with TRAF2, TRAF5, and TRAF6,[108] TRAF6 plays an indispensable role in osteoclast differentiation.[39,90] The other TRAF family members except for TRAF1 have a single N-terminal RING finger domain and are implicated in the signaling pathway downstream of various receptor families, including the TNF receptor superfamily, the Toll like receptor/IL-1 receptor family, IL-17R, IL-25R, and the NOD-like pattern recognition receptors.[109] It was reported that, upon homooligomerization, TRAF6 interacts with a K63-specific E2 conjugating enzyme via the RING finger domain, and in turn mediates the attachment of K63-linked ubiquitin chains to TRAF6 itself (autoubiquitination).[110] The K63-linked ubiquitin chain serves as a docking platform for downstream mediators, TGFβ-activated kinase (TAK) 1-binding proteins (TABs), and mitogen-activated kinase kinase kinase (MAPKKK) TAK1. However, K63-linked autoubiquitination of TRAF6 is not essential for the activation of the cascades downstream of RANK.[111,112] Upon RANKL stimulation, TRAF6 forms a complex with RANK, TAB1, and TAB2 to activate TAK1, which in turn activates NF-κB and MAPKs, such as JNK.[113,114] The essential role of TAK1 in osteoclast differentiation has been demonstrated using mice deficient in TAK1 in osteoclast linage cells.[114,115]

The NF-κB family of transcription factors consists of five members: p50 (processed from p105), p52 (processed from p100), RelA, RelB, and c-Rel.[116,117] Activation of NF-κB depends on canonical and noncanonical pathways.[118] In the canonical pathway, the IKK complex comprised of IKKα, IKKβ, and NF-κB essential modulator (NEMO)/IKKγ induces the phosphorylation and subsequent degradation of IκBs, leading to activation of mainly p50:RelA and p50:c-Rel dimers. The noncanonical pathway is dependent on the activation of the IKKα homodimer activated by the upstream kinase NF-κB-inducing kinase (NIK). IKKα phosphorylates p100 and induces the processing to p52, resulting in activation of the p52:RelB dimer. Mice doubly deficient in p50 and p52 develop severe osteopetrosis due to a lack of osteoclasts, whereas mice lacking either p50 or p52 exhibit no obvious bone phenotype,[119,120] indicating the importance of both the canonical and noncanonical pathways. The disruption of the *Ikkb* or *Rela* gene causes an impairment of osteoclast differentiation. In addition, loss of NIK blocks osteoclast differentiation by inhibiting the nuclear translocation of not only RelB, but also RelA. NEMO positively regulates osteoclast differentiation by suppressing the expression of a negative regulator for the differentiation, recombinant recognition sequence binding protein at the Jκ site (RBP-J).[121] Both the canonical and noncanonical pathways are necessary for RANKL-mediated osteoclastogenesis, but further studies

are needed to obtain a complete understanding of the complex mechanisms underlying the NF-κB activation downstream of RANK.

The important roles of the MAPK pathways downstream of RANKL have been demonstrated in a variety of in vitro experiments. Pharmacological inhibition of p38α and β by SB203580 blocks osteoclast differentiation of the RAW264.7 macrophage cell line.[122] In addition, the cells lacking p38α, the main p38 isoform in osteoclast linages, poorly differentiated into osteoclasts.[123] JNK1 is activated by RANKL and plays a critical role in osteoclast differentiation.[124] ERK1/2 are also activated by RANKL, but the role of ERK1/2 in osteoclast differentiation is controversial. Inhibition of MEK by U0126 and PD98059 promoted osteoclast differentiation in RAW264.7 cells,[125] whereas MEK inhibitor AZD6244 suppressed osteoclast differentiation.[126] Detailed analyses with in vivo models are needed for further understanding of the role of MAPKs in osteoclastogenesis.

The Fos family proteins (c-Fos, FosB, Fra-1, and Fra-2) form the AP-1 transcription complex together with Jun family proteins (c-Jun, JunB, and JunD). The critical role of c-Fos in osteoclastogenesis has been demonstrated by the findings that *cfos*-deficient mice develop osteopetrosis due to a lack of osteoclasts.[127–129] Downstream of RANK, c-Fos expression is induced by transcription regulators, such as the CaMK/cAMP responsive element binding (CREB) protein pathway,[130] NF-κB,[131] peroxisome proliferator activated receptor γ (PPARγ),[132] PPARγ coactivator 1 β (PGC1β),[133,134] and CCAAT/enhancer binding protein α (C/EBPα).[135] Fra-1 compensates for the loss of c-Fos, but *Fra1*-deficient mice not develop osteopetrosis. The abilities of FosB and Fra-2 to rescue the osteoclast differentiation blockade of *cfos*-deficient cells are relatively low. Thus, Fra-1, FosB, and Fra-2 do not exclusively function in the AP-1 signaling pathway in osteoclasts. Activation of c-Jun is also required for osteoclast differentiation.[124] Expression of dominant negative c-Jun in osteoclasts inhibited osteoclast differentiation in vivo. However, since dominant negative c-Jun represses the transcriptional activities of all AP-1 family members, there is the possibility of the involvement of other Jun family molecules in osteoclast development and function.[136] Indeed, studies using conditional knockout mice of JunB indicated the crucial role of JunB in osteoclasts.[137] Although the precise composition of the AP-1 dimers has not been determined in the physiological context, the AP-1 dimer composed of c-Fos and Jun proteins plays critical roles in osteoclast differentiation.

4.2 NFATc1, the Master Transcription Factor of Osteoclast Differentiation

Considering the fact that AP-1 and NF-κB transcription factors are also activated by various cytokines, such as TNF-α and IL-1, other transcription factors have been considered to be specifically involved in RANKL-mediated osteoclast differentiation. Based on the transcriptome analyses using osteoclasts, NFATc1 was identified as a transcription factor highly induced by RANKL and is now well-known to be the master transcription factor of osteoclast differentiation[138] (Fig. 16.2).

RANKL specifically and potently induces NFATc1 expression via TRAF6, c-Fos,[138] and p50/p52 NF-κB.[131] After induction, NFATc1 autoregulates its own promoter and thus enables the robust induction of NFATc1 itself in cooperation with other transcription factors, such as AP-1. NFATc1 is essential for osteoclast differentiation both in vitro[138] and in vivo,[139–141] and the overexpression of NFATc1 induces osteoclast differentiation without RANKL stimulation.[138] It has been shown that transcription factors, such as activating transcription factor 4 (ATF4),[142] B lymphocyte-induced maturation protein 1 (Blimp1),[143,144] leukemia/lymphoma-related factor (LRF),[145] and Jun dimerization protein (Jdp)2[146] negatively regulate NFATc1 induction.

NFATc1 directly controls the expression of various genes critical for osteoclast differentiation and function in cooperation with other transcription factors. Integrin β3, which is essential for both bone attachment and bone-resorbing activity,[147] is induced by NFATc1.[148] TRAP, a lysosome enzyme required for bone development and homeostasis,[149] is regulated by NFATc1 together with AP-1.[150] Cathepsin K, a member of the cysteine proteases important for osteoclastic bone resorption,[151] and immunoglobulin-like receptor osteoclast-associated receptor (OSCAR) are synergistically regulated by NFATc1, PU.1, and MITF.[152–154] Dendritic cell–specific transmembrane protein (DC-STAMP),[155] osteoclast stimulatory transmembrane protein (OC-STAMP)[156] and v-type proton ATPase subunit d2 (encoded by the *Atp6v0d2* gene),[157] which induce the fusion of osteoclast precursor cells, are controlled by NFATc1.[156,158] The expression of DC-STAMP is also regulated by c-Fos[159] and the transcriptional repressor strawberry notch homologue 2 (Sbno2).[160] Furthermore, posttranslational histone modifications, such as acetylation and methylation, are critical for the regulation of gene expression in osteoclasts. Histone deacetylation regulates the expression of c-Fos, NFATc1, and osteoclast-specific genes, such as cathepsin K during osteoclastogenesis.[161,162] Histone deacetylase (HDAC) 3 positively regulates osteoclast differentiation, whereas HDAC7 exerts a suppressive effect. Genome-wide ChIP-seq analysis revealed that the trimethylation of histone H3 lysine 27 (H3K27me3), which is a transcription marker of inactivity, occurs at the transcription start site of the *Nfactc1* gene in osteoclast precursor cells, but is eliminated by RANKL stimulation, suggesting that the H3K27me3 modification is important for NFATc1 induction during osteoclastogenesis.

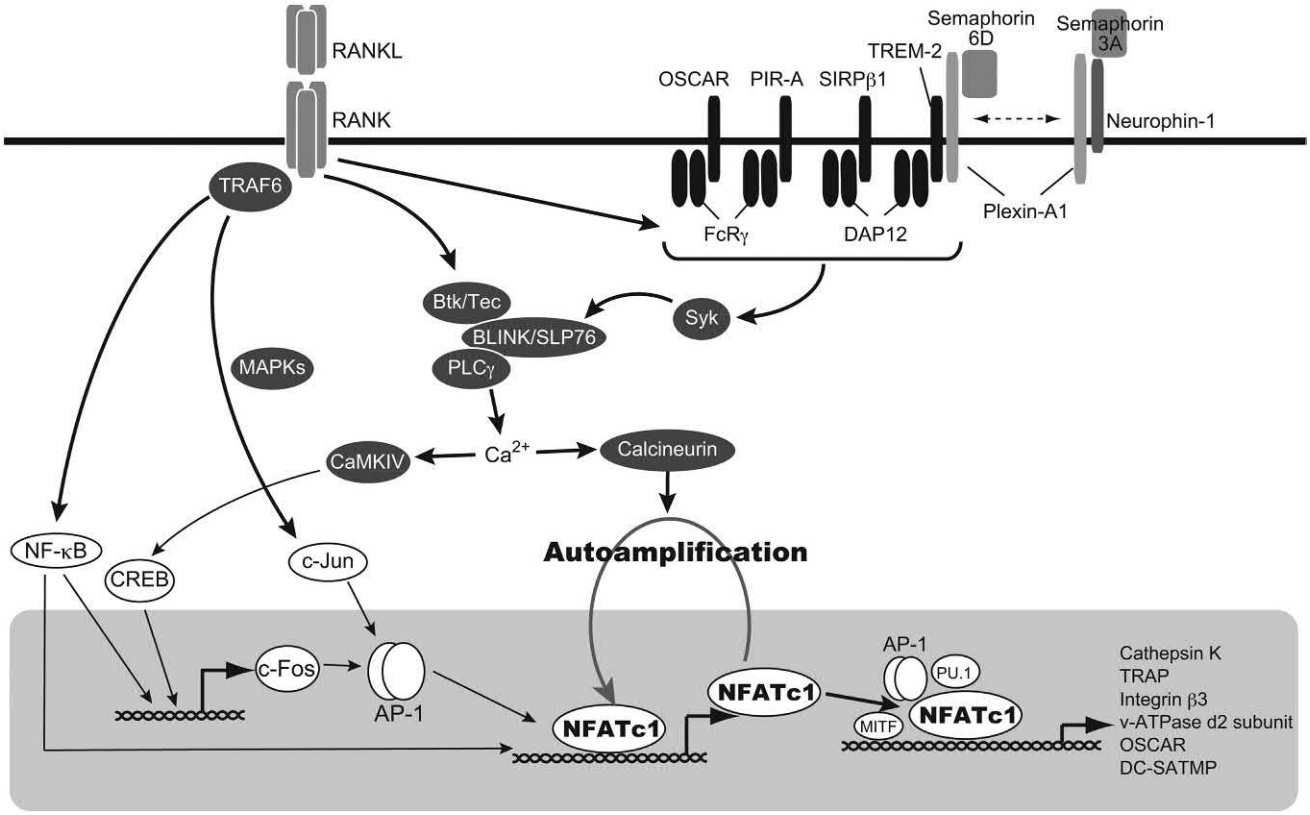

FIGURE 16.2 **NFATc1-centered osteoclastogenic signaling network.** RANKL binds to RANK on osteoclast precursor cells, leading to the activation of certain signaling pathways through TRAF6, including MAPK and NF-κB. RANKL also activates the ITAM signaling mediated by immunoglobulin-like receptors. The NF-κB pathway contributes to the induction and activation of c-Fos, and subsequent NFATc1 induction. The NFATc1 activated by Ca^{2+} signaling regulates the expression of osteoclast-specific genes.

Jumonji domain-containing 3 (Jmjd3), a histone H3K27-specific demethylase, plays a role in regulating NFATc1 expression through the demethylation of H3K27 in osteoclasts.[163]

4.3 Costimulatory Signal for RANK

The nuclear translocation and activation of NFATc1 is promoted by the dephosphorylation of NFATc1 by the Ca^{2+}/calmodulin-dependent phosphatase calcineurin. Calcineurin inhibitors, such as cyclosporine and tacrolimus potently inhibit osteoclast differentiation by suppressing NFATc1.[138] In osteoclast linages, NFATc1 activation is absolutely dependent on the calcium–calcineurin pathway induced by costimulatory signals from immunoglobulin-like receptors, such as OSCAR and triggering receptor expressed in myeloid cells-2 (TREM-2). These receptors associate with the adaptor molecules harboring an immunoreceptor tyrosine-based activation motif (ITAM): Fc receptor common γ subunit (FcRγ) and DNAX-activating protein 12 (DAP12; also known as Tyrobp).[164] Mice deficient in FcRγ do not exhibit any osteoclast defect in vivo or in vitro.[165] Mice deficient in DAP12 also have a normal number of osteoclasts but display mild osteopetrosis,[166] suggesting a role of DAP12 in the bone-resorbing activity of osteoclasts. However, mice doubly deficient in FcRγ and DAP12 exhibit severe osteopetrosis due to a complete lack of osteoclasts.[165] RANKL-induced calcium oscillation and NFATc1 expression are completely abrogated in cells lacking FcRγ and DAP12, indicating that the immunoglobulin-like receptor signal is essential for the activation of the calcium–calcineurin-NFATc1 pathway. Since FcRγ and DAP12 are well known molecules expressed mainly in myeloid cells and NK cells, these findings have had a serious impact on the fields of both immunology and bone biology. In osteoclasts, FcRγ associates with OSCAR and PIR-A, and DAP12 associates with TREM-2, SIRPβ, Myeloid DAP12-associating lectin (MDL)-1 and Siglec-15, respectively[165,167,168] (Fig. 16.2).

Fc receptors bind to the Fc domain of immunoglobulin or immune complexes. FcγRI, FcγRIII, and FcγRV are activating Fc receptors and associated with FcRγ, whereas FcγRIIB is an inhibitory receptor in mice. Among these receptors, FcγRIIB and FcγRIII are highly expressed in osteoclast progenitor cells.[169] FcγRIIB and FcγRIII inhibit osteoclastogenesis by suppressing ITAM signals and sequestering FcRγ from OSCAR and PIR-A,

respectively. However, in autoimmune diseases, such as RA, the immune complex enhances osteoclastogenesis by activating FcγRIII, indicating that this immune complex directly regulates bone metabolism through the regulation of osteoclasts (see Section 5).

Once phosphorylated, the ITAM-containing adaptors recruit spleen tyrosine kinase (Syk). Syk is required for ITAM signaling in osteoclast differentiation because *Syk*-deficient cells fail to differentiate into osteoclasts in response to RANKL.[170] In various immune cells, such as lymphoid and myeloid cells, Tec tyrosine kinase family proteins are well-known targets of Syk[171,172] and regulate its function. ITAM-mediated T- and B-cell receptor signaling is controlled by Itk and Rlk,[173] and Btk and Tec,[174] respectively. In osteoclast linage cells, Btk and Tec are highly expressed and function as essential kinases for ITAM-mediated signaling. Mice deficient in both Btk and Tec develop severe osteopetrosis owing to a lack of osteoclasts.[175] The Tec and Btk activated by RANK cooperate with Syk and SH2-containing leukocyte protein (SLP) family proteins, B-cell linker protein (BLNK) and lymphocyte cytosolic protein 2 (Lcp2; also known as SH2-containing leukocyte protein of 76 kDa, SLP76), to induce efficient phosphorylation of phospholipase Cγ (PLCγ).[175] PLCγ hydrolyzes the phospholipid, phosphatidylinositol-4,5-bisphosphate (PI-4,5-P_2) to generate the second messengers diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3).[176,177] IP_3 provokes a transient increase in the intracellular calcium released from the endoplasmic reticulum (ER) Ca^{2+} store through IP_3 receptors (IP_3Rs) at the ER membrane.[178] IP_3R2 and IP_3R3 are mainly expressed in osteoclast linages. Although cells lacking both of the IP_3Rs fail to differentiate into osteoclasts in vitro due to an impairment of the calcium oscillation,[179] mice deficient in IP_3R2 and IP_3R3 do not show any bone abnormality, suggesting that the loss of IP_3R2 and IP_3R3 is compensated by other, as yet unknown mechanisms in vivo. Calcium oscillation is induced and strictly regulated by both the increased intracellular Ca^{2+} and removal of intracellular Ca^{2+} from the cytosol. During osteoclastogenesis, this process is regulated by the sarco/ER Ca^{2+} ATPase (SERCA) 2 that reuptakes Ca^{2+} into the intracellular Ca^{2+} store,[180] the transmembrane protein 64 (Tmem64) that associates with SERCA2,[181] and regulator of G-protein signaling 10 (RGS10).[182] In summary, the immunoglobulin-like receptor and ITAM-harboring molecules induce costimulatory signals critical for PLCγ activation, RANKL-induced calcium oscillation, and NFATc1 activation (Fig. 16.2).

4.4 Negative Regulators of Osteoclastogenic Signaling

Various negative regulatory molecules are known to exert an effect on inactivating the RANKL signaling pathway in osteoclasts. Mice with a mutation in the *Ptpn6* gene encoding SH2-domain-containing phosphatase 1 (SHP-1), a nonreceptor type of tyrosine protein phosphatase, display a low bone mass due to an increased number of osteoclasts.[183,184] SHP-1 negatively regulates osteoclastogenesis by suppressing the PI3K-Akt pathway[185] and associating with inhibitory Ig-like receptors, such as PIR-B.[186] The inositol phosphatases SH2-domain-containing inositol 5′-phosphatase 1 (SHIP1) and phosphatase and tensin homolog (PTEN) act as negative regulators of osteoclast differentiation.[187,188] In addition, the transcriptional factors interferon regulatory factor-8 (IRF-8)[189] and B cell lymphoma 6 (Bcl6)[143] also contribute to the negative regulation of osteoclastogenesis by directly interacting with NFATc1 and suppressing NFATc1 expression, respectively. In response to RANKL, the expression of IRF-8 and Bcl6 is downregulated through Blimp1.[143,144] The downregulation of IRF-8 is associated with DNA methylation of the *Irf8* gene by the DNA methyltransferase 3A (Dnmt3a).[190] A gain-of-function mutation in the *Sh3bp2* gene causes cherubism characterized by inflammation and enhanced bone resorption in the face. Mice carrying the cherubism mutation in the *Sh3bp2* gene exhibit severe osteoporosis with enhanced bone resorption.[191] In mature osteoclasts, SH3BP2 regulates bone-resorbing activity through the Src and Vav pathways.[192] MicroRNA is known to suppress the expression of its target genes at the translation level. One of the microRNAs, miR-34a, has been shown to inhibit osteoclast differentiation by suppressing the expression of transforming growth factor-β-induced factor 2 (Tgif2), which regulates JNK and NF-κB signals downstream of RANK.[193] Recently, leucine-rich repeat-containing G-protein-coupled receptor 4 (LGR4) was reported to be another receptor for RANKL.[194] LGR4 negatively regulates osteoclastogenesis by inhibiting NFATc1 activation via Gαq, as well as competing with RANK for RANKL binding. This finding may have a profound influence on RANKL biology, but further studies will be needed to test the importance of LGR4-mediated regulation of RANKL under both physiological and pathological conditions.

Osteoclast lineage-specific conditional knockout mice generated by the Cre-loxP system have provided important insights into the essential molecules for osteoclasts, contributing to outstanding advances in the field of osteoclast biology. However, it is important to carefully check the deletion efficiency and the timing of Cre-mediated recombination, since the deletion efficiency depends on the compatibility with flox mice. For example, deletion of the *Nfatc1* gene in NFATc1 flox mice crossed with *LysM-Cre* mice was not observed in bone marrow macrophages and the mice did not exhibit any bone phenotype.[141] Thus, the deletion efficiency and the

protein expression level of the gene need to be carefully evaluated in the osteoclast linages.

4.5 Cell–Cell Communication Between Osteoclasts and Osteoblasts

The entire course of the bone remodeling process is achieved by the interplay among osteoclasts, osteoblasts, and osteocytes, in cooperation with other cells in the bone marrow, not least immune cells. The molecules that function in the cell–cell interaction in bone remodeling have come to be referred to as "communication factors." RANKL is thus the prototypical communication factors, but other molecules have been recently identified as additional communication factors controlling osteoclastogenesis.

The axon guidance molecules the Ephrins and their Eph receptors transduce bidirectional signals through the receptor (forward signaling) and through the ligand (reverse signaling) in contact-dependent cell–cell communication.[195] EphrinB2 and its receptor EphB4 are expressed on osteoclasts and osteoblasts, respectively.[196] The forward signal through EphB4 promotes osteoblast differentiation by activating the small GTPase RhoA, whereas the reverse signal through EphrinB2 suppresses osteoclast differentiation by inhibiting c-Fos and NFATc1.[196] The EphrinB2/EphB4 signal may allow transition from bone resorption to new bone formation by terminating bone resorption and simultaneously inducing bone-formation activity. The Semaphorin family of proteins, which were originally identified as axonal growth cone guidance molecules, regulates the immunoglobulin-like receptor signal. Sema6D, which is a ligand for Plexin-A1 (PlxnA1), stimulates osteoclast differentiation by activating the ITAM signal through the formation of the PlxnA1-TREM2-DAP12 complex.[197] The Sema3A produced by osteoblasts binds to the receptor neuropilin1 (Nrp1) in osteoclast precursor cells and inhibits their differentiation by blocking PlxnA1-TREM2-DAP12 complex formation.[198] By binding to Nrp1/PlxnA1 complex on osteoblast lineage cells, Sema3A also stimulates osteoblast differentiation through activation of the canonical Wnt/β-catenin pathway.[198] Thus, Sema3A exerts an osteoprotective effect by both promoting bone formation and simultaneously inhibiting bone resorption. It was also reported that sensory nerve innervation into bone by neuron-derived Sema3A is involved in bone remodeling during development.[199] Osteoblast-derived Wnt16 suppresses osteoclastogenesis by both inducing OPG in osteoblasts and directly acting on osteoclasts through a noncanonical Wnt signal.[200] On the other hand, osteoblast-derived Wnt5a binds to Ror2 on osteoclast precursor cells and upregulates RANK expression, thereby enhancing RANKL-induced osteoclast differentiation.[201] In addition to these factors, various soluble factors secreted from osteoclasts were reported to act as communication factors regulating osteoblastc bone formation, including Sema4D,[202] leukemia inhibitory factor,[203] CTHRC-1,[204] and PDGF-BB.[205,206] Interestingly, the PDGF-BB from preosteoclasts also regulates angiogenesis in the bone marrow and periosteum to further support bone formation.[206]

5 MECHANISMS UNDERLYING BONE DESTRUCTION IN ARTHRITIS

RA is an autoimmune disease characterized by chronic inflammation of the synovium and subsequent bone destruction in multiple joints.[207] RA is the most representative skeletal disorder directly triggered by an abnormal or/and prolonged activation of the immune system. Although genetic susceptibility and environmental triggers are both reportedly involved in the etiology of RA, the exact cause remains uncertain. To develop effective therapeutic strategies against RA, attention must be paid to how abnormality of the immune system, especially autoreactive T lymphocytes, ultimately leads to the bone destruction. Thus, to explore the mechanism underlying bone destruction associated with RA has been one of the driving motives of osteoimmunology.

In the early 1980s, osteoclast-like cells was identified in the inflamed synovium of rheumatoid joints,[208] but it was not until RANKL was cloned that the importance of osteoclasts in arthritis attracted much attention. The findings that osteoclast formation was consistently observed in synovial cell cultures from patients with RA clearly indicated that the inflamed synovial tissues contain both osteoclast precursor cells and osteoclastogenesis-supporting cells.[209] After RANKL was cloned as a factor essential for osteoclastogenesis, it turned out that RANKL expression was also detected specifically in the synovium of patients with RA.[210,211] Furthermore, the importance of RANKL and osteoclasts in the bone destruction associated with inflammation was demonstrated in mouse models of autoimmune arthritis.[212,213] Mice lacking osteoclasts or osteoclast activity were protected from bone destruction, but not inflammation, in arthritis models. Anti-RANKL and antiosteoclast therapies were shown to exert beneficial effects in treating bone loss in animal models of arthritis.[214,215] In a RA patient with osteopetrosis, bone erosion was hardly observed despite severe inflammation and cartilage destruction.[216] Taken together, these genetic findings demonstrate the indispensable role of osteoclasts in the bone destruction that occurs in RA.

Inflammatory cytokines produced in the inflamed synovial tissues, including TNF-α, IL-6, and IL-1, directly induce RANKL expression on osteoclastogenesis-supporting cells, such as synovial fibroblasts and facilitate

RANKL signaling. RANKL is abundantly expressed in synovial fibroblasts in the inflamed synovium, but has also been shown to be expressed on T and B cells.[6,211,214,217,218] There has been a long-standing debate over the source of RANKL in arthritis. Soon after the cloning of RANKL, in vitro culture experiments showed that fixed activated T cells act directly on osteoclast precursor cells and induce osteoclastogenesis via the RANKL on T cells.[214] However, living T cells do not possess such an osteoclastogenic capacity as they produce cytokines, such as IFN-γ, which exert potent inhibitory effects on osteoclast differentiation.[6] As we will discuss later, one of the helper T cell subsets, Th17 cells, functions as an osteoclastogenic T cell subset, expressing a higher level of RANKL than any other T cell and inducing RANKL expression on mesenchymal cells, such as synovial fibroblasts.[12] Studies using RANKL conditional knockout mice showed that the bone destruction and osteoclast formation in the joints was inhibited in the mice, in which the *Tnfsf11* gene had been deleted in joint mesenchymal cells, including synovial fibroblasts, using *Col6a-Cre* mice. On the other hand, T cell-specific deletion of the *Tnfsf11* gene had no effect on bone destruction. Thus, synovial fibroblasts, not T cells, are functionally most relevant as a source of RANKL in arthritic joints.[219]

5.1 Th17 Cells and Treg Cells in Autoimmune Arthritis

Accumulating evidence lends support to the view that $CD4^+$ T cells play a key role in the pathogenesis of RA. Infiltration of $CD4^+$ T cells into the synovium of the affected joints and the presence of autoantibodies are pathological hallmarks of RA. Genome-wide association studies revealed *PTPN22* and *CCR6*, which are related to TCR signaling and $CD4^+$ T cell migration, respectively, as well as HLA-DRB1 alleles as the most relevant in RA susceptibility.[220–224] CTLA-4-Ig (abatacept), a selective inhibitor of T cell activation, was shown to be effective against RA.[225] Moreover, T cell-depletion protected mice against the development of CIA and KBxN arthritis, which are animal models of RA.[226,227] Thus, considering the primary role of $CD4^+$ T cells in the inflammation and bone destruction of RA, attention must be focused to how T-cell immunity is linked to osteoclast-mediated bone destruction.

Upon TCR activation, naive $CD4^+$ T cells differentiate into different lineages of helper T (Th) cells, depending on the cytokine milieu; Th1, Th2, Th17, inducible Treg (iTreg), and T follicular helper (Tfh) cell subsets. These Th cell subsets are defined by their pattern of cytokine production and immune function. Th1 and Th2 cells are traditionally thought to be the major subsets generated upon antigenic stimulation. Th1 cells, which are induced by IL-12, produce mainly IFN-γ and are critical for host defense against intracellular viral and bacterial pathogens. Th2 cells produce mainly IL-4, IL-5, and IL-13 and contribute to allergic responses and the parasite defense system. Th17 cells, which were discovered in 2000s as an IL-17-producing distinct Th cell subset, confer protection against extracellular bacterial and fungal pathogens, and importantly, contribute to autoimmune inflammation. Activated T cells express not only RANKL but also effector cytokines with either stimulatory or inhibitory effects on osteoclastogenesis.[6,7] Th1 and Th2 cells strongly inhibit osteoclastogenesis by producing IFN-γ and IL-4, respectively. In contrast, Th17 cells mainly potentiate osteoclastogenic activity by producing IL-17, which has the capacity to induce RANKL on osteoclast-supporting mesenchymal cells.[12] Under arthritic conditions, IL-17 produced by Th17 cells directly acts on arthritic synovial fibroblasts and stimulates innate immune cells to produce inflammatory cytokines, such as TNF-α, IL-1β, and IL-6. These cytokines further promote osteoclastogenesis by upregulating RANKL on synovial fibroblasts and directly activating osteoclast precursor cells, resulting in severe bone destruction (Fig. 16.3). Synovial cells stimulated by inflammatory cytokines also produce matrix-degrading enzymes that cause cartilage destruction. Thus, Th17 cells play a central role as the pathogenic link between the inflammatory response and joint destruction in RA. Furthermore, the Th17–synovial fibroblast interaction is deeply associated with RA pathogenesis. Under arthritic conditions, synovial fibroblasts promote the migration of Th17 cells to the inflammatory joint via CCL20, and proliferation of Th17 cells and IL-17 production via IL-6.[228–230] The interaction between the immune cells and synovial fibroblasts may hold the key to understand the joint specificity of RA pathogenesis.

Treg cells are an immunosuppressive $CD4^+$ T cell subset that engages in the maintenance of immunological self-tolerance and immune homeostasis. Their physiological significance has been evidenced by the development of severe autoimmune disease, allergy, and immunopathology in humans and mice with a mutation of forkhead box P3 (Foxp3), a master regulator for Treg cell.[231] In contrast to Th17 cells, Treg cells are reported to have inhibitory effects on RANKL-induced osteoclastogenesis, but no consensus about the mechanism of action has been reached. Some studies have reported that Treg cells suppress osteoclast differentiation via TGF-β and IL-4[232] or TGF-β and IL-10,[233] while others reported that their suppressive effect is cell–cell contact dependent via CTLA-4.[234] By binding to CD80/86 on osteoclast precursor, CTLA-4 induces activation of the enzyme indoleamine 2,3-dioxygenase (IDO), which promotes apoptosis.[235] Using in vivo analyses, Treg cells have been shown to protect against local and systemic bone loss in a mouse model of TNF-α-induced arthritis.[236] In addition, Foxp3 transgenic mice display

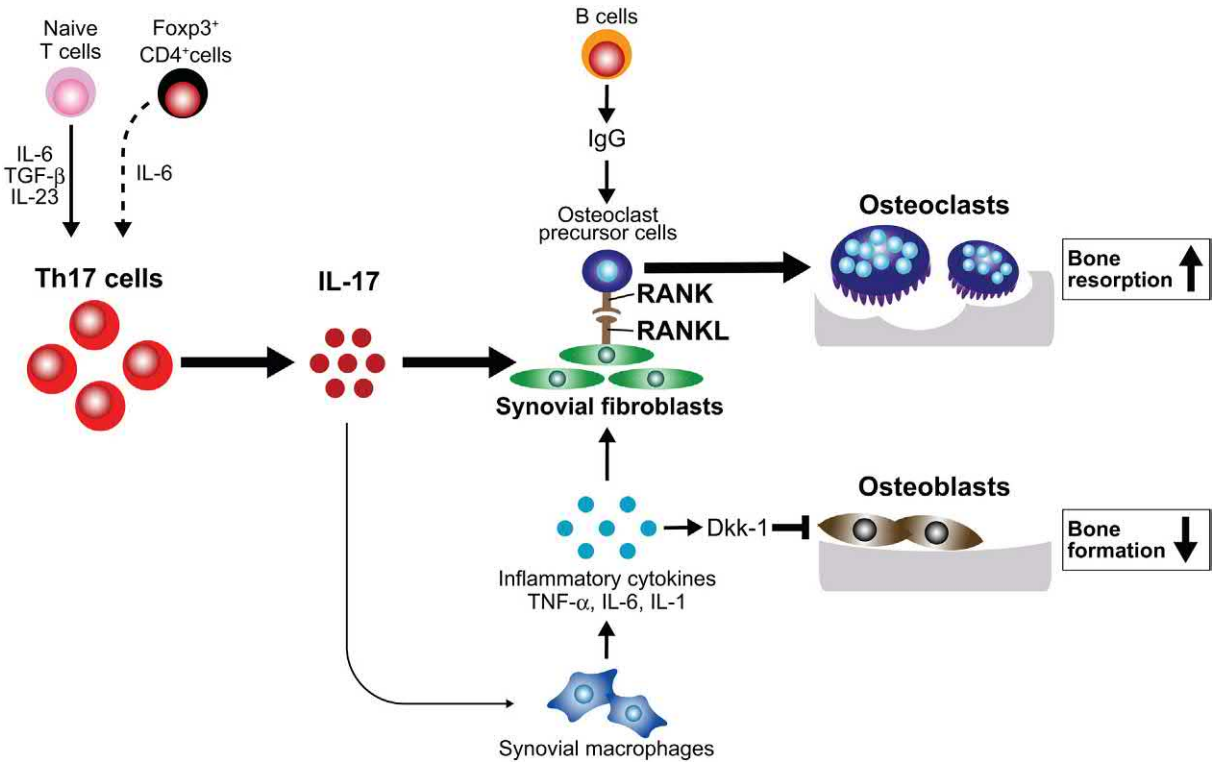

FIGURE 16.3 **Bone destruction in rheumatoid arthritis.** The bone destruction in arthritis occurs in the inflammed synovium at the interface of the immune system and bone. IL-17 produced by Th17 cells upregulates RANKL expression on synovial fibroblasts and induces inflammatory cytokines, such as TNF-α, IL-6, and IL-1 from synovial macrophages. These cytokines further upregulate RANKL expression on synovial fibroblasts and activate osteoclast precursor cells. The IgG immune complex directly promotes osteoclast differentiation. RANKL stimulates osteoclastic bone resorption, while the DKK-1 induced by inflammatory cytokines such TNF-α suppresses bone formation.

high bone mass and are partially resistant to ovariectomy (OVX)-induced bone loss.[237] Taken as a whole, it is likely that Treg cells serve as an inhibitory modulator in bone destruction in RA, but it is important to consider the possibility that the characteristics of Treg cells are affected by the specific inflammatory microenvironment. Although a number of Treg cells have actually been observed within RA patient joint fluid,[57–59] these Treg cells in the joint fluid displayed compromised immunosuppressive function. Studies using a mouse model of autoimmune arthritis demonstrated that CD-25^{lo}Foxp3^{+} T cells did lose Foxp3 expression under arthritic conditions and converted into a novel Th17 cell subset (termed exFoxp3Th17 cells) with the support of the IL-6 produced by arthritic synovial fibroblasts. Notably, in the presence of arthritic synovial fibroblasts, exFoxp3Th17 cells exert a greater capacity for inducing osteoclastogenesis than naïve CD4^{+} T-derived Th17 cells. Moreover, IL-17^{+}FOXP3^{+} T cells were observed in the synovium of RA patients with high disease activity, but not low disease activity, suggesting a contribution of Foxp3^{+} T cell plasticity to the pathogenesis of RA[238] (Fig. 16.3). The conversion of Foxp3^{+} T cells into effector T cells has been reported in diseases, such as diabetes, multiple sclerosis, and asthma, suggesting the importance of exFoxp3 T cells in the pathogenesis of autoimmune and allergic diseases.[239–241]

5.2 Therapeutic Strategies for RA

The inflammatory cytokines, such as TNF-α and IL-6 are responsible for not only local inflammation but also bone destruction through the upregulation of RANKL. The blockade of IL-6 or TNF-α has been shown to be efficacious treatment for RA. Even patients who were unresponsive to an anti-TNF-α (antibody) or anti-IL-6R antibody with regard to the inflammatory index still showed improvement of bone damage, suggesting direct inhibitory effects on osteoclastogenesis.[242,243] The effectiveness of CTLA4-Ig points to the relative contribution of T cell activation even in the bone destruction phase. Since CTLA-4 is also involved in osteoclast regulation as mentioned earlier, it is possible that CTLA4-Ig directly acts on osteoclastogenesis. An anti-RANKL antibody is widely used for the treatment of bone metastasis and osteoporosis and is being tested in clinical trial for bone destruction in RA.[244] An anti-IL-17A Ab has been shown to be less effective than the blockade of IL-6 or TNF-α in RA, despite the

well-established significance of Th17 cells in mouse models of RA.[245,246] It is possible that Th17-related cytokines other than IL-17A may be important for RA pathogenesis. Alternatively, considering that the pathogenesis of RA seems to be heterogeneous in patients, animal models of RA do not always represent all of the patients with the human form of the disease. An anti-IL-17A Ab has been shown to be very effective in psoriatic arthritis and ankylosing spondylitis.[247–249] Thus, it is important to deeply understand the difference in the mechanisms underlying the effects of T cells on bone tissues among RA, psoriatic arthritis, and ankylosing spondylitis. JAK inhibitors are effectively used for RA but the precise mechanisms, by which JAK inhibitors block bone damage, remain elusive.

Successful treatment of RA with B cell–depleting anti-CD20 monoclonal antibodies has highlighted the importance of B cell function in RA.[250,251] Autoantibodies against citrullinated proteins and IgGs are widely used to diagnose RA and form a prognosis for bone damage. Such autoantibodies have the capacity to enhance osteoclastogenesis in human and mouse culture systems.[169,252,253] The IgG immune complex directly regulates osteoclast differentiation via FcRγ receptors under arthritic conditions[169,253] (Fig. 16.3). Thus, the immune complex not only promotes inflammation, but also directly induces bone destruction in arthritis. Synovial fibroblasts produce Dickkopf-1 (DKK-1) in response to inflammatory cytokines, such as TNF-α, leading to inhibition of osteoblastic bone formation (Fig. 16.3). An anti-DKK-1 antibody enhances bone formation and ameliorates bone loss,[254] suggesting that upregulating bone formation may be a helpful strategy for the regeneration of eroded joints. The development of novel strategies for enhancing bone formation and inhibiting bone destruction at the same time is much anticipated in the treatment for RA.

The advances of osteoimmuonology has greatly contributed to the understanding of the mechanisms by which immune system abnormalities lead to the bone destruction in RA and thus provide the molecular basis for the development of the novel therapeutic strategies. The osteoimmunological viewpoint will be indispensable for a better understanding of the pathogenesis of other bone diseases associated with abnormal immune responses, such as periodontitis and ankylosing spondylitis.[255]

6 BONE MARROW MICROENVIRONMENT

HSCs have the capacity to differentiate into all immune cells and reside in microenvironments (niches) in the bone marrow in adults.[256] HSC activities are regulated by both intrinsic and extrinsic signals, the latter of which are from niche cells. Accumulating evidence has revealed that various cell types resident in the bone marrow, including bone cells, endothelial cells, neural cells, and stromal cells, play crucial roles in the regulation of immune cell development and function.[3] Osteoblasts were first reported to contribute as the HSC niche, which brought researchers to pay considerably more attention to the importance of osteoblasts in hematopoiesis. However, the mechanisms by which constituents of the bone marrow microenvironment support HSC activity are profoundly complex, so the true identity of the cells regulating HSCs is still incompletely understood. The role of bone cells in the maintenance of HSCs and immune cells in the bone marrow microenvironment has emerged as one of the most important subjects of osteoimmunology.

Osteoblasts continuously form new bone, providing a structural platform for the maintenance of HSCs in the bone marrow. It was initially proposed that the endosteal surface contains a key component for supporting HSCs.[257–259] In 2003, two independent groups reported the critical role of osteoblasts in HSC regulation in vivo by showing that the osteoblast number was associated with the HSC number using PTH/PTH-related protein receptor (PPR) transgenic and bone morphogenetic protein IA (BMPRIA) conditional knockout mice.[260,261] These pioneering studies highlighted the importance of osteoblasts for the regulation of HSCs. The findings that osteoblast ablation affected the HSC population[262] and that fetal skeletal progenitors have the capacity to reconstitute the ectopic HSC niche formation[263] further supported a close relationship between the osteoblasts and the HSCs in bone marrow. Osteoblasts were also reported to express key molecules for HSC regulation, including N-cadherin, angiopoietin-1, thrombopoietin, and osteopontin.[261,264–266] In contrast, other studies have reported that osteoblasts are less relevant to maintaining HSCs. Biglycan-deficient mice exhibit an osteoporotic phenotype but have a normal number of HSCs.[267] An increase in osteoblasts by strontium ranelate injection had no effect on the HSC number.[268] Furthermore, studies using conditional gene targeting in osteoblasts demonstrated that N-cadherin and Ang-1 on osteoblasts is dispensable for HSC maintenance.[269,270] Thus, osteoblasts may not be required for HSC maintenance under certain conditions.

Various cell types including CAR cells, leptin receptor-expressing ($LepR^+$) perivascular stromal cells, $Nestin^+$ perivascular cells and nonmyelinating Schwann cells are important for HSC maintenance.[271–274] The selective depletion of CAR cells in vivo reduced both the HSC and progenitor number. LepR-expressing perivascular stromal cells were shown to be a major source of stem cell factor in the bone marrow and to support HSCs.[271,275,276] In contrast, osteoblast lineage-specific deletion of stem cell factor or CXCL12 did not affect the HSC number. HSC niche cells thus far been characterized by different

research groups based on cytokine expression pattern, surface markers, and localization in the bone marrow. It will be necessary to integrate all such findings into a unified scheme to ultimately unveil the true nature of HSC niche cells, as well as their regulation.

The contribution of osteoblasts to HSC maintenance may not be as essential as suggested by earlier studies, but it has become clear that osteoblasts are involved in the modulation of immune cell differentiation in the bone marrow. Deletion of the *Cxcl12* gene in osterix-expressing mesenchymal cells, which are mostly osteoblasts, resulted in a decrease in B-lymphoid progenitors in the bone marrow.[262,277,278] A recent study showed that acute inflammation potently suppresses osteoblastic bone formation, resulting in a defect of lymphocyte development in the bone marrow. Osteoblasts play a role in the regulation of common lymphoid progenitors by providing IL-7.[279] The delta-like 4 (DLL4) on osteoblasts also contributes to supporting T cell competent progenitors in the bone marrow.[280] Conditional deletion on osteoblasts of RNase III endonuclease essential for microRNA biogenesis Dicer1 resulted in both impaired osteoblastic differentiation and myelodysplasia, the latter induced by a change in the bone marrow microenvironment,[281] indicating that osteoblast function alteration induced the perturbation of HSCs. The constitutive activation of β-catenin through FoxO1 in osteoblasts induced abnormal proliferation of neutrophils.[282] Taken together, osteoblasts regulate the fate of the immune cell progenitors by a variety of signals in the bone marrow.

Osteoclastic bone resorption is essential for the formation of the bone marrow cavity. Thus, mice lacking osteoclasts exhibit extensive extramedullary hematopoiesis in the spleen and liver because of insufficient space for support of hematopoietic cells within the bone marrow.[24,283] An aberrant microenvironment might provoke impaired immune cell differentiation and function.[284] Indeed, osteopetrotic patients develop anemia and serious infection due to abnormal hematopoiesis.[285–287] In *oc/oc* mice, which have inactive osteoclasts because of a mutation in the *Tcirg1* gene,[288] and mice treated with zoledronic acid, the frequency and absolute number of $Lin^{-}Sca\text{-}1^{+}c\text{-}kit^{+}$ (LSK) cells were decreased. The absence of osteoclast activity induces a severe alteration in endochondral ossification, resulting in a defective HSC niche.[289] It is also shown that inhibition of osteoclast activity by zoledronic acid impairs B cell–development by suppressing IL-7 and CXCL12 expression from stromal cells.[290] These results suggested that niche space formation by osteoclastic bone resorption is required for normal hematopoiesis.

HSCs are retained in the bone marrow because they express CXCR4, which is a receptor for CXCL12 on niche cells. There is a report showing that osteoclasts modulate the interaction between the CXCR4 on HSCs and CXCL12 on niche cells by secreting MMP 9.[291] Thus, HSC mobilization may be induced by the activation of osteoclasts. G-CSF is widely used as an HSC mobilizer in bone marrow transplantation,[292] but several reports have indicated the role of osteoclasts to be dispensable in such G-CSF-induced mobilization. G-CSF injection did not affect the osteoclast number on the endosteal surface. G-CSF-induced mobilization of HSCs is not impaired in osteoclast-deficient mice, such as *op/op*, $cfos^{-/-}$, and $Tnfsf11^{-/-}$ mice, or mice treated with zoledronic acid.[293,290] Instead, osteoblasts and osteocytes are required for the mobilization of HSCs in response to G-CSF.

When osteoclasts degrade the bone matrix, certain factors stored in the matrix are released. Near the sites of bone resorption, the local concentration of Ca^{2+} is considerably higher than in serum. HSCs lacking the calcium-sensing receptor fail to lodge at the endosteal sites near resorbing osteoclasts,[294] suggesting that the high Ca^{2+} level resulting from bone resorption is involved in HSC maintenance. TGF-β plays an important role in regulating HSC quiescence and self-renewal.[274] TGF-β is deposited in bone matrix in an inactive form that is activated by proteolytic enzymes secreted from osteoclasts. In this context, osteoclast activity may be involved in TGF-β-mediated HSC maintenance. Osteoclasts might contribute to HSC regulation by releasing the matrix-embedded factors that control HSCs.

Osteocytes, the most abundant cells in bone, are terminally differentiated osteoblast lineage cells embedded within mineralized bone matrix. Osteocyte-ablated mice exhibited defects in the bone marrow, thymus, and spleen, resulting in severe lymphopenia,[295] but the mechanisms by which osteocytes regulate lymphocyte development remain elusive. Sclerostin (encoded by the *Sost* gene), which is mainly expressed by osteocytes in bone, inhibits the Wnt-signaling pathway by binding to the LRP5/6 receptors in mesenchymal stromal cells.[296] As inhibition of the Wnt pathway leads to decreased bone formation, $Sost^{-/-}$ mice exhibit a high bone mass phenotype.[297] Notably, the number of mature B lymphocytes was reduced in the bone marrow of $Sost^{-/-}$ mice due to the reduced expression of CXCL12.[298] In addition, there is a report showing that osteocytes regulate the differentiation of myeloid linage cells. Osteocyte-specific Gsα-deficient mice have increased neutrophils and platelets due to upregulation of G-CSF.[299] Activation of the PTH receptor on osteoblasts induces an increase in the HSC number, as mentioned previously,[260] whereas activation of the PTH receptor on osteocytes did not affect the HSC number or function despite an increase in osteoblasts.[300] It is thus suggested that PTH signaling in osteocytes is insufficient to increase HSCs. Considering the number of osteocytes in bone tissues, they are suggested to affect the bone marrow microenvironment, but the role of osteocytes in hematopoiesis has been poorly elucidated to

date. More detailed studies will be needed to determine the function of osteocytes in immune cell differentiation in the bone marrow.

Early studies suggested an important role of osteoblasts in the HSC niches. This concept has been modified but nevertheless attracted the attention of various researchers to the role of bone cells in HSC maintenance. The role of osteoblast-lineage cells in hematopoiesis has been proven to be more limited than previously expected, but recent studies have demonstrated that osteoblasts are specifically important for the differentiation of certain immune cells, including lymphoid cells. New techniques of visualizing the bone marrow microenvironment and improvements in genetic manipulation will lead to further insights into the biological significance of bone cells in regulating immune cell development.

7 CONCLUSIONS

The bone is a multifunctional organ that both regulates itself and responds to a range of stimuli, including calcium intake, mechanostress, aging, and inflammation. As the bone carries out diverse functions related to the needs of the skeletal, endocrine, and immune system, studies on bone have been carried out by researchers from different disciplinary fields. However, integrating the knowledge from each discipline is necessary to understand the multifunctional aspects of bone. Osteoimmunology is a good example of such interdisciplinary unification, and has provided crucial insights needed for the development of novel therapeutic strategies in bone and joint diseases, as well as immune disorders. The findings of osteoimmunology from studies on bone destruction in RA will provide a critically important context for a better understanding of other skeletal diseases as well.

CHAPTER

17

Integrating Endocrine and Paracrine Influences on Bone; Lessons From Parathyroid Hormone and Parathyroid Hormone-Related Protein

T. John Martin, Natalie A. Sims

St Vincent's Institute of Medical Research, University of Melbourne, Melbourne, Australia

1 BONE REMODELING AND MODELING

Bone formation and resorption proceed throughout life. When these processes cause changes in bone shape during skeletal growth, the term *modeling* is used. Modeling takes place from the beginning of skeletogenesis during fetal life until the end of the second decade when longitudinal growth of the skeleton is completed. In the modeling process, bone is formed at a location different from the sites of bone resorption, leading to a change in the shape, or macroarchitecture, of the bone. Modeling is responsible for determining the size and shape of bone, such as the simultaneous widening of long bones and expansion of the medullary cavity by coordinated bone formation at the periosteal surface with resorption at the endosteal surface. In contrast, *remodeling* is an adaptive process that occurs throughout life, whereby small packets of bone are resorbed, and then replaced asynchronously all over the skeleton at anatomically distinct sites termed basic multicellular units (BMUs). This process is an integral part of the calcium homeostatic system and provides a mechanism for repair and adaptation to physical stress. Remodeling thus maintains the mechanical integrity of the skeleton by replacing old with new bone, and repairing damaged bone.[1–4] Remodeling is most rapid early in life, and becomes slower from about the third decade in human subjects. It continues with age and in women accelerates over the years of the menopause that are associated with a net bone loss.

The maintenance of adequate trabecular and cortical bone requires that bone formation and resorption are balanced at the BMU during bone remodeling, such that a high or low level of resorption is usually associated with a similar change in the level of bone formation. The theory that resorption is followed by an equal amount of formation, known as "coupling," refers to the process of information transfer within the BMU, by which the level of resorption within each BMU is matched with an equal amount of bone formation. However, the effects of growth and aging during life, including changes in mechanical stress, mean that this theory of equal bone replacement rarely holds true. During growth there is a positive balance, with the amount of bone replaced at individual BMUs exceeding that lost[2] and with ageing gradual attrition of bone occurs due to a negative balance at individual BMUs.[5] In common metabolic states, such as postmenopausal osteoporosis, while coupling exists and both bone formation and resorption are occurring at a higher level than normal, the amount of bone formed is not equal to that resorbed and bone density reduces. The mechanisms involved in remodeling and coupling have been the subject of a number of recent reviews.[6,7]

Until the early 1980s it was understood that circulating hormones and mechanical forces were the primary regulators of bone metabolism. Although both of these are important, the key influences on both modeling and remodeling are now understood to be locally generated. In this chapter we use parathyroid hormone (PTH) and PTH-related protein (PTHrP) as a prime example of how endocrine and related paracrine factors can affect the skeleton.

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00017-4

2 PARATHYROID HORMONE AND PARATHYROID HORMONE-RELATED PROTEIN

The main role of PTH in bone metabolism has been long recognized to be maintenance of calcium homeostasis; PTH releases calcium into the circulation from bone and prevents calcium loss through the kidney, and indirectly, increases calcium absorption through the gastrointestinal tract.[8] The fact that hypercalcemia in many cancers reproduced the biochemical features of primary hyperparathyroidism but without immunoreactive PTH, provided the stimulus to search for a tumor-derived factor with similar properties.[9–11]

The discovery of PTHrP as the factor causing the humoral hypercalcemia of malignancy (HHM)[12] revealed a protein that shared a common receptor with PTH. Each protein was shown by both structural and functional studies to have its receptor binding region and activation domain contained within the first 34 amino-acid residues.[12,13] The two proteins were derived by an early gene duplication event from a common precursor. While PTH is an 84 amino-acid molecule, human PTHrP exists as 139, 141, and 173 amino acid isoforms that each arise by alternative mRNA splicing. Of the first 13 residues of PTH and PTHrP, 8 are identical, with no other identities greater than would be expected by chance. The marked conservation of the PTHrP amino acid sequence up to position 111 throughout many species indicates that important functions might reside within this region.

Both PTH and PTHrP initiate their effects by binding with equal affinity to the same G protein-coupled PTH-receptor-1 (PTHR1).[14] Within bone PTHR1 is expressed in cells of the osteoblast lineage, with greater expression in more mature cells, including osteocytes.[15,16] PTHR1 is also expressed in the kidney tubule. Binding of either peptide to PTHR1 results in activation of adenylyl cyclase/cAMP and protein kinase A (PKA) through $G_s\alpha$, and of calcium/inositol phosphate and protein kinase C through the Gq family of signaling proteins.[14] Activation of either signaling pathway confers a unique array of gene expression, with most changes in gene regulation associated with PKA stimulation. To the present time no unique genetic targets of PTHrP versus PTH have been identified in bone.[17]

Continuous exposure to PTH leads to increased bone resorption and bone loss whereas intermittent administration leads to increased bone mass.[18,19] This is the case also for PTHrP treatment, at least as determined by studies using amino-terminal peptides, such as PTHrP(1–36) and (1–34).[20,21] The cellular and molecular mechanisms by which PTH and PTHrP exert their actions will be considered further, and with our focus on endocrine and paracrine influences on bone, we will attempt to put PTHrP into perspective as the local ligand in bone for the PTH/PTHrP receptor (PTHR1).

3 PTHrP IN BONE; PRODUCTION IN OSTEOBLASTS

Evidence for skeletal production of PTHrP came from several sources. PTHrP protein was identified immunologically in normal human rat fetal bone and cartilage[22–24] and PTHrP mRNA was detected in human and rat osteoblastic sarcoma cell lines,[25] in rat osteoblast-rich cultures and preosteoblastic cell lines,[26,27] and in primary cultures of human bone-derived cells.[28] In situ hybridization analyses localized PTHrP to active osteoblasts on the bone surface of newborn rat calvarial sections[26] and also to spindle-shaped cells of the periosteum, which may represent immature preosteoblasts.[26,29] In areas of endochondral bone formation, PTHrP mRNA was detected in the perichondrium and in maturing chondrocytes in a cell-type and stage-specific manner during fetal rat development.[29] In a rabbit model of intramembranous bone formation, PTHrP mRNA and protein were detected at high levels in osteoblastic cells throughout the bone formation process, including in mature, actively synthetic osteoblasts and matrix-embedded osteocytes.[30]

4 PTHrP FUNCTION IN BONE; LESSONS FROM PTHrP NULL MICE

PTHrP null mice were born with severe skeletal abnormalities and died soon after birth, most likely from respiratory failure, due to defective rib cage formation. Their multiple defects in skeletal development indicated the importance of PTHrP in fetal bone development,[31] but made it difficult to assess the role of PTHrP in adult bone. Whereas haploinsufficient PTHrP(+/−) mice were phenotypically normal at birth, by 3 months of age low bone mass was noted, with markedly lower trabecular thickness and connectivity than controls, and an abnormally high number of adipocytes in the bone marrow.[32] The low bone mass was caused by decreased recruitment of bone marrow precursors and increased osteoblast apoptosis compared to wild type. The role of local osteoblast-derived PTHrP in the process of bone formation was confirmed when this phenotype was recapitulated in transgenic mice with an osteoblast-specific knockout of PTHrP.[33] These mice also demonstrated reduced osteoclast formation, likely due to impaired ability of PTHrP-null osteoblasts to support osteoclast formation. Importantly, mice with PTHrP-deficient osteoblasts were normocalcemic, emphasizing that, unlike the systemic action of PTH, PTHrP paracrine action in bone is not required for calcium homeostasis.

These genetic experiments thus revealed actions of PTHrP that reproduce the known effects of therapeutic application of PTH: to stimulate bone formation by promoting the differentiation of committed osteoblast

precursors and by inhibiting apoptosis of mature osteoblasts and osteocytes.[34] The efficacy of PTH as a skeletal anabolic therapy (i.e., one that increases bone mass) has been established for osteoporosis,[35] and depends on intermittent injections, each achieving a sharp peak of PTH in the blood.[36] More sustained elevation of PTH levels favors osteoclast formation through a prolonged elevation in receptor activator of NF-κB ligand (RANKL) production, which promotes osteoclast production from hemopoietic precursors.

What are the ways in which PTHrP can act as a paracrine/autocrine factor in bone? If local PTHrP levels were persistently high, this could favor osteoclast formation by stimulating RANKL production by the osteoblast lineage. Therefore it might be supposed that for PTHrP to enhance osteoblast differentiation and reduce osteoblast apoptosis, as suggested by the phenotypes of the haploinsufficient and osteoblast-specific PTHrP null mice, control mechanisms must exist to ensure that only short-lived, high levels of PTHrP are available to local targets in order to favor bone formation.

We can only speculate about the nature of the PTHrP molecule that gains access to its adjacent target cells. Is full-length PTHrP secreted, and is that the predominant form that interacts locally with target cells? Does its susceptibility to proteolytic breakdown[37] yield shorter products, even in that local environment? Also to be kept in mind is the strong likelihood that biological activities are exerted by those domains of PTHrP released through proteolytic cleavage. This was exemplified in two studies in mice. In one of these, a knock-in of PTHrP(1–84) lacking both the nuclear localization sequence and C-terminal region while retaining the PTHR1-interacting amino-terminal, resulted in multiple abnormalities and early lethality in mice.[38] Homozygous mice exhibited skeletal growth retardation and osteopenia associated with reduced proliferation and increased apoptosis of osteoblasts. These mice also exhibited early senescence with altered expression patterns and subcellular distribution of proliferative- and senescence-related genes in multiple tissues. In the second model, a knock-in of PTHrP(1–66) which excluded a significant part of the midregion, resulted in a similar, but even more severe phenotype.[39] These mouse genetic studies suggest that many of the actions of PTHrP are not mediated by the PTH1R-interacting amino-terminal region; among the generalized abnormalities, absence of the midregion, nuclear localization sequence, and C-terminal region result in greatly impaired commitment and survival of osteogenic and hematopoietic precursors. Mitogenic and antiapoptotic actions of PTHrP nuclear and C-terminal regions have been noted in smooth muscle,[40] chondrocytes,[41] and breast cancer cells[42]; similar actions may occur in osteoblasts with their absence being responsible for the phenotypes observed.

Perhaps PTHrP release would need to be exquisitely regulated in terms of concentration, location, and time so that in bone remodeling it is presented only briefly to its nearby target cells. On the other hand, the spatio-temporal controls might be such that excessive osteoclast formation is much less likely under physiological conditions, where active BMUs are only in place where required for maintenance of the skeleton, and are therefore relatively limited in number. On the other hand when PTH is presented systemically as a pharmacological agent, new and existing BMUs are activated throughout the skeleton. At the end of this chapter we will present an argument for the proposal that paracrine PTHrP in its remodeling role operates at any one time only at those BMUs that are active, whereas systemic administration of PTH (or of analogs) results in widespread BMU activation, with the consequent possibility of resorption activation, and even of hypercalcemia.

5 ANABOLIC ACTIONS OF PTH AND PTHrP

The anabolic effects of intermittent PTH administration on bone and its therapeutic potential in osteoporosis have been extensively studied. There are several mechanisms proposed for the PTH anabolic effect that require its direct action upon the osteoblast lineage. One is the promotion by PTH of differentiation of committed osteoblast precursors,[18] another being inhibition of osteoblast apoptosis,[43] and a third being action upon the osteocyte to inhibit the production of sclerostin, a powerful inhibitor of bone formation.[44] There are also a number of indirect effects of PTH action, which are discussed in more detail later.

The anabolic effect of PTH is the result predominantly of stimulating remodeling by increasing the number and activity of BMUs, with a net increase eventually in the amount of bone at each BMU.[45–47] There is some effect on modeling also, some of this relating to "overfilling" of BMUs.[47] Consistent with the idea of PTH stimulating remodeling are the observations that the anabolic effect of PTH is greater on trabecular and endocortical bone than on periosteal bone.[35,48] The PTH effect in human subjects is particularly marked on the endocortical surface, which remodels very actively in old age.[49] Making a distinction between remodeling and modeling effects of PTH anabolic treatment becomes important when considering the use of PTH in subjects treated with maximally effective resorption inhibitors, where the osteoclast formation and activity essential for remodeling is prevented.[50,51]

Although PTHrP(1–34) has an anabolic effect when administered therapeutically,[20] the pathogenesis of hypercalcemia in HHM largely reflects the bone-resorbing

properties of PTHrP. With the recognition that PTHrP is the paracrine ligand for the PTHR1 in bone,[33,52] several truncated forms including the PTHR1-interacting portion of the molecule have been investigated as anabolic agents, including PTHrP(1–34), PTHrP(1–36), and PTHrP(1–74). The anabolic action of PTHrP(1–36) in human subjects, as assessed by measurement of bone formation markers, has been suggested to be relatively free of the resorptive effect that is an essential component of the remodeling effect of PTH treatment.[21,36,53,54] In these studies of PTHrP(1–36) daily injection, the doses required to increase levels of anabolic markers are many-fold higher than those of PTH(1–34), even though the two appeared to be equipotent in acute infusion studies of their effects on serum calcium and phosphorus, urinary phosphate handling and nephrogenous cAMP.[55] The possibility of PTHrP(1–36) being purely anabolic[54] is an intriguing one, if difficult to explain. It might be due to a difference in pharmacokinetics of the two, with PTHrP(1–36) degraded more rapidly following injection, and thus not so widely distributed to activate BMUs. The result would be that lesser amounts of active agonist would be made available to PTHR1.

Another explanation has been proposed, based on studies of interaction with the PTHR1 of PTH(1–34) and PTHrP(1–36). In cells engineered to overexpress PTH1R, PTHrP(1–36) and PTH(1–34) differed in their initial receptor interaction mechanisms; the action of PTHrP(1–36) was restricted to the cell surface, while PTH(1–34) was more readily internalized and brought about a more prolonged increase in cyclic AMP in the target cells.[56] The authors suggested that such a differential response might explain why daily injection of PTH(1–34) exhibits a resorption response, while PTHrP(1–36) does so to a much lesser extent. The same argument has been applied to a new analog, abaloparatide, which is identical to PTHrP in its first 21 residues, but has 8 residues different from PTHrP between 22 and 34,[57] and which has also been suggested to have a lesser effect on resorption markers than PTH(1–4) in patients.[58] Abaloparatide behaves in a similar manner to PTHrP(1–36) in the study of initial interaction with receptor.[59] These are interesting cell biology findings, but extrapolating them to provide an explanation for in vivo effects is questionable, without any evidence of differences in cellular effects beyond cyclic AMP generation. It is relevant to note that the nature of PTHrP presented to its target physiologically in bone is not known. In the absence of any data there is no reason to suppose that it presents as PTHrP(1–36). The schema proposed in Fig. 17.1 and discussed later in this chapter is relevant to this point.

6 ENDOCRINE PTH, PARACRINE PTHrP; RELATIONSHIPS IN DEVELOPMENT AND POSTNATAL LIFE

Using a variety of validated assays, circulating PTHrP cannot be convincingly detected in normal human subjects (e.g.[60]). That observation gave rise to the view, soon proved to be correct, that any noncancer role for PTHrP must be as a local paracrine factor. It was clear that in the HHM syndrome, PTHrP is secreted by tumors, circulates as a hormone and acts upon bone and kidney.[60,61] In that situation and in lactation where PTHrP is made in the breast and reaches the circulation,[62] the increased circulating PTHrP exerts effects that very closely mimic those of excess PTH. In fetal life, where PTHrP is made by the fetal parathyroids and placenta, it regulates maternal-to-fetal placental calcium transport.[63] In contrast to these

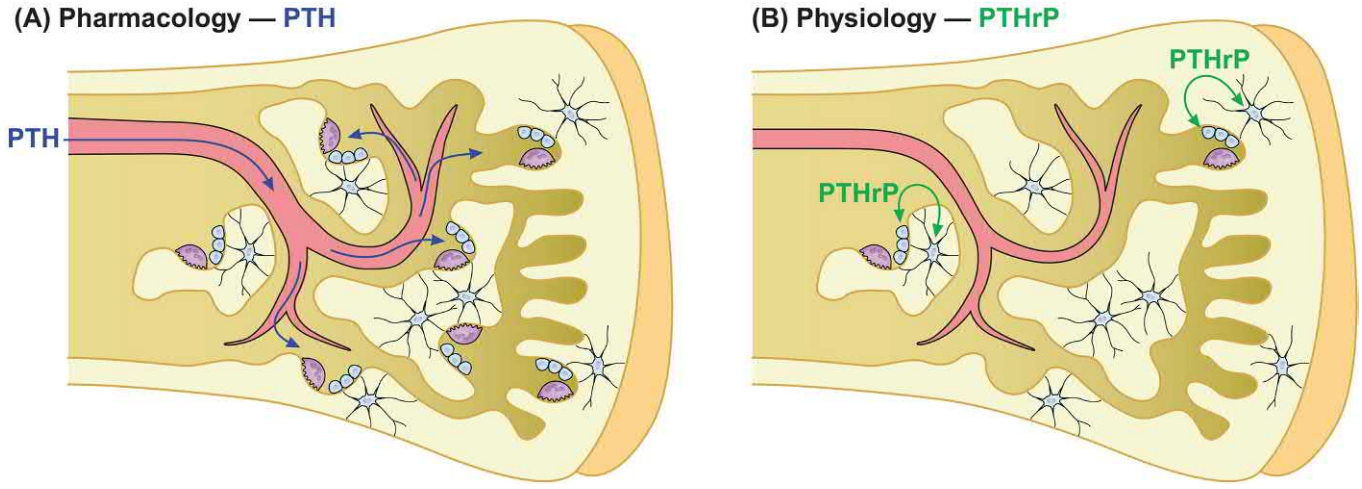

FIGURE 17.1 Contrasting ways in which locally derived parathyroid hormone related protein (PTHrP) and systemically delivered parathyroid hormone (PTH) interact with basic multicellular units (BMUs) in bone remodeling. Whereas systemic PTH is available for widespread activation, resulting in progressively increasing active BMUs, and including dilatation of bone blood vessels (A), locally produced PTHrP acts in those BMUs that are recruited in the normal remodeling process (B). See text for details.

special circumstances in which it functions as a hormone, PTHrP came to be viewed as normally having an autocrine or paracrine role in several different organs of the body.[64,65]

Since the parathyroid glands only develop after mesenchymal condensations are formed at sites of skeletal development, it is the paracrine/autocrine factor PTHrP, secreted locally by chondrocytic cells, that plays the prime role in endochondral bone formation. Studies by Lanske et al.[66] and Vortkamp et al.[67] show that PTHrP and the PTHR1 are downstream effectors of the Indian hedgehog pathway, regulating the correct spatial and temporal progression of chondrocyte differentiation that determines the rate and extent of long bone formation. In this instance, PTHrP has a paracrine role, making use of the PTHR1. A similar paracrine mechanism has been proposed for the skin, where it was shown that PTHR1 is expressed in fibroblasts but not in keratinocytes.[68]

Functional genetic studies have helped to define the relative roles of PTH and PTHrP in calcium homeostasis and bone. The clinical features of hypoparathyroidism in human subjects were recapitulated in adult mice with global ablation of PTH including hypocalcemia and hyperphosphatemia, with increased trabecular and cortical bone volume and a low level of bone remodeling.[69] In contrast, neonatal skeletons had defective growth plate and primary spongiosa development, resulting in less trabecular bone than controls due to decreased osteoblast numbers, as well as hyperporous, nonremodeled cortical bone.[69]

The relationship between the two was investigated further by generating PTH null mice that were haploinsufficient for PTHrP.[70] These mice were still hypoparathyroid, but the PTHrP haploinsufficiency prevented the increase in cortical thickness and reversed the high trabecular bone mass of PTH deficient mice. In this instance, trabecular bone mass was lower than wild type, associated with decreased osteoprogenitor recruitment, increased osteoblast apoptosis, and decreased bone formation. The conclusion therefore was that the PTH null phenotype of increased trabecular bone was caused by increased local production of PTHrP. Whereas in the fetus PTH is essential for bone mineralization and for recruiting osteoprogenitors with locally generated PTHrP being necessary for their future differentiation,[69,70] postnatally, PTH acts on bone primarily to cause resorption and thereby contribute to the maintenance of extracellular fluid calcium. It was clear also in these experiments that PTHrP cannot compensate for the hypocalcemia resulting from PTH insufficiency. Therefore PTHrP does not contribute directly to the maintenance of serum calcium postnatally, but is the main factor stimulating new bone formation, in addition to its actions in development to direct growth plate development by controlling chondrocyte proliferation and differentiation.

Importantly, the mouse genetic studies did not identify an anabolic role for the circulating hormone, PTH, in the adult. Indeed it is difficult to envisage how a circulating hormone could regulate BMUs that are activated asynchronously throughout the skeleton in response to local need. It remains possible though, that circulating PTH could have an anabolic role by influencing bone modeling. Importantly, this could relate to the therapeutic question of whether PTH is capable of any anabolic action when remodeling is totally blocked by powerful resorption inhibitors.[6,50,51]

7 ARE OSTEOCLASTS INVOLVED IN THE ANABOLIC ACTION OF PTH?

The thought that osteoclasts are required for the anabolic action of PTH first arose when the anabolic effect of PTH was significantly reduced in sheep coadministered with a bisphosphonate (tiludronate) as an inhibitor of bone resorption.[71] Treatment of osteoporotic patients concomitantly with PTH and a bisphosphonate resulted in significant early blunting of the anabolic response to PTH,[72,73] with full PTH responsiveness eventually returning after treatment was stopped. Some, but not all studies of the PTH anabolic effect in rats treated concomitantly with bisphosphonates have also shown impaired anabolic responses.

If an osteoclast function is required for the anabolic effect of PTH, how is that connection made since osteoclasts do not express a functional PTH receptor? In rats a single subcutaneous injection of PTH resulted in a transient increase in mRNA for RANKL and a decrease in that for OPG, with maximum effect at 1 h that returned to control within 3 h, contrasting with a persistent elevation of RANKL mRNA observed with a 6 h infusion of PTH.[74] This led to the suggestion that a subtle or transient increase in osteoclast formation or activation might be needed to prepare the bone surface for new matrix deposition. The demonstration that PTH could rapidly stimulate osteoclasts came 30 years ago,[75] showing that intravenous injection of PTH in young rats resulted in transient activation of osteoclasts in vivo, evident within 30 min, and followed only some hours later at high PTH doses by increased osteoclast number. The rapid nature of this response might be explained by the existence of quiescent osteoclast precursors in the proposed osteoclast niche.[76]

Observations in genetically manipulated mice and from human genetics suggest that the osteoclast itself could also be the source of an activity that contributes to the fine control of osteoblast function in bone remodeling,[77,78] and that this might contribute to the anabolic action of PTH. In mice with a high level of bone remodeling induced by a mutation in the receptor used by all

IL-6 family cytokines, glycoprotein 130 (gp130$^{Y757F/Y757F}$ mice) low trabecular bone mass was observed because the level of resorption was relatively greater than that of formation. Thus the coupling process was dissociated in a manner resembling that of estrogen withdrawal. gp130$^{Y757F/Y757F}$ mice crossed with IL-6 null mice had similarly high osteoclast numbers and increased bone resorption, however these mice showed no corresponding elevation in bone formation and thus had extremely low bone mass. This indicated that stimulation of bone formation coupled to the high level of bone resorption in gp130$^{Y757F/Y757F}$ mice was an IL-6-dependent process, but not necessarily showing that it is mediated by IL-6 itself.[79]

Furthermore, in mice deficient in either c-*src*,[80] Pyk2,[81] cathepsin K,[82] or the chloride-7 channel (ClC-7),[83] bone resorption is inhibited without inhibition of bone formation. In each of these knockout mouse lines osteoclast resorption is greatly reduced by the mutation, although osteoclast numbers are not. Indeed in all these cases osteoclast numbers are actually increased, possibly because of reduced osteoclast apoptosis.[84,85] A possible explanation of the uncoupling of resorptive activity and bone formation in these mice is that these osteoclasts, although unable to resorb bone, remain capable of generating a factor (or factors) required for bone formation. This is illustrated by the findings that *c-src*$^{-/-}$ mice retain an anabolic response to PTH injections,[86] whereas mice lacking c-*fos*, which are unable to generate osteoclasts, have reduced bone formation as well as resorption, and show a marked blunting of the anabolic action of PTH.[87]

The foregoing led to the suggestion that what is needed for full expression of the anabolic response to PTH, in addition to its direct effect on the osteoblast lineage, is a transient effect on the osteoclast, achieved by promoting activation, but not necessarily formation of new osteoclasts (Fig. 17.2).[17,77] A number of candidate osteoclast products, termed "coupling factors" have been proposed for this role.[7,88–92] One such pathway is EphrinB2–EphB4, which was suggested following the finding that osteoclast-derived ephrinB2 acts through a contact-dependent mechanism on EphB4, its receptor in the osteoblast, to promote osteoblast differentiation and bone formation.[93] If such a coupling mechanism were to operate it would require many sites of contact between active osteoclasts and differentiating osteoblasts; this appears to occur very uncommonly. Further, the dramatic upregulation of osteoblastic expression of EphrinB2 by PTH suggested that the interaction of EphrinB2 and EphB4 may also be important for the anabolic action of PTH.[17] However, it seems that the need for EphrinB2–EphB4 signaling in the context of PTH action is not one where communication between osteoblasts and osteoclasts is required. In contrast, it is the interaction between EphrinB2 and EphB4 within the osteoblast lineage that is most important. This was established by showing that the PTH anabolic effect was largely blunted both in mice with osteoblast-specific ablation of EphrinB2,[94] and in mice treated with a systemic

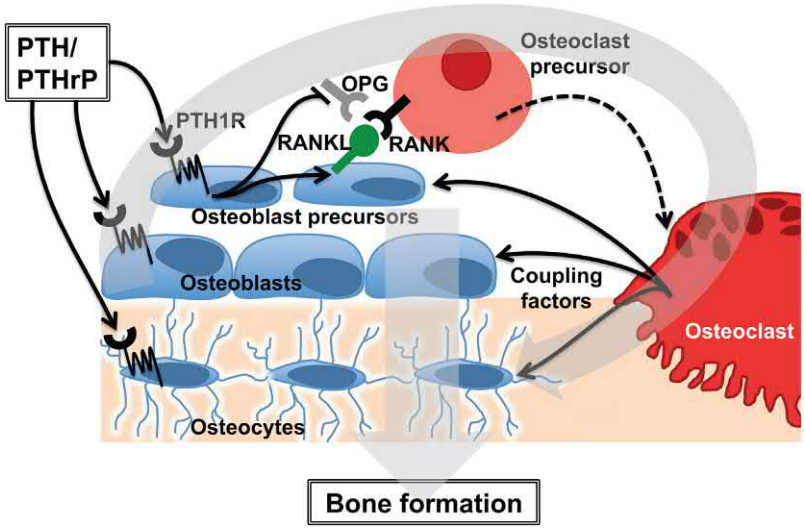

FIGURE 17.2 The communication cycle between osteoblasts and osteoclasts that contributes to PTH and PTHrP anabolic action. PTH and PTHrP act on the PTH receptor (PTH1R) expressed in the osteoblast lineage in committed osteoblast precursors, bone forming osteoblasts and matrix-embedded osteocytes to stimulate bone formation. In addition, PTH receptor action stimulates production of receptor activator of NF-κB ligand (RANKL) and inhibits production of the RANKL decoy receptor osteoprotegerin (OPG). RANKL interacts with its receptor (RANK) on osteoclast precursors to stimulate their differentiation into bone-resorbing osteoclasts. Osteoclasts provide a range of factors, both proteins produced by osteoclasts and growth factors released by their resorption of bone matrix. These coupling factors stimulate bone formation by actions on each stage of osteoblast differentiation. The sum of both the direct action of PTH on the osteoblast lineage, and the stimulation of osteoclast-derived coupling factors, is an increase in bone formation.

inhibitor of the EphrinB2–EphB4 interaction.[95] Further to this, blocking the interaction between EphrinB2 and EphB4 in vitro within the osteoblast lineage reduces osteoblast differentiation and the mineralizing capacity of osteoblastic cells.[17,96] In vivo evidence consolidating this view of the importance of EphrinB2–EphB4 interaction within the osteoblast lineage, not only in the context of PTH anabolic action, but also during normal bone physiology, was that knockout of EphrinB2 in the osteoblast lineage using an Osx-Cre promoter resulted in mice with delayed osteoblast differentiation, increased apoptosis, and reduced mineralization.[94]

Other possibilities for osteoclast-derived factors that could promote osteoblast differentiation include sphingosine-1-phosphate, BMP-6, and Wnt 10b.[88] It might be noted that Wnt10b production by T cells in response to PTH is offered as the explanation for the T cell-mediated effect of PTH on bone formation (see later).[97] Another possibility is cardiotrophin-1 (CT-1), a member of the family of cytokines that signal through the gp130 transducer. This cytokine is expressed in differentiated osteoclasts but not in the osteoblast lineage.[98] As well as indirectly stimulating osteoclast differentiation through stimulation of RANKL production by stromal cells, CT-1 powerfully stimulates bone formation. CT-1, like oncostatin M (OSM), leukemia inhibitory factor (LIF), and PTH, also profoundly decreases sclerostin mRNA expression by osteocytes,[99] thus introducing the concept that osteoclast products might communicate with the osteoblast lineage by signaling directly to the osteocyte (Fig. 17.2).

Whether the osteoclast, either by its resorptive actions or by its production of factors that influence osteoblasts, contributes significantly to the anabolic action of PTH remains a matter for further investigation.

8 GROWTH FACTORS IN THE LOCAL ACTIONS OF PTH AND PTHrP

The role of locally generated growth factors in bone has been explored extensively since the suggestion that bone formation might be coupled to bone resorption by the release of bone forming factors from the bone matrix during resorption (Fig. 17.2).[100] Among matrix substances that could promote osteoblast mitosis or stimulate bone formation in vivo were insulin-like growth factor (IGF) I and II, acidic and basic fibroblast growth factor (FGF), transforming growth factor β (TGFβ) 1 and 2 and TGFβ heterodimers, bone morphogenetic proteins (BMPs) 2, 3, 4, 6, and 7, platelet-derived growth factor, and probably others.[101–104] Most attention has been paid to TGFβ and IGF-1.

Although liver IGF-1 is regulated largely by growth hormone secreted from the pituitary, this is not the case for IGF-1 production in nonliver tissue, such as bone. IGF-I and IGF-II are produced by osteoblasts, and this production is enhanced by PTH stimulation of bone formation.[105,106] When injected together with the IGF-binding protein IGFBP-3 into rats, IGF-I was reported to increase bone volume.[107] Ablation of the IGF-1 receptor in mice resulted in decreased bone mass, despite increased osteoid volume and surface, establishing a likely important role for IGF-1 in bone mineralization.[108] In these mice, and in mice with either global or osteoblast-specific IGF-I deficiency, both the anabolic and catabolic responses to PTH were significantly impaired.[109,110] The conclusion from the mouse studies is that IGF-1, generated locally by cells of the osteoblast lineage, has a significant part to play in the anabolic effect of PTH. The anabolic IGF1 action has been specified to show stimulation of differentiation of recruited stromal stem cells by activating mammalian target of rapamycin (mTOR).[111] The concept surrounding involvement of IGF1 in PTH action has been extended by recent evidence that PTH acts upon osteoblast lineage cells to stimulate aerobic glycolysis, that is, increased glucose consumption and lactate production in the presence of oxygen.[112] This effect is secondary to the increased IGF1 in response to PTH, and notably, pharmacological blockade of glycolysis suppressed the bone anabolic effect of intermittent PTH. The aerobic glycolysis effect and the further link to IGF1 raise interesting questions concerning the local physiological mechanism of PTHrP action, in particular, whether a PTHrP/IGF1 relationship operates in activated BMUs, switching osteoblast lineage cells to produce energy through aerobic glycolysis.

The link between TGFβ and the anabolic effect of PTH is a strong one. When TGFβ is injected next to the periosteum or endosteum, there is a substantial increase in local bone formation in rats and other species.[113,114] Although the local balance is clearly positive, there is also an increase in endocortical bone resorption at the same time. Thus, like IGF-I, and TGFβ seems to stimulate both resorption and formation. Indeed, transgenic overexpression of TGFβ in mice resulted in high turnover bone loss.[115]

Bone is an abundant source of TGFβ. It was proposed that TGFβ, which is produced as an inactive precursor in bone by osteoblasts,[116] is stored as an inactive precursor in the matrix and activated by proteolytic cleavage accomplished by the acid resorptive environment.[117] TGFβ is produced by all osteoblastic cells examined and its production is increased by PTH. The PTH anabolic effect in bone was accompanied by progressive increases in IGF-1 and TGFβ,[105] leading the authors to suggest that both growth factors play roles in the anabolic effect of PTH. Some support for this comes from more recent evidence that active TGFβ1 released during bone resorption couples bone formation to resorption by inducing the migration of bone mesenchymal stem cells to sites of prior resorption, thus making them available for

differentiation and bone formation in remodeling.[118] This would provide an attractive explanation for the concept that osteoblasts are recruited for remodeling from a pool of stem cells, and need to be attracted to remodeling sites to be differentiated and replenish the osteoblast population. Consistent with this idea, when bone resorption was inhibited with a bisphosphonate, so too was the release of active TGFβ and the recruitment of Sca-1+ve stem cells to remodeling sites.[119] This was associated with decreased bone formation. It remains difficult to see how tight quantitative control of the amount of active TGFβ can be exercised if it depends solely on the acidic pH at resorption sites. It may be that the necessary quantitative control is left to the next stage—influences upon the stem cells when they reach the remodeling site. Furthermore, while an action of TGFβ to promote stem cell migration to appropriate sites is plausible, such an effect might contribute to the overall process by which bone formation follows bone resorption. It fits less easily as a mechanism for rapid changes in bone remodeling.

A further level of regulation arises from evidence of an even more intimate association between PTHR1 and TGFβ receptor signaling, with the findings that the TGFβ receptor II (TβRII) can phosphorylate the PTHR1, switching it off by promoting its endocytosis as a PTH1R–TβRII complex.[120] Supporting this model, deletion of TβRII in osteoblasts increased cell surface PTHR1 and signaling, resulting in a bone phenotype similar to that of mice with constitutively active PTHR1.

These findings indicate that active TGFβ is generated at resorption sites, possibly enhanced by PTH/PTHrP, that skeletal stem cells can respond to this TGFβ by mobilizing to remodeling sites, and that TGFβ signaling might control the extent of PTH/PTHrP signaling. These functions answer some of the questions that should be considered regarding the role of local growth factors in the hormone- and cytokine-mediated coupling of bone formation to bone resorption: (1) Which cells produce them and under what circumstances? (2) Do they stimulate bone formation in vivo? (3) Can they be released from the matrix in active form and in controlled amounts during bone resorption? (4) Is there any evidence for an increase in the abundance of these active factors at sites of bone remodeling? and (5) are there regulated mechanisms by which they are activated?

9 gp130 CYTOKINES AS AGENTS OF LOCAL CONTROL OF PTH ACTION

gp130 is a receptor subunit capable of intracellular signaling that is required for the cellular action of the IL-6 family of cytokines. The most well-known are interleukin IL-6 and IL-11, LIF, CT-1, OSM, and ciliary neurotrophic factor. In addition to contributing to inflammation, gp130 signaling cytokines also function in the maintenance of bone homeostasis. Expression of each of these cytokines and their ligand-specific receptors is observed in bone and joint cells,[121,122] and bone-active hormones including PTH and inflammatory cytokines regulate their expression by osteoblasts.[123] gp130 signaling cytokines have been shown to promote the differentiation and activity of osteoblasts, osteoclasts, and chondrocytes. Furthermore, gene-knockout mouse models of cytokines and receptors in this family have identified distinct roles for each of these cytokines in regulating bone resorption, bone formation, and bone growth, and there is much evidence for their roles in the pathogenesis of bone and joint disorders.[124]

The initial interest in gp130 signaling in bone came from its role in the promotion of osteoclast formation. Together with cyclic AMP/PKA and the vitamin D nuclear receptor, gp130 signaling comprised the third major pathway in osteoblastic stromal cells capable of generating osteoclasts in cocultures with hematopoietic cells,[125] ultimately shown to be due to promotion of RANKL production.[126] Thus in such cocultures, treatment with IL-6 and its soluble receptor (sIL-6R) induced osteoclast formation, as did IL-11, OSM, CT-1, and very mildly, LIF, all of which use gp130 as a common transducer.[127,128] When cells from IL-6R-overexpressing transgenic mice were used in crossover cocultures with hematopoietic cells from wild-type mice, the expression of IL-6R by osteoblastic cells was shown to be indispensable for the induction of osteoclasts by IL-6.[129] This clearly demonstrated that, like PTH, stimulation of osteoclast formation by IL-6 required direct action on the osteoblast. A central role of the gp130-coupled cytokines in osteoclast development stimulated by a range of hormones and cytokines was further indicated by the observations that PTH; $1,25(OH)_2D_3$; PGE_2; IL-1; and TNFα all promoted IL-11 production by osteoblastic cells (Fig. 17.3)[130] and addition of neutralizing anti-gp130 to cocultures fully blocked stimulation of osteoclast formation by IL-1, and partly blocked osteoclast formation in response to PTH; $1,25(OH)_2D_3$; and PGE_2.

In mice null for individual ligands or receptor components involved in gp130 signaling, the osteoclast phenotype varies. Adult IL-6 null mice demonstrate normal numbers of osteoclasts, indicating that this cytokine's role in osteoclastogenesis can be compensated for by other factors. However, IL-6 appears to be required for the increased osteoclastogenesis observed in ovariectomy (see later),[131] in catabolic PTH infusion, where IL-6 potentiated the bone-resorbing effect of PTH[132] and in bone destruction in inflammatory arthritis.[133] Genetic deletion of CT-1, LIF, and LIFR all lead to increased osteoclast formation in vivo,[98,134,135] while osteoclast numbers are low in IL-11R and oncostatin M receptor (OSMR) deficient mice.[121,136] This indicates that these cytokines are

required for normal osteoclastogenesis and normal bone remodeling, and their roles are not redundant.

While osteoclasts express only gp130 and IL-6R and respond to IL-6 with increased STAT3 phosphorylation,[137] both osteoblasts and osteocytes respond to many members of this family since they express not only gp130, but also many of the ligand-specific subunits required for cytokine action (IL-6R, IL-11R, CNTFR, LIFR, and OSMR).[99,138,139] OSM, CT-1, IL-11, and LIF all stimulate osteoblast differentiation from stromal cells, and at the same time reduce the ability of these cells to differentiate into adipocytes (Fig. 17.3).[98,121,140] Even though OSM, LIF, CT-1, and IL-11 have the same action on cells in culture, their effects on osteoblast and adipocyte differentiation in vivo are not redundant, since CT-1, LIF, IL-11R, and OSMR deficient mice all demonstrate a low level of bone formation in vivo and increased adipocyte volume within the bone marrow space.[98,121,136,140] The nonredundant roles of these cytokines may stem from the cell-types and conditions under which these cytokines are expressed. For example, in the BMU, CT-1 is expressed only by the osteoclast, while OSM is not expressed in osteoclasts, but is expressed in all osteoblast-lineage cells including osteocytes, as well as activated macrophages within the bone marrow.[141]

OSM, CT-1, and LIF, like PTH, have also been reported to strongly inhibit osteocytic expression of sclerostin,[121] an essential and powerful inhibitor of bone formation that acts as a Wnt signaling antagonist.[142] Although OSM is capable of signaling through a receptor complex containing either LIFR or OSMR, it appears that its influence on both sclerostin expression and bone formation is mediated specifically by LIFR, while its influences on osteoblast/adipocyte commitment and osteoclastogenesis are mediated by OSMR.[121] This receptor-specific divergence of influence of a single cytokine on osteoblasts and osteoclasts appears to be unique to OSM; LIF and CT-1 both stimulate osteoclast formation and inhibit sclerostin through the LIFR.[121] The specific structural interaction between OSM and the LIFR compared to the interaction of LIFR with its "native" ligands CT-1 and LIF is not yet solved.

OSM uses the OSMR to powerfully induce RANKL production and osteoclast formation.[121] For that reason, OSMR–null mice were used to study the anabolic action of PTH. In these mice, the duration of elevated RANKL expression after PTH treatment is prolonged, although the mechanism by which this occurs remains unknown. The result is that intermittent treatment with PTH in vivo resulted in increased bone resorption that negated the anabolic effect of PTH and resulted in bone loss.[123] This indicates that delivery of PTH in an anabolic mode can be readily converted to a catabolic outcome if the stimulation of RANKL and osteoclastogenesis is sufficiently prolonged.

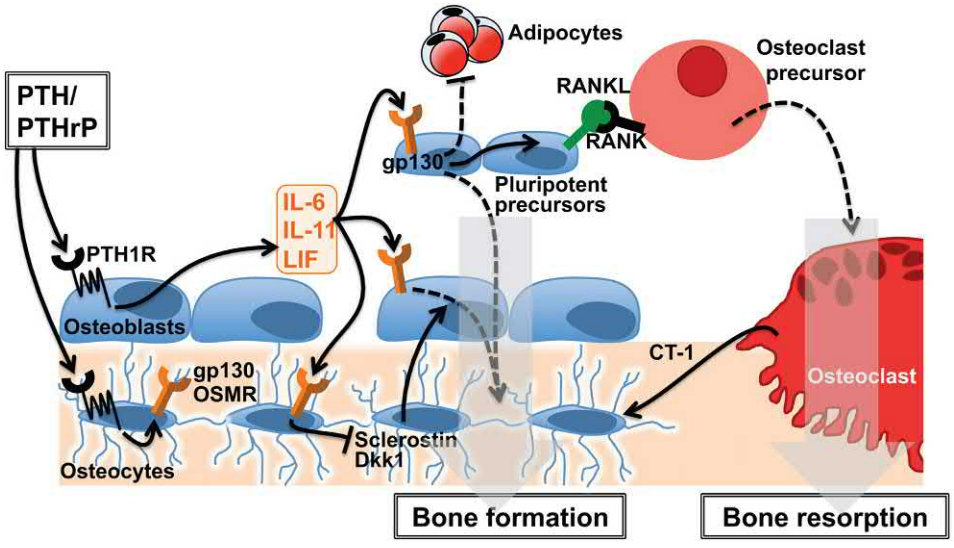

FIGURE 17.3 Contribution of the interleukin 6 (IL-6) family to PTH and PTHrP action in bone. PTH and PTHrP act on the PTH receptor expressed in the osteoblast lineage in committed osteoblast precursors, bone forming osteoblasts, and matrix-embedded osteocytes. This action stimulates production of IL-6 family cytokines including IL-6, interleukin 11 (IL-11) and leukemia inhibitory factor (LIF), as well as promoting expression of the oncostatin M (OSM) receptor (OSMR) and the common receptor for the entire IL-6 family (gp130) in the osteoblast lineage. These locally produced cytokines also act at all stages of osteoblast differentiation. In pluripotent osteoblast precursors they inhibit adipocyte differentiation and promote osteoblast differentiation and bone formation. IL-6 family cytokines promote production of receptor activator of NF-κB ligand (RANKL) that interacts with its receptor (RANK) on osteoclast precursors to stimulate their differentiation into bone-resorbing osteoclasts. IL-6 family cytokines, including cardiotrophin-1 (CT-1) derived from osteoclasts, also act on osteocytes to inhibit production of sclerostin and Dkk1 (Wnt pathway inhibitors); this also promotes bone formation. The action of IL-6 family cytokines on osteocytes is required for PTH anabolic action.

Since IL-6 family cytokines act on osteocytes to inhibit sclerostin expression and signal directly through osteoblasts to promote both bone formation and osteoclastogenesis, it was of interest to determine whether osteoblast-lineage expression of gp130 was required for normal osteoclastogenesis and response to PTH. However, when gp130 was genetically ablated from the osteoblast lineage or in osteocytes (using Osx1Cre or Dmp1Cre, respectively) no significant alteration in osteoclast numbers was observed.[143] In contrast, both mouse models exhibited low trabecular bone mass and reduced cortical material strength due to impaired osteoblastogenesis.[143] In addition, deletion of gp130 in committed osteoclasts again did not result in reduced osteoclast formation, but bone formation was reduced, indicating that any direct effect of IL-6 on osteoclasts promoted its ability to signal to osteoblasts, rather than promoting the activity or differentiation of osteoclasts themselves.[137] Finally, when mice deficient in gp130 in osteocytes were treated with PTH, no anabolic action was observed, either in trabecular or cortical bone.[144] This reduction in PTH anabolic action was associated with reduced expression of PTH1R in osteoblasts lacking gp130 both in vivo and in vitro, which suggests that IL-6 family cytokines promote PTH1R expression. Consistent with this, reductions in the Wnt inhibitors sclerostin and Dkk1, normally associated with PTH treatment were not observed in the gp130-deficient mice (Fig. 17.3). Surprisingly however, the rapid elevations in mRNA levels of RANKL and IL-6 were retained, suggesting that the effect of PTH on osteoclastogenesis may be mediated by osteoblasts at an earlier stage of differentiation than the cells that mediate its anabolic action.

10 SCLEROSTIN AS A LOCAL FACTOR PROMOTING PTH ACTION

As is the case with the gp130 cytokines, downregulation of sclerostin by PTH provides another mechanism through which PTH has its anabolic action. Such a role for sclerostin has been indicated by an impairment in the PTH anabolic effect in both sclerostin deficient, and overexpressing mice,[145] although more recent work suggests this role may be specific to cortical bone.[146] Similar observations have been made in mice that lack Dkk1, another Wnt signalling inhibitor suppressed by PTH.[147] Since one of the major actions of Dkk1 and sclerostin is to prevent the low-density lipoprotein receptor-related protein 5 (LRP5) from contributing to Wnt signaling in bone,[148] it was surprising that the PTH anabolic effect was also not observed in LRP5 deficient mice.[149,150] Furthermore, in one of these studies the osteogenic response to mechanical loading was very greatly reduced in mice LRP5$^{-/-}$ mice.[150] Thus, despite the inadequate processing of a mechanical response to loading, PTH response was maintained, suggesting that the contribution of reduced Dkk1 and sclerostin to the anabolic action of PTH may be independent of LRP5.

Given the dramatic effect of PTH on sclerostin expression, and its contribution to the anabolic action of PTH, it was initially surprising to note a report describing osteocyte-specific deletion of the PTHR1 without a dramatic bone phenotype; only a barely detectable reduction in bone mass was reported.[151] These mice did demonstrate significant hypocalcemia, both under normal conditions, and when hyperparathyroidism was induced by a low calcium diet. This provoked the intriguing suggestion that PTHR1 in osteocytes may regulate calcium homeostasis, either by postulated release of calcium by osteocytic osteolysis, or by osteocyte-mediated influences on the gut or kidney. This may involve fibroblast growth factor 23 (FGF23), a phosphaturic hormone that is produced by osteocytes. Circulating FGF23 levels are increased in hyperparathyroidism.[152] Furthermore, genetically altered mice with constitutively active PTHR1 in osteocytes demonstrate elevated circulating FGF23 levels.[153] This possibility that calcium and phosphate homeostatic effects of PTH may be mediated by osteocytes requires further exploration. The regulation of sclerostin production by gp130 cytokines, particularly OSM[121] might provide an adequate alternative pathway if PTH/PTHrP signaling is blocked.

More recent work on a larger sample size than the initial preliminary study[153] is even more surprising; osteocyte-specific deletion of PTHR1 led to a significant elevation in trabecular bone mass.[154] As expected, these mice exhibited blunted responses to both anabolic and catabolic modes of PTH administration, and blunted sclerostin and RANKL gene responses, confirming a role for osteocytes in these actions of PTH. However, the increased trabecular bone mass and cortical thickness in untreated adult animals suggests that the combination of PTH and PTHrP signaling through the PTHR1 limits accrual of trabecular bone. The increase in bone mass was not associated with any significant alteration in osteoblast or osteoclast numbers, but paradoxically, sclerostin expression was elevated and collagen I mRNA levels were significantly reduced. The cause of the high bone mass phenotype in these mice remains unknown.

11 OTHER INFLUENCES OF PTH/PTHrP ON BONE THROUGH THE BONE MARROW MICROENVIRONMENT

The interaction between the cells on the bone surface and cells within the bone marrow microenvironment is a rapidly developing field, where interactions

between these cells are now understood to be required for maintenance of normal bone volume, and osteoblasts are required for maintenance of the hematopoietic stem cell niche.[155] There is evidence for PTH action on hemopoiesis dating from the 1950s when parathyroid extract was found to enhance the survival of irradiated rats.[156] Later studies showed that hemopoietic defects in thyro-parathyroidectomized rats were rescued with administration of PTH,[157,158] as also was the delayed liver regeneration following partial hepatectomy.[159] More recently, mice with osteoblast-specific expression of a constitutively active PTHR1 demonstrated not only an increase in bone formation and osteoblast number,[160] but also a stromal-cell dependent increase in long-term repopulating hemopoietic stem cells.[161] The same effect on hemopoiesis was observed with exogenous PTH treatment.[161] No hematopoietic defect was noted in mice null for PTHrP in osteoblasts,[33] so the question arise whether it is PTHrP or PTH that has a physiological role in maintaining the HSC niche remains unanswered.

There is evidence also that actions of PTH/PTHrP on bone formation may depend on contributions from other bone marrow populations. For example, T cells have been shown to potentiate PTH-induced cortical bone loss through CD40L signaling,[162] and PTH acts through its receptor on T cells to promote the production of Wnt 10b, which in turn increases osteoblast differentiation and bone formation.[97]

12 THE PTH–PTHrP RELATIONSHIP IN VASCULATURE AND BONE

The discovery of PTHrP in 1987 provided many pathways that have led to deeper understanding of the physiological roles of PTH, in particular revealing that endocrine PTH and paracrine PTHrP engage cooperatively to regulate bone and calcium metabolism, with their interactions at their most complex during early development. We are learning how the hormone, PTH, and the structurally related paracrine factor, PTHrP, share the use of their common receptor in many tissues, with the focus in this chapter on bone and cartilage. The favored current concept is that PTH the hormone regulates calcium homeostasis in development and maturity. PTHrP on the other hand acts during skeletal development to control chondrocyte proliferation and differentiation, and, of these two proteins, PTHrP is the main factor generated locally in the postnatal skeleton and acts through the PTHR1 in bone remodeling, but does not normally contribute to the maintenance of serum calcium. These views have developed largely as a result of the insights provided from mouse genetic experiments (discussed earlier), but much is owed also to pharmacological studies in animals, and to the therapeutic application of PTH in osteoporosis. We might now regard PTH in its application as a skeletal anabolic therapy as a pharmacological reproduction of the local physiological action of PTHrP. This sharing of function between a hormone and its related cytokine is reminiscent of the relationship between growth hormone and IGF-1. As in that case, the relationship is functional in many tissues, and a particularly instructive example comes from the actions of PTHrP and PTH on the vasculature smooth muscle beds.

It had been known since the 1920s that injection of PTH (or parathyroid extract in the early years) resulted in dose-dependent increases in blood flow through a range of vascular beds, accompanied by decreases in blood pressure,[163–165] (reviewed in Ref. 166). At the time these effects, that were observed in many animal species, did not fit easily with what was known for the physiological role of PTH to control blood calcium levels.[163] With the discoveries that followed rapidly after the isolation of PTHrP it became clear that this was a reflection of a local physiological role of PTHrP, which is produced in smooth muscle beds of the stomach and intestine, uterus, urinary bladder, and arterial vessels, acting in all those tissues as a smooth muscle relaxant (reviewed in Refs. [64,65]). PTHrP expressed in smooth muscle acts rapidly to relax the vasculature[167] through an endothelium-independent mechanism, and vasoconstrictors, such as angiotensin II induced a rapid rise in PTHrP production.[168] Thus increased PTHrP production following vasoconstriction could provide a mechanism to limit or reverse this effect through the relaxant action of PTHrP on smooth muscle.

If PTHrP does indeed have a physiological role as a local regulator of vascular smooth muscle tone, being generated and acting in response to local needs, it must be very different when widespread engagement of the vascular PTHR1 receptors takes place with systemic PTH administration. The pharmacological response is a generalized one, with widespread dilatation of vascular beds, increased total blood flow, and decreased blood pressure.[164,165] As in bone, the effects of PTH on vasculature vary with the mode of pharmacological administration: while intermittent PTH increased bone vascular perfusion by approximately 30%, and almost doubled microvessel size, continuous infusion of PTH did not modify vascular perfusion, but reduced microvessel size.[169] Whether these opposing effects on microvessel size might determine the level of osteoclast formation in response to intermittent versus sustained high levels of PTH remains unknown.

The difference between PTH and PTHrP action in bone is not dissimilar to that in the vasculature. The work of Miao et al.[33] shows convincingly in the mouse that haploinsufficiency of PTHrP results in bone loss, and that genetic ablation of PTHrP in the osteoblast lineage recapitulates this deficiency, resulting in a low

turnover bone loss, with reductions in both, bone formation and resorption, but without any change in calcium homeostasis. This low bone remodeling result is determined by changes in PTHrP production locally in bone that influence the behavior of BMUs in the bone remodeling process.

Bone remodeling takes place at many discrete sites throughout the skeleton, but does so asynchronously, and in response to the requirements of responses to loading, of repair of damage, and of replacement of old bone. When PTH is used by intermittent (daily) injection to engage the PTHR1 in bone to increase bone formation, widespread activation of BMUs takes place (Fig. 17.1). This is analogous to the situation described earlier for vascular effects, and both of these are far removed from physiology. The pharmacokinetics required for an anabolic response to PTH is that the peak circulating level of hormone should be short-lived.[36] If the decline in PTH levels is sufficiently prolonged, the dominant effect becomes that of increased osteoclast formation, and hence increased bone resorption. There are several examples for the same, including primary hyperparathyroidism, the prolonged PTH release noted in attempts to develop calcilytics as bone-forming agents,[170] and the prolonged PTH activation in OSM receptor-deficient mice.[123] Further, in mice in which the *PTHR1* is mutated to result in lifelong persistent activation of the PTHR1, the result is increased trabecular bone formation and resorption, especially in cortical bone.[160]

If this portrayal of the PTH–PTHrP relationship holds true, it might be expected that repeated generalized recruitment of BMUs by the daily injection regimen would so increase remodeling activity that this would be reflected in increased circulating and excreted resorption markers. This is what happens within some months of starting PTH intermittent injection therapy.[35] A further corollary relates to the nature of the local PTHrP action. In discussing the mouse genetic data of Karaplis and coworkers, it was suggested that there must be local mechanisms that ensure only brief exposure of the PTHR1–PTHrP, and that this might be achieved by a combination of the short half-life of PTHrP mRNA and the great susceptibility of the protein to proteolytic cleavage.[52] However, this might not be relevant. Whatever the nature of locally derived PTHrP that activates the PTHR1 in remodeling—whether full length protein or a shorter proteolytic product—its duration of action at the remodeling site might not be so crucial, since only a limited number of remodeling sites are involved at any one time in the physiological process, and there is consequently little prospect of prolonged stimulation promoting a generalized increase in resorption.

This discussion is relevant to that earlier, concerning the suggested purely anabolic action of PTHrP(1–36).[54] Explanations offered for this are either that PTH and PTHrP(1–36) have different pharmacokinetics,[171] or that PTH action at the receptor is more prolonged than that of PTHrP(1–36), for which there is evidence[56] (vide supra). The reason behind this is that an effect through the PTHR1 at the BMU of as short a duration as possible could avoid stimulating of osteoclast formation and activity. In contrast, the repeated injection of PTH(1–34) or PTH(1–84) would eventually lead to increased resorption markers.[35,172]

This apparent requirement of a brief exposure of the PTHR1 to agonist in order to achieve an anabolic response, has become a standard view. For example, attempts to develop anabolic therapies by using calcilytic agents to release PTH from the parathyroid gland, have aimed at achieving short-lived peaks of circulating PTH. So far these attempts have not been successful.[170,173,174]

13 CONCLUSIONS

In conclusion, PTH and PTHrP appear to have complementary roles in adult physiology. Of the two, PTH is the primary physiological agent that regulates calcium homeostasis through an endocrine mechanism, while paracrine PTHrP acts at the BMU on osteoblast lineage cells to regulate bone formation and bone resorption. A greater number of BMUs are recruited by the pharmacological action of PTH arriving from the bloodstream (Fig. 17.1). The sheer number of BMUs now active in the bone allows PTH to increase the amount of bone, but there is also a progressive resorptive effect. The physiological action of PTHrP on the other hand is confined to those relatively few BMUs needed at any point of time for engagement in remodeling.

1 INTRODUCTION

In the 21st century, two sharply contrasting disorders of body composition, obesity and osteoporosis, have reached near epidemic proportions and challenged both our scientific and our financial resources. The growing prevalence of these diseases has also enabled investigators to explore new perspectives on the molecular, cellular, and genetic determinants that regulate body composition and energy homeostasis shared by both disorders.[1] This, in turn, has resulted in a sea-change in our understanding of the multiple mechanisms controlling body mass and energy utilization. Shared regulation of bone and fat occurs at several levels, starting with genetic determinants that can affect cellular actions in bone, adipose tissue, and the central nervous system (CNS). Acquisition and maintenance of bone and fat are also mediated through central and peripheral mechanisms including multiple endocrine and paracrine determinants.[2] Importantly, the hypothalamus is the principal controller of these target tissues through neuronal [e.g., sympathetic nervous system (SNS)] and hormonal mediators.[3] In the case of the former, the hypothalamus modulates fat and bone tissue via two major pathways: (1) sympathetic nervous system activation that modulates appetite, insulin sensitivity, energy utilization, and skeletal remodeling; (2) paracrine and endocrine hormonal factors secreted by the hypothalamus. In respect to the latter, paracrine pituitary-activating hormones, such as CRH and TRH can modify metabolic homeostasis through their secondary target glands, the adrenals and thyroid. Similarly the hypothalamus can secrete factors, such as FGF-21, BDNF, oxytocin, Neuromedin U, NPY, melatonin, and IL-6 that impact bone and fat in a systemic fashion.[4,5] Circulating serum factors, such as TNFα and PTHrP, may also play a role in determining how the body utilizes fuel and distributes it to other organs, particularly in states of cachexia.[6] Muscle derived growth factors can have an impact on bone and adipose tissues, particularly inguinal depots in rodents (or subcutaneous depots in humans). Currently one of the most exciting myokines is irisin; a cleaved protein product from muscle after exercise that induces beiging of white adipose tissue (WAT) and also positively impacts cortical bone.[7]

In addition to shared-regulatory determinants between bone and fat, as well as a common central signal from the hypothalamus, bone, and fat cells arise from the same mesenchymal derived progenitor cell, primarily in the bone marrow[8] (Fig. 18.1). There is emerging evidence of significant plasticity between these two lineages, and some have suggested there may be transdifferentiation of these terminally differentiated adult cells. Cell fate decisions in the bone marrow are critical for defining total fat and bone mass particularly since recent studies have hinted that around 10% of adipocytes in peripheral depots may originate from the marrow after bone marrow transplantation.[9] Cell fate within the marrow is also particularly relevant in cases where fuel supplies are low; for example, anorexia nervosa (AN) (see further).[10] New insights from genetic engineering in mice, and clinical disorders, such as AN, where paradoxically fat mass is absent in the periphery but high in the marrow and is accompanied by an impairment in osteogenesis, have allowed investigators to examine the physiologic mechanisms that link bone mass acquisition and maintenance to energy utilization and adipose remodeling.

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00018-6

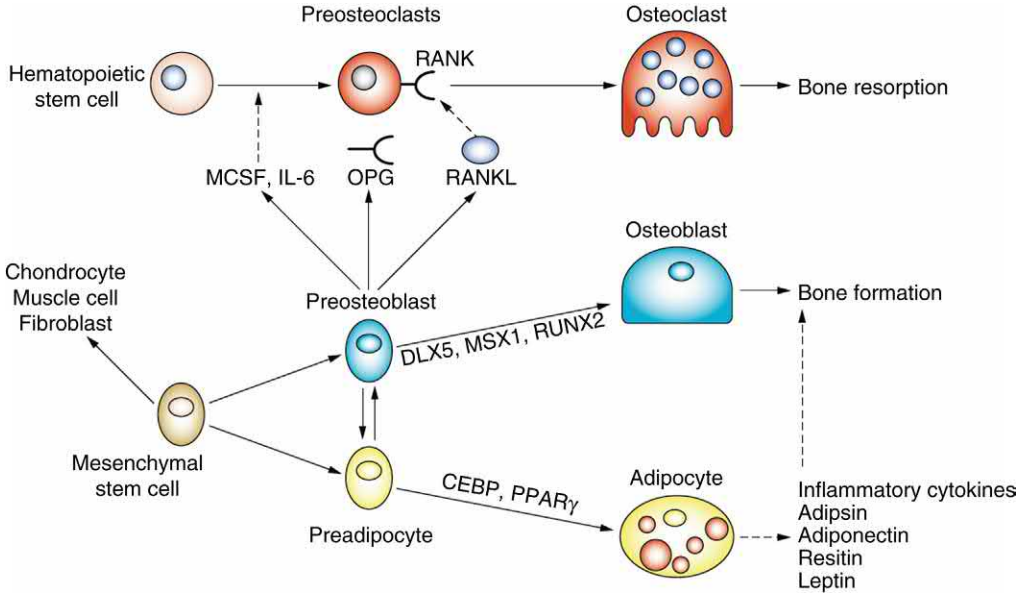

FIGURE 18.1 Cell fate decisions in the bone marrow are dependent on transcriptional factors for bone and fat, as well as energy needs in the niche.

On the other hand, only recently has attention focused on genetic determinants of bone and fat in humans using GWAS as a platform to explore that relationship. In this chapter we will focus on the underlying physiology of metabolic homeostasis as it relates to adipose tissues and the skeleton, as well as progress in defining common genetic determinants and their influence on those regulatory pathways.[11]

2 THE COMPLEX RELATIONSHIP OF ADIPOSE TISSUE TO BONE MASS

Body composition includes the amount and distribution of bone, adipose tissue, and water. Adipose tissue is generally considered within the context of three types of fat, defined by location, function, and morphology: brown adipose tissue (BAT) which is thermogenic and generally found in the interscapular region from birth; WAT, which is the storage depot for triglycerides and fatty acids and is found in visceral, perirenal, and subcutaneous depots; and beige or brown-like adipose tissue, found in some subcutaneous tissue and regulated by sympathetic tone.[12,13] Importantly, the relationship of bone mass to bone remodeling and skeletal density is dependent on the type of adipose tissue, hence one has to be cautious in interpreting the relationship of weight alone, or BMI alone to bone mass or skeletal fragility. Similarly, there are likely to be shared genetic determinants of bone and fat that differs by the type of adipose tissue being considered.

Excess WAT with inflammatory characteristics defines the obesity-metabolic syndrome of accelerated atherogenesis, glucose intolerance, and high serum lipids. Increases in WAT volume in mammals arise most commonly from expansion of adipocytes rather than the recruitment of new preadipocytes, although it has been suggested that approximately 10% of adipocytes in peripheral depots arise de novo per year. There is some debate about the source of brown-like adipose tissue and whether transdifferentiation between white and beige can occur. As such the effects of obesity on bone health are complex; increased mechanical loading due to greater body weight generally has a positive impact on bone, due to adaptations from greater loading on the skeleton while proinflammatory cytokines and adipokines in visceral adipose tissue (VAT) may have a negative impact, particularly on trabecular bone mass. The relationship of BAT to bone mass remains unclear with several lines of evidence to suggest there may be a positive effect, although these data are from association studies.

The interactions between BMI, BMD, and fracture risk have been extensively studied. A metaanalysis of 12 prospective studies involving almost 60,000 individuals by Delaet and coworkers found that increased BMI was associated with a reduced risk of fracture in men and women.[14,15] However, after adjustment for BMD, only the association with decreased hip fractures remained significant. This finding suggested that the positive effect of BMI on fractures is largely mediated through higher BMD, while the residual protective effect of high BMI on hip fractures may be related to the shock-absorbing effect of increased adipose tissue over the greater trochanter. A second metaanalysis reported similar protective effects of obesity on hip fracture.[16] Importantly, recent evidence indicates that overweight and obese individuals, while

being protected from some fractures, are at *increased* risk for ankle, humerus, and vertebral fractures.[17]

Previous assessments of adiposity have relied mainly on BMI or DXA assessments of total body fat, which unlike computed tomography (CT), cannot distinguish subcutaneous adipose tissue (SAT) from VAT. This may be relevant, as these two adipose tissue types have distinctive characteristics in terms of cytokine and adipokine production, insulin sensitivity, thermogenesis, and relationships to bone metabolism. Notably, VAT has a stronger association with metabolic syndrome and T2D than SAT.[18] Growing evidence indicates a negative association between VAT and areal BMD.[19,20] The negative effects of VAT on bone metabolism may be mediated by VAT-associated chronic inflammation and activation of proinflammatory cytokines, including interleukin-6 (IL-6) and tumor necrosis factor α (TNF-α) which induce bone resorption by stimulating osteoclast activity through upregulation of the RANKL/RANK/OPG pathway.[21] Visceral obesity may also affect bone turnover and metabolism through over- and undersecretion, respectively, of adipocyte-derived leptin and adiponectin.[22] On the other hand in a large cross sectional study of extreme microCT in young and older thin and obese individuals, both trabecular and cortical bone mass was higher in the obese subjects.[23] In addition to the factors noted aforementioned, obesity and T2D have been associated with a greater volume of marrow adiposity, which in turn could contribute to enhanced skeletal fragility.[24] These findings raise the intriguing possibility that obesity has differential effects on the skeleton depending on adipose type, depot, and distribution.

There is considerable controversy regarding the direct effect of insulin on bone cells. While evidence from some rodent studies indicates that insulin stimulates osteoblast proliferation and increases histomorphometric indices of bone formation by two- to threefold,[25] recent in vitro studies report that insulin signaling in osteoblasts also promotes bone resorption.[26,27] Similarly, clinical studies across a wide range of hyperinsulinemic states, including polycystic ovary syndrome and lipodystrophy, feature the consistent finding of high BMD.[28] The most direct evidence of the effect of hyperinsulinemia independent of fat mass comes from a study by Abrahamsen and coworkers who measured the association between BMD and insulin sensitivity index following an oral glucose tolerance test.[29] They reported that insulin sensitivity was negatively correlated with total aBMD independent of BMI and that the influence of fat mass on BMD disappeared after adjustment for insulin sensitivity. These data suggest that the effects of the insulin receptor on bone are independent of BMI. In light of the evidence, it would appear that in the early stages of T2D, the detrimental effects on the skeleton due to the metabolic dysregulation of obesity are probably counteracted to a large extent, by the hyperinsulinemia secondary to insulin resistance (in the absence of insulin resistance in skeletal tissues), and to a lesser degree, by the mechanical effects of increased body weight associated with obesity.

The relationship between BAT and bone mass has been much less extensively studied, and is only starting to be investigated as better imaging techniques have defined the volume of BAT by PET/CT. In several reports, the amount of BAT in young and early adult women and men has been positively associated with areal BMD.[30,31] However, when considering these correlations, muscle mass must be considered since there is a strong relationship between BAT and overall muscle volume, likely due to the expression of the common transcription factor Myf5 in both tissues. The relationship between brown-like or beige adipose tissue and bone has also been poorly defined. However, subcutaneous fat tissue has generally been positively related to bone mass in both adolescent and adult individuals, but whether this is related to gravitational forces on the bone, or due to secretory factors is not known. Interestingly, Lecka-Czernik and coworkers have shown that, when beige fat is enhanced by transgenic over expression of the transcription factor, FoxC2, bone mass is increased.[32] Hence, it is apparent that multiple factors determine the relationship of fat to bone.

How do these findings relate clinically to fracture risk and importantly to potential genetic determinants of fracture? As noted, obesity has long been thought to be protective for the skeleton, while low body weight, particularly in elders, is still considered a major risk factor for fractures. In the 10-year fracture risk algorithm (FRAX), now widely used in clinical practice, body mass index (BMI) can be substituted for bone mineral density (BMD), albeit imperfectly, to estimate absolute fracture risk. This relationship can be attributed to greater skeletal protection from falls, excess loading on the skeleton, and the extraovarian contribution of estradiol from aromatase activity in fat tissue. On the other hand, osteoporosis and obesity can coexist. For example, syndromes of fat redistribution, such as Cushing's disease and the drug induced lipodystrophies are associated with low rather than high bone mass.[33] Type II diabetes mellitus, despite the obesity, is actually associated with a greater number of fractures, and thiazolidinediones, highly effective drugs for diabetes, have been reported to increase the risk of peripheral fractures.[34] Furthermore, the extent of fat deposition in vertebral bone marrow correlates negatively with bone mass and indicates a greater fracture propensity.[35] Interestingly, in some cohorts, the percent of total fat mass, when body weight is kept constant, is strongly, but inversely associated with BMD.[36] These findings raise the question of whether fat as an endocrine organ, may exert distant but detrimental effects not only on the vasculature, but also on the skeleton. Finally, a disturbing

picture has emerged from the ongoing obesity epidemic. The prevalence of radial fractures in young adults has increased dramatically over the last decade, and one of the strongest predictors of fracture in this population is excess body weight.[37] The mechanism(s) responsible for this relationship is unknown but is likely to be multifactorial and related to life style, nutrition, and genetic determinants, as well as the load exerted on the upper limb in a fall. To summarize, the complex relationship of obesity to bone mass requires much further delineation and this in turn complicates genetic studies of common determinants for these phenotypes. New GWAS studies for fracture and body composition are currently being analyzed and may provide more insights.

3 A COMMON ORIGIN FOR FAT AND BONE CELLS

Bone marrow surrounds trabecular elements in the skeleton and is composed of multiple cells that are pluripotent.[38] In addition to the hematopoietic elements that include red and white blood cells, platelets, and their progenitors, the bone marrow stroma or connective tissue, contains mesenchymal stromal cells, an adult stem cell population capable of extensive self-renewal and plasticity.[39] Stromal cells are regulated by endocrine, paracrine, and autocrine signals, and in response can enter bone, cartilage, or fat lineages, depending upon the activation of intrinsic transcription factors.[40] The allocation of stem cells into bone forming osteoblasts, some which may enter the circulation, is accelerated after skeletal injury, as well as during the rapid growth phase of puberty and with administration of parathyroid hormone 1–34.[41,42] Runx2/Cbfa1 and osterix are two of several bone-specific transcription factors that are required for this process (Fig. 18.1).[43] In contrast, entry of stromal cells into the fat lineage occurs through activation of the nuclear receptor PPAR-γ2 by endogenous fatty acids or exogenous ligands (Fig. 18.1).[13] Stem cell specification into the fat or bone pathway is often considered as an either-or-paradigm; that is, commitment of these cells is exclusive to one lineage or the other, based principally on PPAR-γ2 complex activation by a class of drugs called the thiazolidinediones (TZDs: rosiglitazone or pioglitazone).[34,44] These agents improve insulin sensitivity and enhance bone resorption while shifting mesenchymal cell fate from preosteoblasts to preadipocytes.[45] The clinical outcome of treatment with the TZDs is often manifested as improved glucose tolerance, associated with modest weight gain and increased marrow adiposity at the expense of skeletal mass.[46] However, in other circumstances, enhanced marrow adipogenesis can coexist with active bone formation, such as the inbred mouse strain, C3H/HeJ, or after treatment with certain PPARG agonists.[45,47] Along these lines, emerging evidence suggests there may be a mixed population of cells that have transcriptional characteristics found in both fat and bone cells. Westendorf and coworkers have noted that some Runx2 positive cells have large perilipin positive lipid droplets in HDAC3 null mice consistent with the hypothesis that these cells are "osteo-adipocytes."[48] Lanske and coworkers have shown that some marrow adipocytes express RANKL, a stromal cell cytokine characteristic of preosteoblasts.[49] Hence, the progression or "switch" of stem cells into either the fat or bone lineage may not be mutually exclusive, and supporting the concept of plasticity during fate decisions. Moreover, genetic determinants are likely to be important at this critical junction for both physiologic and pathologic states (see later).

Although much of what we have learned about the "switching mechanism" in mesenchymal stromal cells has come from basic investigations, clinical experiences have also been very illustrative. For example, glucocorticoids are remarkable for their ability to enhance marrow adipogenesis at the expense of osteoblast differentiation.[50] In the syndrome of glucocorticoid-induced osteoporosis, bone loss is quite rapid at a time when fat mass is enhanced, particularly in central depots. Similarly, the TZDs reduce bone mass, and increase the risk of peripheral fractures possibly because of the switch in stem cell allocation into the adipocyte lineage.[51] Another less well known example of "switching" occurs with aging. Fatty infiltration of the vertebral marrow is a characteristic feature of older individuals, and can be recognized on MRI exams, usually as an incidental finding. Its presence, however, is inversely related to BMD and skeletal integrity in many circumstances.[52] Importantly, cell fate decisions are also related to their metabolic program (see later), which is tied to energy availability and illustrated by the syndrome of AN. Thus, bone and fat cells share a common origin, and their fates are interwoven in a context specific manner. Pharmacological manipulation of mesenchymal stem cells to reduce adipogenesis or enhance osteogenesis is a promising new but yet untested avenue for therapeutic investigations.

4 BIOENERGETICS OF CELLS IN THE BONE MARROW NICHE IN RELATION TO ENERGY NEEDS AND WHOLE BODY METABOLISM

It is likely that cell fate in the niche relates to metabolic flexibility and programming of progenitor cells. Each of the cells in the bone marrow niche has its own specific nutrient requirement in order to survive, particularly in a hypoxic environment linked to ATP demands. In general, the more differentiated the cell, the greater the energy needs. However, within that context, there

are major differences between mature osteoblasts and adipocytes. First, when considering survival and maintenance of MSC stemness in the relative hypoxia of the marrow, there is a need for metabolic adaptation. Stemness allows a stable pool of progenitors that can be called on in numerous circumstances, particularly injury and inflammatory states [53] Hypoxia induces the stabilization of HIF1α, a major transcription factor for stem cells and progenitors, as well as multiple downstream target genes, particularly VEGFα.[54]

Metabolic reprogramming of quiescent cells is necessary to prevent differentiation and this occurs through a shift from oxidative phosphorylation to glycolysis. Importantly, glycolysis, although less efficient in generating ATP than mitochondrial oxidation, reduces oxidative stress and reactive oxygen species (ROS) generation, key elements that drive stem cell differentiation. Although glycolysis is the major driver of ATP generation in MSCs, entrance into a specific differentiation program, either adipogenic or osteogenic, requires distinct metabolic requirements that are very context specific.[55] For adipocytic differentiation, several studies have suggested that mitochondrial oxidation of fatty acids and the generation of ROS are essential to achieve full maturation. The process of glucose entry and fatty acid oxidation through the Krebs Cycle generates more molecules of ATP per mol of glucose (36:1) than glycolysis (2:1), but it comes at a cost as mitochondrial respiration leads to the generation of ROS from the electron transport chain (ETC). ROS (e.g., H_2O_2, superoxides) can further suppress mitochondrial respiration and promote an adipogenic program that is associated with more insulin resistance and less lipolysis.[56,57] Excess ROS in adipocytes may also cause mitochondrial DNA damage or further changes to complex I in the ETC leading to metabolic dysfunction.[58] Although some ROS is generated during normal adipocyte differentiation; much less is produced during early stages of osteoblast maturation.

During osteoblastic differentiation, glycolysis is the predominant ATP generator, even though it is less efficient per mol of glucose.[59] Glycolysis can occur rapidly and can happen in both hypoxic and normoxic states (i.e., Warburg effect). Two key proteins, Glut1, the principal glucose transporter and lactate dehydrogenase (LDH), the enzyme that converts pyruvate to lactate are essential during glycolysis. Karsenty and coworkers showed that in osteoblasts, glucose uptake through the Glut 1 transporter inhibits AMPK, which in turn prevents ubiquitination of runt-related transcription factor 2 (Runx2).[43] In a feed-forward system, Runx2 begins the differentiation program in osteoblasts and increases Glut1 expression. Furthermore, preosteoblasts differentiate under the influence of various ligands, particularly the Wnts and insulin-like growth factors (IGFs). Long and coworkers demonstrated that glycolysis is a major feature of Wnt3a induced osteoblast differentiation.[60] More recently the same group reported that HIF1α which is important for stemness, is also a critical transcriptional regulator of glycolysis, triggered in part, by relative hypoxia in the bone marrow niche.[61] Remarkably, much older ex vivo studies from Neuman and Nichols demonstrated that parathyroid hormone (PTH) treatment produced lactic acid in calvarial osteoblasts supporting the tenet that osteoblasts utilize glycolysis to generate lactate and fuel collagen synthesis and mineralization.[62] Guntur et al. also showed that glycolysis was essential for terminal differentiation of osteoblasts and that oxidative phosphorylation was more important early in the differentiation scheme.[63] Thus, it is likely there is a distinct metabolic program that features a transient phase of oxidative phosphorylation following glycolysis and that is then switched off as glycolysis reemerges as a predominant driver of ATP. Indeed, recent studies suggest that both oxidative phosphorylation and glycolysis are occurring in differentiating cells, and the relative proportion that contributes to ATP determines the final energy production. Too much oxidative phosphorylation or glycolysis can inhibit the other, so there clearly must be a fine context specific balance.

The transient phase of mitochondrial respiration is time sensitive and may occur in vitro between days 3 and 9 of osteoblastic differentiation. During this time period, AMPK is activated and this may induce lipophagy, as well as oxidative phosphorylation.[64] Other studies have shown that metformin, which upregulates AMPK can enhance differentiation but only during specific time periods. In a similar vein, Karner et al. demonstrated that glutaminolysis is also essential for osteoblast differentiation through the Wnt signaling system.[60] Hence, there are at least three substrates for ATP generation and differentiation of MSCs: glutamine, which enters the Krebs Cycle via alpha ketoglutarate; glucose, which through glycolysis can generate lactate, as well as ribose nucleotides via the pentose phosphate shunt; and fatty acids, which are metabolized via acetyl coenzyme A (CoA) in the mitochondria. Generation of acetyl CoA can also lead to enhanced nuclear acetylation that in turn can impact transcriptional processes unifying the processes of protein production and energy utilization. Finally, autophagy cannot be overlooked as a fueling mechanism for the cell particularly during times of stress or nutrient deficiency. AMPK stimulates autophagy, as well as glycolysis and inhibits mammalian target of rapamycin (mTOR) and overall protein synthesis.[65] This would also lead to increased fatty acid entry into the mitochondria for ATP generation as lipophagy is also stimulated.

In summary, the bone marrow niche has significant energy requirements that are tissue and temporal specific. Allocation into the osteoblast or adipocyte lineage is dictated by multiple transcription factors, which in

turn must be governed by specific metabolic programs and their inherent flexibility. Changes in energy availability are certain to alter cell fate decisions and these in turn can impact metabolic homeostasis. Taken together, the determination of the identity of marrow adipocytes as osteoblasts in disguise, or a novel fat cell, is a critical question because of the intimate relationship between adipogenesis and skeletal remodeling, particularly in states of energy insufficiency. Genetic determinants of metabolic programs are certain to link bone and fat metabolism.

5 CONTROL OF SKELETAL AND ADIPOSE TISSUE REMODELING

Bone and fat are functionally related through a complex neuroendocrine circuit that involves the brain, adipose depots, and the skeleton. In mammals, the sympathetic nervous system can drive lipolysis through release of norepinephrine, which activates beta adrenergic receptors of which there are three (β1–3 AR) in adipocytes. The effects of the SNS on bone are more complex (Fig. 18.2) and are driven primarily through activation of the β2AR. Interrelated to the neural modulation of bone and fat, several hormonal factors are also regulatory particularly during puberty. For example, during linear growth and the acquisition of peak bone mass, surges in growth hormone and gonadal steroid secretion provide a stimulus for skeletal expansion, and stem cell recruitment into cartilage and bone. These processes are fueled through lipolysis of WAT. As such, malnutrition or undernutrition can cause short stature and a severe reduction in peak bone-mass. Thus, when considering the regulation of fat and bone by systemic and local factors, it is helpful to classify these as peripheral or central mediators. The peripheral mediators are adipokines that act via the CNS to regulate sympathetic outflow to both fat and bone tissue. Central mediators arise from the CNS as either neural peptides or paracrine factors.

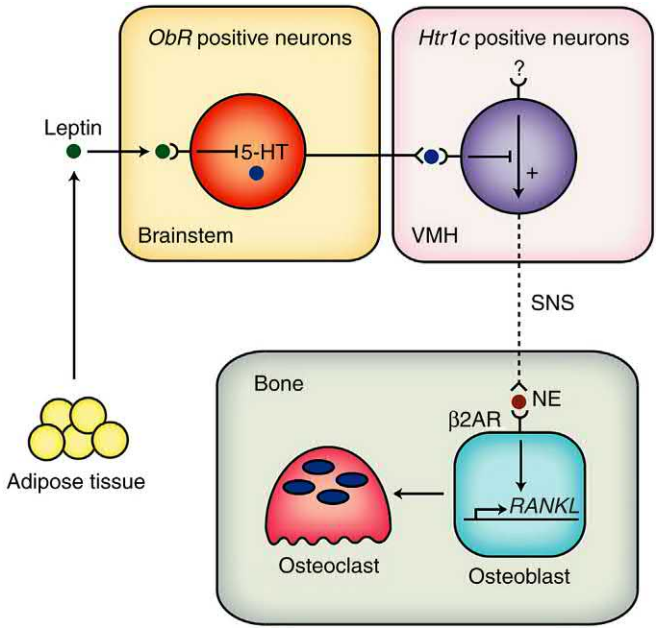

FIGURE 18.2 Adipokine regulation of bone mass via the brain stem and ventromedial hypothalamus and sympathetic nervous system (SNS).

5.1 Adipokine Regulation of Bone Remodeling

Leptin is an adipokine produced by fat cells.[66] The circulating levels of leptin are directly related to total fat mass. Leptin regulates appetite, reproduction, and energy utilization by crossing the blood–brain barrier and binding to a receptor in the hypothalamus. In the ventromedial nucleus of the hypothalamus, leptin triggers activation of the SNS. Deficiencies of, or resistance to leptin can cause obesity, impaired fertility, and changes in appetite, in both rodents and humans.[67,68] Surprisingly, the absence of leptin results in high bone mass, even though gonadal steroids are markedly suppressed in the animal model of total leptin deficiency, the ob/ob mouse. Studies of these mice demonstrated that the high bone mass of leptin deficiency is a result of reduced sympathetic tone innervating β2 adrenergic receptors in osteoblasts (Fig. 18.2). Those observations provided evidence that bone remodeling is regulated by a hypothalamic relay via the sympathetic nervous system, and is primed by leptin, the sensor of peripheral fuel status in fat depots. Not surprisingly, the system is more complex than originally perceived, and includes other hypothalamic networks, such as the neuropeptide CART, melanocortin 4 receptors, the neuropeptide Y receptor system, and neuromedin U.[69,70] Cannibinoid receptors that regulate appetite and energy balance also modulate bone turnover centrally and peripherally, principally by blocking sympathetic innervation. Karsenty et al. have reported that the bone specific protein, osteocalcin, when undercarboxylated regulates insulin secretion, gonadal status, and muscle activity.[71] If validated in humans, this connection provides another step in a complex integrative circuit that regulates body composition, although in this case, the master regulator is the skeleton.

Adiponectin is a secretory peptide made by differentiated adipocytes, primarily from WAT. Its expression occurs late in adipocyte differentiation and is regulated by the master transcription factor PPARG. Adiponectin can induce insulin sensitivity and is thought to be a modulator of glucose transport. It is upregulated by the thiazolidinedione class of antidiabetic agents. Recently, Cawthorn and coworkers demonstrated that adiponectin secretion also occurs in marrow adipose tissue (MAT) and this may regulate glucose levels in AN; a condition

associated with low-energy intake but high insulin sensitivity.[72] In experimental animals, adiponectin has been shown to have dual effects on bone mass; direct and indirect. In respect to the former, adiponectin has been shown to inhibit osteoblast differentiation in the bone marrow; on the other hand, adiponectin can downregulate sympathetic tone, thereby indirectly enhancing bone mass. Karsenty and coworkers have suggested that leptin and adiponectin act in a yin and yang mode in the CNS.[73] Hence, it is apparent from experimental evidence that one locus of control over body composition is modulated through the sympathetic nervous system.

5.2 Sympathetic Nervous System Control Over Fat and Bone Remodeling

Several lines of evidence point toward an efferent sympathetic pathway from the brain-controlling skeletal metabolism. Genetically engineered mice with both a global and conditional deletion of the β2 adrenergic receptor (B2AR) have high bone mass at 8 and 16 weeks of age. Mice treated with isoproterenol, a β-adrenergic receptor agonist, lose bone mass while treatment with the β-adrenergic receptor antagonist propranolol may protect against OVX induced bone loss.[5,74,75] Patients with reflex sympathetic dystrophy, a disease characterized by high sympathetic tone are prone to low bone mass, that at least in some cases can be mitigated by β-blockers.[76] Sympathetic overactivity has also been proposed as a contributing mechanism for microgravity induced bone loss during space flight although long-term studies have not been done.[77]

The link between leptin and bone via a sympathetic efferent was established by Efleritou et al., through failure to reverse the high bone mass phenotype in β2 adrenergic receptor (Adrβ2) deficient mice following ICV infusion of leptin.[78] The expression of Adrβ2 in osteoblasts provided another link in the pathway between hypothalamus and osteoblast, and mice with selective knockout of Adrβ2 on osteoblasts have a high bone mass from increased bone formation and reduced bone resorption (Fig. 18.2). Studies also indicated that sympathetic signaling in osteoblasts is responsible for regulatory control of osteoblast function through inhibition of osteoblast proliferation via circadian clock genes and that the sympathetic nervous system also favors bone resorption by increasing the expression of RANKL.[79–81] The balance of bone formation and resorption from chronic stress induced sympathetic activity may shift to favor bone resorption as seen with chronic stimulation of β-AR with low-dose agonist treatment in mice which induces bone loss mainly via enhanced bone resorption [79] suggesting the control of each cell type by the SNS is temporal. Second generation antipsychotics, such as risperidone, also upregulate sympathetic tone and uncouple remodeling; these effects can also be blocked with propranolol.[82]

6 ANOREXIA NERVOSA: ENERGY, BONE, AND ADIPOSE DEFICIENCIES

In humans, abnormities in fat metabolism associated with clinical states of extreme under- and overnutrition provide a global consideration of the relationship between fat, bone, and energy needs. Congenital lipodystrophies provide some insights, but are rare. The most common and yet most extreme and well studied disorder of low body fat and its effects on bone mass is AN, a primary psychiatric disorder affecting up to 1% of young women. AN is characterized by self-induced starvation, severe decreases in body adipose depots, and muscle mass, functional hypogonadotropic hypogonadism and substrate shunting to preserve vital functions.[83] Paradoxically, bone MAT is markedly enhanced and is now an additional hallmark of the bone component in this disease. Additional physiologic adaptations to starvation that impact bone metabolism and fat mass include hypercortisolemia and growth hormone resistance. Rapid and significant bone loss in adults and inadequate acquisition of bone during the peripubertal period in children is a hallmark of the disorder. In a community based outpatient study of 130 young women with AN, 92% of women were osteopenic and 38% met criteria for osteoporosis.[84] Bone formation is markedly reduced while bone resorption is increased in this disorder, and as noted, MAT is increased.[85] Insulin sensitivity is another metabolic feature of this condition, and in extreme cases can lead to severe hypoglycemia and death. Weight gain causes increases in bone formation, decreases in bone resorption and loss of MAT.[86,87] Estrogen replacement induces a modest reversal of the skeletal and metabolic phenotypes.[88,89]

Several hormone mediators have been linked to low bone mass in AN and estrogen is the most dominant. Its effects on bone relate to its known inhibition of osteoclast-mediated bone resorption. Intriguingly, loss of estrogen during the menopause also leads to bone loss but not to the same degree as in AN, in part presumably because of the timing of such loss. In addition, menopausal estrogen loss is often associated with increased visceral adiposity, which is generally not seen in the setting of chronic AN. Loss of estrogen in AN is due to hypothalamic changes as undernutrition suppresses GnRH pulsatility resulting in hypogonadotropic hypogonadism. However, the increased severity of bone loss in this disorder compared to that seen in other young amenorrheic women, as well as the failure of estrogen replacement to fully improve bone mass implicates other nutritionally dependent factors. For example, deficiencies in ovarian

androgens, hypercortisolemia, and very low serum IGF-1 levels, the latter a nutritionally mediated endogenous bone anabolic factor, may contribute to bone loss.[90]

The strongest predictor of increased bone mass in AN is weight recovery.[10] In a longitudinal study of women with AN, a 0.6% increase in hip bone mass was seen with weight gain. However, return of ovarian function is also a key factor as greater improvement in bone mass is seen in women who regain both weight and menses. Biochemical markers of bone formation increase with weight gain but decreases in bone resorption markers occur only in those women who regain menses and have adequate endogenous production of estrogen.[91]

Hypercortisolemia, thought to be due to activation of the CRH–ACTH–adrenal axis, occurs in AN and elevated cortisol secretion, as well as loss of diurnal rhythmicity.[92] Because hypercortisolemia is known to suppress bone formation and increase marrow adiposity, this effect may contribute to low bone mass in patients with AN.[93] Despite cortisol excess, central adiposity has not been seen, presumably due to the generalized decrease in fat mass. In children with AN, baseline cortisol levels predicted increases in body fat with disease recovery.[94] With weight recovery in adults, truncal fat is also disproportionably increased, hypothesized to occur because of new substrate availability. In such patients, assessment of body composition and fat distribution by anthropometry, dual-energy X-ray absorptiometry, and whole-body MRI demonstrated that waist-to-hip ratios (WHR), total truncal, visceral, and intramuscular adipose tissue were significantly greater than in healthy controls of comparable weight.[95] AN is also characterized by GH resistance with elevated GH levels but decreased hepatic production of IGF-1.[96] There is a negative association between GH secretion, BMI and fat mass. Because GH directly and indirectly through IGF-1, increases bone mass, the lack of GH action also contributes to the very low BMD in this disorder, and possibly, worsens the increase in MAT.

The development of AN during adolescence is of particular concern as pubertal delay may occur.[92] Since adolescence is a time of rapid bone accretion and pubertal changes in body composition, the onset of disease during this critical window in development can dramatically affect peak bone mass accrual with consequences that may endure throughout life. The development of AN in childhood can lead to a reduction in bone size and volumetric BMD. Of note, the site and severity of specific deficits in both these parameters showed a maturational dependency on the age of onset of AN, as well as disease duration.[97] In sum, the skeletal components of this disease are directly related to changes in body composition and energy metabolism and the timing of the disease onset.

Adipokines play a major role in mediating changes in bone and fat mass. As noted previously leptin is an anorexigenic hormone. Anorexigenic and orexigenic hormones impact food regulation, energy expenditure, and bone mass, and vary with body fat. Although weight loss typically precedes amenorrhea in AN, an interesting observation has been that reproductive function can be maintained in some women, despite very low weight.[98] This may be due to several factors, including fat mass and leptin levels. Low-percent body fat and decreases in adipokine secretion, specifically leptin, may be a key mediator of reproductive function and likely impacts bone mass.[99] Although low in both groups, lumbar BMD is higher in eumenorrheic than amenorrheic women with AN, despite similar weight.[92] Of importance, mean percent body fat, total body fat mass, and truncal fat were higher in eumenorrheic than amenorrheic patients. This increase in body fat was associated with higher leptin levels in the eumenorrheic women than the amenorrheic women. Indeed, fat mass emerges as an independent predictor of bone density in regression models, including other variables, such as multiple body composition and gonadal function.[92]

Adiponectin also plays a role in the pathophysiology of the metabolic components of AN. Most but not all studies have found high adiponectin levels with AN.[100] In women with the restrictive subtype of AN, BMI, body fat content, and serum leptin levels were significantly decreased. Of note, an inverse relationship was found between adiponectin levels and BMI such that the elevated adiponectin levels compared to normal controls has been suggested to reflect the marked decrease in body fat in AN.[101] In a study of adolescents with AN, Misra et al. found that adiponectin levels were significantly associated with bone density of the lumbar spine and femoral neck.[102] Although the mechanisms whereby adiponectin might affect bone mass are unclear, changes in fat mass and insulin sensitivity in AN clearly play a central role. In a study,[103] plasma adiponectin levels were elevated in young women with AN compared to controls in the setting of reduced fat mass and impaired insulin-stimulated glucose disposal. Therefore, markedly reduced fat mass increases adiponectin secretion that may then affect bone mass directly or through changes in insulin sensitivity. Cawthorn et al. also demonstrated that high marrow adiposity in anorexia was related to increased serum adiponectin, suggesting this might be the origin of insulin sensitivity in this syndrome.[72] In sum, multiple changes in adipokines contribute to the pathogenesis of low bone mass in patients with AN.

Other appetite regulating hormones that may mediate bone loss in AN include peptide YY (PYY), an anorexigenic hormone, and ghrelin, which is orexigenic. Produced in the intestinal L cells in response to caloric intake, PYY acts via the Y2 receptor, which when deleted

in the hypothalamus, causes increased bone formation in rodents.[104,105] Obesity is associated with low-levels of PYY and these correlate inversely with BMI.[106] PYY levels have been reported to be elevated in AN compared to lean or obese controls.[107] In a study of girls with AN, PYY levels were higher compared to controls and PYY predictors included BMI, fat mass and resting energy expenditure.[10] In addition to the inverse association between fat mass and PYY levels, there was a negative association between fasting PYY levels and fat intake. In that study, PYY levels predicted markers of low bone turnover consistent with hypothesized effects of PYY increases on bone metabolism. This finding is also consistent with the enhanced osteoblastic activity noted in Y2 receptor knock-out studies. In adults with AN, mean overnight PYY levels were strongly and inversely correlated with BMD at the spine, total hip, femoral neck, and radius and, in association analysis, PYY was the primary determinant of spine BMD.[108]

Another appetite hormone linked to both bone and fat in AN is ghrelin. The orexigenic stomach-derived peptide hormone ghrelin is secreted in response to fasting, peaks before meals, and stimulates secretion of both growth hormone and ACTH. Ghrelin levels have been consistently reported to be elevated in AN and positive correlations are found between the ghrelin/obestatin, (i.e., proteins derived from the same gene but act as antagonists), ratio, and BMI.[109,110] Ghrelin also has effects on adipogenesis. Thompson et al. infused ghrelin, des-octanoyl ghrelin, or synthetic GHS-R_{1a} agonists into rats with varying severity GH deficiency of and demonstrated that a major circulating form of ghrelin, des-octanoyl ghrelin, has a direct adipogenic effect.[111] Ghrelin administration increases osteoblast proliferation.[112] In a prospective observational study of adolescents with AN, ghrelin was an important predictor of changes in spine and whole-body bone mass.[113]

The pathophysiologic changes from AN highlight the intimate relationship between fat mass, energy needs, and BMD. Although not a genetic disease, this syndrome has illustrated how complex those interactions are in humans and animal models.

7 GENETICS OF FAT AND BONE IN ANIMAL MODELS

As demonstrated in the previous discussions, fat and bone are intimately linked and their health are a part of the balance inherent in whole body metabolic homeostasis. To assess the genetic and gene × environmental determinants of this interaction, animal models have been a major investigational tool. There are two main categories of studies for identifying association between genes and phenotypes. The first is the reverse genetic study where the starting point is a gene and the goal is to ascertain what and how phenotypes are impacted. The second is a forward genetics study where the starting point is a phenotype or phenotypes and the goal is to uncover the genetic etiology. A historical workhorse of forward genetic mapping in animal models has been the two-strain intercross, with the output of these studies being quantitative trait loci (QTL) or regions of the genome containing polymorphic differences associated with the trait of interest. Given that fat is an important part of meat quality many studies genetically linking fat mass and bone size have been conducted in species of agricultural importance. Most of these studies have looked at fat weight as comapping with bone weight or bone area, which are not traits that we are primarily interested in for understanding bone disease.[114–116] One study in sheep did demonstrate comapping loci on ovine chromosome (Chr) 24 for total carcass fat mass and bone density as measured by CT.[117] Like many QTL mapping studies, these studies suffered from poor mapping resolution, so while these studies can suggest pleiotropy, the possibility of comapping cannot be ruled out.

This issue of comapping between obesity and bone QTL has been explored in greater depth in congenic mouse studies. A congenic is a strain with part of a Chr moved from one genetic background to another. These strains are generated by selective breeding. The resulting animals allow confirmation or de novo establishment that genetic regions contain polymorphism(s) impacting phenotype and allow study of the biology associated with a QTL without necessarily knowing the causative gene. Using a congenic strain wherein C3H/HeJ (C3H) alleles for middistal Chr 6 were introgressed on to a C57BL/6J (B6) background, we showed that there was a locus simultaneously impacting obesity, bone mass, and serum IGF-1 levels. Upon further study, we also showed that this locus impacted marrow fat levels, as well as osteoblast lineage allocations.[118] Using consomic strains, which are akin to congenics, but differ in that a whole Chr has been transferred instead of a region (see reference later), Reed et al., determined that genes on mouse Chr 7 also impact fat mass and bone mass.[119] Using a combination of the F2 intercross strategy and the congenic mouse approach, Jerez-Timaure et al. were able to narrow and partition a wide QTL (38 cM in span) previously associated with fat mass and with BMD on distal mouse Chr 2.[120] Specifically, they used a recombinant progeny approach to narrow this locus down for each phenotype of interest. Thus, they demonstrated that there is actually a cluster of genes impacting various combinations of body composition traits underlying it. The phenotype of BMD comapped with actual fat mass and with percent lean mass (so called leanness) but adiposity (percent total body fat) independent of body size was actually controlled by a separate and slightly

distal genetic region. As the BMD phenotype mapped in this study is whole body BMD as measured by DXA, it is difficult to separate this phenotype from body size.[121] This study is very important as it highlights dangers of declaring pleiotropy for "bone" from "weight" and "adiposity" QTL, despite the obvious physiology that would support, such a hypothesis.

Adiposity and obesity, are well understood to be influenced by environmental factors including factors, such as diet. In a very interesting study of inbred mice fed either a low fat chow diet or high fat–arthrogenic diet, Li and coworkers used structure equation modeling to investigate the link between BMD and fat mass.[122] They concluded that there was a genetic link between these two phenotypes, but the relationship was modified by dietary fat challenge. Specifically, their study suggested that both fat mass and lean mass have direct effects on BMD when mice are fed a high fat diet, but only lean mass, not fat mass has an effect when mice are fed a normal chow diet. While this study was not designed to identify individual genes and loci impacting this relationship, it is an interesting study that highlights that environment influences this fat-bone dynamic.

To address this issue more directly, Leamy et al. mapped QTL for a six skeletal traits in an advanced intercross population of mice made by interbreeding C57BL/6J mice and a strain selected for voluntary high running on a cage wheel.[123] An advanced intercross population or line is a population of animals or plants that has been interbred for more generations than the standard, two-generation F2 intercross. The advantage of an advanced intercross population is that mapping resolution is improved, but the disadvantage is that they take a long time to make and are very costly to maintain.[124] In the Leamy study, the mice examined were at G10 of intercrossing and half of the mice were fed a high fat diet, with the remainder a low fat control diet. While many QTL for femoral, vertebral and whole body BMD were mapped in this study, none were found to interact with dietary fat. A locus on Chr 7 for femoral shape and one on Chr 1 for femoral length were found to interact with dietary fat such that these loci were suppressed by the normal chow diet.

7.1 Shared Genetic Determinants of Bone and Fat in Animal Models

There are no other direct studies of high-fat diet interacting QTL where high fat feeding and control diet were used in the same study. However, two B6 by C3H crosses have been described in the literature. In the first of these, nearly 1000 female F2 mice where used to map loci for volumetric femoral and vertebral BMD.[125] In this study all mice were fed a chow diet. In a second similar study, 145 female and 164 male F2 mice were fed a high fat diet for 14 weeks and loci were mapped for femoral areal BMD.[126] A head-to-head comparison of these two studies provides putative existence of many diet-interacting QTL. One of these QTL is on distal Chr 1. Follow up studies with congenic mice provide evidence that this locus does indeed interact with dietary fat and suggests *Aim2* and a previously uncharacterized gene, *Gm4955* (*AC084073.22)* as likely candidates.[127] Second of these loci is on Chr 6. This locus was discussed previously as one that controls BMD and adiposity, and we have also shown that it interacts with dietary fat. Bioinformatics narrowing of this locus suggested peroxisome proliferator activated receptor gamma (*Pparg*) as a likely candidate gene. We then studied this gene in humans and determined that in men and women, allelic variation in this gene impacted BMD in humans via an interaction with dietary fat.[127]

In summary, there is strong evidence to show a genetic link between obesity, adiposity, and bone. This link is heavily influenced by dietary factors and almost certainly by gut microbiota. Unfortunately, while there have been many loci showing comapping of fat and bone traits, making the determination of pleiotropy has been difficult. Much work still needs to be done to determine which what gene(s) underlie many of these loci and if the impact on bone is via actions in adipose tissue, directly in bone or both.

8 GENETICS OF FAT AND BONE IN HUMANS

Obesity and osteoporosis, and their related quantitative phenotypes, are highly heritable.[128,129] Due to this fact and the enormous burden of each to human health, significant emphasis has been placed on dissecting their genetic basis. The initial genetic studies of obesity and osteoporosis used linkage analysis in families and candidate gene association studies. In retrospect, these approaches were plagued by limitations and, relatively speaking, little was learned. However, the approaches used to understand the genetics of fat and bone in humans have evolved over the last 30 years.[130] This evolution has been driven by large consortia efforts to generate catalogs of human genetic variation [131,132] and technologies capable of genotyping millions of single nucleotide variants (SNVs) in thousands of individuals. These advances have led to the era of genome-wide association studies (GWASs).

GWASs have revolutionized our understanding of complex diseases and disease-associated quantitative traits in humans.[133] In a GWAS, the genotypes of millions of SNVs are evaluated for effects on a disease-related trait, such as BMD, or for a difference in the frequency of

SNV alleles between "disease" cases and controls.[134] The discovery of associated variants by GWAS highlights a genomic region (usually spanning 5–150 Kbp) that contains one or more potential "causal" variants impacting the function or regulation of one or more target genes. Associations can then be dissected to identify which variants and genes are truly causal. One of the advantages of GWAS is that it is an unbiased gene discovery approach. Additionally, the regions identified by GWAS are narrow, implicating a small number of genes, and resolution is only limited by the local extent of linkage disequilibrium.[134] Importantly, recent works suggests that therapeutics targeting genes identified by genetic means (typically GWAS) are twice as likely to make it through the drug development pipeline than drugs targeting genes not implicated by genetics.[135] This suggests that GWAS data will become an increasingly important source of new drug targets.

Traits related to both, obesity and osteoporosis have been interrogated by GWASs. For obesity, GWAS in cohorts with over 100,000 individuals have identified large numbers of loci for body fat percentage,[136] BMI,[15] and body fat distribution (WHR) and waist/hip circumference.[137] The largest GWAS for WHR ($N \sim 224$ K people) identified 49 loci associated with WHR adjusted for BMI and an additional 19 loci associated with waist and hip circumference measures.[137] In addition, the largest GWAS for BMI was performed in ~339 K people and identified 97 loci.[15] Several GWASs have been performed for bone phenotypes. Most notably, BMD has been the trait of choice for GWAS, primarily due to its high heritability ($h^2 > 0.50$) (P, association with fracture [138] and availability in large cohorts. The largest GWAS for BMD was conducted by GEnetic Factors for OSteoporosis Consortium (GEFOS) for lumbar spine and femoral neck BMD in ~32 K individuals (with replication of the most significant associations in another ~50 K people) and identified 64 independent associations.[139]

Several important observations have been made from obesity and BMD GWASs. First, it is clear that each is highly polygenic, meaning that hundreds, if not, thousands of variants are influencing each disease. Second, common variants have small and subtle influences on body composition. All of the significant variants identified in the BMI and BMD GWASs described previously in aggregate ~3% of the phenotypic variance for either phenotype. Third, most genetic variation impacting both phenotypes, identified by GWAS, is noncoding and likely impacting some aspects of gene regulation. However, the most exciting observations coming out of GWAS are that many loci implicate genes not previously demonstrated to be involved in fat or bone biology. This supports the premise that within the GWAS findings data is a tremendous amount of information on very new biology. The challenge we now face is identifying the genes responsible for GWAS loci and ultimately translating those genes into new therapeutics.

8.1 Shared Genetic Determinants of Fat and Bone in Humans

Body weight, and its component phenotypes, lean mass and fat mass, have been demonstrated to be positively associated with BMD. However, the exact role of fat, and its interaction with bone, appears to be much more complicated. While increased fat mass has been shown to provide protection against fractures, recent studies indicate that, increased weight is protective against fractures, but fat mass per se has a negative impact on bone.[140] It is thought that the protective effects of increased weight are due to amplified mechanical forces, which cause bone to adapt by increasing its strength (through increased BMD or bone size). In contrast, adipose tissue itself may have deleterious effects on bone. This latter idea has come from observations that the relationship between fat mass and BMD is negative after adjusting for the effects of body weight (i.e., in individuals with the same body weight, those with higher percent fat mass have lower BMD.[140]

One of the key unanswered questions is what mediates the relationship between fat and bone, the environment or genetics or both? Studies have estimated the environmental and genetic correlations (the extent that the same environments or shared genes are responsible for the phenotypic relationships) between fat and bone.[141] In a study of monozygotic and dizygotic twins Nguyen et al., studied the relationships between lean mass, fat mass, and BMD.[141] They found that most of the association between fat mass and BMD were due to a strong environmental correlation, with a small nonsignificant genetic correlation. However, Zhao et al., demonstrated that after adjusting BMD for the effects of body weight, there was a significant negative genetic correlation between fat mass and BMD.[140] These observations suggest that the positive effects of obesity are mainly driven by environmental factors, whereas the negative impact of adipose tissue independent of body weight are determined, in part, by a common set of genes. Furthermore, the Zhao et al. study demonstrated that shared genes with a positive impact on fat, negatively impacted bone and vice versa.[140] It should be noted that very recent studies which use GWAS results to estimate genetic correlations between traits have shown small, but significant, positive genetic correlations between BMD and BMI and waist-to-hip ratio. This is interesting since the BMD GWAS data used weight-adjusted BMD.

Although these studies suggest that there should be shared sets of genes influencing both, fat and bone, the

results of GWAS to date have not been able to uncover such genes. Pickrell et al. used GWAS data to seek genomic regions harboring associations with more than one disease or trait. Included in their analysis were the GWAS results described previously for waist-to-hip ratio, BMI and BMD.[142] They found no such regions for lumbar spine BMD and obesity phenotypes but one region on Chr 12 (53–54.8 Mbp) linked to femoral neck BMD and WHR. SNVs in the latter region had a positive impact on femoral neck BMD and a negative impact on WHR, consistent with the negative genetic correlations between fat and bone described previously. In a separate study, Liu et al. performed a bivariate GWAS for BMI and BMD.[143] Though none of the variants typed in the study reached genome-wide significance, the top two SNPs were located within introns of the SRY-box 6 (*SOX6*) gene which has been implicated in bone and cartilage development, as a possible contributor to the fat and bone relationship.[144]

In summary, for humans, the genetic relationship between fat and bone appears to be more complex than anticipated and additional studies will be needed to clarify that interaction. However, there is a very strong rationale for pursuing this in depth. Not only could identification of genetic loci lead to specific molecular targeting and the potential for novel therapies for obesity and osteoporosis, but such discoveries could also have profound implications for our understanding of whole body metabolism.

The Cross Talk Between the Central Nervous System, Bone, and Energy Metabolism

Jianwen Wei, Gerard Karsenty

Columbia University, New York, NY, United States

1 INTRODUCTION

Physiology has been approached by two different methodologies. Being the most recent approach, molecular and cellular physiology focuses on studying molecular events occurring within cells, as they relate to a given function or signaling pathway. Earlier on, however, physiology, we will refer to as whole-organism physiology, aimed at identifying interactions between organs through what Claude Bernard called the "milieu intérieur."[1] The study of whole-organism physiology depends upon three fundamental principles. First, no physiological function/process is solely determined by a single organ; this has been verified multiple times through the use of model organisms.[2–4] Second, according to the fundamental concepts of homeostasis forged by W.C. Cannon and L.J. Henderson in the early 20th century, most physiological functions/processes are subjected to a coordinated regulation by several different organs that exert opposite influences on the same function/process.[5,6] This principle is best illustrated by the feedback regulation seen in endocrinology: a regulated organ signals back to a regulating one to limit its influence.[7] Third, regulatory molecules appear during evolution contemporaneously with the functions they regulate not afterward.

In the last half-century, the molecular revolution, especially the advancement of mouse genetics, has greatly transformed our understanding of all biological processes. Specifically, it is the ability to inactivate one gene in a single cell type and in a time-specific manner in the mouse that has led to the identification of many novel endocrine organs and hormones. In this way, mouse genetics has illustrated the value of a whole-organism approach to the study of physiology, provided of course it is conducted one molecule at a time. In this chapter, we review how an approach that is both molecular and whole organism to physiology, has profoundly enriched our views on skeleton biology. To that end, we describe mouse genetics studies pointing toward a coordinated regulation of bone mass and energy metabolism; a central control of bone mass; and the roles of leptin, serotonin, insulin, adiponectin, glucose, and osteocalcin in these pathways.

2 SPECIFIC FEATURES OF BONE AND WHOLE-ORGANISM PHYSIOLOGY

A unique feature of bone is that it is the only tissue in our body that contains a cell type, the osteoclast, whose main function is to resorb (destroy) the tissue in which it resides.[8] This destruction, or resorption, of bone is only one aspect of a biphasic physiological process called bone modeling during childhood, and remodeling during adulthood, in which bone formation invariably follows bone resorption. This constant alternation of bone destruction and bone formation fulfills biological functions of fundamental importance—bone modeling allows the longitudinal growth of the skeleton during childhood and enables one to stand, walk, and run; and bone remodeling that occurs after the arrest of skeletal growth was originally intended to repair micro- and macrodamage, that is, fractures.

Bone is also one of the tissues that cover the largest surface in the body. Hence, the destruction/construction

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00019-8

activity characterizing bone remodeling that occurs constantly and simultaneously in thousands of locations, requires a large and constant supply of energy to bone cells. The hypothesis that bone (re)modeling is an energetically costly physiological process is supported by several clinical observations. For instance, patients with anorexia nervosa, a disease characterized by very limited food intake, develops growth arrest if children and osteoporosis if adults.[9–19] Clinical experiences tell us another thing: osteoporosis, a low-bone-mass, appears when gonadal function declines.[20,21] Taken these observations together, we hypothesized that bone mass accrual, energy metabolism, and reproduction are all coordinated by endocrine regulation.[22] The possible cross talk between these three distinct physiological systems has several important implications. First of all, as it is bone that justifies the existence of this tripartite regulation, the hormones that make it happen should appear during evolution with bone, not before that. Second, the crucial role of the brain in energy homeostasis suggested that bone (re)modeling may be subject to central regulation. Third, there are likely to be feedback loops that originate from bone and that affect energy metabolism and fertility. Current studies supporting the hypothesis that bone mass, metabolism, and reproduction are linked are presented later.

2.1 Coordinated Control of Bone Mass and Energy Metabolism: Regulation of Bone Mass by Adipocytes

Adipose tissue is not only one of the most important organs of energy storage, but also it can function as endocrine organ by secreting several adipokines that are critical to energy homeostasis. Among them, leptin was from the onset the best candidate to test the hypothesis that bone mass, energy metabolism, and reproduction are linked. Leptin, a 16 kDa hormone secreted by adipocytes,[23] regulates appetite, energy expenditure, and fertility by signaling in the brain.[22,24,25–28] Accordingly, *ob/ob* mice, a natural mutant strain lacking a functional leptin gene, are obese and sterile.[23] The same is true for mice lacking the leptin receptor (*db/db* mice).[29] In addition to its role in energy metabolism, leptin is a powerful inhibitor of bone mass accrual. Indeed, mice or humans lacking leptin or its receptor develop a high bone mass phenotype even though they are hypogonadic, a condition that greatly increases bone resorption.[22] This feature suggested that the inhibition of bone mass accrual may be a major function of leptin. This notion has been verified genetically through the use of a partial gain-of-function leptin signaling model, the 1/1 mice, in which the inhibitory phosphorylation Y285 of the leptin receptor was prevented.[30] Remarkably, 1/1 mutant mice display normal appetite, normal energy expenditure, and normal reproductive functions.[30] Yet, they have a low-bone mass phenotype.[31] This observation indicates that leptin's regulation of bone mass requires a lower threshold of leptin signaling than that needed for regulation of energy metabolism and reproduction.

Previous analysis of leptin's mode of action on appetite and reproduction has demonstrated that these functions are centrally mediated[25,26]; therefore it was expected that leptin's regulation of bone would also be mediated by the central nervous system. Accordingly, several sophisticated genetic studies verified the existence of leptin-dependent central control of bone mass. The most convincing argument among them is that a neuron-specific deletion of *Lepr* recapitulates the bone phenotype of ob/ob mice, whereas an osteoblast-specific one does not.[31] There are also known mediators linking–leptin signaling in the brain to the osteoblasts, the ultimate target cell of leptin. The first one is the sympathetic nervous system, which signals through the β2adrenergic receptor (Adrβ2) present in osteoblasts.[27,28] Mice lacking the 2 adrenergic receptor (Adr 2), the only adrenergic receptor expressed at significant levels in osteoblasts, demonstrate the same high bone mass/high bone formation phenotype seen in *ob/ob* mice, and this phenotype cannot be rescued by ICV infusion of leptin.[27] In the osteoblast, the sympathetic tone recruits several transcriptional components of the molecular clock, cMyc and cAMP response element binding (CREB) protein, to inhibit cell proliferation by decreasing the expression of both D-type Cyclins and AP-1 genes.[32] Sympathetic tone also increases protein kinase A phosphorylation of ATF4, a member of the CREB family of transcription factor that is essential for osteoblast differentiation and function. ATF4 induces expression in osteoblasts of the osteoclast differentiation factor RankL[27,33].[34] Thus, sympathetic tone inhibits bone formation and favors bone resorption, which in turn reduces bone mass accrual. As a result, β-blockers antagonizing Adrβ2 can rescue osteoporosis in mice, rats, and even in humans[28]. The second mediator of leptin regulation of bone mass accrual is the cocaine amphetamine-regulated transcript (CART), a 116-amino acid long peptide that is found in the brain and the general circulation and whose production in the hypothalamus is positively regulated by leptin.[35,36] While mice lacking CART do not present any abnormalities in either body weight or reproduction when fed a normal diet, they demonstrate a late onset low bone mass phenotype caused by a sharp increase in bone resorption.[27,37] Indeed, CART acts on osteoblasts to inhibit *RankL* expression and thereby bone resorption.[27,38] The low bone mass/high resorption phenotype observed

in the absence of CART is similar to the one observed in mice deficient in MC4R, another known target of leptin in the hypothalamus,[39] and CART was identified as the downstream mediator of MC4R in its control of bone resorption.[39] The third mediator of leptin known to act on bone is Neuromedin U, an anorexigenic neuropeptide that is produced by neurons in the brain, as well as nerve cells of the small intestine, and whose expression is regulated by leptin.[40] Neuromedin U-deficient mice show a high bone mass/high bone formation phenotype similar to the one seen in *ob/ob* mice, this phenotype cannot be rescued by ICV infusion of leptin.[41] Additional analyses demonstrated that Neuromedin U mediates the leptin-dependent negative regulation of bone formation by acting on the sympathetic tone to alter osteoblast expression of molecular clock genes.[41] The broader implication of these collective results is that the brain controls bone mass accrual.

2.2 Coordinated Regulation of Bone Mass and Energy Metabolism: The Central Mode of Action of Leptin

To decipher the mechanisms whereby leptin regulates bone mass accrual, one needs to know first where it signals in the brain to fulfill this function. Initially, it seemed that the hypothalamus was where all the action was taking place as the leptin receptor is expressed at high levels in neurons of the arcuate (ARC) and of the ventromedial hypothalamic (VMH) nuclei. Moreover, chemical lesioning of these neurons led to hyperphagia and a massive increase in bone mass and bone formation parameters similar to the one observed in *ob/ob* mice and leptin infusions in the third ventricle of ob/ob mice decreased bone mass and appetite only if these hypothalamic neurons were intact.[28] However, this view was challenged by landmark studies showing that the selective inactivation of Lepr in VMH or arcuate neurons did not affect appetite or bone mass.[42,43] One possible interpretation of these seemingly contradictory results is that leptin requires the integrity of hypothalamic neurons to regulate appetite and bone mass, but does not need to bind with them. In other words, leptin could bind to its receptor in other brain structures than the ARC and VMH nuclei where it would control the synthesis of neurotransmitters that will then act in the hypothalamus. The fact that patients chronically treated with serotonin reuptake inhibitors (SSRIs), a class of drugs preventing serotonin reuptake in neurons, can develop bone loss, hyperphagia, and body weight gain suggested that serotonin and leptin signaling may intersect in the brain. This hypothesis was verified experimentally.[44] Serotonin is a neuromediator made only in neurons of the raphe nuclei and is also a hormone inhibiting bone mass accrual when synthesized by the enterochromaffin cells of the duodenum.[44] However, serotonin does not cross the blood–brain barrier, and thus each pool of serotonin must have different functions.[44] Embryonic or postnatal inactivation of tryptophan hydroxylase 2 (Tph2), the rate-limiting enzyme of serotonin synthesis in the brain, showed that brain serotonin is a powerful activator of bone mass accrual, an activator of appetite, and a regulator of energy expenditure. Because serotonin does not cross the blood–brain barrier, this experiment identified it as the first neuromediator to truly affect the bone mass.[44] Axon tracing and cell-specific and time-specific gene inactivation showed that, by signaling in neurons of the VMH nucleus, serotonin causes a decrease in sympathetic output thereby blocking its dual regulation of bone formation and bone resorption. On the other hand, by acting on ARC neurons, serotonin controls appetite and energy expenditure by favoring expression in these neurons of proopiomelanocortin-α (*Pomc*), melanocortin receptor 4 (*MC4R*), and other genes regulating appetite.[44] In-depth molecular studies showed that in both hypothalamic nuclei serotonin fulfills its function through the transcription factor CREB.

Leptin, instead of acting directly on hypothalamic neurons, signals to its receptor expressed on serotonergic neurons present in the brainstem and this binding causes an inhibition of *Tph2* expression and thereby a decrease in serotonin synthesis.[44] Accordingly, serotonin content in *ob/ob* hypothalamic is abnormally high. Removing one allele of *Tph2* from ob/ob mice normalized their brain serotonin content, appetite, energy expenditure, body weight, and bone mass.[44] Subsequently, the molecular bases of this leptin-serotonin-hypothalamus axis were also deciphered. They include calmodulin signaling in VMH neurons activating the transcription factor cyclic AMP-response-element-binding protein (CREB), which induces the expression of genes involved in catecholamine synthesis. This is important because the mediator acting as a bridge between leptin signaling in the brain and in bone cells is the sympathetic nervous system acting on osteoblasts through the β2 adrenergic receptor (Adrb2) and because β-blockers can limit the risk of osteoporotic fractures.[27,28] The fact that leptin inhibits both bone mass accrual and appetite is consistent with the hypothesis that bone acquisition, an energy-expensive process, must be linked to energy (food) intake, otherwise the risk of organ failure anywhere else in the body, at the time of a growth spurt for instance, would be high. This broader view on leptin suggests a simpler explanation of why this hormone appeared during evolution with bone.

3 EXPANDING BONE BIOLOGY WITHOUT PREMEDITATION

These aforementioned studies together with the powerful influence of food/energy intake on bone (re) modeling revealed by clinical observations raise one interesting question. If energy intake is so important for bone, does bone in turn regulate energy metabolism, in other words is bone an endocrine organ regulating energy metabolism? Genetic studies aiming to address this question resulted in identification of a bone–derived hormone and several novel endocrine functions of bone.

Osteocalcin is an osteoblast-specific protein that is secreted in large amounts in the bone ECM, and the genes encoding osteocalcin start to be expressed around the time bone mineralization begins. Even more suggestive was the fact that through the gamma carboxylation of three glutamic acid residues ("Gla" residues) osteocalcin acquires a high affinity for mineral ions.[45] Those were not only the important features of osteocalcin, they were simply the ones that had attracted the attention of most investigators in the field of bone biology ever since osteocalcin was discovered. And yet, neither the inactivation of *Osteocalcin* nor its overexpression in osteoblasts or other cell types had any effects on ECM mineralization in bones or other tissues.[46,47] However, *Osteocalcin*-deficient (*Osteocalcin*$^{-/-}$) mice had two obvious, albeit unexpected, phenotypes. The most overt phenotype was the dramatic increase in abdominal fat compared to wild-type (WT) littermates. A second more subtle observation was that *Osteocalcin*$^{-/-}$ mice started to breed later and became infertile sooner than WT littermates. Thus, the inactivation of an osteoblast-specific protein secreted in the bone ECM influenced two physiological processes that do not directly involve bones: fat accumulation and reproduction.

The surprising nature of these observations brought back to light other features of osteocalcin that had been overlooked. First, like most peptide hormones, osteocalcin is produced as a pre-/promolecule that is sequentially cleaved in osteoblasts, so that only the mature protein is secreted. Second, like many hormones, osteocalcin is present in the general circulation in the ng/mL range in all species tested and its circulating levels follow a circadian rhythm in humans.[48,49] Thus, the phenotypes of *Osteocalcin*$^{-/-}$ mice, and some biochemical characteristics of osteocalcin, suggested that it might be a peptide hormone secreted by osteoblasts. In fact, osteocalcin is not the only hormone synthesized by bone cells. FGF23 is also synthesized by osteoblasts, reaches the general circulation and acts in the kidney to favor phosphate elimination.[50] There is, however, an important difference between FGF23 and osteocalcin: FGF23 regulates phosphate metabolism, a process intimately linked to bone health itself.[47] In contrast, at least one of the functions of osteocalcin—the regulation of fat mass—had no known link to bone health. This set of observations also raised questions of greater significance: why would bone have any other function besides making bone and if it does, what might these functions be?

4 THE ANTICIPATED FUNCTIONS OF OSTEOCALCIN

The difficulty in testing whether osteoblasts affect energy metabolism through osteocalcin is that energy metabolism includes a loosely defined aggregate of processes ranging from food intake to the utilization of nutrients in peripheral tissues. The approach used to circumvent this difficulty was to coculture osteoblasts with other cell types or organ explants that secrete hormones regulating key aspects of energy metabolism. The two structures tested in this experimental scheme were pancreatic islets, given the number of aspects of energy metabolism regulated by insulin, and adipocytes, as leptin indirectly regulates osteoblast function.[22,27,28,44] Supernatants of WT osteoblasts enhanced the expression of *Insulin* in pancreatic islets and of *Adiponectin* in adipocytes. Several criteria of specificity strengthened these findings. For instance, the supernatant of fibroblasts, the cell type that is the most closely related to osteoblasts, failed to stimulate *Insulin* or *Adiponectin* expression. A second criterion of specificity is that among all the hormones expressed by pancreatic islets and adipocytes, only *Insulin* and *Adiponectin* expression was affected by the supernatant of osteoblast cultures. However, none of these changes in gene expression were observed when using the supernatants of *Osteocalcin*$^{-/-}$ osteoblasts identified osteocalcin as an osteoblast-derived hormone that affects *Insulin* and *Adiponectin* expression. These studies also identified the active form of osteocalcin since addition of uncarboxylated but not carboxylated osteocalcin increased Insulin and *Adiponectin* expression in islets and adipocytes, respectively.[51]

The in vivo analysis of the endocrine functions of osteocalcin has greatly benefited from the existence of mouse models of global and osteoblast-specific loss- (*Osteocalcin*$^{-/-}$ and *Osteocalcin*$_{osb}{}^{-/-}$ mice) and gain-of-function of osteocalcin (*Esp*$^{-/-}$ and *Esp*$_{osb}{}^{-/-}$ mice), each model serving as a mirror image control for the other. Consistent with the results of cell-based assays, insulin secretion and β-cell proliferation/mass were both decreased in *Osteocalcin*$^{-/-}$ mice. These mutant mice were also glucose-intolerant and insulin-resistant when fed normal chow, whereas the opposite was true in *Esp*$_{osb}{}^{-/-}$ mice. It remains to be determined what appears as an insulin resistance is rather indicative of the fact that osteocalcin may favor glucose uptake, independently of insulin. Explaining in part their changes in fat mass, energy expenditure was significantly decreased in *Osteocalcin*$^{-/-}$ and

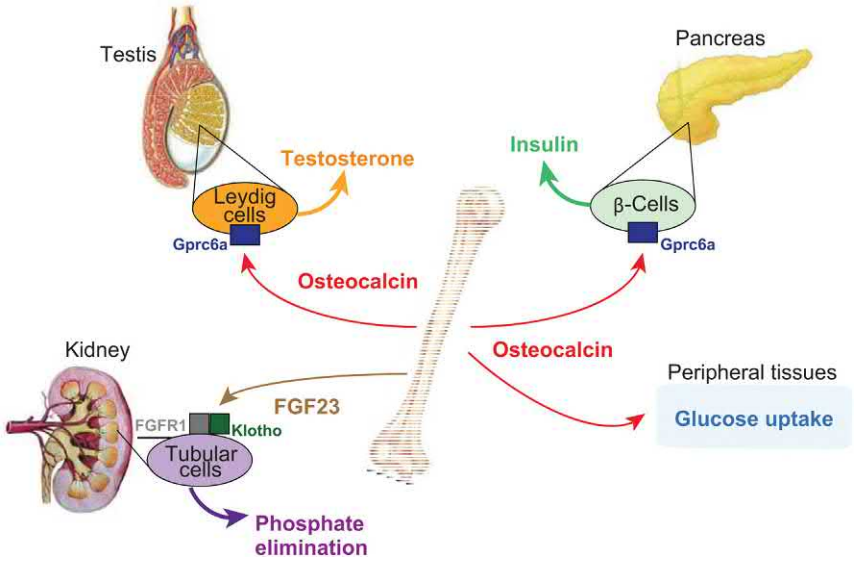

FIGURE 19.1 Schematic representation of the main organs whose functions are affected by osteocalcin (pancreas and testes) and FGF23 (kidney), the two osteoblast-derived hormones. Gprc6a is the receptor for osteocalcin in pancreatic β-cells and Leydig cells of the testes; FGFR1 and Klotho mediates FGF23 signal in tubular cells of the kidney.

increased in $Esp_{osb}^{-/-}$ mice.[51] These observations were recently extended to human pancreatic islets, in which the addition of uncarboxylated osteocalcin increased the expression of the *Insulin* and *Cyclind2* and *Cdk4* genes, two genes needed for β-cell proliferation.[52] Moreover, circulating osteocalcin levels are inversely correlated in adults with fasting glucose, circulating insulin levels, BMI, and body fat.[53]

These results demonstrate that osteocalcin is a bone-derived hormone that regulates β-cell proliferation, *Insulin* expression, and insulin secretion in mice and most likely in humans (Fig. 19.1). They also suggested that the hormonally active form of osteocalcin is the decarboxylated one. This was subsequently confirmed through genetic means.[54] The same coculture assay was used to test whether osteoblasts and presumably osteocalcin favor reproductive functions. Surprisingly, given that osteoporosis is primarily a disease of postmenopausal women, neither the supernatant of osteoblasts nor the uncarboxylated osteocalcin influenced the secretion of estrogen by ovary or follicular cells. In contrast, recombinant osteocalcin and supernatants of WT, but not of $Osteocalcin^{-/-}$ osteoblast cultures induced the secretion of testosterone by Leydig cells of the testes. Here again, the experiment was controlled in several ways; supernatants of no other mesenchymal cell types could increase testosterone secretion by Leydig cells of the testes and osteocalcin did not increase the secretion of estradiol, a derivative of testosterone, by Leydig cells. Extending these cell-based assays, the analysis of cell-specific loss- and gain-of-function mouse models of osteocalcin function, as well as the treatment of Leydig cells with osteocalcin, showed that uncarboxylated osteocalcin signals directly to Leydig cells to favor the expression of all genes encoding the enzymes necessary for testosterone synthesis, but does not affect the expression of *Cyp19* that is needed for the aromatization of testosterone into estradiol. As a result, male mice lacking osteocalcin show typical features of hypotestosteronemia, for example, low sperm count and lower weight of the epididymis and testes (Fig. 19.1). In contrast, the circulating levels of luteinizing hormone (LH) that favor testosterone secretion were increased in $Osteocalcin^{-/-}$ mice.[55]

4.1 The Other Side of Osteocalcin

Once the predicted endocrine functions of osteocalcin were demonstrated, a systematic search for other target organs for this hormone began. With regard to this, $Osteocalcin^{-/-}$ mice, regardless of gender, are markedly more docile than their WT littermates. Initially, this docility was ascribed to the low circulating level of sex steroid hormones that was suspected to exist in $Osteocalcin^{-/-}$ mice of both sexes. However, once it was shown that osteocalcin regulates sex steroid hormones synthesis only in male mice, this phenotype took another dimension and was analyzed rigorously. The docility of female $Osteocalcin^{-/-}$ mice could be traced to a decrease in the synthesis of all monoamine neurotransmitters and to an increase in the synthesis of GABA. In agreement with the extent of these abnormalities and the biological importance of these neurotransmitters, $Osteocalcin^{-/-}$ mice displayed severe behavioral phenotypes, such as increased anxiety and a profound deficit in spatial learning and memory. These abnormalities were caused by a lack of signaling of osteocalcin in the brain since delivery of the hormone in the brain through intracerebroventricular

infusion corrected them. Osteocalcin affects neurotransmitter synthesis because it crosses the blood–brain barrier and binds specifically to serotonergic neurons of the raphe nuclei in the brainstem, to neurons of the CA3 region of the hippocampus and of the dopaminergic nucleus of ventral tegmental area in the midbrain. Hence, these experiments demonstrated a significant influence of bone on neurotransmitter synthesis in the brain and on cognition[55a].

As unexpected as these findings were, another observation was even more surprising. A histological analysis showed that the hippocampi of *Osteocalcin*$^{-/-}$ mice were hypoplastic compared to those of WT littermates. This developmental defect was puzzling because *Osteocalcin* is not expressed during mouse embryogenesis before the last 2 days of gestation). Studying this observation revealed that maternally derived osteocalcin crosses the placenta and favors hippocampus development by preventing neuronal apoptosis. As a result *Osteocalcin*$^{-/-}$ mice exhibited a more severe cognitive deficit when their mothers were also *Osteocalcin*$^{-/-}$. Conversely, providing osteocalcin once a day to pregnant *Osteocalcin*$^{-/-}$ mothers normalize the development of the hippocampus and partly rescue the deficit in memory in their *Osteocalcin*$^{-/-}$ progeny. The observations that maternal osteocalcin contributes to the development of the brain in the embryo before it can make it, identifies osteocalcin, as a molecule responsible for the beneficial influence of the mother's health on the development of the brain and cognitive functions of the offspring (Fig. 19.2). The notion that maternal osteocalcin is present in the embryo before expression of *Osteocalcin* also suggests that osteocalcin may have a broader than anticipated influence on the health of the offspring.

5 QUESTIONS RAISED BY THE FUNCTIONS OF OSTEOCALCIN

The nature, extent, and number of the endocrine functions of osteocalcin raised interesting new questions. Key among them is the identity of the receptor for osteocalcin and the biological relevance of these findings beyond genetically modified mice, in other words whether the endocrine functions of osteocalcin observed in mice are conserved in humans. These questions were addressed through the study of the reproductive functions of osteocalcin. Osteocalcin's stimulation of testosterone secretion by Leydig cells follows a bell-shaped curve reminiscent of what is observed when a ligand binds to a G protein coupled receptor (GPCR). Further supporting this notion, treating Leydig cells with osteocalcin-induced production of cAMP while it failed to induce tyrosine phosphorylation, ERK activation, or intracellular calcium accumulation. These data justified a search for a GPCR that would be expressed in Leydig cells of the testes but not in follicular cells of the ovary and would transduce the osteocalcin signal. This screen identified a single candidate, Gprc6a.[55] Of note, *Gprc6a*$^{-/-}$ mice display metabolic and male reproductive abnormalities similar to those seen in *Osteocalcin*$^{-/-}$ mice.[56] Analysis of cell-specific gene deletion and compound mutant mice lacking one allele of *Osteocalcin* and one allele of *Gprc6a* in Leydig cells or β-cells only verified that Gprc6a mediates the osteocalcin signal in these cell types.[55]

Remarkably, *Gprc6a* is not expressed in any of the brain structures to which osteocalcin binds, *Gprc6a*$^{-/-}$ mice have normal neurotransmitter accumulation in the brain, normal hippocampal development, and normal

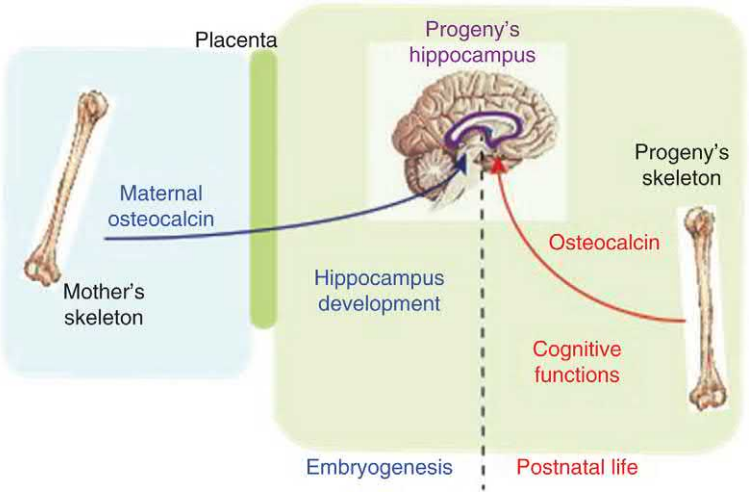

FIGURE 19.2 **Schematic representation of the functions of osteocalcin in the brain.** Maternally derived osteocalcin crosses the placenta, reaches the developing brain, and favors hippocampal development. In adult animals osteocalcin crosses the blood brain barrier regulates the synthesis of various neurotransmitters, prevents anxiety, and favors spatial learning and memory. The receptor for osteocalcin in the brain has not been identified yet.

cognitive functions. These findings ruled out that the cognitive defects seen in *Osteocalcin*$^{-/-}$ mice are secondary to their metabolic or endocrine abnormalities, as these abnormalities are equally severe in *Osteocalcin*−/− and *Gprc6a*$^{-/-}$ mice; on the other hand, they raise the question of the identity of the receptor(s) of osteocalcin in the brain.

Providing evidence that the endocrine functions of osteocalcin also exist in humans was helped by the fact that the reproductive phenotype of *Osteocalcin*$^{-/-}$ mice, low testosterone levels and high-LH circulating levels, bears resemblance to peripheral testicular insufficiency in humans. Sequencing all exons of *Osteocalcin* and *Gprc6a* in 59 of these patients identified 2 unrelated individuals harboring the same dominant negative mutation in a conserved residue of the GPRC6A extracellular domain, a mutation that could not be found in control individuals. Of note, glucose tolerance was also abnormal in both patients. Although more studies are needed, these data suggest that signaling through GPRC6A, presumably by osteocalcin, is required for testosterone synthesis by Leydig cells in humans.

Other questions raised by this work were to determine the potential influence on osteoblasts on insulin and adiponectin, the two hormones whose expression is regulated by osteocalcin. Addressing the relationship between bone and pancreas from the viewpoint of insulin helped explain how osteocalcin, a constituent of the bone ECM, becomes a hormone. Through its signaling in osteoblasts, insulin inhibits the expression of *Osteoprotegerin*, an inhibitor of osteoclast differentiation, thus insulin signaling in osteoblasts favors bone resorption. As the only known means to decarboxylate a protein once outside the cell is a low pH, such as the one reigning within the resorption lacuna, insulin signaling in osteoblasts allows the carboxylated form of osteocalcin present in the bone ECM to be decarboxylated on one particular Gla residue and released in the general circulation. These results that identified bone as a more significant insulin target organ than previously thought led to the demonstration that bone is a site of insulin resistance in diabetic mice. The demonstration that osteocalcin also regulates adiponectin expression led to the realization that in unchallenged mice adiponectin is a powerful regulator of bone formation (Fig. 19.3).[57]

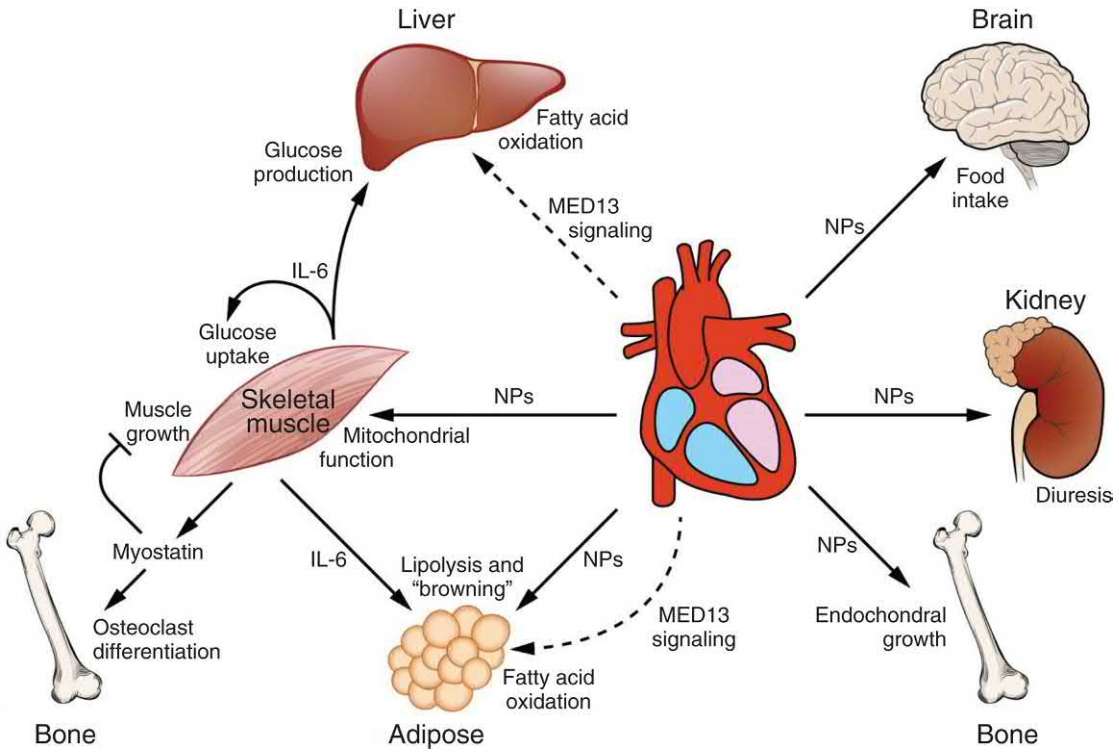

FIGURE 19.3 Schematic representation of endocrine signaling from striated muscles to distal tissues. Myostatin and IL-6 signal from skeletal muscle to distal tissues and also exert autocrine functions to suppress muscle growth and enhance glucose uptake, respectively. Natriuretic peptides (NPs) released from the heart regulate diverse processes in distal tissues. The mediator subunit MED13 acts in the heart to enhance fatty acid oxidation in liver and white adipose tissue. The factor(s) that mediate(s) signaling from cardiac MED13 to distal tissues have not been identified.

More topical questions remain to be addressed. For instance, we do not know how osteocalcin favors energy expenditure or glucose uptake in peripheral tissues. Likewise, the influence of maternal osteocalcin on glucose homeostasis in the offspring has not been accounted for. The fact that another hormone besides LH, be it osteocalcin made in bone, favors sex steroid synthesis in the male but not female gonads raises the question of whether such a hormone exists in females and, if so, which tissue synthesizes it. As for the cognitive functions of osteocalcin, not only do we need to identify its receptor in the brain but we also need to determine whether osteocalcin can improve cognition in WT animals, both young and old. Given the progressive aging of the general population and the paucity of drugs to treat or prevent the age-related decline in cognition this is a question of critical importance. There is one important aspect of bone biology that is worth mentioning in that context. Bone mass remains relatively constant for the first 3 decades of life and begins to decrease thereafter. This decrease is greatly accelerated at the time of menopause in women but eventually aging is associated with a marked decrease in bone mass in both sexes. This observation raises the question of whether bone in its endocrine capacity may in fact delay the age-related decrease in some physiological functions and may prevent the appearance of some aging manifestations. We now have the tools to address the test hypothesis in vivo.

But again the question of broader significance looming behind, the apparently disparate nature of the physiological functions regulated by osteocalcin, is to understand, what were the evolutionary advantages of the endocrine function of bone? Addressing this question in full will require identifying all functions of osteocalcin and possibly the ones of other hormones made by bone cells. Yet, one could use features shared by the known functions of osteocalcin to try to get at the logic of bone as an endocrine organ. It is obvious that male fertility is needed for the survival of any species. To a certain extent, the same can be said of the ability to utilize glucose in peripheral tissues and to remember where food sources and predators are located, for animals living in a hostile environment, such as the ones in which bony vertebrates lived early on. Under this light, the endocrine functions of osteocalcin and the classical functions of bone suggest that this tissue may have conferred evolutionary advantages of two types. By allowing walking and running, bone enabled animals to escape danger and to find food. At the same time, through its endocrine functions bone may have provided a means of survival in hostile environments. This view on the endocrine functions of bone is mainly a tool to search for additional physiological processes it may regulate. One may expect that other bone–derived hormones will be characterized in the future.

CHAPTER

20

Fetal Control of Calcium and Phosphate Homeostasis

Christopher S. Kovacs

Memorial University of Newfoundland, Health Sciences Centre, St. John's, NL, Canada

1 INTRODUCTION

Regulation of mineral and bone homeostasis in the adult is largely achieved through the interactions of parathyroid hormone (PTH), 1,25-dihydroxyvitamin D (calcitriol), fibroblast growth factor-23 (FGF23), calcitonin, and the sex steroids. Over the decades our knowledge had slowly developed from studies in humans and animals through surgical and pharmacological approaches that disrupt the normal regulation of mineral homeostasis, and studies of naturally occurring diseases characterized by altered mineral homeostasis. Our knowledge has rapidly expanded over the past 2 decades with the development of genetically engineered mouse models that enable the function of a single gene to be deduced by eliminating it or over-expressing it in the intact organism, and of molecular methods that enable detailed in vitro analysis of the interactions between ligand and receptor.

In contrast to the adult, comparatively less is known about the regulation of mineral and bone homeostasis in the fetus. This is largely because studying fetuses poses significant technical challenges. Human data have been limited to the analysis of cord blood samples in newborn infants, and pathological examination of embryos and fetuses that died at or before birth. Consequently, much of our understanding about human regulation of fetal mineral homeostasis must be inferred from studies in animals. Genetically engineered mouse models have greatly facilitated the study of fetal mineral homeostasis, but even then the small size of murine fetuses (2.0–2.5 cm and 0.8–1.1 g at term) makes systematic study of them particularly challenging and slow. Consider that the recoverable blood volume of a term fetal mouse is 50–60 μL of whole blood from which 30–40 μL of serum or plasma may be obtainable. Many assays for minerals and hormones require sample sizes of 20–300 μL. In an adult it is possible to measure multiple hormones and minerals from a single blood sample and to collect samples at multiple time points in the same individual, such as in a longitudinal study or as a time course in response to an acute challenge (injection of EDTA, PTH, etc.). But in studies of fetal mice only one blood sample can be obtained and it is inevitably a terminal experiment. Consequently cross-sectional data are obtained from studies of fetal mice, and multiple blood samples may have to be pooled for one measurement.

As this chapter will show regulation of fetal mineral homeostasis differs from the adult (Fig. 20.1). Skeletal patterning begins in the embryo but it is during fetal development that bone formation and mineralization accelerate. The placenta actively transports calcium, phosphorus, and magnesium in order to mineralize the skeleton before birth and maintain appropriate extracellular concentrations of these minerals for normal cellular functioning. The intestines play an insignificant role in fetal mineral metabolism, but after the placental pump is lost at birth, intestinal absorption of minerals becomes critical.

Each section of this chapter will review animal data and then specify whether any human data are available and how they agree or not with the animal data. To avoid exceeding specified limits on the reference list, two recent comprehensive reviews will be cited in place of many original research papers.[1,2]

2 OVERVIEW OF FETAL AND NEONATAL MINERAL METABOLISM

2.1 Animal Data

In all mammalian fetuses that have been studied (rhesus monkeys, sheep, cattle, rats, mice, pigs, and horses) the

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00020-4

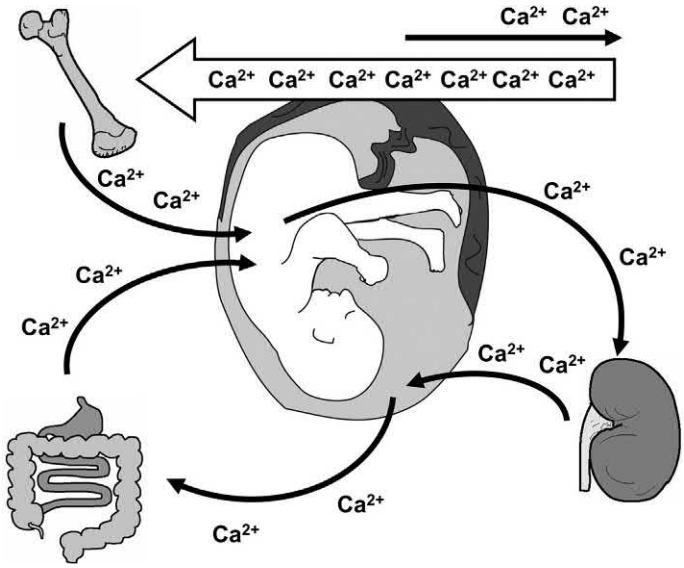

FIGURE 20.1 Circulation of mineral within the fetal–placental unit. Calcium is represented here but these statements apply to phosphorus (phosphate) and magnesium as well. At the top right, the main flux of mineral is across the placenta and through the fetal circulation into bone; however, some mineral returns to the maternal circulation (backflux). On the bottom right, the fetal kidneys filter the blood and excrete mineral into urine, which in turn makes up much of the volume of amniotic fluid. On the bottom left, amniotic fluid is swallowed and its mineral content can be absorbed by the fetal intestines, thereby restoring it to the circulation. The renal–amniotic–intestinal loop is likely a minor component for fetal mineral homeostasis. On the top left, although the net flux of mineral is into bone, some mineral is resorbed from the developing skeleton to reenter the fetal circulation. If placental delivery of mineral is deficient, fetal secondary hyperparathyroidism ensues, which causes more substantial resorption of mineral from the fetal skeleton, reduced skeletal mineral content, and possible fractures occurring in utero or during the birthing process.

serum calcium, ionized calcium, and phosphorus are higher than simultaneous maternal values.[1] This means the fetus is exposed to a high calcium × phosphorus product that can cause soft tissue calcifications in the adult but seems nonhazardous in utero. Serum magnesium is more variable with some studies showing slight increases, decreases, or no change as compared to the maternal value.

The high fetal blood calcium exceeds what the calcium sensing receptor (CaR) sets in the adult, and this level is maintained independent of the maternal blood calcium. Fetal rats remain normocalcemic despite maternal hypocalcemia caused by a calcium-restricted diet, severe vitamin D deficiency, or thyroparathyroidectomy.[1] Similarly fetal blood calcium in mice is unaffected by chronic maternal hypercalcemia (ablation of CaR) or hypocalcemia [ablation of vitamin D receptor, 1α-hydroxylase (CYP27b1), or PTH].[3–6] Chronic maternal hypophosphatemia also has no effect on fetal serum calcium or phosphorus.[7] The maternal blood calcium has also been acutely altered in rodents and primates by infusing calcium, calcitriol, calcitonin, PTH, or EDTA, and these studies have generally shown minimal or no effect on the fetal blood calcium.[1] However, when chronic maternal hypocalcemia in rats was induced at midgestation by parathyroidectomy, the fetuses were normocalcemic for several days but became hypocalcemic during the last few days of gestation.[1] The fetal skeleton rapidly accretes mineral during late gestation, and so it appears that the fetus may be unable to maintain a high fetal serum calcium during that time if the supply in the maternal circulation is very low.

As relative fetal hypercalcemia is robustly maintained across all species studied and often despite maternal hypocalcemia or hypercalcemia, it must have physiological importance. However, survival to the end of gestation is unaffected by significant hypocalcemia in *Pthrp* null, *Pthr1* null, *Hoxa3* null, *Trpv6* null, *Pth* null, *Gcm2* null, *Gp130* null, and *Hoxa3/Pthrp* double mutant fetuses.[1,5,8–13] On the other hand, it is possible that survival after birth is aided by fetal hypercalcemia. The onset of breathing is associated with a marked decrease in the blood calcium by 40% in rodents within the first 12 h after birth, followed by an increase to the adult value during the succeeding day.[1] A lower blood calcium in utero may lead to an even lower trough level in calcium after birth, thereby increasing the risk of tetany and death. Early postnatal mortality of hypocalcemic *Pthrp* null, *Pthr1* null, *Hoxa3* null, *Pth* null, and *Gcm2* null fetuses are conceivably due in part to this mechanism.[1,8,9,14] But the most convincing physiological role for fetal hypercalcemia is to facilitate normal mineralization of the fetal skeleton. Studies in fetal mice have shown that when the serum calcium is at or below the maternal level, then skeletal mineral content at term is significantly reduced.[5,8]

The fetal circulation is characterized by low levels of PTH, calcitriol, and FGF23, and high levels of

PTH-related protein (PTHrP) and calcitonin.[1] PTH appears to be suppressed by the CaR in response to the high fetal blood calcium. Consequently, when CaR is ablated in mice, both serum calcium and PTH rise above the fetal norm.[3] 25-hydroxyvitamin D [25(OH)D] readily crosses the placenta and results in cord blood 25(OH)D levels that are 75%–100% of the maternal value at term.[1] The low-calcitriol levels are due to suppression of the renal CYP27b1 by high serum calcium and phosphorus, low PTH, as well as relatively high activity of the catabolic enzyme, 24-hydroxylase (CYP24A1). The fetal kidneys are capable of upregulating CYP27b1; fetal hyperparathyroidism due to ablation of CaR results in high-calcitriol levels.[3]

As discussed in more detail in later sections, animal studies have shown that absence of parathyroids, PTH, or PTHrP each causes fetal hypocalcemia and hyperphosphatemia,[1,5,8,9,14] whereas fetal absence of calcitonin,[15] vitamin D,[16–18] calcitriol,[6,19] vitamin D receptor,[4,20] or FGF23,[7] do not disturb fetal blood calcium or phosphorus.

Minerals enter the fetus predominantly via the placenta (Fig. 20.1); consequently, control of active mineral transfer across the placenta explains many of the differences between mineral homeostasis of the fetus and the adult. As noted in more detail later, PTHrP regulates placental calcium and possibly magnesium transfer while PTH may also play a role[5,14,21–23]; the regulators of active placental phosphorus transport remain unknown.[1] During the interval of active calcium transfer, the placenta markedly upregulates expression of genes involved in calcium transport, and the fetal skeleton accretes mineral rapidly such that rats attain 95% of skeletal calcium during the last 5 days of gestation.[4,24–27] A small amount of mineral is excreted by the kidneys into the amniotic fluid, which confirms that mineral is not permanently lost since the amniotic fluid can be swallowed and the mineral content will then be reabsorbed. However, this route of mineral entry likely plays an insignificant role in fetal mineral homeostasis.

At birth the mechanisms controlling mineral homeostasis rapidly change. Placental infusions of minerals and hormones are lost upon cutting the umbilical cord, and breathing causes a rise in blood pH. These factors precipitate a 40% decline in blood calcium of rodents after birth. Phosphorus increases over the same interval and then declines. PTH rises to adult normal values by 24–48 h after birth and this precedes (and likely causes) a rise in calcitriol.[1]

In contrast to the fetus, the neonate is dependent upon the intestines for supply of minerals and for the kidneys to reclaim much of the renal filtered load of calcium, and to excrete excess phosphorus. Initially calcium absorption in neonatal rodents is passive and nonsaturable.[1] The high-lactose content of milk increases paracellular diffusion of calcium in the distal small bowel and net bioavailability of dietary calcium.[28] As the neonate matures, passive absorption of calcium declines, enterocytes upregulate expression of the vitamin D receptor and associated calcium transporting genes and proteins, and calcium absorption becomes an active, saturable, and calcitriol-dependent process.[1]

2.2 Human Data

Available data from developing humans are consistent with the animal data. Serum calcium, ionized calcium, magnesium, and phosphorus are all higher than maternal values.[1] The high serum calcium has been demonstrated as early as 15–20 weeks of gestation by fetoscopy. This fetal hypercalcemia appears to be maintained even in situations of maternal hypocalcemia due to severe vitamin D deficiency or hypoparathyroidism.[1] Cord blood measurements in normal fetuses have shown low levels of PTH, calcitriol, and FGF23, and high levels of PTHrP and calcitonin.[1,29] About 80% of the mineral content present in a term fetus is accreted during the third trimester,[30] during which active placental calcium and phosphorus transport takes place.

The onset of breathing causes a 20%–30% fall in the blood calcium followed by an increase to adult levels over the succeeding 24 h, and increases in PTH followed by calcitriol.[31] Intestinal calcium absorption in newborns (more so in preterm babies) is largely passive and nonsaturable,[32,33] facilitated by the high lactose content of human milk.[34,35] As the neonate matures, the intestine become less able to passively absorb calcium and instead active, saturable, and calcitriol-dependent intestinal calcium absorption becomes dominant.[32,36,37] This developmentally programmed maturation of the neonatal intestine explains why preterm babies do not respond to calcitriol but are dependent upon passive absorption of mineral until they become more mature.

3 OVERVIEW OF PLACENTAL MINERAL TRANSPORT

3.1 Animal Data

Active placental transport of calcium and other minerals is required because diffusional flow is insufficient to account for the required rapidity of transfer, and these mineral exchanges occur against electrochemical gradients.[1] Similar to intestinal calcium absorption, calcium presumably enters via gated calcium channels [such as transient receptor potential vanilloid 6 (TRPV6)] in the maternal-facing basement membranes, binds to intracellular proteins in order to shuttle to the opposite basement membrane, and then is pumped out at the fetal-facing

basement membranes by Ca^{2+}-ATPase. In rodent placentas, calcium is likely transported across trophoblasts and cells of the intraplacental yolk sac.

Calbindin-D9k is likely one of the binding proteins that shuttle calcium within trophoblasts and intraplacental yolk sac cells. Its placental expression begins at midgestation but increases many-fold during the interval of rapid placental calcium transfer in rodents. At the same time expression of Ca^{2+}-ATPase doubles while TRPV6 increases 14-fold.[1] All three calciotropic genes colocalize within trophoblasts but in rodent placentas the most intense expression is within the intraplacental yolk sac, a structure that also expresses other calciotropic genes at the highest intensity compared to the surrounding trophoblasts.[10,38] The significance of this yolk sac activity is discussed later.

Whether calbindin-D9k, Ca^{2+}-ATPase, and TRPV6 are essential for placental calcium transport is unclear. Placental calcium transfer has not been assayed in the available knockouts of calbindin-D9k (*S100g*) and Ca^{2+}-ATPase (*Pmca1*, *Pmca2*, and *Pmca4*).[1] Calbindin-D9k expression is reduced within the intraplacental yolk sac of two mouse models that have subnormal rates of placental calcium transfer (*Pthrp* null and *Trpv6* null),[10,38] but whether that is a cause or consequence of reduced placental calcium transfer is unknown. Knockout of *Trpv6* does not reduce intestinal calcium absorption in adult mice, but placental calcium transfer is reduced 40%, skeletal ash weight at term is 50% of wild-type (wt) values, and *Trpv6* null fetuses are severely hypocalcemic.[10] Therefore, TRPV6 must play an important role in placental calcium transfer and fetal calcium homeostasis. Since *Trpv6* null fetuses have reduced placental calcium transport while the adults have no impairment of intestinal absorption, it remains conceivable that *S100g*, *Pmca1*, *Pmca2*, or *Pmca4* null mice might have impaired placental calcium transport despite normal intestinal calcium absorption as adults.

There are significant structural and functional differences among placentas of the various species that have been studied.[1] Placentas of sheep, goats, and pigs have a cotyledonary structure of 60–70 individual units (cotyledons) that are spread over the entire uterine wall. The microscopic structure is epitheliochorial, which means that maternal and fetal circulations are separated by full thicknesses of maternal and fetal tissues. Calbindin-D9k expression is most concentrated in the interplacentomal region that has been postulated to be an important site of calcium transfer between mother and fetus in ruminants. The placentome and interplacentomal region also contain the highest expression of Ca^{2+}-ATPase.

Placentas of primates and rodents are discoid, in which placental tissue is confined to a single plate. The microscopic structure is hemochorial, meaning that fetal trophoblasts have fully invaded the uterine tissue such that maternal blood comes in direct contact with the fetal chorion. Consequently the barriers to exchange of nutrients and waste are reduced as compared to epitheliochorial placentas. Rodent placentas are hemo*trichorial* with three layers of trophoblasts interposed between the maternal and fetal circulations. Trophoblasts form a labyrinthine series of small channels bathed in maternal blood. Rodent placentas also contain the intraplacental yolk sac, a bilayered membrane interposed between fetal and maternal blood vessels (Fig. 20.2). A channel which lies

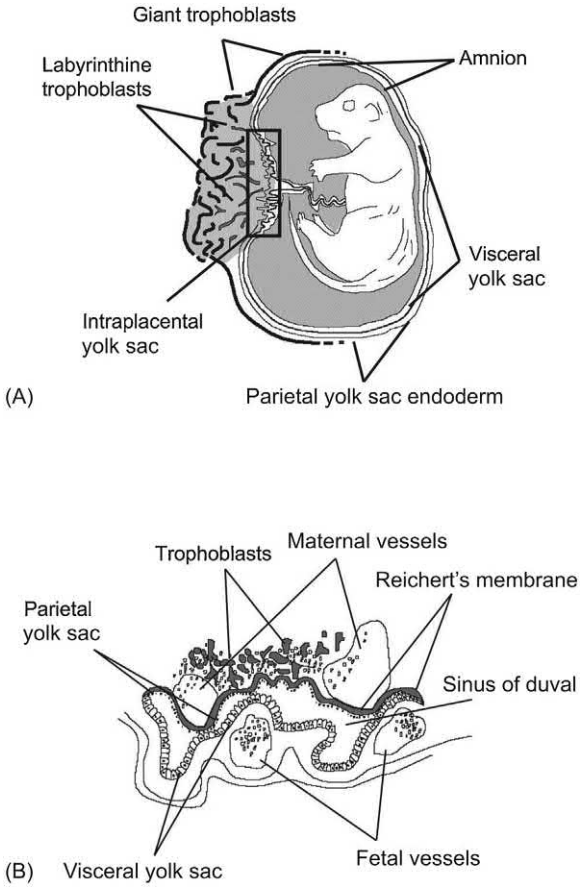

FIGURE 20.2 Anatomy of the intraplacental yolk sac. By the time the mature placenta has formed (A), the compressed yolk sac lines the uterine cavity (decidua) that is not in contact with the placenta, and it overlies the dome of the placenta. The parietal layer and Reichert's membrane are in contact with the decidua and the dome of the placenta, while the columnar or visceral yolk sac layer is in apposition to this layer, separated by the yolk sac cavity. The yolk sac bilayer that overlies the dome of the placenta forms finger-like projections into the placenta near the insertion of the fetal vessels [boxed area in (A), the intraplacental yolk sac]. The intraplacental yolk sac is positioned between maternal and fetal blood spaces, as visualized in detail in (B). Within this structure, the parietal layer and Reichert's membrane overlie maternal blood spaces and vessels, while the columnar layer overlies fetal blood vessels. Between these layers is the sinus of Duval, which also communicates with the yolk sac cavity and the uterine lumen. *Source: Reproduced with permission from Kovacs CS, Chafe LL, Woodland ML, McDonald KR, Fudge NJ, Wookey PJ. Calcitropic gene expression suggests a role for intraplacental yolk sac in maternal–fetal calcium exchange.* Am J Physiol Endocrinol Metab *2002;***282***(3):E721–32, copyright 2002 American Physiological Society.*[38]

in between the two layers is called the sinus of Düval. Although rodent trophoblasts express many calciotropic genes, the expression of calbindin-D9k, Ca^{2+}-ATPase, PTHrP, PTH/PTHrP receptor (PTH1R), TRPV6, vitamin D receptor, and CaR are most intense within the intraplacental yolk sac.[1,38] PTH mRNA has recently been found to be expressed in murine placenta but localization studies have not been done owing to lack of suitable antibodies.[5] Cyp27b1 and Cyp24a1 are expressed by trophoblasts, as are FGF23's coreceptor Klotho, all four FGF receptor subtypes, and all three sodium phosphate cotransporter two subtypes (NaPi2b > NaPi2a and NaPi2c).[7,39] Very-low-level placental expression of FGF23 was confirmed by comparison of normal and *Fgf23* null placentas.[7]

Due to its positioning between the maternal and fetal vessels and its intense expression of calciotropic factors, the intraplacental yolk sac may be a site of maternal–fetal calcium exchange. Moreover the intraplacental yolk sac and its sinus of Düval are continuous with corresponding structures of the extraplacental yolk sac that in turn overlie the uterine epithelium. Hence it is possible that secretions from the uterine epithelium cross the parietal layer of the extraplacental yolk sac to reach the sinus of Düval, travel to the placenta, and enter the fetal circulation across the columnar epithelium within the intraplacental yolk sac. Precedent for this concept is that egg shell calcification proceeds from exuberant uterine secretions of calcium and other minerals. The intraplacental yolk sac may have evolved in rodents as an alternate route for active calcium transport in order to meet the calcium demands created by large litters and a short gestation period. However, owing to its microscopic size and other factors, it hasn't been technically feasible to determine whether calcium or other minerals are being exchanged at this site. A genetic knockout resulting in loss of the intraplacental yolk sac would be one way to test this. Platelet-derived growth factor-alpha is intensely expressed in the intraplacental yolk sac, and a naturally occurring deletion of this gene results in placentas devoid of this structure.[40] However, most pups die at midgestation, too soon for placental calcium transport or skeletal mineralization to be studied.

Two main approaches have been used to assay transfer of calcium, phosphorus, or magnesium across the placenta. The first is an in situ placental perfusion technique used in sheep, goats, and rats. In this procedure the dam remains anesthetized, the fetus is removed, the placenta is connected to a semiclosed circuit, and either autologous fetal blood or a blood substitute is used to perfuse the circuit at a set flow rate and pressure. ^{45}Ca and ^{51}Cr-EDTA (a diffusional marker) are infused into the mother, and repeated sampling from the maternal circulation and umbilical vein enables calculation of radioisotope clearance rates. ^{32}P or ^{28}Mg have also been administered in combination with ^{51}Cr-EDTA. Peptides or pharmacologic agents can be infused into the umbilical artery while the umbilical vein is continuously sampled to determine if the calcium (or phosphorus or magnesium) concentration is altered by the intervention. The main limitations of this technique are that it is done in a single placenta, in the absence of normal fetal regulation, and with the perfusate pressure and rate at arbitrarily set levels.

The in situ placental perfusion technique has recently been miniaturized to the small scale of fetal mice, but in order to successfully catheterize the umbilical vessels the vasculature is first maximally dilated with nitroglycerin.[41,42] ^{45}Ca alone is administered to the mother and only single measurements of ^{45}Ca in the maternal circulation or placental circuit can be obtained. The use of nitroglycerin may confound the experiment by creating artifactual differences between wt and mutant placentas if they differ in factors, such as ambient blood pressure, structure, or responsiveness to vasodilators.

A second technique used in mice keeps the fetus intact and in control of placental function. The pregnant mother is anesthetized for a few seconds in order to receive an intracardiac injection containing ^{45}Ca and ^{51}Cr-EDTA (or ^{32}P and ^{51}Cr-EDTA), and as early as 5 min after the maternal injection, the fetuses are removed so that the amount of isotopes accumulated within each fetus can be measured. As ^{51}Cr-EDTA crosses the placenta by passive diffusion, it serves as a control for differences in flow rate between the individual placentas in one litter. The relative rate of placental calcium or phosphorus transfer for each fetus in the litter can then be determined by expressing the accumulation of ^{45}Ca relative to ^{51}Cr or ^{32}P relative to ^{51}Cr, respectively. Strengths of this procedure include that the dam is awake, fetuses are not disturbed but remain in control of placental function, placental perfusion pressure has not been altered, and 8–10 normal and heterozygous fetuses within each litter serve as controls for the null fetuses and each other. The main limitation is that a relative and not absolute rate of mineral transfer among fetuses is obtained in order to be able to compare results from one experiment to the next.

3.2 Human Data

The calcium transporting cells in human placentas are the syncytiotrophoblasts and there is no structure equivalent to the rodent intraplacental yolk sac.[1] Human placentas are discoid and hemochorial but only a single layer of trophoblasts is interposed between maternal and fetal circulations, making them hemo*monochorial*. Finger-like projections (villi) protrude and float freely in a large intervillous maternal blood-filled space. The trophoblasts intensely express calbindin-D9k, Ca^{2+}-ATPase, and TRPV6. PTHrP mRNA and protein are widely expressed in human syncytiotrophoblasts,

cytotrophoblasts, amnion, decidua and myometrium; the highest levels may be in the amnion. Human trophoblasts also express the PTH1R, CaR, VDR, calcitonin, calcitonin receptor, NaPi2b, FGF receptors, and Klotho.[1]

Although in vitro perfusion studies have been done, no in vivo data about placental function have come from study of human placentas. Despite some differences in structure, hemochorial rodent placentas appear to have similar active transport and diffusion characteristics as hemochorial human placentas, whereas the epitheliochorial placentas of sheep differ significantly in structure and function from human placentas.

4 OVERVIEW OF ENDOCHONDRAL BONE DEVELOPMENT

4.1 Animal and Human Data

The details of endochondral bone development are beyond the scope of this chapter and therefore a brief overview is provided for context of what follows in later sections. The genetic control of endochondral bone development has been derived largely from studies in rodents, including various transgenic and knockout mouse models. The remainder of the data in this section largely derives from study of human embryos and fetuses that aborted or died in obstetrical accidents.

Studies in rodents have shown that early patterning of the embryonic skeleton is dependent upon a multitude of signaling pathways, which include Hox genes, Wnts, Hedgehogs, bone morphogenetic proteins, fibroblast growth factors, Notch/Delta, and other factors.[43,44] Mesenchymal cells are laid down in spatiotemporal patterns where bones of the axial and appendicular skeletons will form. These osteochondral progenitors differentiate into osteoblasts at the site of intramembranous bone formation, which includes the vault of the skull and a few other bones. In the bulk of the developing skeleton these progenitors differentiate into chondroblasts that initiate the process of endochondral bone development.

By the 8th week of gestation in humans, a complete cartilaginous scaffold of the skeleton is present with such fine details as digits and joints already delineated. The scaffold of each long bone lengthens at both ends, with the older cells nearer the center undergoing differentiation, hypertrophy, and then apoptosis. Chondroclasts and osteoclasts resorb the apoptosed chondrocytes and surrounding matrix, vascular invasion occurs, and osteoblasts lay down the primary spongiosa (osteoid) that will become mineralized. Primary ossification centers form in the vertebrae and long bones between the 8th and 12th weeks, but the bulk of mineralization does not occur until the 3rd trimester. Resorption and remodeling of bone to create secondary spongiosa occurs in utero and this resorption will abnormally increase when the fetus is stressed by maternal hypocalcemia. For example, uncontrolled hypocalcemia in a hypoparathyroid woman can lead to secondary hyperparathyroidism in the fetus, manifest by subperiosteal resorption, fractures, and reduced bone mineral content.[1] At the 34th week of gestation, secondary ossification centers form in the femurs, thereby creating true growth plates. But most epiphyses are cartilaginous until after birth when the secondary ossification centers finally form.[45] These growth plates become fused during puberty, after which linear growth ceases.

5 ROLE OF PTHrP

5.1 Animal Data

5.1.1 Regulation of Serum Minerals

PTHrP is present in human cord blood at levels up to 15-fold higher than PTH when expressed in equivalent pmol/L units, and similar high levels have been observed in fetal lambs and rodents.[1] Multiple fetal tissues produce PTHrP and so it is unclear from which source(s) PTHrP in the circulation derives. The placenta may be a dominant source because the normal placental expression of PTHrP is upregulated further in *Pthr1* null mice which have an 11-fold elevation in circulating PTHrP.[9] On the other hand there is conflicting evidence as to whether the fetal parathyroids contribute substantial amounts of PTHrP to the circulation. PTHrP was first detected in parathyroids of fetal sheep by using polyclonal antibodies. Since parathyroidectomy in fetal lambs causes hypocalcemia, but circulating PTH levels are normally low in fetuses, it was inferred that loss of parathyroid-derived PTHrP causes the hypocalcemia. However, no measurements of circulating PTHrP levels were made in these parathyroidectomized fetal lambs. In two subsequent studies PTHrP mRNA was not detected in fetal or adult rat parathyroids by in situ hybridization or real-time PCR (RT-PCR), whereas it was detected by RT-PCR in a third study of adult rat parathyroids.[1] Murine parathyroids have not been studied in isolation to determine if PTHrP mRNA or protein is present. However, absence of parathyroids in *Hoxa3* null and *Gcm2* null fetuses did not alter the plasma PTHrP level,[5,9] and the 11-fold upregulation in plasma PTHrP in *Pthr1* null mice was not associated with any detectable increase in expression of PTHrP mRNA in the neck region.[9] These data suggest that the parathyroids are not the main source of circulating PTHrP in fetal rodents.

PTHrP evidently regulates the fetal blood calcium because in its absence (*Pthrp* null fetuses) the blood calcium falls to the maternal level (Fig. 20.3). Though it does not fall even lower than this is due to a fivefold upregulation

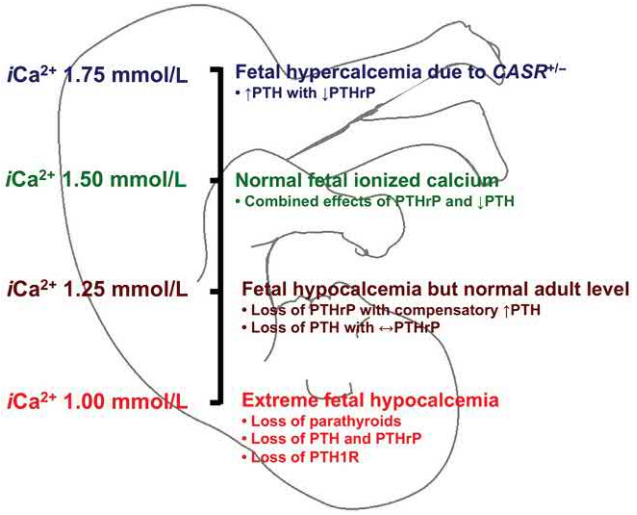

FIGURE 20.3 **Regulation of fetal ionized calcium.** This schematic illustrates changes in ionized calcium as observed in murine fetuses and extrapolated to humans; the levels shown are meant as a guide for relative changes and are not meant to indicated precise values found in human cord blood. The normal ionized calcium level is higher in fetuses than in the normal adult, and is maintained by the combined effects of high concentrations of PTH-related protein (*PTHrP*) and low levels of parathyroid hormone (*PTH*) in the circulation. CaSR likely suppresses PTH in response to the normal high level of calcium in fetal blood. The high fetal blood calcium may be set by a novel calcium-sensing receptor (other than the known CaSR), which regulates PTHrP release from the placenta and possibly other fetal tissues. In the absence of PTHrP, serum calcium falls but is now maintained at the normal adult level through the normal actions of CaSR to regulate PTH. Loss of PTH leads to a similar blood calcium value, approximately equal to the maternal calcium concentration, without a compensatory increase in circulating PTHrP. Combined loss of PTH and PTHrP, loss of parathyroids, or loss of PTH1R, each result in the lowest fetal ionized calcium values. Conversely, inactivating mutations of *CASR* cause PTH and the blood calcium to increase above normal fetal levels, in turn causing PTHrP to become decreased.

of circulating PTH, which is likely stimulated by CaR in order to maintain the normal adult level of blood calcium. The responsiveness of fetal PTH to regulation by CaR has been demonstrated in additional experiments. When CaR is simultaneously ablated (*Pthrp/Casr* double mutants) the fetal PTH and blood calcium rise higher than in *Pthrp* nulls.[3] On the other hand when the amino-terminal effector pathway for PTH and PTHrP are both removed (*Pthr1* nulls), the simultaneous ablation of CaR has no effect on the fetal blood calcium at all (*Pthr1/Casr* double mutants vs. *Pthr1* nulls) (Fig. 20.3).[3]

PTHrP also regulates phosphorus but not magnesium levels in blood because *Pthrp* null fetuses are hyperphosphatemic with normal serum magnesium concentrations.[8,9]

5.1.2 Regulation of Placental Mineral Transfer

PTHrP stimulates placental calcium transfer in fetal sheep and rodents. The original evidence (reviewed in Ref. 1) came from fetal sheep that were thyroparathyroidectomized and treated with thyroid hormone for several days before the fetus was removed and the in situ placental perfusion technique was performed. Placental calcium transfer was significantly reduced in this model but could be increased with infusion into the circuit of autologous blood from intact fetal sheep.[46,47] Additional experiments found that intact and midmolecular fragments of PTHrP each stimulated placental calcium transfer, whereas PTH was ineffective.[21,48–50] These results in isolated, perfused placentas of thyroparathyroidectomized fetal sheep are consistent with the concept that parathyroid-derived PTHrP regulates placental calcium transfer while PTH does not. However, circulating levels of PTHrP were not measured and so it remains unknown whether fetal thyroparathyroidectomy lowers the rate of placental calcium transfer by reducing fetal PTHrP.

Subsequent studies, using a placental calcium transfer technique in intact fetal mice, found that, depending upon the time point studied, *Pthrp* null fetuses had a 25%–40% reduction in the rate of placental calcium transfer as compared to their wt and $Pthrp^{+/-}$ littermates. Treatment with PTH and amino-terminal PTHrP had no effect, whereas intact and midmolecular PTHrP both raised the ^{45}Ca accumulation to normal.[14] These results confirmed that placental calcium transfer is stimulated by PTHrP but not PTH. However, *Pthrp* null fetuses have a threefold increase in endogenous PTH that may have blunted the ability of exogenous PTH to stimulate placental calcium transfer.

Additional studies in other knockout mouse models support the notion that PTHrP regulates placental calcium transfer while PTH may not. Aparathyroid *Hoxa3* null fetuses have undetectable circulating PTH[51] but a normal rate of placental calcium transfer, unaltered plasma PTHrP levels, and normal placental PTHrP expression.[9] *Pthr1* null fetuses have increased circulating PTHrP and PTH and a 50% higher relative rate of placental calcium transfer.[9,14] These *Pthr1* null fetuses are unable to respond to amino-terminal PTH or PTHrP but retain the ability of both hormones to act on any mid- or carboxy-terminal receptors. The high-circulating levels of PTHrP are thought to be stimulating placental calcium transfer through actions on a midmolecular receptor.[9,14]

Contrary evidence about the role of PTHrP comes from the in situ placental perfusion technique adapted for use in mice as described above. Perfused placentas from *Pthrp* null fetuses had an *increased* rate of ^{45}Ca transfer as compared to parallel studies done in wt and $Pthrp^{+/-}$ fetuses.[42] This surprising result may be explainable by the experimental methodology described earlier, most notably the use of nitroglycerin to dilate the placental and umbilical vasculature prior to catheterization of the umbilical vessels. PTHrP is expressed in the smooth muscle vasculature, functions as a smooth muscle relaxant and vasodilator, and exerts effects on vascular development and physiology.[52,53] The *Pthrp* null

placental vasculature likely differs from wt in its ambient pressure, structure, and responsiveness to vasodilators.[53] Consequently, nitroglycerin may have different effects on the vasculature of wt and *Pthrp* null placentas and lead to an artifactual result. Additional concerns about this technique have been detailed elsewhere.[1] Taken at face value, use of the miniaturized in situ placental perfusion technique suggests that PTHrP's role is to inhibit placental calcium transfer rather than to stimulate it. This finding, which is at odds with the bulk of the existing data, as noted above, may be artifactual due to the experimental methodology.

Overall most of the studies in fetal sheep and mice support the concept that a midmolecular form of PTHrP stimulates placental calcium transfer. Whereas the fetal sheep studies imply that the PTHrP is parathyroid derived, studies in aparathyroid fetal mice are more consistent with a placental source. Species differences might also explain the apparently discrepant results of the sheep and mouse studies.

Magnesium and phosphorus are also actively transported across the placenta but whether PTHrP plays a role is uncertain. Midmolecular fragments of PTHrP stimulated magnesium transport across in situ perfused placentas of fetal lambs [21,23] but had no effect in rat placentas.[54] PTHrP did not stimulate placental phosphorus transfer in sheep.[55,56]

5.1.3 Regulation of Endochondral Bone Formation

Within the developing endochondral skeleton, PTHrP is produced by perichondrium and proliferating chondrocytes while the PTH1R is expressed further down the growth plate within prehypertrophic chondrocytes,[57–59] as well as in preosteoblasts and osteoblasts.[60] The critical role that PTHrP plays in endochondral bone formation was first made evident by *Pthrp* null fetuses, which have a chondrodysplasia characterized by dwarfed long bones and deformed growth plates.[61] Further study has shown that PTHrP acts locally to delay terminal differentiation and hypertrophy of chondrocytes. Without PTHrP, hypertrophy begins early and bone formation starts before the cartilaginous template has reached its intended length; consequently, long bones become shorter than normal.[59,62] Conversely, overexpression of PTHrP or expression of an activating mutation of the PTH1R within fetal chondrocytes delays chondrocyte hypertrophy and results in a largely cartilaginous skeleton at birth.[63,64] PTHrP also interacts with Indian hedgehog and the wnt signaling pathway to regulate the lifespan and fate of chondrocytes.[59,65]

Since preosteoblasts and osteoblasts express PTHrP and PTH1R, the *Pthrp* null skeleton might be expected to show decreased expression in osteoblast-specific genes, and reduced bone formation and mineralization. However, *Pthrp* null growth plates normally express collagen α1(I) and collagenase-3, and have upregulated expression of osteocalcin and osteopontin.[61,66] The rapid maturation and apoptosis of the cartilaginous template within the *Pthrp* null skeleton causes bones to mineralize in utero that normally do not mineralize until after birth; moreover, the portions of the ribs and sternum which normally remain cartilaginous in the adult become bone in the *Pthrp* null fetus.[61] As noted earlier, *Pthrp* nulls have threefold increased circulating PTH[8] and this hyperparathyroidism may rescue any deficit in osteoblast function that loss of PTHrP might otherwise cause. Further studies in mice lacking PTH or the PTH1R support this notion (discussed later).

PTHrP expressed within preosteoblasts and osteoblasts does play an important role in regulating bone formation, as confirmed by a model in which the PTHrP gene deletion was targeted to these specific cells. Such mice have reduced bone formation and low bone mass at six weeks of age, confirming that osteoblast-derived PTHrP regulates bone formation.[60] However, the fetal skeletons have not been examined and so it remains unknown whether osteoblast-derived PTHrP is important for fetal bone formation.

As noted above, *Pthrp* null fetuses lack circulating PTHrP, are hypocalcemic (ionized calcium reduced to the maternal level), and have a reduced rate of placental calcium transfer.[8,14] Despite these changes and shorter long bones, the *Pthrp* null skeleton has a normal ash weight and normal content of calcium, magnesium, and phosphorus.[8,14] Why is skeletal mineral content not reduced? The *Pthrp* null skeleton accretes mineral more avidly than normal due to its accelerated and abnormal calcification of skeletal structures, and so its mineral content cannot be meaningfully compared to the normal skeleton.

Overall the evidence is that PTHrP participates in fetal skeletal development by upregulating placental calcium transfer, maintaining a high serum calcium, determining the fate of chondrocytes within the scaffold, and possibly by regulating preosteoblasts and osteoblasts.

5.2 Human Data

PTHrP is expressed by human placentas and may be a major contributor to the high-circulating concentration found in cord blood at term. Human fetal parathyroids have not been examined but PTHrP expression has been detected in adult normal, hyperplastic, and adenomatous parathyroids by Northern, immunohistochemical staining, immunoblot, and both radioimmuno and radioimmunometric assays.[1] A human equivalent of PTHrP gene deletion has not been identified but would presumably be lethal at or before birth if absence of PTHrP has consequences similar to those observed in fetal mice. A microdeletion in the PTHrP gene has been linked to brachydachtyly type E, a condition characterized by short

stature and shortened metacarpals and metatarsals.[67] This is consistent with a role for PTHrP in controlling endochondral bone formation in humans.

6 ROLE OF PTH

6.1 Animal Data

6.1.1 Regulation of Serum Minerals

Despite its low-circulating level in fetuses, PTH is an important regulator of the serum calcium. Loss of PTH, parathyroids, or PTH1R result in significant hypocalcemia as shown by *Pth* null, *Gcm2* null, *Hoxa3* null, and *Pthr1* null fetuses[5,9] and thyroparathyroidectomized fetal sheep. Blood calcium is lowest in fetal mice lacking parathyroids (*Hoxa3* null) or PTH1R (*Pthr1* nulls), whereas it is reduced only to the maternal level in mice lacking PTH (*Pth* nulls) (Fig. 20.3).

Although PTH upregulates in the absence of PTHrP, the converse is not true. Despite significant hypocalcemia, circulating PTHrP is normal in *Pth* null, *Gcm2* null, and aparathyroid *Hoxa3* null fetuses.[5,9] Circulating PTHrP is evidently not regulated by the fetal blood calcium and CaR, but may be responsive to local regulation within the placenta.

PTH regulates serum phosphorus as hyperphosphatemia occurs in thyroparathyroidectomized fetal lambs,[68,69] and in all PTH-deficient mouse models, including *Hoxa3* null, *Gcm2* null, and *Pth* null mouse fetuses.[5,9] Why the serum phosphorus is elevated is not known but decreased utilization of phosphorus for skeletal mineralization is one possible cause (discussed later).

Absence of PTH also leads to lower serum magnesium levels, most notably a 20% decline in aparathyroid *Hoxa3* null fetuses[9] but a much smaller decline in *Gcm2* nulls and *Pth* nulls.

Overall, despite low-circulating levels, PTH is an important regulator of serum calcium, phosphorus, and magnesium, because in its absence these mineral concentrations are reduced.

6.1.2 Regulation of Placental Mineral Transfer

Most studies have suggested that PTH does not regulate placental calcium transfer, and this includes the aforementioned placental studies in thyroparathyroidectomized fetal sheep and *Pthrp* null fetuses in which PTH was ineffective. However, other studies used decapitated fetal rats to simulate thyroparathyroidectomy and found that in situ perfused placentas had a reduced rate of calcium transfer that could be stimulated by exogenous PTH.[1] There was no effect of PTH in placentas from intact animals. The PTH1R is highly expressed within the intraplacental yolk sac,[38] and therefore well positioned to regulate placental mineral transport.

Studies of *Pth* null fetal mice (which completely lack PTH) and *Gcm2* null fetal mice (which have low levels of circulating PTH) have recently delineated a possible role for PTH in regulating placental cation transport.[5] Placental calcium transfer was normal in *Pth* nulls and the circulating PTHrP level was unchanged. However, microarray and RT-PCR analysis of *Pth* null placentas revealed reduced expression of several calciotropic genes (*Trpv6*, *Sg100, Vdr*) and other genes involved in cation and solute transport. To confirm that these changes in gene expression were due to absence of PTH, and to determine if PTH could stimulate placental calcium transfer, *Pth* null fetuses were treated in utero with either saline or full-length PTH before performing the placental calcium transfer experiment. *Pth* null fetuses treated with PTH had a 30% higher rate of ^{45}Ca accumulation as compared to *Pth* null fetuses treated with saline, confirming that PTH can stimulate placental calcium transfer in vivo.[5] PTH treatment also increased the placental expression of *Vdr*, vitamin D binding protein, and other solute carriers.[5]

In contrast to the *Pth* null phenotype, *Gcm2* nulls had a significantly increased rate of placental calcium transfer but no upregulation in PTHrP that could explain it.[5] *Gcm2* nulls also had significantly increased expression of placental *Trpv6*, *Sg100,* and *Vdr* as compared to *Pth* null placentas. *Gcm2* nulls and *Pth* nulls are similarly hypocalcemic and hyperphosphatemic, but only the *Gcm2* nulls upregulated placental calcium transfer and several genes known to be involved in calcium transport. The difference between the two models may be explained by expression of PTH within the placenta. PTH expression was increased in *Gcm2* null placentas and absent or near the limit of detectability in *Pth* null placentas.[5] Therefore, PTH may act locally to regulate placental calcium transfer independent of PTHrP.

Overall, placental expression of PTH and the PTH1R, stimulation of placental calcium transfer and gene expression in response to PTH injection in *Pth* null fetuses, and downregulation of placental genes in the absence of PTH, are all consistent with the conclusion that PTH acts locally in the placenta to regulate the transfer of calcium and other solutes. The effect of PTH may be weaker or conditional on activity of PTHrP, since *Pthrp* null fetuses have reduced placental calcium transfer despite threefold higher circulating PTH.

Experiments in fetal sheep suggest that PTH does not regulate phosphorus transfer[1] while there are no data on placental phosphorus or magnesium transfer in the various mouse models.

6.1.3 Regulation of Endochondral Bone Formation

There is mixed evidence for PTH's role in regulating endochondral bone formation and mineralization. Aparathyroid *Hoxa3* null fetuses in an outbred Black

Swiss background have low skeletal mineral content but otherwise show no abnormality of endochondral bone development or expression of osteoblast-specific genes, including collagen α1(I), collagenase-3, osteocalcin, and osteopontin.[8,9] In the same outbred background, double mutants lacking *Hoxa3* and *Pthrp* have an undermineralized form of the *Pthrp* null chondrodysplasia and are globally smaller than either single mutant.[8] These findings confirm that the chondrodysplasia seen in *Pthrp* nulls is largely due to absence of PTHrP and not the compensatory secondary hyperparathyroidism, while undermineralization of the skeleton results from loss of parathyroids and/or PTH.[8]

In contrast to the phenotype of aparathyroid *Hoxa3* fetuses in the Black Swiss background, *Pth* null fetuses in a C57BL/6 background have slightly shortened tibial metaphyseal lengths, shorter metacarpals and metatarsals, smaller vertebrae, reduced trabecular bone volumes, and fewer osteoclasts and osteoblasts.[11] Modest changes are also seen in expression of genes involved in chondrocyte maturation and apoptosis, mineralization, and vascular invasion of the growth plate.[11] Overall, the structural changes are largely in bone parameters, whereas the cartilaginous indices are little different from wt siblings. *Pth/Pthrp* double mutants are smaller and display an undermineralized form of *Pthrp* null chondrodysplasia (similar to the *Hoxa3/Pthrp* double mutants).[11] The data from this study indicate that PTH regulates bone formation in utero but not chondrocyte development.

A third study back-crossed *Pth* nulls and *Gcm2* nulls (which have little or no circulating PTH) from the original inbred C57BL/6 strains into outbred Black Swiss in order to compare to *Hoxa3* null fetuses.[5] Skeletons of both mutants are undermineralized but to a lesser extent than in *Hoxa3* null,[5,8] and there is no shortening of the long bones or alteration in trabecular bone volumes or skeletal morphology.[5] However, studies of gene expression within the *Pth* null and *Gcm2* null growth plates were not done. It is possible that alterations in serum calcium (which is approximately 0.25 mmol/L higher in Black Swiss[14]), or genetic differences in background strain, may explain why some alterations in bone parameters are seen in *Pth* null fetuses within one but not both background strains.

Overall the evidence indicates that PTH maintains the fetal blood calcium at a level sufficient to facilitate mineral accretion by the developing skeleton. Within developing endochondral bones PTH does not control chondrocytes, while its effects on osteoblast development vary with the genetic background or ambient serum calcium.

6.2 Human Data

The PTH1R is expressed within human placenta and PTH treatment has also been shown to increase ^{45}Ca accumulation in vitro within vesicles created from human syncytiotrophoblast basal membranes.[70] There have been no systematic measurements of fetal or cord blood mineral measurements from human fetuses that lack parathyroids or PTH, such as in DiGeorge syndrome. The animal data discussed above predict that fetal hypoparathyroidism will cause hypocalcemia and hyperphosphatemia in utero, as well as impaired skeletal mineralization.

7 ROLE OF PTHrP AND PTH IN COMBINATION

7.1 Animal Data

7.1.1 Regulation of Serum Minerals

Pthr1 null fetuses have the lowest ionized calcium level, equivalent to *Hoxa3/Pthrp* double mutants, and lower than in aparathyroid *Hoxa3* mutants (Fig. 20.3).[8,14] They are also hyperphosphatemic. PTH and PTHrP have additive roles in regulating the fetal blood calcium and skeletal mineralization since loss of both ligands or their common receptor leads to the greatest decline in blood calcium and skeletal mineral content.[8] However, it remains unclear why the ionized calcium is lower in aparathyroid *Hoxa3* null fetuses than it is in *Pth* or *Gcm2* null fetuses within the same genetic background.

7.1.2 Regulation of Placental Calcium Transfer

Placental calcium transfer is upregulated 50% in *Pthr1* null fetuses, presumably reflecting the 11-fold increase in systemic PTHrP and its actions on a midmolecular receptor.[8,14] This increase is relative to placental blood flow as inferred from the diffusion of ^{51}Cr-EDTA across the placenta. However the *absolute* amount of ^{45}Ca transferred to the *Pthr1* null fetuses is lower than in their wt littermates, in keeping with their much smaller size.[71]

7.1.3 Regulation of Endochondral Bone Formation

Pthr1 null fetuses are globally smaller than wt and display the *Pthrp* null phenotype of accelerated endochondral ossification and dysplasia combined with the *Hoxa3* or *Pth* null phenotype of significant undermineralization of the skeleton.[62] Whereas *Pthrp* null fetuses have normal expression of collagenase-3, upregulation of osteocalcin and osteopontin, and increased mineralization,[66] *Pthr1* fetuses have reduced expression of collagenase-3, osteocalcin, and osteopontin, and reduced mineralization.[66] This suggests that PTH upregulates expression of these osteoblast-specific genes in the *Pthrp* null, while blocking PTH action downregulates these genes in the *Pthr1* nulls. Moreover it indicates that, although placental delivery of mineral is relatively increased, this is insufficient for mineralization of the fetal skeleton. Thus the actions of PTH and PTHrP are needed to maintain the normally

high fetal blood calcium and stimulate osteoblast function and skeletal mineralization.

7.2 Human Data

Loss of the PTH1R in humans leads to Blomstrand chondrodysplasia, characterized by accelerated endochondral ossification and dysplasia that is similar to what has been seen in *Pthr1* null fetal mice.[72,73] It is normally lethal in utero; consequently, no measurements of serum calcium or phosphorus have been obtained.

8 ROLE OF ESTRADIOL

8.1 Animal and Human Data

The sex steroids circulate at low levels during fetal development and it is unclear whether they play essential roles in fetal calcium homeostasis and skeletal development. Mice lacking estrogen receptor alpha or beta, or the aromatase, have normal skeletal lengths at birth and do not develop altered skeletal metabolism until later.[74–76] However, none of these models have been examined during fetal development. Similarly human case reports have demonstrated that absence of the aromatase or the estrogen receptor lead to absent growth spurt, delayed bone maturation, failure of epiphyses to close, and continued growth into adulthood resulting in very tall stature. There are no fetal data beyond noting that birth weight, length, and early development were normal in a man who had inactivating mutations in the estrogen receptor.[77]

9 ROLE OF CALCITONIN

9.1 Animal and Human Data

Calcitonin appears unimportant for fetal and neonatal skeletal development since *Ctcgrp* null fetuses have normal placental calcium transfer, ionized calcium, calciotropic hormone levels, and endochondral bone development, gene expression and mineral content.[15] However, serum magnesium and skeletal magnesium content are both lower than normal, which suggests that calcitonin may regulate magnesium homeostasis.[15] In sharp contrast to this, absence of the calcitonin receptor causes embryonic lethality in mice,[78] a finding that remains unexplained. The calcitonin receptor may have critical roles independent of calcitonin during embryonic development; alternatively, maternal calcitonin may be able to rescue *Ctgrp* null embryos prior to establishment of the placental barrier.

There are no human data, as deletions of either the calcitonin or the calcitonin receptor gene have not yet been recognized in humans.

10 ROLE OF VITAMIN D AND CALCITRIOL

10.1 Animal Data

10.1.1 Regulation of Serum Minerals

Vitamin D and calcitriol are not required for fetal mineral homeostasis. The fetal blood calcium, phosphorus, and PTH remain normal despite severe vitamin D deficiency, ablation of vitamin D receptor, and absence of 1α-hydroxylase. The evidence comes from severely vitamin D–deficient rats,[16–18] *Cyp27b1* null pigs and mice [6,19] and both *Vdr* heterozygous and *Vdr* null mice.[4] These normal serum chemistries and PTH persist after birth until around the time of weaning, after which hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism develop.

10.1.2 Regulation of Placental Mineral Transport

A few early studies demonstrated that pharmacological doses of calcitriol and other analogues could stimulate placental calcium transfer in fetal sheep and rats.[1] However, it appears that the placenta does not require calcitriol to pump calcium, as observed in studies of vitamin D–deficient rats,[79] *Vdr* null fetuses,[4,20] and *Cyp27b1* null fetuses.[6] Severely vitamin D–deficient rats show normal placental expression of calbindinD-9k and Ca^{2+}-ATPase, two factors involved in active placental calcium transfer.[79–81] *Vdr* null fetuses had *increased* placental calcium transfer, normal placental expression of calbindinD-9k and Ca^{2+}-ATPase, and upregulated expression of PTHrP and TRPV6.[4,20] The increase in placental calcium transport in *Vdr* null fetuses may mean that high levels of calcitriol are capable of stimulating placental calcium transport through receptor(s) other than the VDR. Since placental calcium transport is normal in severely vitamin D–deficient fetuses [79] and *Cy27b1* null fetuses,[6] calcitriol must not play a critical role in regulating placental mineral transport.

10.1.3 Regulation of Endochondral Bone Development

Not only the serum chemistries and PTH are normal at birth despite extreme disruptions in vitamin D/calcitriol physiology, but the skeleton is also normal. Severely vitamin D–deficient rats,[16–18] *Cyp27b1* null pigs and mice [6,19] and both *Vdr* heterozygous and *Vdr* null mice[4] have normal skeletal lengths, morphology, ash weight, and mineral content (determined both radiologically and by atomic absorption spectroscopic analysis of ashed bone). Normal, heterozygous, and *Vdr* null fetuses born of $Vdr^{+/-}$ mothers are indistinguishable from each other in all skeletal and biochemical parameters. Conversely heterozygous and null fetuses born of *Vdr* null mothers are smaller and weigh less than their counterparts from *Vdr*

heterozygous mothers, but have normal mineral content after adjustment for their smaller size.[4]

It is not until near the time of weaning that hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and rickets begin to develop in all of these models of disrupted vitamin D/calcitriol physiology.[16,17,19,82–85] This time course parallels a developmentally programed change of intestinal calcium absorption from a nonsaturable, passive process in the newborn to an active, saturable, calcitriol-dependent process.[1] Additional animal data have shown that calcitriol's role can be completely bypassed by initiating a calcium-enriched diet or parenteral calcium infusions at weaning, thereby maintaining a normal skeleton despite absence of vitamin D, vitamin D receptor, or 1α-hydroxylase.[86–88]

Collectively these findings indicate that vitamin D, calcitriol, or its receptor are not required for normal fetal calcium homeostasis, skeletal development, and mineralization. The animal studies predict that human babies born of vitamin D–replete and vitamin D–deficient mothers should be indistinguishable at birth in blood calcium, phosphorus, PTH, skeletal morphology, and mineral content.

10.2 Human Data

10.2.1 Observational Studies and Case Reports

The only systematic study that approaches the detailed analyses that have been done in animal models was published in 1925.[89] Babies that died of obstetrical accidents were examined radiologically and pathologically. The skeletal ash weight and mineral content (by atomic absorption spectroscopy) were indistinguishable between neonates born of normal mothers versus those born of mothers who had severe vitamin D deficiency and osteomalacia.[1] There also were no radiological signs of rickets and centers of ossification were normal.[89] The investigators had been convinced beforehand that they would find evidence of fetal rickets but admitted that they had found none.[89]

In contrast to this detailed analysis, occasional case reports and series have described that skeletal changes suggestive of rickets (usually craniotabes, ulnar cupping, or a widened fontanelle) can be detected at or soon after birth (studies cited in Ref. 1). Craniotabes is softening of the newborn skull bones that is subjectively assessed by palpating the skull; radiographs may suggest thinning of the skull bones or suture lines and fontanelles that are wider than normal. However, craniotabes has been determined to be a nonspecific finding that can be present in 30%–50% of healthy neonates, has no correlation with maternal or neonatal 25(OH)D levels or skeletal signs of rickets, and should not be used to indicate the presence of rickets or vitamin D deficiency.[90–95] Distal ulnar cupping is a normal variant that also should not be used to diagnose rickets.[96] A large or slowly closing anterior fontanelle can be seen with rickets,[97,98] but it is a nonspecific change shared by at least 25 metabolic, genetic, and skeletal disorders.[99,100] In fact, use of a widened fontanelle to presumptively diagnose vitamin D–deficient rickets led to misdiagnosis and maltreatment of a newborn with hypophosphatasia.[101]

In multiple reports that described craniotabes or rickets being present "at birth" the diagnosis was actually made within the first or second week, and so whether the fetus had any signs of rickets was not known.[1] In many cases where skeletal abnormalities suggestive of rickets were reported soon after birth, the mothers had significant malnutrition or anorexia, malabsorption (e.g., celiac disease, pancreatic insufficiency), or very low intakes of both calcium and vitamin D.[1] Consequently, the skeletal findings may not have been due to vitamin D deficiency alone but instead may have been the result of more global nutritional deficiency. This is also supported by the fact that in several reports the affected newborn hemorrhaged to death, an outcome that suggests disorders other than isolated vitamin D deficiency.[102]

The reported worldwide clinical experience with vitamin D deficiency is that hypocalcemia and rickets are not usually diagnosed until weeks to months after birth; rickets has a peak incidence between 6 and 18 months, even in regions where it is endemic.[1,103,104] Similar to the findings in rodents, studies in preterm and term human babies have shown that intestinal calcium absorption matures from a passive, nonsaturable process to an active, saturable, calcitriol-dependent process[1]; this likely explains why hypocalcemia, hypophosphatemia, and rickets do not usually develop until later in postnatal life.

At the extremes of abnormal vitamin D/calcitriol physiology, children with 1α-hydroxylase deficiency (vitamin D dependent rickets type I; VDDR-I) or those lacking the vitamin D receptor (vitamin D dependent rickets type II or hereditary vitamin D resistant rickets; VDDR-II) are also normal at birth.[1] In both conditions hypocalcemia, hypophosphatemia, and rickets eventually develop. Although both conditions can present soon after birth with biochemical abnormalities, VDDR-I usually presents late in the first year while VDDR-II is most often recognized in the second year or later.[1] It is possible that early biochemical abnormalities and rachitic changes have been overlooked in some of these cases, but the natural histories of VDDR-I and VDDR-II are quite compelling for their concurrence with the animal data. The impaired intestinal calcium absorption in VDDR-II patients can be bypassed by repeated calcium infusions or high oral dose calcium, thereby correcting the biochemical abnormalities and preventing or healing rickets.[1] Thus the human genetic disorders and the animal models provide coherent evidence that hypocalcemia and rickets are not present at birth but develop postnatally, and that the biochemical and skeletal abnormalities can be prevented

with administration of calcium alone. These data suggest that calcitriol's role in postnatal skeletal development is indirect through its stimulation of intestinal calcium absorption, whereas the intestines are not an important route of mineral delivery during fetal development.

Additional studies have examined bone mineral content in newborns.[1] In one study, forearm bone mineral content by 5 days of birth did not differ by use of vitamin D supplements during pregnancy.[90] In another, bone mineral content of the lumbar spine, femur, and whole body measured within 15 days after birth in 50 healthy term infants was not altered by vitamin D insufficiency versus sufficiency.[105]

10.2.2 Intervention Studies

More than a dozen randomized clinical trials of vitamin D supplementation during pregnancy have found no effect on cord blood calcium or phosphorus, anthropometric measurements, or radiological evidence of rickets.[1,2] These include a study of 126 babies where controls were severely vitamin D deficient [10 nmol/L 25(OH)D on cord blood], while babies from vitamin D–treated mothers had remarkably high-25(OH)D levels of 138 nmol/L.[106]

Among the few studies that enrolled mainly vitamin D–deficient women and achieved a substantial increase in 25(OH)D during pregnancy, Dawodu studied Arab women who had a mean 25(OH)D of 20.5 nmol/L at baseline, and were randomized to receive 400, 2000, or 4000 IU of vitamin D per day.[107] Achieved cord blood 25OHD levels at delivery were 40, 65, and 90 nmol/L, respectively.[107] No effect was seen on anthropometric parameters at birth or obstetrical outcomes.

Hollis and Wagner completed two studies that examined the effect of high-dose vitamin D supplementation during pregnancy in women who had much higher 25(OH)D levels at study entry. In the first study, 350 women (NCT00292591) randomized at 12–16 weeks of gestation received 400, 2000, or 4000 IU of vitamin D_3 per day,[108] achieved cord blood 25(OH)D was 46, 57, and 66 nmol/L, respectively. In the second study, 160 women (NCT00412087) randomized at 12–16 weeks received 2000 or 4000 IU of vitamin D_3 daily,[109] achieved cord blood 25(OH)D was 55 and 68 nmol/L, respectively. In both studies, apart from higher maternal and cord blood 25(OH)D levels, there was no effect on any obstetrical or neonatal outcome.[108–110] Several posthoc analyses of these two trials have subsequently been published, including analyses of selective pooled data from both studies, out of which some borderline significant results have been obtained.[108,110–113] However, these analyses suffer from lack of adjustment for multiple comparisons, arbitrary grouping of outcomes, double-counting of linked outcomes (preterm labor and preterm delivery), and exclusion of certain ethnicities from the analysis (discussed in Refs. 1,2). The first study's primary objective included bone mineral density of the newborns but this has not been reported.

Most recently, Cooper and Harvey provided preliminary results of the MAVIDOS study from the UK.[114,115] 900 women completed this after randomly being assigned to receive either 1000 IU of vitamin D or placebo beginning at 14 weeks of pregnancy. The study was revealed to be negative in its primary outcome (neonatal bone area, bone mineral content, and bone mineral density within the first 14 days after birth) and secondary outcome (anthropometric and body composition parameters within 48 h of birth).[114,115] A posthoc analysis, which was not prespecified in the clinical trial registrations (ISRCTN 82927713 and EUDRACT 2007-001716-23), suggested a possible benefit on bone mineral content of winter-born babies at 14 days of age. If the apparent benefit on winter-born babies is real and not a chance finding, it may reflect a postnatal effect of vitamin D supplementation during pregnancy, since the neonatal skeleton gains approximately 100 mg of calcium per day over the first 14 days after birth.[1,2] A measurement at 14 days does not indicate bone mineral content at term.

Overall these studies have largely examined the offspring of women who had baseline 25(OH)D values well above the 20 nmol/L threshold that has been shown to result in normal intestinal calcium absorption.[2,116–121] Few studies compared truly vitamin D deficient to vitamin D–replete women during pregnancy. It may take a larger study comparing those extremes to determine if there are differences in fetal or obstetrical outcomes, but ethical considerations may prevent such a study from being carried out in the modern day. The more recently published studies clearly establish the amount of maternal vitamin D intake that may be required to achieve various target levels of 25(OH)D in maternal and cord blood. However, none of these studies provide definitive evidence as to what 25(OH)D level might be optimal for bone health or nonskeletal health of the newborn. The overall results are consistent with the previously cited animal and human observational studies, in that isolated vitamin D deficiency is unlikely to alter serum minerals or skeletal development in utero. However, vitamin D deficiency will cause hypocalcemia and rachitic changes beginning sometime after birth, when the intestines become the main and calcitriol-dependent route of mineral delivery.

10.2.3 Associational Studies

In the last few years a number of associational studies have received significant attention in medical reviews and lay press, sparking concern that higher intakes of vitamin D are needed during pregnancy to insure optimal bone health at birth or later in life. These studies examined associations between single measurements of serum 25(OH)D during pregnancy in the mother and various skeletal outcomes in the fetus, neonate, or child.

In none of these any association was found with weight, skeletal lengths, or bone mineral density at birth.[122–127]

One study measured 25(OH)D at 28–32 weeks in 374 mothers and reported in a subanalysis that a 25(OH)D level below 28 nmol/L was associated with a slightly shorter knee-heel length in the offspring. However, although it was reported as a significant outcome, the difference was not statistically significant after correcting for gestational age.[122] Another study measured maternal 25(OH)D levels at 36 weeks in 424 women and found that 25(OH)D levels *below* 50 nmol/L were associated in the fetus with greater distal femoral metaphyseal cross-sectional area and a novel parameter called the "femoral splaying index."[123] The increased cross-sectional area of the femur was inferred by the authors to represent early rachitic change. In contrast, yet another study found that mothers *above* a median 25(OH)D level of 42.6 nmol/L had babies with a slightly greater tibial cross-sectional area.[124] The authors interpreted the increased cross-sectional area of the tibia to indicate stronger bone. These two studies exemplify how subjective the interpretation has been, with greater cross-sectional area of the metaphysis considered an adverse effect in one study and a benefit in another. Furthermore, the authors who reported a greater cross-sectional area of the tibia subsequently adapted their ultrasound technique to calculate femoral volumes in 357 mother–baby pairs.[127] Maternal 25(OH)D below 75 nmol/L was associated with slightly *reduced* femur length, width, and volume,[127] an association that is in the opposite direction from the original report of greater cross-sectional area of the tibia.[124] The seemingly contradictory results of these various studies could indicate that vitamin D/calcitriol has complex, site-specific effects on skeletal development. Alternatively, these could be chance findings with no true causal link between maternal 25(OH)D during pregnancy and the cross-sectional area or volume of fetal long bones.

A well publicized study by Javaid found no associations between maternal serum 25(OH)D and birth weight, length, placental weight, abdominal circumference, head circumference, or cord blood calcium.[125] At the 9 month follow up, there were still no associations of maternal 25(OH)D with skeletal and anthropometric parameters in the infants. However, at *9 years of age*, the investigators found a modestly lower bone mineral content in children whose mothers had had a serum 25(OH)D level below 27.5 nmol/L during pregnancy, as compared to children of mothers whose 25(OH)D levels had been 50 nmol/L or higher during pregnancy. These findings have been used to promote the theory that vitamin D exposure during fetal development programs childhood peak bone mass and adult risk of osteoporosis.[128] However, a recent study by Lawlor analyzed about 20 times the number of mother–child pairs than Javaid (3960 vs. 198), and found no associations between maternal 25(OH)D during pregnancy and offspring bone mass at age 9 years, as assessed by DXA.[126] Lawlor had about 8 times the number of women with 25(OH)D below 27.5 nmol/L (220 vs. 28 mothers), and therefore should have had greater power to detect an association if one were present.[126]

There are significant caveats about these associational studies. Why the tibia in one study and the femur in another, and not both sites, or more skeletal sites? The possibility of chance findings cannot be excluded, especially if more skeletal sites were examined but not reported. Moreover, these associational studies are confounded by factors which contribute to low maternal 25(OH)D levels, including maternal obesity, lower socioeconomic status, poorer nutrition, and lack of exercise, prenatal care or vitamin supplementation, etc. Therefore, is lower 25(OH)D simply a marker of a less healthy pregnant woman? In the long-term follow-up study by Javaid,[125] much time elapsed between birth (when no effect was seen) and 9 years of age (when lower bone mineral content was found). Did low 25(OH)D in utero program lower bone mineral content at 9 years of age, as the authors of that study contend? Or does the lower maternal 25(OH)D status in late pregnancy indicate lower socioeconomic status, poorer nutrition, obesity, and other factors in the mother that will remain unchanged over the next decade and will be shared with the child, thereby affecting growth and peak bone mass? Associational studies cannot distinguish between these possibilities nor can they prove causation.

Clinical trials are needed to control for the confounding and determine if increased vitamin D intake or supplementation during pregnancy, infancy, or childhood enables a higher peak bone mass to be achieved. To date a few trials of short duration have been done in infants, and either no effect or at best a transient effect on bone mass has been seen.[129–131]

Overall the available evidence (reviewed in more detail in Refs. 1,2) indicates that, in human babies, cord blood calcium, skeletal morphology, and skeletal mineral content, should all be normal at birth despite vitamin D deficiency or VDDR-I and VDDR-II. It is after birth that hypocalcemia and progressive rickets will eventually develop if these disorders remain untreated. The American Academy of Pediatrics and the Institute of Medicine both concluded that a target 25(OH)D blood level of 50 nmol/L is appropriate to optimize bone health for pediatric ages; there is no conclusive evidence that higher blood levels confer any additional benefit.[132]

11 ROLE OF FGF23

11.1 Animal Data

FGF23 plays an important role in regulating phosphorus and skeletal metabolism in the adult.[133,134] It inhibits

renal phosphate transporters (NaPi2a and NaPi2c) to cause renal phosphate wasting, reduces calcitriol by inhibiting Cyp27b1 and upregulating Cyp24a1, stimulates PTH, and reduces intestinal phosphorus absorption by reducing NaPi2b expression and lowering the concentration of calcitriol. In turn these effects influence endochondral bone development and mineralization.

But during fetal development FGF23 appears to not be required since the extremes of high-FGF23 concentrations (*Phex* or *Hyp* null), absence of FGF23 (*Fgf23* null), and absence of the FGF23 coreceptor Klotho (*Klotho* null), do not alter serum phosphorus, renal excretion of phosphorus into amniotic fluid, placental phosphorus transport, endochondral bone development, or skeletal content of calcium and phosphorus.[1,7,39,135] There were some minor changes in the renal and placental expression of genes relevant to phosphorus metabolism, including that renal *Cyp24a1* expression was reduced in *Fgf23* null kidneys, increased in *Phex* null kidneys, and unchanged in *Klotho* null kidneys, but these alterations in gene expression did not affect overall phosphorus and skeletal physiology.[1,7,39,135] It is evidently sometime after birth that FGF23 begins to exert its effects on the kidneys and bone metabolism.

11.2 Human Data

Very limited human data have found that intact FGF23 circulates at low values in cord blood, whereas the inactive C-terminal fragment circulates at twice the adult value.[29,136] Klotho is present in cord blood at sixfold adult and neonatal values, and it is expressed by human trophoblasts.[136] It is unclear whether these circulating concentrations imply relatively decreased, normal, or increased FGF23 activity in the fetal circulation.

There are no cord blood data from genetic disorders that cause excess or absence of FGF23. However, genetic loss of FGF23 (tumor calcinosis) has presented as early as 18 days after birth with hyperphosphatemia and a calcified mass.[137,138] In families with X-linked hypophosphatemic rickets, in which an inactivating mutation in *PHEX* leads to high levels of FGF23, serial observations have revealed that the serum phosphorus can become low during the second to sixth weeks after birth.[139]

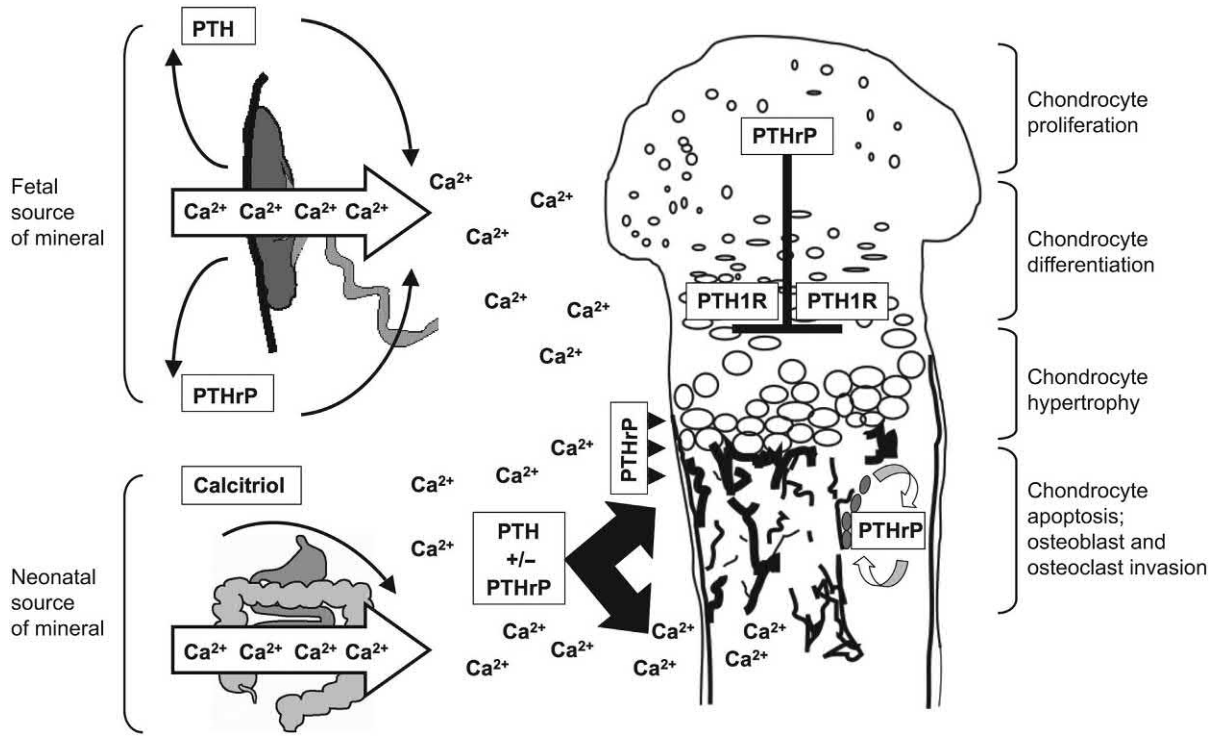

FIGURE 20.4 Relative roles of PTH, PTHrP, calcitriol, and FGF23 during fetal and neonatal life. The placenta is the main source of mineral during fetal life. PTH and PTHrP are expressed within the placenta but may also act on it from systemic sources to stimulate calcium transfer. The intestines are a trivial source of mineral in the fetus but are the main source for the neonate. Intestinal calcium absorption is initially passive but later becomes active, saturable, and calcitriol dependent in the infant. Within the endochondral skeleton, PTHrP is produced by proliferating chondrocytes and perichondrial cells (*arrowheads*) and delays terminal differentiation of prehypertrophic chondrocytes. PTHrP is also produced within preosteoblasts and osteoblasts and stimulates bone formation (*semicircular arrows*). During fetal life PTHrP and PTH act together to maintain high blood calcium and phosphorus levels in order to facilitate mineralization; loss of either PTHrP or PTH causes hypocalcemia and hyperphosphatemia. Calcitriol and FGF23 are not required to regulate serum minerals, endochondral bone formation, or skeletal mineralization in the fetus.

12 CONCLUSIONS

At all life stages adequate delivery of mineral is required for the skeleton to achieve and maintain appropriate mineral content and strength (Fig. 20.4). The placenta requires PTH and PTHrP but not calcitriol, FGF23, or calcitonin to regulate the pumping of mineral from the maternal circulation. Maintaining serum calcium and phosphorus at optimal levels for bone mineralization in utero requires PTH and PTHrP, but not calcitriol, FGF23, or calcitonin. Endochondral bone development in the fetus requires PTH and PTHrP but not calcitriol, FGF23, calcitonin, or (probably) the sex steroids. It is not until the later neonatal period, when intestinal calcium absorption becomes an active process, that skeletal development and mineralization begins to depend upon vitamin D/calcitriol. During the same interval, FGF23 begins to exert its effects on renal phosphorus handling and the synthesis and catabolism of calcitriol. The requirement for vitamin D/calcitriol can be bypassed by increasing the calcium content of the diet or by administering parenteral calcium infusions.

CHAPTER

21

Control of Mineral and Skeletal Homeostasis During Pregnancy and Lactation

Christopher S. Kovacs

Memorial University of Newfoundland, Health Sciences Centre, St. John's, NL, Canada

1 INTRODUCTION

Normal pregnancy demands that women provide sufficient calcium to mineralize the fetal skeleton before birth, and in turn this necessitates several hormone-mediated adjustments in maternal mineral metabolism. Similarly, lactating women must supply sufficient calcium to breast milk to facilitate the nursing infant's continued skeletal growth and mineralization. The adjustments made in each of these reproductive periods differ significantly (Fig. 21.1). Intestinal calcium absorption upregulates during pregnancy whereas skeletal resorption predominates during lactation. The daily calcium needs of the fetus and infant are normally satisfied without requiring increased maternal intake of calcium or causing long-term adverse effects on the maternal skeleton. In turn these adaptations can affect the presentation and management of disorders of mineral metabolism during pregnancy and lactation.

Our knowledge of mineral homeostasis during pregnancy and lactation comes from surgical, pharmacological, and, more recently, genetically engineered animal models. Observational studies and clinical trials have clarified some of the areas where humans and animal models have the same or different adaptations to the challenges of pregnancy and lactation. This chapter will review both animal and human data and clarify where and if the findings differ. To avoid exceeding specified limits on the reference list, the reader is directed to two longer comprehensive reviews that cite the original research papers.[2,3]

2 SKELETAL AND MINERAL PHYSIOLOGY DURING PREGNANCY

The developing fetus requires only a small amount of mineral during the first two-thirds of gestation. After that time the placenta upregulates expression of calbindin-D9, Ca^{2+}-ATPase, transient receptor potential vanilloid 6 (TRPV6), and other genes that may be involved in calcium transport.[3] Active pumping of calcium from the maternal to the fetal circulation then begins and is followed by rapid mineralization of the fetal skeleton. Fetal rats have about 12 mg of calcium at birth of which 95% is accreted during the last 5 days of their 22-day gestation[4]; term fetal mice have about 1.5–2.0 mg of calcium with most of that accreted during the last 4 days of a 19-day gestation.[3] Conversely the human skeleton accretes about 30 g of calcium, 20 mg of phosphorus, and 0.8 mg of magnesium by term, with 80% of each mineral accreted during the third trimester.[4–11] The rate of net calcium transfer ranges from 60 mg per day at week 24 to 300–350 mg per day during the final 6 weeks of pregnancy.[2]

2.1 Mineral Ions and Calciotropic Hormones (Fig. 21.2)

Vascular fluid volume increases during pregnancy, which causes a dilutional fall in serum albumin and with it, a fall in total serum calcium. However, both the ionized calcium (the physiologically important fraction) and the albumin-corrected serum calcium remain unchanged throughout pregnancy in longitudinal studies of humans and some mouse strains.[2] In other animal

Genetics of Bone Biology and Skeletal Disease. http://dx.doi.org/10.1016/B978-0-12-804182-6.00021-6

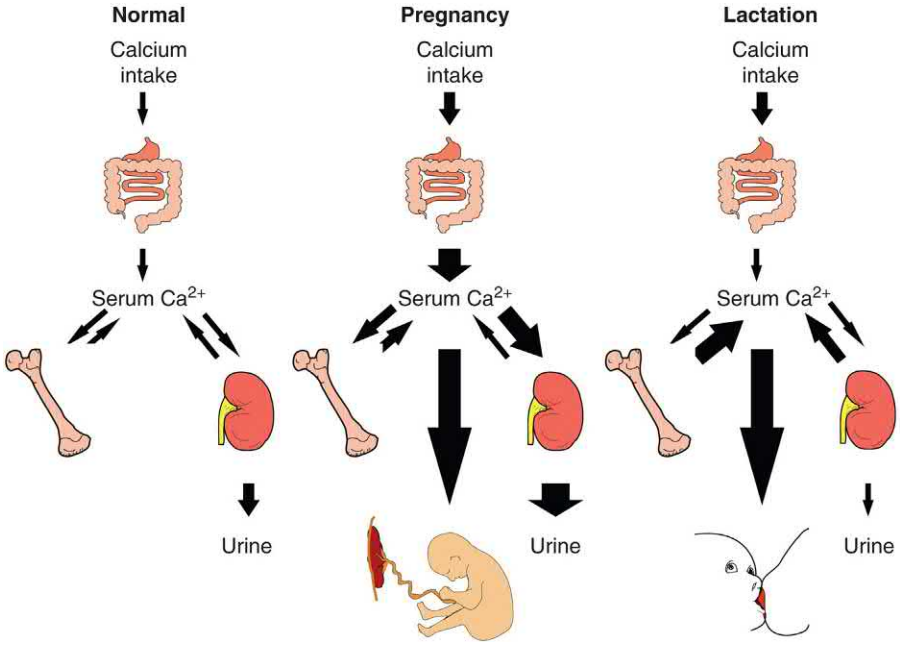

FIGURE 21.1 Schematic illustration contrasting calcium homeostasis in human pregnancy and lactation, as compared to normal. The thickness of arrows indicates a relative increase or decrease with respect to the normal and nonpregnant state. Although not illustrated, the serum (total) calcium is decreased during pregnancy, while the ionized calcium remains normal during both pregnancy and lactation. *Source: Adapted from Kovacs CS, Kronenberg HM. Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation.* Endocr Rev *1997;***18***(6):832–72, copyright 1997, The Endocrine Society.*[1]

models, the mother's ability to regulate her blood calcium may become overwhelmed by the peak fetal demands during late pregnancy. Consequently, the ionized calcium may fall during late pregnancy in rats, deer, and sheep; moreover, larger litter sizes in the rat are associated with a greater decrease in maternal blood calcium.[2]

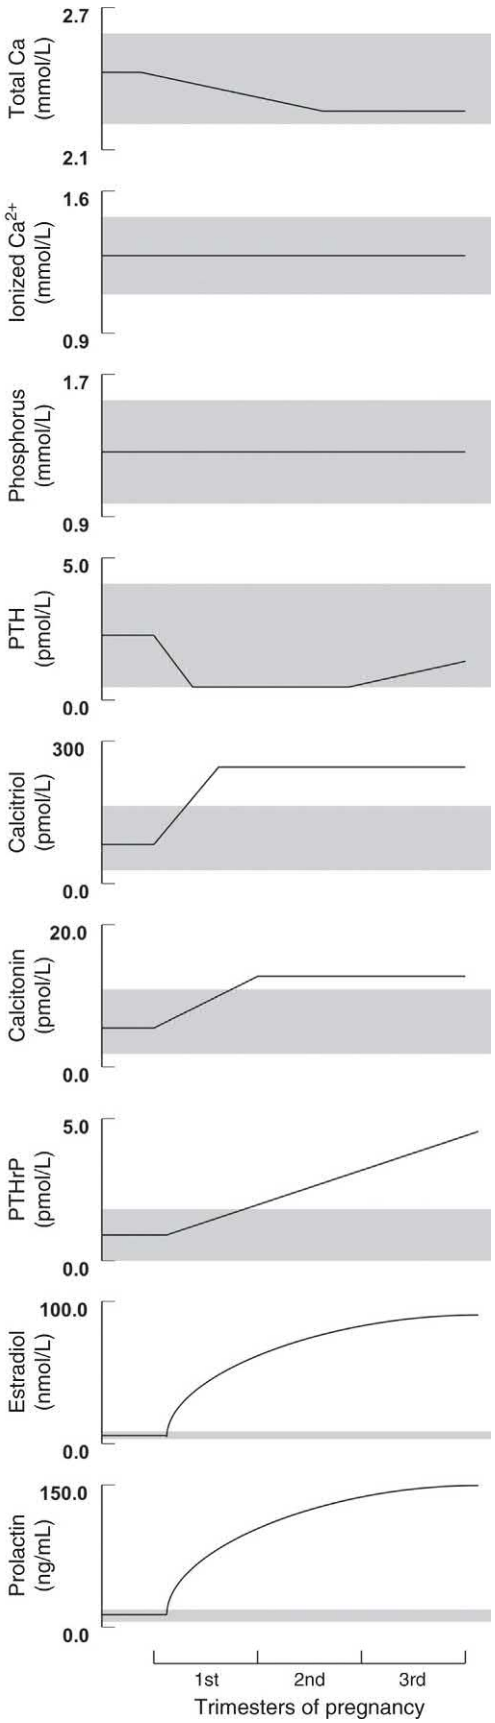
Serum phosphorus and magnesium levels are normal throughout pregnancy in humans and other animals.[2] Urine phosphorus levels decrease in mice,[12] likely due to suppressed parathyroid hormone (PTH).

The older human and animal literature pertaining to PTH values during pregnancy may be confusing. Assays from the 1970s and 80s used polyclonal antibodies that measured biologically inactive C-terminal or N-terminal fragments of the hormone which accumulate during pregnancy. The apparently high PTH levels based on these assays prompted the conclusion that physiological hyperparathyroidism occurs during pregnancy in humans and other animals; however, this appears to be incorrect. With newer "intact" PTH assays, most studies of women from North America and Europe (who generally have a calcium-sufficient diet) have shown that PTH falls toward the lower end of the normal range during the first trimester before increasing to the midnormal range by term.[13–17] In contrast, studies of women from Asia and Africa found that the PTH value does not become suppressed and may exceed the normal range in some individuals.[2,18] These women typically have diets that are low in calcium and high in phytate (which blocks calcium absorption), and that may explain why their PTH levels do not decrease.

Animal data that arise from use of the newer PTH assays remain somewhat variable, influenced by the calcium content of the diet, litter size, and species or strain.[2] Serial measurements in pregnant mice have found that PTH falls to about 20% of the nonpregnant value, with many individual values becoming undetectable.[12,19–21] Consumption of a high-calcium diet results in even lower PTH concentrations.[22,23] In contrast, measurements in pregnant rats have found decreased, no change, or increased PTH; the most common finding is increased PTH accompanied by reduced ionized or albumin-corrected serum calcium.[2] PTH rises earlier and to a higher level in pregnant rats with larger litters or when the calcium content of the diet is reduced.[2]

Overall the available animal and human data suggest that serum PTH normally becomes suppressed during pregnancy in humans and mice unless dietary calcium is insufficient, whereas secondary hyperparathyroidism is often observed in pregnant rats despite a calcium-sufficient diet.

In humans and rodents, total calcitriol levels increase two- to fivefold beginning early in pregnancy and maintain this increase until term; the free level is also increased during all three trimesters.[2] PTH is normally the major stimulator of the renal 1α-hydroxylase, and is critically



required to maintain calcitriol within the normal range of nonpregnant animals and humans. However, during pregnancy in humans and mice, PTH typically declines while calcitriol increases markedly.[2] Moreover a marked pregnancy-related increase in calcitriol occurs despite loss of PTH in *Pth* null mice,[21] parathyroidectomized rats,[24] and parathyroidectomized sheep.[25] These data indicate that calcitriol's rise during pregnancy is not driven by PTH. Instead, there is evidence that PTH-related protein (PTHrP), estradiol (E_2), prolactin (PRL), placental lactogen, and other factors may contribute to upregulation of the renal 1α-hydroxylase during pregnancy.[2]

The source of increased calcitriol production is largely the maternal kidneys, which show a two- to fivefold upregulation in renal 1α-hydroxylase during pregnancy.[2] However, some evidence in pregnant rats indicates that the placenta, fetus, and other maternal tissues may be additional sources of calcitriol due to expression of 1α-hydroxylase. When tritiated 25-hydroxyvitamin D was administered to totally nephrectomized rats, no tritiated calcitriol appeared in nonpregnant dams whereas some tritiated calcitriol (much reduced compared to normal) appeared in pregnant dams.[26,27] Those studies demonstrated that placenta and extrarenal maternal tissues can form calcitriol, but not to the high levels normally achieved during pregnancy. Additional studies in 5/6-nephrectomized rats found high PTH and a 40% reduction in calcitriol in virgin animals, whereas during pregnancy, PTH suppressed to normal and calcitriol increased to the high values normally reached during pregnancy.[28] Rather than proving that extrarenal sources of 1α-hydroxylase account for the normal pregnancy-related increase in calcitriol (as the authors concluded), that study may simply have demonstrated the ability of the remnant kidney to upregulate 1α-hydroxylase in response to the hormonal milieu of pregnancy. After all, the 5/6-nephrectomy model causes only a 50% reduction in creatinine clearance[29] and, as noted above, the pregnancy-related rise in calcitriol was markedly reduced in completely nephrectomized rats.[26,27] More compelling data from 1α-hydroxylase null pigs and *Cyp27b1* null mice suggest that fetus and placenta do not contribute a significant amount of calcitriol to the maternal circulation. Maternal

FIGURE 21.2 Schematic depiction of longitudinal changes in calcium, phosphorus, and calciotropic hormone levels during human pregnancy. Shaded regions depict the approximate normal ranges. Parathyroid hormone (PTH) does not decline in women with low calcium or high phytate intakes, and may even rise above normal. Calcidiol (25OHD) values are not depicted; most longitudinal studies indicate that the levels are unchanged by pregnancy, but may vary due to seasonal variation in sunlight exposure and changes in vitamin D intake. Fibroblast growth factor-23 (FGF23) values cannot be plotted due to lack of data. *Source: Reproduced with permission from Kovacs CS. Maternal mineral and bone metabolism during pregnancy, lactation, and post-weaning recovery.* Physiol Rev *2016;***96***(2):449–547.*[2]

calcitriol was very low to undetectable and comparable to nonpregnant values in these animals that cannot make calcitriol, even though they bore heterozygous placentas and fetuses that could make calcitriol.[23,30] Limited human data come from rare reports of anephric women who had successful pregnancies; in one published report, calcitriol was very low before and during pregnancy, confirming that the pregnancy-related increase in calcitriol is abolished in the absence of maternal kidneys.[31] Overall, while the anephric rat data indicate that extrarenal production contributes some calcitriol to the maternal circulation during pregnancy, it appears likely that, in women and rodents, most of the calcitriol comes from upregulated synthesis in the maternal kidneys.[2]

Serum calcitonin (CT) levels increase during pregnancy and may derive from synthesis within the thyroid, mammary tissue, and placenta.[2] Thyroidectomized women had undetectable CT levels when nonpregnant, but achieved CT levels during pregnancy that were higher than those in nonpregnant women with intact thyroids.[32]

Circulating PTHrP increases during pregnancy and may derive from multiple maternal and fetal tissues, with mammary tissue and placenta being the most likely sources.[2] PTHrP's rise in the maternal circulation does not occur until later in pregnancy and so it is unlikely to explain the early rise in calcitriol. Moreover, there is an evidence that PTHrP's different receptor binding, signaling characteristics, and crystal structure may make it less potent than PTH at stimulating the renal 1α-hydroxylase.[33–36] Whether circulating PTHrP plays a role in maternal calcium homeostasis of pregnancy is unclear, although it has been suggested that the carboxyl-terminal portion of PTHrP (osteostatin) may protect the maternal skeleton from excessive bone resorption.[2] Placental calcium transport is regulated by PTHrP in the fetal circulation, but it is not known whether PTHrP in the maternal circulation plays a role.[2,37]

Fibroblast growth factor-23 (FGF23) is a more recently recognized as a regulator of phosphorus homeostasis but it has not been extensively studied during pregnancy. There are as such no published data on FGF23 levels during human pregnancy; one study found that intact FGF23 values at 24 h after delivery were similar to nonpregnant controls.[38] Serial studies in mice have shown that intact FGF23 increases twofold during pregnancy.[21,39] The physiological significance of increased FGF23 in pregnancy is unclear as serum phosphorus remains unchanged. Moreover, although FGF23 reduces serum calcitriol in nonpregnant *Phex (Hyp)*$^{+/-}$ mice[40] and in *Fgf23* overexpressing mice,[41] serum calcitriol was no different among pregnant mice that had high (*Phex*$^{+/-}$), normal (WT), or reduced (*Fgf23*$^{+/-}$) concentrations of FGF23.[42,43]

PRL and placental lactogen both increase 10 to as much as 100-fold during pregnancy and activate PRL receptors.[2] As osteoblasts express PRL receptors, and PRL receptor-deficient mice show decreased bone formation, PRL or placental lactogen conceivably regulate skeletal metabolism during pregnancy. However, this possibility has not been rigorously studied. A single study manipulated the PRL level in pregnant rats by use of bromocriptine, and found that it blunted a pregnancy-related gain in bone mineral content.[44]

Circulating oxytocin (OT) levels rise as pregnancy progresses.[45] OT's classic role is to stimulate contractions of the uterine muscle, thereby facilitating delivery of the fetus and placenta. But the OT receptor is expressed by osteoclasts and osteoblasts[46] and so OT may also regulate bone metabolism during reproduction. Both male and female mice lacking OT or its receptor have an osteoporotic phenotype characterized by low bone formation.[47] Additional studies have shown that OT stimulates osteoblast differentiation and function, stimulates osteoclast formation, but inhibits osteoclast function and skeletal resorption.[47,48] Whether OT is specifically important for maternal bone metabolism during pregnancy is unclear because it has not been directly studied in vivo.

The production of numerous other hormones increases during pregnancy, including 100-fold increases in E_2, and lesser increases in estrone, estriol, leptin, placental growth hormone, and IGF-1.[2] Pituitary release of growth hormone decreases.[2] The extent to which these play a role in regulating intestinal calcium absorption or skeletal metabolism during pregnancy is unknown.

2.2 Intestinal Absorption of Calcium

Intestinal calcium absorption more than doubles during pregnancy and this appears to be the main mechanism that enables the fetal calcium demand to be met.[2] Placental phosphorus and magnesium absorption are similarly increased.[2] Studies using stable isotopes of calcium and other methods have revealed that intestinal calcium absorption is upregulated by midpregnancy in rodents and 12 weeks of gestation in humans; the most marked increase is late in pregnancy in both species, corresponding to the interval of greatest fetal demand for mineral.[2] A positive calcium balance results by midpregnancy in rodents and humans, and skeletal mineral content may also increase.[20,49] Isotope studies in rats have revealed that 92% of fetal skeletal mineral content derives from the maternal diet during pregnancy.[50]

As total calcitriol levels double or triple during pregnancy, it has been assumed that calcitriol regulates the increased intestinal calcium absorption. However, studies in rodents indicate that a pregnancy-related increase in intestinal calcium absorption precedes the rise in calcitriol and occurs despite severe vitamin D deficiency,[51,52] absence of the vitamin D receptor,[22] or maternal parathyroidectomy.[53] This upregulated calcium absorption is physiologically significant because

vitamin D-deficient rats and *Vdr* null mice both achieved a significant increase in skeletal mineral content during pregnancy, which reached 155% of baseline in *Vdr* nulls.[2,22] In humans intestinal calcium absorption doubles from the first trimester and may precede an increase in free calcitriol.[2] These data suggest that factors other than calcitriol must also stimulate intestinal calcium absorption during pregnancy.

Additional animal studies suggest that the *Vdr* null mouse compensates by upregulating intestinal expression of the calcium channel TRPV6,[22] and that PRL and placental lactogen may stimulate intestinal calcium absorption independently of calcitriol, possibly by stimulating TRPV6.[54–58] Although compelling animal data indicate that calcitriol or its receptor are not required to upregulate intestinal calcium absorption during pregnancy, no studies have examined the effects of vitamin D deficiency on intestinal calcium absorption during human pregnancy. A clinical study found that hyperprolactinemic men and women had calcitriol levels and rates of intestinal calcium absorption that were similar to normoprolactinemic controls[59]; however, the hormonal milieu of hyperprolactinemia differs from that of pregnancy, especially with respect to the relative concentrations of sex steroids.

2.3 Renal Handling of Calcium

In rats and mice a doubling of urine calcium excretion may be present by the second week of gestation.[2,12] In humans the 24-h urine calcium excretion increases from as early as the 12th week and hypercalciuric values are often present, whereas the fasting urine calcium is typically normal or low.[2] Random, nonfasted spot urine samples do not show this increase.[2] Hypercalciuria occurs because of increased intestinal calcium delivery (absorptive hypercalciuria) combined with the effects of suppressed PTH and increased CT to reduce reabsorption of calcium by the renal tubules. Hypercalciuria contributes to an increased risk of kidney stones during pregnancy, and also indicates that many women consume more calcium than needed during pregnancy.

2.4 Skeletal Calcium Metabolism

The skeleton contains over 99% of calcium in the body and represents a substantial reserve that will be borrowed from when dietary intake of calcium is insufficient. The fetus demands a substantial amount of calcium late in pregnancy and this leads to the concern that pregnancy may cause excessive skeletal resorption, low bone mass, and fractures. On the other hand, as intestinal calcium absorption doubles at beginning early in pregnancy, one might predict that bone mineral content will be increased prior to the peak fetal demands for calcium.

Studies in animals have shown that bone turnover increases during pregnancy but this leads to changes in skeletal structure and mineral content, which vary markedly within and between species.[2] Pregnant rats have histomorphometric evidence of increased bone formation and resorption but usually no net change in skeletal mass, mineral content, or bone strength at the end of pregnancy.[2] Those cross-sectional studies examined rats at the beginning versus the end of pregnancy and therefore did not determine whether there were interim changes in bone mass or mineral content at midpregnancy. Cortical bone volumes increase as a result of periosteal bone formation during pregnancy in rats, possibly as an adaptive response to the increasing body weight.[60,61] In mice, bone turnover increases as suggested by consistently higher levels of bone formation [procollagen I N-telopeptides (P1NP) and osteocalcin] and resorption markers [deoxypyridinoline and C-telopeptide (CTX)].[12,20,22] However, the net effect that increased turnover has on skeletal mass and mineral content of wild-type mice varies by skeletal site and genetic background. Serial studies in outbred Black Swiss mice show a progressive gain of 15%–20% in whole body bone mineral content during pregnancy but no change in the spine or hindlimb.[20,22] Conversely, inbred C57BL/6 mice lose about 5% of whole body bone mineral content and 15% of spine bone mineral content but gain more than 5% in the hind limb,[12] while CD-1 mice show no significant changes in mineral content at any skeletal site during pregnancy.[2,62,63]

The only histomorphometric data from women found that bone resorption parameters were higher at 8–10 weeks in 15 women who electively terminated pregnancy as compared to pregnant women at term and nonpregnant controls; however, poor age matching, small sample sizes, and confounding may have led to spurious results.[64] Additional studies have measured bone formation and resorption markers and inferred that bone turnover increases during pregnancy.[2] These studies share a number of confounding problems, including lack of prepregnancy baseline values (comparison to nonpregnant controls or normal ranges); effects of hemodilution on serum markers; increased globular filterate rate and altered creatinine excretion affecting urine values; possible contribution from placental, uterine and fetal sources; degradation and clearance by the placenta; and lack of diurnally timed or fasted specimens. Twenty four hour urine collections eliminate the need for creatinine values and are likely more reliable than spot urine samples during pregnancy. Overall the studies have reported that several markers of bone resorption (urine N-telopetide or CTX, serum CTX, tartrate-resistant alkaline phosphatase, deoxypyridinoline/creatinine, pyridinoline/creatinine, and hydroxyproline/creatinine) are increased from early to midpregnancy onward. Serum markers of bone

formation (osteocalcin, procollagen I carboxypeptides, and bone specific alkaline phosphatase) are often lower in early or midpregnancy as compared to prepregnancy values or normal adult ranges, but increase to normal or above before term.[2] Total alkaline phosphatase increases mainly due to placental production and is not a useful marker of bone formation during pregnancy.

The scant bone biopsy data and the bone biomarkers suggest that bone turnover increases from as early as the 10th week of gestation, but whether this leads to increased, decreased, or no change in bone mass during human pregnancy remains uncertain. Women are in a positive calcium balance by midpregnancy[49] with comparatively little maternal–fetal calcium transfer occurring until the third trimester, and so one might expect that skeletal mineral content should be increased at that time point.

Skeletal calcium content has been assessed in longitudinal studies that measured areal bone mineral density (aBMD).[2] Concerns about fetal radiation exposure have severely limited the data, and the studies are also confounded by changes in body composition (fluid and fat mass), weight, and skeletal volumes, which in turn may cause artifactual changes in the aBMD reading. Early studies used single or dual-photon absorptiometry to study the distal forearm and femur, respectively, and no significant change was found in cortical or trabecular aBMD during pregnancy or between pre- and postpregnancy measurements.[2] More recent studies have used dual X-ray absorptiometry (DXA) which has better precision, but most studies have been quite small with 16 or fewer subjects. Zero change in lumbar spine aBMD was seen in one study but losses of up to 5% of lumbar spine BMD occurred in the remaining studies.[2] However, these studies relied on measurements done up to 18 months before planned conception and 1–6 weeks after delivery with no measurements obtained during pregnancy.[2] Notably the postpartum period is associated with bone density losses of 1%–3% per month (see Section 4) and measurements obtained by 6 weeks postpartum will be confounded by lactational losses.

The largest study involved 92 pregnant Danish women who had DXA measurements of hip, spine, and radius done at baseline (up to 8 months prior to pregnancy), DXA of the forearm repeated during each trimester, and DXA of hip, spine, and radius done again 15 days after delivery. Seventy three women completed the postpartum visit. Compared with 57 controls who completed the same interval of follow up, BMD decreased in pregnant women by 1.8% at the lumbar spine, 3.2% at the total hip, 2.4% at the whole body, and 4% at the ultradistal radius, but increased by 0.5% at the proximal one-third forearm.[65] At the total forearm a 1% difference between pregnant and control became apparent at the third trimester measurement, coinciding with the peak interval of placental–fetal calcium transfer. Apparently all of the pregnancy cohort breastfed, and so lactation-induced bone loss confounded the measurements at day 15 postpartum.

Other longitudinal studies have used serial ultrasound measurements of the os calcis or phalanges and found small decreases during pregnancy in values that correlate with volumetric bone density.[2] However, the significance of changes at these sites is uncertain as compared to the more clinically relevant spine, hip, and radius. Moreover, it is concerning that ultrasound doesn't show any decline in apparent BMD of the os calcis during lactation despite significant losses being detected by DXA at spine and hip[66] (see Section 4). It remains to be shown if this relates to technical differences or site-specific differences in skeletal responses.

Overall, DXA and ultrasound studies lack serial measurements at spine or hip during pregnancy and cannot determine whether aBMD actually increases earlier in pregnancy as suggested by calcium balance studies. The results do suggest that transient declines in skeletal mineral content may occur during normal pregnancy, and can be statistically significant when mean changes in a cohort are analyzed. However, the magnitude of these changes is small and not likely to be detectable or considered significant in an individual subject.

It appears certain that pregnancy causes no long-term changes in skeletal calcium content or strength. There have been many dozens of epidemiological studies of young and older women that have failed to find significant associations of parity (or breast feeding) with bone density or fracture risk.[2,67] Moreover, adolescent pregnancy does not reduce peak bone mass as previously feared. In an NHANES III analysis of 819 women aged 20–25, women who had been pregnant as adolescents had the same BMD as nulliparous women and women who had been pregnant as adults.[68] However, these data do not exclude that transient but clinically significant bone loss might occur during pregnancy in some women; as noted below, more substantial but transient bone loss occurs in most women during lactation.

3 DISORDERS OF BONE AND MINERAL METABOLISM DURING PREGNANCY

3.1 Osteoporosis in Pregnancy

There are no animal models that suggest that osteoporotic fractures may occur as a consequence of normal pregnancy. However, women occasionally present with vertebral compression fractures during pregnancy and may be found to have low BMD shortly afterward.[69] In most cases, lack of baseline data means that low bone density or skeletal fragility preceding pregnancy cannot

be excluded. Some women may experience excessive resorption of calcium from the skeleton due to changes in mineral metabolism induced by pregnancy, and aggravated by factors, such as low dietary calcium and vitamin D deficiency.[69] A high rate of bone turnover is an independent risk factor for fragility fractures in nonpregnant individuals, and so increased bone turnover during normal pregnancy may increase fracture risk. So too the higher maternal weight of pregnancy and anterior position of the gravid uterus increase spine loading and may predispose to crush fractures. Consequently, fragility fractures during or shortly after pregnancy may be the result of preexisting low bone density and fragility disorders, increased bone resorption during pregnancy, higher body weight, and other factors.[69] However, when bone loss does occur, it appears to be transient and without conferring long-term fragility, as suggested by the epidemiological studies mentioned earlier.

Another pregnancy-related disorder is focal, transient osteoporosis of the hip.[69] This is likely not the result of altered mineral and bone metabolism during pregnancy, but instead may be a consequence of local factors. Proposed theories to explain this condition have included femoral venous stasis due to pressure from the pregnant uterus, a form of Sudeck's atrophy or reflex sympathetic dystrophy (causalgia), ischemia, trauma, viral infections, marrow hypertrophy, immobilization, and fetal pressure on the obturator nerve. These patients have unilateral or bilateral hip pain, limp and/or hip fracture in the third trimester or early postpartum. MRI reveals increased water content of the femoral head and the marrow cavity that likely contributes to an artifactually low aBMD by DXA; a joint effusion may also be present. The symptoms and the radiological appearance usually resolve within 2–6 months postpartum.

3.2 Primary Hyperparathyroidism

No animal models of primary hyperparathyroidism have been studied during pregnancy, although both acute and chronic maternal hypercalcemia have been found to suppress the fetal PTH level,[2,70] potentially contributing to neonatal hypoparathyroidism.

The human condition is uncommon with several hundred cases alluded to in the literature; other surgical series suggest that pregnant women represent about 1% of all subjects undergoing parathyroidectomy.[2] Some cases may be overlooked because symptoms of hypercalcemia may not be distinguished from normal constitutional symptoms of pregnancy, and because the normal pregnancy-related fall in serum albumin and PTH may mask the hypercalcemia and elevated PTH level. If the ionized calcium or albumin-corrected serum calcium are elevated with a detectable PTH level, this reliably indicates primary hyperparathyroidism during pregnancy.

The available data from case reports suggest an alarming rate of adverse outcomes for the fetus and neonate, including a 30% rate of spontaneous abortion or stillbirth. Complications have been found in up to 67% of mothers and 80% of their babies.[2] These outcomes are thought to result from fetal and neonatal hypocalcemia, which is precipitated in utero by suppression of the fetal parathyroid glands.[3] In some case reports the parathyroid suppression lasted for months after birth, and in a few it appeared to be permanent.[3] Parathyroidectomy is usually recommended during the second trimester to minimize these outcomes. Case series have reported elective surgery to be well tolerated, and to dramatically reduce the rate of adverse events when compared to earlier cases in the literature. However, those earlier cases had a severe form of primary hyperparathyroidism that is not often seen today—symptomatic, with nephrocalcinosis and renal insufficiency—and so the extent to which surgery actually reduces these outcomes in the milder cases seen today remains uncertain.

Milder, asymptomatic primary hyperparathyroidism has been followed conservatively with successful outcomes, but complications have still occurred in more cases managed medically than in those managed surgically.[71] A potential medical option is Cinacalcet, which acts on the calcium receptor to suppress PTH synthesis and release and to stimulate CT, thereby lowering the blood calcium. It is a Category C medication but has been used in pregnancy in a few cases.[72] However, the calcium receptor is expressed in placenta, fetal parathyroids, and C-cells, and so Cinacalcet may also suppress the fetal parathyroid glands, stimulate fetal CT, and alter the rate of placental calcium transfer. In the absence of definitive data, surgery during the second trimester remains the most conservative and common recommendation for primary hyperparathyroidism during pregnancy.[2,73]

3.3 Familial Hypocalciuric Hypercalcemia

This condition is caused by autosomal dominant, inactivating mutations of the calcium receptor that lead to hypercalcemia and hypocalciuria. Affected individuals develop hypercalcemia in utero and do not suffer from the long-term complications associated with primary hyperparathyroidism. Pregnancy is uneventful but maternal hypercalcemia can adversely affect the fetus and neonate. In pregnant mice bearing a mutation in the calcium receptor, the fetal parathyroids are suppressed, as indicated by a PTH level well below the fetal norm.[70] So too in humans maternal hypercalcemia has been reported to suppress the fetal parathyroids, followed by neonatal hypocalcemia and tetany, even in neonates destined to be hypercalcemic due to inheritance of the mutation.[74,75] The neonate of a woman known to have familial hypocalciuric hypercalcemia should have careful

surveillance for hypocalcemia, whereas unexpected neonatal hypocalcemia should prompt evaluation of the mother for hypercalcemia.

3.4 Hypoparathyroidism

Animal models of hypoparathyroidism during pregnancy have included thyroparathyroidectomized rats and *Pth* null mice. As noted earlier, rats typically develop secondary hyperparathyroidism in the last several days of pregnancy while the fetus is rapidly accreting calcium. Thyroparathyroidectomized rats are even more hypocalcemic while their fetuses have enlarged parathyroids, increased bone resorption, and reduced length and mineral content of the femurs.[2] But as noted earlier, intestinal calcium absorption still doubles during pregnancy in thyroparathyroidectomized rats, and this may offset the development of maternal hypocalcemia. More recently, studies in *Pth* null mice have shown that normal pregnancy-related increases in calcitriol and whole body and spine bone mineral content are achieved.[21] The *Pth* null mice bear normal litters on a typical 1% calcium diet. These findings suggest that loss of PTH may not be as disruptive to calcium homeostasis as it is in the nonpregnant rodent. However, in both thyroparathyroidectomized rats and *Pth* null mice, sudden deaths from presumed hypocalcemia can occur during the last few days of pregnancy, especially in association with anesthesia.

Among reported clinical cases and others that have been shared with the author (many detailed in Ref. 2), some hypoparathyroid women have fewer hypocalcemic symptoms and require significantly less supplemental calcium or calcitriol during pregnancy. This is consistent with the normal suppression of PTH, the rising levels of PTHrP and other hormones that affect calcium metabolism, and animal data which indicate that calcitriol and intestinal calcium absorption both increase despite complete absence of PTH. One recent case report carefully documented how a hypoparathyroid woman required progressively less calcitriol and supplemental calcium as pregnancy progressed, and was off calcitriol altogether by 28 weeks of gestation.[76] Within hours of delivery she developed severe hypocalcemia and required IV calcium and reinstitution of calcitriol supplementation until lactation became fully engaged, which implies that placental factors PTHrP contributed to her reduced need for supplemental calcium or calcitriol.[76]

It is clear from other case reports that some pregnant hypoparathyroid women require increased calcitriol supplementation in order to avoid worsening hypocalcemia. In some of these cases it is evident that the normal dilutional fall in total serum calcium was misinterpreted as worsening hypocalcemia, and led to changes in treatment despite no escalation of symptoms. In still other cases the women clearly had worsening of hypocalcemic symptoms or a demonstrable fall in ionized or albumin-corrected calcium.[2] Consequently, in some hypoparathyroid women the fetal calcium demand overwhelms a woman's ability to maintain her own blood calcium, similar to what has been seen in parathyroidectomized rats.

The ionized calcium or albumin-corrected serum calcium should be maintained in the low-normal to normal range in pregnant women because hypoparathyroidism has been associated with the development of intrauterine fetal hyperparathyroidism and death. Late in pregnancy, the doses of calcitriol and supplemental calcium may need to be reduced or eliminated in order to avoid maternal hypercalcemia caused by rising PTHrP levels.

3.5 Pseudohypoparathyroidism

There are no animal data pertaining to pseudohypoparathyroidism in pregnancy. The available human data are conflicting and echo the data on hypopararhyroidism.[2] In two cases pregnancy normalized the serum calcium level, reduced the PTH level by half, and increased the calcitriol level two- to threefold.[77] But another seven reports of pregnancy in pseudohypoparathyroid women have suggested that increased doses of calcium and calcitriol are needed to maintain the serum calcium in the normal range.[78–81] In some but not all cases there was biochemical confirmation of worsening hypocalcemia during pregnancy.

Pseudohypoparathyroidism may improve during pregnancy due to stimulatory effects of placental lactogen, PRL, and E_2 on the 1α-hydroxylase, as calcitriol levels more than doubled (similar to normal pregnancy) during the second and third trimester for two pseudohypoparathyroid women.[77] Placental production of calcitriol was normal in four pregnancies of pseudohypoparathyroid women[82] but, as noted earlier, it appears that the human placenta contributes little or no calcitriol to the maternal circulation. Normocalcemia must be maintained in the mother to reduced the risk of fetal secondary hyperparathyroidism and its neonatal consequences.[83]

3.6 Pseudohyperparathyroidism

Pseudohyperparathyroidism is PTHrP-mediated hypercalcemia, which can occur during pregnancy as a consequence of excessive release of the hormone from breasts, placenta, or both. Regardless of the source, high calcium, low PTH, and high PTHrP are the expected findings in the pregnant woman. When the breasts are the source of PTHrP, they may be normal sized or large, but the hypercalcemia persists until a bilateral mastectomy is carried out or the production of PTHrP declines postpartum (and especially after weaning).[84–89] When the

placenta is the source, the short half-life of PTHrP in the circulation results in reversal of the biochemical abnormalities within a few hours after delivery. This was illustrated by a woman with marked hypercalcemia, high PTHrP (21 pmol/L), and undetectable PTH, who within hours of an urgent C-section became profoundly hypocalcemic with undetectable PTHrP and elevated PTH.[90]

3.7 Vitamin D Deficiency and Genetic Vitamin D Resistance Syndromes

The actions of calcitriol on the vitamin D receptor are crucial for normal adult mineral homeostasis. In the available animal models, vitamin D deficiency, absence of the vitamin D receptor, or 1α-hydroxylase deficiency each result in hypocalcemia, hypophosphatemia, rickets, and sudden death due to presumed hypocalcemia. However, during pregnancy the critical role of vitamin D/calcitriol appears to be minimized.[2]

The animal models which have been studied during pregnancy include severely vitamin D-deficient rats,[91–94] pigs with a null mutation of the 1α-hydroxylase,[30] *Cyp2b1* null mice,[23] and *Vdr* null mice.[22] Vitamin D deficiency or the genetic mutations result in females that conceive less often, are hypocalcemic, hypophosphatemic, and rachitic, and bear smaller litters than normal. In each model sudden, sporadic maternal deaths may occur during late pregnancy, especially in association with anesthesia. These presumed hypocalcemic deaths may indicate that the mother has difficulty maintaining normocalcemia during the peak interval of placental–fetal calcium transfer. As noted earlier, vitamin D–deficient rats and *Vdr* null mice also upregulate intestinal calcium absorption to the same high rate achieved during pregnancy by normal rats and mice, and gain skeletal mineral content during pregnancy.[2,22] *Cyp2b1* null mice also gain significant bone mineral content while pregnant.[23] A high calcium diet increases the likelihood of conception and larger litters in *Vdr* null mice, but uneventful pregnancies still occur on a normal calcium diet.[95] Another chapter of this book details how the fetus appears relatively unaffected by maternal vitamin D deficiency, lack of 1α-hydroxylase, and absence of the vitamin D receptor. Overall these findings predict that babies born of women who are severely vitamin D deficient will likely have normal cord blood calcium and phosphorus, and normal skeletal morphology and mineral content at birth.

Multiple observational studies and clinical trials have demonstrated that maternal 25-hydroxyvitamin D levels do not change significantly during pregnancy,[2] even in women who start with the extremely low mean value of 20 nmol/L (8 ng/mL).[96] Consequently, it does not appear that pregnant women require higher intakes of vitamin D to maintain a set 25-hydroxyvitamin D level, or that the fetus represents a significant drain on maternal vitamin D stores. No large randomized trials have examined the effects of vitamin D deficiency or insufficiency on human pregnancy. However, available data from small clinical trials of vitamin D supplementation, observational studies, and case reports suggest that, consistent with animal studies, vitamin D deficiency is not associated with any worsening of maternal calcium homeostasis, and the fetus will have a normal serum calcium and fully mineralized skeleton at term (this topic is reviewed in Chapter 20 and in more detail in Refs. 2,3). The only consistent benefit seen in randomized trials is that vitamin D supplementation increases maternal and cord blood 25-hydroxyvitamin D levels without altering cord blood calcium or anthropometric parameters in the baby. High dose vitamin D has been proposed to have nonskeletal benefits, such as reduced preterm delivery, preeclampsia, vaginal infections, etc., but randomized trials using up to the equivalent of 7000 IU of vitamin D daily have found no obstetrical, fetal, or neonatal benefit apart from higher 25-hydroxyvitamin D levels.[2,3,97–103] These negative results do not preclude that vitamin D supplementation might have benefits beyond preventing rickets; however, no benefit has been demonstrated thus far.

In women with absent 1α-hydroxylase (vitamin D-dependent rickets type 1, VDDR-I) treatment with calcium and physiological doses of calcitriol or 1α-cholecalciferol should be adjusted as needed (similar to the management of hypoparathyroidism) to maintain a normal ionized or albumin-corrected serum calcium. In women with absent vitamin D receptors (VDDR-II) there may no responsiveness to calcitriol or cholecalciferol, but adjustments to the calcium content of the diet may be sufficient to maintain a normal ionized or albumin-corrected serum calcium.

3.8 Calcitonin Deficiency

Early animal models of calcitonin deficiency involved thyroparathyroidectomy followed by parathyroid gland autotransplantation and treatment with exogenous thyroid hormone.[104–108] A small (5%–10%) and borderline significant reduction in the ash weight and calcium content of goat metacarpals and metatarsal, and rat femora, were seen when thyroidectomized and sham-operated animals were compared at the end of pregnancy.[104,105,108] A more recent model used *Ctcgrp* null mice, which represent true CT deficiency because the gene encoding CT and CT gene-related peptide-α has been ablated.[109] There were no differences in *Ctcgrp* nulls compared to WT sisters in biochemistries, PTH, calcitriol, or BMC of the whole body, lumbar spine, or hindlimb, suggesting that loss of CT does not impair mineral or skeletal metabolism during pregnancy.[19,20] The surgical models provided modest evidence that an intact thyroid gland may protect the maternal skeleton from loss of bone mineral

during pregnancy, but *Ctcgrp* null mice did not reveal any such protective effect.

Increased serum CT has been proposed to protect the human skeleton from excessive resorption during pregnancy. Totally thyroidectomized women are not truly CT deficient due to production by placenta and breasts, and no women with genetic loss of CT or its receptor have been identified or studied during pregnancy.

3.9 Low Calcium Intake

Studies described earlier in rats have shown that low calcium intake will worsen secondary hyperparathyroidism in the mother during late pregnancy and cause fetal skeletal resorption.[2] This suggests that low calcium intake should be avoided during human pregnancy.

The doubling of intestinal calcium absorption and consequent absorptive hypercalciuria in most pregnant women implies that calcium intake typically exceeds maternal requirements. Intuitively a low maternal calcium intake would be harmful to mother and fetus, and low calcium intake has been found in some pregnant women who present with vertebral fractures.[69] However, clinical trials have shown mixed and inconclusive evidence of maternal or neonatal benefit from calcium supplementation during pregnancy. In one study supplemental calcium failed to alter maternal or neonatal bone density,[110] whereas a randomized trial of 2 g of calcium supplementation versus placebo found that neonatal BMD was improved only in offspring of mothers who started out in the lowest quintile of calcium intake (<600 mg/day).[111] These findings suggest that calcium supplementation may only benefit women (and their babies) who would otherwise have the very lowest intakes of calcium.

Low calcium intake has been associated with increased risk of preeclampsia. Calcium supplementation reduces the risk of preeclampsia when the dietary calcium intake is low, but there is no effect when dietary calcium intake is adequate.[112]

3.10 Hypercalcemia of Malignancy

There are no animal data pertaining to hypercalcemia of malignancy during pregnancy, but there are about ten published clinical cases and the author is aware of others.[2] Surprisingly the baby's outcome is not mentioned in most reports. The neonate may be hypercalcemic at birth but hypocalcemic with respiratory distress afterward, and one baby died out of four cases where the outcome was reported. Intravenous pamidronate has been used to control maternal hypercalcemia during pregnancy with no adverse effect noted in the neonates, and in several cases the mother died within a few months postpartum.

Treatment of hypercalcemia of malignancy during pregnancy may include debulking surgery, hydration, furosemide, and CT. Bisphosphonates and denosumab cross the placenta, and high doses may cause fetal hypocalcemia and disrupt endochondral bone development. Left untreated, maternal hypercalcemia causes fetal hypoparathyroidism with subsequent neonatal tetany. Thus the use of bisphosphonates and denosumab may be considered but only after carefully considering relative benefits and risks in each case.

3.11 FGF23-Related Disorders

Pregnancies are unremarkable in *Phex (Hyp)*$^{+/-}$ mice, a model of X-linked hypophosphatemia (XLH) that leads to FGF23 excess.[42,43,113] Despite the maternal hypophosphatemia, the fetuses display normal serum mineral and calciotropic hormone concentrations, lengths, placental phosphorus transport, skeletal development, and mineralization.[42] Hyperphosphatemic disorders due to loss of FGF23 cannot be studied during pregnancy because *Fgf23* null mice die by several weeks of age,[114] while *Klotho* null mice have marked hypogonadism and die by 9–10 weeks of age.[115]

Hypophosphatemia persists during pregnancy in women with XLH,[116,117] but it remains uncertain whether the hypophosphatemia needs to be treated. Calcitriol and phosphorus supplementation is generally maintained throughout pregnancy in order to ensure adequate delivery of phosphorus to the fetus.[118] There are no published reports on pregnancies in women with hyperphosphatemic disorders caused by deficiency of FGF23 or its coreceptor.

4 SKELETAL AND MINERAL PHYSIOLOGY DURING LACTATION

The neonatal demand for calcium begins at birth and requires an average daily transfer of 210 mg calcium into human breast milk, with much higher outputs documented in wet nurses and other women.[2] Women nursing twins or triplets respectively have double and triple the output of calcium into milk.[2] Analysis of ash weight and mineral content of human babies suggests that the neonatal skeleton accretes about 100 mg of calcium daily.[2,3]

Lactating women temporarily resorb bone to provide much of the calcium content of milk. Lactating rodents have a proportionately higher calcium demand due to their large litters (8–12 pups) and shorter duration of lactation (21 days), and they meet the demand through the combination of increased intestinal calcium absorption and resorption of 20%–30% of the skeleton.

This skeletal demineralization is accomplished by osteoclast-mediated bone resorption and osteocytic osteolysis. It is not controlled by PTH or calcitriol but

appears to be stimulated by mammary gland-derived PTHrP and permitted by low systemic E_2 levels, among other possible factors. It reverses postweaning through mechanisms that remain to be elucidated.[2]

4.1 Mineral Ions and Calciotropic Hormones (Fig. 21.3)

Early in the postpartum period the dilutional effects of pregnancy recede as the vascular volume becomes contracted; the serum albumin returns to normal. Consequently, the total serum calcium may be a reliable measurement during lactation, although the ionized calcium and albumin-corrected serum calcium are still preferred.[2]

Data from lactating rats have shown variable results for ionized or total serum calcium, with modest hypocalcemia, normal values, or even modest hypercalcemia being reported.[2] A lower maternal serum calcium can be provoked in rats or mice by dietary calcium restriction or through intensive lactation imposed by greater litter sizes. Longitudinal studies in lactating mice have found that the ionized calcium and total serum calcium are normal or even slightly elevated when nursing 6–10 pups.[12,20,22,62,63] The lactating rodent's physiology is adapted to deliver substantial calcium to the milk each day from skeletal and intestinal sources, and if that milk is not produced then rebound hypercalcemia will result. This has been observed in lactating *Ctcgrp* null mice which have excessive bone resorption during lactation and become hypercalcemic in the first 24 h after delivery before the pups are fully suckling,[20] and in normal lactating rats and mice which become hypercalcemic upon forced weaning.[2,62,119]

In longitudinal studies done in lactating women, the ionized and albumin-corrected serum increase slightly but remain normal.[2]

In lactating mice and humans, serum phosphorus levels are higher than nonpregnant values and may exceed the normal range.[2] This results from enhanced skeletal

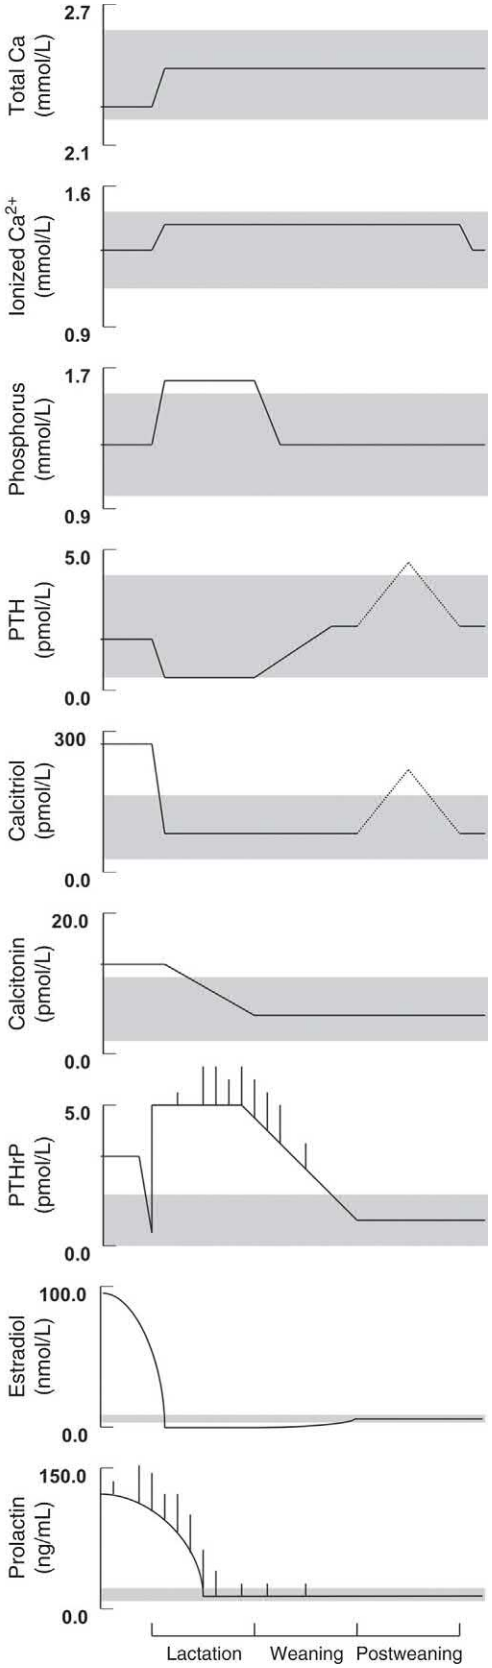


FIGURE 21.3 Schematic depiction of longitudinal changes in calcium, phosphorus, and calciotropic hormone levels during lactation and postweaning skeletal recovery in women. Normal adult values are indicated by the shaded areas. PTH does not decline in women with low calcium or high phytate intakes, and may even rise above normal. Calcidiol (25OHD) values are not depicted; most longitudinal studies indicate that the levels are unchanged by lactation, but may vary due to seasonal variation in sunlight exposure and changes in vitamin D intake. PTH-related protein (PTHrP) and prolactin (PRL) surge with each suckling episode, and this is represented by upward spikes. FGF23 values cannot be plotted due to lack of data. Very limited data suggest that calcitriol and PTH may increase during postweaning, and the lines are dashed to reflect the uncertainty. *Source: Reproduced with permission from Kovacs CS. Maternal mineral and bone metabolism during pregnancy, lactation, and post-weaning recovery.* Physiol Rev *2016;***96***(2):449–547.*[2]

release of phosphate in addition to phosphate absorbed through the diet. Urine phosphorus levels increase above the normal range,[12] likely due to the increased filtered load and phosphaturic influence of PTHrP.

Older literature suggested that PTH is elevated during lactation but relied upon outdated assays that measured biologically inactive fragments. Using modern "intact" PTH assays, lactating rats have high PTH levels which rise even higher with larger litter sizes or dietary calcium restriction.[2] In contrast, Black Swiss and C57BL/6 strains of lactating mice have suppressed PTH beginning early in lactation that remains low until weaning,[12,20,22] while PTH levels are low during the first several days but normal during the rest of lactation in CD1 mice.[62] Studies in parathyroidectomized rats and *Pth* null mice agree that PTH is not required for lactation to proceed normally, as determined by the calcium content of milk, growth of pups, or extent of bone mineral content lost during lactation.[2,21,120] In humans the intact PTH level remains low during the first several months of lactation before rising to normal or above at weaning.[2] Observational studies of hypoparathyroid women (discussed later) confirm that PTH is not required during lactation.

Calcitriol levels are two to five times normal during pregnancy and this increase is sustained during lactation in rats, whereas the values fall to normal in mice.[2,12,121] More intense lactation or dietary calcium restriction leads to higher calcitriol levels in rats, and parathyroidectomy reduces the circulating calcitriol level by 60%. These findings suggest that the increase in calcitriol is dependent in part upon secondary hyperparathyroidism in lactating rats. However, rodents do not require calcitriol for lactation to proceed normally because severely vitamin D–deficient rats, *Cyp27b1* null mice, and *Vdr* null mice lose a normal amount of skeletal mineral content during lactation.[22,23,93,122] In women free and bound calcitriol levels fall to normal within days of parturition and remain there throughout lactation; nursing of twins does not consistently affect calcitriol concentrations.[2]

CT levels are elevated during pregnancy in rodents but rapidly decline to normal. CT and its receptor are expressed in lactating mammary tissue where its role is not established, but loss of CT is associated with upregulation of PTHrP expression in mammary tissue.[2] CT is also expressed in pituitary and there is evidence that it inhibits the expression of PRL.[20,123,124]

In women, CT levels are elevated during pregnancy and remain that way for the first 6 weeks postpartum before declining to normal. CT is expressed in the lactating breast, such that in thyroidectomized women plasma CT rose from undetectable to ~14 pg/mL, while milk CT levels were over 45 times higher than these values.[32] Consequently, thyroidectomized women are not CT deficient when breastfeeding.

Plasma PTHrP levels are increased in lactating rodents and may achieve the highest values measurable apart from during late fetal development.[2,125] The source of circulating PTHrP is the lactating mammary tissue which substantially upregulates PTHrP mRNA during lactation. Suckling induces PTHrP (mRNA and protein) locally in rat mammary glands and this response appears to be mediated by PRL and blocked by bromocriptine.[2] Confirmation that the mammary glands are the source of circulating PTHrP comes from a mouse model in which the PTHrP gene was ablated within mammary tissue at the onset of lactation, and such mice have lower blood levels of PTHrP than in wild-type lactating controls.[121] Additional studies in mice indicate that PTHrP regulates the water and calcium content of milk.[2,126,127] Furthermore, as discussed later, mammary-specific deletion of PTHrP confirms that it is a key factor promoting skeletal resorption during lactation.[121]

In lactating women plasma PTHrP levels at 2–6 pmol/L are significantly higher than in nonpregnant controls, and equivalent (in molar equivalent units) to circulating PTH levels in nonpregnant adults.[2] As is true for rodents, the source of PTHrP is the breasts which effectively become accessory parathyroid-like glands during lactation. PTHrP mRNA is upregulated in mammary tissue and breast milk concentrations of the protein are 10,000 times higher than in the blood of patients with hypercalcemia of malignancy or normal controls. Suckling likely forces some PTHrP into the maternal circulation while most goes into milk; a small rise in the systemic level of PTHrP can be demonstrated after suckling. PTHrP plays a central role during lactation by stimulating resorption of calcium from the maternal skeleton, renal tubular reabsorption of calcium, and (indirectly) suppression of PTH. Clinical studies have determined that PTHrP levels correlate with the amount of BMD lost, negatively with PTH levels, and positively with the ionized calcium levels of lactating women.[2] Occasionally hypercalcemia occurs during lactation and elevated circulating PTHrP levels have been documented in some cases; the hypercalcemia resolves with weaning.[84,128] Furthermore, observations in hypoparathyroid women (discussed later) provide additional evidence of the key role that PTHrP plays in regulating maternal calcium homeostasis during lactation.

PRL is persistently elevated during early lactation and achieves its highest levels after suckling. As the postpartum days pass, basal PRL levels return to normal in between feeds but continue to spike with each suckling episode. PRL plays a key role in initiating and maintaining milk production; dopaminergic agents inhibit PRL and stop milk production. PRL and PRL receptor null mice are infertile but heterozygous-deleted PRL receptor mice demonstrate impaired lactation.[129] PRL may alter bone metabolism by stimulating PTHrP

production in lactating mammary tissue, inhibiting gonadotropin-releasing hormone (GnRH) and ovarian function, and through direct actions in osteoblasts which express the PRL receptor. Clarifying the role of PRL in regulating bone metabolism is particularly challenging because suppressing PRL inhibit milks production and mammary production of PTHrP, and disinhibits GnRH, without requiring PRL to have a direct effect on bone.

OT's known role during lactation is to contract myoepithelial cells within mammary tissue, thereby causing suckling-induced milk ejection. If not ejected, milk stasis leads to apoptosis of mammary cells and lactation ceases. OT reaches peak circulating levels in women within 10 min of the onset of suckling.[130] OT may in part regulate the differentiation and function of osteoblasts and osteoclasts, but because OT null mice cannot lactate, a role for OT in lactational bone metabolism has not been established.[131]

E_2 controls bone metabolism by inhibiting RANKL and stimulating osteoprotegerin production by osteoblasts. E_2 levels are near the detection limit in both nonpregnant and pregnant mice and are slightly but not significantly lower during lactation.[63] Estrus cycles and ovulation continue unabated during lactation in mice with simultaneous pregnancies occurring, and so it is unclear that E_2 levels are sufficiently lower in lactating mice to stimulate bone resorption. In contrast, E_2 levels reach menopausal levels in lactating women and estrogen-deficiency symptoms, such as hot flashes are common. The low E_2 levels in lactating women do stimulate bone resorption, as discussed later.

Lactation induces changes in myriad other hormones, such as luteinizing and follicle stimulating hormone, progesterone (PROG), testosterone, inhibins, and activins. Whether these play roles in regulating skeletal metabolism during lactation has not been investigated.

4.2 Calcium Pumping and Secretion in Mammary Tissue

Mammary epithelial cells pump calcium against a steep concentration gradient. It appears that calcium enters mammary epithelial cells through stretch activated and other channels, and associates with intracellular binding proteins (casein, phosphate, citrate, calbindins, etc.) and the Golgi apparatus (Fig. 21.4). About 30% of calcium transport into milk involves extrusion from the Golgi apparatus through transepithelial secretion.[132,133] The other 70% of calcium entry into milk results from plasma membrane calcium ATPase isoform 2 (PMCA2) pumping calcium across apical membranes directly into milk.[134,135]

The mammary tissue is not a simple drain through which calcium exits the mother; rather, the calcium and fluid content of milk are tightly regulated by suckling, the calcium receptor, PTHrP, PRL, and other factors.[121,126,136] Calcium regulatory genes expressed by lactating mammary tissue include the calcium receptor, PTHrP, CT receptor, 1α-hydroxylase, and vitamin D receptor.[126,137,138]

Recent studies in knockout mice have enabled some aspects of the regulation of calcium transport into mammary epithelial cells and secretion into milk to be understood. PTHrP plays a key role because loss of mammary-derived PTHrP at the onset of lactation leads to reduced bone turnover markers, less bone resorbed, and lower milk calcium content.[121] Conversely, the expression of PTHrP in mammary tissue and the circulation is increased by low E_2, low dietary calcium, high PRL, loss of CT, suckling, and treatment with a bisphosphonate to reduce bone resorption.[2,19,20,63,126,139] The central controller of calcium transport in mammary epithelial cells is the locally expressed calcium receptor which regulates the fluid and calcium content of milk, and mammary production of PTHrP[2,126,127] (Fig. 21.5). A calcimimetic blocks the effect of a low calcium diet to increase mammary production of PTHrP,[126] while ablation of the calcium receptor upregulates mammary gland PTHrP and reduces calcium transport into milk.[127] The calcium receptor stimulates calcium secretion into milk by upregulating expression of PMCA2, expressed on the apical plasma membranes of mammary epithelial cells.[126,134] A null mutation in *Pmca2* leads to milk that has low calcium content.[134] In this way the lactating mammary gland uses the calcium receptor to sense availability of calcium (Fig. 21.5). It stimulates calcium secretion into milk when the supply is adequate, and stimulates the production of PTHrP when the calcium supply is waning. PTHrP's main role is the delivery of calcium to mammary epithelial cells, while PMCA2 controls milk calcium content.

Mice lacking CT and CT gene-related peptide-α display upregulation of PTHrP within mammary tissue and a doubling of milk calcium content, although it remains unknown whether these are direct effects of loss of CT expression within mammary tissue.[19,20]

The demands of the breasts for calcium can provoke maternal hypocalcemia, as observed in rats and mice nursing large litters, and in the condition known as milk fever in cows.

4.3 Intestinal Absorption of Calcium

Lactating rodents maintain a twofold higher rate of duodenal calcium absorption, similar to pregnancy.[2] This may not be dependent upon calcitriol as severely vitamin D–deficient rats and, by inference, *Vdr* null mice have upregulated intestinal calcium absorption during lactation.[51,52,140] Other factors, such as PRL may stimulate intestinal calcium absorption. Upregulated intestinal

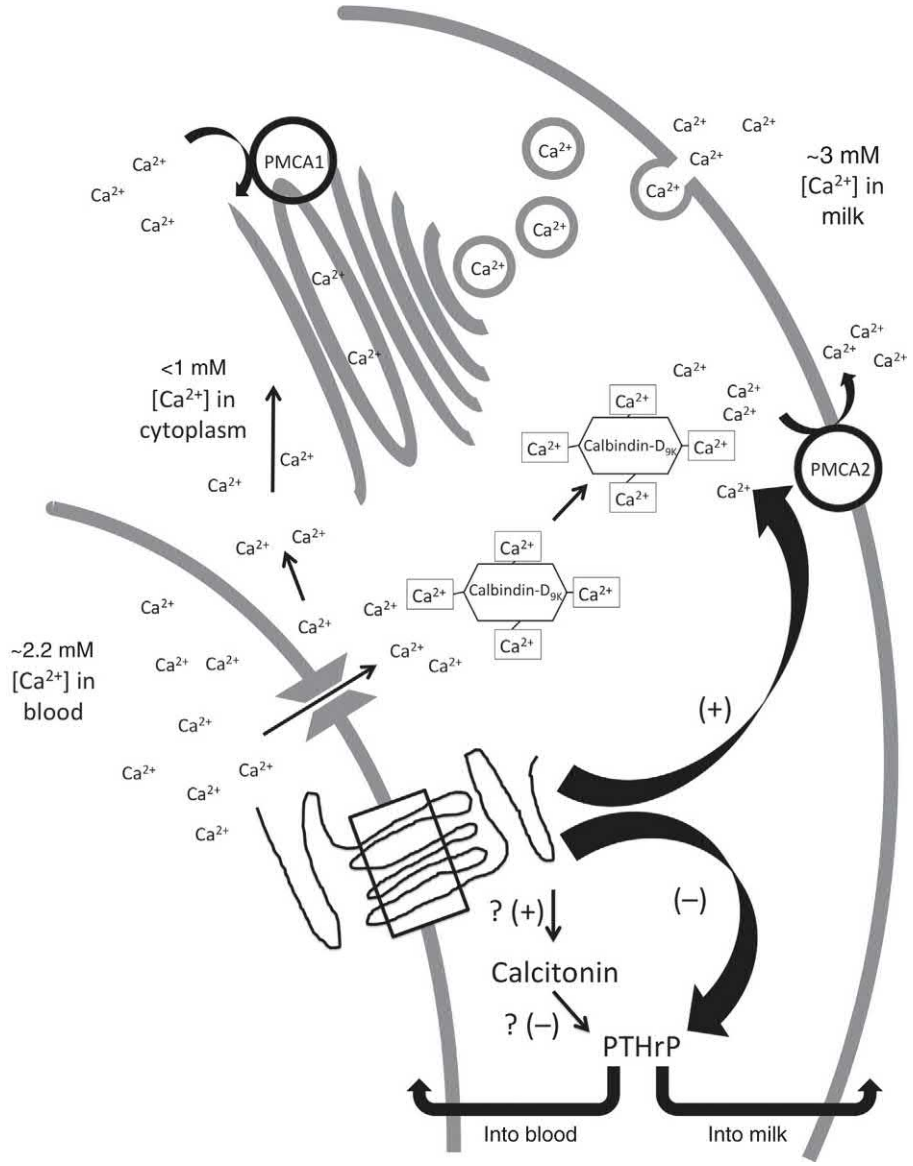

FIGURE 21.4 Calcium transport across mammary epithelial cells into milk. The basolateral (left) and apical (right) basement membranes of a mammary epithelial cell are depicted. Calcium enters the cell through channels that have not been defined; transient receptor potential vanilloid (TRPV6 and TRPV5) are not expressed. About 20%–30% of calcium destined for secretion into milk is pumped into the Golgi apparatus via plasma membrane calcium ATPase (PMCA1), wherein it is packaged into secretory granules containing proteins (casein and α-lactalbumin) and complexes of calcium with phosphate and citrate. These granules are extruded from the Golgi apparatus into milk through transepithelial secretion at the apical membrane. About 70%–80% of calcium entering the cell becomes bound to carrier proteins, such as calbindin-D9k and is shuttled to the apical membrane in the transcellular pathway, from where PMCA2 actively pumps the calcium into milk. Calcium ions binding to the calcium receptor on the basolateral membrane inhibit PTHrP and stimulate PMCA2 to pump calcium into milk. Calcitonin (CT) may also influence these processes, perhaps through regulation by the calcium receptor (which regulates CT in C-cells of the thyroid), as absence of CT causes upregulation of PTHrP within mammary epithelial cells and milk calcium concentration is also increased. PTHrP is released into milk at higher concentrations than it is released into the maternal circulation.

calcium absorption is important in rodents as a low calcium diet causes hypocalcemia and reduced calcium content of the milk.[2,126]

In lactating humans, intestinal calcium absorption promptly decreases to the nonpregnant rate from the doubled rate of pregnancy.[2] Therefore, although rodents require upregulation of intestinal calcium and skeletal resorption to meet the calcium demands of lactation, humans rely mainly on skeletal resorption of mineral.

4.4 Renal Handling of Calcium

Lactating rats and mice show decreased renal calcium excretion.[2,12,20] Similarly, in lactating women the glomerular filtration rate falls during lactation, and renal excretion of

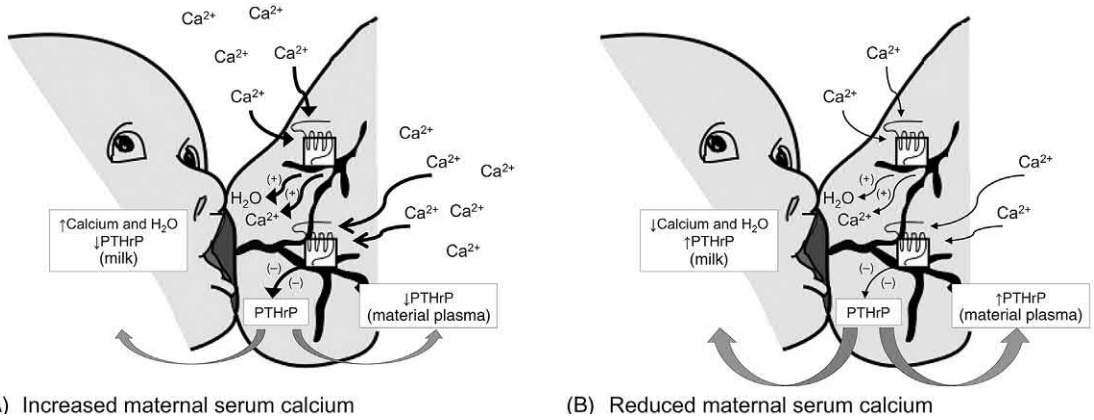

FIGURE 21.5 The role of PTHrP and calcium receptor (CaSR) within the lactating breast. The calcium receptor (represented schematically) is expressed by lactating mammary epithelial cells. It monitors the systemic concentration of calcium to control PTHrP synthesis and, thereby, the supply of calcium to the breast. An increase in serum calcium or administration of a calcimimetic inhibits PTHrP expression (A), whereas a decrease in serum calcium or ablation of the calcium receptor from mammary epithelial cells stimulates PTHrP expression (B). The calcium receptor also directly regulates the calcium and fluid composition of milk independent of PTHrP. Administration of a calcimimetic stimulates calcium and water transport into the breast, while ablation of the calcium receptor results in low milk calcium despite increased PTHrP and systemic hypercalcemia. PTHrP produced by mammary epithelial cells enters the maternal circulation to stimulate maternal bone resorption and renal calcium conservation. It also enters milk at 1,000–10,000-fold higher concentrations, from where it may influence neonatal accrual of calcium.

calcium is typically reduced to levels as low as 50 mg/24 h.[2] These findings suggest that tubular reabsorption of calcium must be increased, perhaps through the actions of PTHrP. This renal calcium conservation contrasts with pregnancy where urinary calcium excretion increases and may exceed the normal range.

4.5 Skeletal Calcium Metabolism

Marked skeletal resorption occurs during lactation in all mammals that have been studied, including rodents and nonhuman primates. Bone formation and resorption markers are both elevated with the most marked increase occurring in resorption markers. Histomorphometric data from lactating animals show increased bone formation but a greater increase in bone resorption parameters.[2] Through a process called osteocytic osteolysis, osteocytes resorb their surrounding matrix to provide additional mineral during lactation.[2,141] This can be visualized by the increased size and prominence of the lacunae that surround osteocytes. The combined effects of osteoclast-mediated resorption and osteocytic osteolysis (Fig. 21.6) cause a net loss of bone mass and mineral content, with more marked reductions at trabecular than cortical sites, and the greatest losses at the lumbar spine. The decline in mineral content has been assessed by determining the total or trabecular ash weight of bone, the mineral content of the ash, and by serial measurement of bone mineral content or density with DXA. By these methods the trabecular mineral content may decline 20%–35% during 3 weeks of normal lactation in the rat and mouse. Greater losses (40% or more) will occur in rodents on a calcium-restricted diet and in response to larger litter sizes, and these changes are sufficient to decrease the mechanical properties of bone and predispose to fracture.[2] Conversely, a calcium-rich diet can suppress the loss of bone during lactation. A 2% calcium intake reduced the skeletal losses incurred by lactation in mice while a 1.4% calcium intake did not alter bone loss in rats.[21,142]

Lactating women also show evidence of increased bone turnover with net resorption of bone, although the extent of loss is much less than in rodents.[2] No histomorphometric data are available. Biochemical markers of bone formation and resorption have been assessed

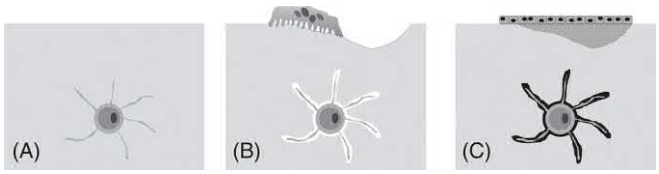

FIGURE 21.6 Osteocytic osteolysis and osteoclast-mediated bone resorption. (A) Quiescent bone with an osteocyte surrounded by its lacuna and canaliculi (*gray* halo and tentacles). (B) Lactation with an osteoclast resorbing bone (resorption pit) while an osteocyte resorbs mineral from its lacuna and pericanalicular spaces (surrounding white regions). (C) Postweaning phase, during which osteoblasts restore bone in areas previously resorbed by osteoclasts (hatched resorption pit), and osteocytes remineralize their lacuna and pericanalicular spaces (surrounding black regions). Evidence from osteocyte-specific ablation of the PTH/PTHrP receptor in mice suggests that bone resorption and osteocytic osteolysis may each account for about 50% of the mineral lost from the skeleton during lactation. *Source: Reprinted with kind permission from Kovacs CS, Ralston SH. Presentation and management of osteoporosis presenting in association with pregnancy or lactation.* Osteoporos Int *2015;***26***(9):2223–41, copyright 2015 Springer Science and Business Media B.V.*[69]

in numerous cross-sectional and longitudinal studies. Potential confounding must be considered as the glomerular filtration rate is reduced during lactation and the intravascular volume is contracted. In general, bone formation and resorption markers are elevated over prepregnancy and pregnancy values, or those obtained in nonpregnant controls, and the most marked elevation occurs in bone resorption markers. Loss of the placenta leads to a rapid fall in total alkaline phosphatase but it may remain above normal due to elevation in the bone-specific fraction.

Changes in bone mineral content have been assessed by serial measurements with SPA, DPA, or DXA. The results are quite variable between individual women and between studies with a decline of 3%–10% in bone mineral content being observed after 2–6 months of lactation at trabecular sites (particularly lumbar spine), with smaller losses at cortical sites and whole body.[2,67] The median loss from the lumbar spine is approximately 8% at 6 months based on all available studies.[2] Some studies in lactating adolescents demonstrated losses of 10%–15% from baseline.[2] The skeletal losses occur at rates of 1%–3% *per month*; by comparison, a loss of more than 1%–2% *per year* is considered rapid in postmenopausal women. Although rodents may resorb less bone on a very high-calcium diet, several interventional studies have demonstrated that calcium supplementation does not reduce the amount of bone lost by women during lactation.[143–146] In a randomized clinical intervention trial that studied the effect of consuming 2.4-g calcium daily, lactating women still lost 6.3% of BMD at the lumbar spine and up to 8% from the radius and ulna, as determined by DXA.[146] The lactational decrease in BMD correlates with the breast milk output,[147] and predicts that women who nurse twins will lose more bone mineral content than women who nurse singletons.

The mechanism for the loss of bone mass and mineral content during lactation has been investigated in several animal models. While not fully explained, low E_2 and increased PTHrP are key factors driving the bone resorption. Estrogen replacement given to mice at the start of lactation reduced the extent of bone lost, but the achieved E_2 levels were nearly eight times the normal value for lactation, and about four times the virgin level.[125] Consequently, those high doses overestimate the contribution of estrogen deficiency in causing bone loss during lactation. Other studies suggested that estrogen deficiency plays only a small role. Ovariectomy in rodents leads to lower E_2 levels than during lactation but the rate of bone loss is slow, typically being assessed several months after surgery as compared to 3 weeks for lactation.[2,125] Also, ovariectomized rats and simultaneously pregnant and lactating rats each lose the same amount of bone as intact rats going through normal lactation.[2] E_2 deficiency induced with GnRH analogues causes little or no loss of skeletal mineral content in several strains of mice as compared to normally lactating controls[125] (and unpublished data).

PTHrP plays a significant role in stimulating bone resorption during lactation was confirmed by the previously described conditional knockout of PTHrP from mammary tissue. Those mice had reduced serum calcium, calcitriol, nephrogenous cAMP, bone turnover markers, and net loss of bone mineral content.[121]

The Wysolmerski lab attempted to replicate the skeletal effects of lactation in virgin mice by continuously administering PTHrP together with E_2 deficiency induced either by a GnRH analogue or by ovariectomy. No significant bone loss occurred from the combined interventions, and the authors concluded that factors other than PTHrP and E_2 deficiency must contribute to lactational bone loss.[125] However, the study was confounded by lack of the pumping drain (i.e., the lactating breast) which actively disposes of resorbed skeletal mineral during lactation. The serum calcium was higher in the combination treatment group as compared to normal lactation, and PTH was suppressed. The higher serum calcium and lack of a "drain" allowed calcium to be recycled back into bone and likely suppressed bone resorption.

PTH is not required as shown by normal lactational losses occurring in parathyroidectomized rats and *Pth* null mice.[2,21] Similarly severely vitamin D–deficient rats and *Vdr* null mice also experience normal lactational losses of mineral content.[22,93,122] As noted earlier, loss of CT more than doubled skeletal losses in mice, which confirms that CT normally protects the maternal skeleton against excessive losses during lactation, at least in rodents.[20] The mice showed not only structural loss of trabecular bone but also prominence of osteocytic lacunae, an indicator of increased osteocytic osteolysis.[148]

Human data also indicate that estrogen deficiency is unlikely to be the main explanation for the speed and magnitude of skeletal resorption that occurs during lactation. Ovariectomy or normal menopause leads to an average annual loss of 1% of skeletal mineral content. Six months of acute estrogen deficiency induced in young women by GnRH agonist therapy leads to 1%–4% losses in trabecular (but not cortical) aBMD, increased urinary calcium excretion, and suppression of calcitriol and PTH.[2] However, during lactation, women are not as estrogen deficient and lose more aBMD (at both trabecular and cortical sites), have normal (as opposed to low) calcitriol levels, and have reduced (as opposed to increased) urinary calcium excretion. The difference between isolated estrogen deficiency and lactation is likely due to the effects of PTHrP which synergizes with estrogen deficiency to markedly stimulate skeletal resorption (Fig. 21.7). Additional data indicate that PTHrP likely causes the bone loss during lactation. In one study of lactating women, higher PTHrP levels correlated with loss of BMD at the

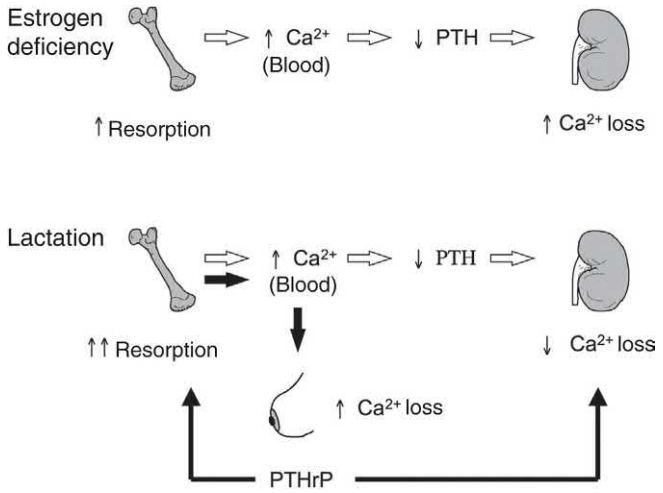

FIGURE 21.7 Schematic depiction of the effects of acute, isolated estradiol (E_2) deficiency from gonadotropin-releasing hormone (GnRH) analog therapy versus lactation. Acute estrogen deficiency (e.g., GnRH analog therapy) increases skeletal resorption and raises the blood calcium; in turn, PTH is suppressed and renal calcium losses are increased. During lactation, the combined effects of PTHrP (secreted by the breast) and estrogen deficiency increase skeletal resorption, reduce renal calcium losses, and raise the blood calcium, but calcium is directed into breast milk. *Source: Reprinted from Kovacs CS, Kronenberg HM. Maternal–fetal calcium and bone metabolism during pregnancy, puerperium, and lactation.* Endocr Rev *1997;***18***(6):832–72, copyright 1997 the Endocrine Society.*[1]

lumbar spine and femoral neck, even after accounting for the effects of E_2 levels, PTH, and breastfeeding status.[149] Case reports mentioned earlier have demonstrated lactational hypercalcemia associated with high PTHrP and increased bone resorption, with postweaning resolution of the hypercalcemia and high PTHrP.

In animal models the decline in mineral content is fully restored after lactation. Histological studies have shown rapid apoptosis of osteoclasts within 24 h of weaning while osteoblast numbers increase further from the high values that were present during lactation.[62,148,150] An interval of rapid bone formation leads to reversal of thinned trabecular plates and cortices, and the depleted mineral content that developed during lactation.[20,62] Osteocytes stimulate bone formation in their lacunae, as demonstrated by the appearance of tetracycline labels postweaning and a return of lacunar size to normal[151] (Fig. 21.6). Bone biomarkers indicate a marked suppression of bone resorption while the bone formation markers maintain the high levels achieved during lactation or increase further.[12,62] The striking difference between lactation and weaning is the sudden and marked suppression of osteoclast numbers and bone resorption parameters at weaning, which leads to uncoupled bone formation by surging numbers of osteoblasts. By DXA, the spine, hindlimb, and whole body return bone mineral content to normal or above within 14 days for Black Swiss mice, and by 21–28 days in other strains of mice.[20,62] By microCT, the bone mass returns to normal at differing rates by each skeletal site, with some taking much longer time than others.[152] The factors that stimulate bone formation during the postweaning interval remain unknown. Studies in parathyroidectomized or severely vitamin D-deficient rats, and genetically engineered mice, have shown that PTH, PTHrP, CT, vitamin D, and the vitamin D receptor are not required, and that deficits as great as 55% of skeletal mineral content, as observed in CT-deleted mice, are fully recovered.[2,12,20–22]

In humans, the bone density losses during lactation appear to be substantially reversed during weaning,[2,67,144] although the speed and completeness of recovery may differ by skeletal site and technique used. This corresponds to a gain in bone density of 0.5%–2% per month in a woman who has weaned her infant. As with the animal models, the mechanism that regulates this interval of marked bone formation is uncertain. Restoration of menses often precedes the start of skeletal recovery and indicates that E_2 levels have likely normalized; however, it does not prove that E_2 stimulates postweaning skeletal recovery. Resumption of menses also indicates that lactation is now less intense, skeletal resorption can decline, and this may simply facilitate skeletal recovery. Clinical experience with estrogen replacement in postmenopausal women has shown that it suppresses osteoclasts but is not a major stimulator of bone formation, and so E_2 is unlikely to account for skeletal recovery after lactation. Moreover in the clinical studies of women who had E_2 deficiency induced for 6 months by treatment with GnRH analogues and lost only 1%–4% of bone mineral content, most of that small deficit persisted a year after return of normal ovarian function.[2]

These short-term losses in bone mass and mineral content cause at most a transient increase in skeletal fragility but no long-term effect in most women. There have been dozens of studies analyzing risk factors for fracture among pre- and postmenopausal women. The vast majority of these studies have found no adverse effect of a history of lactation or lifetime duration of lactation on peak bone mass, bone density, or hip fracture risk; indeed, some studies found that lactation confers a protective effect against future risk of fracture.[2] So too in adolescents it appears that lactation does not imperil the achievement of peak bone mass as previously feared. In an NHANES III analysis of 819 women aged 20–25, women who breastfed as adolescents had higher BMD than women who had not breastfed and nulliparous women.[68] Thus it appears that lactating adolescents and adults recover fully without any long-term adverse effects on the skeleton.

4.6 Brain–Breast–Bone Circuit

The foregoing data suggest that there are key interactions between brain, breast, and bone during lactation (Fig. 21.8). In response to suckling, the pituitary produces

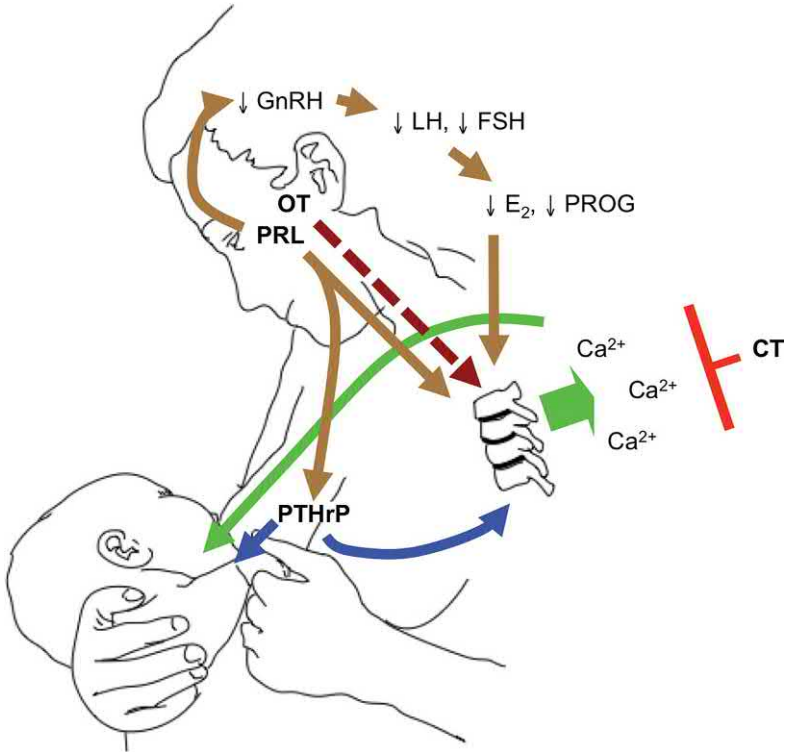

FIGURE 21.8 Breast–brain–bone circuit controls lactation. Suckling and PRL both inhibit the hypothalamic GnRH pulse center, which in turn suppresses the gonadotropins [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)], leading to low levels of the ovarian sex steroids [eE_2 and progesterone (PROG)]. Prolactin may also have direct effects on its receptor in bone cells. PTHrP production and release from the breast are stimulated by suckling, prolactin, low E_2, and the calcium receptor. PTHrP enters the bloodstream and combines with systemically low E_2 levels to markedly upregulate bone resorption and (at least in rodents) osteocytic osteolysis. Increased bone resorption releases calcium and phosphate into the blood stream, which then reaches the breast ducts and is actively pumped into the breast milk. PTHrP also passes into milk at high concentrations, but whether swallowed PTHrP plays a role in regulating calcium physiology of the neonate is uncertain. In addition to stimulating milk ejection, oxytocin (OT) may directly affect osteoblast and osteoclast function (*dashed line*). CT may inhibit skeletal responsiveness to PTHrP and low E_2 given that mice lacking CT lose twice the amount of bone during lactation as normal mice. Not depicted is that CT may also act on the pituitary to suppress prolactin release, and within breast tissue to reduce PTHrP expression and lower the milk calcium content (see text). *Source: Adapted with kind permission from Kovacs CS. Calcium and bone metabolism during pregnancy and lactation.* J Mammary Gland Biol Neoplasia *2005;***10***(2):105–18, copyright 2005 Springer Science and Business Media B.V.*[153]

PRL. Suckling-induced nerve pathways and PRL inhibit gonadotropin releasing hormone in the hypothalamus, in turn suppressing the pituitary gonadotropins [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)] and, thereby, ovarian function. The resulting low E_2 levels upregulate RANKL and downregulate OPG in osteoblasts, thereby stimulating the differentiation and function of osteoclasts and promoting bone resorption. Suckling, PRL, and low E_2 also stimulate PTHrP production by mammary tissue, and suckling forces the release of PTHrP into the maternal circulation from where it synergizes with low E_2 levels to stimulate osteoclast-mediated bone resorption and osteocytic osteolysis. CT is produced by mammary tissue where it may have local actions to regulate the calcium content of milk or PTHrP production, and systemic actions (together with thyroid-derived CT) to suppress osteoclast-mediated bone resorption and inhibit PRL. OT may act not only on the breast to stimulate milk ejection but also on bone to control the differentiation and function of osteoblasts and osteoclasts.

5 DISORDERS OF BONE AND MINERAL METABOLISM DURING LACTATION

5.1 Osteoporosis of Lactation

Lactation disrupts the microarchitecture of bone and reduces its material properties, particularly within the lumbar spine. However, rodents are not susceptible to vertebral compression fractures, likely because ambulation on all fours reduces loading of the spine. No spontaneous fractures were noted in *Ctcgrp* null mice despite a 55% decrease in the mineral content of the spine during lactation.

Ambulating on the hindlimbs loads the axial skeleton; consequently, humans are susceptible to vertebral crush fractures when the material properties of the spine are compromised. Yet for the vast majority of women the

lactational declines in bone density are silent; only rarely do women suffer fragility fractures.[69] In such cases an osteoporotic bone density may be confirmed, but low bone mass prior to pregnancy generally cannot be excluded due to lack of prior DXA measurements. Secondary causes of osteoporosis may be present, including anorexia nervosa, hyperparathyroidism, osteogenesis imperfecta, and corticosteroid or heparin therapy.[69] Some cases might occur when otherwise healthy women with low bone mass cannot tolerate the normal magnitude of skeletal losses during lactation, whereas others may result from excessive bone resorption during lactation, such as from overabundant production of PTHrP by mammary tissue. In at least one case of lactational osteoporosis, PTHrP levels were high for months after weaning.[154] If a woman is known to have severe osteoporosis or very low bone density prior to pregnancy, it may be reasonable to discourage breastfeeding on the presumption that additional skeletal losses would compromise skeletal integrity and lead to fractures.

For most women with confirmed fractures, pharmacological treatment may be unnecessary due to spontaneous increases in bone mass postweaning and typically self-limited duration of any pain.[2,69] A case series of women who presented with vertebral compression fractures during lactation found that bone density increases spontaneously after weaning, consistent with the evidence that bone loss during lactation preceded the fracture but is reversible.[155] Various case reports have described the anecdotal and uncontrolled use of bisphosphonates, strontium, or teriparatide for lactational osteoporosis, but whether the achieved increment in bone density exceeds what occurs naturally postweaning remains unknown.[2,69] Treatment might be best reserved for the most severe cases. Most women can be reassured that the problem does not usually recur after subsequent pregnancies.

5.2 Primary Hyperparathyroidism

There are no animal studies of the effects of primary hyperparathyroidism during lactation, nor are there any human data. However, as lactation programs marked bone resorption due in part to the combined effects of PTHrP and low E_2, hypercalcemia may worsen with breastfeeding. A decision to breast feed may influence whether a parathyroidectomy should be done postpartum.

5.3 Familial Hypocalciuric Hypercalcemia

Mice heterozygous for an inactivating mutation of the calcium receptor lactate normally and their pups grow at the expected rate, but PTHrP expression is upregulated above normal in mammary tissue, while the milk has higher PTHrP and lower calcium content.[127]

There have been no human studies during lactation but the animal data predict that women with familial hypocalciuric hypercalcemia may have more marked PTHrP-stimulated skeletal resorption but a lower calcium content of milk.

5.4 Hypoparathyroidism

Studies of parathyroidectomized rats and *Pth* null mice have shown that lactation proceeds normally, although the mice are prone to sudden postanesthetic deaths from presumed hypocalcemia. In both models bone mass increases after weaning, indicating that bone recovery does not require PTH.[2,21]

Observational studies in women confirm that PTH is not required for normal lactation.[2] There may be increased risk of hypocalcemia in the first day or two, after loss of placental PTHrP and before the milk has come in. Once lactation is established the requirement for supplemental calcitriol and calcium falls substantially, and significant hypercalcemia has occurred when these adjustments haven't been made.[156] In one case high circulating PTHrP levels coincided with a rise in calcitriol and serum calcium.[157] A single case report found a spontaneous 40% increase in lumbar spine BMD and 7.5% increase in femoral neck BMD in a surgically hypoparathyroid woman after weaning, confirming the animal data that substantial skeletal recovery can occur despite the absence of PTH.[158]

5.5 Pseudohypoparathyroidism

No animal models of pseudohypoparathryoidism have been studied during lactation, and management in lactating women has not been documented. The requirement for supplemental calcitriol might well increase during lactation if low E_2 aggravates the renal resistance to PTH. On the other hand, these patients do not have skeletal resistance to PTH and so excessive resorption from the skeleton may occur when high PTHrP and low E_2 levels are added to the mix during lactation. As the outcome is uncertain, these women should be observed more closely with adjustments in calcium and calcitriol intake made as needed.

5.6 Pseudohyperparathyroidism

Occasionally breastfeeding leads to symptomatic, PTHrP-mediated hypercalcemia.[88,154,159,160] It has also developed during the puerperium in a woman who was unable to breastfeed because her baby was critically ill,[84] and in non-lactating women with large breasts.[85–87,161] High levels of PTHrP cause excess skeletal resorption, while intestinal calcium absorption may also increase if production of calcitriol is sufficiently stimulated.

Weaning, breast binders, and dopaminergic medications, should each help reverse the excess production of PTHrP and consequent hypercalcemia. A bisphosphonate or denosumab may also be needed to shut down bone resorption, especially as seen in some women wherein the excess production of PTHrP has persisted for months after weaning.[2]

5.7 Vitamin D Deficiency and Genetic Vitamin D Resistance Syndromes

The animal data described earlier demonstrated that the skeleton resorbs during lactation under the influence of PTHrP, low E_2, and possibly other hormones. Vitamin D and calcitriol do not appear to play a significant role as severely vitamin D–deficient rats and *Vdr* null mice lactate normally and have a normal magnitude of bone loss. After weaning, bone formation increases and *Vdr* null mice restore the lost bone mass, but rats differ on the extent of bone restoration postweaning.[22,93,122]

Very little vitamin D or 25-hydroxyvitamin D passes into milk; consequently, women's 25-hydroxyvitamin D levels are usually unchanged by lactation.[162,163] Case reports, observational studies, and small clinical trials indicate that lactation proceeds normally regardless of vitamin D status, and that breast milk calcium content is unaffected by vitamin D deficiency or by supplementation with doses as high as 6400 IU per day (topic reviewed in detail in Ref. 2). No studies have examined the impact of vitamin D deficiency or insufficiency on skeletal recovery after weaning; however, as dozens of epidemiological studies found no adverse effect of number and duration of lactation on the risk of low bone mass or osteoporosis, and vitamin D insufficiency is common among reproductive age women, it seems probable that skeletal recovery after weaning does not require vitamin D.

5.8 Calcitonin Deficiency

CT deficiency during lactation cause *Ctcgrp* null mice to lose twice the normal amount of bone mineral content during lactation but they fully restore it after weaning.[19,20] The milk calcium content is doubled but whether this is the result of increased availability calcium from bone resorption, or altered calcium transport in the mammary tissue, remains unclear.[19,20] These findings indicate that physiological levels of CT protect the rodent skeleton from excessive resorption during lactation, but it may reflect actions of CT not only in osteoclasts, but also in pituitary lactotrophs and mammary epithelial cells.[20]

Whether CT deficiency alters the physiology of human lactation is unknown. Studies have not been done in lactating thyroidectomized women, and might not be definitive anyway because extrathyroidal production of CT causes a significant increase in circulating CT during lactation. A recent case report described a thyroidectomized woman nursing twins who experienced multiple vertebral compression fractures during lactation; the authors speculated that CT deficiency contributed to marked bone loss confirmed by DXA.[158]

5.9 Low Calcium Intake

Rodents depend upon multiple sources of calcium during lactation, including increased intestinal calcium absorption, decreased renal calcium excretion, and enhanced demineralization of the skeleton. A low calcium intake accentuates skeletal losses and increases the risk of sudden death from presumed hypocalcemia.[2] These findings indicate that, while not optimal, the rodent can derive most of the required calcium from the skeleton. There are no data on the sufficiency of calcium intake needed to ensure skeletal recovery after lactation.

In humans the calcium content of milk may be largely derived from skeletal resorption. Low calcium intake does not alter breast milk calcium content nor does it accentuate maternal bone loss during lactation.[164–167] Conversely high calcium intake also fails to alter breast milk calcium or skeletal resorption during lactation.[143–146] These findings suggest that it may not matter what calcium intake a women has during lactation, but it is remains prudent to maintain the recommended dietary intake of calcium. No studies have examined calcium requirements during the postweaning interval.

5.10 FGF23-Related Disorders

Phex$^{+/-}$ females have excess FGF23 and remain hypophosphatemic and normocalcemic during lactation, with no adverse effects noted on their pups.[113] Milk from *Phex*$^{+/-}$ females has normal phosphorus, calcium, and protein content.[113] Hyperphosphatemic disorders due to loss of FGF23 cannot be studied due to early mortality of *Fgf23* null and *Klotho* null mice.

Serum phosphorus normalized during lactation in a woman with XLH,[116] likely the result of the normal increase in skeletal resorption. However, milk phosphorus content was 50% of normal in two cases,[116,117] and normalized with oral phosphorus supplementation.[116] Low milk phosphorus likely contributed to hypophosphatemia observed in the babies.

6 CONCLUSIONS

During pregnancy and lactation, novel regulatory systems are invoked to meet the challenges for increased calcium and phosphorus delivery. The fetal calcium demand is met by a doubling of intestinal calcium absorption beginning early in pregnancy, an adaptation that

may not be fully explained by a doubling or tripling in calcitriol levels. There may be some contribution of calcium from skeletal stores whereas the maternal kidneys output more calcium than normal during pregnancy. During lactation, skeletal resorption is the dominant mechanism by which calcium is supplied to the breast milk. Renal calcium conservation occurs and only minimal dietary intake of calcium may required. These lactational changes appear to be driven by PTHrP (facilitated by the estrogen deficiency) and not by PTH, calcitriol, or FGF23. Consistent with this, women with very low or high intakes of calcium experience a similar degree of bone loss during lactation. The rapidity of calcium regain by the skeleton of the lactating woman occurs through a mechanism that is not understood. Finally, while a few women will experience fragility fractures in association with pregnancy or lactation, for the vast majority of women these adaptations in calcium and bone metabolism during pregnancy and lactation are silent, without long-term adverse consequences.

SECTION 3

DISORDERS OF BONE AND JOINT

CHAPTER

22

Osteoporosis Genes Identified by Genome-Wide Association Studies

Fernando Rivadeneira, André G. Uitterlinden

Erasmus MC, Rotterdam, The Netherlands

1 INTRODUCTION

Without doubt the field of osteoporosis (just as most of all other medical fields) was revolutionized by the advent of the Human Genome Project[1] at the end of the 1980s. An exponential increase in the number of publications in the field was observed shortly after its launch with the trend continuing to its completion in the year 2001, and even more so thereafter (Fig. 22.1). This impressive wave of studies concerning the genetics of osteoporosis in humans has now begun a new era of discoveries with the advent of so-called genome-wide association studies (GWAS),[2–4] whose design has been comprehensively described in Chapter 3. Before the GWAS era, the literature about the genetics of osteoporosis and fracture had been confined to a very large number of "genome-wide linkage" and "candidate gene association" studies. With few exceptions, the majority were small, inadequately-powered studies generating controversial and frequently nonreproducible reports[5] on variants in about 150 candidate gene regions for osteoporosis (HUgeNet website: https://www.cdc.gov/genomics/hugenet/hugenavigator.htm/). Some shortcomings were tackled in the GENOMOS consortium where large-scaled evidence (n = 20,000–45,000 which, by current standards, is still substantial) was produced on a limited number of "the usual suspects" in genetics of osteoporosis including the estrogen receptor type 1 (*ESR1*),[6] *VDR*,[7] *COLIA1*,[8] *TGFB1*,[9] and low density lipoprotein receptor-related protein 5 (*LRP5*)/*6*[10] genes. These results are summarized in Table 22.1. Although a few polymorphisms were indeed identified as being associated with either bone mineral density (BMD) or fracture (such as for *LRP5* very significantly associated at $p < 5 \times 10^{-8}$, the current standard for declaring genome-wide significance), this effort was restricted to known polymorphisms and did not interrogate the genetic contribution to osteoporosis at a genome-wide level as is now possible in GWAS.

For most complex traits and common diseases[11–13] hundreds if not thousands of variants of weak (but real) effects[14] will be underlying the genetic architecture of the trait and disease. From this perspective, only well-powered studies based on several independent populations (for replication), with a well-defined selection of polymorphisms and gene regions, and a robust control for multiple hypothesis-testing in the analysis, will be suited to identify genuine genetic effects.[15] While the GWAS approach (with some few exceptions) incorporates in its design several of these properties, the number of loci identified depends on the total sample size obtained in a given study: more samples will lead to more GWAS "hits." Therefore, to the present, only a small fraction of all the variants expected to be associated with a complex trait have been detected so far. In addition, some of these loci discovered at a genome-wide significant level [(GWSL) i.e., 1 in 20 or $P = 0.05$ after the Bonferroni correction] may still represent false-positive reports. Nevertheless, after replication in tens to hundreds of thousands of individuals, it is very likely that genome-wide significant signals associated at a stringent $P < 5 \times 10^{-8}$ will be associated with variants which represent true underlying biological mechanisms influencing the trait in question.

Another important aspect for the interpretation of the GWAS discoveries is that, with few exceptions, most of the genes claimed as "underlying the GWAS signals" have been labeled as such without robust functional evidence supporting or demonstrating its candidacy. Usually, allocating a gene to a genetic signal is based on physical distance and current knowledge of biology, neither of which suffices to assign unequivocally the gene to the single nucleotide polymorphism (SNP) effect. Therefore, even though the circumstantial evidence for biologic candidacy may be strong, such assignments should be interpreted with caution until conclusive

evidence becomes available. This will also vary from region to region depending on the relative location of the associated SNPs, the linkage disequilibrium (LD) properties between the markers, the patterns of recombination rate, and the number of genes underlying the signal. All of these parameters must be considered while evaluating the candidacy of the gene(s) underlying the GWAS signals. From this perspective, the likelihood of a gene being responsible for a GWAS signal will be a function of the properties of the signal and the candidacy characteristics (known biological function) of the gene (Table 22.2).

Nevertheless, just as for any candidate gene evaluation, these assessments will be based on previous knowledge about the gene, which by itself constitutes a liability considering that the GWAS approach is a hypothesis-free screen of the genome. This indicates that new and not (properly) annotated areas of the genome will be found in a given GWAS, leaving much new biology to be discovered. This way, not scoring high on the candidacy dimension may just reflect the lack of knowledge, and does not exclude any gene from being truly involved in the biologic mechanisms leading to trait variation.

In addition, the follow-up of these GWAS discoveries requires robust functional evidence linking the human genome sequence to the function of its regulatory elements. This is being facilitated by the Encyclopedia of DNA Elements (ENCODE) Project, which has started a revolution by going beyond the "linear" configuration of regulatory elements challenging the previous context of boundaries and gaps between genes.[16] The knowledge derived from Encyclopedia of DNA Elements provides

TABLE 22.2 Likelihood of a Gene Being Responsible for a GWAS Signal

A. Properties of the GWAS signal arising from a SNP (or a variant in high LD)

1. location in relation to the gene (exonic, intronic, promoter, 3'UTR or intergenic),
2. functionality (promoter/regulatory region, nonsynonymous, synonymous, transcription factor binding, or splice regulation),
3. physical distance from the gene, and
4. colocation in the same LD block of the gene.

B. Candidacy characteristics by which a gene is weighted based on the presence of

1. SNP (or a variant in high LD) constituting an eQTL associated with gene expression,
2. KO model organism (mouse or zebra fish) with a skeletal phenotype,[a]
3. monogenic human syndrome (OMIM) with a skeletal phenotype[a] and
4. involvement in a bone-active pathway.[a]

eQTL, Expression quantitative trait locus; LD, linkage disequilibrium; SNP, single nucleotide polymorphism.
[a] *Candidacy in relation to osteoporosis traits.*

new approximations to the understanding of diverse processes of gene regulation including chromatin interactions, epigenetic states, promoter activities, enhancer binding, and nuclear lamina occupancy to name a few. This knowledge will provide large leaps in the identification of the gene(s) underlying the GWAS signals and in the understanding of new biology.

2 GENOME-WIDE ASSOCIATION STUDIES OF OSTEOPOROSIS

We define the set of candidate osteoporosis genes included in this chapter as those proposed to have been discovered by the GWAS approach within adequately powered settings (n > 10,000 subjects) in relation to BMD, the most accessible and up to now the most prolific of the osteoporosis traits. An overview of GWAS studies on osteoporosis is presented in Table 22.3. The first GWAS report concerning osteoporosis was published in 2007 by Kiel et al.[17] The effort failed to identify any associated loci at a GWSL as a reflection of the limited sample size (n = 1141) and sparse SNP content (100 K) of the study. In 2008, in Richards et al.,[18] variants in *LRP5* and *TNFRSF11B* (OPG) were reported as associated with lumbar spine and femoral neck BMD in 8557 United Kingdom and Dutch individuals. Almost simultaneously, Styrkarsdottir et al. published a report on 5861 Icelandic individuals, with replication in an additional 7925 European individuals,[19] which identified variants mapping also to *TNFRSF11B* (OPG), together with additional ones mapping to the *TNFSF11* (RANKL), *ESR1*, *ZBTB40*, and the major histocompatibility complex loci. A subsequent report from this group published in early 2009 was based on an extended set including 6865 Icelandic individuals, with replication in another 8510 European

individuals.[20] They identified variants mapping to *TNFRSF11A* (RANK), *SOST*, *MARK3*, and *SP7* (osterix). Shortly afterward, variants in the osterix gene were also identified by Timpson et al. in an effort based on 1518 United Kingdom children, followed by replication in adults, including an "extremes truncate selection" of 132 Australian individuals with high or low BMD, and in 3692 individuals of European descent.[21] During mid-2009, Cho et al. published a study examining ultrasound of the radius, tibia and, the heel in 8842 Korean individuals (with replication in additional 7861 individuals) postulating *FAM3C* and *SFRP4* as new BMD loci.[22] Though speed of sound ultrasound does not directly measure BMD, it is associated with fracture risk. At the end of 2009, the genetic factors of osteoporosis (GEFOS) consortium reported a large leap in the discoveries described in Rivadeneira et al.[23] Within the setting of the GEFOS consortium (http://www.gefos.org/), variants were identified in 13 additional loci in a study of 19,195 individuals of Northern European origin. These 13 loci reached genome-wide significance for the first time and included *WLS* (former *GPR177*), *SPTBN1*, *CTNNB1* (β-catenin), *MEPE/SPP1/IBSP*, *MEF2C*, *STARD3NL*, split hand and foot malformation 1 (*SHFM1*), *LRP4*, *SOX6*, *DCDC5*, *FOXC2*, *CRGR1*, and *HDAC5*. After that, two different studies of BMD, using extreme-ascertainment designs based on 800 Chinese and on 1,955 Australian individuals, provided evidence for additional loci after replication in nearly 20,000 individuals (18,898 and 20,898, respectively). In the first study, Kung et al.[24] identified variants in JAG1 associated at a GWSL of $p < 5 \times 10^{-8}$. In the second study, Duncan et al.[25] identified variants mapping to *GALNT3* and *RSPO3* associated at a GWSL, while variants in *SOX4*, *LTBP3*, and *CLNC7* were suggestive of association. With the exception of variants that mapped to major histocompatibility complex and *LBT3*, all other loci described in this chapter have been found associated at GWSL by the recently published second effort on BMD of the GEFOS consortium,[26] which brought the number of identified BMD loci to 56.

To date, about 70 loci have been reported in the literature to be associated with BMD across different populations and age groups (Fig. 22.2). After the successful identification of common variants, most of the attention is now placed on the identification of less frequent and rare variants, which are proposed to be enriched with functional allelic variants.[29] From this perspective it is expected that variants of less-common and rare frequencies can exhibit stronger effect sizes than common variants. Recent efforts in the field of osteoporosis employing whole-genome sequencing (WGS) followed by imputation to larger populations, have proved successful identifying less frequent to rare variants and constitute relative pioneer work in the field of complex traits.[27,30–32] Through the application of WGS of Icelandic individuals, a mutation (C376T) within the *leucine rich repeat-containing G-protein-coupled receptor 4* (LGR4) gene was identified as associated with low BMD and increased risk of fractures.[30] A recent GWAS study drawn in 20,162 Icelandic individuals, and with replication in 10,091 subjects from two studies of European background and other two of East Asian descent,[32] identified variants mapping to a new locus harboring the *PTCH1* gene, the receptor for the three hedgehog morphogens (SHH, IHH, and DHH) as well as new signals across several known loci. In a subsequent effort, two rare mutations in *COL1A2* (MAF = 0.1%) were identified through WGS and shown to be associated with low BMD in 2,894 cases and 206,875 controls derived from the Icelandic population without other signs of osteogenesis imperfecta.[31] Finally, in an effort using the UK10K/1000GP sequencing reference to impute less frequent variants across 53,236 individuals from 27 population-based cohorts of European ancestry,[27] a novel less-frequent (minor allele frequency, MAF = 1.7%) noncoding variant near the *engrailed-1* (*EN1*) gene was identified, exerting large effects on BMD and fracture, with effect size about fourfold greater than those observed for any previously reported common variant.

3 GENES IDENTIFIED BY GENOME-WIDE ASSOCIATION STUDIES ON BONE MINERAL DENSITY

Table 22.4 lists 45 genes from 31 loci with variants consistently associated with BMD at a GWSL of $p < 5 \times 10^{-8,}$ including four with variants of low frequency recently identified with the use of WGS reference panels.

3.1 1p31.3 *WLS*

The (*Drosophila*) wntless homolog is a 135 kDa gene formerly known as G protein-coupled receptor 177 (*GPR177*) gene. WLS is a novel factor part of the highly evolutionary conserved Wnt signaling pathway involved in bone cell differentiation and development. The reported variants, showing association with lumbar spine and femoral neck BMD,[23] map to a narrow LD block within an intronic region of the gene. WLS has been shown to be required for cell surface expression of Wnt3a proteins by HEK cells, and capable of activating nuclear factor-kappa B (NF-κB) when expressed in HEK cells.[34] In addition, Wls has been shown to be a Wnt trafficking regulator in mouse embryogenesis.[35–37]

3.2 1p36.12 *ZBTB40* and *WNT4*

ZBTB40 is a 102 kb gene located in a well-recognized linkage region. GWAS signals in *ZBTB40* were

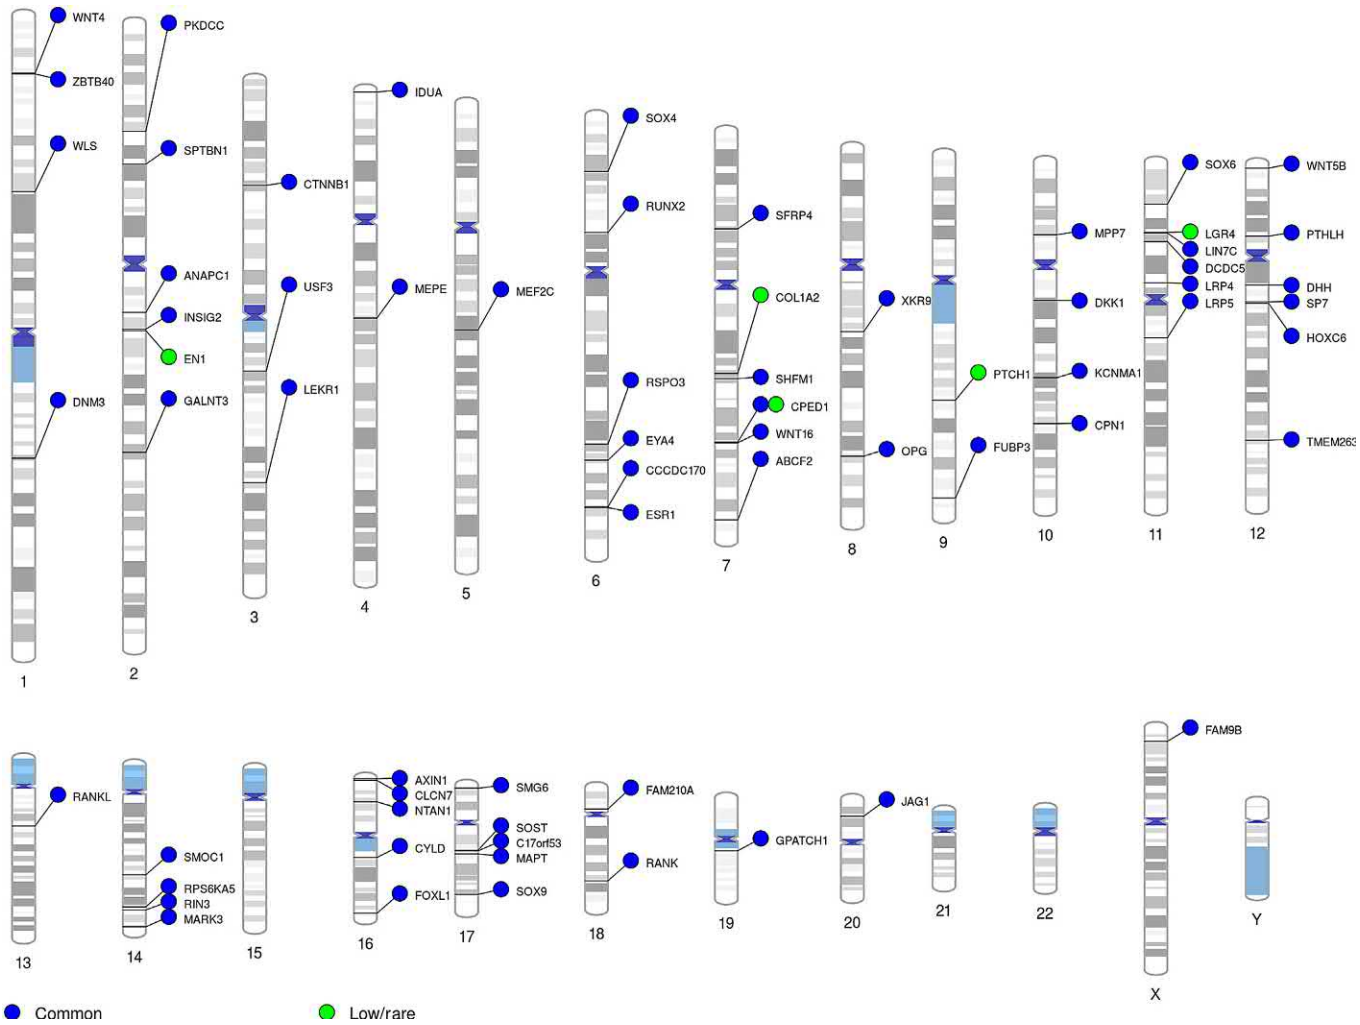

FIGURE 22.2 **Karyogram illustrating the location of identified BMD loci and candidate genes in the genome.**

first reported by Styrkarsdottir et al.[19] as associated with hip and spine BMD, and further replicated in the subsequent GWAS metaanalyses of the GEFOS consortium.[23] In the latter effort, there was evidence for an independent signal mapping to the 5′ region of *WNT4*, a smaller gene of size 27 kb located about 310 kb upstream from *ZBTB40*. *ZBTB40* encodes a protein of unknown function but which is expressed in bone. Given its zinc finger and BT domains, it is likely the protein has DNA binding properties and may be involved in protein–protein interactions. Wnt4 belongs to the Wnt family of signaling proteins and is involved in several developmental processes including regulation of cell fate and patterning during embryogenesis[38] by inhibition of β-catenin. Wnt4 is involved in the control of female development and the prevention of testes formation; mutations in the gene have shown to produce sex reversal syndromes.[39] During hematopoietic stem cell differentiation, WNT4 acts as a noncanonical activator of Wnt signaling,[40] though its role on bone remains unknown.

3.3 2p16.2 *SPTBN1*

SPTBN1 is a 215 kb gene that encodes a subform of β-spectrin, which is a major cytoskeletal scaffold protein. This locus was first reported by Styrkarsdottir et al.[20] as associated with lumbar spine BMD with subsequent replication at GWSL in the first GEFOS metaanalysis.[23] The functional role of this gene in bone remains unclear although, in mice, targeted inactivation of Elf (mouse homolog) results in disruption of transforming growth factor-beta (TGFβ) signaling with severe phenotypic alterations across multiple systems similar to that observed in double knockouts (KOs) of SMAD3 and SMAD4 proteins.[41]

3.4 2q14.2 *EN1*

EN1 is a small gene spanning 6 kb that, as for other Homeobox containing genes, exerts an important role in development. In Drosophila, the "engrailed" (en) gene plays an important role, determining segmentation during

BMD, Bone mineral density; CLSS, Cenani–Lenz syndactyly syndrome; eQTL, expression quantitative trait locus; OPPG, osteoporosis-pseudoglioma syndrome;OPTB2, osteopetrosis, autosomal recessive 2; OPTB4, osteopetrosis, autosomal recessive 4; OPTB7, osteopetrosis, autosomal recessive 7.

development and is required for the formation of posterior compartments. While the exact role of EN1 in human bone metabolism remains to be elucidated, En1 has also been shown to interact with Wnt factors for the regulation of limb patterning in mice.[42] The identification of *EN1* influencing BMD variation and fracture risk, illustrates the advantage provided by using large sequencing-based reference panels to detect variants with low minor allele frequency, which can then be tested for association through imputation in larger GWAS collections.[27] The identified associated variant had a low frequency (MAF = 1.7%) and an unforeseen large effect size (+0.24 SD) on BMD, which is several fold greater than those typically observed with common variants (averaging ~0.02 SD). A recent GWAS in Icelandic individuals[32] identified additional less frequent variants (1.5%) in this *EN1* locus, appearing to hold stronger associations with increased BMD and lower risk of osteoporotic fracture. Further functional and fine-mapping efforts are needed to determine the genetic variants driving the strong associations in this locus.

3.5 2q24.3 *GALNT3*

GALNT3 is a gene of 47 kb encoding for an enzyme involved in biosynthesis of oligosaccharides and has high homology to other members of the GalNAc-transferases family members. Variants in and around *GALNT3* were first reported as associated at GWSL with both hip and lumbar spine BMD in Australian and Northern European populations.[25] Mutations in the GALNT3 gene cause autosomal recessive hyperostosis–hyperphosphatemia syndrome.[43]

3.6 3p22.1 *CTNNB1*

This 65 kb gene encodes β-catenin, a key transcription factor of the Wnt signaling involved in osteoblast differentiation from mesenchymal stem cells[44,45] and regulation of osteoclast activation. β-Catenin dependent (so-called canonical) Wnt signaling is a major regulator of chondrogenesis, osteoblastogenesis, and osteoclastogenesis.[46] Deletion of the gene in osteoblasts results in osteopenia while stabilization results in high bone mass.[47] Common variants located in the 5′ region of the gene were found associated for the first time at GWSL with femoral neck BMD in the first GEFOS metaanalysis.[23]

3.7 4q22.1 IBSP, MEPE, and SPP1

This locus clusters a series of relatively small phylogenetically-related genes encoding for matricellular phosphoglycoproteins important for bone formation and mineralization[33] including *MEPE*, *IBSP* (integrin binding sialoprotein), and *SPP1* [osteopontin (OPN)]. All three genes are expressed in bone and exhibit a skeletal phenotype when deleted. MEPE spans 25 kb and encodes one of these phosphoglycoproteins. Targeted inactivation of Mepe in mice results in increased BMD.[48] Even though the first GEFOS metaanalysis[23] showed that the variants achieving GWSL for association with lumbar spine BMD mapped close to *MEPE*, the involvement of the other genes in the region cannot be ignored. In a previous report, Styrkarsdottir et al.[20] reported variants mapping close to IBSP as suggestive of association with hip BMD.

IBSP is a 13 kb gene located about 42 kb away from *MEPE*, encoding a major structural protein of the bone matrix that binds tightly to hydroxyapatite and appears to form an integral part of the mineralized matrix. In addition, Koller et al.[49] showed that the effect on IBSP was also present in premenopausal women. Ibsp KO mice have impaired bone growth and mineralization, concomitant with dramatically reduced bone formation with thinner cortices, but greater trabecular bone volume than wild-type mice, and low rates of skeletal turnover,[50] indicating impairments of both new bone formation and osteoclast activity.

SPP1 is a small gene spanning 7 kb (located about 122 kb away from *MEPE*) that codes for OPN. Mice with deletion of the *OPN* gene are resistant to ovariectomy–as well as unloading–induced bone loss.[50,51]

3.8 5q14.3 *MEF2C*

MEF2C is a large 187 kb gene encoding a member of the MADS box transcription enhancer factor 2 (MEF2) family of proteins. *MEF2C* has been primarily implicated in muscle function, although it is known to play a role in endochondral ossification[51a] and is a potential regulator of the *SOST* gene by interaction with a conserved enhancer, which is deleted in van Buchem's disease.[52] The first report implicating variants in *MEF2C* as associated with BMD variation in Northern Europeans came from the first GEFOS metaanalysis[23] that has subsequently been replicated.[26] In addition, variants in *MEF2C* have also been associated with human stature.[12]

3.9 6p22.3 *SOX4*

SOX4 is a small intronless gene of about 6 kb encoding a member of the SOX (SRY-related HMG-box) family of transcription factors. *Sox4* homozygous KO mice die, but heterozygous mice display osteopenia and reduced bone strength.[53] Further, in rat osteoblasts, *Sox4* has been shown to be involved in cellular proliferation and differentiation, functioning upstream of *Osx* (Osterix) but independently of *Runx2*. Variants in and around *SOX4* presented with suggestive evidence for association with both hip and lumbar spine BMD in Australian and Northern European populations.[25] This was replicated at a GWSL in the second GEFOS metaanalysis on lumbar spine and femoral neck BMD,[26] with variants mapping in between *CDKAL1* and *SOX4*.

3.10 6q22.33 *RSPO3*

RSpo proteins are general regulators of canonical Wnt signaling, acting through a common biochemical mechanism involving competition with *DKK1* and reduction of the internalization of *LRP6* by the cell.[54] Homozygous RSPO3 KO mice display embryonic lethality, and no mutations in humans have been reported to date. Variants upstream from *RSPO3*, a gene spanning 81 kb, were first reported as associated at GWSL with BMD of the femoral neck and at nominal level with lumbar spine BMD in Australian and Northern European populations.[25] In a recent GWAS combining Icelandic, (other) European and East Asian populations,[32] a new spine BMD signal implicating *RSPO3* was identified through strong correlation with gene expression. The identified variant of moderately low frequency (6.8%) was associated with increased spine BMD levels and a protective effect on osteoporotic fracture.

3.11 6q25.1 *ESR1*

The *ESR1* gene is a very large gene, spanning 473 kb, which historically has been a strong candidate for genetic regulation of bone mass. Three main polymorphisms have been thoroughly studied in many candidate gene studies, including a TA microsatellite repeat in the promoter region, the PvuII and the XbaI restriction fragment length polymorphisms. None of these polymorphisms is associated with BMD variation, as reported by the prospective large-scale individual level metaanalysis from the GENOMOS study involving 18,917 individuals. However they did show a significant association with fracture that was independent of BMD.[55] The first GWAS report postulating variants in the *ESR1* locus as associated at GWSL with BMD variation in humans was performed in Icelandic individuals with replication on other North-Western European populations.[19] This study showed signals mapping to *C6orf97*, while this and other independent variants (not in LD) mapping within *ESR1* were subsequently replicated in larger GWAS.[20,23] Interestingly, this *ESR1* locus not only displays multiple signals (allelic heterogeneity) for BMD, but also for other phenotypes also assessed by GWAS, including breast cancer[56] risk and body height.[12]

3.12 7p14.1 *SFRP4* and *STARD3NL*

Variants in this locus were first reported associated at GWSL with BMD derived from forearm, heel, and finger ultrasound in Korean populations[22] and with lumbar spine BMD in the first GEFOS metaanalysis in European individuals[23] mapping in between the *STARD3NL* and *SFRP4* genes.

STARD3NL is a 52 kb long gene which encodes a cholesterol endosomal transporter but its potential role on bone metabolism remains unclear.

In contrast, *SFRP4* is known to inhibit Wnt signaling and, as shown in SAMP6 mice, *Sfrp4* negatively regulates bone formation and decreases BMD.[57] This inhibition of canonical Wnt signaling is suggested to be mediated by lower responsiveness for the Wnt3A ligand in osteoblasts derived from the SAMP6 strains. Attenuation of canonical Wnt signaling by overexpression of *SFRP4* in osteoblasts results in reduction of trabecular bone mass;[58] a finding consistent with lower BMD and ultrasound properties of the trabecular-rich bone content of the lumbar spine and heel skeletal sites.

3.13 7q21.2 *COL1A2*

The *COL1A2* gene encodes the pro-alpha2 chain of type I collagen whose triple helix comprises two alpha1 chains and one alpha2 chain. Type I collagen is found in most connective tissues being particularly abundant in the cornea, dermis, tendon, and bone tissues. Mutations in this gene are associated with diverse disorders of the connective tissues including osteogenesis imperfecta (types I–IV), familial osteoporosis, Ehlers–Danlos syndrome (type VIIB and the recessive form of the classical type) and atypical Marfan syndrome. As compared to the phenotype resulting from mutations in alpha1 gene (COL1A1), mutations in COL1A2 result in milder compromise across tissues. While previous large GWAS failed to identify common variants associated with osteoporosis traits in either of these genes[23,26,27], recent work using WGS data in Icelanders identified two rare (frequency 0.05%–0.10%) missense mutations, (p.Gly496Ala and p.Gly703Ser) in the *COL1A2* gene that associate with measures of osteoporosis.[31] While carriers of these mutations presented with low BMD at the hip and spine, they lack any sign of osteogenesis imperfecta (other than low BMD), implying that mutations in COL1A2 can affect skeletal phenotypes in distinct ways.

3.14 7q21.3 *SHFM1* and *C7orf76*

This locus was first described in the first GEFOS BMD metaanalysis as holding several variants associated at GWSL with both lumbar spine and femoral neck.[23] These variants map close to *C7orf76*, an open reading frame sequence lacking the classical hallmarks of protein-coding genes. The large LD block harboring the GWAS signal also includes the *SHFM1* gene, also known as "deleted in split-hand/split-foot 1" region or *DSS1* gene. More than a single gene, the region is characterized by genomic rearrangements leading to deletion of *DSS1* and the distalless-related homeogenes *DLX5* and *DLX6*. The latter two genes, code for members of the Wnt signaling pathway and cause ectrodactyly in mice and humans[59] when both are deleted or mutated. This may also be as a consequence of "functional haploinsufficiency" when

the chromosomal rearrangement physically separates the genes from their control elements. The ectrodactyly syndrome is a genetically heterogeneous limb developmental defect characterized by the absence of digital rays and syndactyly of the remaining digits.[60]

3.15 7q31.31 *FAM3C*, *CPED1*, and *WNT16*

Genetic variants in the region mapping close to *FAM3C* spanning 48 kb have been reported in association with derived BMD and speed of sound as measured by quantitative ultrasound in the radius and calcaneus in a Korean population.[22] This chromosome 7 region harbors in addition two other genes including *WNT16* (spanning 16 kb) and *CPED1* (previously known as *C7orf58* and spanning 309 kb). The success of the GWAS approach is well characterized by the discovery of this as a BMD locus, containing among others *WNT16*, now established as a critical molecule in bone biology. In the second GEFOS BMD metaanalysis, variants mapping to *WNT16* were found associated at GWSL with femoral neck and lumbar spine BMD, and also with increased fracture risk.[26] After that, several subsequent GWAS efforts identified independently the same locus when performed in premenopausal women[49]; wrist BMD[61]; total body BMD in children and adults[62]; cortical thickness from pQCT of the tibia[61]; and quantitative ultrasound of the heel[63]; postulating the important influence of *WNT16* on multiple skeletal traits and across different age groups in the life course. After being identified by GWAS, subsequent studies in murine models have started to elucidate the regulatory mechanisms of WNT16. These studies illustrated the skeletal phenotype of Wnt16 KO mice characterized by reduced cortical bone thickness, increased cortical bone porosity, and consequent increased susceptibility to spontaneous fractures.[64] This fragility specific to cortical bone is the consequence of two processes: loss of direct osteoclastogenesis inhibition via noncanonical Wnt pathway activation and loss of an indirect effect of inducing OPG expression in osteoblasts. Furthermore, subsequent work by the same investigators demonstrated how overexpression of *WNT16* increases trabecular bone mass independently of estrogen action.[65] On the other hand, it has also become clear in this locus, independent secondary signals arise from *CPED1*. Different GWAS have identified associations pointing to this gene arising from less frequent variants in the region,[27] associated with BMD at other skeletal sites (i.e., skull)[66] and/or in young populations (i.e., pediatric BMD)[62].

3.16 8q24.12 *TNFRSF11B* (OPG)

Large-scale confirmation that variants in *TNFRSF11B* are associated at GWSL with lumbar spine and femoral neck BMD were first reported in British and Dutch populations (i.e., the Twins UK and the Rotterdam Study)[18] together with other efforts involving Icelandic and Northern European populations (deCODE genetics).[19] This finding was subsequently replicated by several additional efforts[23,25,26,67,68] including Asian populations.[68] The *tumor necrosis factor receptor superfamily member 11b* is a gene that spans 29 kb, which encodes the osteoprotegerin (OPG) protein, an endogenous inhibitor of bone resorption. OPG is integral to the OPG/RANK/RANKL pathway whose relevance in the regulation of bone resorption has been well established.[69] In addition, mutations in this gene have been identified in juvenile Paget's disease (Chapter 26)[70] The functional mechanisms by which *TNFRSF11B* alleles predispose to osteoporosis are incompletely understood but, in the Twins UK and the Rotterdam GWAS, expression of the BMD lowering allele was associated with reduced expression of *TNFRSF11B* in lymphoblasts.[18]

3.17 9q22.32 *PTHC1*

The *Patched homolog 1* gene encodes a member of the patched gene family. The encoded protein is the receptor for sonic hedgehog (SHH), a secreted molecule implicated in the formation of embryonic structures and in tumorigenesis, as well as the desert hedgehog (DHH) and the Indian hedgehog proteins (IHH). Variants mapping to this locus and implicating *PTHC1* were identified very recently by a recent GWAS study drawn in individuals of Icelandic, (other) European and East Asian decent.[32] Association with BMD near the DHH gene, encoding one of the ligands for PTCH1, has previously been reported (see locus 12q13.12 later). The importance of the hedgehog-signaling pathway in skeletal development and metabolism is well established. The pathway is involved in the processes of osteoblastogenesis and chondrocyte differentiation, intramembranous ossification of cranial bones and the endochondral ossification in the rest of the skeletal system.[71] Another form of indirect regulation of osteoblasts on osteoclasts occurs via IHH signaling, inducing osteoclast maturation and promoting bone resorption by increased RANKL expression through upregulation of PTHrP expression.[72] The BMD signal in this locus is also observed in GWAS of human stature,[12] providing evidence for pleiotropic effects of the gene and for the hedgehog pathway being involved in both skeletal traits.

3.18 11p11.2 *LRP4* and *ARGHAP1*

The low density lipoprotein receptor-related protein 4 (*LRP4*) gene spans 62 kb and was proposed as a candidate for regulation of total hip BMD by a GWAS metaanalysis based on Icelandic (deCODE genetics) and Northern European populations,[20] which identified

variants mapping close to the gene associated at suggestive level. A subsequent effort in five Northern European populations found variants in the locus associated at GWSL.[23] Nevertheless, the GWAS signals map within a region of high LD containing several genes including the Rho GTPase activating protein 1 (*ARHGAP1*) gene and the coagulation factor II (*F2*) gene. At the moment it cannot be determined, among them which of the gene is responsible for the reported associations. Regarding the candidacy of *ARGHAP1*, it is known that small GPTases, such as Rho play an important role regulating bone cell activity while *LRP4* is homologous to *LRP5*, which is known to regulate BMD (see Section 3.21). Further work will be required to define the functional mechanisms underlying the associations that have been reported in this genomic region.

3.19 11p14.1 *DCDC5*, *LIN7C*, and LGR4

The doublecortin domain containing 5 (*DCDC5*) and 1 (*DCDC1*) are big genes spanning 297 and 427 kb in this locus, which were initially proposed as possible candidates for regulation of lumbar spine BMD as they were the closest genes to the GWAS signal identified by the first GEFOS GWAS metaanalysis.[23] However, neither gene appears to be highly expressed in bone and subsequent efforts have provided more likely candidates to underlie the associations. In the second GEFOS metaanalysis two independent signals were identified in this locus, one close to *DCDC5* and the other mapping to *Lin-7 Homolog C (LIN7C)*. The latter associated variant constituted a strong so-called expression quantitative trait locus (eQTL) of *LIN7C*. The *LIN7C, crumbs cell polarity complex Component* (*LIN7C*) gene spans 12 kb and functions establishing and maintaining the asymmetric distribution of channels and receptors at the plasma membrane of polarized cells. Variants mapping to the gene have in addition been associated with pediatric BMD postulating an effect on skeletal development.[66]

The *LGR4* gene spans 106 kb and encodes a G-protein coupled receptor that binds R-spondins involved in the WNT and mTOR signaling pathways. A variant (c.376C > T) mapping to this locus was identified in a WGS effort in a sample of Icelandic individuals[73] composed of 4,931 individuals with low BMD and 69,034 controls. The T allele was shown to have a large effect on (decreasing) BMD and was associated with increased risk for osteoporotic fractures, among other disease outcomes (e.g., cancer and CVD). The mutation introduces a rare nonsense mutation into exon 4, which terminates LGR4 and completely disrupts the function of the protein. Recently, LGR4 has been shown to act as a second RANKL receptor that negatively regulates osteoclast differentiation and bone resorption.[74]

3.20 11p15.1 *SOX6*

The SRY (sex determining region Y)-box 6 (*SOX6*), which is a large gene spanning 773 kb, emerged as a candidate for regulation for BMD in the first GEFOS GWAS metaanalysis on populations of European descent, showing a genome-wide significant association signal with femoral neck BMD, situated 297 kb upstream from SOX6.[23] Both *SOX5* and *SOX6* encode transcription factors which play essential roles in chondrocyte differentiation and endochondral ossification, are needed for growth plate multilayered establishment and for proper and timely development of endochondral bones.[75] Therefore, genetic variation in this candidate gene may well be mediating skeletal development and influencing BMD variation at the population level.

3.21 11q13.2 *LRP5*

The *LRP5* gene spans 137 kb and has for decades been known to play an important role in bone biology. Its role as a critical regulator of bone mass was first established by linkage studies[76–78] identifying mutations in the gene as producing the *osteoporosis–pseudoglioma* syndrome[76,79,80] and several presentations of the *high bone mass* syndromes[81–84] including autosomal dominant forms of *type 2 van Buchem disease*[83] and *osteosclerosis/endosteal hyperostosis*.[84]

Genetic variants in the *LRP5* locus have been identified as significant determinants of BMD by several of the GWAS to date[18,23,85] but, interestingly, not in those associations arising from Icelandic populations.[19,20,68] Even though several early candidate gene association studies showed that common variants in *LRP5* underlie variation of BMD in the general population, it was only in the GENOMOS consortium including ≈45,000 individuals (the largest candidate gene study run to date), that two nonsynonymous coding variants were robustly associated with BMD, at a level of significance surpassing the current stringent standards of genome-wide level. An association with risk of fracture was also observed in that study and has been recently confirmed in the latest effort of the GEFOS consortium.[26] Many common *LRP5* variants have been studied in association studies, but the most likely functional candidates are a valine to methionine variant in exon 9 at codon 667 (V667M) and an alanine to valine substitution at position 1330 (A1330V) in exon 18 which are also precisely tagged by the GWAS signal.

3.22 12q13.12 *DHH*

The *Desert Hedgehog* (DHH) gene is a relatively small gene spanning 3.4 kb, which encodes a protein member of the hedgehog gene family of signaling molecules that play

an important role in regulating morphogenesis. DHH exerts an intercellular signal essential for a variety of patterning events during development; also in interaction with HHIP, PTCH1 (see 9q22.32 earlier**)** and PTCH2. Variants in this locus were identified as associated at GWSL with lumbar spine BMD in the second GEFOS metaanalysis.[26]

3.23 12q13.13 SP7

SP7 is a small gene spanning 19 kb which encodes Osterix, a transcription factor exerting an essential role in osteoblast differentiation.[86,87] Variation in the gene was first reported to influence BMD variation in an Icelandic population followed by a report showing its effect on peak bone mass accrual in children from the United Kingdom.[21] Since then, several GWAS have shown association with variants mapping in the SP7 region.[23,25,26] Additional studies are required to investigate the mechanisms underlying these associations with BMD. Noteworthy is the fact that a homozygous single basepair deletion in SP7 has been shown to cause *Type IX osteogenesis imperfecta*.

3.24 13q14.11 *TNFSF11* (RANKL)

The tumor necrosis factor (ligand) superfamily member 11 gene spans 45 kb and encodes RANKL, a member of the TNF superfamily which stimulates bone resorption by activating RANK signaling. Variants in *RANKL* have been consistently associated with lumbar spine BMD[20,23,25,26] since the first report arising from Icelandic populations (deCODE genetics).[19] In a recent report based on peripheral quantitative computed tomography, variants in this locus distinct from those associated with DXA BMD (i.e., not in LD), were associated at GWSL with volumetric and cortical bone density in 999 UK adolescents and 935 young Swedish adults.[88] These findings imply that allelic heterogeneity may be governing the associations with areal and volumetric BMD seen in this locus. Even though the involvement of the OPG-RANK-RANKL pathway in bone metabolism is well established,[69] the exact functional mechanisms by which genetic variation in these genes regulate BMD remains to be investigated.

3.25 14q32.32 *MARK3*

This gene has a size of 119 kb and encodes MAP/microtubule affinity-regulating kinase 3, a member of the AMP kinase superfamily of proteins.[89] Variants in this gene were first reported as associated at GWSL with total hip BMD in an Icelandic population after replication in other European populations.[20] In the first GEFOS metaanalysis on femoral neck and lumbar spine, variants in MARK3 were significant but not at GWSL.[23] Nonetheless, variants in this locus did achieve a GWSL in the most recent effort involving an expanded set of populations of European descent and including East-Asian cohorts.[26] Mechanisms, by which variations in this gene might affect BMD and/or bone physiology, are yet to be described.

3.26 16p13.3 CLCN7 and AXIN1

The chloride channel 7 is a gene spanning 31 kb and coding for ClC-7. CIC-7 is particularly important for regulating pH and needed for the adequate resorptive function of osteoclasts through lysosomal acidification. CLCN7 mutations cause (infantile malignant) *type 4 autosomal recessive osteopetrosis* (OPTB4), and (Albers–Schonberg) *type 2 autosomal dominant osteopetrosis* (OPTA2), also called "marble bone disease." In contrast, the *AXIN1* gene which spans 74 kb encodes a cytoplasmic protein containing G-protein signaling regulation, dishevelled and axin domains. The encoded protein is a component of the β-catenin destruction complex required for regulating CTNNB1 levels through phosphorylation and ubiquitination, which is critical for modulating Wnt-signaling. Variants in this locus were first reported as suggestive of association with total hip, femoral neck, and lumbar spine BMD in Australian populations,[25] while variants in this locus reached genome-wide significance in the second GEFOS metaanalysis of GWAS.[26] Recently, in an Icelandic study[32] a new low frequency signal (frequency of 3.5%) mapping to *AXIN1* was found strongly associated with lumbar spine BMD, but much weaker with hip BMD and fracture. This novel signal was independent from (i.e., not tagged by) the previously reported common SNP (frequency of 43%) in this locus.[25,26]

3.27 16q24.1 *FOXL1* and *FOXC2*

This locus was first identified in the first GEFOS metaanalysis in European populations as containing variants associated with lumbar spine BMD.[23] The region contains a cluster of small genes of the "forkhead" (or winged helix) FOX gene family that are part of the TGFβ pathway and are involved in organogenesis. The GWAS signal maps close to the forkhead box L1 (*FOXL1*) gene of size 5.8 kb and the forkhead box C2 (*FOXC2*) gene spanning 2.5 kb. *FOXL1* is involved in the regulation of multiple processes including metabolism and cell proliferation. Changes in FOXL1 expression have been associated with ontogenesis and diverse oncogenic processes (including osteosarcoma).[90] Mutations in *FOXC2* have been reported as causing the lymphedema–distichiasis syndrome,[91,92] a disorder characterized by lymphedema of the limbs coupled with various other features but no evident skeletal phenotype. Nevertheless,

Foxc2-deficient mice exhibit aortic arch anomalies and defects of skeletogenesis in the craniofacial bones and vertebral column,[93] while inactivating mutations affecting the FOX gene cluster involving *FOXC2* can cause severe malformations of the VACTERL (vertebral, anal, cardiac, tracheoesophageal, renal, and limb) type in humans.[94] Further, *FOXC2* expression is regulated by bone morphogenetic proteins[95] and can effect osteoblast differentiation of mesenchymal cells through activation of canonical Wnt-β-catenin signals[96] and via upregulation of integrin beta 1.[97]

3.28 17q12-22 *CRHR1*

This locus was identified by the first GEFOS GWAS metaanalyses on populations of European descent proposing corticotropin-releasing factor receptor 1 (*CRHR1*) as the closest candidate gene to be influencing BMD variation at the population level.[23] *CRHR1* is a gene that spans 214 kb coding for a member of the corticotropin-releasing factor family of G-protein-coupled receptors that binds neuropeptides involved in regulation of the hypothalamic-pituitary-adrenal pathway. Nevertheless, the involvement of *CRHR1* on this BMD signal cannot be unequivocally determined considering that the GWAS signals lie in a region of very high LD containing many genes. The high LD in the region arises from a common inversion polymorphism spanning about 900 kb, which has been subject to positive selection and which has been highly preserved for more than 3 million years in humans of Northern European descent.[98]

3.29 17q21.31 *SOST* and *HDAC5*

The first GWAS report identifying variants mapping to this locus was based on a discovery setting based on Icelandic individuals. In that study, variants mapped close to an open reading frame sequence (*C17orf53*) and to a 5 kb gene encoding sclerostin. A nonsynonymous variant in *C17orf53* was associated with hip BMD but not at GWSL, while the marker mapping in the vicinity of *SOST* did achieve GWS. Sclerostin is a protein produced by osteocytes that inhibits bone formation by blocking the binding of members of the Wnt family to the LRP5 receptor.[99] This way, *SOST* arises as an excellent candidate for genetic regulation of BMD considering that inactivating mutations of *SOST* cause sclerosteosis and mutations in a downstream enhancer cause van Buchem's disease.[100,101] Variants mapping to *SOST* did not achieve genome-wide significance in the first GEFOS metaanalysis with lumbar spine or femoral neck BMD.[23] Nevertheless, a metaanalysis using a candidate gene approach examining 150 genes on the same exact datasets did identify variants mapping to *SOST* as significantly associated with BMD,[102] while the second GEFOS metaanalysis has now identified variants mapping to *SOST* as associated at GWSL with BMD.[26] Very recently, a new and independent signal in the SOST locus has been reported. A variant (frequency 9.6%) was associated with increased hip and lumbar spine BMD and with lower risk for nonvertebral fractures and particularly a very strong association with vertebral fractures.[32] Further, the first GEFOS metaanalysis also identified variants as associated with FN-BMD at GWS level in this locus, but mapping in an intronic region of the histone deacetylase 5 (*HDAC5*) gene[23] on what appears to be an independent signal from that mapping to *SOST* and the same one arising from *C17orf53*. At present, it is not possible to determine from which gene this signal is arising as the function of *C17orf53* is unknown. On the other hand, *HDAC5* is a 47 kb gene which is ubiquitously expressed and involved in transcriptional regulation through MEF2 inhibition[103] and involved in muscle differentiation.[104]

3.30 18q21.33 *TNFRSF11A*

The tumor necrosis factor receptor superfamily member 11a (*TNFRSF11A*) is a 66 kb gene that encodes the receptor activator of the NF-κB or RANK protein. The RANK receptor is expressed in osteoclasts and plays a critical role in regulating osteoclast differentiation and function, constituting a key element for the stimulation of bone resorption. Mutations in the RANK gene (Chapter 26) are responsible for the osteoclast-poor form of autosomal recessive osteopetrosis associated with hypogammaglobulinemia (OPTB7).[105] The first study to identify common variants in the gene associated at GWSL was on Icelandic populations[20] and subsequently consistently replicated.[23,26]

3.31 20p12 *JAG1*

The first report identifying variants mapping close to *JAG1* as associated with lumbar spine BMD came from Asian populations[24] but has been replicated in the second large-scale metaanalysis of the GEFOS consortium, including populations of both European and Asian descent.[26] Jagged-1 is a ligand of the Notch receptor that, after binding, triggers the release of the intracellular unit of the Notch receptor from the membrane. This unit translocates to the nucleus and activates transcription factors key for cell differentiation and morphogenesis processes.[106] In 2008, two reports in mice showed that Notch signaling stimulates early proliferation of osteoblastic lineages and that when knocked down results in an osteoporosis-like phenotype.[107,108] In addition, *JAG1* may be mediating some anabolic responses considering that PTH stimulation of osteoblast results in expression of *JAG1*.[109]

4 GWAS IN OTHER ETHNIC GROUPS AND FOR OTHER OSTEOPOROSIS PHENOTYPES

It is now clear that BMD is the trait producing the largest yield of identified loci probably due to the combination of favorable properties including its high heritability, measurement precision, and widespread use (allowing collections of samples of large size). Several other genes like *IL21R*,[110] PTH,[110] *ALDH7A1*,[111] *TBC1D8*,[67] *OSBPL1A*,[67] *RAP1A*,[67] *PLCL1*,[112] *RTP3*,[113] *ADAMTS18*,[114] and T*GFBR3*[114] have been postulated as involved in diverse osteoporosis traits including BMD,[110,114] bone geometry,[112,113] fracture,[111] and derived phenotype combinations.[67] Nevertheless, several of the latter reported associations are under or just over the genome-wide significance threshold, are based on small and heterogeneous groups of individuals, or have not been replicated to date in well-powered settings summing several tens of thousands of individuals.[26,27] Even though population-specific findings are a possibility, it has recently been shown that the vast majority of GWAS associations replicate across populations of different ethnic backgrounds.[68] Additional replication is needed to consolidate these findings as robust candidate genes of osteoporosis.

The largest GWAS metaanalysis for skeletal phenotypes to date was recently reported by investigators using data from the UKBiobank Study in relation to estimated BMD from heel ultrasound measurements in 142,487 individuals of European decent.[28] This GWAS effort identified 307 independent SNPs from 203 loci jointly explaining 11.8% of the variation in heel ultrasound estimated BMD. Such a large study highlights the value of expanding the sample size of GWAS and the great potential for identifying new biology as a next step toward driving these discoveries in direction of clinical applications (e.g., risk stratification and identification of new drug targets and indications).

5 CONCLUSIONS

To date at least 70 loci have shown robust association with BMD containing an even larger number of candidate genes potentially underlying these GWAS signals. Here, we have reviewed a subset of them, mainly those common variants that have been reported in the literature associated at GWSL and been replicated, together with the more recent discoveries of rare and low-frequency variants whose identification has been facilitated by the emergence of whole-genome sequenced reference sets. Interestingly, many of these variants map in the vicinity of genes of unknown function (representing cutting-edge new biology), while several other factors

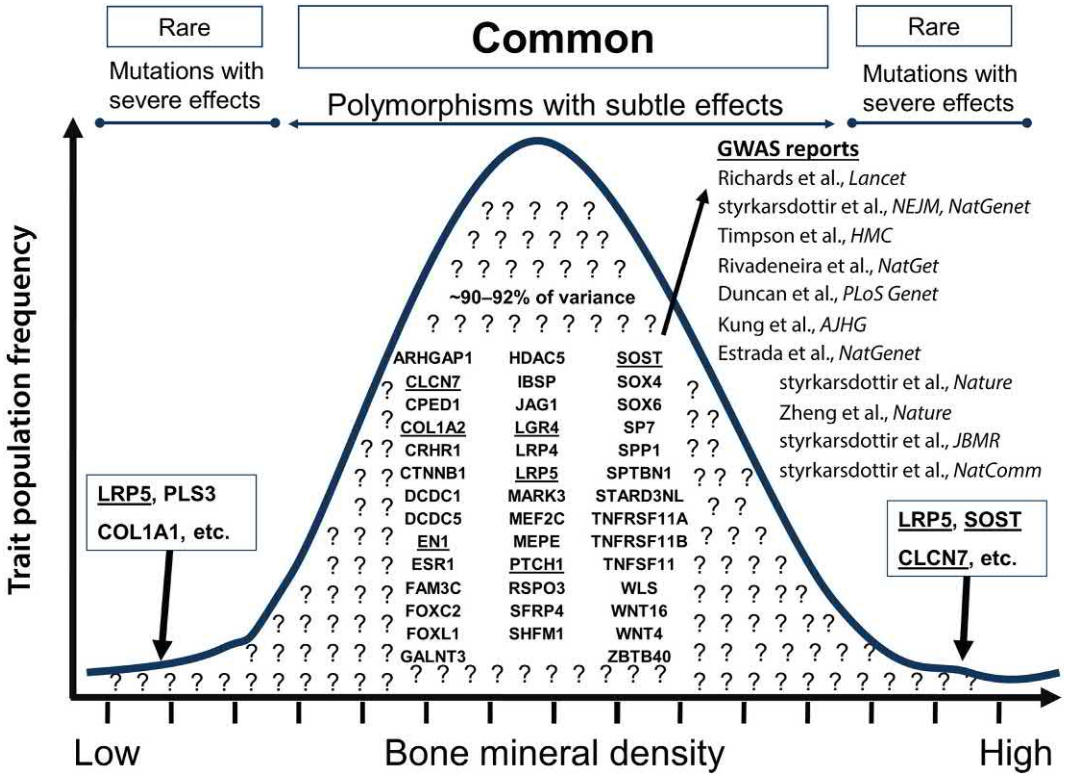

FIGURE 22.3 **Genetic architecture underlying BMD variation.**

cluster within critical biological pathways[115] relevant for bone biology like Wnt signaling, OPG-RANK-RANKL, mesenchymal cell differentiation and the Indian hedgehog pathways. Thus far, these genes identified by GWAS incorporate variants which together explain 8%–10% of the variation in BMD (Fig. 22.3). This suggests that both common and rare variation underlies the genetic architecture of BMD and many more genetic determinants are yet to be identified. While the objective is to keep scrutinizing variants particularly in the low frequency and rare allele spectrum, sequencing studies are not expected to become much bigger considering the still costly investments and computational requirements needed. In contrast, GWAS based on arrays: (1) have become increasingly affordable, (2) contain rare and clinically relevant variants, and (3) will soon reach many millions of samples. Therefore, it is expected that future GWAS will continue to advance the field of complex diseases, osteoporosis included. One of the expectations from genetic studies of common diseases like osteoporosis is the possibility to improve risk prediction (i.e., as compared to what is currently possible with the use of clinical factors and/or biomarkers like BMD). Nevertheless, this goal is not yet feasible to achieve since the small fraction of phenotypic variance explained still provides little added value in terms of prediction; hence, limiting at the moment any such derived clinical utility. From a distinct clinical perspective (i.e., translation to therapies), GWAS have pinpointed many factors in critical molecular pathways (e.g., Wnt signaling), as candidates for therapeutic applications. Such potential is highlighted by the identification (among others) of genes encoding proteins that are currently subject to mediate novel bone medications. This is the case for denosumab, a human monoclonal antibody against RANKL, which is a protein inhibiting bone resorption. Yet even more interesting is the identification of several factors, which can constitute targets for true bone-building drugs, exemplified by the identification of the sclerostin gene for which an anti-sclerostin antibody is in clinical trials. Hence, from the perspective of their therapeutic potential, translation of the GWAS discoveries into clinical applications is an upcoming reality.
