15. Thorup [Th99] developed an algorithm that solves the shortest path problem on undirected networks in $O(m)$ time.

16. Goldberg [Go01] gave an implementation of Dijkstra's algorithm that solves the shortest path problem in $O(m)$ expected time if the arc lengths are positive and uniformly distributed.

17. A very fast implementation of Dijkstra's algorithm is due to R. Dial [Di69], and it runs in $O(m + nC)$ time.

18. A comprehensive discussion of several implementations of Dijkstra's algorithm and the label-correcting algorithm is presented in [AhMaOr93].

19. Computer codes that implement algorithms for single-source shortest paths can be found at

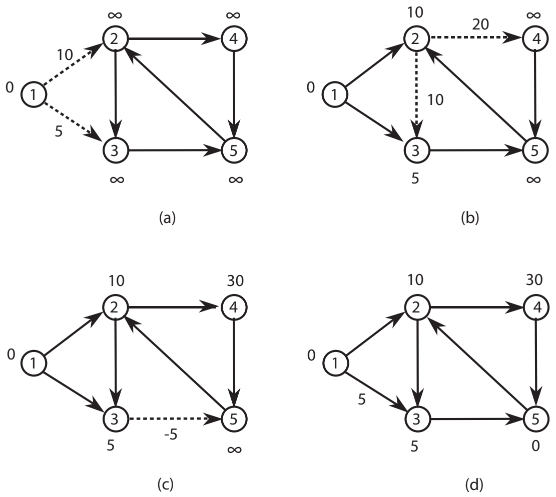
- `http://www.avglab.com/andrew/soft.html`
- `http://www.dis.uniroma1.it/challenge9/`

20. A useful extension of the shortest path problem involves finding the k *shortest paths* in a network. The case $k = 1$ corresponds to a shortest path. More generally, the kth shortest path is one having the kth smallest length among all paths from s to t. Several algorithms for solving the problem of finding the k shortest paths are discussed in [EvMi92].

Examples:

1. The following figure illustrates three iterations of the label-correcting algorithm applied to Example 2 of §10.3.1. LIST is maintained as a queue.

In the first iteration, the source vertex $s = 1$ is examined, and the distance labels of vertices 2 and 3 are decreased to 10 and 5, respectively. At this point, LIST $= [2, 3]$.

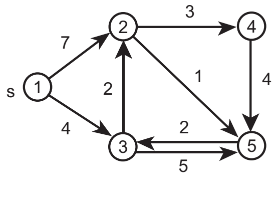


(a) (b) (c) (d)

In the second iteration, vertex 2 is removed from LIST and examined. The distance label of vertex 4 decreases to 30, while the distance label of vertex 3 remains unchanged, giving LIST $= [3, 4]$.

Next, vertex 3 is removed from LIST and examined, triggering a reduction of the distance label of vertex 5 to 0. At this point the current out-tree, defined by the predecessor indices $pred(\cdot)$, consists of arcs $(1, 2)$, $(2, 4)$, $(1, 3)$, and $(3, 5)$.

2. Part (b) of the following figure shows the application of Dijkstra's algorithm to the directed network in part (a) with nonnegative arc costs and $s = 1$. Shown at each iteration are the current distance labels, the vertex selected, and the resulting distance updates. Upon termination, the shortest path lengths $d = (0, 6, 4, 9, 7)$ are realized by the optimal tree T^* having arcs $(1, 3)$, $(3, 2)$, $(2, 4)$, and $(2, 5)$.



(a)

iteration	labels	select	updates
1	(0,∞,∞,∞,∞)	1	d(2) = 7, d(3) = 4
2	(0,7,4,∞,∞)	3	d(2) = min{7,6} = 6 d(5) = 9
3	(0,6,4,∞,9)	2	d(4) = 9 d(5) = min{9,7} = 7
4	(0,6,4,9,7)	5	d(3) = min{4,9} = 4
5	(0,6,4,9,7)	4	d(5) = min{7,13} = 7

(b)

10.3.3 ALGORITHMS FOR ALL-PAIRS SHORTEST PATHS

This section discusses algorithms for finding shortest path distances between every pair of vertices in a directed network with n vertices and m arcs.

Definitions:

Suppose $G = (V, E)$ is a directed network with vertex set V and arc set E, and let c_{ij} be the cost of arc $(i, j) \in E$.

The $n \times n$ ***arc length matrix*** $U = (u_{ij})$ is defined as follows:

$$u_{ij} = \begin{cases} 0 & \text{if } i = j \\ c_{ij} & \text{if } (i,j) \in E \\ \infty & \text{if } i \neq j \text{ and } (i,j) \notin E. \end{cases}$$

Let d_{ij} be the length of a shortest path from vertex i to vertex j, with $d_{ii} = 0$.

Define the $n \times n$ matrix $D^k = (d^k_{ij})$, where d^k_{ij} is the length of a shortest path from vertex i to vertex j subject to the condition that the path contains no more than k arcs.

Define ***minsum matrix multiplication*** $C = A \otimes B$ by $c_{ij} = \min_{1 \leq p \leq n}\{a_{ip} + b_{pj}\}$. Also, define $A^{\otimes k} = A \otimes A \otimes \cdots \otimes A$ (k times).

In the directed path $[i_0, i_1, \ldots, i_r]$ from i_0 to i_r, the vertices $i_1, i_2, \ldots, i_{r-1}$ are called ***internal vertices***. Let $d^k[i, j]$ be the length of a shortest path from vertex i to vertex j subject to the condition that this path uses only $1, 2, \ldots, k-1$ as internal vertices. The $n \times n$ matrix $D^{[k]}$ contains the entries $d^k[i, j]$.

Facts:

1. The length of a shortest path containing at most k arcs can be expressed in terms of shortest path lengths involving at most $k-1$ arcs. Namely, for all vertices i and j

- $d^1_{ij} = u_{ij}$;
- $d^k_{ij} = \min\limits_{1 \leq p \leq n} \{d^{k-1}_{ip} + u_{pj}\}$ for $2 \leq k \leq n-1$;
- if there is no negative cycle, then $d^{n-1}_{ij} = d_{ij}$.

2. $D^k = U^{\otimes k}$ for all $1 \leq k \leq n-1$.

3. For any pair of vertices i and j, the following conditions hold:

- $d^1[i, j] = u_{ij}$;
- $d^{k+1}[i, j] = \min\{d^k[i, j], d^k[i, k] + d^k[k, j]\}$, $1 \leq k \leq n$;
- if there is no negative cycle then $d^{n+1}[i, j] = d_{ij}$.

4. The all-pairs shortest path problem can be solved by applying n times either Algorithm 1 or Algorithm 2 of §10.3.2, considering each vertex once as a source.

5. Specialized algorithms are available to solve the all-pairs shortest path problem: the matrix multiplication algorithm (Fact 6) and the Floyd-Warshall algorithm (Fact 8).

6. *Matrix multiplication algorithm*: This algorithm (Algorithm 3), based on Facts 1 and 2, computes the shortest path distances between all vertex pairs by multiplying two matrices repeatedly, using minsum matrix multiplication.

Algorithm 3: **Matrix multiplication algorithm.**

```
input: directed network $G$ on $n$ vertices
output: shortest distance matrix $D = (d_{ij})$
form the $n \times n$ arc length matrix $U$
compute $D := U^{\otimes(n-1)}$
```

7. If there is no negative cycle, then Algorithm 3 finds all shortest path distances using $O(\log n)$ matrix multiplications, each of which takes $O(n^3)$ time. Hence this algorithm runs in $O(n^3 \log n)$ time and requires $O(n^2)$ space. Zwick [Zw02] showed how the matrix algorithm could be sped up using fast matrix multiplication.

8. *Floyd-Warshall algorithm*: This approach (Algorithm 4) calculates all-pairs shortest path distances in a directed network G and is based on computing conditional shortest path lengths $d[i,j]$.

```
Algorithm 4: Floyd-Warshall algorithm.
  input: directed network $G$ on $n$ vertices
  output: shortest distance matrix $D = (d[i,j])$
  for all $(i,j) \in V \times V$  $d[i,j] := \infty$
  for all $i \in V$  $d[i,i] := 0$
  for all $(i,j) \in E$  $d[i,j] := c_{ij}$
  for $k := 1$ to $n$
    for $(i,j) \in V \times V$
      if $d[i,j] > d[i,k] + d[k,j]$ then $d[i,j] := d[i,k] + d[k,j]$
```

9. If there is no negative cycle, the Floyd-Warshall algorithm correctly computes the matrix of shortest path distances. A single $n \times n$ array D is used to implement the algorithm.

10. Algorithm 4 can be used to detect (and identify) negative cycles by monitoring whenever $d[i,i] < 0$ occurs for some vertex i.

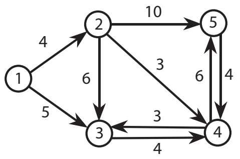
11. Algorithm 4 runs in $O(n^3)$ time and requires $O(n^2)$ space.

12. If the underlying network is dense, that is, $m = \Omega(n^2)$, then the $O(n^3)$ time bound for Algorithm 4 is as good as any other discussed in §10.3.2 or §10.3.3.

13. Algorithm 4 was first discovered by B. Roy in 1959 in the context of determining the transitive closure of a graph; this same algorithm was independently discovered by S. Warshall in 1962. The method was generalized to computing all-pairs shortest paths by R. W. Floyd, also in 1962.

Examples:

1. The matrix multiplication algorithm is applied to the directed network in the following figure.



By Facts 1 and 2, the matrix D^4 is the matrix of shortest path distances.

$$D^1 = \begin{pmatrix} 0 & 4 & 5 & \infty & \infty \\ \infty & 0 & 6 & 3 & 10 \\ \infty & \infty & 0 & 4 & \infty \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & \infty & 4 & 0 \end{pmatrix} \qquad D^2 = \begin{pmatrix} 0 & 4 & 5 & 7 & 14 \\ \infty & 0 & 6 & 3 & 9 \\ \infty & \infty & 0 & 4 & 10 \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & 7 & 4 & 0 \end{pmatrix}$$

$$D^4 = \begin{pmatrix} 0 & 4 & 5 & 7 & 13 \\ \infty & 0 & 6 & 3 & 9 \\ \infty & \infty & 0 & 4 & 10 \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & 7 & 4 & 0 \end{pmatrix}.$$

2. Algorithm 4 is illustrated using the network shown in Example 1.

$$D^{[1]} = \begin{pmatrix} 0 & 4 & 5 & \infty & \infty \\ \infty & 0 & 6 & 3 & 10 \\ \infty & \infty & 0 & 4 & \infty \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & \infty & 4 & 0 \end{pmatrix} \qquad D^{[3]} = \begin{pmatrix} 0 & 4 & 5 & 7 & 14 \\ \infty & 0 & 6 & 3 & 10 \\ \infty & \infty & 0 & 4 & \infty \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & \infty & 4 & 0 \end{pmatrix}$$

$$D^{[5]} = \begin{pmatrix} 0 & 4 & 5 & 7 & 13 \\ \infty & 0 & 6 & 3 & 9 \\ \infty & \infty & 0 & 4 & 10 \\ \infty & \infty & 3 & 0 & 6 \\ \infty & \infty & 7 & 4 & 0 \end{pmatrix}.$$

It can be verified that $D^{[2]} = D^{[1]}$, $D^{[4]} = D^{[3]}$, and $D^{[6]} = D^{[5]}$. Consequently, the matrix $D^{[5]}$ above gives all shortest path distances.

10.3.4 PARALLEL ALGORITHMS

Parallel implementations of certain shortest path algorithms are described here relative to an EREW (exclusive-read, exclusive-write) PRAM (parallel random-access machine). For details of EREW PRAM, see §17.1.4.

Facts:

1. *Label-correcting algorithm*: The parallel implementation of the label-correcting algorithm (§10.3.2) associates a processor with each arc and with each vertex of the network. This algorithm maintains a distance label for each vertex, appropriately initialized. Suppose the distance labels are $d(i)$ at the beginning of an iteration. During the iteration, the processor attached to each arc (i,j) computes a temporary label $d'(i,j) = d(i) + c_{ij}$ in $O(1)$ time. Then the processor associated with vertex j examines incoming arcs at vertex j and sets $d(j) := \min\{d'(i,j) \mid 1 \le i \le n\}$.

2. Using a parallel prefix operation, the distance labels can be updated in $O(\log n)$ time. The label-correcting algorithm performs $O(n)$ iterations and so its running time is $O(n \log n)$ using $O(m)$ processors.

3. *Matrix multiplication algorithm*: The matrix multiplication algorithm of §10.3.3 solves the all-pairs shortest path problem by performing $O(\log n)$ matrix multiplications.

4. Unlike a sequential computer, where matrix multiplication takes $O(n^3)$ time, a parallel computer can perform matrix multiplication in $O(\log n)$ time using $O(n^3)$ processors [Le92]. Consequently, this all-pairs shortest path algorithm runs in $O(\log^2 n)$ time using $O(n^3)$ processors.

10.3.5 APPLICATIONS

Shortest path problems arise in a variety of applications, both as stand-alone models and as subproblems in more complex problem settings. Shortest path problems also arise in surprising ways that on the surface might not appear to involve networks at all. This subsection presents several models based on determining shortest paths.

Applications:

1. *Distribution*: Material needs to be shipped by truck from a central warehouse to various retailers at minimum cost. The underlying network is an undirected road network, with edges representing the roads joining various cities (vertices). The cost of an edge is the per unit shipping cost. Solving the single-source shortest path problem provides a least-cost shipping pattern for the material.

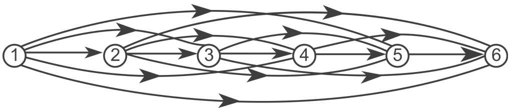
2. *Telephone routing*: A call is to be routed from a specified origin to a specified destination. Here the underlying network is the telephone system, with vertices representing individual users (or switching centers). Since a direct connection between the origin vertex s and the destination vertex t may not be available, one practice is to route the call along a path having the minimum number of arcs (i.e., involving the smallest number of switching centers). This means finding a shortest path with unit lengths on all arcs. Alternatively, each arc can be provided with a measure of delay, and routing can take place along a timewise shortest path from s to t.

3. *Salesperson routing*: A salesperson is to travel by air from city A to city B. The commission obtained by visiting each city along the way can be estimated. An optimal itinerary can be found by solving a shortest path problem on the underlying airline network, represented as a directed network of nonstop routes (arcs) connecting cities (vertices). Each arc (i, j) is given the net cost $c_{ij} = f_{ij} - r_j$, where f_{ij} is the cost of the flight from city i to city j and r_j is the commission obtained by visiting city j. A shortest path from A to B identifies an optimal itinerary.

4. *Investment strategy*: An investor has a fixed amount to invest at the beginning of the year. A variety of different financial opportunities are available for investing during the year, with each such opportunity assumed to be available only at the start of each month. Construct the directed network having a vertex for each month as well as a final vertex $t = 13$. The arc (i, j) corresponds to an investment opportunity beginning in month i and maturing at the start of month j, with its weight c_{ij} being the negative of the profit earned for the duration of the investment. An optimal investment strategy is identified by a shortest path from vertex 1 to vertex t.

5. *Equipment replacement*: A job shop must periodically replace its capital equipment because of machine wear. As the machine ages, it breaks down more frequently and so becomes more expensive to operate. Also, as a machine ages its salvage value decreases. Let c_{ij} denote the cost of buying a particularly important machine at the beginning of period i, plus the cost of operating the machine over the periods $i, i+1, \dots, j-1$, minus the salvage cost of the machine at the beginning of period j. The problem is to design a replacement plan that minimizes the cost of buying, selling, and operating the machine over a planning horizon of n years, assuming that the job shop must have exactly one machine in service at all times.

This problem can be formulated as a shortest path problem on a network G with vertices $i = 1, 2, \dots, n+1$; G contains an arc (i, j) with cost c_{ij} for all $i < j$. There is a one-to-one correspondence between directed paths in G from vertex 1 to vertex $n+1$ and equipment replacement plans. The following figure gives a sample network with $n = 5$. The path $[1, 3, 6]$ corresponds to buying the equipment at the beginning of periods 1 and 3. A shortest path from vertex 1 to vertex $n + 1$ identifies an optimal replacement plan.



6. *Paragraph problem*: The document processing program TEX uses an optimization procedure to decompose a paragraph into several lines so that when lines are left- and right-justified, the appearance of the paragraph will be the most attractive. Suppose that a paragraph consists of words $i = 1, 2, \ldots, n$. Let c_{ij} denote the attractiveness of a line if it begins with the word i and ends with the word $j - 1$. The program TEX uses formulas to compute the value of each c_{ij}. Given the c_{ij}, the decision problem is to decompose the paragraph into several lines of text in order to maximize the total attractiveness (of all lines). This problem can be formulated as a shortest path problem in a manner similar to Application 5.

7. *Tramp steamer problem*: A ship travels from port to port carrying cargo and passengers. A voyage of the steamer from port i to port j earns p_{ij} units of profit and requires $t_{ij} \geq 0$ units of time. Here it is assumed that $\sum_{(i,j)\in W} t_{ij} > 0$ for every directed cycle W in G. The captain of the ship would like to know whether there exists a tour (directed cycle) W for which the daily profit is greater than a specified threshold μ_0; that is, $\sum_{(i,j)\in W} p_{ij} / \sum_{(i,j)\in W} t_{ij} > \mu_0$. By writing this inequality as $\sum_{(i,j)\in W}(\mu_0 t_{ij} - p_{ij}) < 0$, it is seen that there is a tour W with mean daily profit exceeding μ_0 if and only if G contains a negative cost directed cycle W. The shortest path label-correcting algorithm can be used to detect the presence (or absence) of negative cycles (see §10.3.2, Fact 7).

8. *System of difference constraints*: In some linear programming applications (§16.1) with constraints of the form $Ax \leq b$, the $m \times n$ constraint matrix A contains one $+1$ and one -1 in each row, with all other entries being zero. Suppose that the kth row has a $+1$ entry in column j_k and a -1 entry in column i_k; entries in the vector b have arbitrary signs. This linear program defines the following set of m *difference constraints* in n variables $x = (x(1), x(2), \ldots, x(n))$: $x(j_k) - x(i_k) \leq b(k)$ for each $k = 1, 2, \ldots, m$. The problem is to determine whether this system of difference constraints has a feasible solution, and if so, to obtain one.

Associate a graph G with this system of difference constraints; G has n vertices corresponding to the n variables, and the arc (i_k, j_k) of length $b(k)$ results from the constraint $x(j_k) - x(i_k) \leq b(k)$. These constraints are identical with the optimality conditions for the shortest path problem in G, and they can be satisfied if and only if G contains no negative cycle. In this case the shortest path distances give a solution x satisfying the constraints.

9. Examples of Application 8 are also found in telephone operator scheduling, just-in-time scheduling, analyzing the consistency of measurements, and the scaling of data.

10. *Maximin paths*: In a network with capacities (that is, upper bounds on the amount of material that can be sent on each arc), the capacity of a path is the smallest capacity on any of its constituent arcs. A common problem in such networks is to find a path from vertex s to vertex t having the maximum capacity. This represents a path along which the maximum amount of material can flow. Such a *maximin path* can be found efficiently by adapting Dijkstra's shortest path algorithm.

10.4 MAXIMUM FLOWS

The maximum flow problem involves sending the maximum amount of material from a specified source vertex s to another specified sink vertex t, subject to capacity restrictions on the amount of material that can flow along each arc. A closely related problem is the minimum cut problem, which is to find a set of arcs with smallest total capacity whose removal separates s and t.

10.4.1 BASIC CONCEPTS

Definitions:

Let $G = (V, E)$ be a directed network with vertex set V and arc set E (see §10.3.1). Each arc $(i, j) \in E$ has an associated ***capacity*** $u_{ij} \geq 0$. Such a network is called a ***capacitated*** network. Let $n = |V|$ and $m = |E|$.

Suppose s is a specified ***source*** vertex and t is a specified ***sink*** vertex. Then a (***feasible***) ***flow*** is a function $x = (x_{ij})$ defined on arcs $(i, j) \in E$ satisfying

- *mass balance constraints*: $\sum_{\{j|(i,j)\in E\}} x_{ij} = \sum_{\{j|(j,i)\in E\}} x_{ji}$ for all $i \in V - \{s, t\}$;
- *capacity constraints*: $0 \leq x_{ij} \leq u_{ij}$ for all $(i, j) \in E$.

The arc (i, j) is ***saturated*** in flow x if $x_{ij} = u_{ij}$.

The ***value*** of flow x is $v = \sum_{\{j|(s,j)\in E\}} x_{sj}$, the total flow leaving the source vertex.

A ***maximum flow*** is a flow having maximum value.

A ***cut*** $[S, \overline{S}]$ partitions the vertex set V into two subsets S and $\overline{S} = V - S$, and consists of all arcs with one endpoint in S and the other in $\overline{S}$. Arcs directed from S to $\overline{S}$ are ***forward arcs***, and the set of forward arcs is denoted by $(S, \overline{S})$. Arcs directed from $\overline{S}$ to S are ***backward arcs***, and the set of backward arcs is denoted by $(\overline{S}, S)$.

The cut $[S,\overline{S}]$ is an ***s-t cut*** if $s \in S$ and $t \in \overline{S}$. The ***capacity*** of the s-t cut $[S,\overline{S}]$ is $u[S,\overline{S}] = \sum_{(i,j)\in(S,\overline{S})} u_{ij}$.

A ***minimum cut*** is an s-t cut having minimum capacity.

Facts:

1. The flow x_{ij} on arc (i,j) can represent the number of cars (per hour) traveling along a highway segment, the rate at which oil is pumped through a section of pipe in a distribution system, or the number of messages per unit time that can be sent along a data link in a communication system.

2. The mass balance constraints ensure that for all vertices i (other than the source or sink), the total flow out of i equals the total flow into i.

3. The capacity constraints ensure that the flow on an arc does not exceed its stated capacity.

4. Maximum flows arise in a variety of practical problems involving the flow of goods, vehicles, and messages in a network. Maximum flows can also be used to study the connectivity of graphs, the covering of chessboards, the selection of representatives, winning records in tournaments, matrix rounding, and staff scheduling (see §10.4.3).

5. For any s-t flow x, the flow out of s equals the flow into t; that is,

$$\sum_{\{j\,|\,(s,j)\in E\}} x_{sj} \;=\; v \;=\; \sum_{\{j\,|\,(j,t)\in E\}} x_{jt}.$$

6. Removal of the arcs in the s-t cut $Z = [S,\overline{S}]$ from G separates vertex s from vertex t: namely, there is no s-t path in $G - Z$.

7. Let $[S,\overline{S}]$ be any s-t cut in the network. Then the value of the flow x is given by

$$v = \sum_{(i,j)\in(S,\overline{S})} x_{ij} \;-\; \sum_{(j,i)\in(\overline{S},S)} x_{ji}.$$

That is, the net flow across each s-t cut is the same and equals v.

8. *Weak duality theorem*: The value of every s-t flow is less than or equal to the capacity of every s-t cut in the network.

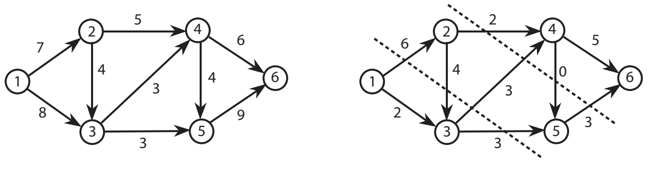
9. If x is some s-t flow whose value equals the capacity of some s-t cut $[S,\overline{S}]$, then x is a maximum flow and $[S,\overline{S}]$ is a minimum cut.

10. *Max-flow min-cut theorem*: The maximum value of the flow from vertex s to vertex t in a capacitated network equals the minimum capacity among all s-t cuts. (L. R. Ford and D. R. Fulkerson, 1956.)

11. A systematic study of flows in networks was first carried out by Ford and Fulkerson [FoFu62]. They developed their max-flow min-cut theorem when working on a classified project for Frank S. Ross and Ted Harris. The goal of the project was to evaluate interdiction strategies on the capacity of the Eastern European rail network to support a conventional war. Their 1955 classified report "Fundamentals of a method for evaluating rail net capacities" was declassified in 1999.

Examples:

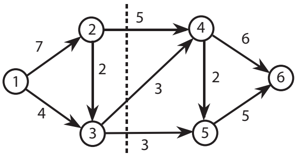
1. Part (a) of the following figure shows a flow network with $s = 1$ and $t = 6$; capacities are indicated along each arc. The function x given in part (b) satisfies the mass balance constraints and the capacity constraints, and hence is a feasible flow. Relative to this flow, arc $(1,2)$ is not saturated since $x_{12} = 6 < 7 = u_{12}$; on the other hand, arc $(3,5)$ is saturated since $x_{35} = 3 = u_{35}$. The flow has value $v = x_{12}+x_{13} = 6+2 = 8$. Here the flow into vertex 6 is $x_{46}+x_{56} = 5+3 = 8 = v$, as guaranteed by Fact 5. The flow value across the s-t cut $[S,\overline{S}]$ with $S = \{1,3\}$ is $x_{12}+x_{34}+x_{35}-x_{23} = 6+3+3-4 = 8$. Similarly, the flow value across the s-t cut $[S,\overline{S}]$ with $S = \{1,2,3,5\}$ is $x_{24}+x_{34}+x_{56}-x_{45} = 2+3+3-0 = 8$. (See Fact 7.) This flow is not, however, a maximum flow.



(a) (b)

2. In Example 1, the s-t cut $[S,\overline{S}]$ with $S = \{1,2,3,5\}$ has capacity $u_{24}+u_{34}+u_{56} = 5+3+9 = 17$. Thus the value of any flow in the network is bounded above (see Fact 8) by 17. The s-t cut $[S,\overline{S}]$ with $S = \{1,3\}$ has capacity $u_{12}+u_{34}+u_{35} = 7+3+3 = 13$. This cut capacity 13 provides an improved upper bound on the value of a flow. In particular, the flow defined in part (b) of the previous figure has value $v = 8 \leq 13$.

3. The following figure shows another feasible flow x' in the network of Example 1. For x', the flow value across the s-t cut $[S,\overline{S}]$ with $S = \{1,2,3\}$ is $v = x_{24}+x_{34}+x_{35} = 5+3+3 = 11$, which equals the s-t cut capacity $u[S,\overline{S}] = u_{24}+u_{34}+u_{35} = 5+3+3 = 11$. By Fact 9, x' is a maximum flow and $S = \{1,2,3\}$ defines a minimum cut $[S,\overline{S}]$.



10.4.2 ALGORITHMS FOR MAXIMUM FLOWS

There are two main classes of maximum flow algorithms: augmenting path algorithms and preflow-push algorithms. Both types of algorithms work on an auxiliary network (called the residual network) associated with the current solution.

Definitions:

Let $G = (V,E)$ be a directed network with $n = |V|$ and $m = |E|$. Let s and t be the specified source and sink, and let U be the largest of the arc capacities u_{ij} in G.

Let $x = (x_{ij})$ be a function defined on the arcs (i,j) of G. Relative to x, the ***outflow*** from vertex i and ***inflow*** to vertex i are given, respectively, by

$$out(i) = \sum_{\{j|(i,j)\in E\}} x_{ij}, \qquad in(i) = \sum_{\{j|(j,i)\in E\}} x_{ji}.$$

The ***excess*** of vertex i is $e(i) = in(i) - out(i)$.

A ***preflow*** is any $x = (x_{ij})$ satisfying

- *relaxed mass balance constraints*: $e(i) \geq 0$ for all $i \in V - \{s, t\}$;
- *capacity constraints*: $0 \leq x_{ij} \leq u_{ij}$ for all $(i, j) \in E$.

Vertex i is ***active*** if $e(i) > 0$.

Given a flow (or a preflow) x, the ***residual capacity*** r_{ij} of the arc $(i, j) \in E$ is the maximum additional flow that can be sent from i to j using arcs (i, j) and (j, i).

The ***residual network*** $G(x)$ with respect to flow x consists of those arcs of G having positive residual capacity.

An ***augmenting path*** is a directed path from vertex s to vertex t in $G(x)$.

The ***capacity*** of a directed path in $G(x)$ is the minimum residual arc capacity appearing on the path.

A set of ***distance labels*** with respect to a preflow (or flow) x is a function $d\colon V \to \{0, 1, 2, \ldots\}$ satisfying

- $d(t) = 0$;
- $d(i) \leq d(j) + 1$ for every arc (i, j) in the residual network $G(x)$.

An arc (i, j) in the residual network $G(x)$ is ***admissible*** with respect to the distance labels $d(\cdot)$ if $d(i) = d(j) + 1$.

Facts:

1. The maximum flow problem on an undirected network can be converted to a maximum flow problem on a directed network. Namely, replace every undirected edge (i, j) of capacity u_{ij} by two oppositely directed arcs (i, j) and (j, i), each with capacity u_{ij}.

2. The residual capacity $r_{ij} = (u_{ij} - x_{ij}) + x_{ji}$. The first term $u_{ij} - x_{ij}$ represents the unused capacity of arc (i, j); the second term x_{ji} represents the amount of flow on arc (j, i) that can be canceled to increase flow from vertex i to vertex j.

3. The capacity of an augmenting path is always positive.

4. *Augmenting path property*: A flow x is a maximum flow if and only if the residual network $G(x)$ contains no augmenting path.

5. *Augmenting path algorithm*: A general augmenting path algorithm (Algorithm 1) is based on Fact 4. It identifies augmenting paths and sends flows on these paths until the residual network contains no such path.

Algorithm 1: **Augmenting path algorithm.**

```
input: directed network $G$, source vertex $s$, sink vertex $t$
output: maximum flow $x$
$x := 0$
while $G(x)$ contains a directed path from $s$ to $t$
   identify an augmenting path $P$ in $G(x)$
   $\delta := \min\{r_{ij} \mid (i, j) \in P\}$
   augment $\delta$ units of flow along $P$ and update $G(x)$
recover an optimal flow $x$ from the final residual network $G(x)$
```

6. *Integrality property*: For networks with integer capacities, Algorithm 1 starts with the zero flow and augments by an integral flow at each iteration. Hence the maximum flow problem with integral capacities always has an optimal integer flow.

7. An augmenting path in $G(x)$ can be identified by any search procedure that starts at vertex s and identifies all vertices reachable from s by directed paths (§8.3.2).

8. Augmenting the flow along P by δ decreases the residual capacities of arcs in P by δ and increases the residual capacities of the reversals of arcs in P by δ.

9. At the last iteration of Algorithm 1, let S be the set of vertices reachable from s. Then $t \in \overline{S}$ and $[S, \overline{S}]$ is a minimum cut.

10. Upon termination of Algorithm 1, an optimal flow x can be reconstructed from the final $G(x)$ using Fact 2. Specifically, let $(i,j) \in E$. If $u_{ij} - r_{ij} \geq 0$ then set $x_{ij} = u_{ij} - r_{ij}$ and $x_{ji} = 0$; otherwise, set $x_{ji} = r_{ij} - u_{ij}$ and $x_{ij} = 0$.

11. Algorithm 1 was independently discovered by L. R. Ford and D. R. Fulkerson (1956) and by P. Elias, A. Feinstein, and C. E. Shannon (1956).

12. The distance label $d(i)$ is a lower bound on the length (number of arcs) of a shortest (directed) path from vertex i to vertex t in the residual network.

13. If some vertex j satisfies $d(j) \geq n$, then vertex j is separated from the sink vertex in the residual network.

14. Algorithm 1 runs in pseudopolynomial time $O(nmU)$ for networks with integer arc capacities. The algorithm may not terminate finitely for networks with irrational capacities.

15. Two specific implementations of Algorithm 1 run in polynomial time:

- By augmenting flow along a shortest path, the number of augmentations is reduced to $O(nm)$, and using very sophisticated data structures this algorithm can be implemented to run in $O(nm \log n)$ time;
- By augmenting flow along a path with maximum residual capacity, the number of augmentations is $O(m \log U)$ and this algorithm can be implemented to run in $O(nm \log U)$ time.

16. *Preflow-push algorithm*: The preflow-push algorithm (Algorithm 2) maintains a preflow at every step and pushes flow on individual arcs instead of along augmenting paths. The basic operation is to select an active vertex and try to remove its excess by pushing flow to neighbors that are "closer" to the sink.

```
Algorithm 2: Preflow-push algorithm.
  input: directed network $G$, source vertex $s$, sink vertex $t$
  output: maximum flow $x$
  compute the shortest path lengths $d(\cdot)$ to vertex $t$
  $d(s) := n$; $x := 0$; $x_{sj} := u_{sj}$ for all arcs $(s,j) \in E$
  while the network contains an active vertex
    select an active vertex $i$ and push_relabel($i$)
  recover an optimal flow $x$ from the final residual network $G(x)$

procedure push_relabel($i$)
  if the network contains an admissible arc $(i,j)$ then
    push $\delta := \min\{e(i), r_{ij}\}$ units of flow from $i$ to $j$
  else $d(i) := \min\{d(j) + 1 \mid (i,j) \in E \text{ and } r_{ij} > 0\}$
```

17. The shortest path lengths calculated in Algorithm 2 represent the minimum number of arcs in a path to vertex t and can be efficiently found by carrying out a breadth-first search relative to t (§9.2.1).

18. In Algorithm 2, if the active vertex currently being examined has an admissible arc (i, j), then increasing the flow on (i, j) by δ decreases r_{ij} by δ and increases r_{ji} by δ. Also, $e(i)$ is decreased by δ and $e(j)$ is increased by δ.

19. In Algorithm 2, if the active vertex currently being examined has no admissible arc, then after its distance label is increased, at least one admissible arc is created.

20. The preflow-push algorithm can be implemented to run in $O(n^2m)$ time. Variations of this algorithm with improved worst-case complexity are described in [AhOrTa89].

21. The highest-label preflow-push algorithm [GoTa86] is a specific implementation of Algorithm 2 that always examines vertices with the largest distance label. This $O(n^2\sqrt{m})$ implementation is currently one of the fastest algorithms to solve the maximum flow problem in practice.

22. Algorithm 2 can be implemented to run in $O(nm \log(n^2/m))$ time using a dynamic tree data structure.

23. Hochbaum [Ho98] introduced the *pseudoflow algorithm*, which is a variant of the preflow-push algorithm. Implementations of the pseudoflow algorithm are among the fastest for solving the maximum flow problem.

24. King, Rao, and Tarjan [KiRaTa94] developed a preflow-push algorithm that runs in $O(nm)$ time whenever $m > n^{1+\epsilon}$ for some fixed $\epsilon > 0$.

25. Goldberg and Rao [GoRa98] developed an augmenting path algorithm that has the best time bound if U is not too large relative to n. The running time when $m \leq n^{4/3}$ is $O(m^{3/2} \log n \log U)$. The running time when $m > n^{4/3}$ is $O(n^{2/3}m \log(n^2/m) \log U)$.

26. Cheriyan and Mehlhorn [ChMe99] developed a preflow-push algorithm that runs in $O(n^3/\log n)$ time. This is the best running time if m is proportional to n^2.

27. Orlin [Or13] developed an augmenting path algorithm that runs in $O(nm)$ time when $m < n^{1.06}$. When combined with the King, Rao, and Tarjan algorithm, this establishes that a maximum flow can be obtained in $O(nm)$ time. Orlin also showed how to solve the maximum flow problem in $O(n^2/\log n)$ time when m is proportional to n.

28. A series of papers starting with Christiano et al. [ChEtal11] and leading to a paper by Kelner et al. [KeEtal14] developed ϵ-optimal solutions for the maximum flow problem on undirected graphs. The algorithms rely on the theory of electrical flows. The best of these algorithms runs in nearly linear time.

29. The books [AhMaOr93] and [CoEtal01] discuss additional versions of augmenting and preflow-push algorithms, as well as specializations of these algorithms to unit capacity networks, bipartite networks, and planar networks.

30. Goldberg and Tarjan [GoTa14] provide a survey of algorithms for the maximum flow problem and discuss the history of running time improvements.

31. Computer codes for solving maximum flow/minimum cut problems can be found at

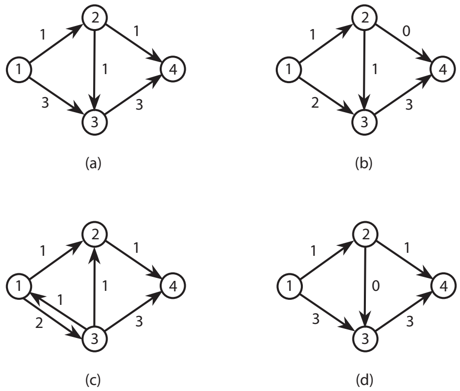
- `http://riot.ieor.berkeley.edu/Applications/Pseudoflow/maxflow.html`

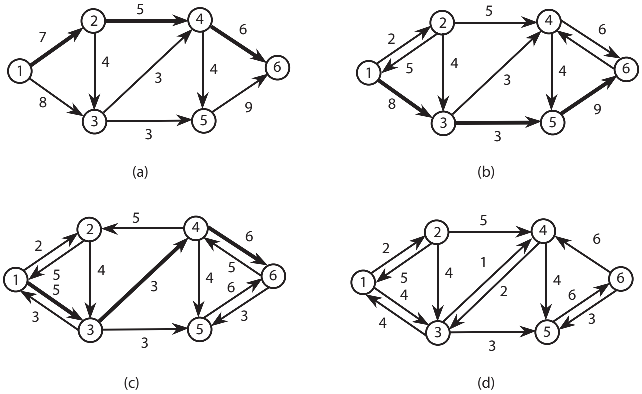
Examples:

1. Part (a) of the following figure illustrates a network G with capacities shown next to each arc. A feasible flow from vertex $s = 1$ to vertex $t = 4$ is displayed in part (b); this flow has value $v = x_{12} + x_{13} = 3$. Every path in G from s to t contains a saturated arc: paths $[1,2,4]$ and $[1,2,3,4]$ have the saturated arc $(1,2)$, and path $[1,3,4]$ has the saturated arc $(3,4)$. Consequently, no additional flow can be pushed in the "forward" direction from s to t. Yet, the current flow x is not a maximum flow.



To find additional flow from s to t, the residual network $G(x)$ is constructed; see part (c) of the figure. An augmenting path in part (c) is $P = [1,3,2,4]$ with (residual) capacity $\delta = 1$. Adding the flow on P to that in part (b) produces the new flow x' in part (d); notice that the flow on arc $(2,3)$ in x has been canceled in this process. The resulting flow x' has flow value $v = 4$. Since the s-t cut $[S,\overline{S}]$ with $S = \{1,2,3\}$ has capacity $u_{24} + u_{34} = 4 = v$, the flow x' is a maximum flow and $S = \{1,2,3\}$ defines a cut having minimum capacity.

2. The following figure illustrates three iterations of the augmenting path algorithm (Algorithm 1). Part (a) of the figure shows a network with capacities indicated on each arc. Here $s = 1$ and $t = 6$. Initially the flow $x = 0$, so the residual network is identical to the original network with $r_{ij} = u_{ij}$ for every arc (i,j).



Suppose that the algorithm identifies path $P^1 = [1,2,4,6]$ as the augmenting path. The algorithm augments $\delta = \min\{r_{12}, r_{24}, r_{46}\} = \min\{7,5,6\} = 5$ units of flow along P^1. This augmentation changes the residual capacities only of arcs in P^1 (or their reverse arcs), yielding the new residual network in part (b).

In the second iteration, suppose the algorithm identifies path $P^2 = [1,3,5,6]$ as the next augmenting path. Then flow is increased by $\delta = \min\{8,3,9\} = 3$ units along P^2; part (c) shows the residual network after the second augmentation.

A third augmentation with $\delta = 1$ occurs along path $P^3 = [1,3,4,6]$ in part (c), giving the residual network shown in part (d).

3. The following figure illustrates three iterations of the preflow-push algorithm on the flow network with capacities given in part (a). Here $s = 1$ and $t = 4$; in addition, the pair $(e(i), d(i))$ is shown beside each vertex i. Part (b) of the figure gives $G(x)$ corresponding to the initial preflow x with $x_{12} = 2$ and $x_{13} = 4$.

Suppose that the algorithm selects vertex 2 for the push/relabel operation. Then arc $(2,4)$ is the only admissible arc and the algorithm pushes $\delta = \min\{e(2), r_{24}\} = \min\{2,1\} = 1$ unit along this arc; part (c) gives the residual network at this stage.

Suppose that the algorithm again selects vertex 2. Since no admissible arc emanates from this vertex, the algorithm performs a relabel operation and gives vertex 2 a new distance label: $d(2) = \min\{d(3)+1, d(1)+1\} = \min\{2,5\} = 2$. The new residual network is the same as the one shown in part (c) except that $d(2) = 2$ instead of 1.

In the third iteration, suppose that vertex 3 is selected. Then $\delta = \min\{e(3), r_{34}\} = \min\{4,5\} = 4$ units are pushed along the arc $(3,4)$; part (d) gives the residual network at the end of this iteration.

10.4.3 APPLICATIONS

A variety of applied problems can be modeled using maximum flows or minimum cuts. The max-flow min-cut theorem (§10.4.1, Fact 10) can also be used to deduce a number of max-min duality results in combinatorial theory. This section discusses a number of such applications.

Applications:

1. *Distribution network*: Oil needs to be shipped from a refinery to a storage facility using the pipelines of an underlying distribution network. Here the refinery corresponds to a particular vertex s in the distribution network, and the storage facility corresponds to another vertex t. The capacity of each arc is the maximum amount of oil per unit time that can flow along it. The maximum flow rate from the source vertex s to the sink vertex t is determined by the value of a maximum s-t flow.

2. Other examples of Application 1 occur in transportation networks, electrical power networks, and telecommunication networks.

3. *System of distinct representatives*: Given is a collection of sets $X_1, X_2, \ldots, X_m$ which are subsets of a given n-set X. A system of distinct representatives (§1.2.2) for the collection is sought, if one exists.

To solve this problem, set up the bipartite network $(V_1 \cup V_2, E)$ in which there is a vertex of V_1 for each set X_i and a vertex of V_2 for each element of X. An arc (i,j) of infinite capacity joins $i \in V_1$ to $j \in V_2$ if $j \in X_i$. Add a source vertex s joined by arcs of unit capacity to each $i \in V_1$, and a sink vertex t with arcs of unit capacity joining each $j \in V_2$ to t. Then a system of distinct representatives exists if and only if the maximum flow in this constructed network has value m. In this case, those arcs (i,j), with $i \in V_1$ and $j \in V_2$, having flow $x_{ij} = 1$ identify a system of distinct representatives selected from the m sets.

4. *Feasible flow problem*: This problem involves finding a flow x in $G = (V, E)$ so that the net flow at each vertex is a specified value $b(i)$, where $\sum_{i \in V} b(i) = 0$. That is, a flow x on the arcs of network G is required, satisfying

- *mass balance constraints*: $\sum\limits_{\{j \mid (i,j) \in E\}} x_{ij} - \sum\limits_{\{j \mid (j,i) \in E\}} x_{ji} = b(i)$ for all $i \in V$;
- *capacity constraints*: $0 \le x_{ij} \le u_{ij}$ for all $(i,j) \in E$.

This can be modeled as a maximum flow problem. Construct the augmented network G' by adding a source vertex s and a sink vertex t to G. For each vertex i with $b(i) > 0$, an arc (s,i) is added to E with capacity $b(i)$; for each vertex i with $b(i) < 0$, an arc (i,t) is added to E with capacity $-b(i)$. Then solve a maximum flow problem from vertex s to vertex t in G'. It can be proved that the feasible flow problem for G has a solution if and only if the maximum flow in G' saturates all arcs emanating from vertex s in G'.

5. Application 4 frequently arises in distribution problems. For example, a known amount of merchandise is available at certain ports and is required at other ports in known quantities. Also the maximum quantity of merchandise that can be shipped on a particular sea route is specified. Determining whether it is possible to satisfy all of the demands by using the available supplies is a feasible flow problem.

6. *Graph connectivity*: In a directed graph G, the *arc connectivity* κ'_{ij} of vertices i and j is the minimum number of arcs whose removal from G leaves no directed path from i to j. The *arc connectivity* $\kappa'(G)$ is the minimum number of arcs whose removal from G separates some pair of vertices (see §8.4.2). The arc connectivity of a graph is an important measure of the graph's reliability or stability. Since $\kappa'(G) = \min\{\kappa'_{ij} \mid (i,j) \in V \times V, i \neq j\}$, the arc connectivity of a graph can be computed by determining the arc connectivity of $n(n-1)$ pairs of vertices. As a matter of fact, the arc connectivity of G can be found by determining only $n-1$ arc connectivities.

The arc connectivity κ'_{ij} can be found by applying the max-flow min-cut theorem (§10.4.1) to the network obtained from G by setting the capacity of each arc (i,j) to 1. In such a unit capacity network, the maximum i-j flow value equals the maximum number of arc-disjoint paths from vertex i to vertex j, and the minimum i-j cut capacity equals the minimum number of arcs required to separate vertex i and vertex j. This shows that the maximum number of arc-disjoint paths from vertex i to vertex j equals the minimum number of arcs whose removal disconnects all paths from vertex i to vertex j. (This result is a variation of Menger's theorem in §8.4.2; it was independently discovered by

Ford and Fulkerson and by Elias, Feinstein, and Shannon.) Consequently, κ'_{ij} equals the maximum i-j flow value in the network, and the arc connectivity $\kappa'(G)$ can be determined by solving $n-1$ maximum flow problems in a unit capacity network.

7. *Tournaments*: Consider a round-robin tournament between n teams, assuming each team plays against every other team c times and no game ends in a draw. It is claimed that α_i for $1 \le i \le n$ is the number of victories accrued by the ith team at the end of the tournament. Verifying whether the nonnegative integers $\alpha_1, \alpha_2, \ldots, \alpha_n$ are possible winning records for the n teams can be modeled as a feasible flow problem.

Define a directed network $G = (V, E)$ with vertex set $V = \{1, 2, \ldots, n\}$ and arc set $E = \{(i, j) \in V \times V \mid i < j\}$. Let x_{ij}, $i < j$, represent the number of times team i defeats team j. The total number of times team i defeats teams $i+1, i+2, \ldots, n$ is $\sum_{\{j|(i,j)\in E\}} x_{ij}$. Since the number of times team i defeats a team $j < i$ is $c - x_{ji}$, it follows that the total number of times that team i defeats teams $1, 2, \ldots, i-1$ is $(i-1)\,c - \sum_{\{j|(j,i)\in E\}} x_{ji}$. However, there are two constraints:

- The total number of wins α_i of team i must equal the total number of times it defeats teams $1, 2, \ldots, n$, giving

$$\sum_{\{j|(i,j)\in E\}} x_{ij} - \sum_{\{j|(j,i)\in E\}} x_{ji} = \alpha_i - (i-1)c \;\text{ for all } i \in V;$$

- A possible winning record must also satisfy $0 \le x_{ij} \le c$ for all $(i, j) \in E$.

Consequently, $\{\alpha_i\}$ define a possible winning record if these two constraints have a feasible solution x. Let $b(i) = \alpha_i - (i-1)c$. Since $\sum_{i\in V} \alpha_i$ and $\sum_{i\in V} (i-1)c$ are both equal to $\frac{cn(n-1)}{2}$, the total number of games played, it follows that $\sum_{i\in V} b(i) = 0$. The problem of finding a feasible solution to the two constraints is then a feasible flow problem.

8. *Matchings and covers*: The max-flow min-cut theorem can also be used to prove a max-min result concerning matchings and covers in a directed bipartite graph $G = (V_1 \cup V_2, E)$. (See §8.1.3.) The subset $E' \subseteq E$ is a *matching* (§10.2.1) if no two arcs in E' are incident with the same vertex. The subset $V' \subseteq V_1 \cup V_2$ is a *vertex cover* if every arc in E is incident to at least one vertex in V'. Create the network G' from G by adding vertices s and t, as well as arcs (s, i) with capacity 1 for all $i \in V_1$ and arcs (j, t) with capacity 1 for all $j \in V_2$. All other arcs of G' correspond to arcs of G and have infinite capacity. Then each matching of cardinality v defines a flow of value v in G', and each s-t cut of capacity v induces a corresponding vertex cover with v vertices. Application of the max-flow min-cut theorem establishes the desired result. Namely, in a bipartite graph $G = (V_1 \cup V_2, E)$, the maximum cardinality of any matching equals the minimum cardinality of any vertex cover of G.

9. *0-1 matrices*: Suppose $A = (a_{ij})$ is a 0-1 matrix. Associate with A the directed bipartite graph $G = (V_1 \cup V_2, E)$, where V_1 is the set of row indices and V_2 is the set of column indices. Place an arc $(i, j) \in E$ whenever $a_{ij} = 1$. A matching in G now corresponds to a set of "independent" 1s in the matrix A: i.e., no two of these 1s are in the same row or the same column. Also, a vertex cover of G corresponds to a set of rows and columns in A that collectively cover all the 1s in the matrix. Applying the result in Application 8 shows that the maximum number of independent 1s in A equals the minimum number of lines (rows and/or columns) needed to cover all the 1s in A. This result is known as König's theorem (§6.6.1).

10.5 MINIMUM COST FLOWS

The minimum cost flow problem involves determining the least cost shipment of a commodity through a capacitated network in order to satisfy demands at certain vertices using supplies available at other vertices. This problem generalizes both the shortest path problem (§10.3) and the maximum flow problem (§10.4).

10.5.1 BASIC CONCEPTS

Definitions:

Let $G = (V, E)$ be a directed network with vertex set V and arc set E (see §10.3.1). Each arc $(i, j) \in E$ has an associated ***cost*** c_{ij} and a ***capacity*** $u_{ij} \geq 0$. Let $n = |V|$ and $m = |E|$.

Each vertex $i \in V$ has an associated supply/demand $b(i)$. If $b(i) > 0$, then vertex i is a ***supply vertex***; if $b(i) < 0$, then vertex i is a ***demand vertex***.

A (***feasible***) ***flow*** is a function $x = (x_{ij})$ defined on arcs $(i, j) \in E$ satisfying

- *mass balance constraints*: $\sum\limits_{\{j|(i,j)\in E\}} x_{ij} - \sum\limits_{\{j|(j,i)\in E\}} x_{ji} = b(i)$ for all $i \in V$,
- *capacity constraints*: $0 \leq x_{ij} \leq u_{ij}$ for all $(i, j) \in E$,

where $\sum\limits_{i\in V} b(i) = 0$.

The ***cost*** of flow x is $\sum\limits_{(i,j)\in E} c_{ij}x_{ij}$.

A ***minimum cost flow*** is a flow having minimum cost.

A ***pseudoflow*** is a function $x = (x_{ij})$ satisfying the arc capacity constraints; it may violate the mass balance constraints.

The ***residual network*** $G(x)$ corresponding to a flow (or pseudoflow) x is defined in the following manner. Replace each arc $(i, j) \in E$ by two arcs (i, j) and (j, i). Arc (i, j) has cost c_{ij} and ***residual capacity*** $r_{ij} = u_{ij} - x_{ij}$, and arc (j, i) has cost $-c_{ij}$ and ***residual capacity*** $r_{ji} = x_{ij}$. The residual network consists only of arcs with positive residual capacity.

The ***potential*** of vertex i is a quantity $\pi(i)$ associated with the mass balance constraint at vertex i. With respect to a given set of vertex potentials, the ***reduced cost*** of an arc (i, j) in the residual network $G(x)$ is $c^\pi_{ij} = c_{ij} - \pi(i) + \pi(j)$.

The ***cost*** of path P in $G(x)$ is $c(P) = \sum\limits_{(i,j)\in P} c_{ij}$; its ***reduced cost*** is $c^\pi(P) = \sum\limits_{(i,j)\in P} c^\pi_{ij}$.

A ***negative cycle*** is a directed cycle W in $G(x)$ for which $c(W) < 0$.

Facts:

1. The mass balance constraints ensure that the net flow out of each vertex i is equal to $b(i)$. Thus, if there is excess flow out of vertex i, then $b(i) > 0$ and i is a supply vertex. If $b(i) < 0$, then more flow enters i than leaves i, meaning that vertex i is a demand vertex.

2. Minimum cost flows arise in practical problems involving the least cost routing of goods, vehicles, and messages in a network. Minimum cost flows can also be used in models of warehouse layout, production and inventory problems, scheduling of personnel, automatic classification of chromosomes, and racial balancing of schools. (See §10.5.3.)

3. Let $\{\pi(i) \mid i \in V\}$ be any set of vertex potentials.

- If P is a path from i to j in $G(x)$, then $c^\pi(P) = c(P) - \pi(i) + \pi(j)$.
- If W is a cycle in $G(x)$, then $c^\pi(W) = c(W)$.

4. *Negative cycle optimality conditions*: A feasible flow x is a minimum cost flow if and only if the residual network $G(x)$ contains no negative cycle.

5. *Reduced cost optimality conditions*: A feasible flow x is a minimum cost flow if and only if some set of vertex potentials π satisfies $c^\pi_{ij} \geq 0$ for every arc (i, j) in $G(x)$.

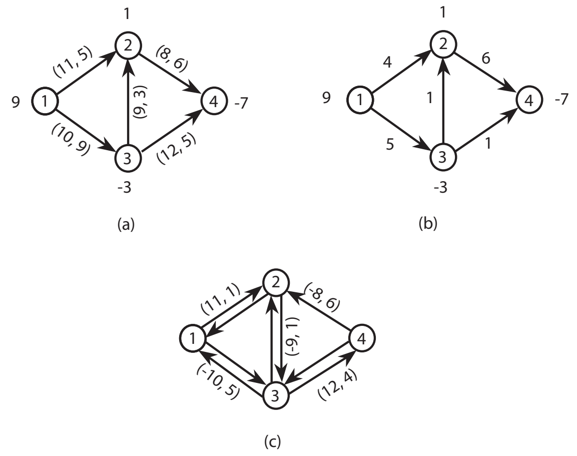
6. *Complementary slackness optimality conditions*: A feasible flow x is a minimum cost flow if and only if there exist vertex potentials π such that for every arc $(i, j) \in E$

- if $c^\pi_{ij} > 0$, then $x_{ij} = 0$;
- if $c^\pi_{ij} < 0$, then $x_{ij} = u_{ij}$;
- if $0 < x_{ij} < u_{ij}$, then $c^\pi_{ij} = 0$.

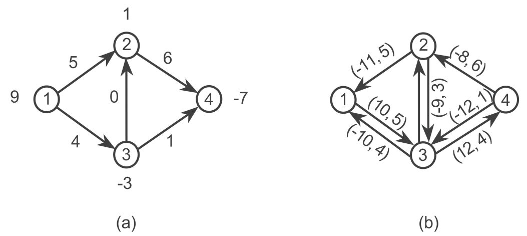
Examples:

1. In the flow network of part (a) of the following figure, $b(i)$ is shown next to each vertex i and (c_{ij}, u_{ij}) is shown next to each arc (i, j).

The function $x = (x_{ij})$ given in part (b) satisfies the mass balance constraints for each vertex. For example, the flow out of vertex 2 is $x_{24} = 6$ and the flow into vertex 2 is $x_{12} + x_{32} = 5$, so that flow out minus flow in equals $6 - 5 = 1 = b(2)$. Also the capacity constraints for all arcs are satisfied: e.g., $x_{12} = 4 \leq 5 = u_{12}$. Thus x is a feasible flow, with cost 163. The residual network $G(x)$ corresponding to the flow x is shown in part (c). Selected arcs of $G(x)$ are labeled with their cost and residual capacity. The directed cycle $W = [1, 2, 3, 1]$ in $G(x)$ has cost $11 - 9 - 10 = -8$ and so W is a negative cycle. By Fact 4, this flow x is not a minimum cost flow.



2. Part (a) of the following figure shows another feasible flow x' for the network in Example 1, with cost 155.



The corresponding residual network $G(x')$ is given in part (b), in which each arc is labeled with its cost and its residual capacity. Using the vertex potentials $\pi = (0, -14, -10, -22)$, the reduced cost of arc $(2,1)$ in the residual network is $c_{21}^{\pi} = -11-(-14)+0 = 3$; likewise $c_{32}^{\pi} = 9 - (-10) - 14 = 5$. The remaining reduced costs are found to be zero, so $c_{ij}^{\pi} \geq 0$ for all arcs (i,j) in $G(x)$. By Fact 5, x' is a minimum cost flow for the given network.

3. Alternatively, the optimality of the flow x' in part (a) of the figure for Example 2 can be verified using Fact 6. As in Example 2, let $\pi = (0, -14, -10, -22)$. Arc $(3,2)$ of the original network G in part (a) of the figure of Example 1 has positive reduced cost $c_{32}^{\pi} = 9 - (-10) - 14 = 5$ and $x'_{32} = 0$. Arc $(1,2)$ has $c_{12}^{\pi} = 11 - 0 - 14 = -3 < 0$ and $x'_{12} = u_{12}$. The remaining arcs $(1,3), (2,4), (3,4)$ have zero reduced cost. Consequently, the complementary slackness optimality conditions are satisfied and the flow x' achieves the minimum cost.

10.5.2 ALGORITHMS FOR MINIMUM COST FLOWS

A variety of algorithms are available to solve the minimum cost flow problem. Three algorithms are described in this section: the cycle-canceling algorithm, the successive shortest path algorithm, and the network simplex algorithm.

Definitions:

Let $G = (V, E)$ be a directed network with $n = |V|$ and $m = |E|$; let U denote the largest arc capacity and let C denote the largest arc cost (in absolute value) in G.

For a given pseudoflow $x = (x_{ij})$, the ***imbalance*** of vertex $i \in V$ is $e(i) = b(i) + \sum\limits_{\{j \mid (j,i) \in E\}} x_{ji} - \sum\limits_{\{j \mid (i,j) \in E\}} x_{ij}$.

An ***excess vertex*** is one with a positive imbalance, and a ***deficit vertex*** is one with a negative imbalance.

A ***spanning tree solution*** $x = (x_{ij})$ consists of a spanning tree T of $G = (V, E)$ in which each nontree arc (i, j) has either $x_{ij} = 0$ or $x_{ij} = u_{ij}$.

A spanning tree solution is ***feasible*** if the mass balance constraints and capacity constraints are satisfied.

Facts:

1. *Cycle-canceling algorithm*: The cycle-canceling algorithm (Algorithm 1) is based on the negative cycle optimality conditions (§10.5.1, Fact 4). It starts with a feasible flow and successively augments flow along negative cycles in the residual network until there is no negative cycle.

Algorithm 1: **Cycle-canceling algorithm.**

```
input: directed network $G$
output: minimum cost flow $x$
establish a feasible flow $x$ in the network
while $G(x)$ contains a negative cycle
   identify a negative cycle $W$
   $\delta := \min\{r_{ij} \mid (i,j) \in W\}$
   augment $\delta$ units of flow along $W$ and update $G(x)$
recover an optimal flow $x$ from the final residual network $G(x)$
```

2. As shown in §10.4.3, an initial feasible flow can be found by solving a maximum flow problem.

3. *Integrality property*: For problems with integer arc capacities and integer vertex supplies/demands, Algorithm 1 starts with an integer flow, at each iteration augments by an integral amount of flow, and thus produces an optimal flow that is integer. Thus any minimum cost flow problem with integer supplies, demands, and capacities always has an optimal solution that is integer.

4. A negative cycle W in the residual network can be identified in $O(nm)$ time by using a queue implementation of the label-correcting algorithm (§10.3.2, Fact 5).

5. Augmenting the flow along W by δ decreases the residual capacities of arcs in W by δ and increases the residual capacities of the reversals of arcs in W by δ.

6. Upon termination of Algorithm 1, an optimal flow x can be reconstructed from the final $G(x)$; see §10.4.2, Fact 10.

7. For problems with integer supplies, demands, and arc capacities, the cycle-canceling algorithm runs in pseudopolynomial time $O(nm^2CU)$.

8. If flow is augmented along a negative cycle W in $G(x)$ that minimizes the ratio $\frac{1}{|W|}\sum_{(i,j)\in W} c_{ij}$ among all directed cycles in $G(x)$, then this implementation runs in polynomial time [GoTa88].

9. *Successive shortest path algorithm*: The successive shortest path algorithm (Algorithm 2) starts with the pseudoflow $x = 0$. It proceeds by selecting an excess vertex k and a deficit vertex l, and then augmenting flow along a minimum cost path from vertex k to vertex l in $G(x)$.

```
Algorithm 2: Successive shortest path algorithm.
  input: directed network $G$
  output: minimum cost flow $x$
  $x := 0$
  $e(i) := b(i)$ for all $i \in V$
  initialize $V^+ := \{i \mid e(i) > 0\}$ and $V^- := \{i \mid e(i) < 0\}$
  while $V^+ \neq \emptyset$
    select a vertex $k \in V^+$ and a vertex $l \in V^-$
    identify a shortest path $P$ in $G(x)$ from vertex $k$ to vertex $l$
    $\delta := \min\{e(k), -e(l), \min\{r_{ij} \mid (i,j) \in P\}\}$
    augment $\delta$ units of flow along $P$
    update $e$, $G(x)$, $V^+$, and $V^-$
  recover an optimal flow $x$ from the final residual network $G(x)$
```

10. If in Algorithm 2 reduced costs c^π_{ij} are used instead of arc costs c_{ij}, then Dijkstra's algorithm (§10.3.2, Algorithm 2) can be applied to determine a shortest path P in the residual network.

11. Augmenting the flow along P by δ decreases the residual capacities of arcs in P by δ and increases the residual capacities of the reversals of arcs in P by δ. It also decreases $e(k)$ by δ and increases $e(l)$ by δ.

12. The solution maintained by the successive shortest path algorithm always satisfies the reduced cost optimality conditions (§10.5.1, Fact 5). The final solution is in addition feasible, and so is an optimal solution of the minimum cost flow problem.

13. For problems with integer supplies, demands, and arc capacities, the shortest augmenting path algorithm runs in pseudopolynomial time.

14. Several implementations of the shortest augmenting path algorithm run in polynomial or even strongly polynomial time. Orlin [Or88] describes an implementation running in $O(m \log n(m+n \log n))$ time, currently the fastest strongly polynomial-time algorithm to solve the minimum cost flow problem.

15. If a minimum cost flow problem has an optimal solution, then it has an optimal spanning tree solution.

16. Given a spanning tree solution x, with flows on nontree arcs (i,j) specified (at either 0 or u_{ij}), the flows on the tree arcs are uniquely determined by the mass balance constraints.

17. Given a spanning tree solution x, vertex potentials π can be determined such that

- $\pi(1) = 0$;
- $c^\pi_{ij} = 0$ for all tree arcs (i,j).

18. *Complementary slackness optimality conditions*: Suppose x is a feasible spanning tree solution with vertex potentials determined as in Fact 17. Then x is a minimum cost flow if

- $c^{\pi}_{ij} \geq 0$ for all nontree arcs (i,j) with $x_{ij} = 0$;
- $c^{\pi}_{ij} \leq 0$ for all nontree arcs (i,j) with $x_{ij} = u_{ij}$.

19. *Network simplex algorithm*: The network simplex algorithm (Algorithm 3) is a specialized version of the well-known linear programming simplex method (§16.1.3). It maintains a spanning tree solution and at each iteration transforms the current spanning tree solution into an improved spanning tree solution until optimality is reached.

```
Algorithm 3: Network simplex algorithm.
  input: directed network $G$
  output: minimum cost flow $x$
  determine an initial spanning tree solution with associated tree $T$
  let $x$ be the flow and $\pi$ the corresponding vertex potentials
  while a nontree arc violates the complementary slackness optimality conditions
     select an entering arc $(k,l)$ violating its optimality condition
     add arc $(k,l)$ to $T$, augment the maximum possible flow in the cycle thus
           created, and determine the leaving arc $(p,q)$
     update the tree $T$, the flow $x$, and the vertex potentials $\pi$
```

20. Using appropriate data structures, the network simplex algorithm can be implemented very efficiently. The network simplex algorithm is one of the fastest algorithms to solve the minimum cost flow problem in practice.

21. The network simplex algorithm has a exponential worst-case time bound. Orlin [Or97] provided the first polynomial-time implementations of the (generic) network simplex algorithm.

22. Detailed descriptions of Algorithms 1–3, as well as several other algorithms for finding minimum cost flows, can be found in [AhMaOr93].

23. Computer codes for solving the minimum cost flow problem can be found at

- `http://www.avglab.com/andrew/soft.html`
- `http://lemon.cs.elte.hu/trac/lemon`

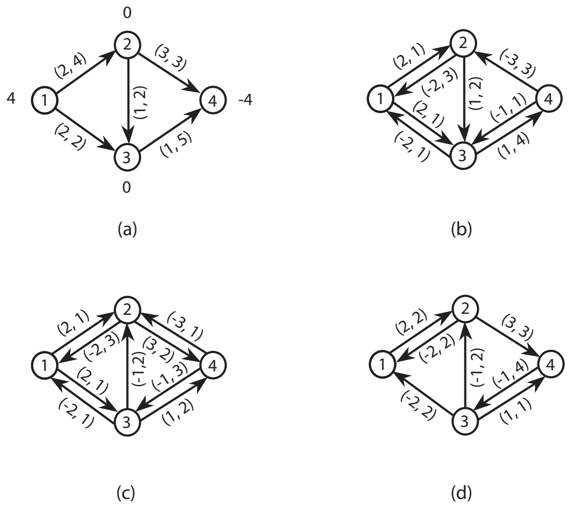
Examples:

1. The following figure illustrates the cycle-canceling algorithm. Part (a) of this figure depicts the given flow network, with $b(i)$ shown for each vertex i and (c_{ij}, u_{ij}) for each arc (i,j). Part (b) shows the residual network corresponding to the flow $x_{12} = x_{24} = 3$ and $x_{13} = x_{34} = 1$.

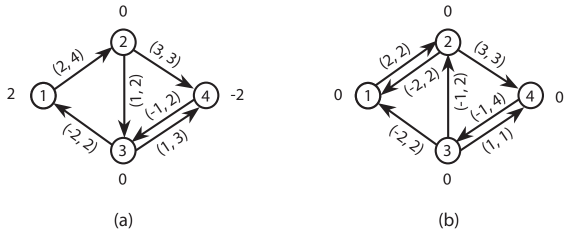
In the first iteration, suppose the algorithm selects the negative cycle $[2,3,4,2]$ with cost -1. Then $\delta = \min\{r_{23}, r_{34}, r_{42}\} = \min\{2,4,3\} = 2$ units of flow are augmented along this cycle. Part (c) shows the modified residual network.

In the next iteration, the algorithm selects the cycle $[1,3,4,2,1]$ with cost -2 and augments $\delta = 1$ unit of flow. Part (d) depicts the updated residual network which contains no negative cycle, so the algorithm terminates. From part (d), an optimal flow pattern is deduced: $x_{12} = x_{13} = x_{23} = 2$ and $x_{34} = 4$.

2. The successive shortest path algorithm is illustrated using the flow network in part (a) of the figure for Example 1. The initial residual network $G(x)$ for $x = 0$ is the same as



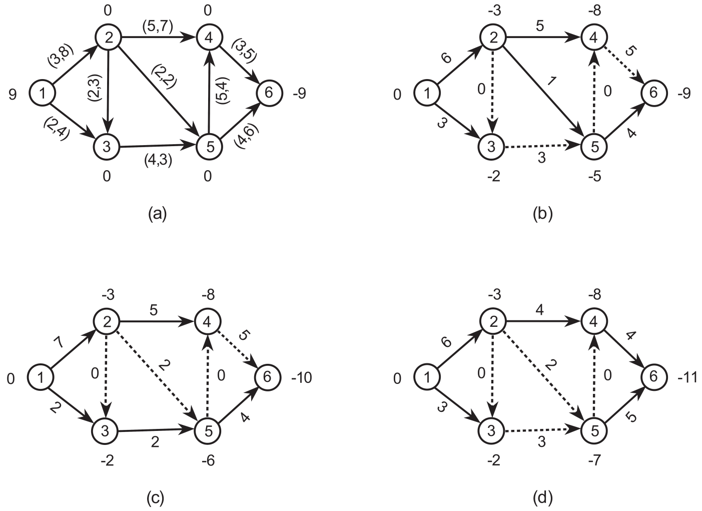
that of part (a). Initially, the imbalances are $e = (4, 0, 0, -4)$, so that $V^+ = \{1\}$ and $V^- = \{4\}$, giving $k = 1$ and $l = 4$. The shortest path from vertex 1 to 4 in $G(x)$ is $[1, 3, 4]$, and the algorithm augments $\delta = 2$ units of flow along this path. The following figure shows the residual network after this augmentation, as well as the updated imbalance at each vertex.



The sets V^+ and V^- do not change, so again $k = 1$ and $l = 4$. The shortest path from vertex 1 to vertex 4 is now $[1, 2, 3, 4]$, and the algorithm augments $\delta = 2$ units of flow along this path. Part (b) of the figure shows the resulting residual network. Now $V^+ = V^- = \emptyset$ and the algorithm terminates.

3. The following figure illustrates the network simplex algorithm. Part (a) of this figure depicts the given flow network, with $b(i)$ shown for each vertex i and (c_{ij}, u_{ij}) for each arc (i, j).

A feasible spanning tree solution is shown in part (b) of the figure; each nontree arc (dashed line) has flow at either its lower or upper bound. The unique flows on the tree arcs (solid lines) are determined by the mass balance constraints. A set of vertex potentials (obtained using Fact 17) are also shown in part (b). Relative to these potentials π, the reduced costs for the nontree arcs are given by $c^{\pi}_{23} = 2 - (-3) - 2 = 3$, $c^{\pi}_{35} = 4 - (-2) - 5 = 1$, $c^{\pi}_{54} = 5 - (-5) - 8 = 2$, and $c^{\pi}_{46} = 3 - (-8) - 9 = 2$. Since arc $(3, 5)$, with flow at its upper bound, violates the optimality conditions of Fact 18, it is added to the current tree producing the cycle $[1, 2, 5, 3, 1]$. The maximum flow that can be sent along this cycle without violating the capacity constraints is 1 unit, which forces the flow on arc $(2, 5)$ to its upper bound. Arc $(2, 5)$ is then removed from the current tree and arc $(3, 5)$ is added to the current tree.



Part (c) of the figure gives the new flow as well as the new vertex potentials. Since $c^{\pi}_{46} = 3 - (-8) - 10 = 1$, arc $(4,6)$ is added to the spanning tree, forming the cycle $[1,3,5,6,4,2,1]$. The maximum flow that can be sent along this cycle without violating the capacity constraints is 1 unit, which forces arc $(3,5)$ out of the tree.

Part (d) gives the new flow as well as the new vertex potentials. Since the complementary slackness optimality conditions are satisfied, the current flow is optimal.

10.5.3 APPLICATIONS

Minimum cost flow problems arise in many industrial settings and scientific domains, often in the form of distribution or routing problems. The minimum cost flow problem also has less transparent applications, several of which are presented in this section.

Applications:

1. *Distribution*: A common application of the minimum cost flow problem involves the distribution at minimum cost of a product from manufacturing plants (with known supplies) to warehouses (with known demands). A similar scenario applies to the distribution of goods from warehouses to retailers as well as the flow of raw materials and intermediate goods through various machining stations in a production line.

2. *Routing*: The routing of cars through an urban street network and the routing of calls through a telephone system can be modeled using minimum cost flows. In either case, the items (cars, calls) must be sent from certain specified origins to other specified destinations, with capacity constraints on the total flow on each arc (road, communication link). This is done to minimize total (or average) delay in the system.

3. *Directed Chinese postman problem*: Leaving from the post office, a mail carrier needs to visit all houses on a postal route, delivering and collecting letters, and then return to the post office. The carrier would like to cover this route by traveling the minimum possible distance. (See also §8.4.3.) In this variation, known as the *directed Chinese postman problem*, each street is assumed to be directed, so the problem is defined on a directed network $G = (V, E)$ whose arcs (i, j) have an associated nonnegative length c_{ij}. It is desired to find a directed walk (§8.3.2) of minimum length that starts at some vertex (the post office), visits each arc of the network at least once, and returns to the starting vertex. In an optimal walk, some arcs may be traversed more than once. If x_{ij} represents the number of times arc (i, j) is traversed, then this problem can be formulated as

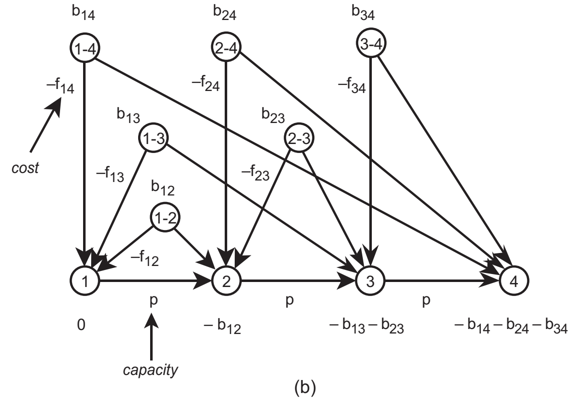
$$\begin{array}{rl}\text{minimize:} & \sum\limits_{(i,j)\in E} c_{ij}x_{ij} \\ \text{subject to:} & \sum\limits_{\{j|(i,j)\in E\}} x_{ij} - \sum\limits_{\{j|(j,i)\in E\}} x_{ji} = 0 \text{ for all } i \in V, \\ & x_{ij} \geq 1 \text{ for all } (i,j) \in E.\end{array}$$

This problem is a minor variant of the minimum cost flow problem where each arc has a lower bound of one unit of flow. From an optimal flow x^* for this problem, an optimal tour can be constructed in the following manner. First, replace each arc (i, j) with x^*_{ij} copies of the arc, each carrying a unit flow. Next, decompose the resulting network into a set of directed cycles. Finally, connect the directed cycles to form a closed walk.

4. *Optimal loading of a hopping airplane*: A small commuter airline uses a plane with capacity of at most p passengers on a "hopping flight", as shown in part (a) of the following figure. The flight visits the cities $1, 2, 3, \ldots, n$ in a fixed sequence. The plane can pick up passengers at any city and drop them off at any other city. Let b_{ij} denote the number of passengers available at city i who want to go to city j, and let f_{ij} denote the fare per passenger from city i to city j. The airline would like to determine the number of passengers that the plane should carry between various origins and destinations in order to maximize the total fare per trip while never exceeding the capacity of the plane.

Part (b) of the following figure shows a minimum cost flow formulation of this hopping plane flight problem. The network displays data only for those arcs with nonzero cost or finite capacity. Any arc without a displayed cost has zero cost; any arc without a displayed capacity has infinite capacity. For example, three types of passengers are available at vertex 1: those whose destination is vertex 2, vertex 3, or vertex 4. These three types of passengers are represented by the vertices 1-2, 1-3, and 1-4 with supplies b_{12}, b_{13}, and b_{14}. A passenger available at any such vertex, say 1-3, either boards the plane at its origin vertex by flowing through the arc $(1\text{-}3, 1)$, thus incurring a cost of $-f_{13}$ units, or never boards the plane, represented by flowing through the arc $(1\text{-}3, 3)$.

(a)



(b)

5. *Leveling mountainous terrain*: In building road networks through hilly or mountainous terrain, civil engineers must determine how to distribute earth from high points to low points of the terrain to produce a leveled roadbed. To model this, construct a *terrain graph*, an undirected graph G whose vertices represent locations with a demand for earth (low points) or locations with a supply of earth (high points). An edge of G indicates an available route for distributing the earth, and the cost of this edge is the cost per truckload of moving earth between the corresponding two locations. The following figure shows a portion of a sample terrain graph. A leveling plan for a terrain graph is a flow (set of truckloads) that meets the demands at vertices (levels the low points) by the available supplies (earth obtained from high points) at minimum trucking cost. This can be solved as a minimum cost flow problem on the terrain graph.

10.6 COMMUNICATION NETWORKS

Modern communication networks consist of two main components. Using high-capacity links, the backbone network interconnects switching centers and gateway vertices that carry and direct traffic through the communication system. Local access networks transfer traffic between the backbone network and the end users. This section presents several optimization models used in the design of such communication networks.

10.6.1 CAPACITATED MINIMUM SPANNING TREE PROBLEM

The capacitated minimum spanning tree problem arises in the design of local access tree networks in which end users generate and retrieve data from other sources, always through a specified control center (e.g., a communication switch of the backbone network). In this problem, user sites are to be interconnected at minimum cost by means of subtrees, which are in turn connected to the control center. The total traffic in each subtree is limited by a capacity constraint.

Definitions:

Let $N = \{1, 2, \ldots, n\}$ be a set of ***terminals*** and let 0 denote a specified ***control center***. The complete undirected graph $G = (V, E)$ has vertex set $V = N \cup \{0\}$ and contains all possible edges between distinct vertices of V (§8.1.3).

The ***cost*** of connecting distinct vertices $i, j \in V$ is $c_{ij} = c_e$, where $e = (i, j) \in E$.

The ***demand*** w_i at vertex $i \in N$ is the amount of traffic to be transmitted to the control center.

Relative to a spanning tree T (§9.2.1) of G, vertex j is a ***root vertex*** if it is adjacent to vertex 0. Vertex i is ***assigned*** to root vertex j if j is on the unique path in T joining i to the control center. The set of all vertices assigned to j defines the ***subtree*** T_j of T. This subtree has ***demand*** $D(T_j) = \sum\limits_{i \in T_j} w_i$.

A ***capacitated minimum spanning tree*** (***CMST***) is a spanning tree T of G composed of subtrees $T_{j_1}, T_{j_2}, \ldots, T_{j_r}$ such that

- $\sum\limits_{e \in T} c_e$ is minimum;
- the demand in each T_j is at most Q, a specified capacity.

For $j \in N$, let $y_j \in \{0, 1\}$ indicate whether vertex j is a root vertex.

For $i, j \in N$, let $x_{ij} \in \{0, 1\}$ indicate whether vertex i is assigned to root vertex j, and let $z_{ij} \in \{0, 1\}$ indicate whether edge (i, j) belongs to the spanning tree T.

Given a vector z, the subgraph $G(N, E_z)$ of G ***induced by z*** has vertex set N and edges $e \in E_z$ if $z_e > 0$. Similarly, given a vector (z, y), the subgraph ***induced by*** $(\boldsymbol{z}, \boldsymbol{y})$, written $G(V, E_{zy})$, has vertex set V; it contains every edge of E_z plus each edge from j to 0 where $y_j > 0$.

Relative to a given vector z, $C(i, j)$ denotes the set of all ***i-j cuts*** $[S, \overline{S}]$ in the graph $G(N, E_z)$. (See §10.4.1.)

If $S \subseteq V$, then $E(S) = \{(i,j) \in E \mid i,j \in S\}$ contains all edges between vertices of S.

For $I \subset N$, let $b(I)$ be the minimum number of subtrees needed to pack all terminals in I. That is, $b(I)$ is the optimal solution to the ***bin packing problem*** (§16.3.2) with bins of capacity Q and items of size w_i for every $i \in I$.

A set $S \subset N$ is a ***cover*** if $\sum_{i\in S} w_i > Q$. If also $(\sum_{i\in S} w_i) - w_k \leq Q$ for all $k \in S$, then S is a ***minimal cover***.

Facts:

1. The CMST problem has the following 0-1 integer linear programming formulation (§16.1.8):

$$\begin{aligned}
\text{minimize:}\quad & \sum_{i=1}^{n-1}\sum_{j=i+1}^{n} c_{ij}z_{ij} + \sum_{j=1}^{n} c_{0j}y_j\\
\text{subject to:}\quad & \sum_{j=1}^{n} x_{ij} = 1, \text{ for all } i \in \{1,2,\ldots,n\}\\
& \sum_{i=1}^{n} w_i x_{ij} \leq Q y_j, \text{ for all } j \in \{1,2,\ldots,n\}\\
& x_{ij} \leq y_j, \text{ for all } i,j \in \{1,2,\ldots,n\}\\
& x_{ij} \leq \sum_{e\in K} z_e, \text{ for all } i,j \in \{1,2,\ldots,n\}\ (i \neq j) \text{ and for all } K \in C(i,j)\\
& \sum_{e} z_e + \sum_{j} y_j = n\\
& x_{ij} \in \{0,1\}, \text{ for all } i,j \in \{1,2,\ldots,n\}\\
& y_j \in \{0,1\}, \text{ for all } j \in \{1,2,\ldots,n\}\\
& z_{ij} \in \{0,1\}, \text{ for all } i,j \in \{1,2,\ldots,n\}\ (i \neq j).
\end{aligned}$$

2. In Fact 1,

- the first set of constraints ensures that each vertex is assigned to a root vertex;
- the second set of constraints ensures that the flow through any root vertex is no more than the capacity Q;
- the third set of constraints ensures that vertex i can be assigned to vertex j only if j is a root vertex;
- the fourth set of constraints ensures that if vertex i is assigned to root vertex j, then there must be a path between i and j;
- the fifth set of constraints guarantees that $G(V, E_{zy})$ is a tree.

3. *Savings heuristic*: This greedy heuristic (Algorithm 1) begins with n components, each a single vertex, and successively merges pairs of components to reduce the total cost by the largest amount.

4. The quantity s_{uv} computed in Algorithm 1 represents the *savings* in joining subtrees T_u and T_v to one another, compared to joining both to vertex 0.

5. The savings heuristic, developed by Esau and Williams [EsWi66], was one of the first heuristics developed for the CMST problem.

6. The savings heuristic, surprisingly effective in practice, has attracted significant attention. Relatively simple adjustments have been proposed to improve its performance while maintaining its simplicity.

- Dai and Fujino [DaFu00] use component-oriented savings computations in order to increase its efficiency;

- Bruno and Laporte [BrLa02] propose enhancements to the procedure to connect subtrees;
- Öncan and Altinel [ÖnAl09] introduce parametric improvements which control edge selections and combine distance and demand information in its savings criterion.

Algorithm 1: **Savings heuristic.**

```
input: undirected network $G$, control center 0, capacity limit $Q$
output: an approximate capacitated minimum spanning tree $T^*$
$U := \{1, 2, \ldots, n\}$
$T_u := \{u\}$ for $u \in U$
while true
  for $u \in U$
    compute $f_u$, the minimum cost of connecting the control center 0 to component $T_u$
  $S := \emptyset$
  for $u, v \in U$ $(u \neq v)$
    if $D(T_u \cup T_v) \leq Q$ then
      compute $s_{uv}$, the difference between $\max\{f_u, f_v\}$ and the minimum cost of connecting $T_u$ to $T_v$
      if $s_{uv} > 0$ then $S := S \cup \{(u, v)\}$
  if $S = \emptyset$ then return
  else
    choose $u_0, v_0$ such that $s_{u_0 v_0} = \max\{s_{uv} \mid (u, v) \in S\}$
    merge $T_{u_0}$ and $T_{v_0}$, creating a new subtree indexed by $\min\{u_0, v_0\}$, and update $U$ appropriately
```

7. *Optimal tour partitioning heuristic*: This heuristic (Algorithm 2), developed by Altinkemer and Gavish [AlGa88], is based on finding a traveling salesman tour (§10.7.1) in a certain derived graph.

Algorithm 2: **Optimal tour partitioning heuristic.**

```
input: undirected network $G$, control center 0, capacity limit $Q$
output: an approximate capacitated minimum spanning tree $T^*$
find a traveling salesman tour on the vertex set $V = N \cup \{0\}$
let $0 = x^{(0)}, x^{(1)}, \ldots, x^{(n)}$ be an ordering of the vertices on the tour
construct the directed graph $H$ with vertex set $V$ and arc costs $C_{jk}$:
  if $j < k$ and $\sum_{i=j+1}^{k} w_{x^{(i)}} \leq Q$ then $C_{jk} := c_{x^{(0)},x^{(j+1)}} + \sum_{i=j+1}^{k-1} c_{x^{(i)},x^{(i+1)}}$
  else $C_{jk} := \infty$
find a shortest path $P$ from $x^{(0)}$ to $x^{(n)}$ in $H$
use $P = [x^{(0)}, x^{(u)}, x^{(v)}, \ldots, x^{(t)}, x^{(n)}]$ to define $T^*$ via the subtrees
  $\{x^{(0)}, x^{(1)}, x^{(2)}, \ldots, x^{(u)}\}$, $\{x^{(0)}, x^{(u+1)}, x^{(u+2)}, \ldots, x^{(v)}\}$, $\ldots$,
      $\{x^{(0)}, x^{(t+1)}, x^{(t+2)}, \ldots, x^{(n)}\}$
```

8. In Algorithm 2, every path from $x^{(0)}$ to $x^{(n)}$ in the directed graph H generates a collection of subtrees satisfying the capacity restriction.

9. The performance of Algorithm 2 depends on the initial traveling salesman tour chosen. If an optimal traveling salesman tour is used, then the worst-case relative error bound of the algorithm is $4 - \frac{4}{Q}$. That is, $\widehat{Z}/Z^* \leq 4 - \frac{4}{Q}$, where $\widehat{Z}$ is the cost of the heuristic solution generated and Z^* is the cost of the optimal design.

10. *Exact algorithms*: A number of exact algorithms are based on mathematical programming approaches:

- Gavish [Ga85] develops a Lagrangian relaxation based algorithm and uses it to solve problems with homogeneous (unit) demands;
- Araque, Hall, and Magnanti [ArHaMa90] derive valid inequalities and facets for the CMST problem;
- Hall [Ha96] and Bienstock, Deng, and Simchi-Levi [BiDeSi94] develop additional valid inequalities and facets and use them in a branch-and-cut algorithm;
- Gouveia and Martins [GoMa99], [GoMa00], [GoMa05] propose branch-and-cut algorithms over hop-indexed formulations with tight lower bounds for unitary demand problems;
- Uchoa et al. [UcEtal08] present a robust branch-cut-and-price algorithm over an arc formulation strengthened by an exponential number of constraints on q-arb structures. Various powerful cuts are implemented without increasing the complexity of the problem and which improve upon previous formulations.

11. The CMST formulation given in Fact 1 can be improved by adding the various inequalities listed in Facts 12–15.

12. *Knapsack inequalities*: Let S be a minimal cover. For every $l \in N$, the inequality

$$\sum_{i \in S} x_{il} \leq (|S| - 1) y_l$$

is valid for the CMST problem.

13. *Subtour elimination inequalities*: For any $I \subset N$, let $\mathcal{P} = \{S_1, S_2, \ldots, S_{|I|}\}$ be a partition of $N - I$ into $|I|$ subsets, some of which may be empty. For every $i \in I$, let S_i be the unique subset from $\mathcal{P}$ associated with it. Then

$$\sum_{e \in E(I)} z_e + \sum_{j \in I} y_j + \sum_{i \in I} \sum_{j \in S_i} x_{ij} \leq \sum_{i \in I} \sum_{j \in N} x_{ij}$$

is valid for the CMST problem.

14. *Generalized subtour elimination inequalities*: For any $I \subset N$, the inequality

$$\sum_{e \in E(I)} z_e \leq |I| - b(I)$$

is valid for the CMST problem.

15. *Cluster inequalities*: Consider p sets of vertices $S_1, S_2, \ldots, S_p \subset N$ with $p \geq 3$. If the conditions

- $S_0 = \bigcap_{i=1}^{p} S_i \neq \emptyset$, and $S_i - S_0 \neq \emptyset$ for $i = 1, 2, \ldots, p$
- $\sum_{i \in S_k \cup S_l} w_i > Q$ for all $1 \leq k < l \leq p$

are satisfied, then

$$\sum_{i=1}^{p} \sum_{e \in E(S_i)} z_e \leq \sum_{i=1}^{p} |S_i| - 2p + 1$$

is valid for the CMST problem.

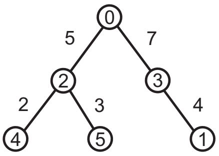
16. *Metaheuristics*: Since 1995 there has been growing interest in metaheuristics with the aim of solving larger, more difficult instances. The methods proposed include neighborhood exploration [AhOrSh01], [AhOrSh03], [AmDoVo96], [SoDuRi03], tabu search [ShEtal97], ant colony optimization [ReLa06], filter-and-fan algorithms [ReMa11], and genetic algorithms [RuEtal15].

Examples:

1. The following figure presents data for a problem involving $n = 5$ terminals and a control center 0. Part (a) gives the cost c_{ij} of constructing each edge (i, j) as well as the demand w_i at each vertex i. The objective is to construct a minimum cost set of subtrees connected to vertex 0, in which the demand generated by any subtree is at most $Q = 150$. Part (b) shows a feasible capacitated spanning tree T, which contains two root vertices (at 2 and 3). The total demand in subtree T_2 is $w_2 + w_4 + w_5 = 150 \leq Q$ and the total demand in subtree T_3 is $w_1 + w_3 = 95 \leq Q$. The spanning tree T has total cost 21, the sum of the displayed edge costs c_{ij}.

	c_{ij}				c_{0i}	w_i
i \ j	2	3	4	5		
1	2	4	3	4	8	40
2		5	2	3	5	35
3			6	5	7	55
4				4	6	50
5					6	65

(a)

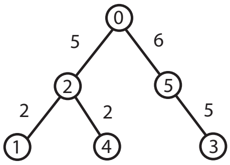


(b)

2. Algorithm 1 is applied to the problem data in the figure of Example 1. To begin, five subtrees are selected, each a single vertex and each joined to the control center 0. Thus, $f_1 = 8$, $f_2 = 5$, $f_3 = 7$, $f_4 = 6$, and $f_5 = 6$. Then $s_{12} = 8 - 2 = 6$, $s_{13} = 8 - 4 = 4$, $\ldots$, $s_{35} = 7 - 5 = 2$, and $s_{45} = 6 - 4 = 2$. The largest savings occurs for $(1, 2)$ so T_1 and T_2 are merged, giving the new tree T_1 with root vertex 2 and the single edge $(1, 2)$. Next, the f_u and s_{uv} are updated. For example, $f_1 = \min\{8, 5\} = 5$, $f_3 = 7$, and $s_{13} = 7 - \min\{c_{13}, c_{23}\} = 7 - 4 = 3$. The largest savings is found to be s_{14}, so T_1 and T_4 are merged, giving the new tree T_1 with root vertex 2 and edges $(1, 2)$ and $(2, 4)$. At the next stage T_3 and T_5 are merged, giving the new tree T_3 with root vertex 5 and the single edge $(3, 5)$. Since no further merging can take place (without violating the capacity constraint), the savings heuristic terminates with the spanning tree shown in the following figure (see next page), having total cost 20.

10.6.2 CAPACITATED CONCENTRATOR LOCATION PROBLEM

The capacitated concentrator location problem is frequently used to locate concentrators in local access networks and switching centers in the backbone network. In either case,



concentrators of fixed capacity are to be located at a subset of possible sites. Each given terminal of the network is to be connected to exactly one concentrator, so that the concentrator's capacity is not exceeded. A feasible configuration having minimum total cost is then sought.

Definitions:

Let $N = \{1, 2, \ldots, n\}$ be a specified set of ***terminals***, where terminal i uses w_i units of ***capacity***. Let $M = \{1, 2, \ldots, m\}$ be a set of possible ***sites*** for concentrators, each of fixed capacity Q.

The bipartite graph $G = (V, E)$ has vertex set $V = N \cup M$ and edges (i, j) for all possible assignments connecting terminal $i \in N$ to a concentrator at site $j \in M$.

If a concentrator is located at site j, the ***set-up cost*** is v_j, for $j \in M$. The ***connection cost*** of connecting terminal i to a concentrator at site j is c_{ij}, for $i \in N$ and $j \in M$.

The ***capacitated concentrator location problem*** (***CCLP***) involves finding locations for concentrators and an assignment of terminals to concentrators such that

- the sum of set-up and connection costs is minimum;
- the total capacity required by the terminals assigned to each concentrator is at most Q.

For $j \in M$, let $y_j \in \{0, 1\}$ indicate whether a concentrator is located at site j.

For $i \in N$ and $j \in M$, let $x_{ij} \in \{0, 1\}$ indicate whether terminal i is connected to a concentrator at site j.

Facts:

1. There are two variants of capacity constraints, based on (a) each concentrator's processing capacity, and (b) the number of connection ports. Han and Raja [HaRa03] study an extended version of the problem with both types of constraints.

2. The classical capacitated concentrator location problem with only processing capacity constraints (i.e., variant (a)) is also known as the *single source capacitated facility location problem.*

3. The classical CCLP has the following 0-1 integer linear programming formulation (§16.1.8):

$$\begin{aligned}
\text{minimize:}\quad & \sum_{i=1}^{n}\sum_{j=1}^{m} c_{ij}x_{ij} + \sum_{j=1}^{m} v_j y_j \\
\text{subject to:}\quad & \sum_{j=1}^{m} x_{ij} = 1, \text{ for all } i \in N \\
& \sum_{i=1}^{n} w_i x_{ij} \le Q y_j, \text{ for all } j \in M \\
& x_{ij} \le y_j, \text{ for all } i \in N,\ j \in M \\
& x_{ij} \in \{0,1\}, \text{ for all } i \in N,\ j \in M \\
& y_j \in \{0,1\}, \text{ for all } j \in M.
\end{aligned}$$

4. In Fact 3,

- the first set of constraints ensures that each terminal is connected to exactly one concentrator;
- the second set of constraints ensures that the concentrator's capacity is not exceeded;
- third set of constraints ensures that terminal i can be assigned to a concentrator at site j only if a concentrator is located at site j.

5. In variant (b), $w_i = 1$, for all $i \in N$ and Q is the number of connection ports.

6. A number of algorithms have been proposed for this problem, most of which are based on a Lagrangian relaxation approach, while some are based on polyhedral analysis [NeWo99].

7. Yang, Chu, and Chen [YaChCh12] present a cut-and-solve algorithm which they apply to large sized instances.

8. Guastaroba and Speranza [GuSp14] extend the kernel search framework with variants based on variable fixing to binary integer linear programming models and apply it to this problem with high-quality results. The heuristic is based on optimally solving a sequence of subproblems, where each subproblem is restricted to a subset of the decision variables. The subsets of decision variables are constructed starting from the optimal values of the linear relaxation.

Examples:

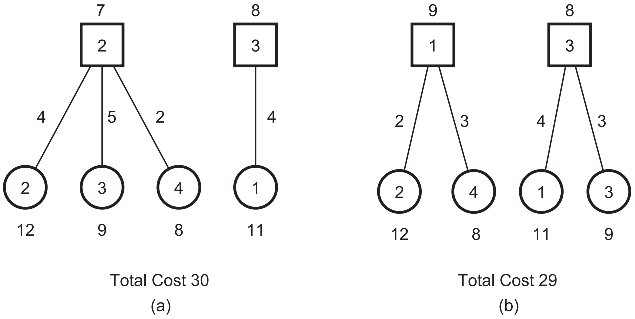
1. The following table shows the data for a problem with four terminals i and three possible sites j for locating concentrators. Let the capacity of any concentrator be $Q = 30$ for variant (a) and $Q = 2$ for variant (b).

	c_{ij}			
i \ j	1	2	3	w_i
1	8	6	4	11
2	2	4	3	12
3	5	5	3	9
4	3	2	6	8
v_j	9	7	8	

2. For variant (a), one feasible configuration is to connect terminals $2, 3, 4$ to a concentrator at site 2, and to connect terminal 1 to a concentrator at site 3. See part (a) of the following figure.

The concentrator at site 2 has total capacity $w_2+w_3+w_4 = 29 \le 30$ and the concentrator at site 3 has total capacity $w_1 = 11 \le 30$. The connection cost is $c_{22} + c_{32} + c_{42} + c_{13} = 15$ and the set-up cost is $v_2 + v_3 = 15$, giving a total cost of 30. Another feasible configuration, shown in part (b), is to connect terminals 2 and 4 to a concentrator at site 1, and to connect terminals 1 and 3 to a concentrator at site 3. The connection cost is 12 and the set-up cost is 17, giving the smaller total cost 29.

3. For variant (b) only the second configuration is feasible.



10.6.3 NETWORK DESIGN PROBLEM

Fiber-optic and opto-electronic cable technologies, together with traditional copper cables, provide many possible choices for link capacities and offer economies of scale. In the capacity assignment problem, a point-to-point communication demand is given between various pairs of vertices of the (typically, backbone) network. The objective is to install links of several types (capacities) to transfer all communication demand without violating link capacities and to do so at minimum total cost. The special case involving two types of transmission media, also referred to in the literature as the two-facility network design problem or the network loading problem, is discussed here.

Definitions:

Let $G = (V, E)$ be an undirected graph with vertex set V and edge set E.

Each communication demand is represented by a ***commodity*** $k \in K$, where K is the set of commodities. Commodity $k \in K$ has a required flow in G of d_k units between its ***origin vertex*** $O(k)$ and its ***destination vertex*** $D(k)$.

Two types of cables can be installed: ***low capacity*** cables have capacity L, and ***high capacity*** cables have capacity H. Let a_e (b_e) denote the ***installation cost*** for each low capacity (high capacity) cable on edge $e \in E$.

The ***network design problem*** (***NDP***) involves finding a mix of low and high capacity cables for each edge of G such that

- the total installation cost is minimum;
- all communication demands d_k are met;
- the flow on each edge does not exceed its installed capacity.

Let $x_e = x_{ij}$ ($y_e = y_{ij}$) be the number of low capacity (high capacity) cables installed on edge $e = (i, j)$.

Let f_{ij}^k be the amount of commodity k that flows from i to j on edge (i, j).

Facts:

1. The NDP has the following mixed integer linear programming formulation (§16.1.8):

$$
\begin{aligned}
\text{minimize:}\quad & \sum_{e\in E}(a_e x_e + b_e y_e)\\
\text{subject to:}\quad & \sum_{j\in V} f^k_{j,O(k)} - \sum_{j\in V} f^k_{O(k),j} = -d_k,\ \text{for all } k\in K\\
& \sum_{j\in V} f^k_{j,D(k)} - \sum_{j\in V} f^k_{D(k),j} = d_k,\ \text{for all } k\in K\\
& \sum_{j\in V} f^k_{ji} - \sum_{j\in V} f^k_{ij} = 0,\ \text{for all } k\in K \text{ and for all } i\in V\setminus\{O(k),D(k)\}\\
& \sum_{k\in K}(f^k_{ij}+f^k_{ji}) \le Lx_{ij}+Hy_{ij},\ \text{for all } (i,j)\in E\\
& x_e, y_e \ge 0 \text{ integer, for all } e\in E\\
& f^k_{ij}, f^k_{ji} \ge 0,\ \text{for all } (i,j)\in E \text{ and for all } k\in K.
\end{aligned}
$$

2. In Fact 1,

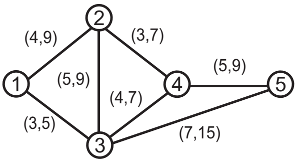
- the first three sets of constraints are the standard mass balance constraints (see §10.4.1);
- the next set of constraints enforces the capacity constraint on the total flow through edge $e=(i,j)$.

3. The NDP becomes harder to solve when more than one type of facility is involved, due to the complexity of the cost structure. The two-facility NDP is strongly NP-hard as it contains the fixed-charge NDP and the Steiner tree problem as special cases.

4. Various polyhedral approaches for network design problems are discussed in [BiGu95] and [MaMiVa95]. Hamid and Agarwal [HaAg15] consider 3-partitions of the original graph and derive a family of facets that significantly strengthen the linear formulation and reduce the integrality gap.

Example:

1. In the network G of the following figure, the costs (a_e, b_e) are shown for each edge e; here $L=2$ and $H=5$. There are $k=3$ communication demands (commodities): $d_1=12$ between vertices 1 and 4, $d_2=10$ between vertices 2 and 5, and $d_3=9$ between vertices 1 and 5. A feasible assignment of flows and capacities to edges is displayed in part (b) of the figure. For instance, edge $(1,3)$ carries 7 units of commodity 1 and 9 units of commodity 3, for a total flow of 16 units. There are three high capacity cables and one low capacity cable installed on this edge giving a total capacity of $3H+L=17$, at a cost of $3\cdot 5+1\cdot 3=18$. The total installation cost for this assignment is 114.



(a)

		f_{ij}^k			
e	1	2	3	x_e	y_e
(1,2)	5			0	1
(1.3)	7		9	1	3
(2,3)		4		0	1
(2,4)	5	6		3	1
(3,4)	7		3	0	2
(3,5)		4	6	0	2
(4,5)		6	3	0	2

(b)

10.6.4 MODELS FOR SURVIVABLE NETWORKS

The introduction of fiber-optic technology has provided high capacity links and makes it possible to design communication networks with low-cost sparse topologies. Unfortunately, sparse networks are very vulnerable; a failure in one edge or vertex can disconnect many users from the rest of the network. This is the prime motivation for studying the design of survivable networks.

Definitions:

Let $G = (V, E)$ be an undirected graph with vertex set V and edge set E.

The ***cost*** of establishing edge $e \in E$ is given by c_e. The cost of a subnetwork $H = (V, F)$ of G is $\sum\limits_{e \in F} c_e$.

Associated with every vertex $s \in V$ is a corresponding number r_s, indicating a desired level of ***redundancy***.

A spanning subnetwork $H = (V, F)$ of G is said to satisfy the ***edge (vertex) connectivity requirement*** if for every distinct pair $s, t \in V$ there are at least $r_{st} = \min\{r_s, r_t\}$ edge-disjoint (vertex-disjoint) paths between s and t in H.

Define x_e, for $e = (i, j)$, to be the number of edges connecting vertex i to vertex j.

Facts:

1. The problem of designing a minimum cost subnetwork that satisfies all edge connectivity requirements has the following integer programming formulation (§16.1.8):

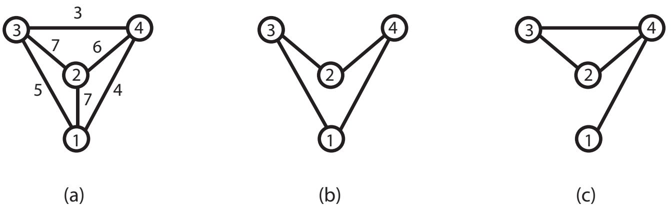
$$\begin{aligned} \text{minimize:} \quad & \sum_{e \in E} c_e x_e \\ \text{subject to:} \quad & \sum_{e \in [S, \overline{S}]} x_e \ge \max_{(i,j) \in [S, \overline{S}]} r_{ij}, \text{ for all } S \subset V,\ S \ne \emptyset \\ & x_e \ge 0 \text{ integer, for all } e \in E. \end{aligned}$$

2. The model in Fact 1, analyzed by Goemans and Bertsimas [GoBe93], allows multiple edges connecting the same two vertices.

3. Grötschel, Monma, and Stoer [GrMoSt92] analyze a related survivability model in which multiple edges are forbidden. In this case, x_e is restricted to be 0 or 1 in the formulation of Fact 1.

Examples:

1. Part (a) of the following figure shows a network G having four vertices and six edges; the cost c_e of each edge e is also displayed.



Suppose that the specified redundancies are $r_1 = 1$ and $r_2 = r_3 = r_4 = 2$. The spanning subnetwork H shown in part (b), with cost 22, satisfies the vertex connectivity requirement. For example, there are $\min\{r_3, r_4\} = 2$ vertex-disjoint paths joining vertices 3 and 4 in H: namely, $[3, 2, 4]$ and $[3, 1, 4]$. Also, there are $\min\{r_2, r_4\} = 2$ vertex-disjoint paths joining vertices 2 and 4: $[2, 4]$ and $[2, 3, 1, 4]$.

2. Part (c) of the figure for Example 1 shows another spanning subnetwork H' with cost 20 that satisfies the stated vertex connectivity requirement. For example, there are $\min\{r_2, r_4\} = 2$ vertex-disjoint paths joining vertices 2 and 4 in H': $[2, 4]$ and $[2, 3, 4]$. Notice that there is $\min\{r_1, r_3\} = 1$ path joining 1 and 3 in H', but not two such vertex-disjoint paths.

10.6.5 CONNECTED FACILITY LOCATION PROBLEM

In designing the last mile of telecommunication networks, the fiber-to-the-curb strategy can be modeled as the connected facility location problem. Namely, fiber optic cables run to a cabinet serving a neighborhood; end users connect to this cabinet using copper connections; and expensive switching devices are installed in these cabinets. The relevant problem is to minimize the overall cost of the network by determining positions of cabinets, deciding which customers to connect to them, and how to reconnect cabinets among each other and to the backbone.

Definitions:

Let $G = (V, E)$ be an undirected graph with vertex set V and edge set E.

The vertex set V is partitioned into three disjoint sets D, F, S: D is the set of ***demand vertices***, F is the set of potential ***facility vertices***, and S is the set of potential ***Steiner vertices***. Thus, $V = D \cup F \cup S$.

Facility opening costs $c_i \geq 0$ are incurred for each open facility $i \in F$. ***Assignment costs*** $a_{ij} \geq 0$ are incurred for assigning customer $j \in D$ to a facility $i \in F$. ***Core edge costs*** $b_{ij} \geq 0$ are incurred for any edge $(i, j) \in E(F \cup S)$ if it is used by the ***Steiner tree*** T connecting open facilities.

The vertices in S may be viewed as pure Steiner vertices and can only be used in the tree T as Steiner vertices, while the vertices in F may be used as Steiner vertices in the tree T with no facility opening cost incurred if no customers are assigned to them.

The final network cost is given by $\sum_{i \in Z} c_i + \sum_{(i,j) \in E(T)} b_{ij} + \sum_{j \in D} a_{i(j)j}$, where $i(j)$ is the facility serving demand vertex j, Z is the set of open facilities, and T is a Steiner tree connecting the open facilities.

The ***connected facility location*** (***ConFL***) ***problem*** involves finding a subset of open facilities such that

- each customer is assigned to exactly one open facility;
- a Steiner tree connects all open facilities;
- the total network cost is minimized.

Let $x_e = x_{ij} \in \{0, 1\}$ ($y_e = y_{ij} \in \{0, 1\}$) indicate whether an assignment edge (core edge) is installed on edge (i, j).

Let $z_i \in \{0, 1\}$ indicate whether there is an open facility at vertex i.

Specify vertex $r \in D$ as the root vertex for the Steiner tree and designate a commodity k for each demand vertex that has origin r and destination $k \in D$.

Let f_{ij}^k be the amount of commodity k that flows from i to j on edge (i,j) for demand vertex $k \in D$.

Facts:

1. Problem ConFL has the following mixed integer programming formulation (§16.1.8):

$$\begin{array}{rl}
\text{minimize:} & \sum_{i \in F} c_i z_i + \sum_{(i,j) \in E(S \cup F)} b_{ij} y_{ij} + \sum_{i \in F,\, j \in D} a_{ij} x_{ij} \\
\text{subject to:} & \sum_{i \in F} x_{ij} = 1, \text{ for all } j \in D \\
& x_{ij} \le z_i, \text{ for all } i \in F \text{ and for all } j \in D \\
& \sum\limits_{j \in V} f_{ji}^k - \sum\limits_{j \in V} f_{i,j}^k = -1, \text{ for } i = r \text{ and for all } k \in D \\
& \sum\limits_{j \in V} f_{ji}^k - \sum\limits_{j \in V} f_{ij}^k = 1, \text{ for } i = k \text{ and for all } k \in D \\
& \sum\limits_{j \in V} f_{ji}^k - \sum\limits_{j \in V} f_{ij}^k = 0, \text{ for } i \in V \setminus \{r, k\} \text{ and for all } k \in D \\
& f_{ij}^k \le y_{ij}, \text{ for all } (i,j) \in E(S \cup F) \text{ and for all } k \in D \\
& f_{ij}^k \le x_{ij}, \text{ for all } i \in F, \text{ for all } j \in D, \text{ and for all } k \in D \\
& x_{ij} \in \{0,1\}, \text{ for all } (i,j) \in E \\
& y_{ij} \in \{0,1\}, \text{ for all } (i,j) \in E(S \cup F) \\
& z_l \in \{0,1\}, \text{ for all } l \in S \cup F \\
& f_{ij}^k \ge 0, \text{ for all } (i,j) \in E \text{ and for all } k \in D.
\end{array}$$

2. In Fact 1,

- the first two sets of constraints enforce that each customer is assigned to an open facility;
- the next set of constraints are the standard mass balance constraints (§10.4.1);
- the last two sets of constraints ensure that flow is only routed through edges on the tree.

3. The ConFL problem encompasses a family of network problems that combine facility location and network design; namely, the rent-or-buy problem, the Steiner tree star problem, and the general Steiner tree star problem.

4. Various approximation algorithms, heuristics and exact methods have been proposed.

5. Bardossy and Raghavan [BaRa10] propose a dual-based local heuristic to obtain both a high-quality heuristic solution and a tight lower bound. In the first stage the problem is modeled as a directed Steiner tree problem with a unit degree constraint at the root vertex. Then a dual-ascent procedure is applied to obtain a lower bound and a feasible solution to the problem. In the second stage a local search procedure is used to improve the feasible solution.

6. Gollowitzer and Ljubic [GoLj11] present various mixed integer programming formulations and compare the models in terms of their bounds and computational time.

Example:

1. Consider the network G with vertices $D = \{1,2,3,4,5,6,7\}$, $F = \{8,9,10,11\}$, and $S = \{12,13\}$, as seen in part (a) of the following figure. Edges of G are defined by a complete bipartite graph between facilities and demand vertices, and a complete graph between facilities and potential Steiner nodes. The assignment costs a_{ij} and the core edge costs b_{ij} are shown in part (c) and part (d), respectively. The facility opening cost is $c_i = 1$ for all facility vertices. A feasible assignment of customers to facilities and the connection of open facilities is displayed in part (b) of the figure. The overall cost for this solution is 22. The total assignment cost is 10, the total core edge cost for T is 9, and the total facility opening cost is 3. Vertex 9 plays the role of a Steiner vertex and so does not incur an opening cost. This solution turns out to be optimal.

(d)

10.6.6 REGENERATOR LOCATION PROBLEM

In optical telecommunication networks, an optical signal can only travel a maximum distance before its quality deteriorates to the point that it must be regenerated by a regenerator on the network. As the cost of a regenerator is high, the goal is to deploy as few regenerators as possible in the network, while ensuring that all vertices can communicate with one another.

Definitions:

Let $G = (N, E)$ be a ***communication graph*** with vertex set N and edge set E.

Let $S \subseteq N$ be the set of ***candidate locations*** where regenerators can be placed, and let $T \subseteq N$ be the set of ***terminal vertices*** that must communicate with one another.

Each edge $e = (i, j) \in E$ represents a ***simple path*** between i and j. In other words, the length of the path does not exceed the maximum distance that can be traveled by the optical signal such that no regenerator is necessary between them.

The ***installation cost*** for placing a regenerator at location $i \in S$ is c_i.

The ***regenerator location problem*** (***RLP***) involves locating regenerators in the candidate locations S such that

- the total regenerator installation cost is minimum;
- all terminal vertices can communicate with one another.

Let $x_i \in \{0,1\}$ indicate whether a regenerator is located at vertex i.

Specify a vertex $r \in T$ as the source vertex for all communications. Define a commodity k for each terminal vertex $k \in T \setminus \{r\}$ that has origin r and destination k.

Let $y_{rj} \in \{0,1\}$ indicate whether there is any flow from r to j on edge (r,j).

Let f_{ij}^k be the amount of commodity k that flows from i to j on edge (i,j) for terminal vertex k.

Facts:

1. The RLP has the following mixed integer linear programming formulation (§16.1.8):

$$\begin{aligned}
\text{minimize:}\quad & \sum_{i\in S} c_i x_i \\
\text{subject to:}\quad & \sum_{j\in N} f_{ji}^k - \sum_{j\in N} f_{ij}^k = -1, \text{ for } i = r \text{ and for all } k \in T\setminus\{r\} \\
& \sum_{j\in N} f_{ji}^k - \sum_{j\in N} f_{ij}^k = 1, \text{ for } i = k \text{ and for all } k \in T\setminus\{r\} \\
& \sum_{j\in N} f_{ji}^k - \sum_{j\in N} f_{ij}^k = 0, \text{ for } i \in N\setminus\{r,k\} \text{ and for all } k \in T\setminus\{r\} \\
& f_{ij}^k \le x_j, \text{ for all } (i,j)\in E \text{ and for all } k \in T \\
& f_{rj}^k \le y_{rj}, \text{ for all } j \in N\setminus\{r\} \text{ and for all } k \in T \\
& \sum_{(r,j)\in E} y_{rj} \le 1 + Mx_r \\
& x_i \in \{0,1\}, \text{ for all } i \in S \\
& y_{rj} \in \{0,1\}, \text{ for all } (r,j) \in E \\
& f_{ij}^k \ge 0, \text{ for all } (i,j)\in E \text{ and for all } k \in T.
\end{aligned}$$

2. In Fact 1,

- the first three sets of constraints are the standard mass balance constraints (see §10.4.1);
- the next set of constraints enforces the installation of a regenerator for passing communications;
- the following sets of constraints ensure that the source vertex r has unit degree or a regenerator installed. Here M is a sufficiently large constant with $M \ge |T|-2$.

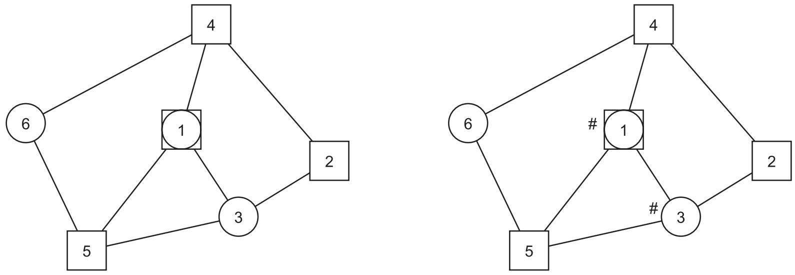
3. The regenerator location problem is NP-hard.

4. Chen, Ljubic, and Raghavan [ChLjRa15] establish that the RLP is equivalent to the vertex-weighted directed Steiner forest problem. Using this fact, they derive various integer and mixed integer programming formulations. They also propose construction heuristics combined with local search.

5. When $N = S = T$, Chen, Ljubic, and Raghavan [ChLjRa10] show that the RLP is equivalent to a maximum leaf spanning tree problem.

Example:

1. In the communication graph G of the following figure, $S = \{1,3,6\}$, $T = \{1,2,4,5\}$, and the regenerator installation cost is 1 for all locations. A feasible installation of regenerators that ensures communication between all terminal vertices is displayed in part (b) of the figure, where # indicates the location of regenerators. The total regenerator installation cost is 2.



(a) (b)

10.7 DIFFICULT ROUTING AND ASSIGNMENT PROBLEMS

An *exact* algorithm for a combinatorial optimization problem is a procedure that produces a verifiable optimal solution to every instance of this problem. A *heuristic* algorithm produces a feasible (although not necessarily optimal) solution to each problem instance. This section discusses exact and heuristic approaches to three classical combinatorial optimization problems: the traveling salesman problem, the vehicle routing problem, and the quadratic assignment problem. These three problems have in common the goal of minimizing the cost of movement or travel, generally of people or of materials.

10.7.1 TRAVELING SALESMAN PROBLEM

In the traveling salesman problem, a salesman starts out from a home city and is to visit in some order a specified set of cities, returning home at the end. This journey is to be designed to incur the minimum total cost (or distance). While the traveling salesman problem has attracted the attention of many mathematicians and computer scientists, it has resisted attempts to develop an efficient solution algorithm.

Definitions:

Let $G = (V, E)$ be a complete graph (§8.1.3) with $V = \{1, 2, \ldots, n\}$ the set of vertices and E the set of all edges joining pairs of distinct vertices.

Each edge $(i, j) \in E$ has an associated ***cost*** or ***distance*** c_{ij}.

The ***distance*** between set $S \subseteq V$ and vertex $j \notin S$ is $d_S(j) = \min\{c_{ij} \mid i \in S\}$.

A ***Hamilton cycle*** or ***tour*** in G is a cycle passing through each vertex $i \in V$ exactly once. (See §8.4.4.)

The ***cost*** of a cycle C is $\sum\limits_{(i,j)\in C} c_{ij}$.

The ***traveling salesman problem*** (***TSP***) requires finding a Hamilton cycle in G of minimum total cost.

The costs (distances) satisfy the ***triangle inequality*** if $c_{ij} \le c_{ik} + c_{kj}$ holds for all distinct $i, j, k \in V$.

In a ***Euclidean*** TSP, each vertex i corresponds to a point x_i in $\mathcal{R}^2$ and c_{ij} is the distance between x_i and x_j, relative to the standard real inner product (§6.1.4).

Tour construction procedures generate an approximately optimal TSP tour from the costs c_{ij}.

Tour improvement procedures attempt to find a smaller cost tour, given an initial (often random) tour.

Composite (***hybrid***) procedures construct a starting tour from one of the tour construction procedures and then attempt to find a smaller cost tour using one or more of the tour improvement procedures.

A ***k-change*** or ***k-opt exchange*** of a given tour is obtained by deleting k edges from the tour and adding k other edges to form a new tour. A tour is ***k-optimal*** (***k-opt***) if it is not possible to improve the tour via a k-change.

Metaheuristics are general-purpose procedures (such as tabu search, simulated annealing, genetic algorithms, or neural networks) for heuristically solving difficult optimization problems; these general methodologies for searching complex solution spaces can be specialized to handle specific types of optimization problems.

Facts:

1. The TSP is possibly the most well-known network optimization problem, and it serves as a prototype for difficult combinatorial optimization problems in the theory of algorithmic complexity (§17.5.2).

2. The first use of the term "traveling salesman problem" in a mathematical context appears to have occurred in 1931–1932.

3. There are numerous applications of the TSP: drilling of printed circuit boards, cluster analysis, sequencing of jobs, x-ray crystallography, archaeology, cutting stock problems, robotics, and order-picking in a warehouse (see Examples 7–11).

4. There are $\frac{(n-1)!}{2}$ different Hamilton cycles in the complete graph G. This means that brute force enumeration of all Hamilton cycles to solve the TSP is not practical. (See Example 1.)

5. The TSP is an NP-hard optimization problem (§17.5.2). This remains true even when the distances satisfy the triangle inequality or represent Euclidean distances.

6. If certain edges (i,j) of G are missing, then c_{ij} can be assigned a sufficiently large value M; e.g., one can set M to be greater than the sum of the n largest edge costs. The TSP can then be solved on the complete graph G. If the (exact) solution obtained has any edges with cost M, then there is no Hamilton cycle in the original graph.

7. *Asymmetric traveling salesman problem*: Certain applications require finding a minimum cost directed Hamilton cycle in a directed network H; here it is not required that $c_{ij} = c_{ji}$ holds for all arcs (i,j) of H. This asymmetric (directed) TSP can be transformed into a TSP problem on an undirected network [JüReRi95].

8. A seminal paper of G. B. Dantzig, D. R. Fulkerson, and S. M. Johnson (1954) solved a 49-city TSP to optimality by adding cutting planes (§16.1.8) to a linear programming relaxation of the problem.

9. Although ingenious exact algorithms for the TSP have been proposed by numerous authors, most encounter problems with storage and/or running time for cases with more than five hundred vertices.

10. Exact approaches to the TSP are computationally intensive, especially for large networks. Thus a large number of heuristic approaches have been developed to produce useful, but not necessarily optimal, solutions to the TSP.

11. The wealth of TSP heuristics can be categorized into four broad classes: tour construction procedures, tour improvement procedures, composite procedures, and metaheuristics.

12. *Nearest neighbor heuristic*: This construction method (Algorithm 1) builds up a tour by successively adding new vertices that are closest to a growing path.

Algorithm 1: **Nearest neighbor heuristic.**

```
input: undirected network $G = (V, E)$, costs $c_{ij}$
output: a traveling salesman tour
$i_0$ := any vertex of $G$ {the starting vertex}
$W := V - \{i_0\}$
$P := \emptyset$
$v := i_0$
while $W \neq \emptyset$
   let $k \in W$ be such that $c_{vk} = \min\{c_{vj} \mid j \in W\}$
   add $(v, k)$ to $P$
   $W := W - \{k\}$
   $v := k$
add $(k, i_0)$ to the path $P$ to produce a tour
```

13. Using appropriate data structures, Algorithm 1 can be implemented to run in $O(n^2)$ time.

14. Suppose z_{NN} is the cost of a tour constructed by the nearest neighbor heuristic and z_{OPT} is the cost of an optimal TSP tour. Then there are examples for which $\frac{z_{\text{NN}}}{z_{\text{OPT}}}$ is $\Theta(\log n)$. This means that the cost of the tour produced by Algorithm 1 cannot be bounded above by a constant times the cost of an optimal TSP tour.

15. *Nearest insertion heuristic*: This construction method (Algorithm 2) builds up a tour from smaller cycles by successively adding a vertex that is closest to the current cycle C. The new vertex is inserted between two successive vertices in the cycle, in the best possible way.

Algorithm 2: **Nearest insertion heuristic.**

```
input: undirected network $G = (V, E)$, costs $c_{ij}$
output: a traveling salesman tour
$i$ := any vertex of $G$ {the starting vertex}
$j$ := subscript such that $c_{ij} = \min\{c_{ir} \mid r \in V - \{i\}\}$
$S := \{i, j\}$
$C := \{(i, j), (j, i)\}$
while $S \neq V$
   let $k$ be such that $d_S(k) = \min\{d_S(r) \mid r \in V - S\}$
   $S := S \cup \{k\}$
```

```
    find an edge $(u,v) \in C$ so $c_{uk} + c_{kv} - c_{uv} = \min\{c_{xk} + c_{ky} - c_{xy} \mid (x,y) \in C\}$
    add $(u,k)$ and $(k,v)$ to $C$, and remove $(u,v)$ from $C$
```

16. Using appropriate data structures, Algorithm 2 can be implemented to run in $O(n^2)$ time.

17. Suppose z_{NI} is the cost of a tour constructed by the nearest insertion heuristic and z_{OPT} is the cost of an optimal TSP tour. If the values c_{ij} satisfy the triangle inequality, then $\frac{z_{\text{NI}}}{z_{\text{OPT}}} \leq 2$ holds for all TSP instances.

18. *Clarke and Wright savings heuristic*: This construction method (Algorithm 3) builds up a tour by successively adding an edge (i,j) having the largest *savings* s_{ij}, the benefit from directly connecting vertices i and j compared with joining each directly to a central vertex.

```
Algorithm 3: Clarke and Wright savings heuristic.
  input: undirected network $G = (V,E)$, costs $c_{ij}$
  output: a traveling salesman tour
  select any vertex (for example, 1) as the starting vertex
  compute $s_{ij} = c_{1i} + c_{1j} - c_{ij}$ for distinct $i,j \in V - \{1\}$
  order the savings $s_{i_1j_1} \geq s_{i_2j_2} \geq \cdots \geq s_{i_tj_t}$
  $P := \emptyset$
  $k := 0$
  while $|P| < n - 2$
    $k := k + 1$
    if $P \cup \{(i_k, j_k)\}$ is a vertex-disjoint union of paths then add $(i_k, j_k)$ to $P$
  connect the endpoints of $P$ to vertex 1, forming a tour
```

19. Using appropriate data structures, Algorithm 3 can be implemented to run in $O(n^2 \log n)$ time.

20. *Christofides' heuristic*: This construction method (Algorithm 4) builds up a tour from a minimum spanning tree to which are added certain other small cost edges. It is assumed that the costs satisfy the triangle inequality.

```
Algorithm 4: Christofides' heuristic.
  input: undirected network $G$, costs $c_{ij}$
  output: a traveling salesman tour
  $T :=$ minimum spanning tree of $G$ with respect to the costs $c_{ij}$ (see §10.1)
  let $S$ contain all odd-degree vertices in $T$
  find a minimum cost perfect matching $M$ (§10.2) relative to vertices $S$ of $G$ and
    using the costs $c_{ij}$
  obtain a closed trail $C$ by adding $M$ to the edges of $T$
  remove all edges but two incident with vertices of degree greater than 2 by ex-
    ploiting the triangle inequality, transforming $C$ into a tour
```

21. Using appropriate data structures, Algorithm 4 can be implemented to run in $O(n^3)$ time.

22. Suppose z_{C} is the cost of a tour constructed by Christofides' heuristic and z_{OPT} is the cost of an optimal TSP tour. If the c_{ij} satisfy the triangle inequality, then $\frac{z_{\text{C}}}{z_{\text{OPT}}} \le \frac{3}{2}$ holds for all TSP instances.

23. The following table [JüReRi95] compares several of the most popular tour construction procedures on a set of 30 Euclidean TSPs from the literature with known optimal solutions. These problems range in size from 105 to 2,392 vertices. Surprisingly, the savings heuristic is the best tour construction heuristic of those tested. These results are consistent with those of other studies.

heuristic	*average percent above optimality*
nearest neighbor	24.2
nearest insertion	20.0
Christofides	19.5
modified nearest neighbor	18.6
cheapest insertion	16.8
random insertion	11.1
farthest insertion	9.9
savings	9.8
modified savings	9.6

24. The best known tour improvement heuristics for the TSP involve edge exchanges (Algorithm 5). Often the initial tour is chosen randomly from the set of all possible tours.

Algorithm 5: **General edge-exchange heuristic.**

```
input: undirected network $G$, initial tour
output: a traveling salesman tour
repeat improve the tour using an allowable edge exchange
until no additional improvement can be made
```

25. Specialized versions of Algorithm 5 typically use 2-opt exchanges, 3-opt exchanges, and more complicated *Lin-Kernighan* [JüReRi95] edge exchanges. Such exchange techniques have been used to generate excellent solutions to large-scale TSPs in a reasonable amount of time.

26. Edge-exchange procedures are typically more expensive computationally than tour construction procedures.

27. Tour improvement procedures typically require a "downhill move" (i.e., a strict reduction in cost) in order for edge exchanges to be made. As a result, they terminate with a local minimum solution.

28. Since the 2-opt exchange procedure is weaker than the 3-opt procedure, Algorithm 5 will generally terminate at an inferior local optimum using 2-opt exchanges instead of 3-opt exchanges. The Lin-Kernighan procedure will generally terminate with a better local optimum than will a 3-opt exchange procedure.

29. In practice, it often makes sense to apply a composite procedure. The strategy is to get a good initial solution rapidly (by tour construction), which is then improved by an edge-exchange procedure.

30. The following table [JüReRi95] compares several composite procedures on the same sample problems described in Fact 23. In each case, the initial tour is constructed using the nearest neighbor heuristic (Algorithm 1). The improvement procedures include 2-opt, 3-opt, two variants of Lin-Kernighan, and iterated Lin-Kernighan. Iterated Lin-Kernighan is the most computationally burdensome of the edge-exchange procedures, but it consistently obtains results that are within 1% of optimality.

heuristic	*average percent above optimality*
2-opt	8.3
3-opt	3.8
Lin-Kernighan (variant 1)	1.9
Lin-Kernighan (variant 2)	1.5
Iterated Lin-Kernighan	0.6

31. *Metaheuristics*: Unlike Algorithm 5 (which permits only downhill moves), metaheuristics [OsKe95] allow the possibility of nonimproving moves. For example, uphill moves can be accepted either randomly (simulated annealing) or based upon deterministic rules (threshold accepting). Memory can be incorporated in order to prevent revisiting local minima already evaluated and to encourage discovering new ones (tabu search, see §16.9).

Other metaheuristics such as evolutionary strategies, genetic algorithms, and neural networks have also been applied to the TSP. To date, neural networks and tabu search have been less successful than the other approaches.

32. For a detailed history of the TSP, see the first chapter of [LaEtal85] as well as the very accessible exposition in [Co12].

33. The article [La10] provides a concise guide to the most effective exact and heuristic approaches for the TSP.

34. Software for the traveling salesman problem can be found in [LoPu07].

35. A library of sample problems, with their best known solutions, is available at

- `http://comopt.ifi.uni-heidelberg.de/software/TSPLIB95`

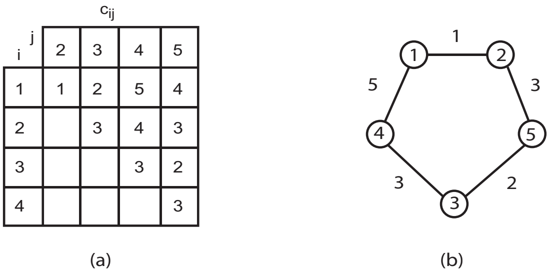
36. To date, the largest non-trivial instance solved to optimality has 85,900 cities (solved in 2006).

37. For exact algorithms, we refer interested readers to [ApEtal07].

Examples:

1. *Brute force enumeration*: Suppose that a TSP solution is required for the complete graph G on $n = 25$ cities. By Fact 4, there are $\frac{24!}{2} \approx 3.1 \times 10^{23}$ Hamilton tours in the graph G. Even with a supercomputer that is capable of finding and evaluating each such tour in one nanosecond (10^{-9} seconds), it would take over 9.8 million years of uninterrupted computations to determine an optimal TSP tour. This example illustrates how quickly brute force enumeration of Hamilton tours becomes impractical.

2. Part (a) of the following figure shows the costs c_{ij} for a five city TSP. An initial tour can be constructed using the nearest neighbor heuristic (Algorithm 1). Let the initial vertex be $i_0 = 1$, so $W = \{2, 3, 4, 5\}$. The closest vertex of W to 1 is 2, with $c_{12} = 1$, so edge $(1, 2)$ is added to the current path. A closest vertex of $W = \{3, 4, 5\}$ to 2 is 5, so edge $(2, 5)$ is added to the path. Continuing in this way, edges $(5, 3)$ and edge $(3, 4)$ are added, giving the path $P = [1, 2, 5, 3, 4]$ and the tour $[1, 2, 5, 3, 4, 1]$ with total cost $1 + 3 + 2 + 3 + 5 = 14$. This tour is displayed in part (b).



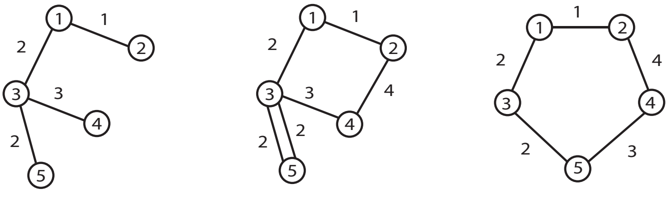
c_{ij} — i \ j	2	3	4	5
1	1	2	5	4
2		3	4	3
3			3	2
4				3

(a) (b)

3. Suppose that the nearest insertion heuristic (Algorithm 2) is applied to the problem data in part (a) of the figure for Example 2, starting with the initial vertex $i = 1$. The nearest vertex to i is $j = 2$, giving the initial cycle $C = \{(1,2),(2,1)\}$. The closest vertex to this cycle is $k = 3$, producing the new cycle $C = \{(1,2),\ (2,3),\ (3,1)\}$. Relative to $S = \{1,2,3\}$, $d_S(4) = 3$ and $d_S(5) = 2$, so vertex 5 will next be added to the cycle. Since $c_{15} + c_{52} - c_{12} = 6$, $c_{25} + c_{53} - c_{23} = 2$, and $c_{15} + c_{53} - c_{13} = 4$, vertex 5 is inserted between vertices 2 and 3 in the current cycle, giving $C = \{(1,2),\ (2,5),\ (5,3),\ (3,1)\}$. Finally, vertex 4 is added between vertices 2 and 5, producing the tour $C = \{(1,2),(2,4),(4,5),(5,3),(3,1)\}$ with total cost 12.

4. The savings heuristic (Algorithm 3) can alternatively be applied to the problem specified in part (a) of the figure for Example 2. The savings $s_{23} = c_{12} + c_{13} - c_{23} = 1 + 2 - 3 = 0$. Similarly, $s_{24} = 2$, $s_{25} = 2$, $s_{34} = 4$, $s_{35} = 4$, and $s_{45} = 6$. This produces the ordered list of edges $[(4,5),(3,4),(3,5),(2,4),(2,5),(2,3)]$. Considering edges in turn from this list gives the path $P = [3,4,5,2]$. Adding edges from the endpoints of P to vertex 1 produces the tour $[1,3,4,5,2,1]$ with total cost 12.

5. Christofides' heuristic (Algorithm 4) is now applied to the problem given in part (a) of the figure for Example 2. A minimum spanning tree T consists of the following edges: $(1,2)$, $(1,3)$, $(3,5)$, $(3,4)$; see part (a) of the following figure. Vertices $2,3,4,5$ have odd degree and $\{(2,4),(3,5)\}$ constitutes a minimum cost perfect matching on these vertices. Adding these edges to those of T produces the multi-graph in part (b) of the following figure. Replacing edges $(4,3)$ and $(3,5)$ having aggregate cost 5 by the single edge $(4,5)$ of cost 3 produces the tour in part (c), having total cost 12.



(a) (b) (c)

6. To illustrate edge exchanges, consider the tour of cost 14 in part (b) of the figure for Example 2. Removal of edges $(1,4)$ and $(3,5)$ disconnects the cycle into two disjoint paths. Join the endpoints of one path to the endpoints of the other with edges $(1,3)$ and $(4,5)$ to create a new tour $[1,2,5,4,3,1]$ of smaller cost 12. No further pairwise exchanges reduce the cost of this tour, so this tour is a 2-opt local minimum solution.

7. *Delivery routes*: A delivery truck must visit a set of customers in a city and then return to the central garage after completing the route. Determining an optimal (i.e., shortest time) delivery route can be modeled as a traveling salesman problem on a city street network. Here the vertices represent the customer locations and the cost c_{ij} of edge (i, j) is the driving time between locations i and j.

8. *Printed circuit boards*: One application of the TSP occurs in fabricating printed circuit boards. Holes at a number of fixed locations have to be drilled through the board. The objective is to minimize the total time needed to move the drilling head from position to position. Here the vertices i correspond to the locations of the holes as well as the starting position of the drill. The cost c_{ij} represents the time required to move the drilling head from i and reposition it at j. A minimum cost traveling salesman tour gives an optimal way of sequencing the drilling of the holes.

9. *Order-picking*: In a warehouse, a customer order requires a certain subset of the items stored there. A vehicle must be sent to pick up these items and then return to the central dispatch location. Here the vertices are the locations of the items as well as the central dispatch location. The costs are the times needed to move the vehicle from one location to the other. A minimum cost traveling salesman tour then gives an optimal order in which to retrieve items from the warehouse.

10. *Job sequencing*: In a factory, materials must be processed by a series of operations on a machine. The set-up time between operations varies depending on the order in which the operations are scheduled. Determining an optimal ordering that minimizes the total set-up time can be formulated as a traveling salesman problem.

10.7.2 VEHICLE ROUTING PROBLEM

Private firms and public organizations that distribute goods or provide services to customer locations rely on a fleet of vehicles. Given demands for service at numerous points in a transportation network, the vehicle routing problem requires determining which customers are to be serviced by each vehicle and the order in which customers on a route are to be visited.

Definitions:

Let $G = (V, E)$ be a complete graph with $V = \{1, 2, \ldots, n\}$ the set of vertices and E the set of all edges joining pairs of distinct vertices (§8.1.3).

Vertex 1 is the ***central depot***, whereas the other vertices represent ***customer locations***. Customer location i has a known ***demand*** w_i.

Each edge $(i, j) \in E$ has an associated ***distance*** or ***cost*** c_{ij}.

There are also available a number of ***vehicles***, each having the same ***capacity*** Q.

A ***route*** is sequence of customers visited by a vehicle that starts and ends at the central depot.

The ***vehicle routing problem*** (***VRP***) requires partitioning the set of customers into a set of delivery routes such that

- the total distance traveled by all vehicles is minimum;
- the total demand generated by the customers assigned to each route is $\le Q$.

In a ***construction*** heuristic for the VRP, subtours are joined as long as the resulting subtour does not violate the vehicle capacity.

An ***improvement*** heuristic employs successive edge exchanges that reduce the total distance without violating any vehicle capacity constraint.

A ***two-phase*** heuristic implements a cluster first/route second philosophy, in which customers are first partitioned into groups G_k with $\sum_{i \in G_k} w_i \le Q$, after which a minimum distance sequencing of customers is found within each group.

Facts:

1. The TSP (§10.7.1) is a special case of the VRP in which there is a single vehicle with unlimited capacity.

2. The VRP is an NP-hard optimization problem (§17.5.2).

3. VRPs with more than 100 vertices are difficult to solve to optimality. The state-of-the-art exact method is branch-and-cut-and-price.

4. Most solution strategies for large VRPs are heuristic in nature, involving construction, improvement, and two-phase methods as well as metaheuristics.

5. In 1959 G. B. Dantzig and J. H. Ramser first formulated the general vehicle routing problem and developed a heuristic solution procedure. This solution technique was applied to a problem involving the delivery of gasoline to service stations.

6. The Clarke and Wright savings heuristic (§10.7.1) is a construction approach, originally proposed for the VRP. Algorithm 6 outlines this heuristic, which begins with each customer served by a different vehicle and successively combines routes in order of nonincreasing savings $s_{ij} = c_{1i} + c_{1j} - c_{ij}$ to form a smaller set of feasible routes.

```
Algorithm 6: Clarke and Wright savings heuristic.
  input: undirected network $G = (V, E)$, costs $c_{ij}$, capacity limit $Q$
  output: a set of delivery routes
  $R_i$ := route consisting of edges $(1, i)$ and $(i, 1)$ for $i \in V - \{1\}$
  compute $s_{ij} = c_{1i} + c_{1j} - c_{ij}$ for distinct $i, j \in V - \{1\}$
  order the savings $s_{i_1 j_1} \ge s_{i_2 j_2} \ge \cdots \ge s_{i_t j_t}$
  for $k := 1$ to $t$
    if $R_{i_k}$ and $R_{j_k}$ have combined demand at most $Q$ then merge $R_{i_k}$ and $R_{j_k}$
```

7. In two-phase methods, a minimum distance ordering of customers within each specified cluster of vertices can be found by solving a TSP (§10.7.1).

8. In the past two decades, metaheuristics such as simulated annealing, tabu search, genetic algorithms, record-to-record travel, and iterated neighborhood search have been applied quite successfully to VRPs.

9. [LaRoVi14] compared the performances of a selected set of successful metaheuristics. In terms of objective function values, the parallel algorithm that combined a heuristic local search improvement with integer programming [GrGoWa11] performed best on both CMT (50 to 200 customers) and GWKC (240 to 483 customers) benchmark instances.

10. Extensions to the basic VRP include modifications for asymmetric distances (c_{ij} need not equal c_{ji}), heterogeneous fleets, constraints on the distance of every route, multiple depots, time windows for deliveries, split deliveries, arc routing, inventory routing, prize collecting routing, pick-up and delivery, and multi-objective routing.

11. A survey of 25 commercial software products for vehicle routing problems is available in [HaPa16]. This survey discusses interfaces with mapping systems, cloud-based solutions, computer platforms supported, extensions to the basic VRP that are incorporated, and significant installations of the product for industrial customers.

12. A list of free vehicle routing software can be found in [WaEtal16].

13. Datasets and best-known solutions for VRPs are available at

- `http://neo.lcc.uma.es/vrp/`

Examples:

1. The following table gives the data for a VRP involving six customers in which vehicle capacity is 820. The route $[1,2,4,6,1]$ is not feasible since the total demand of customers on this route is $w_2+w_4+w_6 = 486+326+24 = 836 > 820$. Since $\sum_{i=2}^{7} w_i = 1967$, at least $\lceil 1967/820 \rceil = 3$ routes will be needed to service all demands. The routes $[1,5,2,6,1]$, $[1,3,1]$, and $[1,4,7,1]$ constitute a feasible set of routes with (respective) demands 800, 541, and 626. In this feasible solution, the total distance traveled by the first vehicle is $c_{15} + c_{52} + c_{26} + c_{61} = 131$, by the second is $c_{13} + c_{31} = 114$, and by the third is $c_{14} + c_{47} + c_{71} = 181$, for a total distance of 426.

customer	2	3	4	5	6	7
demand	486	541	326	290	24	300

c_{ij}	2	3	4	5	6	7
1	19	57	51	49	4	92
2		51	10	53	25	53
3			49	18	30	47
4				50	11	38
5					68	9
6						94

2. The Clarke and Wright heuristic is applied to the problem specified in the table of Example 1. For instance, $s_{35} = c_{13} + c_{15} - c_{35} = 57 + 49 - 18 = 88$. The largest savings occurs for $s_{57} = 132$ and $w_5 + w_7 = 590 \leq 820$, so the initial routes $[1,5,1]$ and $[1,7,1]$ are merged to produce the feasible route $[1,5,7,1]$ with distance 150. The next largest savings occur for $s_{47} = 105$, $s_{37} = 102$, and $s_{35} = 88$; however, neither customer 3 nor customer 4 can be inserted into the route $[1,5,7,1]$ without exceeding the vehicle capacity. The next largest savings is $s_{24} = 60$, giving the new feasible route $[1, 2, 4, 1]$ with demand 812 and distance 80. Continuing in this fashion eventually finds $s_{36} = 31$ and constructs the route $[1, 3, 6, 1]$ with demand 565 and distance 91. This feasible set of three routes has total distance $150 + 80 + 91 = 321$, smaller than that for the feasible solution given in Example 1.

10.7.3 QUADRATIC ASSIGNMENT PROBLEM

The quadratic assignment problem deals with the relative location of facilities that interact with one another in some manner. The objective is to minimize the total cost of interactions between facilities, with distance often used as a surrogate for measures such as dollar cost, fatigue, or inconvenience.

Definitions:

There are n ***facilities*** to be assigned to n predefined ***locations***, where each location can accommodate any one facility.

The ***fixed cost*** c_{ij} is the cost of assigning facility i to location j.

The ***flow*** f_{ij} is the level of interaction between facilities i and j.

The ***distance*** d_{ij} between locations i and j is the per unit cost of interaction between the two locations. Typically, it is measured using the rectilinear or Euclidean distance between the locations.

An ***assignment*** is a bijection ρ from the set of facilities onto the set of locations.

The ***linear assignment problem*** (***LAP***) is the problem of finding an assignment ρ that minimizes $\sum_i c_{i,\rho(i)}$.

The ***quadratic assignment problem*** (***QAP***) is the problem of finding an assignment ρ that gives the minimum value z_{QAP} of $\sum_i c_{i,\rho(i)} + \sum_{i,p} f_{ip} d_{\rho(i),\rho(p)}$.

In some partial assignment for the QAP, let $\mathcal{F}$ be the set of facilities (possibly empty) that have already been assigned and $\mathcal{L}$ be the set of locations having assigned facilities.

Facts:

1. The following table gives a variety of situations that can be formulated using the QAP model.

facilities	*interaction*
departments in a manufacturing plant	flow of materials
departments in an office building	flow of information, movement of people
departments in a hospital	movement of patients and medical staff
buildings on a campus	movement of students and staff
electronic component boards	connections
computer keyboard keys	movement of fingers
runners in a relay team	transfer time of a baton
airport terminals and gates	flow of passengers with connecting flights
turbine blades	slight variations in blade weights, that need to be balanced

2. The interdependence of facilities due to interactions between them leads to the quadratic nature of the objective function in the QAP.

3. If the facilities are independent of each other (there are no interactions between them), the QAP reduces to the LAP, which can be solved in polynomial time (§10.2.2).

4. The TSP is a special case of the QAP (see Example 4).

5. The QAP is an NP-hard optimization problem (§17.5.2).

6. Exact solution of the QAP is limited to fairly small problems, generally of size 30 or smaller.

7. A lower bound on completions of a partial assignment for the QAP is given by

$$\begin{aligned} \min \ & \sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip}d_{\rho(i),\rho(p)} \\ & + \sum_{i\in\mathcal{F}}\sum_{p\notin\mathcal{F}} \big(f_{ip}d_{\rho(i),\rho(p)} + f_{pi}d_{\rho(p),\rho(i)}\big) \\ & + \sum_{i\notin\mathcal{F}} c_{i,\rho(i)} + \sum_{i\notin\mathcal{F}}\sum_{p\notin\mathcal{F}} f_{ip}d_{\rho(i),\rho(p)}. \end{aligned}$$

The first two terms in this expression are the known fixed and interaction costs of assignments already made; the third term captures the interaction costs between assigned facilities and those yet to be assigned; and the last two terms represent the fixed and interaction costs of assignments not yet made.

8. A minimum value z^* can be calculated for the last three terms in the lower bound expression of Fact 7 by solving a LAP such that each cost term is a lower bound on the incremental costs that would be incurred if facility $i \notin \mathcal{F}$ is assigned to location $j \notin \mathcal{L}$.

9. *Gilmore-Lawler lower bound*: This lower bound for z_{QAP} is given by

$$\sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip}d_{\rho(i),\rho(p)} + z^*,$$

where z^* is found as in Fact 8.

10. The Gilmore-Lawler lower bound allows the QAP to be solved using a branch-and-bound (implicit enumeration) technique (§16.1.8).

11. The following table provides alternative tighter lower bounds for exact solution of the QAP. Here SDP refers to Semidefinite Programming and RLT refers to the Reformulation-Linearization Technique.

lower bounds	*references*

12. There are several ways to linearize the QAP by defining additional variables and constraints. However, none of the linearizations proposed so far has proved to be computationally effective.

13. Heuristic methods for solving the QAP can be classified as limited enumeration, construction methods, improvement methods, hybrid methods, and metaheuristics. A survey of exact and heuristic solution methods for the QAP is found in [KuHe87]; experimental comparisons of heuristic approaches appear in [BuSt78] and [Li81].

14. *Limited enumeration*: There are two distinct approaches for limiting the search for an optimal QAP solution using a branch-and-bound approach:

- The search can be curtailed by placing a limit on the computation time or the number of subproblems examined. Since an optimal solution is often found fairly early in a branch-and-bound procedure, especially if a good branching rule is available, this approach may find an optimal (or a near-optimal) solution while saving on the significant cost of proving optimality.
- The gap between the lower and upper bound is largest at higher levels of a branch-and-bound tree. Thus a relatively large gap can be used to fathom subproblems at higher levels, and this gap can be decreased gradually as the search reaches lower levels of the tree.

15. *Construction methods*: These heuristics start with an empty assignment and add assignments one at a time until a complete solution is obtained. The rule used to choose the next assignment can employ various viewpoints:

- *a local view*: select a facility having the maximum interaction with a facility already assigned; locate it to minimize the cost of interaction between facilities;
- *a global view*: take into account assignments already made as well as future assignments to be made.

16. Suppose that k assignments have already been made. Using statistical properties, the expected value for the completion of the partial assignment is given by the following expression, whose terms are analogous to those in Fact 7:

$$\begin{aligned} EV = {} & \sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip}d_{\rho(i),\rho(p)} \\ & + \frac{\sum\limits_{i\in\mathcal{F}}\sum\limits_{p\notin\mathcal{F}}\sum\limits_{j\notin\mathcal{L}} \big(f_{ip}d_{\rho(i),j} + f_{pi}d_{j,\rho(i)}\big)}{n-k} \\ & + \frac{\sum\limits_{i\notin\mathcal{F}}\sum\limits_{j\notin\mathcal{L}c_{ij}}}{n-k} + \frac{\sum\limits_{i,p\notin\mathcal{F}} f_{ip}\big(\sum\limits_{j,q\notin\mathcal{L}} d_{jq}\big)}{(n-k)\,(n-k-1)}. \end{aligned}$$

The low computational requirements of computing EV make this a good choice to guide a construction heuristic [GrWh70].

17. *Improvement methods*: These heuristics start with a suboptimal solution (often randomly generated) and attempt to improve it through partial changes in the assignments. Several important issues arise in designing an improvement heuristic:

- *type of exchange*: The choices are pairwise, triple, or higher-order exchanges. The use of pairwise exchanges has been found to be the most effective in terms of solution quality and computational burden. Higher-order exchanges can be beneficial but are generally used in a limited way because of the significant increase in computation time.
- *scope of exchange*: The procedure can use a local approach that considers only the exchange of adjacent facilities, or a global approach that considers all possible exchanges. Current computing capabilities allow the use of a global approach, which has been found to be more effective.

- *choice of exchange*: The procedure can effect an exchange as soon as an improving move is found, or can evaluate all possible exchanges and choose the best. The first improvement option is more common.
- *order of evaluation*: The possible exchanges can be evaluated in a random or some predetermined order. This is relevant only if the "first improvement" approach is used, as is often the case. One simple but effective solution is to consider facilities in the fixed order of decreasing total interactions, so that exchanges with potentially large savings are evaluated first.

18. *Hybrid methods*: Unlike improvement procedures, which tend to get trapped at local minima, hybrid methods use multiple restarts from a set of diversified solutions. Hybrid procedures combine the power of improvement routines with diversified solutions obtained through construction methods.

19. *Metaheuristics*: In recent years, metaheuristics such as simulated annealing, tabu search, and genetic algorithms have been developed to help improvement procedures avoid the trap of local minima and have been applied with success to the QAP. Metaheuristics have been able to find the best known solutions for the commonly used benchmark problems in the literature and remain an active area of research on the QAP.

20. A recent survey of the QAP is provided in [Dr15]. The most successful metaheuristic so far for solving the QAP is the hybrid genetic algorithm.

21. Research papers, software, datasets, test instances, and solutions can be found in QAPLIB at

- `http://anjos.mgi.polymtl.ca/qaplib/`

Examples:

1. The following table gives the data c_{ij}, f_{ij} for a QAP with four facilities and four locations.

c_{ij}	1	2	3	4
1	1	3	2	1
2	2	1	4	3
3	4	2	4	4
4	3	1	2	2

f_{ij}	1	2	3	4
1	0	1	3	4
2	1	0	2	1
3	3	2	0	3
4	4	1	3	0

The fixed locations $1, 2, 3, 4$ occur at equally-spaced points along a line, with unit distances between successive points, so that $d_{ij} = |i - j|$. For the assignment ρ specified by $\rho(1) = 1, \rho(2) = 4, \rho(3) = 2, \rho(4) = 3$ the fixed cost is $c_{11} + c_{24} + c_{32} + c_{43} = 8$. Because the flows and distances are symmetric, the interaction cost is $2(f_{12}d_{14} + f_{13}d_{12} + f_{14}d_{13} + f_{23}d_{42} + f_{24}d_{43} + f_{34}d_{23}) = 44$. The total cost of assignment ρ is then $8 + 44 = 52$.

2. The assignment in Example 1 can be improved by a pairwise exchange. Namely, instead of assigning facilities 1 and 2 (respectively) to locations 1 and 4, they are assigned to the interchanged locations 4 and 1. This gives $\sigma(1) = 4, \sigma(2) = 1, \sigma(3) = 2, \sigma(4) = 3$. Then the fixed cost incurred is $c_{14} + c_{21} + c_{32} + c_{43} = 7$ and the interaction cost is $2(f_{12}d_{41} + f_{13}d_{42} + f_{14}d_{43} + f_{23}d_{12} + f_{24}d_{13} + f_{34}d_{23}) = 40$. The total cost 47 is lower than that for the assignment ρ in Example 1. In fact σ is an optimal QAP assignment.

3. The QAP arises in designing the layout of a manufacturing facility. A number of products are to be made in this facility and different products require different operations in given sequences for completion. These operations are performed by n departments: e.g., turning, milling, drilling, heat treatment, and assembly. Knowing the sequence of operations and the volume of each product to be produced, it is possible to calculate the flow f_{ij} from any department i to another department j. There are n physical locations, with distance d_{ij} between locations i and j. The fixed cost of assigning department i to location j is c_{ij}, representing the cost of building foundations and installing support equipment (cables, pipes) for the machines. Then the objective is to assign departments to locations in order to minimize the sum of fixed and interaction costs.

4. The TSP (§10.7.1) can be formulated as a special case of the QAP, where the n cities correspond to locations and a position number (facility) in the tour is to be associated with each city. Let $f_{12} = f_{23} = \cdots = f_{n1} = 1$ and $f_{ij} = 0$ otherwise. The distance d_{ij} represents the cost of traveling between cities i and j, and let all fixed costs c_{ij} be zero. Then a solution to this QAP gives an optimal labeling of cities with their positions in an optimal TSP tour.

10.8 SMALL-WORLD NETWORKS

The concept of a "small-world network" is well known in both the scientific literature and in popular culture. It is often associated with the term "six degrees of separation", which indicates the relatively small number of steps in a chain linking random individuals. Small-world networks are neither random, nor perfectly ordered. Rather they display the important characteristics of small average distance between vertices, small diameter, and a high degree of clustering. Many social networks exhibit the small-world property, as well as a number of other naturally occurring networks (the structure of the Internet, ecological food webs, transportation networks, and biological networks). This section presents an introduction to the structure and dynamics of small-world networks.

10.8.1 BASIC CONCEPTS

This subsection provides important graph definitions and concepts useful in quantitatively characterizing network structures that arise in nature and society. It allows one to compare and contrast random, structured, and small-world networks.

Definitions:

Let $G = (V, E)$ be a simple undirected graph, with $n = |V|$ and $m = |E|$. The vertex subset $S \subseteq V$ forms an ***induced subgraph*** $G[S] = (S, E[S])$ if $E[S] = \{(i, j) \mid i, j \in S,\ (i, j) \in E\}$. The largest connected component of G and the corresponding induced subgraph are indicated by $S \subseteq V$ and $G[S]$, respectively.

The ***open neighborhood*** of vertex $i \in V$ is denoted $N(i) = \{j \mid (i, j) \in E\}$.

The ***degree*** of vertex i is $d_i = |N(i)|$ and $\bar{d} = \frac{1}{n}\sum_{i \in V} d_i$ is the ***average degree*** of G. A ***d-regular graph*** is a graph in which the degree of each vertex is equal to d.

The ***triangle degree*** of vertex i is $t_i = |\{(j, k) \mid j, k \in N(i),\ (j, k) \in E\}|$: namely, the number of triangles containing vertex i.

The ***distance*** between vertices $i, j \in V$ is the length $l(i, j)$ of a shortest path between them. The ***diameter*** of G is the largest distance between any two vertices in G: $\text{diam}(G) = \max_{i,j \in V} l(i, j)$.

Note: If G is not connected, we consider the diameter of the largest component $\mathrm{diam}(G[S])$ instead.

The ***average distance*** in G is defined as $\bar{l} = \bar{l}(G) = \sum\limits_{i,j \in V,\, i<j} l(i,j)/\binom{n}{2}$.

The ***clustering coefficient*** C of a graph is

$$C = \frac{3 \times (\text{number of triangles})}{\text{number of connected triples}},$$

where a ***connected triple*** consists of three vertices connected by two or more edges.

The ***local clustering coefficient*** C_i of vertex i is

$$C_i = \frac{\text{number of triangles connected to vertex } i}{\text{number of connected triples centered on vertex } i}$$

and the ***Watts-Strogatz clustering coefficient*** C_{WS} is the average of the local clustering coefficients:

$$C_{\mathrm{WS}} = \frac{1}{n} \sum_{i \in V} C_i.$$

Facts:

1. Many empirical studies of practical small-world networks imply that distances in the network are considered to be "small" when they are orders of magnitude smaller than the order n of the network [Ba16]. Hence, network distances can be considered "small" when $\bar{l}(G) = O(\ln n)$ and $\mathrm{diam}(G) = O(\ln n)$.

2. The number of distinct triangles in G is equal to $\frac{1}{3}\sum_{i \in V} t_i$.

3. The clustering coefficient C is a measure of *transitivity*: namely, the probability that two random neighbors of a vertex are neighbors of each other [Ne10].

4. The factor 3 in the numerator of C arises since each triangle produces three closed triples.

5. Equivalently, C can be defined in terms of t_i and d_i:

$$C = \frac{\sum_{i \in V} t_i}{\sum_{i \in V} \binom{d_i}{2}}.$$

6. The alternative clustering coefficient C_{WS} was proposed by Watts and Strogatz [WaSt98].

7. Since the local clustering coefficient can be alternatively represented as $C_i = t_i/\binom{d_i}{2}$, C_{WS} can also be equivalently expressed in terms of t_i and d_i:

$$C_{\mathrm{WS}} = \frac{1}{n} \sum_{i \in V} \frac{t_i}{\binom{d_i}{2}}.$$

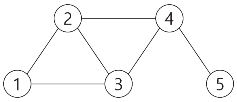
8. The clustering coefficients satisfy $0 \le C \le 1$ and $0 \le C_{\mathrm{WS}} \le 1$.

9. The clustering coefficients C and C_{WS} are both good measures of network transitivity. Random networks display low transitivity, and thereby both C and C_{WS} for such networks usually converge to zero as $n \to \infty$. In contrast, these clustering coefficients for a network with high transitivity usually fall within the interval $[0.1, 1]$.

10. Whereas random networks tend to have a small average distance and a small clustering coefficient, small-world networks have a small average distance and a large clustering coefficient.

Examples:

1. The following graph on five vertices has the degree sequence $d_1 = 2,\ d_2 = d_3 = d_4 = 3,\ d_5 = 1$ and the triangle degrees $t_1 = 1,\ t_2 = t_3 = 2,\ t_4 = 1,\ t_5 = 0$.



By Fact 5, the clustering coefficient C is computed as

$$C = \frac{\sum_{i=1}^{5} t_i}{\sum_{i=1}^{5} \binom{d_i}{2}} = \frac{1+2+2+1+0}{1+3+3+3+0} = 0.6.$$

By Fact 7, the local clustering coefficients are $C_1 = 1,\ C_2 = C_3 = \frac{2}{3},\ C_4 = \frac{1}{3},\ C_5 = 0$ and so C_{WS} is computed as

$$C_{\mathrm{WS}} = \tfrac{1}{5}\textstyle\sum_{i=1}^{5} C_i = \tfrac{1}{5}\left(1 + \tfrac{2}{3} + \tfrac{2}{3} + \tfrac{1}{3} + 0\right) = \tfrac{8}{15} \approx 0.53.$$

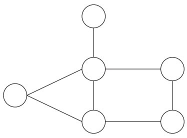
Notice that $C > C_{\mathrm{WS}}$ holds in this example.

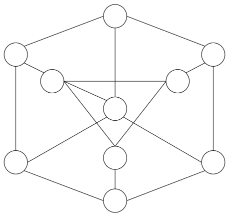
2. In general, there is no order relation between these two definitions of the clustering coefficient (C and C_{WS}). For instance, suppose we delete vertex 5 from the graph in Example 1 and consider the graph $\widetilde{G} = G[V \backslash \{5\}]$. Then $C(\widetilde{G}) = 3/4 = 0.75$ and $C_{\mathrm{WS}}(\widetilde{G}) = 5/6 \approx 0.83$, yielding $C < C_{\mathrm{WS}}$ for the graph $\widetilde{G}$.

3. Although C need not be equal to C_{WS}, there are types of graphs where the equality $C = C_{\mathrm{WS}}$ holds. For example, every regular graph satisfies $C = C_{\mathrm{WS}}$. Namely, for any d-regular graph G with t_G triangles in total

$$C = C_{\mathrm{WS}} = \frac{3t_G}{n\binom{d}{2}}.$$

There are graphs that are not regular, but still satisfy $C = C_{\mathrm{WS}}$, as occurs in the following two graphs. In the first graph $C = C_{\mathrm{WS}} = 1/4$, while in the second graph $C = C_{\mathrm{WS}} = 1/12$. Thus, regularity is a sufficient but not a necessary condition for $C = C_{\mathrm{WS}}$.





10.8.2 RANDOM GRAPH MODELS

The classical random graph model was mostly motivated by an observation that social connections are formed with omnipresent randomness. Although this random graph model is not sufficient to explain the properties of social and other real-world networks, it still plays a significant role in studying the small-world phenomena.

Definitions:

In the ***$G_{n,m}$* random model**, n vertices are connected by m randomly placed edges.

In the ***$G_{n,p}$* random model**, each pair of vertices has an edge connecting them with a fixed probability p.

Let n_k be the number of vertices having degree k in a simple graph $G = (V, E)$. The ***degree distribution*** of G is given by $p_k = n_k/n$ for $k = 0, 1, \dots, n-1$.

A discrete random variable ξ follows a ***binomial distribution*** $B(N, p)$ with parameters N and p if

$$Pr(\xi = k) = \binom{N}{k} p^k (1-p)^{N-k} \text{ for } k = 0, 1, \dots, N.$$

A discrete random variable η follows a ***Poisson distribution*** $P(\lambda)$ with parameter λ if

$$Pr(\eta = k) = \frac{\lambda^k}{k!} e^{-\lambda} \text{ for } k = 0, 1, 2, \dots.$$

Facts:

1. Erdős and Rényi [ErRé60] proposed the $G_{n,m}$ random model, while Gilbert [Gi59] proposed the $G_{n,p}$ random model. Both $G_{n,m}$ and $G_{n,p}$ are commonly referred as to *Erdős-Rényi random graphs* or *uniform random graphs*.

2. The $G_{n,m}$ and $G_{n,p}$ models behave identically for $p = m/\binom{n}{2}$ under several conditions. While this subsection focuses on the more popular $G_{n,p}$ random graph model, most of the results obtained for $G_{n,p}$ carry over to $G_{n,m}$ [Ne03].

3. Since p_k is the fraction of vertices with degree k in G, the degree distribution of G reflects the probability that a randomly selected vertex of a graph has a specified degree.

4. *Binomial degree distribution*: The degree distribution of $G_{n,p}$ is binomial with the parameters $n-1$ and p [Ne10]: namely,

$$p_k = \binom{n-1}{k} p^k (1-p)^{n-k-1} \text{ for } k = 0, 1, \dots, n-1.$$

Since $E[B(N, p)] = Np$ (see §7.3.3), the average degree $\bar{d}$ is well estimated by $(n-1)p$.

5. *Poisson degree distribution*: For large sparse random graphs, the degree distribution of $G_{n,p}$ is well approximated by a Poisson distribution with mean $\bar{d}$. Specifically, if n tends to infinity and $\bar{d} \ll n$, then it can be shown [Ba16] that for $k \ll n$

$$p_k \approx \frac{\bar{d}^k}{k!} e^{-\bar{d}} \ .$$

Hence $G_{n,p}$ graphs are also referred to as *Poisson random networks*. Although $\bar{d} \ll n$, $\bar{d}$ still can be sufficiently large and can tend to infinity (but at a much slower rate than n).

6. *Size of a random network*: While the number of edges of $G_{n,m}$ is constant and equal to m, the number of edges of $G_{n,p}$ is random but densely concentrated around its expectation $E[m(G_{n,p})] = p\binom{n}{2}$, due to the properties of the binomial distribution.

7. *Approximate equivalence of the models*: In the limit of large n, models $G_{n,m}$ and $G_{n,p}$ exhibit very similar properties when m is close to $p\binom{n}{2}$. Particularly, if $p(1-p)n^2 \to \infty$ and a certain property Q holds for $G_{n,m}$ for all consecutive values of m in the range $p\binom{n}{2} - \sqrt{p(1-p)}n < m < p\binom{n}{2} + \sqrt{p(1-p)}n$, then Q holds for $G_{n,p}$ as well. The converse holds for a rich class of convex properties [Bo98].

8. *Order of the giant component*: The giant connected component emerges in a uniform random graph after an average degree passes the critical point $\bar{d} = 1$. Poisson networks with $1 < \bar{d} < \ln n/n$ are said to be in a *supercritical regime*. They have a single giant component containing a fraction $u = n_S/n$ of all vertices, which can be approximated as

$$u \approx -\frac{W(-\bar{d}e^{-\bar{d}})}{\bar{d}},$$

where W is the principal branch of *the Lambert W-function* [Ne10]. For random graphs with $\bar{d} > \ln n/n$ (*connected regime*) the giant connected component contains all vertices making $S = V$ and $u = 1$.

9. *Diameter*: The following results hold for *connected* Erdős-Rényi (Poisson) networks.

- Simple calculations can yield a good approximation for the diameter of a uniform random graph [Ba16], [Ne10]:

$$\mathrm{diam}(G_{n,p}) = \Theta\left(\frac{\ln n}{\ln \bar{d}}\right).$$

- If $np \to \infty$ for an Erdős-Rényi graph $G_{n,p}$, then the following result holds asymptotically almost surely [ChLu04]:

$$\mathrm{diam}(G_{n,p}) = (1 + o(1))\frac{\ln n}{\ln np}.$$

- For a Poisson random graph $G_{n,p}$ with $\bar{d} = \lambda > 1$ (thus, $p \approx \lambda/n$), the equality

$$\mathrm{diam}(G_{n,p}) = \frac{\ln n}{\ln \lambda} + 2\frac{\ln n}{\ln \lambda_\star} + O_{\mathrm{p}}(1)$$

  is valid, where $\lambda_\star$ is a "dual"-parameter of λ given by the formula $\lambda_\star = -W(-\lambda e^{-\lambda})$ and $O_{\mathrm{p}}(1)$ denotes a sequence of random variables X_n *bounded in probability* [JaLuRu00]. This result is a stronger form of the result obtained by Fernholz and Ramachandran [FeRa07] for Poisson random graphs.

10. *Clustering coefficient*: The clustering coefficient of a uniform random graph is $C = p$ or, equivalently, $C = O(1/n)$. For large sparse networks, C converges to 0 as $n \to \infty$. However, Albert and Barabási [AlBa00] argued that clustering coefficients in real-world networks tend not to follow the results obtained for uniform random graphs.

11. Although uniform random graphs exhibit small distances (logarithmic in the order of the network), their clustering coefficient tends to zero as n increases. The latter fact is the main flaw of this model in the context of small-world networks. This flaw is addressed by the models presented in the next section.

10.8.3 WATTS-STROGATZ MODEL

The Watts-Strogatz model [WaSt98] combines the small diameter and high clustering properties. This subsection summarizes the main characteristics of this model and its extensions.

Definitions:

A ***lattice*** (or ***grid***) is a graph whose vertices correspond to integer coordinate points in an n-dimensional Euclidean space and whose edges connect every vertex to its c closest vertices.

The ***Watts-Strogatz model*** (W-S model, $G^{\mathrm{WS}}_{c,p}$) generates networks using the following steps:

1. Define the number of vertices n, the lattice parameter c, and the rewiring parameter $p \in [0,1]$, where $n \gg c \gg \ln n \gg 1$ and c must be even.
2. Place n vertices in a "ring" and connect each vertex to its c closest vertices. Note that the resulting graph is a one-dimensional lattice with periodic boundary conditions.
3. "Rewire" each edge (i,j) with probability p. This means that we shift one of its ends j to a new position randomly selected from the rest of the vertices in the ring (ensuring that no two vertices are joined by more than one edge and no vertex has a self-loop), whereas the other end i remains at the same position.

The ***Newman-Watts model*** (N-W model, $G^{\mathrm{NW}}_{c,p}$) was proposed by Newman and Watts [NeWa99] in order to analyze the W-S model theoretically. The N-W model is a modification of the W-S model, obtained by slightly revising the W-S network generation algorithm. Instead of rewiring, the generation algorithm for the N-W model adds extra edges to the underlying lattice. Namely, the algorithm generates a new edge with probability p for each edge in the initial lattice. The endpoints of each newly generated edge are chosen uniformly at random.

The ***Dorogovtsev-Mendes model*** (D-M model, $G^{\mathrm{DM}}_{n,p}$) was proposed by Dorogovtsev and Mendes [DoMe00] as an alternative small-world network model. The D-M model is built by adding an extra vertex as a "central point" and connecting it with each vertex in the underlying lattice with probability p. The edges emanating from the central vertex have weights $1/2$ as opposed to unit weights of the edges on the initial ring.

Facts:

1. The assumptions stated in the W-S model include sparsity ($n \gg c$), connectivity ($c \gg \ln n$), and a proper size ($\ln n \gg 1$) of the network.

2. Consider the W-S model. If $p \to 0$, then $\bar{l}(G^{\mathrm{WS}}_{c,p}) \sim n/(2c) \gg 1$ and $C(G^{\mathrm{WS}}_{c,p}) \approx C_{\mathrm{WS}}(G^{\mathrm{WS}}_{c,p}) \sim (3(c-2))/(4(c-1))$, which is approximately $3/4$ for large values of c. If $p \to 1$, then $\bar{l}(G^{\mathrm{WS}}_{c,p}) \approx \bar{l}(G_{n,p}) \sim \ln n / \ln c$ and $C(G^{\mathrm{WS}}_{c,p}) \approx C_{\mathrm{WS}}(G^{\mathrm{WS}}_{c,p}) \approx C(G_{n,p}) \sim c/n$. In particular, small average distance and high clustering are observed simultaneously (i.e., the network becomes "small-world") for small values of p, usually $0.001 < p < 0.01$.

3. The N-W model is equivalent to the W-S model if p is small, which is the case when the W-S model becomes a small-world network.

4. In the N-W model, as well as in the W-S model, the average distance increases linearly with the network size n for $p = 0$, whereas it increases logarithmically with n for $p = 1$. Newman et al. [NeMoWa00] employed a mean-field approximation to show that the transition between these growth rates occurs in the region where the average number of added shortcuts $s = ncp/2$ is about one. More specifically, as $n \to \infty$, $s \gg 1$ and c, p are fixed the average distance between vertices increases logarithmically with n, since

$$\bar{l}(G^{\mathrm{NW}}_{c,p}) \approx \frac{\ln(ncp)}{c^2 p} = \Theta\left(\ln n\right).$$

Thus, the N-W model shows that the addition of only a small fraction of random shortcuts to a large underlying lattice can yield a small-world effect.

5. Newman [Ne10] estimated the clustering coefficient of the N-W model in the limit of large n:

$$C(G^{\mathrm{NW}}_{c,p}) \approx \frac{3(c-2)}{4(c-1)+8cp+4cp^2}.$$

Therefore, $C(G^{\mathrm{NW}}_{c,p}) \approx 3/(4(1+p)^2)$ for sufficiently large c. In other words, the N-W model with reasonably small values of p exhibits high clustering.

6. *Asymptotic bounds on the diameter*: Bollobás and Chung [BoCh88] derived a strong asymptotic result for the diameter of a cycle plus a random matching, which can be considered as a rough approximation of the N-W model with parameters $c = 2$ and $p = 1/2$ (for such parameters the size of a random matching and an estimated number of added shortcuts are both equal to $n/2$). If G is a cycle on n vertices plus a random matching, then

$$\log_2 n - \theta < \mathrm{diam}(G) \le \log_2 n + \log_2 \ln n + \theta$$

asymptotically almost surely (that is, with probability tending to 1 as $n \to \infty$), where θ is a small constant (at most 10).

7. Dorogovtsev and Mendes [DoMe00] obtained an asymptotic expression for $\bar{l}$ as $p \to 0$ and $n \to \infty$ in the D-M model:

$$\frac{\bar{l}(G^{\mathrm{DM}}_{n,p})}{n} \sim \frac{2\rho - 3 + (\rho+3)e^{-\rho}}{\rho^2},$$

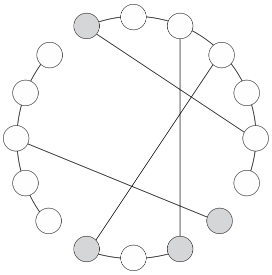
where $\rho = np$ is fixed. Furthermore, consider any function $\rho(n) \to \infty$, which implies $\bar{l}(G^{\mathrm{DM}}_{n,p}) \sim 2n/\rho$. Thus, if one chooses any $p(n) = \Theta(1/\ln n)$, then

$$\bar{l}(G^{\mathrm{DM}}_{n,p}) = \Theta(\ln n).$$

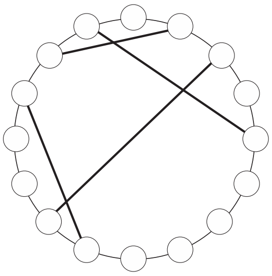
Hence, with a proper choice of $p(n)$, the D-M model exhibits small-world distances as $n \to \infty$.

Examples:

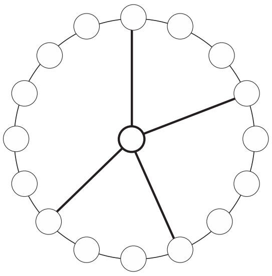
1. The following figure illustrates a W-S network generated with $n = 16$ vertices, placed in a ring with $c = 2$. The four shaded vertices are selected for rewiring; one end of an edge incident to each such vertex is randomly linked to another vertex, giving the "middle" edges shown in the picture.



2. The following figure illustrates an N-W network generated with $n = 16$ vertices, placed in a ring with $c = 2$. Four new edges (shown highlighted) are randomly generated and added to this ring.



3. The following figure illustrates a D-M network generated with $n = 16$ vertices, placed in a ring with $c = 2$. An extra vertex is added to the network and connected to some other randomly selected vertices in the ring. The added edges are shown highlighted.



10.8.4 KLEINBERG'S GEOGRAPHICAL SMALL-WORLD MODEL

This subsection considers a natural generalization of the W-S small-world network model, referred to as the geographical small-world model, for which there exists a decentralized algorithm capable of finding short paths in logarithmic time with high probability.

Definitions:

In an r-dimensional lattice, l_1-distances are measured by $d(u, v) = \sum_{k=1}^{r} |u_k - v_k|$, where $u = (u_1, \ldots, u_r)$ and $v = (v_1, \ldots, v_r)$.

Kleinberg's small-world model, which is a modified version of the N-W model, is obtained by adding random directed edges to an r-dimensional lattice, based on l_1-distance. In the underlying lattice, each vertex has a directed link to any other vertex within lattice l_1-distance ξ, for a user-defined constant $\xi \geq 1$; such neighbors are called *local contacts*. Also q *long-range connections* (u, v) for each vertex u are generated with probability proportional to $d(u, v)^{-\alpha}$ for each vertex v; here α is a user-defined parameter.

Local search (or, equivalently, ***decentralized search***) $\mathcal{L}$ in Kleinberg's model is designed to imitate Milgram's small-world experiment (see §10.8.7). Suppose that a starting vertex i is given a message that it must forward to a target vertex j. At each iteration, a current vertex should choose which of its neighbors to send the message to. Meanwhile, it uses only local information, i.e., it knows only geographical distances between its neighbors and the target vertex j. In Kleinberg's decentralized algorithm every current vertex connects to a neighbor that is geographically closest to vertex j. These consecutive choices determine a path from i to j via local search.

The ***expected delivery time*** $T_{\mathcal{A}}$ of a search algorithm $\mathcal{A}$ is the expected number of steps taken by the algorithm to deliver the message over a generated network.

A particular version of Kleinberg's model is based upon probabilities determined by rank rather than by physical distances. The ***rank*** of a vertex v with respect to a vertex u is defined as the number of other vertices that are geographically closer to u than to v: i.e.,

$$\text{rank}_u(v) = |\{w \mid d(w,u) < d(v,u)\}|.$$

Facts:

1. Kleinberg's geographical small-world model [Kl00] was originally constructed on a two-dimensional lattice ($r = 2$). If no specific information about r is given, this original model with $r = 2$ will be assumed and denoted $G^{\text{K}}_{\alpha,q,\xi}$.

2. If α is large, then long-range edges have a small chance of being created, whereas if α is close to 0, then long-range edges may appear in the network with a reasonably high probability. When $\alpha = 0$, Kleinberg's model generates additional edges according to a uniform distribution, which is equivalent to the directed N-W model on the two-dimensional lattice (we treat every undirected edge (u,v) in the underlying lattice of the N-W model as two directed edges (u,v) and (v,u)).

3. For every graph G and algorithm $\mathcal{A}$, the inequality $T_{\mathcal{A}}(G) \geq \bar{l}(G)$ holds.

4. In large Kleinberg networks, local search can be carried out most efficiently when $\alpha = 2$, as supported by the following theoretical results [Kl00]:

- For Kleinberg's model with $0 \leq \alpha < 2$, arbitrary $q \geq 1$, $\xi \geq 1$, and any decentralized algorithm $\mathcal{A}$
$$T_{\mathcal{A}}(G^{\text{K}}_{\alpha,q,\xi}) = \Omega(n^{(2-\alpha)/3}).$$
As a consequence, despite the fact that there exist paths between every pair of vertices whose lengths are $O(\ln n)$ for the two-dimensional N-W model (the case $\alpha = 0$), there is no decentralized algorithm capable of finding those chains in logarithmic time.
- For Kleinberg's model with $\alpha = 2$, $q = 1$, $\xi = 1$, and the decentralized algorithm $\mathcal{L}$ (Kleinberg's local search)
$$T_{\mathcal{L}}(G^{\text{K}}_{\alpha,q,\xi}) = O(\ln^2 n).$$
- For Kleinberg's model with $\alpha > 2$, arbitrary $q \geq 1$, $\xi \geq 1$, and any decentralized algorithm $\mathcal{A}$
$$T_{\mathcal{A}}(G^{\text{K}}_{\alpha,q,\xi}) = \Omega(n^{(\alpha-2)/(\alpha-1)}).$$

In computational experiments on Kleinberg networks with several hundred million vertices, local search performed most efficiently for values of α in the range $[1.5, 2]$. Moreover, as the network size increases, the most "efficient" value for α approaches 2 [Kl00].

5. *Rank-based friendship* is a concept based on the assumption that a directed edge (u,v) is randomly generated with probability p_{uv} proportional to $\text{rank}_u(v)^{-\beta}$, where β is a predetermined parameter. If vertices are uniformly distributed in a Euclidean two-dimensional space according to the l_1-norm, then $\text{rank}_u(v)$ is approximately $2d(u,v)^2$. Thus, a rank-based friendship network with $\beta = 1$ is approximately the same as Kleinberg's network with $\alpha = 2$, since $p_{uv} \propto d(u,v)^{-2}$ for both models.

6. *Blog network*: Liben-Nowell et al. [LiEtal05] employed the rank-based friendship principle to analyze roughly 500,000 users of the blogging site *LiveJournal*. In their case, the rank of a target user v with respect to a primary user u indicates how far v

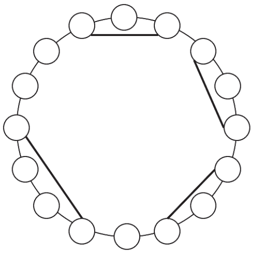
lives from u in comparison with other users connected with u via *LiveJournal*. Liben-Nowell et al. investigated the following question: if we consider all vertex pairs (u, v) with $\text{rank}_u(v) = x$ for some fixed integer $x \geq 1$, what fraction $f(x)$ of these pairs are actual friends? They computationally found that $f(x)$ follows a power law (see §10.8.5) with exponent in the range $(-1.15, -1.2)$. This experimental finding supports the statement (see Facts 4–5) that $\beta = 1$ is an adequate choice for the rank-based friendship model.

7. *Facebook network*: Backstrom et al. [BaSuMa10] also considered rank-based friendship. They analyzed the Facebook network at that time and estimated the exponent β to be very close to 1. In their case, the bulk of the distribution was approximated by $x^{-0.95}$. These results are consistent with those of Liben-Nowell et al. and further support the formula $p_{uv} \propto \text{rank}_u(v)^{-1}$ as the best choice for the rank-based friendship model.

8. Regarding Kleinberg's model based upon an r-dimensional lattice with $r > 2$, Easley and Kleinberg [EaKl10] pointed out that local search is efficient for networks built by adding long-range contacts to lattices in $r > 2$ dimensions, when the exponent α is equal to r.

Example:

1. The following figure illustrates an undirected version of Kleinberg's small-world model generated with $n = 16$ vertices, placed in a ring with $\xi = 1$. (Note that any instance of the directed Kleinberg model can be easily transformed into an instance of the undirected Kleinberg model by drawing an edge (u, v) if either the edge (u, v) or (v, u) exists.) New edges were randomly generated with probability $p_{uv} \propto d(u, v)^{-2}$ for each vertex pair (u, v). As a result, four new edges (shown highlighted) were added to this ring. The corresponding distances for the four pairs are 2, 2, 2, 3, which are shorter than the ones of the N-W model instance described in §10.8.3, Example 2 (which are 3, 4, 5, 8).



10.8.5 POWER-LAW RANDOM NETWORKS AND THEIR SMALL-WORLD PROPERTIES

In contrast to the Erdős-Rényi model, most real-world networks have degree distributions substantially different from the Poisson distribution that uniform graphs exhibit for large n. Several empirical studies suggest that many real-world networks follow a power-law degree distribution [AiChLu02], [BaAl99], [Ne03]. These observations motivated work on developing more realistic random network models that mitigate the shortcomings of the Erdős-Rényi model. This subsection reviews the facts associated with random network models having general degree distributions, as well as the important special cases of power-law random networks.

Definitions:

Given the number of vertices n and degree sequence $\{d_1, d_2, \ldots, d_n\}$, the ***configuration model*** generates networks using the following steps:

1. For each vertex $i \in V$, attach d_i "half-edges" (also called "stubs").
2. Randomly connect the ends of the half-edges together, one pair at a time.

The ***generalized random graph model*** generates graphs in which vertices $i, j \in V$ are connected with edge probability

$$p_{ij} = \frac{w_i w_j}{2m},$$

where $\{w_1, w_2, \ldots, w_n\}$ is a given sequence of expected degrees chosen from a distribution of interest.

The ***power-law degree distribution*** is defined by

$$p_k = Ck^{-\beta} \quad \text{for } k = k_{\min}, \ldots, k_{\max},$$

where p_k is the fraction of vertices with degree k, C is a normalization factor, β is the decay exponent, and $k_{\min}$, $k_{\max}$ are (respective) lower and upper limits on the possible values of k.

The ***pure power-law degree distribution*** is given by

$$p_k = Ck^{-\beta} \quad \text{for } k \geq 1,$$

where $C = 1/\zeta(\beta)$ (the Riemann zeta function).

The ***power-law degree distribution with exponential cutoff*** is given by

$$p_k = Ck^{-\beta}e^{-k/\kappa} \quad \text{for } k \geq 1,$$

where C is a normalization constant and κ is an exponential cutoff parameter.

Remark: The three defined versions of power laws are discrete distributions and should not be confused with continuous power-law distributions.

Notation: G_β^{gen} denotes a graph produced by the generalized random graph model with an expected degree sequence $\{w_i\}$ sampled from the pure power-law distribution having parameter β. G_β^{pl} denotes a theoretical power-law graph with parameter β, that is, a graph with a power-law degree distribution with an exponent β that is assumed to exist; it is used only in theoretical derivations. G_β^{conf} denotes a graph produced by the configuration model with a degree sequence that follows the pure power-law distribution with parameter β. $G_{\beta,\kappa}^{\text{conf}}$ denotes a graph generated by the configuration model with an expected degree sequence drawn from the power-law distribution with exponential cutoff and parameters β, κ.

Facts:

1. The configuration model is one of the most popular generalized random network models. This process generates every possible topology having the given parameters with equal probability [Ne10].

2. Graphs generated by the configuration model can contain loops and multi-edges. The common way to transform such graphs into simple ones is to delete any loops and multi-edges. As n becomes large, the density of loops and multi-edges tends to 0 for the configuration model, and the degree distribution of the resulting simple graphs is close to the given one. Since we focus on the behavior of graphs for large n, such self-loops and multi-edges will be disregarded.

3. The paramount property of the configuration model is that the probability p_{ij} of edge (i,j) appearing is given by

$$p_{ij} = \frac{d_i d_j}{2m} \text{ as } n \to \infty.$$

4. The property given in Fact 3 makes the configuration model similar to the generalized random graph model, which was proposed by Chung and Lu [ChLu04].

5. Despite the fact that the final degree sequence of the generalized random graph model is not exactly equal to the desired degree sequence in general, this model has notable calculation advantages. As in the case of the configuration model, we ignore self-loops and multi-edges produced by the generalized random graph model.

6. For the power-law degree distribution with exponential cutoff, κ is typically a fixed large positive constant, but it can also be represented as a function of n.

7. The normalization constant C for the power-law degree distribution with exponential cutoff turns out to be $[\mathrm{Li}_\beta(e^{-1/\kappa})]^{-1}$, where $\mathrm{Li}_n(x)$ is the nth polylogarithm of x.

8. *Small distances in* G_β^{gen}: Chung and Lu [ChLu04] showed that distances in power-law graphs generated via the generalized random graph model are small (or even "ultra-small").

- For a power-law random graph G_β^{gen} with exponent $\beta > 3$ and average degree $\bar{d} > 1$, both the average distance and diameter are $\Theta(\ln n)$ almost surely. More precisely, when n becomes very large

$$\bar{l}(G_\beta^{\mathrm{gen}}) = (1 + o(1))(\ln n / \ln \tilde{d}),$$
$$\mathrm{diam}(G_\beta^{\mathrm{gen}}) = \Theta(\ln n),$$

  hold almost surely, where $\tilde{d} = \sum_{i\in V} w_i^2 / \sum_{i\in V} w_i$ denotes the second-order average degree. These equalities are corroborated by the approximation results obtained by Cohen and Havlin [CoHa03]: $\bar{l}(G_\beta^{\mathrm{pl}}) \propto \ln n$ for $\beta > 3$ and $n \gg 1$.

- For $\beta = 3$ a power-law random graph G_β^{gen} has

$$\mathrm{diam}(G_\beta^{\mathrm{gen}}) = \Theta(\ln n)$$

  almost surely and

$$\bar{l}(G_\beta^{\mathrm{gen}}) = \Theta(\ln n / \ln \ln n)$$

  as $n \to \infty$. The respective approximation results by Cohen and Havlin support the latter formula: $\bar{l}(G_\beta^{\mathrm{pl}}) \approx \ln n / \ln \ln n$ for $\beta = 3$ assuming $\ln \ln n \gg 1$.

- Consider a power-law random graph G_β^{gen} with exponent $2 < \beta < 3$, average degree $\bar{d} > 1$, and maximum degree $\Delta(G_\beta^{\mathrm{gen}})$ satisfying $\ln \Delta \gg \ln n / \ln \ln n$. Then almost surely

$$\mathrm{diam}(G_\beta^{\mathrm{gen}}) = \Theta(\ln n)$$

  and

$$\bar{l}(G_\beta^{\mathrm{gen}}) \le (2 + o(1))[\ln \ln n / \ln(1/(\beta - 2))]$$

  as $n \to \infty$.

9. *Small distances in* G_β^{conf}: Newman et al. [NeStWa01] derived approximation results for the pure power-law distribution realized via the configuration model as $n \to \infty$. Assuming that G_β^{conf} is connected and $\beta > 3$

$$\bar{l}(G_\beta^{\mathrm{conf}}) \approx \frac{\ln n + \ln[\zeta(\beta)/\zeta(\beta-1)]}{\ln[\zeta(\beta-2)/\zeta(\beta-1) - 1] + 1}.$$

More precisely, for sufficiently large n, the average distance in pure power-law graphs grows logarithmically: i.e., $\bar{l}(G_\beta^{\text{conf}}) \approx \Theta(\ln n)$.

10. *Small distances in* $G_{\beta,\kappa}^{\text{conf}}$: Dorogovtsev et al. [DoMeSa03] obtained the following approximation results for power-law graphs with exponential cutoff generated by the configuration model.

- For a graph $G_{\beta,\kappa}^{\text{conf}}$ with exponent $2 < \beta < 3$ and large but finite cutoff parameter κ, the average distance is $\Theta(\ln n)$. More specifically, for large n
$$\bar{l}(G_{\beta,\kappa}^{\text{conf}}) \sim \frac{e^{1/\kappa}}{3-\beta} \ln n.$$
- For a graph $G_{\beta,\kappa}^{\text{conf}}$ with exponent $2 < \beta < 3$ and cutoff $\kappa \propto n^\epsilon$, the average distance is ultrasmall: i.e., $\bar{l}(G_{\beta,\kappa}^{\text{conf}}) \sim \Theta(\ln \ln n)$. Specifically, as $n \to \infty$
$$\bar{l}(G_{\beta,\kappa}^{\text{conf}}) \sim \frac{\ln \ln n}{\ln(1/(\beta-2))},$$
which matches the results of Chung and Lu for G_β^{gen} with $2 < \beta < 3$.
- Graphs $G_{\beta,\kappa}^{\text{conf}}$ with exponent $\beta = 3$ and a cutoff parameter that is polynomial in n (i.e., $\kappa \propto n^\epsilon$) have average distance
$$\bar{l}(G_{\beta,\kappa}^{\text{conf}}) \sim (1+\epsilon)\frac{\ln n}{\ln \ln n}$$
for large n. This coincides with the results of Chung and Lu for G_β^{gen} with $\beta = 3$.

11. *Clustering in power-law graphs*: For any graph generated by the configuration model using a given degree distribution, the clustering coefficient can be directly estimated as follows [Ne10]:
$$C = \frac{1}{n} \frac{[\bar{d^2} - \bar{d}]^2}{(\bar{d})^3}.$$

Here $\bar{d}$ and $\bar{d^2}$ are the first (average degree) and second moments of the degree distribution. If both of these moments are bounded, then the clustering coefficient converges to zero as $n \to \infty$. This is not the case for power-law graphs and even for graphs with a degree distribution having a power-law tail. Usually, their second moment diverges while the average degree is fixed or bounded.

Example:

1. To illustrate Fact 11, let G_β^{pl} be a graph having a power-law distribution with parameter β for $k \geq k_{\min}$ and an arbitrary distribution for $k < k_{\min}$. If one cuts it off (in a simple graph) at $k = n$, this results in the following approximation of the second moment for $2 < \beta < 3$:
$$\bar{d^2}(G_\beta^{\text{pl}}) \sim n^{3-\beta}.$$

Therefore, as n becomes very large, the clustering coefficient grows as
$$C(G_\beta^{\text{pl}}) \sim 1/n^{\beta-2},$$

which still converges to zero, but at a much slower rate (especially for values of β close to 2) than the clustering coefficient of a uniform random network.

10.8.6 EVOLVING RANDOM NETWORKS WITH SMALL-WORLD PROPERTIES

Models of network growth (formation) are an important class of random network models whose primary goal is to mimic growth processes that may take place in modern dynamically changing real-world networks, such as the World Wide Web, the Internet, and social networks. Such growth models include Price's model [Pr76], uniform attachment [BaAlJe99], preferential attachment [BaAl99] (the well-known Barabási-Albert model) and its generalizations [Ne03], a variety of hybrid models of uniform and preferential attachment [DoMe01], [JaRo07], [Vá03], and several nonlinear preferential attachment models [JeNéBa03], [KrReLe00]. In general, it is difficult to theoretically calculate diameters and shortest path lengths for growing network models; however, some of these models have been shown to generate networks that exhibit small-world properties. These models are reviewed in this subsection.

Definitions:

Price's model generates directed graphs. A new vertex is added at each time period and its out-degree is defined according to a fixed distribution with mean μ. That newly appearing vertex is connected to already existing vertices chosen at random with probability proportional to their current degree plus a positive parameter μ_0.

In the ***Barabási-Albert model***, a new vertex is added to the growing network at each time period; it is connected to μ already existing vertices, selected with probability proportional to their current degree. The initial state of the Barabási-Albert model is a clique of cardinality μ at time 0. Note that the Barabási-Albert model is similar to Price's model, but it generates undirected graphs.

The ***Klemm-Eguíluz model*** has as its initial state a clique of cardinality μ at time 0. Each vertex of the network can be either in the *active* state or in the *inactive* state. There are always μ active vertices in the network at the end of every time period. At each step, a new vertex joins the growing network and becomes active. This new vertex is connected to the existing network with μ edges. Each of these edges is connected either to a randomly chosen vertex (with probability p) or to one of the μ active vertices (with probability $1-p$). In the former case, random vertices are chosen with probability proportional to their vertex degree at time t. At the end of each iteration, one of the active vertices is deactivated. Vertex i is selected for deactivation with probability inversely proportional to its degree at time t: i.e., $p_i \propto d_i(t)^{-1}$.

The ***Jackson-Rogers model*** adds, at each step, a new vertex to the existing network. This new vertex identifies μ_1 "parent vertices" uniformly and forms a directed (undirected) link with each of them with probability p_1. Furthermore, μ_2 vertices are uniformly selected from the out-neighborhoods (neighborhoods) of the "parent vertices" and directed (undirected) links from the new vertex to the chosen μ_2 vertices are formed with probability p_2 each. It is worth noting that μ_2 vertices are selected independently of whether a certain "parent vertex" has been linked to the new vertex. The initial state of the Jackson-Rogers model is a clique on $(\mu_1+\mu_2+1)$ vertices. Henceforth, we will concentrate on the undirected version of the Jackson-Rogers model.

Notation: $G_\mu^{\mathrm{BA}}(t)$ denotes a graph generated at time t by the Barabási-Albert model with parameter μ. $G_{\mu,p}^{\mathrm{KE}}(t)$ denotes a graph generated at time t by the Klemm-Eguíluz model with parameters μ and p. $G_{\mu,\rho}^{\mathrm{JR}}(t)$ denotes an undirected graph generated at time t by the undirected version of the Jackson-Rogers model, where $\mu = p_1\mu_1 + p_2\mu_2$ and $\rho = p_1\mu_1/p_2\mu_2$.

Facts:

1. Price's model [Pr76] is a network formation model aiming at simulating citation networks, which are naturally directed. Price called the respective formation mechanism *cumulative advantage*. He was one of the first to discover a power law governing the out-degree distribution. Indeed, Price's model with parameters μ_0 and μ exhibits a power-law out-degree distribution with the exponent $\beta = 2 + \mu_0/\mu$ in the limit of large n.

2. The Barabási-Albert model [BaAl99], also known as the preferential attachment model, is related to Price's model. The main difference is that the Barabási-Albert model considers undirected edges, while the Price model considers directed edges.

3. The Klemm-Eguíluz model [KlEg02b] represents a hybrid between the highly clustered dynamic model [KlEg02a] and the Barabási-Albert model. The cases $p = 0$ and $p = 1$ correspond to the highly clustered model and the Barabási-Albert model, respectively. The Klemm-Eguíluz model is often considered for the values of $0 < p \ll 1$.

4. The Jackson-Rogers model [JaRo07] is based on the idea of "meeting-based formation", and it represents a crossover between uniform attachment ($p_1 = 1$, $p_2 = 0$) and preferential attachment ($p_1 = 0$, $p_2 = 1$, $\mu_1 = \mu_2 \geq 1$) mechanisms. In this model μ is the expected number of edges formed at each iteration and ρ is the ratio of the numbers of edges formed using these two attachment mechanisms.

5. *Small distances in* G_μ^{BA}: Bollobás and Riordan [BoRi04] discovered the most significant result about the diameter of the preferential attachment model for a slight modification of the Barabási-Albert model. Here the network formation process is allowed to add multiple edges between pairs of vertices and self-loops for single vertices. This model is a very close approximation to the preferential attachment model.

- If a graph G_μ^{BA} is formed using preferential attachment with $\mu = 1$, then the diameter of its largest component S is

  $$\mathrm{diam}(G_\mu^{\mathrm{BA}}[S]) = \Theta(\ln n)$$

  asymptotically almost surely, as $n \to \infty$. More precisely,

  $$Pr[(1/\gamma - \epsilon)\ln n \leq \mathrm{diam}(G_\mu^{\mathrm{BA}}[S]) \leq (1/\gamma + \epsilon)\ln n] \to 1$$

  as $n \to \infty$, where ϵ is some positive real number and γ is the solution of $\gamma e^{1+\gamma} = 1$.

- If a graph G_μ^{BA} is formed via preferential attachment with $\mu \geq 2$, then asymptotically almost surely G_μ^{BA} is connected and has diameter smaller than $\ln n$:

  $$\mathrm{diam}(G_\mu^{\mathrm{BA}}) = \Theta\left(\frac{\ln n}{\ln \ln n}\right)$$

  as $n \to \infty$. Specifically,

  $$Pr[(1-\epsilon)\ln n/\ln\ln n \leq \mathrm{diam}(G_\mu^{\mathrm{BA}}) \leq (1+\epsilon)\ln n/\ln\ln n] \to 1$$

  as $n \to \infty$, where ϵ is a small positive real number.

These results show that the Barabási-Albert model generates graphs with small diameter.

6. *Clustering in* G_μ^{BA}: Klemm and Eguíluz [KlEg02b] derived an approximate expression for the average local clustering of the preferential attachment model. Namely, based on estimations for the Barabási-Albert model, they showed

$$C_{\mathrm{WS}}(G_\mu^{\mathrm{BA}}) = \Theta((\ln^2 n)/n)$$

as $n \to \infty$. More rigorously, $C_{\text{WS}}(G_\mu^{\text{BA}}) \sim \mu(\ln^2 n)/(8n)$, which still converges to zero for large n but is larger than the average local clustering of a random network $C_{\text{WS}}(G_{n,p}) \sim \bar{d}/n$ by a factor of $O(\ln^2 n)$. Thus, the Barabási-Albert model exhibits some transitivity, which is higher than that of random networks, but might still not be sufficient to model real-life small-world networks.

7. *Small distances in $G_{\mu,p}^{\text{KE}}$:* Klemm and Eguíluz only managed to empirically estimate average distances in their model for different values of $p \in [0, 1]$. They simulated 100 independent realizations of graphs having order $n = 10^4$ and average degree $\bar{d} = 20$ (with $\mu = 10$) for each value of p.

- Computational experiments suggested that the average path length in the simulated graphs $G_{\mu,p}^{\text{KE}}$ with $p = 0$ grows linearly, that is
$$\bar{l}(G_{10,0}^{\text{KE}}) \propto n,$$
which is similar to the behavior of regular one-dimensional lattices.
- Klemm-Eguíluz graphs generated for intermediate values of p are expected to produce average distances that grow logarithmically, since $\bar{l}(G_{\mu,1}^{\text{KE}}) \propto \ln n / \ln \ln n$ for $\mu \geq 2$. Indeed, computational experiments confirmed that
$$\bar{l}(G_{10,0.1}^{\text{KE}}) \propto \ln n$$
for sufficiently large n. Thus, empirical evidence suggests that crossover Klemm-Eguíluz graphs exhibit small average distances.

8. *Clustering in $G_{\mu,p}^{\text{KE}}$:* The average local clustering coefficient of the Klemm-Eguíluz model with $p = 1$ is proportional to $(\ln^2 n)/n$ for large n because $G_{\mu,1}^{\text{KE}} = G_\mu^{\text{BA}}$. By contrast, the average local clustering coefficient for the highly clustered model ($p = 0$) reaches the asymptotic value 5/6. More precisely,

$$C_{\text{WS}}(G_{\mu,0}^{\text{KE}}) \approx \frac{5}{6} - \frac{7}{30\mu} + O\left(\frac{1}{\mu^2}\right),$$

i.e., the Klemm-Eguíluz model has very high transitivity for relatively large values of the parameter μ [KlEg02b]. Computational experiments also showed that for the crossover model with $p = 0.1$ the average local clustering coefficient is lower than 5/6 but still reaches an asymptotic value greater than zero. Therefore, the crossover model with values $0 < p \ll 1$ is believed to exhibit not only short average distances but also high transitivity. This conclusion is supported by the empirical evidence obtained by Klemm and Eguíluz.

9. *Small distances in $G_{\mu,\rho}^{\text{JR}}$:* Jackson and Rogers [JaRo07] conducted computational experiments on several real-world networks (fitted to undirected Jackson-Rogers graphs) supporting their conjecture that

$$\text{diam}(G_{\mu,\rho}^{\text{JR}}) = O(\ln n)$$

for various combinations of the model parameters.

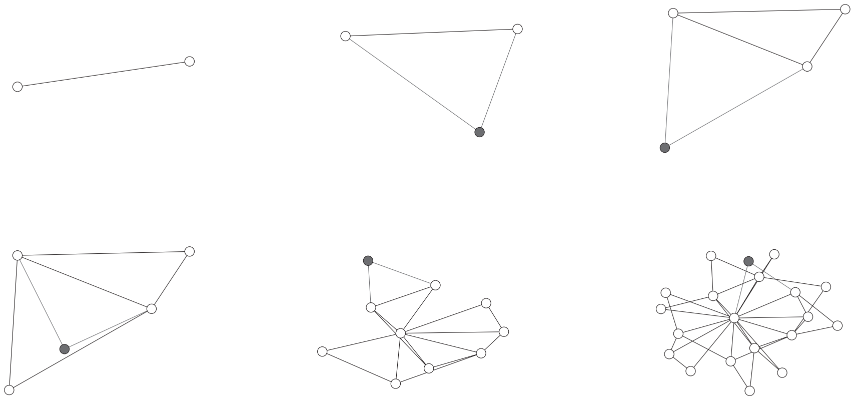
10. *Clustering in $G_{\mu,\rho}^{\text{JR}}$:* The Jackson-Rogers model exhibits high clustering under the following conditions: μ must be an integer, $\rho > 1$, and if $p_1 \geq \rho$, then μ_1 and $p_2\mu_2/\mu_1$ both must be positive integers. Under such assumptions the average local clustering coefficient of the model converges to the fixed number

$$C_{\text{WS}}(G_{\mu,\rho}^{\text{JR}}) = \frac{6p_1}{(1+\rho)[(3\mu - 2)(\rho - 1) + 2\mu\rho]}$$

as $n \to \infty$, thus confirming that the Jackson-Rogers model has high transitivity, which is consistent with small-world characteristics.

Example:

1. The following six graphs illustrate the growing procedure of the Barabási-Albert model with $\mu = 2$. The process starts with a clique of cardinality $\mu = 2$. Then the model sequentially adds a new vertex (shown highlighted) and connects it to two other vertices which are selected with probability proportional to their current degree. The diagrams show the succession of graphs for $n = 2, 3, 4, 5, 10, 20$ vertices.



10.8.7 APPLICATIONS

Small-world networks arise in a variety of applications, ranging from manmade technological networks to naturally occurring networks in biology, economics, and society. This subsection presents several examples of small-world networks.

1. *Milgram's small-world experiment*: The social psychologist Stanley Milgram pioneered the study of path lengths in real-world social networks through several sets of small-world experiments. Probably the most well-known of these experiments are the 1967 *Kansas study* [Mi67] and the 1969 *Nebraska study* [TrMi69]. In both experiments, a target person in the Boston area was chosen, and a set of randomly selected individuals in Nebraska (or Kansas) were asked to mail a letter to someone they know who would be most likely to have some relation to the target person. The mean number of intermediaries in the network paths between "starters" and the target turned out to be 5.2, which transforms into the average distance 6 if rounded up. Over 20 years later, this result was popularized by John Guare's 1990 play "Six Degrees of Separation" [Gu90] and the movie with the same title. Since then, the concepts of small-world networks and six degrees of separation have been well appreciated both in the scientific literature and in popular culture.

2. *Dodds' small-world experiment*: After Milgram's work, small-world experiments were repeated and extended in several studies. One such study was conducted by Dodds et al. [DoMuWa03] using email messages. The researchers selected more than 60,000 participants who were given instructions in order to reach one of 18 target persons from 13 different countries. Every "starter" was provided some personal information about the assigned target. This experiment was conducted on a significantly larger scale than

Milgram's study as a result of the power of modern internet technology (24,000 email chains were initiated). The results of Dodds' experiment corroborated the fundamental conclusions of Milgram's studies. The average path length of successfully completed chains was 4.05, smaller than Milgram's value 5.2. Besides, Dodds' experiment accounted for uncompleted chains and it estimated that starters could reach their targets in a median of five to seven steps.

3. *Collaboration/coauthorship networks*: Collaboration/coauthorship networks represent prominent examples of real-life small-world networks. Perhaps the most well-known such networks are the collaboration network of mathematics researchers (where two researchers are connected by a link if they have ever written a joint paper) and the network of Hollywood actors (where two actors are connected if they have appeared in the same movie). In these networks, the role of a central vertex is traditionally given to Paul Erdős and to Kevin Bacon, respectively. The shortest distance from each vertex to the central vertex is traditionally referred to as that individual's *Erdős number* or *Bacon number*. It turns out that the values of the Erdős number and Bacon number for all vertices in the respective collaboration networks are small (many mathematicians have an Erdős number of at most 5, and the average Bacon number for all actors in the database is about 3), which confirms the small-world structure of these networks.

Coauthorship networks for other scientific disciplines can be similarly analyzed. The following table summarizes characteristics of such networks, demonstrating that these networks exhibit small average distances and diameters, as well as high clustering coefficients (compared to what would be observed if edges in these networks were added uniformly and randomly). This confirms that coauthorship networks do exhibit small-world properties.

	Biology	*Physics*	*Computer* Science	*Mathematics*	*Economics*
number of authors (n)	1,520,251	52,909	11,994	253,339	81,217
log number of authors ($\ln n$)	14.2	10.9	9.4	12.4	11.3
mean # authors per paper	3.75	2.53	2.22	1.45	1.56
average # collaborators ($\bar{d}$)	18.10	9.70	3.59	3.90	1.67
size of largest component (n_S)	1,395,693	44,337	6,396	208,200	33,027
average distance ($\bar{l}_S$)	4.6	5.9	9.7	7.6	9.5
diameter (diam_S)	24	20	31	27	29
average edge probability (p)	1×10^{-5}	2×10^{-4}	3×10^{-4}	2×10^{-5}	2×10^{-5}
clustering coefficient (C)	0.066	0.430	0.496	0.150	0.136

4. *Large-scale real-world networks*: Adamic [Ad99] showed that the World Wide Web (WWW) network has a small-world topology. She considered a graph that was a representation of the WWW at the site level, based on data collected by Jim Pitkow at Xerox PARC. The graph contained around 50 million documents and 259,794 sites. After the deletion of leaf vertices, it was reduced to an undirected graph of order $n = 153{,}127$. Adamic estimated the average path length $\bar{l}$ to be 3.1 and the average local clustering coefficient C_{WS} to be 0.1078, much larger than the average local clustering coefficient of the respective random graph (that would be 2.3×10^{-4}). In a second experiment, Adamic considered the respective directed graph or, more precisely, its largest strongly connected component on $n_S = 64{,}826$ vertices. Here $\bar{l}(G[S]) \approx 4.3$ (average directed distance) and $C_{\text{WS}} \approx 0.081$, in contrast to 1.05×10^{-3} for the corresponding random graph. Hence, this study provided strong evidence supporting the conjecture about the small-world nature of the WWW.

In a related study, Albert et al. [AlJeBa99] also investigated the average shortest path length in the World Wide Web, in which web pages (URLs) are vertices and hyperlinks are directed edges. Using local connectivity measurements, they constructed a topological model of the WWW. They employed the finite size scaling procedure to assess the average distance in the WWW by measuring distances in samples of increasing size. They calculated $\bar{l} \approx 0.35 + 0.89 \ln n$, which implies that the average path length in the WWW is around 18.59, since the size of the WWW was estimated to be 8×10^8 at that time. Currently its size is believed to be $\approx 10^{12}$, and so the average distance can be predicted to be close to 25. These results do not contradict Adamic's conclusions because they dealt with different objects in the WWW. Since every site includes many web pages, the order of Albert's graph was substantially greater than the order of Adamic's graph, thus making the estimated $\bar{l}$ much smaller for the latter graph. Unlike Adamic's study, Albert et al. did not study transitivity properties of the WWW.

Leskovec and Horwitz [LeHo08] constructed a network based on one month (June 2006) of communication activities from the Microsoft Instant Messenger network. The initial dataset contained 240 million users, but they extracted 180 million users who had participated in at least one conversation during the selected time period. The undirected communication network contained 1.3×10^9 edges among active users, where an edge was constructed for each pair of individuals who communicated. The largest connected component appeared to include 99.9% of all the vertices and, more importantly, it was estimated to have $\bar{l}(G[S]) \approx 6.6$. In addition, Leskovec and Horwitz found that the graph was well clustered with $C_{\text{WS}} \approx 0.137$, which was rather large for such a massive network.

One of the most extensive studies of the small-world nature of social networks was conducted by Backstrom et al. [BaEtal12]. They analyzed the dataset of all Facebook users active as of May 2011. The resulting graph, with $n \approx 7.21 \times 10^8$ and $m \approx 6.9 \times 10^{10}$ (symmetric friendship links were considered as its edges), was shown to have $O(\ln n)$ average distance. In particular, they found that $\bar{l} \approx 4.74$, utilizing the diffusion-based algorithm HyperANF to do estimations. Moreover, they coined the term "four degrees of separation", referring to the 3.74 intermediaries used on average. Recently, researchers at Facebook updated the estimation of the average shortest path length obtained by Backstrom et al. Edunov et al. [EdEtal16] analyzed the Facebook network, which had became larger (containing approximately twice as many users compared to May 2011) and more interconnected. Their estimation, done via the Flajolet-Martin algorithm, showed that the average distance in the Facebook graph was about 4.57, meaning 3.57 intermediaries on average (this led to the term "three and a half degrees of separation").

10.9 NETWORK REPRESENTATIONS AND DATA STRUCTURES

To carry out network optimization algorithms efficiently, careful attention needs to paid to the design of the data structures supporting these algorithms. There are alternative ways to represent a network—differing in their storage requirements and their efficacy in executing certain fundamental operations. These representations need to incorporate both the topology of the underlying graph and also any quantitative information present in the network (such as cost, length, capacity, demand, or supply). Standard representations of networks, and trees in particular, are discussed in this section.

10.9.1 NETWORK REPRESENTATIONS

There are various ways to represent networks, just as there are various ways to represent graphs (§8.1.4, §8.3.1). In addition it is necessary to incorporate quantitative information associated with the vertices and edges (or arcs) of the network. While the description here concentrates on directed networks, extensions to undirected networks are also indicated.

Definitions:

Let $G = (V, E)$ be a directed graph (§8.3.1) with vertex set $V = \{1, 2, \ldots, n\}$ and arc set E. Define $m = |E|$ to be the number of arcs in G.

The ***adjacency set*** $A(i) = \{(i, j) \mid (i, j) \in E\}$ for vertex i is the set of arcs emanating from i. (See §10.3.1.)

The ***adjacency matrix*** for G is the 0-1 matrix $A_G = (a_{ij})$ having $a_{ij} = 1$ if $(i, j) \in E$ and $a_{ij} = 0$ if $(i, j) \notin E$. (See also §6.6.2 and §8.3.1.)

The ***arc list*** for G (see §8.3.1) can be implemented using two arc-length arrays FROM and TO:

- For each arc $(i, j) \in E$ there is a unique $1 \leq k \leq m$ satisfying FROM$(k) = i$ and TO$(k) = j$.
- Arcs are listed in the parallel FROM and TO arrays in no particular order.

The ***linked adjacency list*** for G is given by a vertex-length array START and a singly-linked list ARCLIST of arc records:

- START(i) points to the first record for vertex i in this list, corresponding to a specified first element of $A(i)$.
- Each arc $(i, j) \in A(i)$ has an associated arc record, which contains the fields TO and NEXT. Specifically, ARCLIST.TO gives the adjacent vertex j, and ARCLIST.NEXT points to the next arc record in $A(i)$. If there is no such following record, ARCLIST.NEXT = **null**.

The ***forward star*** for G is given by a vertex-length array START and an arc-length array TO, with the latter in one-to-one correspondence with arcs $(i, j) \in E$:

- START(i) gives the position in array TO of the first arc leaving vertex i.
- The arcs of $A(i)$ are found in the consecutive positions START(i), START$(i) + 1$, ..., START$(i + 1) - 1$ of array TO. If arc (i, j) corresponds to position k of TO, then TO$(k) = j$.

- By convention, an additional dummy vertex $n+1$ is added, with $\text{START}(n+1) = m+1$.

Facts:

1. An undirected graph can be represented by replacing each undirected edge (i,j) by two oppositely directed arcs (i,j) and (j,i).

2. The adjacency matrix, the arc list, the linked adjacency list, and the forward star are four standard representations of a directed (or undirected) graph.

3. The linked adjacency list and forward star structures are commonly used implementations of the *lists-of-neighbors* representation (§8.3.1).

4. The following table shows the (worst-case) computational effort required to carry out certain fundamental operations on G: finding an arc, deleting an arc (once found), adding an arc, and scanning the adjacency set of an arbitrary vertex i. Here $\alpha_i = |A(i)| \le n$.

representation	*find arc*	*delete arc*	*add arc*	*scan* $A(i)$
adjacency matrix	$O(1)$	$O(1)$	$O(1)$	$O(n)$
arc list	$O(m)$	$O(1)$	$O(1)$	$O(m)$
linked adjacency list	$O(\alpha_i)$	$O(1)$	$O(1)$	$O(\alpha_i)$
forward star	$O(\alpha_i)$	$O(n+m)$	$O(n+m)$	$O(\alpha_i)$

5. The storage requirements of the four representations are given in the following table for both directed and undirected graphs. For the last two representations, each undirected edge appears twice: once in each direction.

representation	*storage* (*directed*)	*storage* (*undirected*)	*exploit sparsity?*
adjacency matrix	n^2	$\frac{n^2}{2}$	*no*
arc list	$2m$	$2m$	*yes*
linked adjacency list	$n+2m$	$n+4m$	*yes*
forward star	$n+m$	$n+2m$	*yes*

6. As seen in the table of Example 5, all representations other than the adjacency matrix representation can exploit sparsity in the graph G. That is, the storage requirements are sensitive to the actual number of arcs and the computations will generally proceed more rapidly when G has relatively few arcs.

7. Quantitative data for network vertices (such as supply and demand) can be stored in an associated vertex-length array, thus supplementing the standard graph representations.

8. Quantitative data for network arcs (such as cost, length, capacity, and flow) can be accommodated as follows:

- For the adjacency matrix representation, costs (or lengths) c_{ij} can be imbedded in the matrix A_G itself. Namely, redefine $A_G = (a_{ij})$ so that $a_{ij} = c_{ij}$ if $(i,j) \in E$, whereas a_{ij} is an appropriate special value if $(i,j) \notin E$. For instance, in the shortest path problem (§10.3.1), $a_{ij} = \infty$ can be used to signify that $(i,j) \notin E$. Additional $n \times n$ arrays would be needed, however, to represent more than one type of arc data.
- For the arc list representation, additional arrays parallel to the arrays FROM and TO can be used to store quantitative arc data.

- For the linked adjacency list representation, additional fields within the arc record can be used to store quantitative arc data.
- For the forward star representation, additional arrays parallel to the array TO can be used to store quantitative arc data.

9. The arc list representation is best suited for arc-based processing of a network, such as occurs in Kruskal's minimum spanning tree algorithm (§10.1.2).

10. The arc list representation is a convenient form for the input of a network to an optimization algorithm. Often this external representation is converted within the algorithm to a more suitable internal representation (linked adjacency list or forward star) before executing the steps of the optimization algorithm.

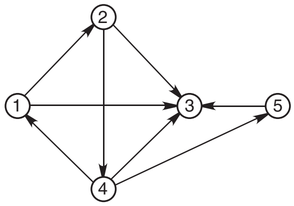
11. The linked adjacency list and forward star representations are best suited to carrying out vertex-based explorations of a graph, such as a breadth-first search or a depth-first search (§9.2.1). It is also ideal for carrying out Prim's minimum spanning tree algorithm (§10.1.2) as well as most shortest path algorithms (§10.3.2).

12. Especially in the case of undirected graphs, the linked adjacency list and forward star representations can be enhanced by use of an additional arc-length array MIRROR. The array MIRROR allows one to move from the location of arc (i, j) to the location of arc (j, i) in constant time.

13. The linked adjacency list is typically used when the structure of the graph can dynamically change (as by addition/deletion of arcs or vertices). On the other hand, the forward star representation is appropriate for static graphs, in which the graph structure does not change.

Examples:

1. A directed graph G with five vertices and eight arcs is shown in the following figure.



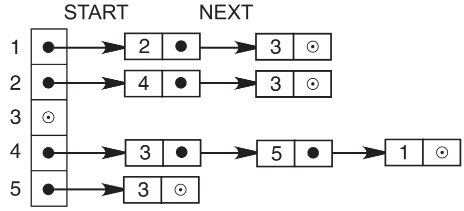
The 5×5 adjacency matrix for G is given by

$$A_G = \begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array} \begin{array}{c} \begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \end{array} \\ \begin{pmatrix} 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 \end{pmatrix} \end{array}$$

2. An arc list representation of the directed graph in the figure of Example 1 is given in the following table.

FROM	1	2	1	4	2	4	4	5
TO	2	4	3	1	3	5	3	3

3. The following figure shows a linked adjacency list representation of the directed graph of Example 1. The symbol ⊙ is used to indicate a **null** pointer.



4. The following figure shows a forward star representation of the directed graph in Example 1. Since $A(3) = \emptyset$, it is necessary to set START(3) = START(4) = 5. For example, the arcs in $A(4)$ are associated with positions [START(4), . . . , START(5) − 1] = [5, 6, 7] of the TO array. Similarly, the single arc emanating from vertex 5 is associated with position [START(5), . . . , START(6) − 1] = [8] of the TO array.

	START
1	1

7	1
8	3

10.9.2 TREE DATA STRUCTURES

Since trees are important objects in optimization problems, as well as useful data structures in their own right (see §9.1), additional representations and features of trees are given here.

Definitions:

If T is a rooted tree with root r (§9.1.2), then the ***predecessor function*** $pred\colon V \to V$ is defined by $pred(r) = 0$, and $pred(j) = i$ if vertex i is the parent of j in T. (See §10.3.1.)

The ***principal subtree*** T_j rooted at vertex j is the subgraph of T induced by all descendants of j (including j). (See §9.1.2.)

The ***cardinality*** $card(j)$ of vertex j in a rooted tree T is the number of vertices in its principal subtree T_j.

The ***least common ancestor*** $least(i, j)$ of vertices i and j in a rooted tree is the vertex of largest depth (§9.1.2) that is an ancestor of both i and j.

Facts:

1. A rooted tree is uniquely specified by the mapping $pred(\cdot)$.

2. In a rooted tree with root r, $depth(r) = 0$ and $depth(j) = 1 + depth(pred(j))$ for $j \neq r$.

3. In a rooted tree, $height(i) = 0$ if i is a leaf. If i is not a leaf, then $height(i) = 1 + \max\{height(j) \mid j \text{ a child of } i\}$.

4. In a rooted tree, $card(i) = 1$ if i is a leaf. If i is not a leaf, $card(i) = 1 + \sum\{card(j) \mid j \text{ a child of } i\}$.

5. The predecessor, depth, height, and cardinality of a rooted tree T can all be calculated while carrying out a preorder or postorder traversal (§9.1.3) of T:

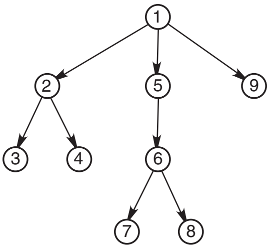
- The predecessor and depth can be calculated while advancing from the current vertex to an unvisited vertex.
- The height and cardinality can be updated when retreating from a vertex all of whose children have been visited.

6. The depth of a vertex is a monotone increasing function on each path from the root.

7. The height and cardinality are monotone decreasing functions on each path from the root.

Examples:

1. The following figure shows a tree T rooted at vertex 1. Here the vertices have been numbered according to a preorder traversal of T. The accompanying table gives the predecessor, depth, height, and cardinality of each vertex of T.



vertex	1	2	3	4	5	6	7	8	9
pred	0	1	2	2	1	5	6	6	1
depth	0	1	2	2	1	2	3	3	1
height	3	1	0	0	2	1	0	0	0
card	9	3	1	1	4	3	1	1	1

2. Certain applications (such as cycle detection in the network simplex algorithm, §10.5.2) require finding the least common ancestor $least(i, j)$ of vertices i and j in a rooted tree.

3. The calculation of $least(i, j)$ can be carried out efficiently, in $O(n)$ time, by using Algorithm 1.

4. Algorithm 1 is based on Fact 6 and employs two auxiliary data structures, the predecessor and depth functions. It repeatedly backs up from a vertex of larger depth until the least common ancestor is found.

Algorithm 1: **Least common ancestor.**

```
input: rooted tree $T$, vertices $i$ and $j$
output: least common ancestor of $i$ and $j$
```

```
procedure $least(i, j)$
while $i \neq j$
  if $depth(i) > depth(j)$ then $i := pred(i)$
  else if $depth(i) < depth(j)$ then $j := pred(j)$
  else $i := pred(i)$, $j := pred(j)$
return $i$
```

PARTIALLY ORDERED SETS

INTRODUCTION

Partially ordered sets play important roles in a wide variety of applications, including the design of sorting and searching methods, the scheduling of tasks, the study of social choice, and the study of lattices. This chapter covers the basic concepts involving partially ordered sets, the various types of partially ordered sets, the fundamental properties of these sets, and their important applications.

A table of notation used in the study of posets is given following the glossary.

GLOSSARY

antichain: a subset of a poset in which no two distinct elements are comparable.

atom: in a poset, an element of height 1.

atomic lattice: a lattice such that every element is a join of atoms (or equivalently, such that the atoms are the only join-irreducible elements).

auxiliary graph (of a simple graph G): the graph G' whose vertices are the edges of G, with vertex e_1 adjacent to vertex e_2 in G' if and only if e_1 and e_2 are adjacent edges in G, but do not lie on a 3-cycle in G.

biorder representation (on a digraph D): a pair of real-valued functions f, g on the vertex set V_D such that $u \to v$ is an arc if and only if $f(u) > g(v)$.

bipartite poset: a poset of height at most 2.

Boolean algebra: the poset whose domain is all subsets of a given set, partially ordered by inclusion.

Borda consensus function (on a set of social choice profiles): the consensus function that ranks the alternatives by their Borda count.

Borda count (of an alternative social choice x): the sum, over all individual rankings, of the number of alternatives x "beats".

bounded poset: a poset with both a unique minimal element and a unique maximal element.

u,v-bypass (in a directed graph): a u,v-path of length at least two such that there is also an arc from u to v.

Cartesian product (of two posets $P = (X, R)$ and $P' = (X', R')$): the poset $P \times P' = (X \times X', S)$, such that $(x, x')S(y, y')$ if and only if xRy and $x'R'y'$.

chain: a subset of a poset in which every two elements are comparable.

k-chain: a chain of size k, i.e., a chain on k elements.

chain-product: the Cartesian product of a collection of chains.

comparability digraph (of a poset (X, R)): the simple digraph whose vertex set is the domain X and which has an arc from x to y if and only if $x \leq y$.

comparability graph (of a poset (X, R)): the simple graph whose vertex set is the domain X and which has an edge joining distinct vertices x and y if and only if $x \leq y$.

comparability invariant (for posets): an invariant f such that $f(P) = f(Q)$ whenever posets P and Q have the same comparability graph.

comparable elements (in a poset (X, R)): elements x and y such that either $(x, y) \in R$ or $(y, x) \in R$.

consecutive chain (in a ranked poset): a chain whose elements belong to consecutive ranks.

consensus function (on a set of social choice profiles): a function that assigns to each possible profile $P = \{P_i \mid i \in I\}$ on a set of alternatives a linear ordering (ties allowed) of those alternatives.

consensus ranking (on a set of social choice profiles): the linear ordering of the alternatives assigned by the consensus function.

cover graph (of a poset (X, R)): the graph with vertex set X and edge set consisting of the pairs satisfying the cover relation.

cover relation (of a poset (X, R)): the relation on X consisting of the pairs (x, y) such that $x > y$ in R and such that there is no "intermediate" element z with $x > z > y$.

cover diagram: a synonym for the Hasse diagram.

critical pair (in a poset): an ordered incomparable pair that cannot be made comparable by adding any other single incomparable pair as a relation.

dependent edge (in an acyclic directed graph): an arc from u to v such that the graph contains a u,v-bypass.

dimension (of a poset): the minimum number of chains in a realizer of the poset.

distributive lattice: a lattice in which the meet operator distributes over the join operator, so that $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$ for all x, y, z.

divisor lattice: the poset $D(n)$ of divisors of n, in which $x \leq y$ means that y is an integer multiple of x.

downset (in a poset): a subposet I such that if $x \in I$ and if $y < x$, then $y \in I$; also called an ideal.

dual (of a poset $P = (X, R)$): the poset $P^* = (X, S)$ such that $x \leq y$ in S if and only if $y \leq x$ in R.

extension (of a poset $P = (X, R)$): a poset $Q = (X, S)$ such that $R \subseteq S$; meaning that xRy implies xSy.

k-family (in a poset): a subposet containing no chain of size $k + 1$.

Ferrers digraph: a digraph having a biorder representation.

filter (generated by an element x in a poset P): the upset $U[x] = \{y \in P \mid y \geq x\}$.

filter (generated by a subset in a poset P): given a subset A of P, the upset $U[A] = \bigcup_{x \in A} U[x]$.

filter (in a poset): a subposet whose domain is the set-theoretic complement of the domain of an ideal.

forbidden subposet description (of a class of posets): a characterization of the class as the class of all posets that does not contain any of the posets in a specified collection.

geometric lattice: an atomic, upper semimodular lattice of finite height.

greatest lower bound (***glb***) (of elements x and y in a poset): a common lower bound z such that every other common lower bound z' satisfies the inequality $z \geq z'$. Such an element, if it exists, is denoted $x \wedge y$.

graded poset: a poset in which all maximal chains have the same length.

Hasse diagram (of a poset): a straight-line drawing of the cover graph in the plane so that the lesser element of each adjacent pair is below the greater.

height (of a poset): the maximum size of a chain in that poset.

height (of an element x of a poset): the maximum length $h(x)$ of a chain that has x as its maximal element.

ideal (generated by an element x in a poset P): the downset $D[x] = \{y \in P \mid y \leq x\}$.

ideal (generated by a subset A in a poset P): the downset $D[A] = \bigcup_{x \in A} D[x]$.

ideal (in a poset): a subposet I such that if $x \in I$ and if $y < x$, then $y \in I$.

incomparability graph (of a poset P): the edge-complement of the associated comparability graph $G(P)$.

incomparable pair (in a poset (X, R)): a pair $x, y \in X$ such that neither $x \leq y$ nor $y \leq x$ in R.

integer partition: a nonincreasing nonnegative integer sequence having finitely many nonzero terms, with trailing zeros added as needed for comparison.

intersecting family: a collection of subsets of a set such that every pair of members has nonempty intersection.

intersection (of partial orderings $P = (X, R)$ and $Q = (X, S)$ on the set X): the poset $(X, R \cap S)$ that includes the comparisons present in both.

intersection (of posets (X, R) and (X, S)): the poset $(X, R \cap S)$.

interval (in a poset): the subposet which contains all elements z such that $x \leq z \leq y$.

interval order: a poset in which there is an assignment to its members of real intervals, such that $x < y$ if and only if the interval for y is totally to the right of the interval for x.

interval representation (of a poset P): a collection of real intervals corresponding to an interval order for P.

isomorphic (posets): posets $P = (X, R)$ and $Q = (Y, S)$ such that there is a poset isomorphism $P \to Q$.

isomorphism (of lattices): an order-preserving bijection from one lattice to another that also preserves greatest lower bounds and least upper bounds of pairs.

isomorphism (of posets): a bijection from one poset to another that preserves the order relation.

join: given $\{x, y\}$, another name for the least upper bound $x \vee y$.

join-irreducible element (in a lattice): a nonzero element that cannot be expressed as the join of two other elements.

Jordan-Dedekind chain condition: the condition for a poset that every interval has finite length.

lattice: a poset in which every pair of elements has both a greatest lower bound and a least upper bound.

lattice (of bounded sequences): the set $L(m,n)$ of length-m real sequences $a_1,\ldots,a_m$ such that $0 \leq a_1 \leq \cdots \leq a_m \leq n$.

lattice (of order ideals in a poset $P = (X,R)$): the set $J(P)$ of order ideals of P, ordered by inclusion.

least upper bound (***lub***) (of elements x and y in a poset): a common upper bound z such that every other common upper bound z' satisfies the inequality $z' \geq z$. Such an element, if it exists, is denoted $x \vee y$.

length (of a chain): the number of cover relations in the chain; in other words, one less than the number of elements in the chain.

length (of a poset): the length of a longest chain, which is one less than the height of that poset. (Sometimes *height* is used synonymously with length.)

lexicographic ordering (of the Cartesian product of posets): the ordering for the Cartesian product of the domains in which $(x_1,x_2) \leq (y_1,y_2)$ if and only if $x_1 < y_1$ or $x_1 = y_1$ and $x_2 \leq y_2$; this is not the usual ordering of the Cartesian product of posets.

linear extension (of a poset): an extension of the poset that is a chain.

linear order: See *total order*.

linearly ordered set: a poset in which every pair of elements is comparable.

linear sum (of two disjoint posets P and P'): the poset in which all the elements of poset P lie "below" all those of poset P'.

locally finite poset: a poset in which every interval is finite.

lower bound (of elements x and y in a poset): an element z such that $x \geq z$ and $y \geq z$.

lower semimodular lattice: a lattice whose dual is upper semimodular.

majority rule property (for a consensus function): the property that x will be preferred to y if and only if a majority of the individuals prefer x to y.

maximal element (in a poset): an element such that no other element is greater.

meet (of elements x and y): another name for the greatest lower bound $x \wedge y$.

meet-irreducible element (of a lattice): a nonzero element that cannot be expressed as the meet of two other elements.

minimal element (in a poset): an element such that no other element is less.

minimum realizer encoding (of a poset): a poset that lists for each element its position on each extension in a minimum realizer.

modular lattice: a lattice in which $x \wedge (y \vee z) = (x \wedge y) \vee z$ for all x, y, z such that $z \leq x$.

module (in a graph G): a vertex subset $U \subseteq V_G$ such that each vertex outside U is adjacent to all or none of the vertices in U.

k-norm (of a sequence $a = \{a_i\}$): the sum $\sum_i \min\{k, a_i\}$, whose value is commonly denoted $m_k(a)$.

k-norm of a chain partition: the k-norm of its sequence of chain sizes.

normalized matching property (for a graded poset): the property stating that for every rank k and every subset A of rank P_k, the set A^* of elements in the rank P_{k+1} that are comparable to at least one element of A satisfies the inequality $\frac{|A^*|}{N_{k+1}} \geq \frac{|A|}{N_k}$.

order module in a poset: a set S of elements such that every element outside S is above all of S, below all of S, or incomparable to all of S.

order-preserving mapping (from poset $P = (X, R)$ to poset $Q = (Y, S)$): a function $f: X \to Y$ such that $f(x) \leq f(y)$ whenever $x \leq y$ in P.

order relation (on a set X): a relation R such that (X, R) is a partially ordered set.

partially ordered set: a pair $P = (X, R)$ consisting of a set X and a relation R that is reflexive, antisymmetric, and transitive.

partition lattice: the poset Π_n of partitions of the set $[n] = \{1, \ldots, n\}$, where $\pi < \sigma$ if π is a refinement of σ.

permutation graph: a graph whose vertices can be placed in 1-1 correspondence with the elements of a permutation of $[n] = \{1, \ldots, n\}$, such that v_i is adjacent to v_j if and only if the larger of $\{i, j\}$ comes first in the permutation.

planar poset: a poset with a Hasse diagram that has no edge-crossings.

plurality consensus function (on a set of social choice profiles): the consensus function in which the winner(s) is (are) the alternative(s) appearing in the greatest number of top ranks, after which the winner(s) is (are) deleted and the procedure is repeated to select the next rank of the consensus ranking, etc.

poset: a partially ordered set.

profile (on a set of alternative social choices): a set $P = \{P_i \mid i \in I\}$ of linear rankings (ties allowed) of the alternatives, one for each member of a set I of "individuals" participating in the decision process.

quasi-transitive orientation (on a simple graph G): an assignment of directions to the edges of G so that whenever there is an xy-arc and a yz-arc, there is also an arc between x and z.

rank (of a graded poset P): the length $r(P)$ of any maximal chain in P.

rank function (on a poset): an integer-valued function r on the elements of the poset so that "y covers x" implies that $r(y) = r(x) + 1$.

ranked poset: a poset having a rank function.

kth rank of a ranked poset: the subset P_k of elements for which $r(x) = k$.

rank parameters (of a subset F of elements in a ranked poset P): the numbers $f_k = |F \cap P_k|$.

ranking: a poset P whose elements are partitioned into ranks $P_1, \ldots, P_k$ such that two elements are incomparable in the poset if and only if they belong to the same rank.

realizer (of a poset P): a set of linear extensions of P whose intersection is P.

refinement (of a set partition σ): replacement of each block $B \in \sigma$ by some partition of B.

regular covering (of a poset by chains): a multiset of maximal chains such that for each element x the fraction of the chains containing x is $\frac{1}{N_{r(x)}}$, where $N_{r(x)}$ is a Whitney number.

self-dual poset: a poset isomorphic to its dual.

semimodular lattice: an upper semimodular lattice.

semiorder: a poset on which there is a real-valued function f and a real number $\delta > 0$ such that $x < y$ if and only if $f(y) - f(x) > \delta$.

shadow (of a family of sets $\mathbf{F}$): the collection of sets containing every set that is obtainable by selecting a set in $\mathbf{F}$ and deleting one of its elements.

size (of a finite poset): the number of elements.

Sperner property (for a graded poset): the property that some single rank is a maximum antichain.

k-Sperner property (for a graded poset): the property that the poset has a maximum k-family consisting of k ranks.

standard k-chain: the poset $\{1, \ldots, k\}$, under the usual ordering of the integers, written $\underline{k}$.

standard example of an n-dimensional poset: the subposet S_n of the Boolean algebra $\underline{2}^n$ induced by the singletons and their complements.

strict Sperner property: the property of a graded poset that all maximum antichains are single ranks.

strong Sperner property: the property that a graded poset P is k-Sperner for all $k \leq r(P)$.

Steinitz exchange axiom: for a closure operator $\sigma\colon 2^E \to 2^E$, the rule that $p \notin \sigma(A)$ and $p \in \sigma(A \cup q)$ imply $q \in \sigma(A \cup p)$.

sublattice (of a lattice): a subposet that contains the meet and join of every pair of its elements.

submodular height function (in a lattice): a height function h such that $h(x \wedge y) + h(x \vee y) \leq h(x) + h(y)$ for all x, y.

subposet (of a poset (X, R)): a poset (Y, S) such that $Y \subseteq X$ and $S = R \cap (Y \times Y)$.

subset lattice: the Boolean algebra $\underline{2}^n$, that is, the Cartesian product of n copies of the standard 2-chain.

subspace lattice: the set $L_n(q)$ of subspaces of an n-dimensional vector space over a q-element field, partially ordered by set inclusion.

symmetric chain (in a ranked poset P): a chain that has an element of rank $r(P) - k$ whenever it has an element of rank k.

symmetric chain decomposition (of a ranked poset): a partition of that poset into symmetric consecutive chains.

symmetric chain order: a poset with a symmetric chain decomposition.

topological ordering (of an acyclic digraph): a linear extension of the poset it represents.

topological sort: an algorithm that arranges the elements of a partially ordered set into a total ordering that is compatible with the original partial ordering.

total order (of a set): an order relation in which each pair of distinct elements is comparable.

transitive orientation (on a simple graph): an assignment of directions to the edges of a simple graph G so that whenever there is an xy-arc and a yz-arc, there is also an xz-arc.

triangular chord (for a walk $x_1, \ldots, x_k$ in an undirected graph): an edge between vertices x_{i-1} and x_{i+1}, two apart on the walk.

upper bound (of elements x and y in a poset): an element z with $x \leq z$ and $y \leq z$.

upper semimodular lattice: a lattice in which whenever x covers $x \wedge y$, it is also true that $x \vee y$ covers y.

upset (in a poset): a filter.

weak order: a ranking, i.e., a poset P whose elements are partitioned into ranks $P_1, \ldots, P_k$ such that two elements are incomparable if and only if they belong to the same rank.

kth Whitney number (of a ranked poset P): the cardinality $|P_k|$ of the kth rank; written $N_k(P)$.

width (of a poset): the maximum size of an antichain in the poset.

Young lattice: the lattice of integer partitions under component-wise ordering.

poset notation	
notation	*meaning*
$y \geq x$	$x \leq y$
$x < y$	$x \leq y$ and $x \neq y$
$x \| y$	$x \not\leq y$ and $y \not\leq x$
0	minimal element in a bounded poset
1	maximal element in a bounded poset
$[x, y]$	the interval $\{z \mid x \leq z \leq y\}$
$\underline{k}$	standard k-chain
$P_1 + P_2$	disjoint union of posets
$P_1 \oplus P_2$	linear sum of two posets
$P_1 \times P_2$	Cartesian product of two posets
P^n	iterated Cartesian product of n copies of P
P^*	dual of poset P
$D(n)$	divisibility poset of the integer n
$r(P)$	rank of a graded poset P
$N_k(P)$	kth Whitney number (= cardinality of kth rank) of P
$w(P)$	width of P (= maximum size of an antichain)
$D[x]$	downset (ideal) $\{y \mid y \leq x\}$
$D(x)$	downset (ideal) $\{y \mid y < x\}$
$U[x]$	upset (filter) $\{y \mid y \geq x\}$
$U(x)$	upset (filter) $\{y \mid y > x\}$
$x \vee y$	lub of x and y
$x \wedge y$	glb of x and y

11.1 BASIC POSET CONCEPTS

11.1.1 COMPARABILITY

The integers and the real numbers are totally ordered sets, since every pair of distinct elements can be compared. In a partially ordered set, some pairs of elements may be incomparable. For example, under the containment relation, the sets $\{1,2\}$ and $\{1,3\}$ are incomparable.

Definitions:

A ***partial ordering*** (or ***order relation***) R on a set X is a binary relation that is

- *reflexive*: for all $x \in S$, xRx;
- *antisymmetric*: for all $x, y \in S$, if xRy and yRx, then $x = y$;
- *transitive*: for all $x, y, z \in S$, if xRy and yRz, then xRz.

Note: $x \leq y$ or $x \leq_P y$ are often written in place of xRy or $(x,y) \in R$. Also, $y \geq x$ means $x \leq y$. The notation $\preceq$ is sometimes used in place of $\leq$. See the table following the glossary for further poset notation.

A ***partially ordered set*** (or ***poset***) $P = (X, R)$ is a pair consisting of a set X, called the ***domain***, and a partial ordering R on X. Writing $x \in P$ means that $x \in X$. The notation $(X, \leq)$ is often used instead of (X, R) to designate a poset.

The ***size*** of a finite poset P is the number of elements in the domain.

The elements x and y are ***comparable*** (***related***) in P if either $x \leq y$ or $y \leq x$ (or both, in which case $x = y$).

A ***totally ordered set*** (or ***linearly ordered set***) is a poset in which every element is comparable to every other element.

The elements x and y are ***incomparable*** (***unrelated***) if they are not comparable. Writing $x \parallel y$ indicates incomparability.

Element x is ***less than*** element y, written $x < y$, if $x \leq y$ and $x \neq y$. (The notation $\prec$ is sometimes used in place of $<$.)

Element x is ***greater than*** element y, written $x > y$, if $x \geq y$ and $x \neq y$.

An element x of a poset is ***minimal*** if the poset has no element less than x.

An element x of a poset is ***maximal*** if the poset has no element greater than x.

A poset is ***bounded*** if it has both a unique minimal element (denoted "0") and a unique maximal element (denoted "1").

The ***comparability digraph*** $D(P)$ of a poset $P = (X, R)$ is the digraph with vertex set X, such that there is an arc from x to y if and only if $x \leq y$.

The ***comparability graph*** $G(P)$ of a poset $P = (X, R)$ is the simple graph with vertex set X, such that $xy \in E_G$ if and only if x and y are comparable in P, where $x \neq y$.

The ***incomparability graph*** of a poset P is the edge-complement of the comparability graph $G(P)$.

The ***induced poset*** of an acyclic digraph D is the poset whose elements are the vertices of D and such that $x \leq y$ if and only if there is a directed path from x to y.

The element y ***covers*** the element x in a poset if $x < y$ and there is no intermediate element z such that $x < z < y$.

The ***cover graph*** of poset P is the graph with vertex set X such that x and y are adjacent if and only if one of them covers the other in P.

A ***Hasse diagram*** (or ***cover diagram*** or ***diagram***) of poset P is a straight-line drawing of the cover graph in the plane such that the lesser element of each pair satisfying the cover relation is lower in the drawing.

A poset is ***planar*** if it has a Hasse diagram without edge-crossings.

A ***subposet*** of $P = (X, \leq)$ is a subset $Y \subseteq X$ with the relation $x \leq y$ in Y if and only if $x \leq y$ in X.

The ***interval*** $[x, y]$ in poset P is the subposet that contains all elements z such that $x \leq z \leq y$.

A poset P is ***locally finite*** if every interval in P has finitely many elements.

An ***order-preserving mapping*** from poset $P = (X, \leq_P)$ to poset $Q = (Y, \leq_Q)$ is a function $f\colon X \to Y$ such that $x \leq_P x'$ implies $f(x) \leq_Q f(x')$.

An ***isomorphism of posets*** $P = (X, R)$ and $Q = (Y, S)$ is a bijection $f\colon X \to Y$ that preserves the order relation: whenever $x_1 \leq_P x_2$, then $f(x_1) \leq_Q f(x_2)$.

Isomorphic posets are posets $P = (X, R)$ and $Q = (Y, S)$ such that there is a poset isomorphism $P \to Q$. This is sometimes indicated informally by writing $P = Q$.

Poset $Q = (Y, S)$ ***is contained in*** (or ***imbeds in***) poset $P = (X, R)$ if Q is isomorphic to a subposet of P.

A poset P is ***Q-free*** if P does not contain a poset isomorphic to Q.

Facts:

1. Every finite nonempty poset has a minimal element and a maximal element.

2. The comparability digraph $D(P)$ of a poset P is an acyclic digraph.

3. The minimal elements of a poset P induced by a digraph D are the *sources* of D; that is, they are the vertices at which every arc points outward.

4. The maximal elements of a poset P induced by a digraph D are the *sinks* of D; that is, they are the vertices at which every arc points inward.

5. The element y covers the element x in a poset P induced by a digraph D if and only if there is an arc in digraph D from x to y and there is no other directed path from x to y.

6. Suppose that the poset P is induced from an acyclic digraph D. Then the comparability digraph of P is the transitive closure of D.

7. Two different posets cannot have the same Hasse diagram, but they may have the same cover graph or the same comparability graph.

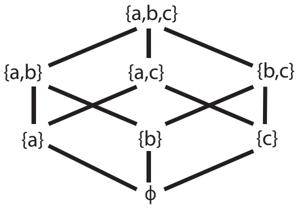
8. There is a polynomial-time algorithm to check whether a graph G is a comparability graph, but the problem of deciding whether there exists a poset for which G is the cover graph is NP-complete.

Examples:

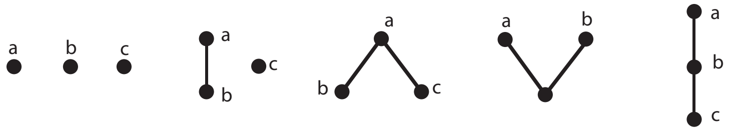
1. Any collection of subsets of the same set forms a poset when the subsets are partially ordered by the usual inclusion relation $X \subseteq Y$.

2. *Boolean algebra*: The Boolean algebra on a set X is the poset consisting of all the subsets of X, ordered by inclusion.

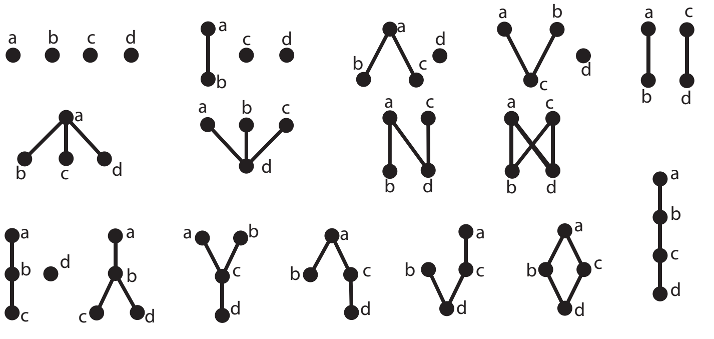
3. The Boolean algebra on the set $\{a, b, c\}$ has the following Hasse diagram. The only maximal element is $\{a, b, c\}$. The only minimal element is $\emptyset$.



4. There are five different isomorphism types of posets of size three, whose Hasse diagrams are as follows.

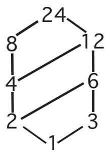


5. There are 16 different isomorphism types of posets of size four, whose Hasse diagrams are as follows.



6. *Divisibility poset*: The divisibility poset on the set I of positive integers, denoted $D(I)$, has the relation $x \leq y$ if y is an integer multiple of x. A number y covers a number x if and only if the quotient $\frac{y}{x}$ is prime.

7. The set $D(n)$ of divisors of n forms a subposet of $D(I)$, for any positive integer n. The set $D(n)$ is identical to the interval $[1, n]$ in $D(I)$. For instance, the following figure is the Hasse diagram of $D(24) = [1, 24]$.

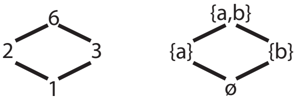


8. The interval $[3, 30]$ in $D(I)$ has domain $\{3, 6, 12, 15, 30\}$. The interval $[2, 24]$ has domain $\{2, 4, 6, 8, 12, 24\}$.

9. The poset $D(I)$ is infinite, but locally finite.

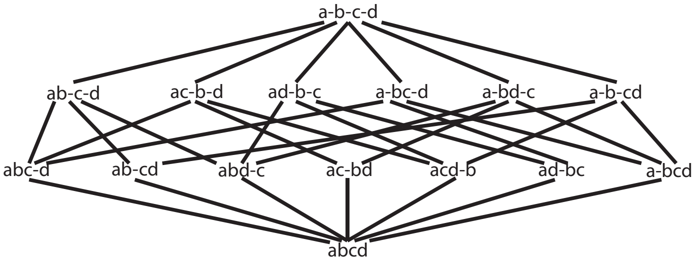
10. The Boolean algebra of all subsets of an infinite set is not a finite poset. Nor is it locally finite, since each interval from a finite set to an infinite superset is infinite.

11. The poset $D(6)$ is isomorphic to the poset of subsets of $\{a, b\}$, as seen next.



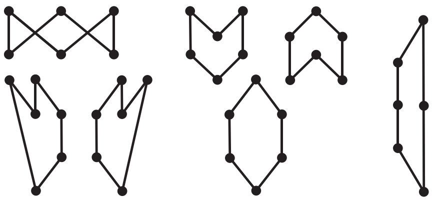
12. To generalize Example 11, if $p_1, \ldots, p_n$ are distinct primes, then the divisibility poset $D(p_1 \ldots p_n)$ is isomorphic to the poset of subsets of a set of n objects.

13. The partitions of a set form a poset under refinement, as illustrated for the set $\{a, b, c, d\}$. A notation such as *ab-c-d* means a partition of the set $\{a, b, c, d\}$ into the subsets $\{a, b\}$, $\{c\}$, $\{d\}$.



14. The 6-cycle is the comparability graph of exactly one (isomorphism type of) poset, which has the following Hasse diagram.

15. The 6-cycle is the cover graph of seven posets, all of which are planar. They have the following Hasse diagrams.



11.1.2 CHAINS, ANTICHAINS, AND POSET OPERATIONS

Definitions:

A ***chain*** is a subset S of mutually comparable elements of a poset P, or sometimes the subposet of P formed by such a subset.

The ***length*** of a finite chain C is $|C|-1$, i.e., the number of edges in the Hasse diagram of that chain, regarded as a poset.

A ***k-chain*** is a chain of size k, i.e., a chain on k elements.

The ***standard k-chain*** $\underline{k}$ is a fixed k-chain, presumed to be disjoint from other objects in the universe of discourse.

The ***height of a poset*** P is the maximum size of a chain in P.

The ***height of an element*** x in a poset P is the maximum length $h(x)$ of a chain in P that has x as its maximal element.

A ***bipartite poset*** is a poset of height at most 2.

A ***chain-product*** (or ***grid***) is the Cartesian product of a collection of chains.

An ***antichain*** (or ***clutter*** or ***Sperner family***) is a subset S of pairwise incomparable elements of a poset P, or sometimes the subposet of P formed by such a subset.

A chain or antichain is ***maximal*** if it is contained in no other chain or antichain.

A chain or antichain in a finite poset is a ***maximum*** chain or antichain if it is one of maximum size.

The ***disjoint union*** of two posets $P=(X,R)$ and $P'=(X',R')$ with $X\cap X'=\emptyset$ is the poset $(X\cup X', R\cup R')$, denoted $P+P'$.

The ***linear sum*** of two posets $P=(X,R)$ and $P'=(X',R')$ with $X\cap X'=\emptyset$ is the poset $(X\cup X', R\cup R'\cup(X\times X'))$, denoted $P\oplus P'$. (This puts all of poset P "below" poset P'.)

The ***Cartesian product*** $P\times P'$ (or ***direct product*** or ***product***) of two posets $P=(X,R)$ and $P'=(X',R')$ is the poset $(X\times X', S)$, such that $(x,x')S(y,y')$ if and only if xRy and $x'R'y'$.

The ***iterated Cartesian product*** of n copies of a poset $P=(X,\leq)$, written P^n, is the set of n-tuples in P, such that $(x_1,\ldots,x_n)\leq(y_1,\ldots,y_n)$ if and only if $x_j\leq y_j$ for all $j=1,\ldots,n$.

The ***lexicographic ordering*** of the Cartesian product $P_1\times P_2$ of the domains of two posets is the partial ordering in which $(x_1,x_2)\leq(y_1,y_2)$ if and only if $x_1<y_1$, or $x_1=y_1$ and $x_2\leq y_2$.

The ***dual*** of a poset P, denoted P^*, is the poset on the elements of P defined by the relation $y\leq_{P^*}x$ if and only if $x\leq_P y$.

A ***self-dual poset*** is a poset that is isomorphic to its dual.

Facts:

1. Every k-chain is isomorphic to the linear sum $\underline{1}\oplus\underline{1}\oplus\cdots\oplus\underline{1}$ of k copies of $\underline{1}$.

2. Every antichain of size k is isomorphic to the disjoint union $\underline{1}+\underline{1}+\cdots+\underline{1}$ of k copies of $\underline{1}$.

3. The chains are characterizable as the class of $(\underline{1}+\underline{1})$-free posets.

4. The cover graph of a chain is a path.

5. The comparability graph of a chain of size n is the complete graph K_n.

6. The antichains are the class of $\underline{2}$-free posets.

7. The comparability graph of an antichain has no edges.

8. The maximum size of a chain in a finite poset P equals the minimum number of antichains needed to cover the elements of P, that is, the minimum number of antichains whose union equals the domain of poset P.

9. The bipartite posets are precisely the $\underline{3}$-free posets.

10. The bipartite posets are the posets whose comparability graph and cover graph are the same.

11. Every maximal chain of a finite poset P extends from a minimal element of P to a maximal element of P, and successive pairs on a maximal chain satisfy the cover relation of P.

12. The Cartesian product of two posets is a poset.

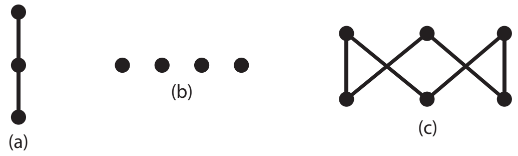
13. A poset and its dual have the same comparability graph and the same cover graph.

14. The Hasse diagram of the dual of a poset P can be obtained from the Hasse diagram of P either by reflecting through the horizontal axis or by rotating 180 degrees.

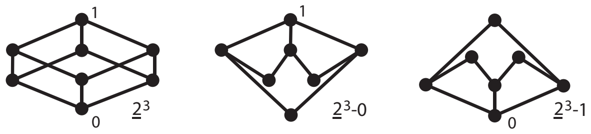
15. The set of order-preserving maps from a poset P to a poset Q forms a poset, denoted by Q^P, under "coordinate-wise ordering": $f \leq g$ in Q^P if and only if $f(x) \leq_Q g(x)$ for all $x \in P$.

Examples:

1. The following figure shows: (a) a 3-chain, (b) an antichain of width 4, and (c) a bipartite poset.



2. The poset $\underline{2}^3$ is not planar, even though it has a planar cover graph. However, deleting its minimal element or maximal element leaves a planar subposet.



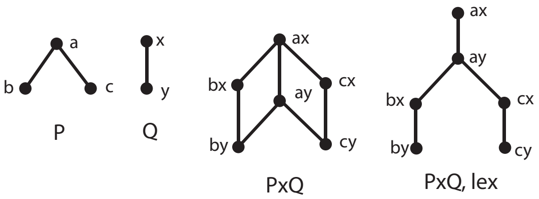
3. The cover graph of the poset $\underline{2}^n$ is isomorphic to the n-dimensional cube, whose vertices are the bitstrings of length n, with bitstrings adjacent if they differ in one position. Each bit encodes the possible presence of an element of the set of which B_n is the Boolean algebra (§5.8.1).

4. The interval in the Boolean algebra $\underline{2}^n$ between an element of rank k and an element of rank $l \geq k$ is isomorphic to the poset $\underline{2}^{l-k}$.

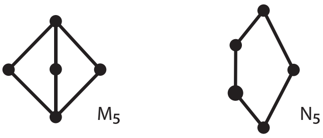
5. Every maximal chain in the Boolean algebra $\underline{2}^n$ has size $n+1$ and length n, and there are $n!$ such chains. There are maximal antichains as small as one element.

6. In general, the poset $D(n)$ is isomorphic to a chain product, one factor for each prime divisor of n. The elements of $D(n)$ can be encoded as integer vectors $\{a_1, \ldots, a_n \mid 0 \leq a_i < e_i\}$, where n is a product of distinct primes with powers $e_1, \ldots, e_n$, and $a \leq b$ if and only if $a_i \leq b_i$ for all i.

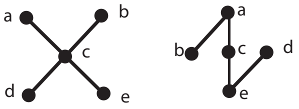
7. The Hasse diagrams for two possible partial orderings on the Cartesian product of the domains of two posets are shown in the following figure.



8. The two posets $M_5 = \underline{1} \oplus (\underline{1} + \underline{1} + \underline{1}) \oplus \underline{1}$ and $N_5 = \underline{1} \oplus (\underline{2} + \underline{1}) \oplus \underline{1}$ are used in §11.1.5 in a forbidden subposet description.



9. The following posets are self-dual.



11.1.3 RANK, IDEALS, AND FILTERS

Definitions:

A ***graded poset*** is a poset in which all maximal chains have the same length.

The ***rank*** $r(P)$ of a graded poset P is the length of any maximal chain.

A ***rank function*** r on a poset P is an assignment of integers to the elements so that the relation y covers x implies that $r(y) = r(x) + 1$.

A ***ranked poset*** is a poset having a rank function.

The ***kth rank*** of a ranked poset P is the subset P_k of elements x for which $r(x) = k$.

The ***kth rank parameter*** of a subset of elements F in a ranked poset P is the cardinality $|F \cap P_k|$ of the number of elements of F in the kth rank of P.

The ***kth Whitney number*** $N_k(P)$ of a ranked poset P is the cardinality $|P_k|$ of the kth rank.

The ***length of a poset*** P is the length of a longest chain in P, which is one less than the height of P. *Note*: Sometimes "height" is used synonymously with length.

The ***Jordan-Dedekind chain condition*** for a poset is that every interval has finite length.

The ***width of a poset*** P, denoted $w(P)$, is the maximum size of an antichain in P.

An ***ideal*** (or ***downset***, ***order ideal***, or ***hereditary family***) in a poset P is a subposet I such that if $x \in I$ and $y < x$, then $y \in I$.

A ***filter*** (or ***upset*** or ***dual ideal***) in a poset P is a subposet F whose domain is the set-theoretic complement of the domain of an ideal.

The ***ideal generated by an element*** x in a poset P is the downset $D[x] = \{y \in P \mid y \leq x\}$. The related notation $D(x)$ means the downset $\{y \in P \mid y < x\}$.

The ***ideal generated by a subset*** A in a poset P is the downset $D[A] = \bigcup_{x \in A} D[x]$. The related notation $D(A)$ means the downset $\bigcup_{x \in A} D(x)$.

The ***filter generated by an element*** x in a poset P is the upset $U[x] = \{y \in P \mid y \geq x\}$. The related notation $U(x)$ means the upset $\{y \in P \mid y > x\}$.

The ***filter generated by a subset*** A in a poset P is the upset $U[A] = \bigcup_{x \in A} U[x]$. The related notation $U(A)$ means the upset $\bigcup_{x \in A} U(x)$.

A ***forbidden subposet description*** of a class of posets is a characterization of that class as the class of all posets that does not contain any of the posets in a specified collection. (This generalizes the concept of Q-free.)

Facts:

1. A graded poset has a rank function, in which the rank of each element is defined to be its height.

2. If posets P_1, P_2 have rank functions r_1, r_2, then the Cartesian product $P = P_1 \times P_2$ is ranked, so that the element $x = (x_1, x_2)$ has rank $r(x) = r_1(x_1) + r_2(x_2)$.

3. In a Cartesian product of finite ranked posets P_1 and P_2, the Whitney numbers for the Cartesian product $P = P_1 \times P_2$ satisfy the equation $N_k(P) = \sum_i N_i(P_1) N_{k-i}(P_2)$.

4. The Boolean algebra on a set X of cardinality n is isomorphic to $\underline{2}^n$, the Cartesian product of n copies of $\underline{2}$. This poset isomorphism type is often denoted B_n.

5. The Boolean algebra on a set X of cardinality n is a graded poset, with rank function $r(S) = |S|$, and with Whitney numbers $N_k(\underline{2}^n) = \binom{n}{k}$.

6. The sequence of Whitney numbers on the Boolean algebra on a set X of cardinality n is symmetric, since $\binom{n}{k} = \binom{n}{n-k}$. It is also unimodal, since the sequence rises monotonically to the maximum and then falls monotonically.

7. *Sperner's theorem*: The only maximum antichains in the Boolean algebra $\underline{2}^n$ are the middle ranks (one such rank if n is even, two if n is odd). Thus the width of $\underline{2}^n$ is $\binom{n}{\lfloor n/2 \rfloor}$.

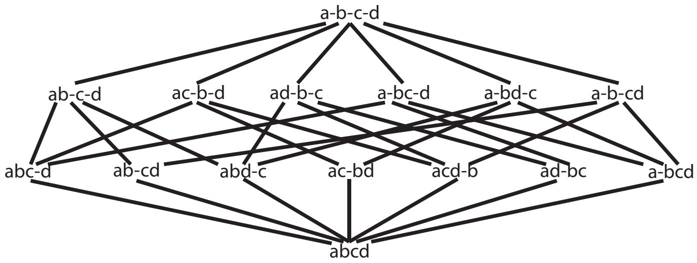
8. The maximal elements of an ideal form an antichain, as do the minimal elements of a dual ideal; these yield natural bijections between the set of antichains in a poset P and the sets of ideals or dual ideals of P.

9. The divisibility poset $D(I)$ on the integers satisfies the Jordan-Dedekind chain condition.

Examples:

1. In the poset P of partitions of $\{a, b, c, d\}$ under inverse refinement, illustrated next, the Whitney numbers are $N_1(P) = 1$, $N_2(P) = 6$, $N_3(P) = 7$, and $N_4(P) = 1$.

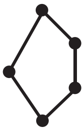
2. In the poset of partitions of $\{a, b, c, d\}$ under inverse refinement, the ideal $D[ac\text{-}bd]$ is the set $\{ac\text{-}bd, a\text{-}bd\text{-}c, ac\text{-}b\text{-}d, a\text{-}b\text{-}c\text{-}d\}$, and the ideal $D(ac\text{-}bd)$ is the set $\{a\text{-}bd\text{-}c, ac\text{-}b\text{-}d, a\text{-}b\text{-}c\text{-}d\}$.



3. In the poset of partitions of $\{a, b, c, d\}$ under inverse refinement, the filter $U[a\text{-}bd\text{-}c]$ is the set $\{$*a-bd-c*, *abd-c*, *ac-bd*, *a-bcd*, *abcd*$\}$, and the filter $U(a\text{-}bd\text{-}c)$ is the set $\{$*abd-c*, *ac-bd*, *a-bcd*, *abcd*$\}$.

4. In the graded poset $D(n)$ of divisors of n, the rank $r(x)$ is the sum of the exponents in the prime power factorization of x. The Whitney numbers of $D(n)$ are symmetric because the divisors x and $\frac{n}{x}$ have "complementary" ranks. If n is a product of k distinct primes, then $D(n) \cong \underline{2}^k$.

5. The following Hasse diagram corresponds to an ungraded poset, because the lengths of its maximum chains differ, i.e., they are length 2 and length 3.



6. In the divisibility poset $D(I)$, the subposet $D(n)$ of divisors of n is a finite ideal, and the non-multiples of n form an infinite ideal, whose complement is the infinite filter $U(n)$ of numbers that are divisible by n.

11.1.4 LATTICES

Lattices are posets with additional properties that capture some aspects of the intersection and the union of sets and (more generally) of the greatest common divisor and least common multiple of positive integers. (See also §5.7.)

Definitions:

A (***common***) ***upper bound*** for elements x, y in a poset is an element z such that $x \leq z$ and $y \leq z$.

A ***least upper bound*** (or ***lub***, pronounced "lub") for elements x, y in a poset is a common upper bound z such that every other common upper bound z' satisfies the inequality $z \leq z'$. Such an element, if it exists, is denoted $x \vee y$.

The ***join*** of x and y is the lub $x \vee y$.

A (***common***) ***lower bound*** for elements x, y in a poset is an element z such that $x \geq z$ and $y \geq z$.

A ***greatest lower bound*** (or ***glb***, pronounced "glub") for elements x, y in a poset is a common lower bound z such that every other common lower bound z' satisfies the inequality $z \geq z'$. Such an element, if it exists, is denoted $x \wedge y$.

The ***meet*** of x and y is the glb $x \wedge y$.

A ***lattice*** is a poset in which every pair of elements has both a lub and a glb.

A lattice is ***bounded*** if it has both a unique minimal element (denoted "0") and a unique maximal element (denoted "1").

A nonzero element of a lattice L is ***join-irreducible*** (or simply ***irreducible***) if it cannot be expressed as the lub of two other elements. The subposet formed by the join-irreducible elements of L is denoted by $P(L)$.

A nonzero element of a lattice L is ***meet-irreducible*** if it cannot be expressed as a glb of two other elements. The subposet formed by the meet-irreducible elements of L is denoted by $Q(L)$.

A ***complement*** of an element x of a lattice is an element $\overline{x}$ such that $x \vee \overline{x} = 1$ and $x \wedge \overline{x} = 0$.

A ***complemented lattice*** is a lattice in which every element has a complement.

A ***lattice isomorphism*** is an order-preserving bijection from one lattice to another that also preserves glbs and lubs.

An ***atom*** of a poset is an element of height 1.

A lattice is ***atomic*** if every element is a lub of atoms (or equivalently, if the atoms are the only join-irreducible elements).

A ***sublattice*** of a lattice L is a subposet P such that $x \wedge y$ and $x \vee y$ are in P for all x and $y \in P$.

The ***divisor lattice*** is the poset $D(n)$ of the positive integer divisors of n, in which $x \leq y$ means that y is an integer multiple of x.

The ***subset lattice*** is the Boolean algebra $\underline{2}^n$, that is, the Cartesian product of n copies of the standard 2-chain.

The ***subspace lattice*** $L_n(q)$ is the set of subspaces of an n-dimensional vector space over a q-element field, partially ordered by set inclusion.

The ***lattice of (order) ideals*** $J(P)$, for any poset $P = (X, R)$, is the set of order ideals of P, ordered by inclusion.

The ***lattice of bounded sequences*** $L(m, n)$ has as members the length-m real sequences $a_1, \ldots, a_m$ such that $0 \leq a_1 \leq \cdots \leq a_m \leq n$.

An ***integer partition*** is a nonincreasing nonnegative integer sequence having finitely many nonzero terms, with trailing zeros added as needed for comparison.

The ***Young lattice*** is the lattice of integer partitions under component-wise ordering.

A ***refinement*** of a set partition σ replaces each block $B \in \sigma$ by some partition of B.

The ***partition lattice*** is the poset Π_n of partitions of the set $[n] = \{1, \ldots, n\}$, where $\pi < \sigma$ if π is a refinement of σ.

Facts:

1. If $z \leq x$ in a lattice, then $x \wedge (y \vee z) \geq (x \wedge y) \vee z$.

2. *4-point lemma*: If each of the elements z, w is less than or equal to each of the elements x, y in a lattice, then $z \vee w \leq x \wedge y$.

3. An element z is a least upper bound for x and y if and only if it is a unique minimal element among their common upper bounds.

4. Every finite lattice is bounded.

5. Every chain-product is a lattice.

6. If a locally finite poset P with a unique maximal element 1 also has a well-defined glb operation, then P is a lattice.

7. Not all lattices are ranked. In particular, the lattice of integer partitions under dominance ordering is unranked.

8. Every interval in a lattice is a sublattice, but not every sublattice is an interval.

9. In the subspace lattice $L_n(q)$, the Whitney numbers (§11.1.3) satisfy the equation

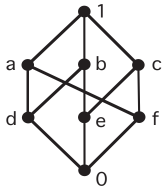
$$N_k(L_n(q)) = \frac{(q^n-1)(q^{n-1}-1)\dots(q^{n-k+1}-1)}{(q^k-1)(q^{k-1}-1)\dots(q^1-1)}.$$

10. In the subspace lattice $L_n(q)$, the Whitney number $N_k(L_n(q))$ equals the *Gaussian coefficient* $\left[{n \atop k}\right]_q$ (§2.3.2), which appears in algebraic identities and in analogues of results on subsets.

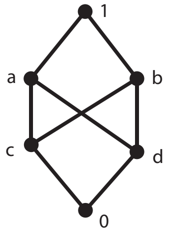
11. The Whitney number $N_k(\Pi_n)$ of partitions of the set $[n]$ into $n-k$ blocks is the *Stirling subset number* $\left\{{n \atop n-k}\right\}$ (§2.5.2). This has no closed formula, but the inclusion-exclusion principle yields $\left\{{n \atop t}\right\} = \sum_{i=0}^{t}(-1)^i \frac{(t-i)^n}{t!}$.

Examples:

1. The poset specified by the following Hasse diagram is a lattice.



2. The poset specified by the following Hasse diagram is *not* a lattice. Although every pair of elements has a common upper bound, none of the three common upper bounds for the elements c and d is a least upper bound.



3. Two 5-element lattices that occur as subposets of $\underline{2}^3$ but not as sublattices of $\underline{2}^3$ are $M_5 = \underline{1} \oplus (\underline{1}+\underline{1}+\underline{1}) \oplus \underline{1}$ and $N_5 = \underline{1} \oplus (\underline{2}+\underline{1}) \oplus \underline{1}$.

4. In the divisor lattice $D(n)$, $a \wedge b = \gcd(a,b)$ and $a \vee b = \operatorname{lcm}(a,b)$.

5. The join-irreducible elements of the divisibility lattice $D(I)$ are the powers of primes.

6. In the subset lattice $\underline{2}^n$, $a \wedge b = a \cap b$ and $a \vee b = a \cup b$.

7. The join-irreducible elements of the subset lattice $\underline{2}^n$ are the singleton sets.

8. The subspace lattice $L_n(q)$ is a graded lattice, with rank $r(U) = \dim U$.

9. In the subspace lattice $L_n(q)$, the meet of subspaces U and V is their intersection $U \cap V$, and the join is the unique minimal subspace containing their union.

10. In the lattice of order ideals $J(P)$, glb and lub are given by intersection and union. Hence $J(P)$ is a sublattice of the Boolean lattice $\underline{2}^{|P|}$; equality holds if and only if P is an antichain.

11. The lattice $J(P)$ of ideals of a poset $P = (X, R)$ is finite, with $1_{J(P)} = X$ and $0_{J(P)} = \emptyset$. It is graded, with rank function $r(I) = |I|$.

12. By the correspondence between ideals of a poset $P = (X, R)$ and their antichains of maximal elements, the lattice $J(P)$ of ideals is also a lattice on the antichains of P. The corresponding ordering on antichains is $A \le B$ if every element of A is less than or equal to some element of B.

13. The lattice $L(m, n)$ of bounded sequences is a sublattice of $\underline{n+1}^m$, and $L(m, n) = J(\underline{m} \times \underline{n}) = L(n, m)$. The natural isomorphism maps a sequence $a \in L(m, n)$ to the order ideal of $\underline{m} \times \underline{n}$ generated by $\{(m + 1 - i, a_i) \mid a_i > 0\}$.

14. The lattice $L(m, n)$ is a sublattice of the Young lattice.

15. In the partition lattice Π_n, $13|4|2|5 < 123|45$; the order of the blocks and the order of elements within each block are irrelevant.

16. The partition lattice Π_n is a graded poset, with $1_{\Pi_n} = [n]$ and $0_{\Pi_n} = 1|2|\cdots|n$. The common refinement of π and σ with the fewest blocks is the greatest lower bound (meet) of π and σ.

17. The lattice Π_3 is isomorphic to the lattice M_5.

18. In the ordering on antichains of a poset P defined by $A \le B$ if every element of A is less than or equal to some element of B, the maximum antichains of P induce a sublattice.

11.1.5 DISTRIBUTIVE AND MODULAR LATTICES

Definitions:

A lattice L is ***distributive*** if glb distributes over lub in L, that is, if $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$ for all $x, y, z \in L$.

A lattice L is ***modular*** if $x \wedge (y \vee z) = (x \wedge y) \vee z$ for all $x, y, z \in L$ such that $z \le x$.

A lattice L is (***upper***) ***semimodular*** if for all $x, y \in L$, "x covers $x \wedge y$" implies "$x \vee y$ covers y".

A lattice L is ***lower semimodular*** if the reverse implication holds (equivalently, if the dual lattice L^* is semimodular).

The height function h of a lattice L is a ***submodular height function*** if $h(x \wedge y) + h(x \vee y) \le h(x) + h(y)$ for all $x, y \in L$.

A lattice is ***geometric*** if it is atomic, semimodular, and has finite height.

A ***closure operator*** on the subsets of a set E is a function $\sigma\colon 2^E \to 2^E$ that maps each set to a superset of itself, is order-preserving with respect to set inclusion, and is "idempotent": $\sigma(\sigma(A)) = \sigma(A)$.

The ***closed subsets*** of a set E, with respect to a closure operator $\sigma\colon 2^E \to 2^E$, are the sets with $\sigma(A) = A$.

The ***Steinitz exchange axiom*** for a closure operator $\sigma\colon 2^E \to 2^E$ is the rule that $p \notin \sigma(A)$ and $p \in \sigma(A \cup q)$ imply $q \in \sigma(A \cup p)$.

Facts:

1. The smallest nondistributive lattices are $M_5 = \underline{1}\oplus(\underline{1}+\underline{1}+\underline{1})\oplus\underline{1}$ and $N_5 = \underline{1}\oplus(\underline{2}+\underline{1})\oplus\underline{1}$, which are illustrated in §11.1.2, Example 8.

2. A lattice is distributive if and only if it occurs as a sublattice of $\underline{2}^n$ for some n.

3. Every sublattice of a distributive lattice is a distributive lattice.

4. The product of distributive lattices L_1 and L_2 is a distributive lattice, with $(x_1, x_2) \wedge (y_1, y_2) = (x_1 \wedge y_1, x_2 \wedge y_2)$ and $(x_1, x_2) \vee (y_1, y_2) = (x_1 \vee y_1, x_2 \vee y_2)$.

5. In a lattice L, distributivity and the dual property that $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$ for all $x, y, z \in L$ are equivalent. Hence the dual of a distributive lattice is a distributive lattice.

6. A lattice L is modular if and only if $c \in [a \wedge b, a]$ implies $a \wedge (b \vee c) = c$ for all $a, b \in L$ (equivalently, if $c \in [b, b \vee d]$ implies $b \vee (c \wedge d) = d$ for all $b, d \in L$).

7. Let $\mu_a\colon L \to L$ be the operation "take the glb with a", and let $\nu_b\colon L \to L$ be the operation "take the lub with b". A lattice L is modular if and only if for all $a, b \in L$, the intervals $[a \wedge b, a]$ and $[b, a \vee b]$ are isomorphic sublattices of L, with lattice isomorphisms given by ν_b and μ_a.

8. If y covers x in a semimodular lattice L, then for all $z \in L$, $x \vee z = y \vee z$ or $x \vee z$ is covered by $y \vee z$.

9. A lattice L with a lower bound is semimodular if and only if the following is true: the height function of L is submodular and in each interval the maximal chains all have the same length.

10. A lattice is modular if and only if it does not have N_5 as a sublattice.

11. Every distributive lattice is modular, because in a distributive lattice $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z) = (x \wedge y) \vee z$ if $z \leq x$.

12. A modular lattice is distributive if and only if it does not have M_5 as a sublattice.

13. Given a closure operator, the closed sets form a lattice under inclusion with meet and lub given by intersection and closure of the union, respectively.

14. If a closure operator σ satisfies the Steinitz exchange axiom, then the lattice of closed sets is semimodular.

15. The lattice $L_n(q)$ is semimodular. (This follows from the previous fact.)

16. A poset is a geometric lattice if and only if it is the lattice of closed sets of a matroid, ordered by inclusion (§12.4). (The span operator in a matroid, which adds to X every element whose addition to X does not increase the rank, is a closure operator that satisfies the Steinitz exchange axiom.)

17. A geometric lattice is distributive if and only if it has the form $\underline{2}^n$, and the corresponding matroid is the free matroid, in which all subsets of the elements are independent.

18. A complemented distributive lattice is a Boolean algebra.

Examples:

1. Among nondistributive lattices, the lattice M_5 is modular, and the lattice N_5 is not (which explains the notation).

2. The subspace lattices $L_n(q)$ are not distributive.

3. The partition lattice Π_n is semimodular but not modular for $n > 3$. The lattice $L_n(q)$ is semimodular.

4. The partition lattice Π_n is geometric, and it is the lattice of closed sets of the cycle matroid of the complete graph K_n.

5. For $n \geq 3$, the lattice $\Pi(n)$ is not distributive.

6. The Boolean lattice $\underline{2}^n$, the divisor lattice $D(N)$, the lattice $J(P)$ of order ideals of a poset, and the bounded sequence lattice $L(m, n)$ are distributive.

11.2 POSET PROPERTIES

11.2.1 POSET PARTITIONS

Definitions:

A ***chain partition*** of a poset is a partition of the domain of that poset into chains.

The ***k-norm of a sequence*** $x = \{x_i\}$ of real numbers is the sum $\sum_i \min\{k, x_i\}$, whose value is commonly denoted $m_k(x)$.

The ***k-norm of a chain partition* C** of a poset, denoted $m_k(\mathbf{C})$, means the k-norm of the sequence of sizes of the chains in the partition.

A ***k-family*** in a poset P is a subposet containing no chain of size $k + 1$. The size of a maximum k-family in P is denoted by $d_k(P)$.

A partition of a poset P into chains is ***k-saturated*** if $m_k(\mathbf{C}) = d_k(P)$.

A chain in a ranked poset is ***symmetric*** if it has an element of rank $r(P) - k$ whenever it has an element of rank k.

A chain is ***consecutive*** if its elements belong to consecutive ranks.

A ***symmetric chain decomposition*** of P is a partition of P into symmetric consecutive chains.

A ***symmetric chain order*** is a poset with a symmetric chain decomposition.

A graded poset has the ***Sperner property*** if some single rank is a maximum antichain.

A graded poset has the ***strict Sperner property*** if all maximum antichains are single ranks.

A poset P has the ***k-Sperner property*** if it has a maximum k-family consisting of k ranks.

A poset has the ***strong Sperner property*** if it is k-Sperner for all $k \leq r(P)$.

A graded poset P satisfies the ***normalized matching property*** if for every k and every subset A of P_k, the set A^* of elements in P_{k+1} that are comparable to at least one element of A satisfies the inequality $\frac{|A^*|}{N_{k+1}} \geq \frac{|A|}{N_k}$, where N_k and N_{k+1} are Whitney numbers.

A ***regular covering by chains*** is a multiset of maximal chains such that for each $x \in P$ the fraction of the chains containing x is $\frac{1}{N_{r(x)}}$.

To obtain the ***bracket representation*** of a subset S of $[n] = \{1, \ldots, n\}$, first represent the subset S as a length-n "parenthesis-vector", in which the jth bit is a right parenthesis if $j \in S$ and a left parenthesis if $j \notin S$. Then wherever possible, recursively, match a left parenthesis to the nearest unmatched right parenthesis that is separated from it only by previously matched entries.

An ***on-line partitioning algorithm*** processes the elements of a poset as they are "revealed". Once an element is assigned to a cell, it remains there; there is no backtracking to change earlier decisions.

Facts:

1. *Dilworth's theorem*: If P is a finite poset, then the width of P equals the minimum number of chains needed to cover the elements of P.

2. Dilworth's theorem also holds for infinite posets of finite width.

3. The 1-families are the antichains.

4. Every k-family is a union of k antichains.

5. A k-family in P can be transformed into an antichain in $P \times \underline{k}$ of the same size, and vice versa, and hence $d_k(P) = w(P \times \underline{k})$.

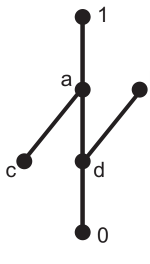
6. The discussion of saturated partitions is generally restricted to finite posets.

7. If α_k is the number of chains of size at least k in a k-saturated chain partition of P, then $\Delta_k(P) \geq \alpha_k \geq \Delta_{k+1}(P)$, where $\Delta_k(P) = d_k(P) - d_{k-1}(P)$ for $k \geq 1$.

8. *Littlewood-Offord problem*: Let $A = \{a_1, \ldots, a_n\}$ be a set of vectors in $\mathcal{R}^d$, with each vector having length at least 1. Let $R_1, \ldots, R_k$ be regions in $\mathcal{R}^d$ of diameter at most 1. Then of the 2^n subsets of A, the number whose sum lies in $\bigcup_i R_i$ is at most $d_k(\underline{2}^n)$.

9. *Greene-Kleitman (GK) theorem*: For every finite poset P and every $k \geq 0$, there is a chain partition of P that is both k-saturated and $(k+1)$-saturated.

10. The GK theorem is best possible, since there are infinitely many posets for which no chain partition is both k-saturated and l-saturated for any nonconsecutive nontrivial values for k, l; the smallest has six elements (see the following illustration). The GK theorem extends in various ways to directed graphs.



11. Dilworth's theorem is the special case of the GK theorem for $k = 0$ (every chain partition is 0-saturated).

12. Every product of symmetric chain orders is a symmetric chain order.

13. The lattice of bounded sequences $L(m, n)$ (§11.1.4) has a symmetric chain decomposition if $\min\{m, n\} \leq 4$. It is not known whether $L(m, n)$ in general has a symmetric chain decomposition.

14. The lattice $L(m, n)$ has the Sperner property.

15. The partition lattice $\Pi(n)$ fails to satisfy the Sperner property if n is sufficiently large.

16. The Boolean lattice $\underline{2}^n$ and the subspace lattice $L_n(q)$ satisfy the strict Sperner property.

17. Every symmetric chain order has the strong Sperner property, and a symmetric chain decomposition is k-saturated for all k.

18. The class of graded posets that have the strong Sperner property and a symmetric unimodal sequence of Whitney numbers is closed under Cartesian product.

19. When $N_k \leq N_{k+1}$, the normalized matching property implies Hall's condition for the existence of a matching saturating P_k in the bipartite graph of the relations between the two levels.

20. Two subsets of the Boolean lattice in $[n]$ are on the same chain of the "bracketing decomposition" if and only if they have the same bracketing representation. This provides an explicit symmetric chain decomposition of $\underline{2}^n$. This generalizes for multisets ($D(N)$).

21. *Dedekind's problem*: This is the problem of computing the total number of antichains in the Boolean algebra $\underline{2}^n$. By using the bracketing decomposition, this number is calculated to be at most $3^{\binom{n}{\lfloor n/2 \rfloor}}$. Asymptotically, for even n, the number is

$$2^{\binom{n}{n/2}} e^{\binom{n}{n/2-1}} [2^{-n/2} + n^2 2^{-n-5} - n 2^{-n-4}(1 + o(1))].$$

The exact values for $n \leq 7$ are 3; 6; 20; 168; 7,581; 7,828,354; and 2,414,682,040,998. The stated estimate gives 7,996,118 for $n = 6$.

22. *Universal set sequences*: A universal set sequence on a set S is a sequence that contains every subset of S as a consecutive subsequence. The bracketing decomposition yields a universal set sequence on $[n]$ of length asymptotic to $\frac{2}{\pi} 2^n$.

23. If two sets, x and y, are chosen independently according to a probability distribution on the Boolean lattice $\underline{2}^n$, then the probability that x is contained in y is at least $\binom{n}{\lfloor n/2 \rfloor}^{-1}$.

24. There is an on-line algorithm that partitions posets of height k into $\binom{k+1}{2}$ antichains. This is best possible, even for 2-dimensional posets.

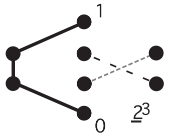
25. There is an on-line algorithm that partitions posets of width k into $\frac{5^k - 1}{4}$ chains.

26. It is impossible to design an on-line algorithm that partitions every poset of width k into fewer than $\binom{k+1}{2}$ chains.

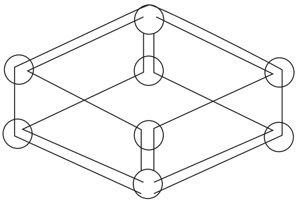
27. There is an on-line algorithm to partition every poset of width 2 into five chains, and this is best possible.

Examples:

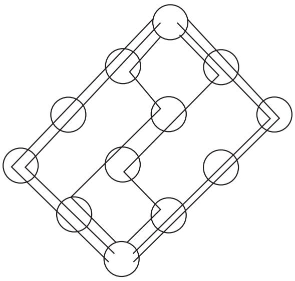
1. A symmetric chain decomposition of the Boolean lattice $\underline{2}^3$ is shown next.



2. A regular chain covering of the Boolean lattice $\underline{2}^3$ is shown next.



3. The poset $\underline{3} \times \underline{4}$ has a regular covering by six chains, using two chains twice and two other chains once each.



4. The poset $\underline{3} \times \underline{4}$ satisfies the Sperner property but not the strict Sperner property, since it has a maximum antichain (size three) that is not confined to a single rank.

5. Dilworth's theorem can be used to demonstrate the following result: Any sequence of n^2+1 real numbers contains a monotone subsequence of length $n+1$ (Erdős and Szekeres, 1935). Let the given sequence be $a_1, a_2, \ldots, a_{n^2+1}$. Define the poset $P = \{(k, a_k) \mid k = 1, \ldots, n^2+1\}$, with $(i, a_i) \leq (j, a_j) \Leftrightarrow i < j$ and $a_i \leq a_j$. Assume then that the given sequence does not contain a monotone nondecreasing subsequence of length $n+1$. Since a chain in P corresponds to a monotone nondecreasing subsequence, each chain can contain at most n elements, and so we require at least $n+1$ chains to cover P. Since an antichain corresponds to a monotone nonincreasing subsequence, Dilworth's theorem assures us that there exists an antichain of size at least $n+1$ and so a monotone nonincreasing subsequence of length at least $n+1$.

11.2.2 LYM PROPERTY

Definitions:

The ***LYM inequality*** for a family F in a ranked poset P is the inequality $\sum\limits_{x \in F} \frac{1}{N_{r(x)}} \leq 1$, where $N_{r(x)}$ is a Whitney number.

A poset P is an ***LYM order*** (or satisfies the ***LYM property***) if every antichain $F \subseteq P$ satisfies the LYM inequality.

Facts:

1. The LYM property was discovered independently for $\underline{2}^n$ by Lubell, Yamamoto, and Meshalkin.

2. The LYM property, the normalized matching property, and the existence of a regular covering by chains are equivalent.

3. The LYM property implies the Sperner property and also implies the strong Sperner property (but not the strict Sperner property).

4. Every LYM order that has symmetric unimodal Whitney numbers has a symmetric chain decomposition. In particular, $L_n(q)$ is a symmetric chain order.

5. It is not known whether every LYM poset has a chain decomposition that is k-saturated for all k.

6. A product of LYM orders may fail the LYM property.

7. A product of LYM orders whose sequence of Whitney numbers is log-concave is an LYM order with a log-concave sequence of Whitney numbers. (A sequence $\{a_n\}$ is *log-concave* if $a_n^2 \geq a_{n-1}a_{n+1}$ for all n.)

8. The divisor lattice $D(N)$ is an LYM order, which follows from the previous fact.

9. The partition lattice $\Pi(n)$ is an LYM order if and only if $n < 20$.

10. The Boolean lattice $\underline{2}^n$ and the subspace lattice $L_n(q)$ have regular coverings by chains and hence are LYM orders.

11. If $\{\lambda_x\}$ is an assignment of real-valued weights to the elements of an LYM poset P, then for every subset $G \subset P$ and every regular covering $\mathbf{C}$ of P,

$$\sum_{x \in G} \frac{\lambda_x}{N_{r(x)}} \leq \max_{C \in \mathbf{C}} \{ \sum_{y \in C \cap G} \lambda_y \}.$$

Example:

1. The lattice $L(m,n)$ of bounded sequences is an LYM order if and only if $\min\{m,n\} \leq 2$ or $(m,n) = (3,3)$.

11.2.3 RANKINGS, SEMIORDERS, AND INTERVAL ORDERS

A chain names the "better" of any pair according to a single scale. Realistically, some comparisons may yield indifference. Several families of "chain-like" partial orders successively relax the requirements on indifference.

Definitions:

A poset P is a ***ranking*** or ***weak order*** if its elements are partitioned into ranks $P_1, \ldots, P_k$ such that two elements are incomparable if and only if they belong to the same rank.

A poset P is a ***semiorder*** if there is a real-valued function f and a fixed real number $\delta > 0$ (δ may be taken to be 1) such that $x < y$ if and only if $f(y) - f(x) > \delta$. The pair (f, δ) is a ***semiorder representation*** of the poset P.

A poset P is an ***interval order*** if there is an assignment of real intervals to its members such that $x < y$ if and only if the interval for y is totally to the right of the interval for x. The collection of intervals is called an ***interval representation*** of the poset P.

A ***biorder representation*** on a digraph D is a pair of real-valued functions f, g on the vertex set V_D such that $u \to v$ is an arc if and only if $f(u) > g(v)$.

A ***Ferrers digraph*** (or ***Ferrers relation*** or ***biorder***) is a digraph having a biorder representation. (Also see §2.5.1.)

Facts:

1. Rankings model a single criterion of comparison with "ties" allowed, as in voting.

2. A poset is a ranking if and only if its comparability graph is a complete multipartite graph.

3. A ranking assigns a score $f(z)$ to each element z such that $x < y$ if and only if $f(x) < f(y)$.

4. The forbidden subposet characterization of a ranking is $\underline{1} + \underline{2}$.

5. Semiorders were introduced to model intransitivity of indifference; a difference of a few grains of sugar in a coffee cup or a few dollars in the price of a house is not likely to affect one's attitude, but pounds of sugar or thousands of dollars will. The threshold δ in a semiorder representation indicates a "just-noticeable difference".

6. A poset is a semiorder if and only if its incomparability graph is a unit interval graph, that is, an interval graph (§8.1.3) such that all intervals are of unit length.

7. An interval representation of a semiorder P with semiorder representation (f, δ) is obtained by setting $I_x = [f(x) - \frac{\delta}{2} + \epsilon,\ f(x) + \frac{\delta}{2} - \epsilon]$.

8. *Scott-Suppes theorem*: The forbidden subposet characterization of a semiorder is $\{\underline{1} + \underline{3}, \underline{2} + \underline{2}\}$.

9. The number of nonisomorphic semiorders on an n-element set is the Catalan number $C_n = \frac{1}{n+1}\binom{2n}{n}$ (§3.1.3).

10. Interval orders model a situation where the value assigned to an element is imprecise.

11. The incomparability graph of an interval order is an interval graph.

12. Every poset whose incomparability graph is an interval graph is an interval order. This follows from the forbidden subposet characterization of interval orders.

13. The forbidden subposet characterization of an interval order is $\underline{2} + \underline{2}$.

14. A poset P is an interval order if and only if both the collections of "upper holdings" $U(x) = \{y \in P \mid y > x\}$ and "lower holdings" $D(x) = \{y \in P \mid y < x\}$ form chains under inclusion, in which case the number of distinct nonempty upper holding sets and distinct nonempty lower holding sets is the same. Construction of these chains yields a fast algorithm to compute a representation for an interval order or semiorder.

15. The strict comparability digraph of an interval order is a Ferrers digraph, with $f(x)$ and $g(x)$ denoting the left and right endpoints of the interval assigned to x. This is the strict comparability digraph of a poset because $f(x) \leq g(x)$ for all x. The "upper holdings" and "lower holdings" for an interval order become predecessor and successor sets for a Ferrers digraph.

16. For a digraph D with adjacency matrix $A(D)$, the following are equivalent:

- D has a biorder representation (and is a Ferrers digraph);
- $A(D)$ has no 2-by-2 submatrix that is a permutation matrix;
- the successor sets of D are ordered by inclusion;
- the predecessor sets of D are ordered by inclusion;
- the rows and columns of $A(D)$ can be permuted independently so that to the left of a 1 is a 1.

17. The greedy algorithm is an optimal on-line algorithm for partitioning an interval order into the minimum number of antichains. It uses at most $2h - 1$ antichains to recursively partition an interval order of height h, and this is best possible.

18. There is an on-line algorithm to partition every interval order of width k into $3k-2$ chains, and this is best possible. Equivalently, the maximum number of colors needed for on-line coloring of interval graphs with clique size k is $3k-2$.

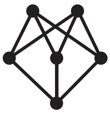
19. No on-line partitioning algorithm colors all trees with a bounded number of colors.

20. *"Universal" interval orders*: Since the ordering of the interval endpoints is all that matters, interval representations may be restricted to have integer endpoints. The poset $I[0,n]$ or $\mathbf{I}_n$ denotes the interval order whose interval representation consists of all intervals with integer endpoints in $\{0,\ldots,n\}$.

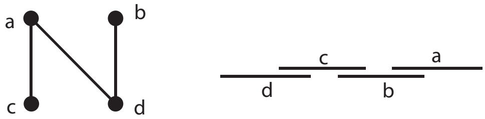
21. Every finite interval order is a subposet of some $I[0,n]$.

Examples:

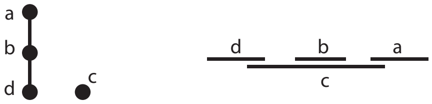
1. The following Hasse diagram represents a poset that is a ranking. Its three ranks are indicated by the levels in the diagram.



2. The following Hasse diagram represents a poset that is a semiorder: for instance, with $\delta = 1$, define $f(a) = 2$, $f(b) = 1.3$, $f(c) = 0.8$, and $f(d) = 0$. It is not a ranking, by Fact 4, because $\underline{1} + \underline{2}$ is a subposet. The interval representation of its incomparability graph is at the right.



3. The following Hasse diagram represents a poset that is an interval order. The interval representation of its incomparability graph is at the right. By Fact 8, it is not a semiorder.



4. The skill of a tennis player may vary from day to day, leading to use of an interval $[a_x, b_x]$ to represent player x. In this case player x *always* beats player y if $a_x > b_y$.

5. The interval order $I[0,3]$ is not a semiorder.

11.2.4 APPLICATION TO SOCIAL CHOICE

When there are more than two candidates for a public office, it is not obvious what is the "best" way to select a winner. Any rule has its pluses and minuses, from the standpoint of public policy. Social choice theory analyzes the effect of various rules for deciding the outcomes of preferential rankings.

Definitions:

A ***profile*** on a set A of "alternatives" (e.g., candidates for a public office) is a set $P = \{P_i \mid i \in I\}$ of linear rankings (ties allowed) of A, one for each member of a set I of "individuals" (e.g., voters).

A ***consensus function*** (or ***social choice function***) is a function ϕ that assigns to each possible profile $P = \{P_i \mid i \in I\}$ on a set A of alternatives a linear order (ties allowed) of A called the ***consensus ranking*** for P.

A consensus function upholds ***majority rule*** provided it ensures that x is preferred to y if and only if a majority of the individuals prefer x to y.

Plurality is the consensus function in which the winner(s) is (are) the alternative(s) appearing in the greatest number of top ranks, after which the winner(s) is (are) deleted and the procedure is repeated to select the next rank of the consensus ranking, etc.

The ***Borda count*** of an alternative x is the sum, over individual rankings, of the number of alternatives x "beats". The resulting ***Borda consensus function*** ranks the alternatives by their Borda count.

Facts:

1. Plurality can elect someone ranked last by a majority.

2. *Condorcet's paradox*: Some profiles have no decisive consensus (i.e., producing a single winner) that upholds majority rule.

3. The Borda count is subject to abuse.

4. *Arrow's impossibility theorem*: No consensus function exists that satisfies the following four axioms, which were formulated in an attempt to develop a consensus function ϕ that avoids the difficulties cited in the facts above:

- *monotonicity*: If $a > b$ in $\phi(P)$ and if profile P' agrees with profile P except for moving alternative a upward in some or all rankings, then $a > b$ in $\phi(P')$.
- *independence of irrelevant alternatives*: If profiles P and P' agree within a set $A' \subseteq A$, then $\phi(P)$ and $\phi(P')$ have the same restriction to A'. This axiom implies that votes for extraneous alternatives do not affect the determination of the consensus ranking among the alternatives within the subset A'.
- *nondegeneracy*: Given $a, b \in A$, there is a profile P such that $a > b$ in $\phi(P)$. This axiom implies that the structure of the outcome is independent of renaming the alternatives.
- *nondictatorship*: There is no $i \in I$ such that $a > b$ in P_i implies $a > b$ in $\phi(P)$.

Examples:

1. Suppose that $A = \{a, b, c\}$ is the set of alternatives, and suppose that the profile consists of the three rankings $a > b > c$, $c > a > b$, and $b > c > a$. Then for each alternative, there is another alternative that is preferred by $\frac{2}{3}$ of the population.

2. The U.S. presidential election of 1912 had three candidates: Wilson (W), Roosevelt (R), and Taft (T). It is estimated that 45% of the voters ranked $W > R > T$, that 30% ranked $R > T > W$, and that 25% ranked $T > R > W$. Wilson won the election, garnering a plurality of the popular vote, but a majority of the population preferred Roosevelt to Wilson. Moreover, 55% regarded Wilson as the least desirable candidate.

3. Consider a close election, with four individuals preferring x to y to all other alternatives. A fifth individual prefers y to x. If there are enough other alternatives, the fifth individual can throw a Borda-count election to y by placing x at the bottom.

11.2.5 LINEAR EXTENSIONS AND DIMENSION

By adding additional comparison pairs to a partial ordering on a set, ultimately a total ordering is obtained. Each of the many ways to do this is called an extension of the original partial ordering.

Definitions:

An ***extension*** of a poset $P = (X, R)$ is a poset $Q = (X, S)$ such that $R \subseteq S$ (i.e., xRy implies xSy).

A ***linear extension*** of a poset P is an extension of P that is a chain.

A ***topological sort*** is an algorithm that accepts a finite poset as input and produces a linear extension of that poset as output.

A ***topological ordering*** of an acyclic digraph is a linear extension of the poset arising from it.

The ***intersection of two partial orderings*** $P = (X, R)$ and $Q = (X, S)$ on the same set X is the poset $(X, R \cap S)$ that includes the relations common to both.

A ***realizer*** of a poset P is a set of linear extensions of P whose intersection is P.

The ***order dimension*** (or ***dimension***) of P, written $\dim(P)$, is the minimum cardinality of a realizer of P.

The ***standard example*** S_n of an n-dimensional poset is the subposet of $\underline{2}^n$ induced by the singletons and their complements.

An ***alternating k-cycle*** in a poset P is a sequence of ordered incomparable pairs $\{(x_i, y_i)\}_{i=1}^{k}$ such that $y_i \leq x_{i+1}$, where subscripts are taken modulo k.

A ***critical pair*** (or ***unforced pair***) in a poset P is an ordered incomparable pair that cannot be made comparable by adding any other single incomparable pair as a relation.

A linear extension L of a poset P **puts** Y **over** X, where X and Y are disjoint subposets, if y is above x in L whenever (x, y) is an incomparable pair with $x \in X$, $y \in Y$.

Given a subposet $Q \subseteq P$, an ***upper extension*** of Q is a linear extension of P that puts $P - Q$ over Q.

Given a subposet $Q \subseteq P$, a ***lower extension*** of Q is a linear extension of P that puts $P - Q$ below Q.

The ***minimum realizer encoding*** of a poset lists for each element its position on each extension in a minimum realizer.

The ***probability space*** on the set of all linear extensions of a (finite) poset P is obtained by taking each linear extension to be equally likely. The notation $Pr(x < y)$ denotes the proportion of linear extensions in which element x comes below element y.

Facts:

1. Every poset is the intersection of all its linear extensions, from which it follows that the concept of dimension is well defined.

2. Given incomparable elements x and y in a poset P, there is a linear extension of P in which x appears above y.

3. The chains are the only posets of dimension 1.

4. Every antichain has dimension 2, because the intersection of a linear order and its dual is an antichain.

5. Topological sort is used to organize activities having a precedence ordering into a sequential schedule.

6. The list of minimal forbidden subposets for dimension 2 consists of ten isolated examples and seven one-parameter families.

7. If Q is a subposet of P, then $\dim(Q) \le \dim(P)$.

8. The dimension of a product of k chains (each of size at least 2) is k.

9. A poset has dimension at most k if and only if it imbeds in a product of k chains.

10. The dimension of a poset P equals the minimum integer n such that P is a subposet of $\mathcal{R}^n$.

11. The standard example S_n is a bipartite poset whose comparability graph is obtained from the complete bipartite graph $K_{n,n}$ by deleting a complete matching.

12. The minimum realizer encoding of an n-element poset of dimension k takes only $O(kn \log n)$ bits, instead of the $O(n^2)$ bits of the order relation. Thus, posets of small dimension have concise representations.

13. In the sense of Fact 12, the dimension of a poset may be regarded as a measure of its “space complexity”.

14. The dimension of a poset P equals the minimum number of linear extensions containing all the critical pairs of P.

15. The dimension of a poset P is equal to the chromatic number of the hypergraph whose vertex set is the set of critical pairs and whose edges are the sets of critical pairs forming minimal alternating cycles.

16. The cover graph of the standard example S_n (of an n-dimensional poset) is $K_{n,n}$-(1-factor).

17. If X and Y are disjoint subposets of a poset P, then P has a linear extension L putting Y over X if and only if P contains no $\underline{2} + \underline{2}$ with minimal elements in Y and maximal elements in X.

18. $\dim(P) \le w(P)$. A realizer of size $w(P)$ can be formed by taking upper extensions of the chains in a partition of P into $w(P)$ chains.

19. $\dim(P) \le \frac{|P|}{2}$. The standard example S_n shows that this bound is the best possible.

20. *One-point removal theorem*: For every $x \in P$, $\dim(P) \le 1 + \dim(P - x)$.

21. For every poset P, there exist four elements $\{x, y, z, w\}$ such that $\dim(P) \le 2 + \dim(P - \{x, y, z, w\})$. It is conjectured that, for every poset P, there exist two elements $\{x, y\}$ such that $\dim(P) \le 1 + \dim(P - \{x, y\})$.

22. A poset has dimension 2 if and only if the complement of its comparability graph is also a comparability graph; thus there is a polynomial-time algorithm to decide whether a poset has dimension 2. However, recognizing posets of dimension k is NP-complete for every fixed k at least 3.

23. If P is a finite poset that is not a chain, then P has a pair of elements x, y such that

$$0.2764 \simeq \frac{1}{2} - \frac{1}{2\sqrt{5}} \le Pr(x < y) \le \frac{1}{2} + \frac{1}{2\sqrt{5}} \simeq 0.7236.$$

24. *The $\frac{1}{3}$-$\frac{2}{3}$ conjecture*: This conjecture states that there is always a pair of elements, x and y, such that $\frac{1}{3} \le Pr(x < y) \le \frac{2}{3}$.

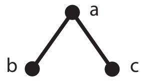
25. The traditional name *topological sort* is commonly used in applications. However, a topological sort is *not* a sort in the standard meaning of that word. Nor is it directly related to what mathematicians call *topology*.

26. Algorithm 1 carries out a topological sort on a given poset; also see §8.3.4.

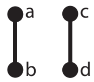
```
Algorithm 1: Topological sort.
  input: a finite poset $(X = \{x_1, \ldots, x_n\}, \leq)$
  output: a compatible total ordering $A = x_1 \leq x_2 \leq \cdots \leq x_n$ of the elements of $X$
  for $j := 1$ to $n$
      $x_j :=$ a minimal element of $X$
      $X := X - \{x_j\}$
```

Examples:

1. The following poset has the linear extensions *abc* and *acb* and it is the intersection of these extensions. Thus its dimension is 2.



2. The following poset has six linear extensions: *abcd*, *acbd*, *acdb*, *cdab*, *cadb*, and *cabd*. Since it is the intersection of *abcd* and *cdab*, its dimension is 2.



3. The bipartite poset S_3 whose comparability graph and cover graph is the 6-cycle $1, \overline{2}, 3, \overline{1}, 2, \overline{3}$ has dimension 3. The realizer $\{23\overline{1}1\overline{23}, 13\overline{2}2\overline{13}, 12\overline{3}3\overline{12}\}$ establishes the upper bound. Every realizer must have an extension with $\overline{1}$ below 1, one with $\overline{2}$ below 2, and one with $\overline{3}$ below 3. No two of these can occur in the same linear extension, so the dimension is at least 3.

4. More generally, for the elements $i \in [n]$ of the standard example S_n, a realizer must include distinct linear extensions in which the singleton $\{i\}$ appears above its complement, and any n such extensions suffice.

5. For the standard example S_n of dimension n, the critical pairs are $\{\overline{i}, i\}$; this reflects the fact that, in a realizer, the extensions need to put i above $\overline{i}$, for each i. Each pair of critical pairs forms a minimal alternating cycle. Viewing the minimal alternating cycles as edges creates a hypergraph, namely the complete graph K_n, with chromatic number n.

6. Let N be the bipartite poset with minimal elements a and b and maximal elements c and d, in which a lies below c, and b lies below c and d. This poset has five linear extensions, namely $a < b < c < d$, $a < b < d < c$, $b < a < c < d$, $b < a < d < c$, and $b < d < a < c$. Thus $Pr(a < b) = \frac{2}{5}$.

7. *Application of posets to sorting*: The objective of a sort is to arrange the elements of a set X into a sequence by posing sequential queries of the form: "is $x < y$ true?". At any time, the state of cumulative knowledge is representable by a poset $P = (X, R)$, such that the linear extensions of P are remaining candidates for the final sequence order. A desirable query substantially reduces the number of candidates for extensions no matter whether the answer is yes or no, most especially finding a pair, x and y, such that $Pr(x < y)$ is close to $\frac{1}{2}$. Thus, Fact 23 shows that the worst case time to sort, in the presence of partial information given by a poset P, is $\Omega(\log |P|)$.

8. *Application of posets to searching*: The objective of searching a poset P in which item $s(x)$ is stored at location x is to determine whether a target item α is present in P. Each step of the search probes a location and compares its value against the target item. The worst case requires determining for each $x \in P$ whether the item at location x is greater or less than α, so the searching problem is the problem of identifying the downset $D_\alpha = \{x \in P \mid s(x) < \alpha\}$. A probe of location x splits the remaining possible downsets into those that contain x and those that do not. The former remain as candidates if $s(x) < \alpha$; the latter remain if $s(x) > \alpha$. A hypothetical adversary would arrange the value $s(x)$ so that the response would leave the larger portion of the ideals. Thus, the number $c(P)$ of probes required in the worst case is at least $\lceil \log_2 i(P) \rceil$, where $i(P)$ denotes the number of ideals in poset P.

11.2.6 POSETS AND GRAPHS

From the graph-theoretic viewpoint, a comparability graph is by definition a simple graph (§8.1.1) that has a transitive orientation. Comparability graphs are perfect graphs, which motivates most study of comparability graphs.

Definitions:

A ***transitive orientation*** on a simple graph G is an assignment of directions to the edges so that whenever there is an xy-arc and a yz-arc, there is also an xz-arc.

A ***quasi-transitive orientation*** on a simple graph G is an assignment of directions to the edges so that whenever there is an xy-arc and a yz-arc, there is also an arc between x and z.

A ***triangular chord*** for a walk $x_1, \ldots, x_k$ in an undirected graph G is an edge between vertices x_{i-1} and x_{i+1}, two apart on the walk.

The ***auxiliary graph*** for a simple graph G is the graph G' whose vertices are the edges of G, with vertex e_1 adjacent to vertex e_2 in G' if and only if edges e_1 and e_2 are adjacent in graph G but do not lie on a 3-cycle.

A ***module*** in a graph G is a vertex subset U such that each vertex outside U is adjacent to all or none of the vertices in U.

An ***order module*** in a poset P (or ***autonomous set***) is a set S of elements such that every element outside S is above all of S, below all of S, or incomparable to all of S.

A ***comparability invariant*** for posets is an invariant f such that $f(P) = f(Q)$ whenever posets P and Q have the same comparability graph.

A ***permutation graph*** is a graph whose vertices can be placed in 1-1 correspondence with the elements of a permutation of $[n] = \{1, \ldots, n\}$ such that v_i is adjacent to v_j if and only if the larger of i and j comes first in the permutation.

A ***u,v-bypass*** in a directed graph is a u,v-path of length at least two such that there is also an arc from u to v.

A ***dependent edge*** in an acyclic directed graph is an arc from u to v such that the graph contains a u,v-bypass.

Facts:

1. For a simple graph G, the following are equivalent:

- G has a transitive orientation;
- G has a quasi-transitive orientation;
- every closed odd walk of G has a triangular chord;
- the auxiliary graph G' is bipartite.

The implications from top to bottom are straightforward, as is the proof that if the auxiliary graph G' is bipartite then G has a quasi-transitive orientation. The proof that if G has a quasi-transitive orientation then G has a transitive orientation takes more work. The last characterization gives an algorithm to decide whether G is a comparability graph in $O(n^3)$ time, where n is the number of vertices. The proof is constructive, so a transitive orientation can also be obtained.

2. In any graph, the set of all vertices, the singleton sets of vertices, and the empty set are always modules.

3. Modules yield a forbidden subgraph characterization of comparability graphs. The minimal forbidden induced subgraphs consist of eight infinite families and ten special examples.

4. If two partial orders have the same comparability graph, then one can be transformed into the other by a sequence of moves involving reversing all the relations inside an order module S, i.e., by replacing the partial order induced on S by its dual, and preserving all relations between S and its complement.

5. Let f be a poset invariant such that $f(P) = f(P^*)$ for all posets P, and such that, if poset Q is obtained from P by replacing a module in P with another module having the same value of f, then $f(Q) = f(P)$. Then the invariant f is a comparability invariant.

6. Height, width, dimension, and number of linear extensions are all comparability invariants.

7. A graph is the complement of a comparability graph if and only if it is the intersection graph of the curves representing a collection of continuous real-valued functions on $[0, 1]$.

8. The following conditions are equivalent for a graph G:

- G is a permutation graph (adjacency representing the inversions of a permutation);
- $\overline{G}$ is the comparability graph of a 2-dimensional partial order;
- G and $\overline{G}$ are comparability graphs.

9. Isomorphism of permutation graphs can be tested in $O(n^2)$ time. Some NP-complete scheduling problems become polynomial when the poset of precedence constraints is 2-dimensional.

10. A directed graph corresponds to the diagram of some partial order if and only if it contains no cycles or bypasses.

11. Every graph that is the cover graph of some poset is triangle-free.

12. If a graph has chromatic number less than its girth, then it is the cover graph of some poset. In particular, a 3-chromatic graph is a cover graph if and only if it is triangle-free.

13. It is NP-complete to decide whether a 4-chromatic graph is a covering graph.

14. The smallest triangle-free graph that is not a cover graph is the 4-chromatic Grötzsch graph with 11 vertices.

15. The maximum number of dependent edges among the orientations of a graph G is equal to the cycle rank $\beta(G) = |E| - |V| + 1$.

16. If a graph G has chromatic number less than its girth (§8.7.2), then for all i such that $0 \leq i \leq \beta(G)$, the graph has an acyclic orientation with exactly i dependent edges.

17. The cover graph of a modular lattice is bipartite.

18. A modular lattice is distributive if and only if its cover graph does not contain the complete bipartite graph $K_{2,3}$.

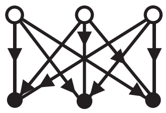
19. The subgraph of the cover graph of $\underline{2}^{2k+1}$ induced by the k-sets and $(k+1)$-sets is a vertex-transitive $(k+1)$-regular bipartite graph. The graph is known to contain cycles using more than 80% of its vertices. The *Erdős revolving door conjecture* asserts that this graph is Hamiltonian.

20. *Gallai-Milgram theorem*: The vertices of a digraph D can be covered using at most $\alpha(D)$ disjoint paths, where $\alpha(D)$ is the maximum size of an independent set in D.

21. Dilworth's theorem (§11.2.1) is the special case of the Gallai-Milgram theorem for comparability digraphs.

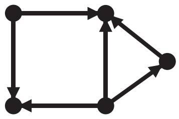
Examples:

1. A transitive orientation for a bipartite graph can be obtained by assigning all the edge directions from one part to the other, as shown here for $K_{3,3}$:

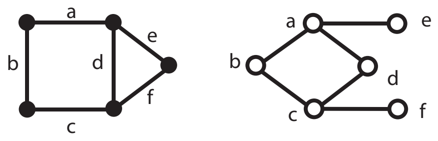


2. An odd cycle of length ≥ 5 has no quasi-transitive orientation (see Fact 1).

3. Inserting a triangular chord into a 5-cycle permits the resulting graph to have a transitive orientation, as shown in the following figure.



4. The following figure shows a graph and its auxiliary graph.



5. Any subset of either part of a complete bipartite graph is a module, since the other vertices in its part are not adjacent to any vertex in the module, and the vertices in the other part of the bipartition are each adjacent to all the vertices in the module.

6. Deleting a 1-factor from $K_{n,n}$, for $n \geq 3$, yields a graph with no module other than the complete set of vertices, the singletons, and the empty set.

COMBINATORIAL DESIGNS

INTRODUCTION

In broad terms, the study of combinatorial designs is the study of the structure of collections of subsets of a finite set when these collections of subsets satisfy certain prescribed properties. In particular, a block design has the property that every one of these subsets has the same size k and every *pair* of points in the set is in exactly the same number of these subsets. Latin squares are also fundamental in this area and can be thought of in this context, but they are commonly thought of as $n \times n$ arrays with the property that each cell contains one element from an n-set and each row and each column contain each element exactly once. Some of the questions of general interest include: existence of designs, enumeration of nonisomorphic designs, and the study of subdesigns of designs.

Matroids generalize a variety of combinatorial objects, such as matrices and graphs. These structures arise naturally in a variety of combinatorial contexts and provide a framework for the study of many problems in combinatorial optimization and graph theory.

Much of the information in §12.1–12.3 is condensed from [CoDi07], which provides a comprehensive treatment of combinatorial designs. The main source for the material in §12.4 is [Ox11].

GLOSSARY

affine plane: a set of points and a set of subsets of points (called lines) such that every two points lie on exactly one line, if a point does not lie on a line L there is exactly one line through the point that does not intersect L, and there are three points that are not collinear.

affine space (of dimension n): the set $\mathrm{AG}(n, q)$ of all cosets of subspaces of an n-dimensional vector space over a field of order q.

automorphism (a design D): an isomorphism from D onto D.

balanced incomplete block design (BIBD): given a finite set X (of *points*), a collection of subsets (called *blocks*) of X of the same size such that every point belongs to the same number of blocks, and each pair of points belongs to the same number of blocks. The BIBD is described by five parameters: size of X, number of blocks, number of blocks to which every element of X belongs, size of each block, and number of blocks to which each pair of distinct points belongs.

basis (for a matroid): a maximal independent set in the matroid.

basis axioms: a set of axioms that specifies the set of bases of a matroid.

binary matroid: a matroid that is isomorphic to a vector matroid of a matrix over the field $GF(2)$.

biplane: symmetric design in which every pair of distinct points belongs to exactly two blocks.

block: each of the subsets in a design.

circuit: a minimal dependent set in a matroid.

circuit axioms: a set of axioms that specifies the set of circuits of a matroid.

closed set: in a matroid, a subset of its ground set that is equal to its closure.

closed under duality: the property of a class of matroids that the dual of a matroid in the class is also in the class.

closure (of a subset of the ground set in a matroid): given a subset X of the ground set E in a matroid, the set of all points $x \in E$ such that the rank of $X \cup \{x\}$ is equal to the rank of X.

closure axioms: a set of axioms that specifies the properties that a closure operator of a matroid must satisfy.

closure operation: the mapping $K \to \mathbf{B}(K)$, where K is a set of positive integers and $\mathbf{B}(K)$ is the set of positive integers v for which there exists a (v, K)-PBD.

cobasis (of a matroid): a basis of the dual of a matroid.

cocircuit (of a matroid): a circuit of the dual of a matroid.

cographic matroid: a matroid isomorphic to the cocyle matroid of a graph.

coindependent set (of a matroid): an independent set of the dual of a matroid.

coloop (of a matroid): a loop of the dual of a matroid.

combinatorial geometry: a simple matroid.

complete set of mutually orthogonal Latin squares: a set of $n-1$ mutually orthogonal Latin squares of side n.

conjugate: Let L be an $n \times n$ Latin square on symbol set E_3, with rows indexed by the elements of the n-set E_1 and columns indexed by the elements of the n-set E_2. Let $\mathcal{T} = \{(x_1, x_2, x_3) \mid L(x_1, x_2) = x_3\}$. Let $\{a, b, c\} = \{1, 2, 3\}$. The (a, b, c)-conjugate of L, $L_{(a,b,c)}$, has rows indexed by E_a, columns by E_b, and symbols by E_c, and is defined by $L_{(a,b,c)}(x_a, x_b) = x_c$ for each $(x_1, x_2, x_3) \in \mathcal{T}$.

connected: the property of a matroid that it cannot be written as the direct sum of two nonempty matroids.

cycle matroid (of a graph): the matroid on the edge-set of the graph whose circuits are the cycles of the graph.

t-design: a t-(v, k, λ) design.

t-(v, k, λ) design: a pair $(X, \mathcal{A})$ where X is a set of v elements (points), $\mathcal{A}$ is a family of k-subsets (blocks) of X, and every t-subset of X occurs in exactly λ blocks.

development (of a difference set D): the incidence structure dev(D) whose points are the elements of G and whose blocks are the translates $D + g = \{d + g \mid d \in D\}$.

dual (of an incidence structure): the incidence structure obtained by interchanging the roles of points and lines.

dual (of a matroid): given a matroid M, the matroid on the same set as M whose bases are the complements of the bases of M.

equivalent (Latin squares): two Latin squares L and L' of side n are equivalent if there are three bijections, from the rows, columns, and symbols of L to the rows, columns, and symbols, respectively, of L', that map L to L'.

Fano plane (or **projective plane of order 2**): the $(7, 7, 3, 3, 1)$ design with point set $X = \{0, \ldots, 6\}$ and the block set $\mathcal{A} = \{013, 124, 235, 346, 450, 561, 602\}$.

flat: closed set.

t-flat: a subspace of projective dimension t of a projective space; a coset of a subspace of affine dimension t of an affine space.

k-GDD: a group divisible design with $\lambda = 1$ and $K = \{k\}$.

graphic matroid: a matroid that is isomorphic to the cycle matroid of some graph.

ground set: the set of points of a matroid.

group divisible design (or ***(K, λ)-GDD***): given an integer λ and a set of positive integers K, a triple $(X, \mathcal{G}, \mathcal{A})$ where X is a set (of *points*), $\mathcal{G}$ is a partition of X into at least two subsets (called *groups*), $\mathcal{A}$ is a family of subsets of X (called *blocks*) such that: if A in $\mathcal{A}$, then $|A| \in K$, a group and a block contain at most one common point, and every pair of points from distinct groups occurs in exactly λ blocks.

group-type (or ***type***): for a group divisible design, the multiset $\{|G| : G \in \mathcal{G}\}$.

Hadamard design: a symmetric $(4n-1, 2n-1, n-1)$ design.

Hadamard matrix: an $n \times n$ matrix H with all entries ± 1 that satisfies $H^{\mathrm{T}}H = nI$.

hyperplane: a subspace of projective dimension $n-1$ of a projective space of projective dimension n; a coset of a subspace of affine dimension $n-1$ of an affine space of affine dimension n; a maximal nonspanning set of a matroid.

idempotent: the property of a Latin square (or partial Latin square) that for all i, cell (i, i) is occupied by i.

imbedded Latin square: An $n \times n$ partial Latin square P is imbedded in a Latin square L if the upper $n \times n$ left corner of L agrees with P.

incidence matrix (of a (v, b, r, k, λ) design): the $b \times v$ matrix with (i, j)-entry equal to 1 if the ith block contains the jth element, and 0 otherwise.

incidence structure: the structure $(V, B, \mathcal{I})$ consisting of a finite set V of *points*, a finite set B of *lines*, and an incidence relation $\mathcal{I}$ between them.

independent set: any set in a special collection of subsets of the ground set in a matroid.

index: the number of blocks to which each pair of distinct points in a design belongs.

isomorphism (of block designs $(V, \mathcal{B})$ and $(W, \mathcal{C})$): a bijection $\psi\colon (V, \mathcal{B}) \to (W, \mathcal{C})$ under which $\psi(B)$ occurs as a block in $\mathcal{C}$ the same number of times that B occurs as a block in $\mathcal{B}$.

isomorphism (of matroids): a bijection between the ground sets of two matroids that preserves independence.

isotopic: equivalent.

Kirkman's schoolgirl problem: the problem of arranging fifteen schoolgirls in five subsets of size 3 for a walk on each of seven days so that every pair of girls walks together exactly once.

Kirkman triple system: a $(v, 3, 1)$ resolvable BIBD, together with a resolution of it.

Kronecker product: for $m \times p$ matrix $M = (m_{ij})$ and $n \times q$ matrix $N = (n_{ij})$, the $mn \times pq$ matrix given by

$$M \times N = \begin{pmatrix} m_{11}N & m_{12}N & \cdots & m_{1p}N \\ \vdots & \vdots & & \vdots \\ m_{m1}N & m_{m2}N & \cdots & m_{mp}N \end{pmatrix}.$$

Latin rectangle: a $k \times n$ ($k < n$) array in which each cell contains a single element from an n-set such that each element occurs exactly once in each row and at most once in each column.

Latin square: a Latin square of side n is an $n \times n$ array in which each entry contains a single element from a set S of size n such that each element occurs exactly once in each row and exactly once in each column.

line: a subspace of projective dimension 1 of a projective space; a coset of a subspace of affine dimension 1 of an affine space.

loop (in a matroid): an element e of the matroid such that $\{e\}$ is a circuit.

matroid: an ordered pair $M = (E(M), \mathcal{I}(M))$ where E (the ground set) is a finite set and $\mathcal{I}$ is a collection of subsets (independent sets) of E such that: the empty set is independent; every subset of an independent set is independent; and if X and Y are independent and $|X| < |Y|$, then there is an element e in $Y - X$ such that $X \cup \{e\}$ is independent.

matroid representable over a field: a matroid that is isomorphic to the vector matroid of some matrix over the field F.

multiplier (of a difference set D in a group G): an automorphism φ of G such that $\varphi(D) = D + g$ for some $g \in G$.

mutually orthogonal: the property of a set of Latin squares that every two are orthogonal.

orthogonal: property of two $n \times n$ Latin squares $A = (a_{ij})$ and $B = (b_{ij})$ that all n^2 ordered pairs (a_{ij}, b_{ij}) are distinct.

orthogonal array (of size N with k constraints, s levels, and strength t): a $k \times N$ array with entries from a set of $s \geq 2$ symbols, having the property that in every $t \times N$ submatrix every $t \times 1$ column vector appears the same number of times.

pairwise balanced design (***PBD***): for a set K of positive integers, a design (v, K, λ) consisting of an ordered pair $(X, \mathcal{A})$ where X is a set of size v and $\mathcal{A}$ is a collection of subsets of X with the property that every pair of elements of X occurs in exactly λ blocks, and for every block $A \in \mathcal{A}$, $|A| \in K$; a pairwise balanced design is called a (v, K)-PBD when $\lambda = 1$.

parallel class: a collection of blocks that partition the point set of a design.

parallel elements: in a matroid, two elements that form a circuit.

partial Latin square: an $n \times n$ array with cells, each of which is either empty or else contains exactly one symbol, such that no symbol occurs more than once in any row or column.

partial transversal (of length k): in a Latin square, a set of k cells, each from a different row and each from a different column, such that no two contain the same symbol.

paving matroid: a matroid such that the number of elements in every circuit is at least as large as the rank of the matroid.

PBD-closure: for a set K of positive integers, the set $\mathbf{B}(K) = \{v \mid \text{there exists a } (v, K)\text{-PBD}\}$.

planar: the property of a matroid that it is isomorphic to the cycle matroid of a planar graph.

plane: a subspace of projective dimension 2 of a projective space; a coset of a subspace of affine dimension 2 of an affine space.

projective plane: a finite set (of points) and a set of subsets of points (called lines) such that every two points lie on exactly one line, every two lines intersect in exactly one point, and there are four points with no three collinear; equivalently, a symmetric $(n^2+n+1, n+1, 1)$ design.

projective space (of dimension n): for a field F of order q and an $(n+1)$-dimensional vector space S over F, the set $\mathrm{PG}(n,q)$ of all subspaces of S.

rank (of a matroid): the rank of the ground set of the matroid.

rank (of a set in a matroid): the cardinality of every maximal independent subset of the set.

rank axioms: a set of axioms that specifies the properties that a rank function on a matroid must satisfy.

reduced Latin square: a Latin square such that the elements in the first row and the elements in the first column occur in natural order.

regular matroid: a matroid that is representable over all fields.

replication number: the number of blocks to which each point in a design belongs.

representable over a field: the property of a matroid that it is isomorphic to a vector matroid of some matrix over the field.

resolution: a partition of the family of blocks of a balanced incomplete block design into parallel classes.

resolvable: the property of a balanced incomplete block design that it has at least one resolution.

simple matroid: a matroid that has no loops or parallel elements.

simple (t-design): a t-design that contains no repeated blocks.

spanning set (of a matroid): for matroid M, a subset of the ground set E of rank $r(M)$.

Steiner triple system: a balanced incomplete block design in which each block has three elements and each pair of points occurs in exactly one block; that is, a $(v, 3, 1)$ design.

subdesign: a collection of points and blocks in a block design that is itself a block design.

subsquare: for $k < n$, a Latin square of side k whose rows and columns are chosen from a Latin square of side n.

symmetric block design: a (v, b, r, k, λ) design where the number of points v equals the number of blocks b.

ternary matroid: a matroid isomorphic to a vector matroid of a matrix over $GF(3)$.

transversal: in a Latin square of side n, a set of n cells, one from each row and column, containing each of the n symbols exactly once.

transversal design: a k-GDD having k groups of size n and uniform block size k.

transversal matroid: given a family of sets, the matroid whose independent sets are partial transversals of this family.

type: See *group-type*.

uniform matroid: the matroid with $1, 2, \ldots, n$ as ground set, and all subsets of size less than a specified number as independent sets.

$\boldsymbol{(v, k, \lambda)}$ ***design***: a BIBD with parameters (v, b, r, k, λ).

$\boldsymbol{(v, k, \lambda; n)}$ ***difference set*** (of order $n = k - \lambda$): a k-subset D of a group G (of order v) where every nonzero element of G has exactly λ differences $d - d'$ with elements from D.

vector matroid: the matroid on the columns of a matrix whose independent sets are the linearly independent sets of columns.

void design: a BIBD with at most one element.

12.1 BLOCK DESIGNS

12.1.1 BALANCED INCOMPLETE BLOCK DESIGNS

Definitions:

A ***balanced incomplete block design*** (***BIBD***) with parameters (v, b, r, k, λ) is a pair $(X, \mathcal{A})$, where X is a set, $\mathcal{A}$ is a collection of subsets of X, the five parameters are nonnegative integers, either $v \in \{0, 1\}$ (the *void* designs) or $v > k > 0$, and the parameters represent the following:

- v (***order***): the size of X (elements of X are ***points***, ***varieties***, or ***treatments***);
- b (***block number***): the number of elements of $\mathcal{A}$ (elements of $\mathcal{A}$ are ***blocks***);
- r (***replication number***): the number of blocks to which every point belongs;
- k (***block size***): the common size of each block;
- λ (***index***): the number of blocks to which every pair of distinct points belongs.

Note: A BIBD is often referred to as a *design*. Different notations are used for balanced incomplete block designs: (v, b, r, k, λ) BIBD, (v, k, λ) BIBD and $S_\lambda(2, k, v)$. In this chapter (v, k, λ) design will be used. See Fact 6.

A ***Steiner triple system*** is a $(v, \frac{v(v-1)}{6}, \frac{v-1}{2}, 3, 1)$ design, i.e., a BIBD in which each block has size 3 and each pair of points occurs in exactly one block. A Steiner triple system is denoted STS(v) or $S(2, 3, v)$. (Jakob Steiner, 1796–1863)

The ***incidence matrix*** of a (v, b, r, k, λ) design is the $b \times v$ matrix $A = (a_{ij})$ defined by

$$a_{ij} = \begin{cases} 1 & \text{if the } i\text{th block contains the } j\text{th point} \\ 0 & \text{otherwise.} \end{cases}$$

Facts:

1. Balanced incomplete block designs are used in the design of experiments when the total number (v) of objects to be tested is greater than the number (k) that can be tested at any one time. They are used to design experiments where the subjects must be divided into subsets (blocks) of the same size to receive different treatments, such that each subject is tested the same number of times and every pair of subjects appears in the same number of subsets.

2. Designs are useful in many areas, such as coding theory, cryptography, group testing, and tournament scheduling. Detailed coverage of these and other applications of designs can be found in Chapter V of [CoDi07].

3. The word "balanced" refers to the fact that λ remains constant. If λ changes depending on the pair of points chosen, the design is not balanced.

4. The word "incomplete" refers to the fact that $k < v$, that is, the size of each block is less than the number of varieties.

5. *Necessary conditions for existence*: If there is a (v, b, r, k, λ) design for particular v, b, r, k, and λ, then the parameters must satisfy

- $vr = bk$;
- $\lambda(v-1) = r(k-1)$;
- $b \geq v$. (Fisher's inequality, 1940) (Ronald A. Fisher, 1890–1962)

6. If a (v, b, r, k, λ) design exists, $r = \frac{\lambda(v-1)}{k-1}$ and $b = \frac{\lambda v(v-1)}{k(k-1)}$. In view of these two relationships, (v, b, r, k, λ) designs are commonly referred to simply by the three parameters — v, k, λ — as a (v, k, λ) design.

7. *Necessary conditions for existence*: If there is a (v, k, λ) design for particular v, k, and λ, then

- $\lambda(v-1) \equiv 0 \pmod{k-1}$;
- $\lambda v(v-1) \equiv 0 \pmod{k(k-1)}$.

8. *Existence of* (v, k, λ) *designs*:

- $(v, 3, \lambda)$ design: exists for all v satisfying the necessary conditions given in Fact 5, namely
  - ◇ if $\lambda \equiv 2$ or $4 \pmod 6$ and $v \equiv 0$ or $1 \pmod 3$
  - ◇ if $\lambda \equiv 1$ or $5 \pmod 6$ and $v \equiv 1$ or $3 \pmod 6$
  - ◇ if $\lambda \equiv 3 \pmod 6$ and $v \equiv 1 \pmod 2$
  - ◇ if $\lambda \equiv 0 \pmod 6$ and $v \neq 2$;
- $(v, 4, \lambda)$ design: exists for all v and λ satisfying the necessary conditions given in Fact 5;
- $(v, 5, \lambda)$ design: exists for all v satisfying the necessary conditions given in Fact 5 except for the case $v = 15, \lambda = 2$;
- $(v, 6, \lambda)$ design: exists for all v satisfying the necessary conditions given in Fact 5, if $\lambda > 1$;
- $(v, 6, 1)$ design: exists for all $v \equiv 1$ or $6 \pmod{15}$, $v \geq 31$, $v \notin \{36, 46\}$, with 29 possible exceptions, the largest being 801. (The first few open cases are 51, 61, 81, and 166.)

9. *Existence of Steiner triple systems*: A Steiner triple system with v points exists if and only if $v \equiv 1$ or $3 \pmod 6$. (Kirkman)

10. *Wilson's asymptotic existence theorem*: Given k and λ, there exists a $v_0(k, \lambda)$ such that a (v, k, λ) design exists for all $v \geq v_0(k, \lambda)$ that satisfy the necessary conditions given in Fact 5 and make b and r integral. It is known that $v_0(k, \lambda) < \exp(\exp(k^{k^2}))$.

11. Assume that $(V, \mathcal{B})$ is a (v, k, λ) design. Let $\overline{\mathcal{B}} = \{V - B \mid B \in \mathcal{B}\}$. Then $(V, \overline{\mathcal{B}})$ is a $\left(v, v-k, \lambda\frac{(v-k)(v-k-1)}{k(k-1)}\right)$ design, the *complement* of $(V, \mathcal{B})$.

12. Given two Steiner triple systems with v_1 and v_2 points, respectively, a Steiner triple system with v_1v_2 points can be constructed as follows: Let an STS(v_1) be defined on the point set $\{x_1, \dots, x_{v_1}\}$ and an STS(v_2) be defined on the point set $\{y_1, \dots, y_{v_2}\}$. Define an STS(v_1v_2) on the point set $\{z_{ij} \mid 1 \le i \le v_1, 1 \le j \le v_2\}$ where $z_{mn}z_{pq}z_{rs}$ is a block in STS(v_1v_2) if and only if one of the following holds:

- $m = p = r$ and $y_ny_qy_s$ is a block in STS(v_2);
- $n = q = s$ and $x_mx_px_r$ is a block in STS(v_1);
- $x_mx_px_r$ is a block in STS(v_1) and $y_ny_qy_s$ is a block in STS(v_2).

13. The following table lists different types of block designs and their features.

name	*block size*	*size of subset covered*	*# times covered*	*other properties*
balanced incomplete block design BIBD §12.1.1	k	2	λ	
pairwise balanced design PBD §12.1.6	various	2	λ	also called a linear space if $\lambda = 1$
Steiner triple system STS §12.1.1, §12.1.5	3	2	1	
Kirkman triple system KTS §12.1.4	3	2	1	resolvable
resolvable balanced incomplete block design RBIBD §12.1.4	k	2	λ	resolvable
projective plane PG$(2,q)$ §12.2.3	$q+1$	2	1	#points = #blocks $= q^2+q+1$
affine plane AG$(2,q)$ §12.2.3	q	2	1	resolvable
symmetric design SBIBD §12.2.2	k	2	λ	#points = #blocks
t-design t-(v,k,λ) §12.1.5	k	$t \ge 2$	λ	
Steiner system $S(t,v,k)$ §12.1.5	k	$t \ge 2$	1	

Examples:

1. The following is a $(4,4,3,3,2)$ design: $X = \{a,b,c,d\}$, blocks $\{abc, abd, acd, bcd\}$.

2. *Affine plane of order* 3 [a $(9,3,1)$ *design*]: Here the point set is $X = \{0,\dots,8\}$ and the block set is $\mathcal{A} = \{012, 345, 678, 036, 147, 258, 048, 156, 237, 057, 138, 246\}$. Also see §12.2.3. This design is known as $AG(2,3)$. This is a Steiner triple system.

3. Each of the following is a Steiner triple system (a $(v,3,1)$ design). In each of the following a set of *base blocks* $B_i = \{b_{i1}, b_{i2}, b_{i3}\}$ in the group $\mathcal{Z}_v$ is given. To get all the blocks of the design, take all distinct translates $B_i + g = \{b_{i1}+g, b_{i2}+g, b_{i3}+g\}$, for all $g \in \mathcal{Z}_v$, for each of the base blocks B_i.

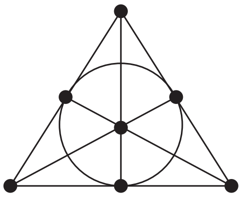
$v = 7$: $\{0,1,3\}$ (mod 7) [Fano plane]

$v = 15$: $\{0,1,4\}$ $\{0,2,8\}$ $\{0,5,10\}$ (mod 15) [The last base block has only 5 $(=\frac{v}{3})$ distinct translates. This is a *short orbit* and occurs for all orders $v \equiv 3 \pmod 6$.]

$v = 19$: $\{0,1,4\}$ $\{0,2,9\}$ $\{0,5,11\}$ (mod 19)

$v = 21$: $\{0,1,3\}$ $\{0,4,12\}$ $\{0,5,11\}$ $\{0,7,14\}$ (mod 21)
$v = 25$: $\{0,1,3\}$ $\{0,4,11\}$ $\{0,5,13\}$ $\{0,6,15\}$ (mod 25)
$v = 27$: $\{0,1,3\}$ $\{0,4,11\}$ $\{0,5,15\}$ $\{0,6,14\}$ $\{0,9,18\}$ (mod 27)
$v = 31$: $\{0,1,3\}$ $\{0,4,11\}$ $\{0,5,15\}$ $\{0,6,18\}$ $\{0,8,17\}$ (mod 31)
$v = 33$: $\{0,1,3\}$ $\{0,4,10\}$ $\{0,5,18\}$ $\{0,7,19\}$ $\{0,8,17\}$ $\{0,11,22\}$ (mod 33)
$v = 37$: $\{0,1,3\}$ $\{0,4,9\}$ $\{0,6,21\}$ $\{0,7,18\}$ $\{0,8,25\}$ $\{0,10,24\}$ (mod 37)
$v = 39$: $\{0,1,3\}$ $\{0,4,9\}$ $\{0,6,20\}$ $\{0,7,18\}$ $\{0,8,23\}$ $\{0,10,22\}$ $\{0,13,26\}$ (mod 39).

4. *Fano plane* or *projective plane of order* 2, PG(2,2): A $(7,7,3,3,1)$ design with point set $X = \{0,\ldots,6\}$ and block set $\mathcal{A} = \{013, 124, 235, 346, 450, 561, 602\}$, shown in the following figure. (Often, as here, a block $\{a,b,c\}$ is written as abc.) Also see §12.2.3. (Gino Fano, 1871–1952)



The incidence matrix of the Fano plane is

$$\begin{pmatrix} 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 \end{pmatrix}$$

12.1.2 ISOMORPHISM AND AUTOMORPHISM

Definitions:

Two designs $(V, \mathcal{B})$ and $(W, \mathcal{C})$ are ***isomorphic*** if there is a bijection $\psi\colon V \to W$ under which $\psi(B) = \{\psi(x) \mid x \in B\}$ occurs as a block in $\mathcal{C}$ the same number of times that B occurs as a block in $\mathcal{B}$. Such a bijection is an ***isomorphism***.

An ***automorphism*** of a design D is an isomorphism from D onto D.

The ***automorphism group*** of a design D is the set of all automorphisms for D with composition as the group operation.

Facts:

1. Nonisomorphic Steiner triple systems of order v have been enumerated for $v \leq 19$. Up to isomorphism, there are unique designs of order 3, 7, and 9; there are precisely two nonisomorphic designs of order 13, and 80 of order 15. At that point, an explosion occurs: the number of nonisomorphic STS(19) is 11,084,874,829.

2. The number of nonisomorphic STS(v) is at least $(e^{-5}v)^{v^2/6}$ for large v. (Wilson)

3. The following table lists the parameter sets (v, k, λ) that satisfy the necessary conditions for the existence of a block design, with $r \leq 15$ and $3 \leq k \leq \frac{v}{2}$. The parameter sets are ordered lexicographically across the rows of the table by r, k and λ (in this order). The column N contains the number of pairwise nonisomorphic (v, k, λ) designs or the best known lower bound for this number. The notation "?" indicates that no design with these parameters is known to exist, but that existence has not been ruled out.

v	k	λ	N	v	k	λ	N	v	k	λ	N

12.1.3 SUBDESIGNS

Definition:

Let Y be a subset of w points in a (v,k,λ) design. If every block of the BIBD contains 0, 1, or k of the points in Y, then a (w,k,λ) design is obtained by taking those blocks that contain k points from Y. This BIBD on w points is a ***subdesign***, called a (w,k,λ) subdesign.

Facts:

1. If there is a $(v,k,1)$ design containing a $(w,k,1)$ subdesign, then $v \geq (k-1)w+1$. (The parameter lists $(v,k,1)$ and $(w,k,1)$ must satisfy the necessary conditions of §12.1.1, Fact 6.)

2. In the cases $k=3$ and $k=4$, the necessary conditions of §12.1.1, Fact 5 for the presence of a subdesign are sufficient. That is, in the case of $k=3$, for all $v \geq 2w+1$, with both $v,w \equiv 1$ or 3 mod 6), there exists a $(v,3,1)$ design that contains a $(w,3,1)$ subdesign. In the case $k=4$, for all $v \geq 3w+1$, with both $v,w \equiv 1$ or 4 (mod 12) there exists a $(v,4,1)$ design that contains a $(w,4,1)$ subdesign.

Example:

1. *A construction for a Steiner triple system of order* $2v+1$ *given a Steiner triple system of order* v: A variant of this construction dates back at least to Thomas P. Kirkman in 1847. The original STS(v) is a subdesign of the resulting STS($2v+1$).

Let $(X,\mathcal{A})$ be an STS(v) with $X=\{x_0,x_1,\ldots,x_{v-1}\}$. For each $i=0,1,\ldots,v-1$, let $F_i=\{\{x+i,-x+i\} \mid x \in \mathcal{Z}_v, x \neq 0\} \cup \{i,\infty\}$. Then for each $i=0,,\ldots,v-1$, construct the triples $\{a,b,x_i\}$ where $\{a,b\} \in F_i$. The set of all such triples in addition to the original triples in $\mathcal{A}$ is the desired STS($2v+1$) on the point set $X \cup \{0,1,\ldots,v,\infty\}$.

For $v=7$, the following STS(15) is obtained. The last row of triples is an STS(7).

$\{0,\infty,x_0\}$ $\{1,6,x_0\}$ $\{2,5,x_0\}$ $\{3,4,x_0\}$
$\{1,\infty,x_1\}$ $\{2,0,x_1\}$ $\{3,6,x_1\}$ $\{4,5,x_1\}$
$\{2,\infty,x_2\}$ $\{3,1,x_2\}$ $\{4,0,x_2\}$ $\{5,6,x_2\}$
$\{3,\infty,x_3\}$ $\{4,2,x_3\}$ $\{5,1,x_3\}$ $\{6,0,x_3\}$
$\{4,\infty,x_4\}$ $\{5,3,x_4\}$ $\{6,2,x_4\}$ $\{0,1,x_4\}$
$\{5,\infty,x_5\}$ $\{6,4,x_5\}$ $\{0,3,x_5\}$ $\{1,2,x_5\}$
$\{6,\infty,x_6\}$ $\{0,5,x_6\}$ $\{1,4,x_6\}$ $\{2,3,x_6\}$
$\{x_0,x_1,x_3\}$ $\{x_1,x_2,x_4\}$ $\{x_2,x_3,x_5\}$ $\{x_3,x_4,x_6\}$ $\{x_4,x_5,x_0\}$ $\{x_5,x_6,x_1\}$ $\{x_6,x_0,x_2\}$.

12.1.4 RESOLVABLE DESIGNS

Definitions:

A ***parallel class*** is a collection of blocks that partition the point set.

A ***resolution*** of a BIBD is a partition of the family of blocks into parallel classes. A resolution contains exactly r parallel classes.

A BIBD is ***resolvable***, denoted RBIBD, if it has at least one resolution.

A $(v, 3, 1)$ RBIBD, together with a resolution of it, is a ***Kirkman triple system***, written KTS(v).

Facts:

1. Necessary conditions for existence of a (v, k, λ) RBIBD are

- $\lambda(v-1) \equiv 0 \pmod{k-1}$;
- $v \equiv 0 \pmod{k}$.

2. If a (v, k, λ) RBIBD exists, then $b \geq v + r - 1$ where b is the number of blocks. When $b = v + r - 1$ (or equivalently, $r = k + \lambda$) the RBIBD has the property that two nonparallel lines intersect in exactly $\frac{k^2}{v}$ points. (R. C. Bose, 1901–1987)

3. A KTS(v) exists if and only if $v \equiv 3 \pmod 6$.

4. The following table summarizes the current state of knowledge concerning the existence of resolvable designs.

For the values of k and λ given, the number of parameter sets (v, k, λ) satisfying all necessary conditions for the existence of a resolvable (v, k, λ) design for which the existence of a resolvable (v, k, λ) design is not known is given under the column headed "*exceptions*". The column headed "*largest possible exception*" gives the largest v satisfying the necessary conditions for the existence of a resolvable (v, k, λ) design for which a resolvable (v, k, λ) design is not known.

k	λ	*exceptions*	*largest possible exception*
3	1	none	
3	2	6	
4	1	none	
4	3	none	
5	1		645
5	2	15	395
5	4	10,15	195
6	5	none	
6	10	none	
7	6	14	462
8	1		24,480
8	7		1,488

Example:

1. *Kirkman's schoolgirl problem*: In 1850, Kirkman posed the following: fifteen young ladies in a school walk out three abreast for seven days in succession; it is required to arrange them daily, so that no two walk twice abreast. (Thomas P. Kirkman, 1806–1895)

This is equivalent to finding a resolution of some $(15, 3, 1)$ design (or a KTS(15)). Seven nonisomorphic solutions exist; the following is one solution to Kirkman's schoolgirl problem:

Monday	*Tuesday*	*Wednesday*	*Thursday*	*Friday*	*Saturday*	*Sunday*
9,10,12	10,11,13	11,12,14	12,13,15	13,14,9	14,15,10	15,9,11
15,8,1	9,8,2	10,8,3	11,8,4	12,8,5	13,8,6	14,8,7
13,2,7	14,3,1	15,4,2	9,5,3	10,6,4	11,7,5	12,1,6
11,3,6	12,4,7	13,5,1	14,6,2	15,7,3	9,1,4	10,2,5
14,4,5	15,5,6	9,6,7	10,7,1	11,1,2	12,2,3	13,3,4

12.1.5 t-DESIGNS AND STEINER SYSTEMS

Definitions:

A ***t*-(*v*, *k*, λ) *design*** (also denoted $S_\lambda(t,k,v)$ and written ***t-design***) is a pair $(X, \mathcal{A})$ that satisfies the following properties:

- X is a set of v elements (called *points*);
- $\mathcal{A}$ is a family of subsets (*blocks*) of X, each of cardinality k;
- every t-subset of distinct points occurs in exactly λ blocks.

A t-design is ***simple*** if it contains no repeated blocks.

A ***Steiner system*** is a t-$(v,k,1)$ design.

A ***Steiner triple system***, denoted STS(v), is a $(v,3,1)$ design. (See §12.1.1.)

A ***Steiner quadruple system***, denoted SQS(v), is a 3-$(v,4,1)$ design.

Facts:

1. A (v,k,λ) design (a BIBD) is a 2-(v,k,λ) design.

2. If $s < t$, then a t-(v,k,λ) design is also an s-(v,k,μ) design, where $\mu = \lambda \frac{\binom{v-s}{t-s}}{\binom{k-s}{t-s}}$.

3. As a consequence of Fact 2, a t-(v,k,λ) design only exists if $\lambda\binom{v-s}{t-s} \equiv 0 \pmod{\binom{k-s}{t-s}}$ for every $0 \le s \le t$; these are the *divisibility conditions*.

4. t-(v,k,λ) designs exist for all t. A t-$(v, t+1, ((t+1)!)^{2t+1})$ design exists if $v \ge t+1$ and $v \equiv t \pmod{[(t+1)!]^{2t+1}}$. (Teirlinck)

5. If a t-(v,k,λ) design exists, where $t = 2s$ is even, then the number of blocks $b \ge \binom{v}{s}$. (This generalizes Fisher's inequality, §12.1.1, Fact 5.)

6. When $\lambda = 1$, until 2014 t-designs were known only for $t \le 5$, and the construction of a 6-$(v,k,1)$ design was one of the outstanding open problems in the theory of combinatorial designs. In 2014, Keevash established that for every t and k, t-$(v,k,1)$ designs exist when v satifies the divisibility conditions (from Fact 3) and v is sufficiently large.

7. Much less is known about the existence of t-(v,k,λ) designs with $t \ge 3$ compared to BIBDs:

- For $t = 3$, several infinite families are known.
- For every prime power q and $d \ge 2$, there exists a 3-$(q^d+1, q+1, 1)$ design, known as an *inversive geometry*. When $d = 2$, these designs are known as *inversive planes*.
- A 3-$(v,4,1)$ design (*Steiner quadruple system*) exists if and only if $v \equiv 2$ or $4 \pmod 6$.

Examples:

1. The following is a 3-$(8,4,1)$ design:

$$\begin{aligned}
&X = \{\infty, 0, 1, 2, 3, 4, 5, 6\}\\
&\mathcal{A} = \{\{0,1,3,\infty\},\ \{1,2,4,\infty\},\ \{2,3,5,\infty\},\ \{3,4,6,\infty\},\ \{4,5,0,\infty\},\\
&\qquad \{5,6,1,\infty\},\ \{6,0,2,\infty\},\ \{2,4,5,6\},\ \{3,5,6,0\},\ \{4,6,0,1\},\\
&\qquad \{5,0,1,2\},\ \{6,1,2,3\},\ \{0,2,3,4\},\ \{1,3,4,5\}\}
\end{aligned}$$

2. *Simple t-designs (t = 4, 5)*: For $t = 4$ or 5 and $v \leq 30$, the only t-$(v, k, 1)$ designs known to exist are those having the following parameters:

4-(11, 5, 1) 5-(12, 6, 1) 4-(23, 7, 1)
5-(24, 8, 1) 4-(27, 6, 1) 5-(28, 7, 1).

3. *Simple t-designs (t = 6)*: For $t = 6$ and $v \leq 20$, the only t-(v, k, λ) designs known to exist are those having the following parameters:

6-(14, 7, 4) 6-(19, 7, 4) 6-(19, 7, 6) 6-(20, 9, 112) 6-(22, 7, 8)
6-(20,10,7m), $m \in \{48, 58, 62, 63, 67, 68\}$.

12.1.6 PAIRWISE BALANCED DESIGNS

Definitions:

Given a set K of positive integers and a positive integer λ, a ***pairwise balanced design***, written (v, K, λ)-PBD, is an ordered pair $(X, \mathcal{A})$ where X is a set (of *points*) of size v and $\mathcal{A}$ is a collection of subsets (*blocks*) of X such that

- every pair of elements of X occurs together in exactly λ blocks;
- for every block $A \in \mathcal{A}$, $|A| \in K$.

When $\lambda = 1$, λ can be omitted from the notation and the design is called a (v, K)-PBD or a ***finite linear space***.

Given a set K of positive integers, let $\mathbf{B}(K)$ denote the set of positive integers v for which there exists a (v, K)-PBD. The mapping $K \to \mathbf{B}(K)$ is a ***closure operation*** on the set of subsets of the positive integers, as it satisfies the following properties:

- $K \subseteq \mathbf{B}(K)$;
- $K_1 \subseteq K_2 \Rightarrow \mathbf{B}(K_1) \subseteq \mathbf{B}(K_2)$;
- $\mathbf{B}(\mathbf{B}(K)) = \mathbf{B}(K)$.

The set $\mathbf{B}(K)$ is the ***closure*** of the set K.

If K is any set of positive integers, then K is ***PBD-closed*** (or ***closed***) if $\mathbf{B}(K) = K$.

If K is a closed set, then there exists a finite subset $J \subseteq K$ such that $K = \mathbf{B}(J)$. This set J is a ***generating set*** for the PBD-closed set K.

If J is a generating set for K and if $s \in J$ is such that $J - \{s\}$ is also a generating set for K, then s is ***inessential*** in K; otherwise s is ***essential***.

A ***basis*** is a generating set consisting of essential elements.

Facts:

1. A (v, k, λ) design is a special case of a PBD in which the blocks are only permitted to be of one size, k.

2. *Necessary conditions for existence*: The existence of a (v, K)-PBD (with $v > 0$) implies

- $v \equiv 1 \pmod{\alpha(K)}$
- $v(v-1) \equiv 0 \pmod{\beta(K)}$

where $\alpha(K)$ is the greatest common divisor of the integers $\{k - 1 \mid k \in K\}$ and $\beta(K)$ is the greatest common divisor of the integers $\{k(k-1) \mid k \in K\}$.

3. *Asymptotic existence*: Given K, there exists a constant c_k such that a (v, K)-PBD exists for all $v \geq c_k$ that satisfy the necessary conditions of Fact 2. The constant c_k is, in general, unspecified. In practice, considerable further work is usually required to obtain a concrete upper bound on c_k.

Examples:

1. The following is a $(10, \{3, 4\})$-PBD:

$$\{1,2,3,4\}, \{1,5,6,7\}, \{1,8,9,10\}, \{2,5,8\}, \{2,6,9\}, \{2,7,10\}$$
$$\{3,5,10\}, \{3,6,8\}, \{3,7,9\}, \{4,5,9\}, \{4,6,10\}, \{4,7,8\}$$

2. The following table lists closures of some subsets of $\{3, 4, \ldots, 8\}$. From Fact 3, for a given set K there are only a finite number of values of v (satisfying the necessary conditions) for which there does not exist a (v, K)-PBD. These exceptional cases are listed in this table for some small sets K. Since $7 \in B(3)$, it is not necessary to include 7 in the list of sets whose closures are given, when 3 is present. Genuine exceptions (values of v satisfying the necessary conditions for the existence of a (v, K)-PBD for which it has been *proven* that no such design can exist) are shown in boldface, while possible exceptions (neither existence or nonexistence of a (v, K)-PBD is known) are shown in normal type.

12.1.7 GROUP DIVISIBLE DESIGNS AND TRANSVERSAL DESIGNS

Definitions:

A ***group divisible design*** (or (K, λ)-GDD) is a triple $(X, \mathcal{G}, \mathcal{A})$ where X is a set (of *points*), $\mathcal{G}$ is a partition of X into at least two subsets (called *groups*), $\mathcal{A}$ is a family of subsets of X (called *blocks*) such that

- if A in $\mathcal{A}$, then $|A| \in K$;
- a group and a block contain at most one common point;
- every pair of points from distinct groups occurs in exactly λ blocks.

If $\lambda = 1$, a (K, λ)-GDD is often denoted by K-GDD. If $K = \{k\}$, a K-GDD is written k-GDD.

The ***group-type*** (or ***type***) of a GDD is the multiset $\{|G| \mid G \in \mathcal{G}\}$. Usually an "exponential notation" is used to describe the type of a GDD: a GDD of type $t_1^{u_1} t_2^{u_2} \ldots t_k^{u_k}$ is a GDD where there are u_i groups of size t_i for $1 \le i \le k$.

A ***transversal design*** TD(k, n) is a k-GDD of type n^k (that is, one having k groups of size n and uniform block size k).

Fact:

1. The existence of a TD(k, n) is equivalent to the existence of $k-2$ mutually orthogonal Latin squares of side n. (§12.3.2.)

12.2 SYMMETRIC DESIGNS AND FINITE GEOMETRIES

12.2.1 FINITE GEOMETRIES

Definitions:

A finite ***incidence structure*** $(V, \mathcal{B}, \mathcal{I})$ consists of a finite set V of *points*, a finite set $\mathcal{B}$ of *lines*, and an *incidence relation* $\mathcal{I}$ between them. (Equivalently, a finite incidence structure is a pair $(V, \mathcal{B})$, where $\mathcal{B} = \{\, \{v \mid (v, b) \in \mathcal{I}\} \mid b \in \mathcal{B}\,\}$. In this case, lines are sets of points.)

The ***dual*** incidence structure is obtained by interchanging the roles of points and lines.

Let F be a finite field, and let S be an $(n{+}1)$-dimensional vector space over F. The set of all subspaces of S is the ***projective space of projective dimension n*** over F. When F is the Galois field $GF(q)$ (see §5.6.3), the projective space of projective dimension n is denoted PG(n, q).

Subspaces of projective dimensions 0, 1, 2, and n are ***points***, ***lines***, ***planes***, and ***hyperplanes***, respectively; in general, subspaces of projective dimension t are ***t-flats***. PG$_t(n, q)$ denotes the incidence structure of points and t-flats in PG(n, q) (incidence is just containment as subspaces). Often, PG$_1(n, q)$ is denoted PG(n, q) (taking the structure of points and lines as the natural geometry of the underlying space).

Let S be an n-dimensional vector space over a finite field F. The set of all cosets of subspaces of S is the ***affine space of affine dimension n*** over F. When F is the Galois field $GF(q)$, the affine space of affine dimension n is denoted AG(n, q).

Cosets of subspaces of (affine) dimension 0, 1, 2, and $n{-}1$ of an affine space of affine dimension n are ***points***, ***lines***, ***planes***, and ***hyperplanes***, respectively. In general, cosets of subspaces of affine dimension t are ***t-flats***. AG$_t(n, q)$ denotes the incidence structure of points and t-flats in AG(n, q) (incidence is containment). Often, AG$_1(n, q)$ is denoted AG(n, q) (taking the structure of points and lines as the natural geometry of the underlying space).

Note: The term *finite geometry* often just means finite incidence structure. However, incidence structures are often too unstructured to be of much (geometric) interest. Hence the term is sometimes reserved to cover only incidence structures satisfying additional axioms such as those given in §12.2.3, Fact 3 for projective planes.

Facts:

1. *Projective geometries*: For q a prime power and $1 \le t < n$, $\mathrm{PG}_t(n,q)$ is a $\left(\frac{q^{n+1}-1}{q-1}, \frac{q^{t+1}-1}{q-1}, \frac{(q^{n-1}-1)(q^{n-2}-1)\ldots(q^{n-t-1}-1)}{(q^{t-1}-1)(q^{t-2}-1)\ldots(q-1)}\right)$ design.

2. *Affine geometries*: For q a prime power and $1 \le t < n$, $\mathrm{AG}_t(n,q)$ is a $\left(q^n, q^t, \frac{(q^{n-1}-1)(q^{n-2}-1)\ldots(q^{n-t-1}-1)}{(q^{t-1}-1)(q^{t-2}-1)\ldots(q-1)}\right)$ design.

12.2.2 SYMMETRIC DESIGNS

Definitions:

A (v, b, r, k, λ) block design is ***symmetric*** if the number of points equals the number of blocks, that is, $v = b$.

A symmetric design with $\lambda = 2$ is a ***biplane***. The parameters of a biplane are $v = \binom{k}{2}+1$, $k = k$, $\lambda = 2$.

Facts:

1. In a symmetric (v, k, λ) design, $r = k$.

2. If a symmetric (v, k, λ) design exists, then

- if v is even, then $k - \lambda$ is a perfect square;
- if v is odd, then the Diophantine equation $x^2 = (k-\lambda)y^2 + (-1)^{(v-1)/2}\lambda z^2$ has a solution in integers, not all of which are zero. (Bruck-Ryser-Chowla; the theorem is often referred to as BRC.)

3. For every positive integer k there is a symmetric $(2^{k+2}-1, 2^{k+1}-1, 2^k-1)$ block design.

4. If p is prime and k is a positive integer, there is a symmetric $(p^{2k}+p^k+1, p^k+1, 1)$ block design.

5. In a symmetric design any two blocks intersect in exactly λ points.

6. The *dual* incidence structure obtained by interchanging the roles of points and blocks is also a BIBD with the same parameters (hence the term symmetric).

7. The dual of a symmetric design need not be isomorphic to the original design.

8. Given a symmetric (v, k, λ) design, and a block A of this design, if the points not in A are deleted from all blocks which intersect A, the design obtained is the *derived design*. Its parameters are $(k, v-1, k-1, \lambda, \lambda-1)$.

9. Given a symmetric (v, k, λ) design, and given a block A of this design, delete the block A, and delete all points in A from all other blocks. The resulting design is the *residual design*, and has parameters $(v-k, v-1, k, k-\lambda, \lambda)$. (See Example 1.)

10. Any $(v-k, v-1, k, k-\lambda, \lambda)$ design is a *quasi-residual design*.

11. Any quasi-residual BIBD with $\lambda = 1$ or 2 is residual (Hall-Connor); but for $\lambda = 3$, there are examples of quasi-residual BIBDs that are not residual.

12. If there is a symmetric (v, k, λ) design with $n = k - \lambda$, then $4n - 1 \le v \le n^2 + n + 1$. When $v = 4n - 1$ it is a *Hadamard design*; when $v = n^2 + n + 1$ it is a *projective plane*.

13. The only known biplanes have parameters $(7, 4, 2)$, $(11, 5, 2)$, $(16, 6, 2)$, $(37, 9, 2)$, $(56, 11, 2)$, and $(79, 13, 2)$.

14. The only known symmetric designs with $\lambda = 3$ have parameters $(11, 6, 3)$, $(15, 7, 3)$, $(25, 9, 3)$, $(31, 10, 3)$, $(45, 12, 3)$, and $(71, 15, 3)$.

15. Although infinitely many symmetric designs with $\lambda = 1$ are known, there is no other value of λ for which this is known to be true.

Example:

1. In the symmetric $(15, 7, 3)$ design in the following table, if the block b_0 is removed and if all the points in b_0 are removed from the blocks $b_1, \dots, b_{14}$, the resulting design is the residual design. It has parameters $(8, 4, 3)$ and its blocks are given on the right.

b_0 :	0	1	2	3	4	5	6
b_1 :	0	1	2	7	8	9	10
b_2 :	0	1	2	11	12	13	14
b_3 :	0	3	4	7	8	11	12
b_4 :	0	3	4	9	10	13	14
b_5 :	0	5	6	7	8	13	14
b_6 :	0	5	6	9	10	11	12
b_7 :	1	3	5	7	9	11	13
b_8 :	1	3	6	7	10	12	14
b_9 :	1	4	5	8	10	11	14
b_{10} :	1	4	6	8	9	12	13
b_{11} :	2	3	5	8	10	12	13
b_{12} :	2	3	6	8	9	11	14
b_{13} :	2	4	5	7	9	12	14
b_{14} :	2	4	6	7	10	11	13

12.2.3 PROJECTIVE AND AFFINE PLANES

Definitions:

A ***projective plane*** is a finite set of *points* and a set of subsets of points (called *lines*) such that

- every two points lie on exactly one line;
- every two lines intersect in exactly one point;
- there are four points with no three collinear.

An ***affine plane*** is a set of *points* and a set of subsets of points (called *lines*) such that

- every two points lie on exactly one line;
- if a point does not lie on a line L, there is exactly one line through the point that does not intersect L;
- there are three points that are not collinear.

Facts:

1. A finite projective plane is a symmetric $(n^2+n+1, n+1, 1)$ design, for some positive integer n, called the *order* of the projective plane. The projective plane has n^2+n+1 points and n^2+n+1 lines. Each point lies on $n+1$ lines and every line contains exactly $n+1$ points.

2. *Principle of duality*: Given any statement about finite projective planes that is a theorem, the dual statement (obtained by interchanging "point" and "line" and interchanging "point lying on a line" with "line passing through a point") is a theorem.

3. Any symmetric design with $\lambda = 1$ is a projective plane.

4. The existence of a projective plane of order n is equivalent to the existence of a set of $n-1$ mutually orthogonal Latin squares (MOLS) of side n.

5. Existence of projective planes: Very little is known about the existence of projective planes:

- There exists a projective plane of order p^k whenever p is prime and k is a positive integer. (See Fact 10.)
- There is no projective plane known for any order n that is not a power of a prime. The smallest open order is 12.
- There is no projective plane of order 10 or any $n \equiv 6 \pmod 8$.
- There exist projective planes for every order q^2 and q^3 when q is a prime power that cannot be constructed by the method of Fact 9; such planes are called nondesarguesian.
- There are four nonisomorphic projective planes of order 9, three of which are nondesarguesian.
- The following table summarizes the known facts about the existence and number of projective planes of order n, for $1 \le n \le 12$:

order	2	3	4	5	6	7	8	9	10	11	12
number of projective planes	1	1	1	1	0	1	1	4	0	≥ 1	?

6. The proof by Lam, Thiel, and Swiercz in 1989 that there is no projective plane of order 10 involved great amounts of computer power and time. For details, see [CoDi07].

7. The existence of a projective plane of order n is equivalent to the existence of an affine plane of order n.

8. A finite affine plane is a $(n^2, n, 1)$ design, for some positive integer n. The affine plane has n^2 points and $n^2 + n$ lines. Each point lies on $n + 1$ lines and every line contains exactly n points. The integer n is the *order* of the affine plane.

9. Any affine plane of order n has the property that the lines can be partitioned into $n + 1$ parallel classes each containing n lines and hence is a resolvable block design.

10. *A direct construction of a projective plane of every order $q = p^k$, when p is prime and k is a positive integer*: Consider the three-dimensional vector space $\mathcal{F}_q^3$ over GF(q). This vector space contains $\frac{q^3-1}{q-1} = q^2 + q + 1$ 1-dimensional subspaces (lines through the origin $(0, 0, 0)$) and an equal number of 2-dimensional subspaces (planes through the origin). Now construct an incidence structure where the points are the 1-dimensional subspaces, the lines are the 2-dimensional subspaces, and a point is on a line if the 1-dimensional subspace (associated with the point) is contained in the 2-dimensional subspace (associated with the line). This structure satisfies the axioms and thus is a projective plane (of order q). Projective planes such as this, coming from finite fields via the construction in this example, are *desarguesian planes*.

11. *A construction of a projective plane of order n from an affine plane of order n*: To construct the projective plane of order n from the affine plane of order n, use the fact that the lines of the affine plane can be partitioned into $n+1$ parallel classes each containing n lines. To each line in the ith parallel class adjoin the new symbol ∞_i. Add one new line, namely $\{\infty_1, \infty_2, \ldots, \infty_{n+1}\}$. Now each line contains $n+1$ points, there are n^2+n+1 total points, and each pair of points is on a unique line—this is the projective plane of order n.

12. *A construction of an affine plane of order n from a projective plane of order n:* The affine plane of order n is the residual design of the projective plane of order n. See §12.2.2, Fact 9 for the construction.

Examples:

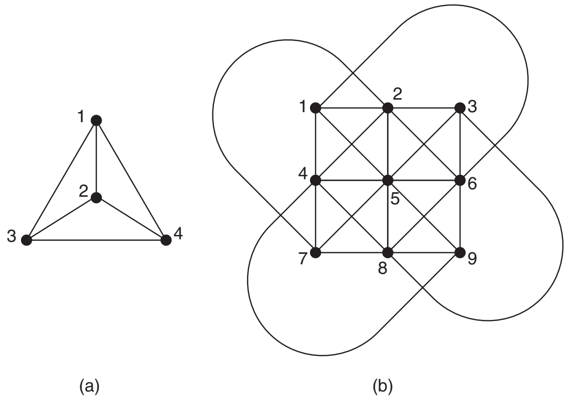
1. The Fano plane (§12.1.1, Example 3) is the projective plane of order 2.

2. The affine plane of order 2 is given in part (a) of the following figure. The set of points is $\{1,2,3,4\}$. The six lines are

$$\{1,2\} \qquad \{3,4\} \qquad \{1,3\} \qquad \{2,4\} \qquad \{1,4\} \qquad \{2,3\}.$$

The three parallel classes are

$$\{\{1,2\},\{3,4\}\} \qquad \{\{1,3\},\{2,4\}\} \qquad \{\{1,4\},\{2,3\}\}.$$



3. The affine plane of order 3 is given in part (b) of the figure of Example 2. The set of points is $\{1,2,3,\ldots,9\}$. The twelve lines (listed in order in four parallel classes of three lines each) are

$$\begin{array}{ll} \{1,2,3\},\{4,5,6\},\{7,8,9\} & \{1,4,7\},\{2,5,8\},\{3,6,9\} \\ \{1,5,9\},\{6,2,7\},\{4,8,3\} & \{3,5,7\},\{2,4,9\},\{8,6,1\}. \end{array}$$

4. Using the construction in Fact 11 on the affine plane of order 3 (Example 3) yields the projective plane of order 3 with thirteen points $\{1,2,3,4,5,6,7,8,9,\infty_1,\infty_2,\infty_3,\infty_4\}$ and thirteen lines:

$$\begin{array}{ccc} \{1,2,3,\infty_1\} & \{4,5,6,\infty_1\} & \{7,8,9,\infty_1\} \\ \{1,4,7,\infty_2\} & \{2,5,8,\infty_2\} & \{3,6,9,\infty_2\} \\ \{1,5,9,\infty_3\} & \{6,2,7,\infty_3\} & \{4,8,3,\infty_3\} \\ \{3,5,7,\infty_4\} & \{2,4,9,\infty_4\} & \{8,6,1,\infty_4\} \end{array}$$
$$\{\infty_1,,\infty_2,\infty_3,\infty_4\}.$$

12.2.4 HADAMARD DESIGNS AND MATRICES

Definitions:

A ***Hadamard matrix*** H of order n is a square $n \times n$ matrix all of whose entries are ± 1 that satisfies the property that $H^{\mathrm{T}}H = nI$ where I is the $n \times n$ identity matrix and H^{T} is the transpose of H.

If $M = (m_{ij})$ is an $m \times p$ matrix and $N = (n_{ij})$ is an $n \times q$ matrix, the ***Kronecker product*** is the $mn \times pq$ matrix $M \times N$ given by

$$M \times N = \begin{pmatrix} m_{11}N & m_{12}N & \cdots & m_{1p}N \\ m_{21}N & m_{22}N & \cdots & m_{2p}N \\ \vdots & \vdots & & \vdots \\ m_{m1}N & m_{m2}N & \cdots & m_{mp}N \end{pmatrix}.$$

A ***Hadamard design*** of order $4n$ is a symmetric $(4n-1, 2n-1, n-1)$ design. The ***dimension*** of the Hadamard design is n.

Facts:

1. A necessary condition for the existence of a Hadamard matrix of order n is that $n = 1$, $n = 2$, or $n \equiv 0 \pmod 4$.

2. $HH^{\mathrm{T}} = nI = H^{\mathrm{T}}H$.

3. The rows [columns] of a Hadamard matrix are pairwise orthogonal (when considered as vectors of length n).

4. If a row of a Hadamard matrix is multiplied by -1, the result is a Hadamard matrix. Similarly, if a column of a Hadamard matrix is multiplied by -1, the result is a Hadamard matrix.

5. By multiplying rows and columns of a Hadamard matrix by -1, a Hadamard matrix can be obtained where the first row and column consist entirely of $+1$s. A Hadamard matrix of this type is *normalized*.

6. In a normalized Hadamard matrix of order $4n$, every row and column (except the first) contains $+1$ and -1 exactly $2n$ times each.

7. Of all $n \times n$ matrices with entries from $\{-1, +1\}$, a Hadamard matrix H has the maximal determinant. $|\det H| = n^{n/2}$.

8. The Kronecker product of two Hadamard matrices is a Hadamard matrix. Thus, if there are Hadamard matrices of order m and n, then there is a Hadamard matrix of order mn.

9. If there exist Hadamard matrices of orders $4m$, $4n$, $4p$, $4q$, then there exists a Hadamard matrix of order $16mnpq$. (Craigen, Seberry, and Zhang)

10. Let q be a positive integer. Then there exists a Hadamard matrix of order $2^s q$ for every $s \geq \lfloor 2\log_2(q-3) \rfloor$. (Seberry)

11. A Hadamard design of order $4n$ exists if and only if a Hadamard matrix of order $4n$ exists. See the construction in Fact 15.

12. *Hadamard's conjecture*: The fundamental question concerning Hadamard matrices remains the *existence question.* The *Hadamard conjecture* is that there exist Hadamard matrices of order $4n$ for all $n \geq 1$. This remains unproved.

13. Currently the smallest order for which the existence of a Hadamard matrix is open is 668. Because of Fact 8 and the existence of a Hadamard matrix of order 2, if q is an odd number and there exists a Hadamard matrix of order 2^sq, then there exists a Hadamard matrix of order 2^tq for all $t \geq s$.

The following table gives values of t such that a Hadamard matrix of order 2^tn is known, for odd $n < 999$ (n is obtained by adding the three indices of the entry). The notation "." indicates $t = 2$.

14. *A general construction for Hadamard matrices of order $q+1$ when q is an odd prime power and $q \equiv 3 \pmod 4$*:

- construct a $q \times q$ matrix $C = (c_{ij})$ indexed by the elements of the field GF(q) by letting

$$c_{ij} = \begin{cases} 1, & \text{if } i-j \text{ is a square in GF}(q) \\ -1, & \text{if } i-j \text{ is not a square in GF}(q); \end{cases}$$

- construct a Hadamard matrix H of order $q+1$ from C by adding a first column of all -1s and then a top row of all 1s.

This method is used in Example 1 to construct the Hadamard matrix of order 12.

15. *Constructing Hadamard designs from Hadamard matrices, and vice versa*: Assume that there exists a Hadamard matrix of order $4n$. Let H be a normalized Hadamard matrix of this order. Remove the first row and column of H and replace every -1 in the resulting matrix by a 0. The final $(4n-1) \times (4n-1)$ matrix can be shown to be the incidence matrix of a $(4n-1, 2n-1, n-1)$ Hadamard design.

This process can be reversed to construct a Hadamard matrix from a Hadamard design.

Example:

1. The smallest examples of Hadamard matrices are the following:

$$\begin{pmatrix} 1 \end{pmatrix}, \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

$$\begin{pmatrix} -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{pmatrix},$$

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ -1 & 1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 \\ -1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 \\ -1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 \\ -1 & -1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 \\ -1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 & -1 \\ -1 & -1 & -1 & -1 & 1 & -1 & 1 & -1 & 1 & 1 & 1 & 1 \\ -1 & 1 & -1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 \\ -1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 & 1 \\ -1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 & 1 & 1 & 1 \\ -1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 & 1 & 1 \\ -1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 & 1 \end{pmatrix}.$$

12.2.5 DIFFERENCE SETS

Note: In this section, only difference sets in abelian groups are considered.

Definitions:

Let G be an additively written group of order v. A k-subset D of G is a $\boldsymbol{(v, k, \lambda; n)}$ ***difference set of order*** $\boldsymbol{n = k - \lambda}$ if every nonzero element of G has exactly λ representations as a difference $d - d'$ $(d, d' \in D)$. The difference set is ***abelian***, ***cyclic***, etc., if the group G has the respective property.

The ***development*** of a difference set D is the incidence structure $\text{dev}(D)$ whose points are the elements of the group G and whose blocks are the *translates* $D + g = \{d + g \mid d \in D\}$, $g \in G$.

A ***multiplier*** of a difference set D in a group G is an automorphism φ of G such that $\varphi(D) = D + g$ for some $g \in G$. If φ is a multiplier and $\varphi(h) = th$ for all $h \in G$, then t is a ***numerical*** multiplier.

Facts:

1. Both the group G itself and $G - \{g\}$ (for an arbitrary $g \in G$) are $(v, v, v; 0)$ and $(v, v - 1, v - 2; 1)$ difference sets. In the table of Example 2, these *trivial* difference sets are excluded.

2. The complement of a $(v, k, \lambda; n)$ difference set is again a difference set with parameters $(v, v - k, v - 2k + \lambda; n)$. Therefore only $k \leq \frac{v}{2}$ (the case $k = \frac{v}{2}$ is actually impossible) is considered.

3. The existence of a $(v, k, \lambda; n)$ difference set is equivalent to the existence of a symmetric (v, k, λ) design $\mathcal{D}$ admitting G as a point regular automorphism group; that is, for any two points p and q, there is a unique group element g which maps p to q. The design $\mathcal{D}$ is isomorphic with dev(D).

4. There are many symmetric designs which do not have difference set representations.

5. Since difference sets can yield symmetric designs, the parameters v, k, and λ must satisfy the trivial necessary conditions for the existence of a symmetric design ($\lambda(v-1) = k(k-1)$) and must also satisfy the Bruck-Ryser-Chowla condition (§12.2.2, part 2 of Fact 2).

6. If φ is a multiplier of the difference set D, then there is at least one translate $D+g$ of D which is fixed by φ.

7. *The multiplier theorem*: Let D be an abelian $(v, k, \lambda; n)$ difference set. If p is a prime that satisfies $(p, v) = 1$, $p|n$, and $p > \lambda$, then p is a numerical multiplier.

8. *The multiplier conjecture*: Every prime divisor p of n that is relatively prime to v is a multiplier of a $(v, k, \lambda; n)$ difference set; that is, the condition $p > \lambda$ in Fact 7 is unnecessary.

Examples:

1. A $(11, 5, 2; 3)$ difference set in the group $\mathcal{Z}_{11}$ is $\{1, 3, 4, 5, 9\}$.

2. The following table lists abelian difference sets of order $n \leq 15$. (See Fact 1.) One difference set for each abelian group is listed. In general, there will be many more examples. There are no other groups or parameters with $n \leq 15$ for which the existence of a difference set is undecided.

In the column "group" the decomposition of the group as a product of cyclic subgroups is given. If the group is cyclic, the integers modulo the group order are used to describe the difference set.

n	v	k	λ	*group*	*difference set*
2	7	3	1	(7)	1 2 4

12.3 LATIN SQUARES AND ORTHOGONAL ARRAYS

12.3.1 LATIN SQUARES

Definitions:

A ***Latin square*** of *side* n is an $n \times n$ array in which each entry contains a single element from an n-set S, such that each element of S occurs exactly once in each row and exactly once in each column.

A Latin square of side n (on the set $\{1, 2, \ldots, n\}$ or on the set $\{0, 1, \ldots, n-1\}$) is ***reduced*** or in ***standard form*** if in the first row and column the elements occur in increasing order.

Let L be an $n \times n$ Latin square on symbol set E_3, with rows indexed by the elements of the n-set E_1 and columns indexed by the elements of the n-set E_2. Let $\mathcal{T} = \{(x_1, x_2, x_3) \mid L(x_1, x_2) = x_3\}$ and $\{a, b, c\} = \{1, 2, 3\}$. The (a, b, c)-***conjugate*** of L, $L_{(a,b,c)}$, has rows indexed by E_a, columns by E_b, and symbols by E_c, and is defined by $L_{(a,b,c)}(x_a, x_b) = x_c$ for each $(x_1, x_2, x_3) \in \mathcal{T}$.

The ***transpose*** of a Latin square L, denoted L^{T}, is the Latin square which results from L when the roles of rows and columns are exchanged; that is, $L^{\mathrm{T}}(i, j) = L(j, i)$.

A Latin square L of side n is ***symmetric*** if $L(i, j) = L(j, i)$ for all $1 \le i \le n$, $1 \le j \le n$.

A Latin square L of side n is ***idempotent*** if $L(i, i) = i$ for all $1 \le i \le n$.

A ***transversal*** in a Latin square of side n is a set of n cells, one from each row and column, containing each of the n symbols exactly once.

A ***partial transversal of length k*** in a Latin square of side n is a set of k cells, each from a different row and each from a different column, such that no two contain the same symbol.

Two Latin squares L and L' of side n are ***equivalent*** (or ***isotopic***) if there are three bijections, from the rows, columns, and symbols of L to the rows, columns, and symbols, respectively, of L', that map L to L'.

Two Latin squares L and L' of side n are ***main class isotopic*** if L is isotopic to some conjugate of L'.

Let $k < n$. If in a Latin square L of side n the k^2 cells defined by k rows and k columns form a Latin square of side k, then the cells are a Latin ***subsquare*** of L.

An $n \times n$ array L with cells that are either empty or contain exactly one symbol is a ***partial*** Latin square if no symbol occurs more than once in any row or column.

A partial Latin square is ***symmetric*** (or ***commutative***) if whenever cell (i, j) is occupied by x, cell (j, i) is also occupied by x, for every $1 \le i \le n$, $1 \le j \le n$.

A partial Latin square is ***idempotent*** if cell (i, i) is occupied by i, for all i.

A ***Latin rectangle*** is a $k \times n$ $(k < n)$ array in which each cell contains a single element from an n-set such that each element occurs exactly once in each row and at most once in each column.

An $n \times n$ partial Latin square P is said to be ***imbedded*** in a Latin square L if the upper $n \times n$ left corner of L agrees with P.

Facts:

1. The multiplication table of any (multiplicative) group is a Latin square.

2. For each positive integer k a reduced Latin square can be constructed using the following format:

$$\begin{array}{cccccc}
1 & 2 & 3 & \cdots & k{-}1 & k \\
2 & 3 & 4 & \cdots & k & 1 \\
3 & 4 & 5 & \cdots & 1 & 2 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
k{-}1 & k & 1 & \cdots & k{-}3 & k{-}2 \\
k & 1 & 2 & \cdots & k{-}2 & k{-}1
\end{array}$$

3. Every Latin square has 1, 2, 3, or 6 distinct conjugates.

4. A symmetric Latin square of even side can never be idempotent.

5. A symmetric idempotent Latin square of side n is equivalent to a 1-factorization of the complete graph K_{n+1} on $n + 1$ points. A Latin square of side n is equivalent to a 1-factorization of the complete graph $K_{n,n}$.

6. Every idempotent Latin square has a transversal (the main diagonal).

7. Some Latin squares have no transversals. One such class of Latin squares is composed of the addition tables of the integers modulo $2n$ for every $n \ge 1$, or in general the addition table of any group that has a unique element of order 2.

8. Every Latin square of side n has a partial transversal of length k where

$$k \ge \max\{n - \sqrt{n}, n - 15(\log n)^2\}. \quad \text{(P. W. Shor)}$$

9. A Latin square of side n with a proper subsquare of side k exists if and only if $k \le \lfloor \frac{n}{2} \rfloor$.

10. There exists a Latin square of side n with *no* proper subsquares if $n \neq 2^a3^b$ or if $n = 3$, 9, 12, 16, 18, 27, 81, 243.

11. A partial Latin square of side n with at most $n-1$ filled cells can always be completed to a Latin square of side n.

12. A $k \times n$ $(k < n)$ Latin rectangle can always be completed to a Latin square of side n.

13. Let L be a partial Latin square of order n in which cell (i, j) is filled if and only if $i \leq r$ and $j \leq s$. Then L can be completed to a Latin square of order n if and only if $N(i) \geq r + s - n$ for $i = 1, 2, \ldots, n$, where $N(i)$ denotes the number of elements in L that are equal to i. (H. Ryser)

14. A partial $n \times n$ Latin square can be imbedded in a $t \times t$ Latin square for every $t \geq 2n$.

15. An $n \times n$ partial symmetric Latin square can be imbedded in a $t \times t$ symmetric Latin square for every even $t \geq 2n$.

16. The number of distinct Latin squares, the number of main classes, and the number of equivalence classes of Latin squares of side n go to infinity as $n \to \infty$. For $1 \leq n \leq 3$, there is one main class and one equivalence class. The number of main classes and equivalence classes of Latin squares of side $4 \leq n \leq 10$ are given in the following table:

n	4	5	6	7	8	9	10
main	2	2	12	147	283,657	19,270,853,541	34,817,397,894,749,939
equiv.	2	2	22	563	1,676,257	115,618,721,533	208,904,371,354,363,006

Examples:

1. A 4×4 Latin square on $\{1, 2, 3, 4\}$, where $1, 2, 3, 4$ represent four brands of tires, gives a way to test each brand of tire on each of the four wheel positions on each of four cars: the i, j-entry of the Latin square is the brand of tire to be tested on wheel position i of car j.

2. A Latin square of side 8 on the symbols $0, 1, \ldots, 7$:

$$\begin{array}{cccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 \\
1 & 0 & 3 & 4 & 5 & 6 & 7 & 2 \\
2 & 3 & 5 & 0 & 6 & 7 & 4 & 1 \\
3 & 4 & 0 & 7 & 1 & 2 & 5 & 6 \\
4 & 5 & 6 & 1 & 7 & 0 & 2 & 3 \\
5 & 6 & 7 & 2 & 0 & 3 & 1 & 4 \\
6 & 7 & 4 & 5 & 2 & 1 & 3 & 0 \\
7 & 2 & 1 & 6 & 3 & 4 & 0 & 5
\end{array}$$

3. A Latin square of side 4 and its six conjugates:

$$\begin{array}{ccc}
\begin{array}{cccc} 1 & 4 & 2 & 3 \\ 2 & 3 & 1 & 4 \\ 4 & 1 & 3 & 2 \\ 3 & 2 & 4 & 1 \end{array} &
\begin{array}{cccc} 1 & 2 & 4 & 3 \\ 4 & 3 & 1 & 2 \\ 2 & 1 & 3 & 4 \\ 3 & 4 & 2 & 1 \end{array} &
\begin{array}{cccc} 1 & 3 & 2 & 4 \\ 2 & 4 & 1 & 3 \\ 4 & 2 & 3 & 1 \\ 3 & 1 & 4 & 2 \end{array} \\
\text{(1,2,3)-conjugate} & \text{(2,1,3)-conjugate} & \text{(3,2,1)-conjugate}
\end{array}$$

$$\begin{array}{c}\begin{array}{cccc}1&2&4&3\\3&4&2&1\\2&1&3&4\\4&3&1&2\end{array}\\\text{(2,3,1)-conjugate}\end{array}\qquad\begin{array}{c}\begin{array}{cccc}1&3&4&2\\3&1&2&4\\2&4&3&1\\4&2&1&3\end{array}\\\text{(1,3,2)-conjugate}\end{array}\qquad\begin{array}{c}\begin{array}{cccc}1&3&2&4\\3&1&4&2\\4&2&3&1\\2&4&1&3\end{array}\\\text{(3,1,2)-conjugate}\end{array}$$

4. The following gives the main classes of Latin squares of sides 4, 5, and 6. No two Latin squares listed are main class isotopic.

$$n=4:\ \begin{array}{cccc}0&1&2&3\\1&0&3&2\\2&3&0&1\\3&2&1&0\end{array}\quad\begin{array}{cccc}0&1&2&3\\1&0&3&2\\2&3&1&0\\3&2&0&1\end{array}\qquad n=5:\ \begin{array}{ccccc}0&1&2&3&4\\1&2&3&4&0\\2&3&4&0&1\\3&4&0&1&2\\4&0&1&2&3\end{array}\quad\begin{array}{ccccc}0&1&2&3&4\\1&0&3&4&2\\2&3&4&0&1\\3&4&1&2&0\\4&2&0&1&3\end{array}$$

$$n=6:\ \begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&3&4&5&0&1\\3&2&5&4&1&0\\4&5&0&1&2&3\\5&4&1&0&3&2\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&3&4&5&0&1\\3&2&5&4&1&0\\4&5&0&1&3&2\\5&4&1&0&2&3\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&4&5&2\\2&3&0&5&1&4\\3&4&5&0&2&1\\4&5&1&2&0&3\\5&2&4&1&3&0\end{array}$$

$$\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&4&5&2\\2&3&0&5&1&4\\3&4&5&0&2&1\\4&5&1&2&3&0\\5&2&4&1&0&3\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&4&5&2\\2&3&1&5&0&4\\3&4&5&1&2&0\\4&5&0&2&3&1\\5&2&4&0&1&3\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&4&5&2\\2&3&4&5&0&1\\3&4&5&2&1&0\\4&5&0&1&2&3\\5&2&1&0&3&4\end{array}$$

$$\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&4&0&5&1&3\\3&5&1&4&0&2\\4&2&5&0&3&1\\5&3&4&1&2&0\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&4&0&5&1&3\\3&5&1&4&0&2\\4&2&5&1&3&0\\5&3&4&0&2&1\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&4&0&5&1&3\\3&5&1&4&2&0\\4&3&5&1&0&2\\5&2&4&0&3&1\end{array}$$

$$\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&2&5&4\\2&4&0&5&3&1\\3&5&4&0&1&2\\4&2&5&1&0&3\\5&3&1&4&2&0\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&0&3&4&5&2\\2&3&1&5&0&4\\3&5&4&1&2&0\\4&2&5&0&1&3\\5&4&0&2&3&1\end{array}\quad\begin{array}{cccccc}0&1&2&3&4&5\\1&2&0&4&5&3\\2&0&1&5&3&4\\3&5&4&1&0&2\\4&3&5&2&1&0\\5&4&3&0&2&1\end{array}$$

5. The following are a Latin square of side 7 with a subsquare of side 3 (3×3 square in upper left corner) and a Latin square of order 12 with no proper subsquares.

$$\begin{array}{ccccccc}
1 & 2 & 3 & 4 & 5 & 6 & 7 \\
2 & 3 & 1 & 6 & 4 & 7 & 5 \\
3 & 1 & 2 & 7 & 6 & 5 & 4 \\
4 & 7 & 5 & 1 & 3 & 2 & 6 \\
7 & 5 & 6 & 3 & 2 & 4 & 1 \\
6 & 4 & 7 & 5 & 1 & 3 & 2 \\
5 & 6 & 4 & 2 & 7 & 1 & 3
\end{array}
\qquad
\begin{array}{cccccccccccc}
1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & a & b & c \\
2 & 3 & 4 & 5 & 6 & 1 & 8 & 9 & a & b & c & 7 \\
3 & 1 & 5 & 2 & 7 & 8 & 4 & a & 6 & c & 9 & b \\
4 & 5 & 6 & 7 & 1 & 9 & b & c & 8 & 3 & 2 & a \\
5 & 6 & 2 & 8 & a & 7 & 9 & b & c & 4 & 1 & 3 \\
6 & c & 8 & 1 & 3 & a & 2 & 7 & b & 9 & 4 & 5 \\
7 & 8 & 1 & a & c & b & 5 & 4 & 2 & 6 & 3 & 9 \\
8 & 9 & b & 3 & 4 & c & a & 6 & 5 & 1 & 7 & 2 \\
9 & b & 7 & c & 2 & 5 & 1 & 3 & 4 & 8 & a & 6 \\
a & 7 & c & b & 9 & 4 & 6 & 1 & 3 & 2 & 5 & 8 \\
b & 4 & a & 9 & 8 & 3 & c & 2 & 7 & 5 & 6 & 1 \\
c & a & 9 & 6 & b & 2 & 3 & 5 & 1 & 7 & 8 & 4
\end{array}$$

6. The partial Latin square $\begin{array}{ccc} 1 & \cdot & 2 \\ \cdot & 3 & 1 \\ 4 & 1 & \cdot \end{array}$ is imbedded in the Latin square $\begin{array}{cccc} 1 & 4 & 2 & 3 \\ 2 & 3 & 1 & 4 \\ 4 & 1 & 3 & 2 \\ 3 & 2 & 4 & 1 \end{array}$.

12.3.2 MUTUALLY ORTHOGONAL LATIN SQUARES

Definitions:

Two Latin squares $A = (a_{ij})$ and $B = (b_{ij})$ of order n are ***orthogonal*** if the n^2 ordered pairs (a_{ij}, b_{ij}) $(1 \leq i, j \leq n)$ are distinct. (The relation of orthogonality is symmetric.)

A set of Latin squares $\{A_1, \ldots, A_k\}$ is a set of ***mutually orthogonal Latin squares*** (MOLS) if A_i and A_j are orthogonal for all $i, j \in \{1, \ldots, k\}$ $(i \neq j)$. The maximum number of MOLS of order n is written $N(n)$. It is customary to define $N(0) = N(1) = \infty$.

A set of $n-1$ MOLS of side n is a ***complete set*** of MOLS.

Facts:

1. If $n \geq 2$, then $N(n) \leq n-1$.

2. If n is a prime power, then $N(n) = n-1$.

3. $N(n) \geq 2$ for all $n \geq 3$, except $n = 6$. (Bose-Parker-Shrikhande)

4. $N(n) \geq 3$ for all $n \geq 4$ except for $n = 6$ and possibly $n = 10$. The table that follows gives the best known lower bounds for $N(n)$ for $0 \leq n \leq 499$. Add the row and column indices to obtain the order.

5. $N(n) \to \infty$ as $n \to \infty$. (Chowla, Erdős, Straus)

6. $N(n \times m) \geq \min\{N(n), N(m)\}$. (MacNeish)

7. The existence of $n-1$ MOLS of order n is equivalent to the existence of a projective plane of order n (an $(n^2+n+1, n+1, 1)$ design) and an affine plane of order n (an $(n^2, n, 1)$ design). (§12.2.3)

8. The existence of a set of $k-2$ mutually orthogonal Latin squares of order n is equivalent to the existence of a transversal design TD(k, n). (§12.1.7)

9. A set of $k-2$ MOLS of order n is equivalent to an $OA(n, k)$ (§12.3.3).

10. *Constructing a complete set of MOLS of order q for q a prime power*: A complete set of MOLS of order q for q a prime power can be constructed as follows:

- for each $\alpha \in GF(q) - \{0\}$, define the Latin square $L_\alpha(i,j) = i + \alpha j$, where $i, j \in GF(q)$ and the algebra is performed in $GF(q)$.

The set of Latin squares $\{L_\alpha \mid \alpha \in GF(q) - \{0\}\}$ is a set of $q-1$ MOLS of side q.

11. Let n_k be the largest order for which the existence of k MOLS is unknown. So if $n > n_k$, then there exist at least k MOLS of order n. See the following table:

k	n_k	k	n_k	k	n_k	k	n_k	k	n_k
2	6	5	60	8	2,766	11	7,222	14	7,874
3	10	6	74	9	3,678	12	7,286	15	8,360
4	22	7	570	10	5,804	13	7,288		

12. *Constructing a set of r MOLS of size $mn \times mn$ from a set of r MOLS of size $m \times m$ and a set of r MOLS of size $n \times n$:* Let $A_1, \ldots, A_r$ and $B_1, \ldots, B_r$ be two sets of MOLS, where each $A_i = (a_{xy}^{(i)})$ is of size $m \times m$ and each $B_i = (b_{xy}^{(i)})$ is of size $n \times n$. Construct a set $C_1, \ldots, C_r$ of $mn \times mn$ MOLS as follows: for each $k = 1, \ldots, r$, let

$$C_k = \begin{pmatrix} D_{11}^{(k)} & D_{12}^{(k)} & \cdots & D_{1m}^{(k)} \\ D_{21}^{(k)} & D_{22}^{(k)} & \cdots & D_{2m}^{(k)} \\ \vdots & \vdots & & \vdots \\ D_{m1}^{(k)} & D_{m2}^{(k)} & \cdots & D_{mm}^{(k)} \end{pmatrix}$$

where

$$D_{ij}^{(k)} = \begin{pmatrix} (a_{ij}^{(k)}, b_{11}^{(k)}) & (a_{ij}^{(k)}, b_{12}^{(k)}) & \cdots & (a_{ij}^{(k)}, b_{1n}^{(k)}) \\ (a_{ij}^{(k)}, b_{21}^{(k)}) & (a_{ij}^{(k)}, b_{22}^{(k)}) & \cdots & (a_{ij}^{(k)}, b_{2n}^{(k)}) \\ \vdots & \vdots & & \vdots \\ (a_{ij}^{(k)}, b_{n1}^{(k)}) & (a_{ij}^{(k)}, b_{n2}^{(k)}) & \cdots & (a_{ij}^{(k)}, b_{nn}^{(k)}) \end{pmatrix}.$$

Note: In 1782 Leonhard Euler considered the following problem:

> A very curious question, which has exercised for some time the ingenuity of many people, has involved me in the following studies, which seem to open a new field of analysis, in particular in the study of combinations. The question revolves around arranging 36 officers to be drawn from six different ranks and at the same time from six different regiments so that they are also arranged in a square so that in each line (both horizontal and vertical) there are six officers of different ranks and different regiments.

A solution to Euler's problem would be equivalent to a pair of orthogonal Latin squares of order 6, the symbol set of the first consisting of the six ranks and the symbol set of the second consisting of the six regiments. Euler convinced himself that his problem was incapable of solution and goes even further:

> I have examined a very great number of tables ... and I do not hesitate to conclude that one cannot produce an orthogonal pair of order 6 and that the same impossibility extends to $10, 14, \ldots$ and in general to all the orders which are unevenly even.

Euler was proven correct in his claim that an orthogonal pair of order 6 does not exist [G. Tarry, 1900]; however, in 1960 Euler was shown to be wrong for all orders greater than 6. (See the Bose-Parker-Shrikhande theorem, Fact 3.)

Examples:

1. Two mutually orthogonal Latin squares of side 3:

$$\begin{array}{ccc} 1 & 2 & 3 \\ 2 & 3 & 1 \\ 3 & 1 & 2 \end{array} \qquad \begin{array}{ccc} 1 & 2 & 3 \\ 3 & 1 & 2 \\ 2 & 3 & 1 \end{array}$$

2. Three mutually orthogonal Latin squares of side 4:

$$\begin{array}{cccc} 1 & 2 & 3 & 4 \\ 4 & 3 & 2 & 1 \\ 2 & 1 & 4 & 3 \\ 3 & 4 & 1 & 2 \end{array} \qquad \begin{array}{cccc} 1 & 2 & 3 & 4 \\ 3 & 4 & 1 & 2 \\ 4 & 3 & 2 & 1 \\ 2 & 1 & 4 & 3 \end{array} \qquad \begin{array}{cccc} 1 & 2 & 3 & 4 \\ 2 & 1 & 4 & 3 \\ 3 & 4 & 1 & 2 \\ 4 & 3 & 2 & 1 \end{array}$$

3. Two MOLS of order 10:

$$\begin{array}{cccccccccc}
0 & 4 & 1 & 7 & 2 & 9 & 8 & 3 & 6 & 5 \\
8 & 1 & 5 & 2 & 7 & 3 & 9 & 4 & 0 & 6 \\
9 & 8 & 2 & 6 & 3 & 7 & 4 & 5 & 1 & 0 \\
5 & 9 & 8 & 3 & 0 & 4 & 7 & 6 & 2 & 1 \\
7 & 6 & 9 & 8 & 4 & 1 & 5 & 0 & 3 & 2 \\
6 & 7 & 0 & 9 & 8 & 5 & 2 & 1 & 4 & 3 \\
3 & 0 & 7 & 1 & 9 & 8 & 6 & 2 & 5 & 4 \\
1 & 2 & 3 & 4 & 5 & 6 & 0 & 7 & 8 & 9 \\
2 & 3 & 4 & 5 & 6 & 0 & 1 & 8 & 9 & 7 \\
4 & 5 & 6 & 0 & 1 & 2 & 3 & 9 & 7 & 8
\end{array}
\qquad
\begin{array}{cccccccccc}
0 & 7 & 8 & 6 & 9 & 3 & 5 & 4 & 1 & 2 \\
6 & 1 & 7 & 8 & 0 & 9 & 4 & 5 & 2 & 3 \\
5 & 0 & 2 & 7 & 8 & 1 & 9 & 6 & 3 & 4 \\
9 & 6 & 1 & 3 & 7 & 8 & 2 & 0 & 4 & 5 \\
3 & 9 & 0 & 2 & 4 & 7 & 8 & 1 & 5 & 6 \\
8 & 4 & 9 & 1 & 3 & 5 & 7 & 2 & 6 & 0 \\
7 & 8 & 5 & 9 & 2 & 4 & 6 & 3 & 0 & 1 \\
4 & 5 & 6 & 0 & 1 & 2 & 3 & 7 & 8 & 9 \\
1 & 2 & 3 & 4 & 5 & 6 & 0 & 9 & 7 & 8 \\
2 & 3 & 4 & 5 & 6 & 0 & 1 & 8 & 9 & 7
\end{array}$$

12.3.3 ORTHOGONAL ARRAYS

Definition:

An ***orthogonal array of size*** N, with k *constraints* (or of *degree* k), s *levels* (or of *order* s), and *strength* t, denoted $\mathrm{OA}(N, k, s, t)$, is a $k \times N$ array with entries from a set of $s \geq 2$ symbols, having the property that in every $t \times N$ submatrix, every $t \times 1$ column vector appears the same number $\lambda = \frac{N}{s^t}$ of times. The parameter λ is the *index* of the orthogonal array.

Note: An $\mathrm{OA}(N, k, s, t)$ is also denoted by $\mathrm{OA}_\lambda(t, k, s)$; in this notation, if t is omitted it is understood to be 2, and if λ is omitted it is understood to be 1.

Facts:

1. An $\mathrm{OA}_\lambda(k, v)$ is equivalent to a transversal design $\mathrm{TD}_\lambda(k, v)$.

2. $\mathrm{OA}_1(t, k, s)$ are known as *MDS codes* in coding theory.

3. An $\mathrm{OA}_\lambda(k, n)$ exists only if $k \leq \left\lfloor \frac{\lambda v^2 - 1}{v - 1} \right\rfloor$ (Bose-Bush bound). Generally one is interested in finding the largest k for which there exists an $\mathrm{OA}_\lambda(k, n)$ (for a given λ and n).

The following table gives the best known upper bounds and lower bounds for the largest k for which there exists a $\mathrm{OA}_\lambda(k, n)$, for $1 \leq n \leq 18$ and $2 \leq \lambda \leq 10$. Entries for which the upper and lower bounds match are shown in boldface.

12.4 MATROIDS

Linearly independent sets of columns in a matrix and acyclic sets of edges in a graph share many similar properties. Hassler Whitney (1907–1989) aimed to capture these similarities when he defined matroids in 1935. These structures arise naturally in a variety of combinatorial contexts. Moreover, they are precisely the hereditary families of sets for which a greedy strategy produces an optimal set.

12.4.1 BASIC DEFINITIONS AND EXAMPLES

Definitions:

A ***matroid*** M (also written $(E,\mathcal{I})$ or $(E(M),\mathcal{I}(M))$) is a finite set E (the ***ground set*** of M) and a collection $\mathcal{I}$ of subsets of E (***independent sets***) such that

- the empty set is independent;
- every subset of an independent set is independent ($\mathcal{I}$ is *hereditary*);
- if X and Y are independent and $|X| < |Y|$, then there is $e \in Y - X$ such that $X \cup \{e\}$ is independent.

Subsets of E that are not in $\mathcal{I}$ are ***dependent***.

A ***basis*** of a matroid is a maximal independent set. The collection of bases of M is denoted $\mathcal{B}(M)$.

A ***circuit*** of a matroid is a minimal dependent set. The collection of circuits of M is denoted $\mathcal{C}(M)$.

Matroids M_1 and M_2 are ***isomorphic*** ($M_1 \cong M_2$) if there is a one-to-one function φ from $E(M_1)$ onto $E(M_2)$ that preserves independence; that is, a subset X of $E(M_1)$ is in $\mathcal{I}(M_1)$ if and only if $\varphi(X)$ is in $\mathcal{I}(M_2)$.

For a matroid M with ground set E and $A \subseteq E$, all maximal independent subsets of A have the same cardinality, called the ***rank*** of A, written $r(A)$ or $r_M(A)$. The rank $r(M)$ of M is $r(E)$.

A ***spanning set*** of a matroid M is a subset of the ground set E of rank $r(M)$.

A ***hyperplane*** of a matroid M is a maximal nonspanning set.

The ***closure*** $\text{cl}(X)$ (or $\sigma(X)$) of X is $\{x \in E \mid r(X \cup \{x\}) = r(X)\}$.

A set X is a ***closed set*** or ***flat*** if $\text{cl}(X) = X$.

A ***loop*** of M is an element e such that $\{e\}$ is a circuit.

If $\{f, g\}$ is a circuit, then f and g are ***parallel elements***.

Matroid M is a ***simple matroid*** (or ***combinatorial geometry***) if it has no loops and no parallel elements.

A ***paving matroid*** is a matroid M in which all circuits have at least $r(M)$ elements.

Various classes of matroids are defined in the following table.

matroid M	*ground set* $E(M)$	*independent sets* $\mathcal{I}(M)$	*bases* $\mathcal{B}(M)$	*circuits* $\mathcal{C}(M)$
uniform matroid, $U_{m,n}$ $(0 \le m \le n)$	$\{1, 2, \ldots, n\}$	$\{I \subseteq E :$ $\lvert I\rvert \le m\}$	$\{B \subseteq E :$ $\lvert B\rvert = m\}$	$\{C \subseteq E :$ $\lvert C\rvert = m+1\}$
$M(G)$, ***cycle matroid*** of graph G	$E(G)$, the edges of G	$\{I \subseteq E(G) \mid$ I contains no cycle$\}$	for connected G: edge-sets of spanning trees	edge-sets of cycles
$M[A]$, ***vector matroid*** of matrix A over field F	column labels of A	$\{I \subseteq E \mid I$ labels a linearly independent multiset of columns$\}$	labels of maximal linearly independent sets of columns	labels of minimal linearly dependent multisets of columns
transversal matroid, $M(\mathcal{A})$, of family $\mathcal{A} = (A_1, A_2, \ldots, A_m)$ where $A_j \subseteq E$	E	partial transversals of $\mathcal{A}$: sets $\{x_{i_1}, \ldots, x_{i_k}\}$, $i_1 < \ldots < i_k$ and $x_{i_j} \in A_{i_j}$	maximal partial transversals of $\mathcal{A}$	minimal sets that are not partial transversals

Matroid M is in the specified class if M satisfies the indicated condition:

- ***graphic***: $M \cong M(G)$ for some graph G;
- ***planar***: $M \cong M(G)$ for some planar graph G;
- ***representable over*** F: $M \cong M[A]$ for some matrix A over the field F;
- ***binary***: representable over $GF(2)$, the 2-element field;

- ***ternary***: representable over $GF(3)$;
- ***regular***: representable over all fields.

Facts:

1. If a matroid M is graphic, then $M \cong M(G)$ for some connected graph G.

2. *Whitney's 2-isomorphism theorem*: Two graphs have isomorphic cycle matroids if and only if one can be obtained from the other by performing a sequence of the following operations:

- choose one vertex from each of two components and identify the chosen vertices;
- produce a new graph from which the original can be recovered by applying the previous operation;
- in a graph that can be obtained from the disjoint union of two graphs G_1 and G_2 by identifying vertices u_1 and v_1 of G_1 with vertices u_2 and v_2 of G_2, *twist* the graph by identifying, instead, u_1 with v_2 and u_2 with v_1.

3. If A' is obtained from the matrix A over the field F by elementary row operations, deleting or adjoining zero rows, permuting columns, and multiplying columns by nonzero scalars, then $M[A'] \cong M[A]$. The converse of this holds if and only if F is $GF(2)$ or $GF(3)$.

4. If a matroid M is representable over F and $r(M) \geq 1$, then $M \cong M[I_{r(M)}|D]$, where $I_{r(M)}|D$ consists of an $r(M) \times r(M)$ identity matrix followed by some other matrix D over F.

5. A matroid M is regular if and only if M can be represented over the real numbers by a *totally unimodular matrix* (a matrix for which all subdeterminants are 0, 1, or -1).

6. A matroid M is regular if and only if M is both binary and ternary.

7. The smallest matroids not representable over any field have eight elements.

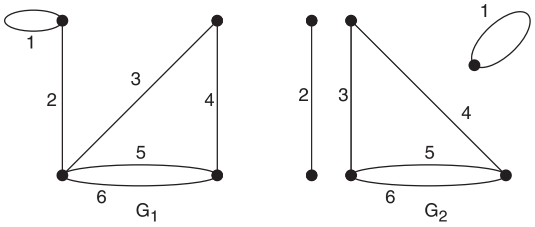
8. *Conjecture*: For all $n \geq 9$, more than half of all matroids on $\{1, 2, \ldots, n\}$ are paving.

9. The following table lists the numbers of nonisomorphic matroids, simple matroids, and binary matroids with up to nine elements:

$\lvert E(M)\rvert$	0	1	2	3	4	5	6	7	8	9
matroids	1	2	4	8	17	38	98	306	1,724	383,172
simple	1	1	1	2	4	9	26	101	950	376,467
binary	1	2	4	8	16	32	68	148	342	848

Examples:

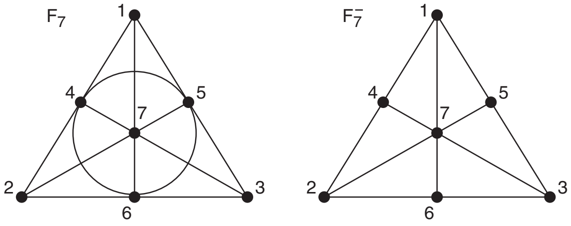
1. Let M be the matroid with $E(M) = \{1, 2, \ldots, 6\}$ and $\mathcal{C}(M) = \{\{1\}, \{5, 6\}, \{3, 4, 5\}, \{3, 4, 6\}\}$. Then $\mathcal{B} = \{\{2, 3, 4\}, \{2, 3, 5\}, \{2, 3, 6\}, \{2, 4, 5\}, \{2, 4, 6\}\}$. The following figure shows that M is graphic and binary since $M = M(G_1) = M(G_2)$ and $M = M[A]$ with A being interpreted over $GF(2)$; M is regular since $M = M[A]$ when A is interpreted over any field F. Also M is transversal since $M = M(\mathcal{A})$ where $\mathcal{A} = (\{2\}, \{3, 4\}, \{4, 5, 6\})$.



$$A = \begin{array}{c} \begin{array}{cccccc} 1 & 2 & 3 & 4 & 5 & 6 \end{array} \\ \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} \end{array}$$

2. *Fano and non-Fano matroids*: Given a finite set E of points in the plane and a collection of lines (subsets of E with at least three elements), no two of which share more than one common point, there is a matroid with ground set E whose circuits are all sets of three collinear points and all sets of four points no three of which are collinear. Two such matroids are shown in the following figure. Each has ground set $\{1, 2, \ldots, 7\}$. On the right is the non-Fano matroid F_7^-. It differs from the Fano matroid F_7 on the left by the collinearity of 4, 5, and 6 in the latter.

The matrix in this figure represents F_7 over all fields of characteristic 2, and represents F_7^- over all other fields. F_7 is binary but non-ternary; F_7^- is ternary but non-binary. Both are non-uniform, non-regular, non-graphic, and non-transversal.



$$\begin{array}{c} \begin{array}{ccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 \end{array} \\ \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix} \end{array}$$

12.4.2 ALTERNATIVE AXIOM SYSTEMS

Matroids can be characterized by many different axiom systems. Some examples of these systems follow. Throughout, E is assumed to be a finite set and 2^E stands for the set of subsets of E.

Definitions:

Circuit axioms: A subset $\mathcal{C}$ of 2^E is the set of circuits of a matroid on E if and only if $\mathcal{C}$ satisfies

- $\emptyset \notin \mathcal{C}$;
- no member of $\mathcal{C}$ is a proper subset of another;
- *circuit elimination*: if C_1, C_2 are distinct members of $\mathcal{C}$ and $e \in C_1 \cap C_2$, then $\mathcal{C}$ has a member C_3 such that $C_3 \subseteq (C_1 \cup C_2) - \{e\}$.

Note: The circuit elimination axiom can be strengthened to the following:

- *strong circuit elimination*: if $C_1, C_2 \in \mathcal{C}$, $f \in C_1 - C_2$, and $e \in C_1 \cap C_2$, then $\mathcal{C}$ has a member C_3 such that $f \in C_3 \subseteq (C_1 \cup C_2) - \{e\}$.

Basis axioms: A subset $\mathcal{B}$ of 2^E is the set of bases of a matroid on E if and only if

- $\mathcal{B}$ is nonempty;
- if $B_1, B_2 \in \mathcal{B}$ and $x \in B_1 - B_2$, then there is an element $y \in B_2 - B_1$ such that $(B_1 - \{x\}) \cup \{y\} \in \mathcal{B}$.

Rank axioms: A function r from 2^E into the nonnegative integers is the rank function of a matroid on E if and only if, for all subsets X, Y, Z of E

- $0 \le r(X) \le |X|$;
- if $Y \subseteq Z$, then $r(Y) \le r(Z)$;
- *submodularity*: $r(X \cup Y) + r(X \cap Y) \le r(X) + r(Y)$.

Closure axioms: A function cl from 2^E into 2^E is the closure operator of a matroid on E if and only if, for all subsets X and Y of E

- $X \subseteq \mathrm{cl}(X)$;
- if $X \subseteq Y$, then $\mathrm{cl}(X) \subseteq \mathrm{cl}(Y)$;
- $\mathrm{cl}(\mathrm{cl}(X)) = \mathrm{cl}(X)$;
- *MacLane-Steinitz exchange*: if $x \in E$ and $y \in \mathrm{cl}(X \cup \{x\}) - \mathrm{cl}(X)$, then $x \in \mathrm{cl}(X \cup \{y\})$.

Fact:

1. If M is a matroid with ground set E and $I \subseteq E$, the following statements are equivalent:

- I is an independent set of M;
- no circuit of M contains I;
- some basis of M contains I;
- $r(I) = |I|$;
- for every element e of I, $e \notin \mathrm{cl}(I - \{e\})$.

12.4.3 DUALITY

Definitions:

For a matroid M, let $\mathcal{B}^*(M) = \{E(M) - B \mid B \in \mathcal{B}(M)\}$. Then $\mathcal{B}^*(M)$ is the set of bases of a matroid M^*, called the ***dual*** of M, whose ground set is also $E(M)$.

Bases, circuits, loops, and independent sets of M^* are called ***cobases***, ***cocircuits***, ***coloops***, and ***coindependent sets*** of M.

For a graph G, the ***cocycle matroid*** (or ***bond matroid***) of G is the dual of $M(G)$ and is denoted by $M^*(G)$.

A matroid M is ***cographic*** if $M \cong M^*(G)$ for some graph G.

A class of matroids is ***closed under duality*** if the dual of every member of the class is also in the class.

Facts:

1. For all matroids M, $(M^*)^* = M$.

2. For all matroids M, the rank function of M^* is given by $r^*(X) = |X| - r(M) + r(E - X)$.

3. The cocircuits of every matroid M are the minimal sets having nonempty intersection with every basis of M.

4. The cocircuits of every matroid M are the minimal nonempty sets C^* such that $|C^* \cap C| \neq 1$ for every circuit C of M.

5. For every graph G, the circuits of $M^*(G)$ are the minimal edge cuts of G.

6. A graphic matroid is cographic if and only if it is planar.

7. The following classes of matroids are closed under duality: uniform matroids, matroids representable over a fixed field F, planar matroids, and regular matroids. The classes of graphic and transversal matroids are not closed under duality.

8. The following are special sets and their complements in a matroid M and M^*:

X	basis of M	independent set of M	circuit of M
$E - X$	basis of M^*	spanning set of M^*	hyperplane of M^*

Example:

1. The following are duals of some basic examples:

matroid	*dual*
$U_{m,n}$	$U_{n-m,n}$
$M(G)$ (G planar)	$M(G^*)$, where G^* is any dual of G
$M[I_r\|D]$ ($[I_r\|D]$ an $r \times n$ matrix)	$M[-D^T\|I_{n-r}]$, same order of column labels as $[I_r\|D]$

12.4.4 FUNDAMENTAL OPERATIONS

Definitions:

Three basic constructions for matroids M, M_1, and M_2 are defined in the following table. $M\backslash T$ and M/T are also written as $M|(E-T)$ and $M.(E-T)$ and are called the ***restriction*** and ***contraction*** of M to $E - T$; $M\backslash\{e\}$ and $M/\{e\}$ are written as $M\backslash e$ and M/e.

matroid	$\mathcal{I}$	$\mathcal{C}$	*rank*
$M\backslash T$ (***deletion*** of T from M)	$\{I \subseteq E(M) - T \mid I \in \mathcal{I}(M)\}$	$\{C \subseteq E(M) - T \mid C \in \mathcal{C}(M)\}$	$r_{M\backslash T}(X) = r_M(X)$
M/T (***contraction*** of T from M)	$\{I \subseteq E(M) - T \mid I \cup B_T \in \mathcal{I}(M)$ for some B_T in $\mathcal{B}(M\|T)\}$	minimal nonempty members of $\{C - T \mid C \in \mathcal{C}(M)\}$	$r_{M/T}(X) = r_M(X \cup T) - r_M(T)$
$M_1 \oplus M_2$ (***direct sum*** of M_1 and M_2)	$\{I_1 \cup I_2 \mid I_j \in \mathcal{I}(M_j)\}$	$\mathcal{C}(M_1) \cup \mathcal{C}(M_2)$	$r_{M_1 \oplus M_2}(X) = r_1(X \cap E(M_1)) + r_2(X \cap E(M_2))$

Matroid N is a ***minor*** of matroid M if N can be obtained from M by a sequence of deletions and contractions. The minor N is ***proper*** if $N \neq M$.

A matroid is ***connected*** if it cannot be written as the direct sum of two *nonempty matroids* (matroids with nonempty ground sets).

Facts:

In each of the following, M, M_1, and M_2 are matroids.

1. $M\backslash X\backslash Y = M\backslash(X \cup Y) = M\backslash Y\backslash X$; $M/X/Y = M/(X \cup Y) = M/Y/X$; and $M\backslash X/Y = M/Y\backslash X$.

2. $M_1 \oplus M_2 = M_2 \oplus M_1$.

3. $(M/T)^* = M^*\backslash T$; and $(M\backslash T)^* = M^*/T$. (Deletion and contraction are dual operations.)

4. *The scum theorem*: Every minor of M can be written as $M\backslash X/Y$ for some independent set Y and coindependent set X. (The name derives from the fact that an isomorphic copy of every simple minor of a matroid occurs at (that is, floats to) the top of the lattice.) (D. A. Higgs) [CrRo70]

5. The following are equivalent:

- M is connected;
- M^* is connected;
- every two distinct elements of M are in a circuit;
- there is no proper nonempty subset T of $E(M)$ such that $M\backslash T = M/T$;
- there is no proper nonempty subset T of $E(M)$ such that $r(T) + r(E(M) - T) = r(M)$;
- there is no proper nonempty subset T of $E(M)$ such that $r(T) + r^*(T) = |T|$.

6. If M is connected, then M is uniquely determined by the set of circuits containing some fixed element of $E(M)$.

7. If M is connected and $e \in E(M)$, then $M\backslash e$ or M/e is connected.

8. $F_7 \oplus F_7^-$ is not representable over any field.

Examples:

1. $U_{m,n}\backslash e = U_{m,n-1}$ unless $m = n$ when $U_{m,n}\backslash e = U_{m-1,n-1}$.

2. $U_{m,n}/e = U_{m-1,n-1}$ unless $m = 0$ when $U_{m,n}/e = U_{m,n-1}$.

3. $M(G)\backslash e = M(G\backslash e)$ where $G\backslash e$ is obtained from G by deleting the edge e.

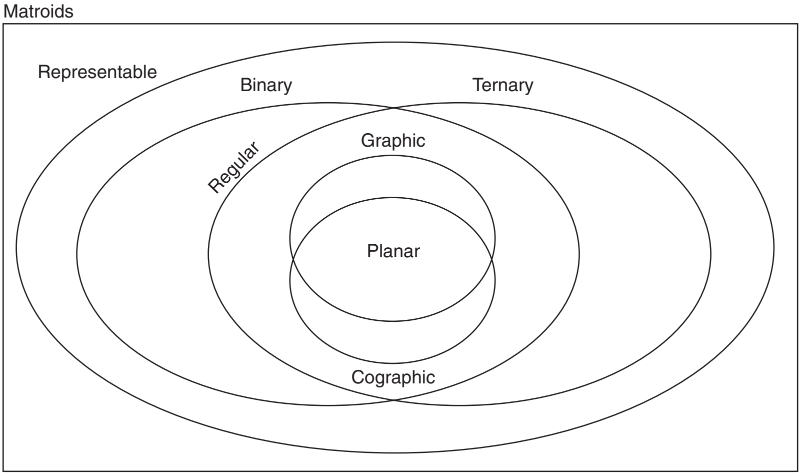
4. $M(G)/e = M(G/e)$ where G/e is obtained from G by contracting the edge e.

5. $M[A]\backslash e$ is the vector matroid of the matrix obtained by deleting column e from A.

6. If e corresponds to a standard basis vector in A, then $M[A]/e$ is the vector matroid of the matrix obtained by deleting both the column e and the row containing the one of e.

12.4.5 CHARACTERIZATIONS

Many matroid results characterize various classes of matroids. Some examples of such results appear below. The Venn diagram in the following figure indicates the relationship between certain matroid classes.



Definitions:

Let M_1 and M_2 be two binary matroids such that $E(M_1) \cap E(M_2) = T$, $M_1|T = M_2|T$, and no cocircuit of M_1 or M_2 is contained in T. The 2-***sum*** and 3-***sum*** of M_1 and M_2 are matroids on $(E(M_1) \cup E(M_2)) - T$ whose flats are those sets $F - T$ such that $F \cap E(M_i)$ is a flat of M_i for $i = 1, 2$. The 2-sum occurs when $|T| = 1$, $|E(M_i)| \geq 3$, and T is not a loop of M_i, and the 3-sum occurs when $|E(M_i)| \geq 7$ and T is a 3-element circuit of M_i.

Facts:

1. The following are equivalent for a matroid M:

- M is uniform;
- every circuit of M has $r(M) + 1$ elements;
- every circuit of M meets every cocircuit of M.

2. The following are equivalent for a matroid M:

- M is binary;
- for every circuit C and every cocircuit C^*, $|C \cap C^*|$ is even;
- for every circuit C and every cocircuit C^*, $|C \cap C^*| \neq 3$;
- for all $C_1, C_2 \in \mathcal{C}$, $(C_1 - C_2) \cup (C_2 - C_1)$ is a disjoint union of circuits.

3. The class of regular matroids is the class of matroids that can be constructed by direct sums, 2-sums, and 3-sums from graphic matroids, cographic matroids, and copies of R_{10} (the matroid that is represented over $GF(2)$ by the ten 5-tuples with exactly three ones). (This last fact is the basis of a polynomial-time algorithm to determine whether a real matrix is totally unimodular.)

4. *Excluded-minor theorems*: Many classes of matroids are *minor-closed*; that is, every minor of a member of the class is also in the class. Such classes can be characterized by listing their *excluded minors* (those matroids that are not in the class but have all their proper minors in the class). Some important examples of such results are given in the following table. The class of transversal matroids is not minor-closed since a contraction of a transversal matroid need not be transversal.

class	*excluded minors*	*class*	*excluded minors*
binary	$U_{2,4}$	*ternary*	$U_{2,5}, U_{3,5}, F_7, F_7^*$
uniform	$U_{0,1} \oplus U_{1,1}$	*graphic*	$U_{2,4}, F_7, F_7^*, M^*(K_5), M^*(K_{3,3})$
paving	$U_{0,1} \oplus U_{2,2}$	*regular*	$U_{2,4}, F_7, F_7^*$

12.4.6 THE GREEDY ALGORITHM

Definitions:

For a finite set E, let $\mathcal{I}$ be a subset of 2^E satisfying the first two axioms for independent sets in the definition of matroid (§12.4.1). Let w be a real-valued function on E. For $X \subseteq E$, define the ***weight*** of X by $w(X) = \sum_{x \in X} w(x)$, and let $w(\emptyset) = 0$.

Facts:

1. Matroids have an important relationship to the greedy algorithm (Algorithm 1) that makes them important in optimization problems.

Algorithm 1: **The greedy algorithm for** $(\mathcal{I}, w)$**.**

```
$X_0 := \emptyset$; $j := 0$
while $E - X_j$ contains an element $e$ such that $X_j \cup \{e\} \in \mathcal{I}$
    $e_{j+1}$ := an element $e$ of maximum weight such that $X_j \cup \{e\} \in \mathcal{I}$
    $X_{j+1} := X_j \cup \{e_{j+1}\}$
    $j := j + 1$
$B_G := X_j$
```

2. $\mathcal{I}$ (a subset of 2^E satisfying the first two axioms for independent sets in the definition of matroid) is the set of independent sets of a matroid on E if and only if, for all real-valued weight functions w on E, the set B_G produced by the greedy algorithm is a maximal member of $\mathcal{I}$ of maximum weight.

Example:

1. Let G be a connected graph with each edge e having a cost $c(e)$. Define $w(e) = -c(e)$. Then the greedy algorithm is just Kruskal's algorithm (§10.1.2) and B_G is the edge-set of a spanning tree of minimum cost.

DISCRETE AND COMPUTATIONAL GEOMETRY

INTRODUCTION

This chapter outlines the theory and applications of various concepts arising in two rapidly growing, interrelated areas of geometry: discrete geometry (which deals with topics such as space filling, arrangements of geometric objects, and related combinatorial problems) and computational geometry (which deals with the many aspects of the design and analysis of geometric algorithms). A more extensive treatment of discrete and computational geometry can be found in [TóORGo17].

GLOSSARY

anti-aliasing: the filtering out of high-frequency spatial components of a signal, to prevent artifacts, or aliases, from appearing in the output image.

aperiodic (prototile): a prototile in d-dimensional Euclidean space such that the prototile admits a tiling of the space, yet all such tilings are nonperiodic.

arrangement (of lines in the plane): the planar straight-line graph whose vertices are the intersection points of the lines and whose edges connect consecutive intersection points on each line (it is assumed that all lines intersect at a common point at infinity).

arrangement graph: a graph associated with a Euclidean or projective line arrangement, or a big circle arrangement.

aspect ratio (of a simplex): the ratio of the radius of the circumscribing sphere to the radius of the inscribing sphere of the simplex; for a triangulation, the largest aspect ratio of a simplex in the triangulation.

basis (of a point configuration in $\mathcal{R}^d$): a subset of the point configuration that is a simplex of the ambient space $\mathcal{R}^d$.

basis (of a vector configuration in $\mathcal{R}^d$): a subset of the vector configuration that is a basis of the ambient space $\mathcal{R}^d$.

big-circle arrangement: the intersection of a central plane arrangement with the unit sphere in $\mathcal{R}^3$.

boundary (of a polyhedron): the vertices, edges, and higher-dimensional facets of the polyhedron.

cell (of a line arrangement): a connected component of the complement in $\mathcal{R}^2$ of the union of the points on the lines.

centerpoint (of a point configuration P of size n): a point q, not necessarily in P, such that for any hyperplane containing q there are at least $\lceil \frac{n}{d+1} \rceil$ points in each semispace induced by the hyperplane.

central hyperplane arrangement (in $\mathcal{R}^d$): a finite set of central hyperplanes, not all of them going through the same point.

central plane arrangement (in $\mathcal{R}^3$): a finite set of central planes.

chain: a planar straight-line graph with vertices $v_1, \ldots, v_n$ and edges $\{v_1, v_2\}$, $\{v_2, v_3\}$, $\ldots$, $\{v_{n-1}, v_n\}$.

chirotope: for an ordered point configuration, the set of all signed bases of the configuration; for an ordered vector configuration, the set of all signed bases of the configuration.

circuit (of a set of labeled vectors $V = \{v_1, \ldots, v_n\}$): the signed set $C = (C^+, C^-)$, where $C^+ = \{\, j \mid \alpha_j > 0 \,\}$ and $C^- = \{\, j \mid \alpha_j < 0 \,\}$, of indices of the nonnull coefficients α_j in a minimal linear dependency $V' = \{v_{i_1}, \ldots, v_{i_k}\}$ of V with $\sum_{j=1}^{k} \alpha_j v_{i_j} = \underline{0}$.

class library: in an object-oriented computer language, a set of new data types and operations on them, activated by sending a data item a message.

closed half-space: the set of all points on a hyperplane and the points on one side of the same hyperplane.

cluster of rank 3 hyperline sequences (associated with a vector configuration): the ordered set of stars, one for each point in the configuration.

cluster of stars (associated with a point configuration): the ordered set of stars, one for each point in the configuration.

cocircuit (of a labeled vector configuration V): a signed set $C = (C^+, C^-)$ of the set $\{1, 2, \ldots, n\}$, induced by a subset of $d-1$ vectors spanning a central hyperplane h. For an arbitrary orientation of h, C^+ is the set of indices of elements in V lying in h^+ and C^- is the set of indices of elements in V lying in h^-.

computational convexity: the study of high-dimensional convex bodies.

contraction (on element i in a rank d central plane arrangement): the arrangement obtained by identifying h_i with $\mathcal{R}^{d-1}$ and intersecting it with all the other hyperplanes to obtain a rank $d{-}1$ arrangement with one fewer element.

convex: the property of a subset of a Euclidean space that for every pair of points in the set the linear segment joining them is contained in the set.

convex body: a closed and bounded convex set with nonempty interior.

convex d-polyhedron: the intersection of a finite number of closed half-spaces in $\mathcal{R}^d$.

convex decomposition (of a polyhedron): its partition into interior disjoint convex pieces.

convex hull (of a set of points): the smallest convex set containing the given set of points.

convex polygon: a polytope in the plane.

convex polyhedron: the intersection of a finite number of half-spaces.

convex polytope: a bounded convex polyhedron.

convex position: the property of a set of points that it is the vertex set of a polytope.

convex set: a subset of d-dimensional Euclidean space such that for every pair of distinct points in the set, the segment with these two points as endpoints is contained in the set.

covering: a family of convex bodies in d-dimensional Euclidean space such that each point belongs to at least one of the convex bodies.

cyclic d-polytope: the convex hull of a set of $n \geq d+1$ points on the moment curve in $\mathcal{R}^d$. The moment curve in $\mathcal{R}^d$ is defined parametrically by $x(t) = (t, t^2, \ldots, t^d)$.

Davenport-Schinzel sequence (of order s): a sequence of characters over an alphabet of size n such that no two consecutive characters are the same, and for any pair of characters, a and b, there is no alternating subsequence of length $s+2$ of the form $\ldots a \ldots b \ldots a \ldots b \ldots$.

deletion: the removal of a point (vector, line, etc.) from a configuration and recording the oriented matroid (chirotope, circuits, cluster of stars, etc.) only for the remaining points.

density (of a covering): the common value (if it exists) of the lower density and upper density of the covering.

density (of a packing): the common value (if it exists) of the lower density and upper density of the packing.

dual polytopes: two polytopes P and Q such that there exists a one-to-one correspondence δ between the set of faces of P and Q, where two faces $f_1, f_2 \in P$ satisfy $f_1 \subset f_2$ if and only if $\delta(f_1) \supset \delta(f_2)$ in Q.

duality transformation: a mapping of points to lines and lines to points that preserves incidences.

Euclidean hyperplane arrangement (in $\mathcal{R}^d$): a finite set of affine hyperplanes, not all of them going through the same point.

Euclidean line arrangement: a finite set of planar lines, not all of them going through the same point.

Euclidean pseudoconfiguration of points: a pair consisting of a planar set of points and a pseudoline arrangement, such that for every pair of distinct points there exists a unique pseudoline incident with them.

k-face: an open set of dimension k that is part of the boundary of a polyhedron; 0-faces, 1-faces, and $(d-1)$-faces of a d-polyhedron are called *vertices*, *edges*, and *facets*.

face vector (of a d-polyhedron): the d-dimensional vector $(f_0, f_1, \ldots, f_{d-1})$, where f_i is the number of i-dimensional faces of the d-polyhedron.

face-to-face (tiling): a tiling of d-dimensional Euclidean space by convex d-polytopes such that the intersection of any two tiles is a face of each tile, possibly the (improper) empty face.

general position: the property of a set of vectors in $\mathcal{R}^d$ that every subset of d elements is a basis; property of a set of points in $\mathcal{R}^d$ that every subset of d elements is a simplex.

genus (of a manifold 3-polyhedron): the genus number of its boundary, if the boundary is a 2-manifold.

geographic information system (***GIS***): an information system designed to capture, store, manipulate, analyze, and display spatial or geographically-referenced data.

geometric constraint solving: the problem of locating a set of geometric elements given a set of constraints between them.

graphical user interface (***GUI***): a mechanism that allows a user to interactively control a computer program with a bitmapped display by using a mouse or pointer to select menu items, move sliders or valuators, etc.

Grassmann-Plücker relations (***rank 3***): the identities $[123][145] - [124][135] + [125][134] = 0$ satisfied by the determinants $[ijk] = \det(v_i, v_j, v_k)$, for any five vectors $v_i, 1 \leq i \leq 5$.

half-space: one of the two connected components of the complement of a hyperplane.

ham-sandwich cut: a hyperplane that simultaneously bisects d point configurations in d-dimensional Euclidean space.

hyperplane: in d dimensions the set of all points on a $(d-1)$-dimensional plane.

hyperplane arrangement: the partitioning of the Euclidean space $\mathcal{R}^d$ into connected regions of different dimensions (vertices, edges, etc.) by a finite set of hyperplanes.

isogonal (tiling): a tiling such that the group of symmetries acts transitively on the vertices of the tiles.

isomorphic (vector or point configurations): configurations having the same order type, after possibly relabeling their elements.

isotoxal (tiling): a tiling such that the group of symmetries acts transitively on the edges of the tiles.

lattice (tiling): a tiling of d-dimensional Euclidean space by translates of a tile such that the corresponding translation vectors form a d-dimensional lattice.

k-level (in a given nonvertical arrangement of n lines): the lower boundary of the set of points in $\mathcal{R}^2$ having exactly k lines above and $n-k$ below.

line arrangement: the partitioning of the plane into connected regions (cells, edges, and vertices) induced by a finite set of lines.

lower density (of a covering $\mathcal{C}$): $\underline{\nu}(\mathcal{C}) = \liminf\limits_{R\to+\infty} \frac{\sum_{K_i \cap B_R \neq \emptyset} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)}$, where each K_i is a convex body in the covering $\mathcal{C}$ of d-dimensional Euclidean space and B_R is the closed ball of radius R centered at the origin.

lower density (of a packing $\mathcal{P}$): $\underline{\delta}(\mathcal{P}) = \liminf\limits_{R\to+\infty} \frac{\sum_{K_i \subset B_R} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)}$, where each K_i is a convex body in the packing $\mathcal{P}$ of d-dimensional Euclidean space and B_R is the closed ball of radius R centered at the origin.

lower envelope (of a nonvertical line arrangement): the half-plane intersection of the half-planes below the lines of the arrangement.

manifold d-polyhedron: a polyhedron whose boundary is topologically the same as a $(d-1)$-manifold; i.e., every point on the boundary of a manifold d-polyhedron has a small neighborhood that looks like an open d-ball.

mathematical programming: the large-scale optimization of an objective function of many variables subject to constraints.

minor (of an oriented matroid given by hyperline sequences): an oriented matroid obtained by a sequence of deletions and/or contractions.

monohedral (tiling): a tiling $\mathcal{T}$ of d-dimensional Euclidean space in which all tiles are congruent to one fixed set T, the (metrical) prototile of $\mathcal{T}$.

nonconvex polyhedron: the union of a set of convex polyhedra such that the underlying space is connected and nonconvex.

non-manifold d-polyhedron: a d-polyhedron that does not have a manifold boundary.

nonperiodic (tiling): a tiling such that its group of symmetries contains no translation other than the identity.

normal (tiling): a tiling of d-dimensional Euclidean space by convex polytopes such that there exist positive real numbers r and R such that each tile contains a Euclidean ball of radius r and is contained in a Euclidean ball of radius R.

oracle: an algorithm that gives information about a convex body.

order type (of a vector or point configuration): the collection of all semi-spaces of the configuration.

oriented matroid: a pair $\mathcal{M} = (n, \mathcal{L})$, where $\mathcal{L}$, the set of covectors of $\mathcal{M}$, is a subset of $\{+, -, 0\}^n$ and satisfies the properties: $0 \in \mathcal{L}$; if $X \in \mathcal{L}$, then $-X \in \mathcal{L}$; if $X, Y \in \mathcal{L}$, then $X \circ Y \in \mathcal{L}$; if $X, Y \in \mathcal{L}$ and $i \in S(X, Y) = \{i \mid X_i = -Y_i \neq 0\}$, then there is $Z \in \mathcal{L}$ such that $Z_i = 0$; for each $j \notin S(X, Y)$, $Z_j = (X \circ Y)_j = (Y \circ X)_j$.

oriented matroid given by a chirotope: an abstract set of points labeled $\{1, \ldots, n\}$, together with a function satisfying the chirotope axioms.

packing: a family of convex bodies in d-dimensional Euclidean space such that no two have an interior point in common.

parallel algorithm: an algorithm that concurrently uses more than one processing element during its execution.

parallel random access machine (***PRAM***): a synchronous machine in which each processor is a sequential RAM, and processors communicate using a shared memory.

parametric search: an algorithmic technique for solving optimization problems.

periodic (tiling): a tiling of d-dimensional Euclidean space such that the group of all symmetries of the tiling contains translations in d linearly independent directions.

planar straight-line graph: a planar graph such that each edge is a straight line.

point configuration (of dimension d): a finite set of points affinely spanning $\mathcal{R}^d$.

point location problem: the problem of determining which region of a given subdivision of $\mathcal{R}^d$ contains a given point.

polar-duality of vectors and central planes (in $\mathcal{R}^3$): a mapping associating with a vector v in $\mathcal{R}^3$ an oriented central plane h having v as its normal vector, and vice versa.

polyhedron: the intersection of a finite number of closed half-spaces in d-dimensional Euclidean space.

polytope: a bounded polyhedron.

d-polytope: a convex d-polyhedron for which there exists a d-dimensional cube containing it inside; that is, a bounded convex d-polyhedron.

$\mathcal{H}$-polytope: a polytope defined as the intersection of d half-spaces in d-dimensional Euclidean space.

$\mathcal{V}$-polytope: a polytope defined as the convex hull of d points in d-dimensional Euclidean space.

projective line arrangement: a finite set of projective lines in the projective plane.

prototile: the single tile used repeatedly in a monohedral tiling.

pseudoline arrangement: a finite collection of simple planar curves that intersect pairwise in exactly one point, where they cross.

Radon partition (of a set of labeled points P): a signed set $C = (C^+, C^-)$ of points of P such that the convex hull of the points in C^+ intersects the convex hull of the points in C^-.

randomized algorithm: an algorithm that makes random choices during its execution.

range counting problem: the problem of counting the number of points of a given set of points that lie in a query range.

range emptiness problem: the problem of determining if a query range contains any points of a given set of points.

range reporting problem: the problem of determining all the points of a given set of points that lie in a query range.

rank 3 hyperline sequence (associated with some vector $v \in V \subseteq \mathcal{R}^3$): an alternating circular sequence of subsets of indices, obtained by rotating an oriented central plane in counterclockwise order around the line through v.

ray: a half-line that is directed away from its endpoint.

ray shooting problem: the problem of determining the first object in a set of geometric objects that is hit by a query ray.

real random access machine (***real RAM***): a model of computation in which values can be arbitrarily long real numbers, and all standard operations such as $+, -, \times$, and $\div$ can be performed in unit time regardless of operand length.

realizable (pseudoline arrangement): a pseudoline arrangement isomorphic to a line arrangement.

reflex edges: edges of a nonconvex 3-polyhedron that subtend an inner dihedral angle greater than 180°.

regular (polygon): a polygon with all sides congruent and all interior angles equal.

regular (polytope): a d-polytope ($d > 0$) with all its facets regular ($d{-}1$)-polytopes that are combinatorially equivalent; a regular 0-polytope is a vertex.

regular (tiling): a monohedral tiling of the plane with a regular polygon as prototile.

reorientation (of a vector configuration $V = \{v_1, \ldots, v_n\}$): a vector configuration $V' = \{v'_1, \ldots, v'_n\}$ such that each v'_i is equal to v_i or $-v_i$.

semiregular (polyhedron): a convex polyhedron with each face a regular polygon, but where more than one regular polygon can be used as a face.

semiregular (tiling): a tiling of the plane using n prototiles with the same numbers of polygons around each vertex.

semi-space (of a configuration induced by a hyperplane): the set of indices of the configuration lying on one side of the hyperplane.

semi-space (of a vector or point configuration): a semi-space induced by some hyperplane.

k-set (of a point configuration): a semi-space of the configuration of size k.

d-dimensional simplex (or ***d-simplex***): a d-polytope with $d+1$ vertices.

simplicial complex: a triangulation of a polyhedron such that for any two simplices in the triangulation, either the intersection of the simplices is empty or is a face of both simplices.

simplicial polytope: a polytope in which all faces are simplices.

(***standard affine***) ***pseudo polar-duality***: the association between an x-monotone pseudoline arrangement $L = \{l_1, \ldots, l_n\}$ given in slope order and a pseudo configuration of points (P, L'), $P = \{p_1, \ldots, p_n\}$, given in increasing order of the x-coordinates and with L' being x-monotone, satisfying the property that the cluster of stars associated with L and to P are the same.

straight-line dual: given the Voronoi diagram of a set $\{p_1, \ldots, p_n\}$ of points in the plane, the planar straight-line graph whose vertices are the points in the set, with two vertices p_i and p_j adjacent if and only if the regions $V(p_i)$ and $V(p_j)$ share a common edge.

strictly convex: the property of a convex set that its boundary contains no line segment.

symmetry (of a tiling): a Euclidean motion that maps each tile of the tiling onto a tile of the tiling.

tile: an element of a tiling.

tiling (of Euclidean d-space): a countable family $\mathcal{T}$ of closed topological d-cells of $\mathcal{R}^d$ that cover $\mathcal{R}^d$ without gaps and overlaps.

triangulation (of a d-polyhedron): a convex decomposition in which each convex piece of the decomposition is a d-simplex.

triangulation (of a simple polygon): an augmentation of the polygon with nonintersecting diagonal edges connecting vertices of the polygon such that in the resulting planar straight-line graph every bounded face is a triangle.

uniform chirotope: a chirotope function that takes nonzero values on all d-tuples.

upper density (of a covering $\mathcal{C}$): $\overline{\nu}(\mathcal{C}) = \limsup_{R\to+\infty} \frac{\sum_{K_i \cap B_R \neq \emptyset} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)}$, where each K_i is a convex body in the covering $\mathcal{C}$ of d-dimensional Euclidean space and B_R is the closed ball of radius R centered at the origin.

upper density (of a packing $\mathcal{P}$): $\overline{\delta}(\mathcal{P}) = \limsup_{R\to+\infty} \frac{\sum_{K_i \subset B_R} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)}$, where each K_i is a convex body in the packing $\mathcal{P}$ of d-dimensional Euclidean space and B_R is the closed ball of radius R centered at the origin.

upper envelope (of a nonvertical line arrangement): the half-plane intersection of the half-planes above the lines of the arrangement.

vector configuration (of dimension d): a finite set of vectors spanning $\mathcal{R}^d$.

visibility graph: given n nonintersecting line segments in the plane, the graph whose vertices are the endpoints of the line segments, with two vertices adjacent if and only if they are visible from each other.

visibility problem: the problem of finding what is visible, given a configuration of objects and a viewpoint.

Voronoi cell (with center c_i): the convex polyhedral set $V_i = \{\, x \in \mathcal{R}^d : |x - c_i| = \min_j |x - c_j|\, \}$, where $c_1, c_2, \ldots$ are centers of unit balls in a packing of d-dimensional Euclidean space.

Voronoi diagram (of the set of points $\{p_1, \ldots, p_n\}$ in d-dimensional Euclidean space): the partition of d-dimensional Euclidean space into convex polytopes $V(p_i)$ such that $V(p_i)$ is the locus of points that are closer to p_i than to any other point in p_j.

zone (of a line in an arrangement): the set of cells of the arrangement intersected by the line.

zonotope: the vector (Minkowski) sum of a finite number of line segments.

13.1 ARRANGEMENTS OF GEOMETRIC OBJECTS

A wide range of applied fields (statistics, computer graphics, robotics, geographical databases) depend on solutions to geometric problems: polygon intersection, visibility computations, range searching, shortest paths among obstacles, just to name a few. These problems typically start with "consider a finite set of points (or lines, segments, curves, hyperplanes, polygons, polyhedra, etc.)". The *combinatorial* properties of these sets, or arrangements, of objects (incidence, order, partitioning, separation, convexity) set the foundations for the *algorithms* developed in the field of computational geometry.

In this chapter attention is focused on the most studied and best understood arrangements of geometric objects: points, lines, and hyperplanes. Introducing the concepts relies on linear algebra. The combinatorial properties studied belong, however, to a relatively new field, the theory of oriented matroids, which has sometimes been described as *linear algebra without coordinates*.

Several fundamental types of questions are asked about these arrangements. The most basic is the classification problem, whose goal is to find combinatorial parameters allowing the partitioning of the (uncountable) set of all possible arrangements of n objects into a finite number of equivalence classes. Examples of such structures for point and line arrangements include semi-spaces, Radon partitions, chirotopes, hyperline sequences, etc. They satisfy simple properties known as axiomatic systems for oriented matroids, which lead to the definition of an abstract class of objects generalizing finite point and vector sets. In dimension 2, oriented matroids can be visualized topologically as pseudoline arrangements. The numerous definitions needed to introduce arrangements and oriented matroids will be complemented in this section by the most important facts, such as counting the number of finite point, line, and pseudoline arrangements, deciding when a pseudoline arrangement is equivalent to a line arrangement, and basic algorithmic results.

13.1.1 POINT CONFIGURATIONS

The simplest geometric objects are points in some d-dimensional space. Most of the other objects of interest for applications of computational geometry (sets of segments, polygons, polyhedra) are built on top of, and inherit, geometric structure from sets of points.

The setting for computational geometry problems is the Euclidean (affine) space $\mathcal{R}^d$ and most of its fundamental concepts (convexity, proximity) belong here in a natural way. However, some standard techniques, such as polarity and duality, as well as the abstraction to oriented matroids, are better explained in the context of vector spaces.

Several categories of concepts are introduced in this section, and these are developed and used in the subsequent subsections: vector and point configurations, hyperplanes and half-spaces, convexity, and some combinatorial parameters associated with vector or point configurations, relevant to applications (in statistics, pattern recognition or computational geometry): signed bases, semi-spaces, k-sets, centerpoints.

Definitions:

The (***standard***) ***real vector space*** of dimension d is the vector space $\mathcal{R}^d = \{\underline{x} \mid \underline{x} = (x_1, \ldots, x_d), x_i \in \mathcal{R}\}$, with vector addition $\underline{x} + \underline{y} = \{x_1 + y_1, \ldots, x_d + y_d\}$ and scalar multiplication $\alpha\underline{x} = \{\alpha x_1, \ldots, \alpha x_d\}$. A vector in $\mathcal{R}^d$ is a ***d-dimensional vector***.

A ***linear combination*** of a set of vectors $\{v_1, \ldots, v_n\}$ is a vector of the form $\sum_{i=1}^n \alpha_i v_i$, for coefficients $\alpha_1, \ldots, \alpha_n \in \mathcal{R}$.

A ***linearly independent set*** of vectors is a set of vectors $\{v_1, \ldots, v_k\}$ such that a linear combination of them equals the zero vector ($\sum_{i=1}^k \alpha_i v_i = \underline{0}$) if and only if $\alpha_i = 0$ for all $i = 1, \ldots, k$.

A ***basis*** of $\mathcal{R}^d$ is a maximal set of linearly independent vectors, i.e., one that is no longer independent if a new element is added.

A basis is an ***ordered basis*** if it is given as an ordered set.

The ***sign*** of an ordered basis is the sign of the determinant of the $d \times d$ matrix with columns given in order by the vectors of the ordered basis.

A ***linearly dependent set*** of vectors $V = \{v_1, \ldots, v_k\}$ is a set of vectors for which there exists a linear combination with at least one nonzero coefficient yielding the $\underline{0}$ vector; i.e., $\sum_{i=1}^k \alpha_i v_i = \underline{0}$ with some $\alpha_i \neq 0$.

The ***linear space*** spanned by a set of vectors $V = \{v_1, \ldots, v_k\}, v_i \in \mathcal{R}^d$, is the set of all linear combinations of vectors of V.

A ***linear k-dimensional subspace*** of $\mathcal{R}^d$ ($k \leq d$) is the set of all linear combinations of k linearly independent vectors $v_1, \ldots, v_k$ in $\mathcal{R}^d$.

A ***line*** through $v \in \mathcal{R}^d$ is the 1-dimensional linear subspace of $\mathcal{R}^d$ induced by $v \neq \underline{0}$.

Euclidean space of dimension d is $\mathcal{R}^d$ seen as an affine space. It is sometimes identified with the d-dimensional affine hyperplane $x_{d+1} = 1$ in $\mathcal{R}^{d+1}$.

A (***d-dimensional***) ***point*** is an element of $\mathcal{R}^d$ seen as a Euclidean space.

An ***affine combination*** of a set of points $\{p_1, \ldots, p_n\}$ is a point of the form $\sum_{i=1}^n \alpha_i p_i$, with $\alpha_i \in \mathcal{R}$ and $\sum_{i=1}^n \alpha_i = 0$.

An ***affinely independent set of points*** is a set of points $\{p_1, \ldots, p_k\}$ such that no point is an affine combination of the others.

A ***simplex*** of $\mathcal{R}^d$ is a maximal set of affinely independent vectors. It is an ***ordered simplex*** if it is given as an ordered set.

The ***extended matrix*** of an ordered simplex $\{p_1, \ldots, p_{d+1}\}$ is the $(d+1) \times (d+1)$ matrix with its ith column equal to $(p_i, 1)$.

The ***sign*** of an ordered simplex is the sign of the determinant of the extended matrix of the simplex.

An ***affinely dependent*** set of points $P = \{p_1, \ldots, p_k\}$ is a set of points such that one of the points is an affine combination of the others.

The ***affine space*** spanned by a set of points $P = \{p_1, \ldots, p_k\}$, with $p_i \in \mathcal{R}^d$, is the set of all affine combinations of points of P. It is an affine subspace of $\mathcal{R}^d$.

The ***affine k-dimensional subspace*** of $\mathcal{R}^d$ $(k \leq d)$ is the set of all affine combinations of k affinely independent points $p_1, \ldots, p_k$ in $\mathcal{R}^d$.

A ***linear function*** is a function $h\colon \mathcal{R}^d \to \mathcal{R}$ such that $h(x_1, \ldots, x_d) = \sum_{i=1}^{d} a_i x_i + a_{d+1}$.

A linear function is ***homogeneous*** if $a_{d+1} = 0$.

The ***affine hyperplane*** induced by a linear function h is the set $h^0 = \{x \in \mathcal{R}^d \mid h(x) = 0\}$.

An affine hyperplane is a ***central hyperplane*** if h is a homogeneous linear function.

An ***oriented hyperplane*** is a hyperplane, together with a choice of a positive side for the hyperplane. This amounts to choosing a (homogeneous or affine) linear function h to generate it, together with all those of the form αh, $\alpha > 0$.

A ***reorientation*** of an oriented hyperplane is a swapping of the negative and positive sides of the hyperplane (or, changing the generating linear function h to $-h$).

The ***open half-spaces*** induced by an oriented hyperplane h are $h^+ = \{\underline{x} \mid h(x) > 0\}$ (the ***positive side*** of h^0) and $h^- = \{x \mid h(x) < 0\}$ (the ***negative side*** of h^0). The sets h^+, h^0, and h^- form a partition of $\mathcal{R}^d$: $\mathcal{R}^d = h^+ \cup h^- \cup h^0$, and h^+, h^-, and h^0 are pairwise disjoint.

The ***closed half-spaces*** induced by h are $h^+ \cup h^0$ and $h^- \cup h^0$.

A ***convex combination*** of a set of points $\{p_1, \ldots, p_n\}$ is a point of the form $\sum_{i=1}^{n} \alpha_i p_i$ with $\alpha_i \in \mathcal{R}$, $\alpha_i > 0$, and $\sum_{i=1}^{n} \alpha_i = 1$.

The ***segment*** with endpoints $p_1 \neq p_2$ is the set of all convex combinations of p_1 and p_2.

A set of points $\{p_1, \ldots, p_k\}$ is ***convexly independent*** if no point is a convex combination of the others. The points are also said to be in ***convex position***.

A ***convex set*** in $\mathcal{R}^d$ is a set $S \subseteq \mathcal{R}^d$ such that if p_1 and p_2 are distinct points in S, then the segment with endpoints p_1 and p_2 is contained in S.

The ***convex hull*** of a finite set of points P is the set of all convex combinations of points of P.

A ***convex polytope*** is the convex hull of a finite set of points. Its boundary consists of faces of dimension 0 (*vertices*), 1 (*edges*), ..., $d-1$ (*facets*).

The ***face description*** of a convex polytope is a data structure storing information about all the faces and their incidences.

A ***convex polygon*** is the convex hull of a finite set of points in $\mathcal{R}^2$.

A ***vector configuration*** [***point configuration***] of dimension d is a finite set of n vectors $\{v_1, \ldots, v_n\}$ $(v_i \in \mathcal{R}^d)$ spanning $\mathcal{R}^d$ [points $\{p_1, \ldots, p_n\}$ $(p_i \in \mathcal{R}^d)$ affinely spanning $\mathcal{R}^d$].

A configuration is ***labeled*** if its elements are given as an ordered set. (It may be given as the set of columns of a $d \times n$ matrix with real entries.)

The ***rank*** of a vector configuration [point configuration] in $\mathcal{R}^d$ is the number d $[d+1]$.

A set of vectors [points] in $\mathcal{R}^d$ is in ***general position*** if every subset of d elements is a basis [simplex].

An ***affine configuration*** (or ***acyclic vector configuration***) is a configuration with a central hyperplane containing all the vectors of the configuration on one side.

A ***reorientation*** of a vector configuration $V = \{v_1, \ldots, v_n\}$ is a vector configuration $V' = \{v'_1, \ldots, v'_n\}$ with each v'_i equal to either v_i or $-v_i$.

A ***reorientation class*** is the set of all labeled vector configurations which are reorientation equivalent.

A ***point configuration*** $P \subset \mathcal{R}^d$ ***induced by an acyclic vector configuration*** $V \subset \mathcal{R}^{d+1}$ contained in a half-space h^+ is the set of all points p obtained as follows: take the affine plane h' in h^+ parallel to h and tangent to the unit sphere S^d in $\mathcal{R}^{d+1}$; the intersection of the line through vector $v \in V$ with the plane h' is a point $p \in h'$. $\mathcal{R}^d$ is identified with the affine plane h'.

A ***semi-space*** of a vector configuration [point configuration] V induced by an oriented central hyperplane [affine hyperplane] h is the set of indices of the elements in V lying on one side of the hyperplane.

A ***semi-space of a vector configuration*** [***point configuration***] V is a semi-space induced by some hyperplane h.

The ***order type*** of a vector or point configuration V is the collection of all semi-spaces of V.

Isomorphic vector or point configurations are configurations having the same order type, after possibly relabeling their elements.

A ***k-set*** of a point configuration P is a semi-space of P of size k $(0 \le k \le n)$.

A ***centerpoint*** of a point configuration P of size n is a point q, not necessarily in P, such that if h is a hyperplane containing q there are at least $\lceil \frac{n}{d+1} \rceil$ points in each semi-space induced by h.

A ***ham-sandwich cut*** is a hyperplane that simultaneously bisects d point configurations $P_1, P_2, \ldots, P_d$ in $\mathcal{R}^d$.

Facts:

1. A basis of the vector space $\mathcal{R}^d$ has d elements and a simplex of the affine space $\mathcal{R}^d$ has $d+1$ elements.

2. The rank of the $d \times n$ matrix associated with an n-vector configuration in $\mathcal{R}^d$ is d; the rank of the matrix associated with a point configuration in $\mathcal{R}^d$, extended with a row of 1s, is $d+1$.

3. The determinant of a $d \times d$ matrix whose columns are a basis of $\mathcal{R}^d$ and the determinant of the $(d{+}1) \times (d{+}1)$ extended matrix of a simplex in $\mathcal{R}^d$ are nonnull.

4. If $\{v_1, \ldots, v_d\}$ is a basis, then for any vector v_{d+1}, $\{v_1, \ldots, v_d, v_{d+1}\}$ is linearly dependent.

5. The intersection of linear subspaces [affine subspaces, convex subspaces] of $\mathcal{R}^d$ is linear [affine, convex].

6. The intersection of k central hyperplanes [affine hyperplanes] in $\mathcal{R}^d$ $(k \le d)$ is a linear subspace [affine subspace]. Its dimension is at least $d-k$.

7. Every affine subspace of $\mathcal{R}^d$ is a convex set.

8. *Carathéodory's theorem*: Each point in the convex hull of a set of points $P \subset \mathcal{R}^d$ lies in the convex hull of a subset of P with at most $d+1$ points.

9. *Radon's theorem*: Each set of at least $d+2$ points in $\mathcal{R}^d$ can be partitioned into two disjoint sets whose convex hulls intersect in a nonempty set.

10. *Helly's theorem*: Let $\mathcal{S}$ be a finite family of n convex sets in $\mathcal{R}^d$ $(n \geq d+1)$. If every subfamily of $d+1$ sets in $\mathcal{S}$ has a nonempty intersection, then there is a point common to all the sets in $\mathcal{S}$.

11. Every point configuration admits a centerpoint.

12. For every d configurations of points in $\mathcal{R}^d$, there exists a ham-sandwich cut.

13. *Upper bound theorem*: The number of facets of the convex hull of an n-point configuration in $\mathcal{R}^d$ is $O(n^{\lfloor d/2 \rfloor})$. This bound is obtained for configurations of points on the moment curve $P = \{p(t) \mid t \in \{t_1, \ldots, t_n\} \subseteq \mathcal{R}\}$, where $p(t) = (t, t^2, \ldots, t^d) \in \mathcal{R}^d$.

14. The number of semi-spaces of a rank $d+1$ vector or point configuration of n elements is $O(n^d)$. The maximum is attained for points in general position.

15. For $d = 2$, let $e_k(n)$ denote the maximum number of k-sets of any planar n-point configuration. Then $\Omega(n \log k) \leq e_k(n) \leq O(nk^{\frac{1}{3}})$.

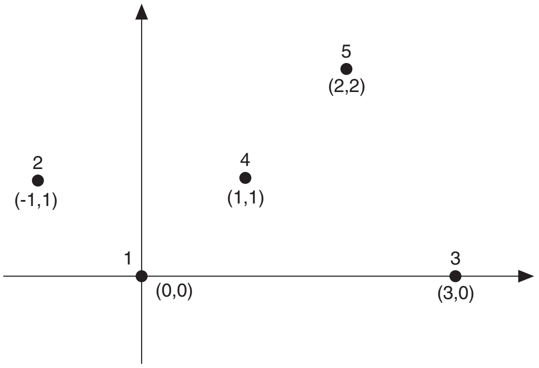
16. *Erdős-Szekeres problem*: If $c(k)$ is the maximum number of planar points in general position such that no k are in convex position, then $2^{k-2} \leq c(k) \leq \binom{2n-4}{n-2}$.

17. The face description of the convex hull of a point set of size n in $\mathcal{R}^d$ can be computed optimally in $O(n \log n)$ time if $d = 2$ or $d = 3$, and $O(n^{\lfloor \frac{d}{2} \rfloor})$ time for $d > 3$.

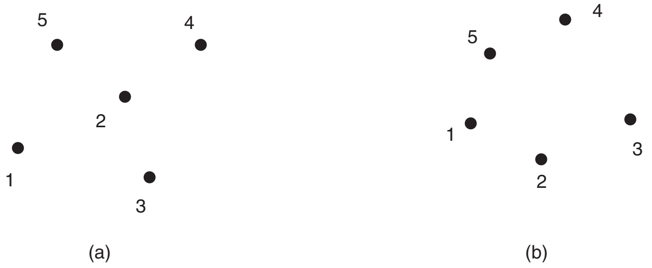
18. A ham-sandwich cut in dimension 2 can be found in linear time.

Examples:

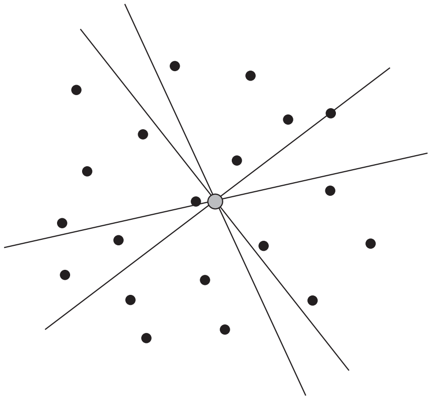
1. The configuration of points in the following figure is given by the columns of the matrix $\begin{pmatrix} 0 & -1 & 3 & 1 & 2 \\ 0 & 1 & 0 & 1 & 2 \end{pmatrix}$. It is not in general position: the three points 1, 4, and 5 are collinear. The extended matrix is $\begin{pmatrix} 0 & -1 & 3 & 1 & 2 \\ 0 & 1 & 0 & 1 & 2 \\ 1 & 1 & 1 & 1 & 1 \end{pmatrix}$. Because $\det \begin{pmatrix} 0 & -1 & 3 \\ 0 & 1 & 0 \\ 1 & 1 & 1 \end{pmatrix} < 0$, the simplex 123 is negative. Some semi-sets are: $\{3\}$ (1-set), $\{2,5\}$ (2-set), $\{1,3,4\}$ (3-set), etc. The convex hull is $\{1,3,5,2\}$.



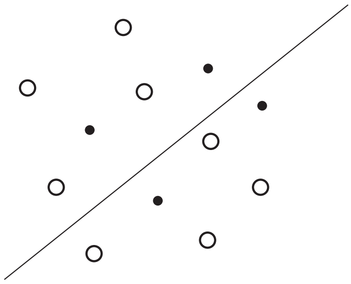
2. The two configurations of points from the figure of Example 1 and part (a) of the following figure are isomorphic, but those in parts (a) and (b) of the following figure are not. This can be seen because, for example, they have different numbers of points on their convex hulls.



3. The grey point in the following figure is a centerpoint of the point configuration of black points. Some of the separating lines have been shown: they have at least $\frac{1}{3}$ of the points on each side.



4. The line in the following figure is a ham-sandwich cut: it simultaneously bisects the black and the white points.



13.1.2 LINE AND HYPERPLANE ARRANGEMENTS

Line arrangements and affine point configurations in the plane are related via polar-duality, a transformation which is better understood in terms of 3-dimensional vectors and central planes or using the projective and spherical models. Several types of combinatorial data can be directly translated from the primal setting to the polar. As a consequence, theorems and algorithms on line arrangements follow directly from their counterparts on point configurations, and vice versa. This powerful tool has been used successfully in computational geometry for the design of efficient algorithms. It also generalizes to higher dimensions, where hyperplane arrangements are polar-dual to point configurations in $\mathcal{R}^d$.

Definitions:

A (***Euclidean***) ***line in*** $\mathcal{R}^2$ is an affine subspace of dimension 1. A line is induced by a linear function $l(x, y) = ax + by + c$ and any of its multiples of the form αl. A line is ***oriented*** if a direction has been chosen for it. Its induced half-spaces are called half-planes and denoted by l^+ and l^-.

A ***nonvertical line*** is a line given by an equation of the form $y = ax + b$, where a is called the ***slope*** and b the y-intercept of the line. It is oriented in increasing order of the x-coordinates of its points and its induced half-planes are above/below it.

A (***Euclidean***) ***line arrangement*** is a set $\mathcal{L} = \{l_1, \ldots, l_n\}$ of planar lines, not all of them going through the same point; that is, $\bigcap_{i=1}^{n} l_i = \emptyset$. If the lines are oriented, this is an ***arrangement of oriented lines***. It is ***labeled*** if it is given as an ordered set.

A line arrangement is in ***general position*** if no three lines have a point in common.

An ***x-monotone curve*** is a curve intersecting each vertical line in exactly one point.

A ***half-plane intersection*** is the planar region lying in the intersection of a finite set of half-planes. It is described by the (circular) list of the lines incident to its boundary.

An ***upper envelope*** [***lower envelope***] of a nonvertical line arrangement is the boundary of the half-plane intersection of the half-planes above [below] the lines of the arrangement.

The ***k-level*** in a nonvertical arrangement of n lines $(1 \leq k \leq n)$ is the lower boundary of the set of points in $\mathcal{R}^2$ having exactly k lines above and $n - k$ below.

The ***cell of a line arrangement*** is a connected component of the complement in $\mathcal{R}^2$ of the union of the points on the lines.

The ***zone of a line*** l ***in an arrangement*** $\mathcal{L}$ $(l \notin \mathcal{L})$ is the set of cells of the arrangement $\mathcal{L}$ intersected by l.

A ***central plane arrangement*** in $\mathcal{R}^3$ is a finite set of central planes. The arrangement is ***oriented*** if the planes are oriented.

An ***acyclic*** (or ***affine***) ***central plane arrangement*** in $\mathcal{R}^3$ is a central plane arrangement such that there is a point in $\mathcal{R}^3$ that lies on the positive side of all these planes.

The (***standard***) ***line arrangement*** induced by a central plane arrangement is the arrangement of the lines of intersection of the central planes with an affine plane h in $\mathcal{R}^3$ that is not parallel with any plane of the arrangement. If the central planes are oriented, an orientation is induced on the lines by keeping the positive side of a line within the positive side of the corresponding plane.

A ***big circle*** is the intersection of the unit sphere S^2 in $\mathcal{R}^3$ with a central plane. If the plane is oriented, the circle is given an orientation so that the positive side of the plane lies on the left of the circle.

A ***big-circle arrangement*** is the intersection of a central plane arrangement with the unit sphere S^2 in $\mathcal{R}^3$. It is oriented if the planes are oriented.

The ***big-circle arrangement induced by a central plane arrangement*** is the arrangement of the big circles of intersection of the central planes with the sphere S^2 in $\mathcal{R}^3$. It is oriented if the planes are oriented.

The ***projective plane*** P^2 is the sphere S^2 in $\mathcal{R}^3$ with the antipodal points identified.

A ***projective line*** is the projective curve induced by identifying the antipodal points of a big circle on S^2.

A ***projective line arrangement*** is a finite set of projective lines in the projective plane P^2.

The ***projective line arrangement induced by a central plane arrangement*** is the projective arrangement obtained by the antipodal point identification of the big-circle arrangement on S^2 induced by the central plane arrangement.

An ***arrangement graph*** is a graph associated with a Euclidean or projective line arrangement, or a big-circle arrangement. Its ***vertices*** correspond to intersection points of lines (or circles) and its ***edges*** correspond to line (or arc) segments between two intersection points.

Note: For the Euclidean case, typically only the bounded line segments are considered as edges (but by adding extra dummy vertices "at infinity", the infinite extremities of each line among the edges can be included). For the Euclidean or spherical case, if the lines are oriented, the arrangement graph is directed, with the edges oriented to be compatible with the orientation of the lines or circles.

Isomorphic arrangements are arrangements having isomorphic arrangement graphs. (This applies to Euclidean lines, big-circles (oriented or not), and projective lines.)

A ***polar-duality of vectors and central planes*** in $\mathcal{R}^3$ is a mapping $\mathcal{D}$ associating a vector $v \in \mathcal{R}^3$ with an oriented central plane having v as its normal vector, and vice versa.

A ***polar-duality of points and lines*** in the affine space $\mathcal{R}^2$ is any mapping $\mathcal{D}$ associating a point $p \in \mathcal{R}^2$ with an oriented line l in $\mathcal{R}^2$ and vice versa, by the following general procedure: map the points to vectors via some imbedding of $\mathcal{R}^2$ as an affine plane in $\mathcal{R}^3$, apply the polar-duality of vectors and central planes, and then intersect the polar central planes with some affine plane (identified with $\mathcal{R}^2$) to get lines.

A (***standard***) ***affine polar-duality*** is a mapping $\mathcal{D}$ between nonvertical lines and points in $\mathcal{R}^2$, associating the point $(a, -b)$ with the line $y = ax + b$, and vice versa.

A ***Euclidean hyperplane*** [***central hyperplane***] ***arrangement*** in $\mathcal{R}^d$ is a finite set $\mathcal{H} = \{h_1, \ldots, h_n\}$ of affine hyperplanes [central hyperplanes], not all of them going through the same point. If the hyperplanes are oriented, the arrangement is oriented.

The following are generalizations to an arbitrary affine space $\mathcal{R}^d$ [vector space $\mathcal{R}^{d+1}$] of previously defined concepts in affine dimension 2 [vector space $\mathcal{R}^3$]:

- ***arrangements of big*** $(\boldsymbol{d-1})$***-spheres*** on S^d generalize big-circle arrangements on S^2;
- ***projective arrangements*** of hyperplanes in P^d generalize projective arrangements of lines in P^2;
- the ***polar-duality*** between vectors and central hyperplanes in $\mathcal{R}^{d+1}$ associates with a vector the hyperplane normal to it;

- the ***face lattice*** of a hyperplane (central, affine, projective) or sphere arrangement, a data structure storing information on faces and their incidences, generalizes the arrangement graph, and is used to define isomorphism of arrangements.
- the ***k-level*** in an affine arrangement of nonvertical hyperplanes is the lower boundary of the set of points having exactly k hyperplanes above them.

Facts:

1. A bounded cell in a Euclidean line arrangement is a convex polygon.

2. The k-level of a nonvertical line arrangement is an x-monotone piecewise linear curve incident with vertices and lines of the arrangement.

3. The upper envelope is the 0-level of an arrangement of nonvertical lines.

4. In a simple big-circle arrangement, every pair of big circles intersects in exactly two points, which are antipodal on the sphere.

5. The arrangement graphs of planar line arrangements or spherical big-circle arrangements are planar imbedded graphs. The arrangement graph of a projective line arrangement is projective-planar. The *faces* or *cells* of these graphs are the connected components of the complement of the union of lines or circles.

6. The association among central plane arrangements, big-circle arrangements, and projective arrangements preserves isomorphisms. The standard association of an affine line arrangement and big-circle arrangement to an acyclic plane arrangement preserves isomorphisms.

7. In a simple Euclidean arrangement of n lines, the number of vertices is $\binom{n}{2}$, the number of segments (bounded or unbounded) is n^2, and the number of cells (bounded or unbounded) is $\binom{n}{2} + n + 1$. No nonsimple arrangement exceeds these values.

8. *Zone theorem*: The total number of edges (bounded or unbounded) in a zone of an arrangement of n lines is at most $6n$.

9. $\mathcal{D}(\mathcal{D}(v)) = v$ and $\mathcal{D}(\mathcal{D}(h)) = h$, for every vector v and hyperplane h.

10. *Incidence preserving*: If $v \in h$, then $\mathcal{D}(h) \in \mathcal{D}(v)$, for every vector v and hyperplane h.

11. *Orientation preserving*: If $v \in h^+$, then $\mathcal{D}(h) \in \mathcal{D}(v)^+$, for every vector v and hyperplane h.

12. *Basic properties of the standard affine polar-dual transformation*:

- *polar-duality preserves above/below properties*: if a point p is above line l, then the polar line $\mathcal{D}(p)$ is below the polar point $\mathcal{D}(l)$;
- the polar-dual of a configuration of points P is an arrangement of nonvertical lines $\mathcal{L} = \mathcal{D}(P)$, and vice versa;
- the polar-dual of a set of points given in increasing order of their x-coordinates is a set of lines given in increasing order of their slopes;
- the polar-dual of the set of points on the convex hull of P is the set of lines on the upper and lower envelopes of the polar arrangement $\mathcal{D}(P)$; convex hull computation dualizes to half-plane intersection;
- semi-spaces of P dualize to vertices, edges, and cells of the polar arrangement $\mathcal{D}(P)$;
- isomorphic arrangements of lines dualize to isomorphic configurations of points;

- the polar-duals of lines p_ip_j inducing $(k-1)$-sets and k-sets in a point configuration $P = \{p_1, \ldots, p_n\}$ are the vertices $l_i \cap l_j$ on levels k and $n-k$ of the polar-dual arrangement $L = \{l_1, \ldots, l_n\}$.

13. The polar-dual of an acyclic vector configuration in $\mathcal{R}^3$ is an acyclic central plane arrangement.

14. The upper envelope of a line arrangement can be computed optimally in $O(n \log n)$ time.

15. The arrangement graph of a line arrangement can be computed in $O(n^2)$ time and space.

16. The face incidence lattice of a hyperplane arrangement in $\mathcal{R}^d$ can be computed in $O(n^d)$ time and space.

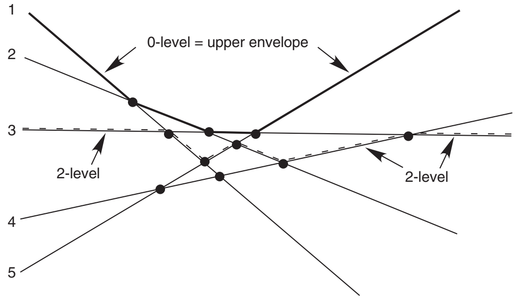
17. The standard polar-duality is ubiquitously used in computational geometry. For example, it is used to derive algorithms for half-plane intersection from convex hull algorithms, to translate between line slope and point x-coordinate selection, and to compute the visibility graph in $O(n^2)$ time using the polar-dual arrangement graph. See [Ed87] (Chapter 12) for a collection of such problems.

18. In computational geometry, k-levels are related to the furthest k-neighbors Voronoi diagrams via a lifting transformation that reduces the computation of dimension d Voronoi diagrams to dimension $d + 1$ arrangements of hyperplanes.

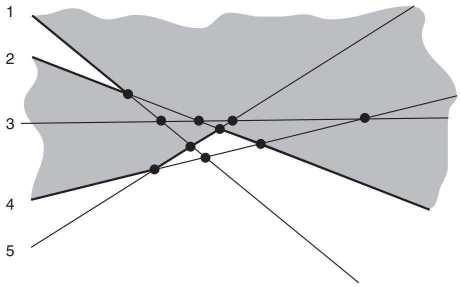
19. k-levels in arrangements, as polar-duals to k-sets, have an abundance of applications in statistics.

Examples:

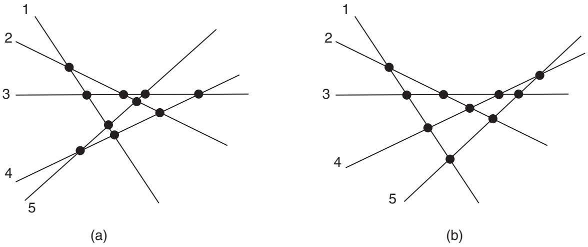
1. The following figure shows a line arrangement in general position. The arrangement graph has 10 vertices corresponding to the black points (which could be labeled with pairs of indices of lines such as $12, 13$, etc.), 15 edges corresponding to the bounded line segments such as $(12, 13)$, and $2 \times 5 = 10$ unbounded edges. The upper envelope (0-level), whose list of lines is $\{1, 2, 3, 5\}$, is shown highlighted. The dashed piecewise linear curve is the 2-level.



2. The zone of line 3 in the line arrangement $\{1, 2, 4, 5\}$ from the figure of Example 1 is depicted in the following figure. It has five cells (one bounded, four unbounded), whose boundaries sum up to 12 segments.

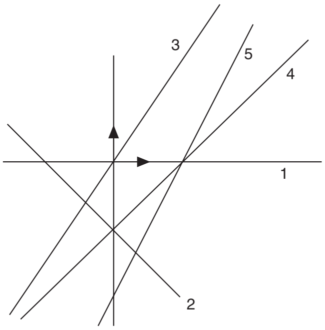


3. The line arrangements in the figure for Example 1 and part (a) of the following figure are isomorphic. Those in parts (a) and (b) of the following figure are not isomorphic.



(a) (b)

4. The following figure illustrates the standard polar-duality. The arrangement is polar-dual to the configuration of points in the figure of §13.1.1, Example 1; hence the lines are given by the equations 1: $y = 0$, 2: $y = -x-1$, 3: $y = 3x$, 4: $y = x-1$ and 5: $y = 2x-2$. In the primal configuration, point 2 is above line 13. In the polar-dual, line 2 is below the intersection point of lines 1 and 3.



13.1.3 PSEUDOLINE ARRANGEMENTS

Pseudoline arrangements represent a natural generalization of line arrangements, retaining incidence and orientation properties, but not straightness. They provide a topological representation for rank 3 oriented matroids (see §13.1.4), which in turn abstract combinatorial properties of vector configurations and oriented line arrangements.

Definitions:

A ***pseudoline*** is a planar curve (which may be given an orientation). It is ***x-monotone*** if the curve is x-monotone.

A ***pseudoline arrangement*** is a finite collection of simple planar curves that intersect pairwise in exactly one point, where they cross, and not all of which have a point in common. It is ***labeled*** if the pseudolines are given in a fixed order $\{l_1, \ldots, l_n\}$ and ***oriented*** if the pseudolines are oriented.

A pseudoline arrangement is ***realizable*** or ***stretchable*** if it is isomorphic to a line arrangement.

Note: The following terms, defined in §13.1.1 and §13.1.2 for line arrangements, have straightforward generalizations to pseudoline arrangements: open half-planes, general position, cell, arrangement graph, isomorphism, upper/lower envelope, k-level, zone.

Facts:

1. Every arrangement of pseudolines is isomorphic to an arrangement of x-monotone piecewise linear pseudolines (a wiring diagram such as shown in the figure of Example 2).

2. The arrangement graph of a pseudoline arrangement in general position has $\binom{n}{2}$ vertices, n^2 edges, and $\binom{n}{2} + n + 1$ faces.

3. The number of edges in a zone of a pseudoline in a pseudoline arrangement is at most $6n$.

4. Let $e_k(n)$ be the number of edges on the k-level of a pseudoline arrangement. Then $\Omega(n \log k) \leq e_k(n) \leq O(nk^{\frac{1}{3}})$.

5. The logarithm of the number of isomorphism classes of pseudoline arrangements is $\Theta(n^2)$. The same number for line arrangements is $\Theta(n \log n)$.

6. There exist nonstretchable pseudoline arrangements.

7. It is NP-hard to decide whether a pseudoline arrangement is stretchable.

8. Pseudoline stretchability is decidable in PSPACE.

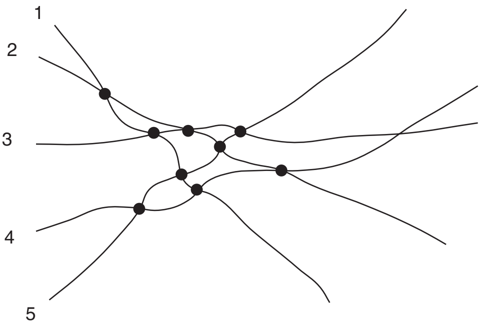
9. Assume that a predicate is given for deciding when the intersection point of two pseudolines is above or below a third pseudoline. Then the algorithms for computing the upper envelopes, half-space intersection, or the arrangement graph of a line arrangement can be adapted to work for pseudoline arrangements.

10. In computational geometry, some algorithmic solutions can be found by reducing the problem to structures behaving like pseudolines — for example, computing the boundary of a union or intersection of unit circles in $\mathcal{R}^2$, all having at least one point in common.

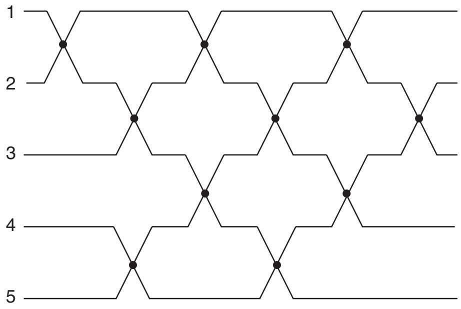
11. It is an open problem whether better algorithms can be devised by making explicit use of the straightness of the lines in geometric problems. So far, the only problem where an explicit gap in efficiency between lines and pseudolines has been displayed is in the number of comparisons needed to sort the x-coordinates of the vertices of line versus x-monotone pseudoline arrangements.

Examples:

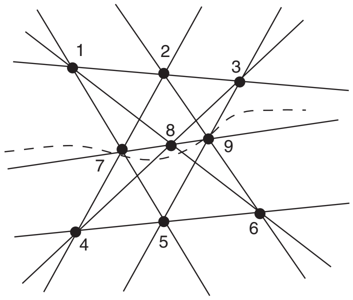
1. The pseudoline arrangement in the following figure is stretchable, because it is isomorphic to the line arrangement in the figure of §13.1.2, Example 1.



2. The following figure shows a standard way of representing a pseudoline arrangement as an x-monotone piecewise linear curve arrangement called a *wiring diagram*. The arrangement is the same as in the figure of Example 1.



3. *A nonstretchable pseudoline arrangement*: The theorem of Pappus in plane geometry states that if the points 1, 2, 3 and 4, 5, 6 are collinear and in this order on two lines, then the three intersection points of the pairs of lines $7 = (15, 24)$, $8 = (16, 34)$, and $9 = (26, 35)$ are also collinear. See the following figure. The perturbed arrangement obtained by replacing the line through $7, 8, 9$ with the dashed pseudoline is not stretchable, since it violates the theorem of Pappus.



13.1.4 ORIENTED MATROIDS

General oriented matroids are abstractions of vector configurations and oriented hyperplane arrangements. Affine oriented matroids model the corresponding situation in affine spaces. They capture in various types of data structures (semi-spaces, chirotopes, Radon partitions, arrangement graphs, hyperline sequences) combinatorial information about n-element configurations. This forms the basis of the classification of all n-point sets into a finite number of equivalence classes. Each data structure satisfies a set of simple properties, or axioms, which characterize a wider class of objects collectively referred to as oriented matroids.

To simplify the exposition, in some cases only the axiomatization corresponding to points in general position will be presented. Not all oriented matroids arise geometrically from vector sets, but they do have a topological representation via pseudohyperplane arrangements. In rank 3, affine oriented matroids are modeled by pseudoline arrangements. Many geometric algorithms working with line arrangements or, by polarity, point configurations, make use of no more than oriented matroid properties and can be extended to pseudolines.

As potential applications, oriented matroids lay the foundations for a rigorous theory of geometric program verification and testing.

Definitions:

Let $E_n = \{1, \ldots, n\}$ and $\overline{E}_n = \{1, \ldots, n\} \cup \{\overline{1}, \ldots, \overline{n}\}$. Triplets $(i, j, k) \in \overline{E}_n^3$ are denoted ijk.

A ***signed set*** $X = (X^+, X^-)$ is a partition of a finite set X into a ***positive part*** X^+ and a ***negative part*** X^-. That is, $X = X^+ \cup X^-$ and $X^+ \cap X^- = \emptyset$. In E_n a signed set may be denoted as a signed sequence of indices, such as $1\,\overline{2}\,3\,4$ for $(\{1, 3, 4\}, \{2\})$.

The ***complement of a signed set*** $X = (X^+, X^-)$ is the set $-X = (X^-, X^+)$.

The ***support of a signed set*** $X = (X^+, X^-)$ is the unsigned set X.

The ***size of a signed set*** $X = (X^+, X^-)$ is the size of the support of X.

The ***signed double covering*** of a finite set X is the set $\overline{X} = X^+ \cup X^-$, where $X^+ = X$ and $X^- = \{\overline{x} \mid x \in X\}$ is a signed distinct copy of X (its elements called *negated elements*), $X^+ \cap X^- = \emptyset$. If $x \in X^-$, then $\overline{x}$ is the corresponding nonnegated element in X^+.

A ***basis*** of a vector configuration [point configuration] $V \subset \mathcal{R}^d$ is a subset of V, identified by a d-set of indices, which is a basis [simplex] of the ambient space $\mathcal{R}^d$. A ***signed basis*** is an ordered basis together with its sign.

The ***chirotope*** of an ordered vector configuration [point configuration] is the set of all signed bases of V.

An ***alternating function*** is a function $f\colon E_n^d \to R$ such that the sign of $f(i_1, \ldots, i_d)$ is preserved under an even permutation and negated under an odd permutation of the d-tuple $(i_1, \ldots, i_d)$.

An ***antisymmetric function*** is a function $f\colon \overline{E}_n^d \to \mathcal{R}$ such that its sign changes when one of the parameters is negated. [For example, $f(\overline{i}_1, i_2, \ldots, i_d) = -f(i_1, i_2, \ldots, i_d)$.]

The (***rank 3***) ***Grassmann-Plücker relations*** are the identities

$$[1\,2\,3][1\,4\,5] - [1\,2\,4][1\,3\,5] + [1\,2\,5][1\,3\,4] = 0$$

satisfied by the determinants $[i\,j\,k] = \det(v_i, v_j, v_k)$, for any five vectors $v_i, 1 \leq i \leq 5$.

The (***rank d***) ***Grassmann-Plücker relations*** are the identities

$$[i_1 \ldots i_{d-2} 1\,2][i_1 \ldots i_{d-2} 3\,4] - [i_1 \ldots i_{d-2} 1\,3][i_1 \ldots i_{d-2} 2\,4] + [i_1 \ldots i_{d-2} 1\,4][i_1 \ldots i_{d-2} 2\,3] = 0$$

satisfied by the determinants $[i_1 \dots i_{d-2} j\, k] = \det(v_{i_1}, \dots, v_{i_{d-2}}, v_j, v_k)$, for any $d+2$ vectors v_{i_j} $(1 \le j \le d{-}2)$ and v_i $(1 \le i \le 4)$.

Chirotope axioms (***rank d***): A function $\chi\colon \overline{E}_n^d \to \{-1, 0, +1\}$ is a chirotope of rank d if it satisfies the following conditions:

- χ is alternating and antisymmetric;
- for any $d+2$ generic points $i_1 \dots i_{d-2} 1\,2\,3\,4$, the signs $\chi(i_1 \dots i_{d-2} j\, k)$ of the six triplets involved in the Grassmann-Plücker relations are such that equality is possible.

A ***uniform chirotope*** is a chirotope function that takes nonzero values on all d-tuples.

Chirotope axioms (***uniform, rank 3***): A function $\chi\colon \overline{E}_n^3 \to \{-1, +1\}$ is a uniform chirotope of rank 3 if it satisfies the following conditions:

- χ is alternating and antisymmetric;
- for any five generic points a, b, i, j, k, if $\chi(a\, b\, i) = \chi(a\, b\, j) = \chi(a\, b\, k) = +1$ and $\chi(a\, i\, j) = \chi(a\, j\, k) = +1$, then $\chi(a\, i\, k) = +1$.

The chirotope χ is ***affine*** if, in addition, it satisfies the following axiom:

- for any four points i, j, k, l, if $\chi(i\, j\, k) = \chi(i\, k\, l) = \chi(i\, l\, j) = +1$, then $\chi(j\, k\, l) = +1$.

An ***oriented matroid given by a chirotope*** is an abstract set of points labeled $\{1, \dots, n\}$, together with a function χ satisfying the chirotope axioms.

The ***circuit*** of a set of labeled vectors $V = \{v_1, \dots, v_n\}$ is the signed set $C = (C^+, C^-)$, where $C^+ = \{j \mid \alpha_j > 0\}$ and $C^- = \{j \mid \alpha_j < 0\}$, of indices of the nonnull coefficients α_j in a *minimal* linear dependency $V' = \{v_{i_1}, \dots, v_{i_k}\}$ of V with $\sum_{j=1}^{k} \alpha_j v_{i_j} = \underline{0}$. If C is a circuit, its complement $-C$ is also a circuit.

A ***Radon partition*** of a set of labeled points P is a signed set $C = (C^+, C^-)$ of points of P such that the convex hull of the points in C^+ intersects the convex hull of the points in C^-.

A ***minimal Radon partition*** (or ***circuit***) is a Radon partition whose support is minimal with respect to set inclusion.

An ***oriented matroid*** of an ordered vector [point] configuration given by its circuits is the set of all circuits of V.

A set $\mathcal{C}$ of signed subsets of E_n satisfies the ***circuit axioms*** if

- $\emptyset \notin \mathcal{C}$;
- if $C \in \mathcal{C}$ then $-C \in \mathcal{C}$;
- (*minimality*): if $C = (C^+, C^-)$ is a circuit, then no subset of the support of $\mathcal{C}$ is the support of another circuit;
- (*exchange*): if C_1 and C_2 are two circuits such that $C_1 \ne -C_2$ and $e \in C_1^+ \cap C_2^-$, then there exists another circuit D such that $e \notin D$, $D^+ \subset C_1^+ \cup C_2^+$, and $D^- \subset C_1^- \cup C_2^-$.

The ***oriented matroid given by its circuits*** is an abstract set E_n together with a set of signed sets $\mathcal{C}$ satisfying the circuit axioms.

A ***cocircuit*** of a labeled vector configuration V is a signed set $C = (C^+, C^-)$ of E_n, induced by a subset of $d-1$ vectors spanning a central hyperplane h. For an arbitrary orientation of h, C^+ is the set of indices of elements in V lying in h^+ and C^- is the set of indices of elements in V lying in h^-.

The ***cocircuit axioms*** are the conditions obtained from the circuit axioms by replacing "circuit" with "cocircuit".

An ***oriented matroid given by its cocircuits*** is an abstract set E_n, together with a set of signed sets $\mathcal{C}$ satisfying the cocircuit axioms.

A ***circular sequence*** of period k is a doubly infinite sequence $(q_i)_{i\in\mathcal{Z}}$ with $q_i = q_{i+k}$ for all $i \in \mathcal{Z}$.

A ***signed permutation*** of a set S is a permutation of S whose elements are also assigned a sign; for example, $1\,\overline{3}\,4\,2$, where 3 is negative and 1, 2, and 4 are positive.

An ***alternating circular sequence*** is a circular sequence $(q_i)_{i\in\mathcal{Z}}$ with half-period k, defined with elements from a signed double covering $q_i \in \overline{X}$ and satisfying the property $q_i = \overline{q}_{i+k}$ for all $i \in \mathcal{Z}$.

A ***representation*** of an alternating circular sequence can be obtained from any of its subsequences of k consecutive elements (half period) $\{q_1, \ldots, q_k\}$.

A ***star*** (or ***rank 3 hyperline sequence***) associated with a point $p_i \in P \subseteq \mathcal{R}^2$ [vector $v_i \in V \subseteq \mathcal{R}^3$] is an alternating circular sequence of subsets of indices in $\overline{E}_n$ obtained by rotating an oriented line [oriented central plane] in counterclockwise order around p_i [the line through vector v_i] and recording the successive positions where it coincides with lines [central planes] defined by pairs of points (p_i, p_j) with $p_j \in P \setminus \{p_i\}$ [vectors (v_i, v_j), with $v_j \in V \setminus \{v_i\}$]. If a point p_j is encountered by the rotating line in the positive direction from p_i, it will be recorded as a positive index, otherwise it will be recorded as a negative index. When the points are not in general position, several may become simultaneously collinear with the rotating line, and they are recorded as one subset L^i_j. The sequence is denoted by a half-period $s_I = (L^i_1, L^i_2, \ldots, L^i_{k_i})$, where $L^i_j \subset \overline{E}_n \setminus \{i, \overline{i}\}$.

A ***cluster of stars*** (or ***rank 3 hyperline sequences***) ***associated with a point*** (***or vector***) ***configuration*** P is the ordered set of n stars $s_1, \ldots, s_n$, one for each point $p_i \in P$.

A ***uniform cluster of stars*** is a cluster of stars corresponding to a set of points in general position. (Each star is a sequence of individual indices.)

An ***oriented matroid of a vector*** (***or point***) ***set*** V ***given by its cluster of stars*** is the cluster of stars associated with V.

A ***star*** (or ***rank 3 hyperline sequence***) ***associated with an element*** c_i ***of a big-circle arrangement*** $C = \{c_1, \ldots, c_n\}$ on S^2 is an alternating circular sequence of subsets of indices in $\overline{E}_n$ obtained by traversing the oriented big circle in its given direction and recording in order the intersections of c_i with the other big circles c_j $(j \neq i)$. Each intersection is recorded as a signed index j: positive if c_j crosses c_i from left to right, negative otherwise.

The ***cluster of stars*** (or ***rank 3 hyperline sequences***) ***associated with a big-circle arrangement*** is the set of n stars $s_1, \ldots, s_n$, one for each circle $c_i \in C$.

The ***cluster of stars associated with an oriented central plane arrangement*** in $\mathcal{R}^3$ [***line arrangement in*** $\mathcal{R}^2$] is the cluster of stars of the big-circle arrangement associated with the central plane arrangement [to the central plane arrangement induced by the line arrangement via the imbedding of $\mathcal{R}^2$ as the plane $z = 1$ in $\mathcal{R}^3$].

The ***cluster of stars associated with a pseudoline arrangement*** [***a pseudoconfiguration of points***] is the generalization from straight lines to pseudolines obtained by recording the order of the vertices of the arrangement along a pseudoline (positive or negative according to whether the line crossing at that vertex comes from right or left) [the circular counterclockwise order of the pseudolines incident with a point].

A ***cluster of stars permutation*** is an ordered set of alternating circular sequences $s_1, \ldots, s_n$ with the property that the representative half-period of sequence s_i is a signed permutation of the set $E_n \setminus \{i\}$.

A ***chirotope function associated with a set of cluster of stars permutations*** $s_1, \ldots, s_n$ is a function $\chi\colon E_n^3 \to \{-1, +1\}$ defined by $\chi(i\,j\,k) = +1$ if, in the ith sequence s_i and in a half period of it where both j and k occur positively, j occurs before k. Otherwise $\chi(i\,j\,k) = -1$.

A set E_n, together with an ordered set of alternating circular sequences $s_1, \ldots, s_n$, satisfies the ***cluster of stars axioms*** (***uniform, rank 3***) if the set of sequences are cluster of star permutations whose associated chirotope function is alternating.

A (***uniform, rank 3***) ***oriented matroid given by its cluster of stars*** is a set E_n together with n alternating sequences satisfying the cluster of stars axioms.

An abstract set $\overline{E}_n$, together with a set of n^{d-2} (uniform) alternating sequences (indexed by $(d{-}2)$-tuples $(i_1, \ldots, i_{d-2})$), is an ***oriented matroid given by its hyperline sequences*** (***uniform, rank d***) if the chirotope function $\chi\colon E_n^d \to \{-1, +1\}$ associated with it is alternating. [The function $\chi\colon E_n^d \to \{-1, +1\}$ is defined by $\chi(i_1 \ldots i_{d-2} j\,k) = +1$ if in the star indexed by $i_1, \ldots, i_{d-2}$ and in a half period where both j and k occur positively, j occurs before k. Otherwise $\chi(i_1 \ldots i_{d-2} j\,k) = -1$.]

Deletion is the removal of a point (vector, line, etc.) from a configuration and recording the oriented matroid (chirotope, circuits, cluster of stars, etc.) only for the remaining points.

In a rank d central plane arrangement, the ***contraction*** on element i is obtained by identifying h_i with $\mathcal{R}^{d-1}$ and intersecting it with all the other hyperplanes to obtain a rank $d{-}1$ arrangement with one less element.

The ***oriented matroid obtained by a one-element deletion*** in the hypersequence representation is the matroid obtained by removing the element from all the hyperline sequences of the original oriented matroid, and discarding all hyperline sequences whose labels contain that element.

The ***oriented matroid obtained by a one-element contraction*** in the hypersequence representation is the matroid obtained by retaining only the hyperline sequences whose labels contain the element, and dropping it from the labels.

A ***rank 2 contraction*** of a cluster of stars is one of the stars.

A ***minor*** of an oriented matroid given by hyperline sequences is an oriented matroid obtained by a sequence of deletions and/or contractions.

A (***Euclidean***) ***pseudoconfiguration of points*** is a pair (P, L) with $P = \{p_1, \ldots, p_n\}$ a planar set of points and $L = \{l_1, \ldots, l_m\}$ a pseudoline arrangement, such that for every pair of distinct points (p_i, p_j) there exists a unique pseudoline $l_ij \in L$ incident with them.

If a pseudoline arrangement is intersected with a vertical line l_v $(x = -M)$, for some very large constant M, and all the vertices of the arrangement lie to the right of l_v, then the order in which the pseudolines in L cross v_h (decreasing by the y-coordinates of the crossings) is the (increasing) ***slope order of the pseudolines***.

The (***standard affine***) ***pseudo polar-duality*** is the association between an x-monotone pseudoline arrangement $L = \{l_1, \ldots, l_n\}$ given in slope order and a pseudo configuration of points (P, L'), $P = \{p_1, \ldots, p_n\}$, given in increasing order of the x-coordinates and with L' being x-monotone, satisfying the property that the cluster of stars associated with L and to P is the same.

Facts:

1. Cocircuits correspond to semi-spaces, when the defining hyperplane is incident with $d-1$ independent elements of the configuration.

2. In the rank d uniform oriented matroid associated with a vector configuration in general position in $\mathcal{R}^d$, all the d-tuples are bases, all the $(d+1)$-tuples are supports of circuits, and all the $(n-d+1)$-tuples are supports of cocircuits.

3. The oriented matroid associated with an affine vector configuration V and the affine oriented matroid associated with the affine point configuration induced by V are the same.

4. The chirotope function χ associated with the cluster of stars of a vector or point configuration is an alternating and antisymmetric function.

5. The two given systems of chirotope axioms are equivalent (for the uniform case).

6. The hyperline sequences of a contraction by one element of a central plane arrangement are the induced rank $(d-1)$ contraction by that element of the set of rank d hyperline sequences of the original arrangement.

7. The induced rank $(d-1)$ contraction of a set of rank d hyperline sequences is a rank $(d-1)$ set of hyperline sequences.

8. A minor of an oriented matroid (given by its hyperline sequences) is an oriented matroid.

9. For two labeled vector (or point) configurations V_1 and V_2, the following statements are equivalent:

- V_1 and V_2 have the same chirotope;
- V_1 and V_2 have the same order type;
- V_1 and V_2 have the same hyperline sequences;
- V_1 and V_2 have the same minors.

Moreover, for any reorientation of V_1 or V_2:

- V_1 and V_2 have the same oriented matroid given by circuits;
- V_1 and V_2 have the same oriented matroid given by cocircuits.

This justifies the unique name *oriented matroid* for the equivalence class of vector configurations with the same chirotope (or clusters, order type, etc.), and for a reorientation class of an oriented matroid.

10. For a labeled vector configuration V in $\mathcal{R}^{d+1}$, the following statements are equivalent:

- V is acyclic (affine);

- there is a labeled point configuration P in $\mathcal{R}^d$ whose oriented matroid (or order type or chirotope) is the same as the oriented matroid of V.

11. Multiplying the elements of a vector configuration by a positive scalar yields a vector configuration with the same oriented matroid. In particular, for any vector configuration V in $\mathcal{R}^{d+1}$, there exists an equivalent vector configuration on the d-sphere.

12. For any vector configuration, there exists a reorientation of some of its vectors which makes it affine.

13. The set of circuits of an affine (acyclic) vector configuration does not contain the *positive* cycle $(E_n, \emptyset)$.

14. Two projective line arrangements with the same arrangement graph have polar-dual configurations of points in the same reorientation class (and this can be generalized to arbitrary dimension d).

15. If a labeled vector configuration in $\mathcal{R}^3$ and a labeled oriented arrangement of central planes are polar-dual, then they have the same hyperline sequences (and this can be generalized to arbitrary dimension d).

16. The number of oriented matroids of rank d and size n is $2^{O(n^{d-1})}$.

17. The number of realizable oriented matroids of rank d and size n is $2^{O(n \log n)}$.

18. *Folkman-Lawrence topological representation theorem*: Every oriented matroid of rank d can be represented as a $(d-1)$-pseudosphere arrangement on S^d.

19. Every affine oriented matroid of rank 3 can be represented as a pseudoline arrangement and as a (polar-dual) pseudoconfiguration of points.

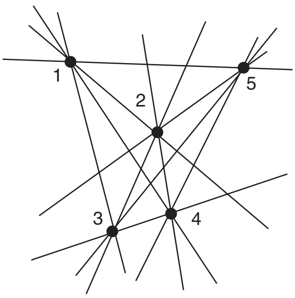
20. There exist nonrealizable oriented matroids of any rank.

21. Realizable oriented matroids cannot be characterized by a finite set of excluded minors.

Examples:

1. The function $\chi(i,j,k) = \text{sign}\det(v_i, v_j, v_k)$, for $v_l \in V = \{v_1, \ldots, v_n\} \subset \mathcal{R}^3$, is alternating antisymmetric.

2. The following figure shows an example of a point configuration in general position, together with the connecting lines.



Its oriented matroid is given by

- chirotope: 1 2 3−, 1 2 4−, 1 2 5+, 1 3 4+, 1 3 5+, 2 3 4+, 2 3 5+, 3 4 5+. The other signed triplets are computed by antisymmetry and alternation.
- minimal Radon partitions: $1\,\overline{2}\,\overline{3}\,4$, $1\,\overline{2}\,3\,5$, $1\,\overline{2}\,4\,5$, $\overline{1}\,3\,\overline{4}\,5$, $\overline{2}\,3\,\overline{4}\,5$ and their complements.

- cocircuits: $3\,4\,\overline{5}$, $2\,4\,5$, $2\,\overline{3}\,5$, $2\,3\,4$, $\overline{1}\,4\,5$, $1\,3\,\overline{5}$, $\overline{1}\,3\,4$, $1\,2\,5$, $1\,2\,\overline{4}$, $1\,2\,3$ and their complements.
- cluster of stars: $1\colon 3\,4\,2\,5$, $2\colon 1\,\overline{5}\,3\,4$, $3\colon 1\,\overline{4}\,\overline{5}\,\overline{2}$, $4\colon 5\,2\,1\,3$, and $5\colon 1\,2\,3\,4$. (An arbitrary half-period was chosen for the circular sequences.)

3. The oriented matroid given as a cluster of stars for the line arrangement in the figure of §13.1.2, Example 1 (or for the pseudoline arrangement in the figure of §13.1.3, Example 1) is

$$1\colon 2\,3\,5\,4,\quad 2\colon \overline{1}\,3\,5\,4,\quad 3\colon \overline{1}\,\overline{2}\,5\,4,\quad 4\colon 5\,\overline{1}\,\overline{2}\,\overline{3},\quad 5\colon \overline{4}\,\overline{1}\,\overline{2}\,\overline{3}.$$

The orientation of the lines is assumed to be in increasing order of the x-coordinates. Its minor by the deletion of element 3 is $1\colon 2\,5\,4$, $2\colon \overline{1}\,5\,4$, $4\colon 5\,\overline{1}\,\overline{2}$, and $5\colon \overline{4}\,\overline{1}\,\overline{2}$. Its contraction on point 3 is $\overline{1}\,\overline{2}\,5\,4$.

13.2 SPACE FILLING

Discrete geometry is the study of discrete arrangements of objects in Euclidean and non-Euclidean spaces. This subject dates back to the early 1610s when J. Kepler studied packings of Euclidean space with equally-sized spheres, formulating a conjecture about the greatest possible density of such a packing that was unsettled until the late 1990s. The modern systematic development of the subject began in the late 1940s with the work of L. Fejes Tóth. The Hungarian school he founded focused mainly on packing and covering problems. Two areas from discrete geometry, dense sphere packings and tilings, occupy a substantial part of this section on space filling. Both areas have been active areas of research for the past 75 years.

13.2.1 PACKING

The most important results on packings are centered around density and contact numbers, including kissing numbers, foam problems, and soft packings.

Definitions:

A ***convex body*** in $\mathcal{R}^d$ is a compact convex subset of $\mathcal{R}^d$ with nonempty interior.

A family $\mathcal{P} = \{K_1, K_2, \ldots\}$ of the convex bodies $K_1, K_2, \ldots$ in $\mathcal{R}^d$ forms a ***packing*** of $\mathcal{R}^d$ if no two of the convex bodies $K_1, K_2, \ldots$ have an interior point in common.

Let $\mathcal{P} = \{K_1, K_2, \ldots\}$ be a packing of $\mathcal{R}^d$ and let B_R be the closed ball of radius R centered at the origin in $\mathcal{R}^d$. The ***lower density*** and ***upper density*** of $\mathcal{P}$ are defined by

$$\underline{\delta}(\mathcal{P}) = \liminf_{R\to+\infty} \frac{\sum_{K_i \subset B_R} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)} \quad \text{and} \quad \overline{\delta}(\mathcal{P}) = \limsup_{R\to+\infty} \frac{\sum_{K_i \subset B_R} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)}.$$

If $\underline{\delta}(\mathcal{P}) = \overline{\delta}(\mathcal{P}) = \delta(\mathcal{P})$, then $\delta(\mathcal{P})$ is called the ***density*** of $\mathcal{P}$.

For a convex body $K \subset \mathcal{R}^d$, let $\delta(K)$ denote the largest (upper) density of packings by congruent copies of K in $\mathcal{R}^d$. In particular,

$\delta_T(K)$ = the largest (upper) density of packings by translates of K in $\mathcal{R}^d$;

$\delta_L(K)$ = the largest (upper) density of packings by lattice translates of K in $\mathcal{R}^d$.

Let $\mathcal{P} = \{B_1^d, B_2^d, \ldots\}$ be a packing of unit balls in $\mathcal{R}^d$ with centers $c_1, c_2, \ldots$. The ***Voronoi cell*** with center c_i is the convex polyhedral set $V_i = \{x \in \mathcal{R}^d \mid |x - c_i| = \min_j |x - c_j|\}$.

The ***kissing number*** problem asks for the maximum number $k(d)$ of nonoverlapping unit balls that can touch a unit ball in the d-dimensional Euclidean space $\mathcal{R}^d$.

The ***Hadwiger number*** (or ***translative kissing number***) of the convex body K in $\mathcal{R}^d$, denoted by $H(K)$, is the largest number of nonoverlapping translates of the convex body K that can all touch K.

The ***isoperimetric quotient*** of the convex body K in $\mathcal{R}^d$ is $\text{iq}(K) = \frac{(\text{Svol}(\text{bd}(K)))^d}{(\text{Vol}(K))^{d-1}}$, where Svol(bd($K$)) denotes the $(d-1)$-dimensional surface volume of the boundary bd(K) of K and Vol(K) stands for the d-dimensional volume of K.

The ***contact graph*** of a finite unit ball packing in $\mathcal{R}^d$ is the (simple) graph with vertices corresponding to the packing elements and where two vertices are connected by an edge if and only if the corresponding two packing elements touch each other.

The number of edges of a contact graph is called the ***contact number*** of the underlying unit ball packing.

The ***contact number problem*** asks for the largest contact number, that is, for the maximum number $c(n,d)$ of edges that a contact graph of n nonoverlapping unit balls can have in $\mathcal{R}^d$. Analogously, the largest contact number of packings by n translates of a convex body K in $\mathcal{R}^d$ is denoted by $c(K,n,d)$.

Let $\mathcal{T}$ be a tiling of $\mathcal{R}^3$ into convex polyhedra $P_i, i = 1, 2, \ldots$, each containing a unit ball P_i containing the closed 3-dimensional ball B_i having radius 1 for $i = 1, 2, \ldots$. Assuming that there is a finite upper bound for the diameters of the convex cells in $\mathcal{T}$, we say that $\mathcal{T}$ is a ***normal tiling*** of $\mathcal{R}^3$ with the underlying packing $\mathcal{P}$ of the unit balls $B_i, i = 1, 2, \ldots$.

The (***lower***) ***average surface area*** $\underline{s}(\mathcal{T})$ of the cells in $\mathcal{T}$ is defined by

$$\underline{s}(\mathcal{T}) = \liminf_{L\to\infty} \frac{\sum_{\{i \mid B_i \subset C_L\}} \text{sarea}(P_i \cap C_L)}{\text{card}\{i \mid B_i \subset C_L\}},$$

where C_L denotes the cube centered at the origin o with edges parallel to the coordinate axes of $\mathcal{R}^3$ and with edge length L; here sarea(S) and card(S) denote the surface area and cardinality of the set S. (Note that $\underline{s}(\mathcal{T})$ is independent of the choice of the coordinate system of $\mathcal{R}^3$.)

Let $P = \{c_i + B^d \mid i = 1, 2, \ldots$ with $|c_j - c_k| \geq 2$ for all $1 \leq j < k\}$ be an arbitrary infinite packing of unit balls in $\mathcal{R}^d$. For any $d \geq 2$ and $\lambda \geq 0$ let $P_\lambda = \bigcup_{i=1}^{+\infty}(c_i + (1+\lambda)B^d)$ denote the outer parallel domain of $P = \bigcup_{i=1}^{+\infty}(c_i + B^d)$ having outer radius λ and let

$$\bar{\delta}_d(P_\lambda) = \limsup_{R\to+\infty} \frac{\text{Vol}(P_\lambda \cap RB^d)}{\text{Vol}(RB^d)}$$

be the (upper) density of the outer parallel domain P_λ assigned to the unit ball packing P in $\mathcal{R}^d$. Finally, let

$$\bar{\delta}_d(\lambda) = \sup_P \bar{\delta}_d(P_\lambda)$$

be the largest density of the outer parallel domains of unit ball packings having outer radius λ in $\mathcal{R}^d$. Then we say that the family $\{c_i + (1+\lambda)B^d \mid i = 1, 2, \dots\}$ of closed balls of radii $1+\lambda$ is a ***packing of soft balls*** with penetrating constant λ if $P = \{c_i + B^d \mid i = 1, 2, \dots\}$ is a unit ball packing of $\mathcal{R}^d$.

In particular, $\bar{\delta}_d(P_\lambda)$ is the (upper) **density of the soft ball packing** $\{c_i + (1+\lambda)B^d \mid i = 1, 2, \dots\}$ with $\bar{\delta}_d(\lambda)$ the largest density of packings of soft balls of radii $1+\lambda$ with penetrating constant λ.

Facts:

1. There are two major problems concerning density:

- Given a convex body $K \subseteq \mathcal{R}^d$, find efficient packings with congruent copies of K; i.e., find packings with congruent copies of K in $\mathcal{R}^d$ having "relatively high" density.
- Find a "good" upper bound for $\delta(K)$.

2. Sphere packing in n-dimensional space, for n large, is important in designing codes that are efficient and unlikely to contain errors when data is transmitted.

3. If K is a convex body in $\mathcal{R}^d$, $\dfrac{2\zeta(d)}{\binom{2d}{d}} \leq \delta_L(K) \leq \delta_T(K) \leq \delta(K)$, where $\zeta(d) = 1 + \frac{1}{2^d} + \frac{1}{3^d} + \cdots$ denotes Riemann's zeta function.

4. If K is a centrally symmetric convex body in $\mathcal{R}^d$, $\dfrac{\zeta(d)}{2^{d-1}} \leq \delta_L(K) \leq \delta_T(K) \leq \delta(K)$.

5. Facts 3 and 4 have been improved slightly for different classes of convex bodies and subclasses of centrally symmetric convex bodies. See [DaRo47], [ElOdRu91], and [Sc63].

6. For each d, $(d-1)\dfrac{\zeta(d)}{2^{d-1}} \leq \delta_L(B^d) \leq \delta_T(B^d) = \delta(B^d)$.

7. For every convex domain D, $\delta_L(D) = \delta_T(D)$.

8. For every centrally symmetric convex domain D, $\delta_L(D) = \delta_T(D) = \delta(D)$.

9. There exists an ellipsoid C in $\mathcal{R}^3$ for which $\delta_L(C) < \delta(C)$.

10. The class of convex bodies $C \subseteq \mathcal{R}^d$ for which $\delta_L(C)$, $\delta_T(C)$, and $\delta(C)$ can be determined (for a given d) is very small.

11. The densest packing of unit balls in $\mathcal{R}^3$ has density $\delta(B^3) = \frac{\pi}{\sqrt{18}} = 0.7404...$, which is attained by the "cannonball packing" [Ha05], [Ha12]. This fact was conjectured by Johannes Kepler in the 17th century. It was proved by Thomas Hales in 1998. His proof was based on examining a large number of cases, following an approach first conceived by Fejes Tóth in 1953. Hales's proof by exhaustion relied on complex computer calculations, and, after extensive examination over many years, was generally believed to be complete. To remove any doubt, Hales and a large team embarked on an effort to produce a formal proof of the conjecture. After more than 11 years, Hales and 21 collaborators succeeded in completing a formal proof using the proof assistants Isabelle and HOL Light.

12. No packing of unit balls in $\mathcal{R}^8$ has density greater than $\frac{\pi^4}{384} = 0.2536...$, the density of the E_8-lattice packing [Vi16].

13. The Leech lattice achieves the optimal sphere packing density in $\mathcal{R}^{24}$ with $\delta(B^{24}) = \frac{\pi^{12}}{12!} = 0.001929...$ and it is the only periodic packing in $\mathcal{R}^{24}$ with that density [CoEtal16].

14. The Cohn-Elkies linear programming bound [CoEl03] improves on all upper bounds for $\delta(B^d)$ obtained earlier in dimensions $4 \le d \le 128$ [CoZh14]. On the other hand, for $d \ge 129$ the best bounds are $2^{-(1+o(1))d} \le \delta(B^d) \le 2^{-(0.5990\ldots+o(1))d}$. See [KaLe78], [Va11], and [Ve13].

15. The known values of $k(d)$ are $k(2) = 6$ (trivial), $k(3) = 12$ ([ScVa53]), $k(4) = 24$ ([Mu08]), $k(8) = 240$ ([OdSl79]), and $k(24) = 196{,}560$ ([OdSl79]). In general, $k(d) \le 2^{0.401d(1+o(1))}$ [KaLe78].

16. $c(n,2) = \lfloor 3n - \sqrt{12n-3} \rfloor$ holds for all $n \ge 2$ [Ha74]. On the other hand, one has $6n - 7.863n^{\frac{2}{3}} < c(n,3) < 6n - 0.926n^{\frac{2}{3}}$ for all $n \ge 2$, and $c(n,d) < \frac{1}{2}k(d)\, n - \frac{1}{2^d}\delta(B^d)^{-\frac{d-1}{d}} n^{\frac{d-1}{d}} < \frac{1}{2}2^{0.401d(1+o(1))}n - \frac{1}{2^d}2^{0.599(1+o(1))(d-1)}n^{\frac{d-1}{d}}$ for all $d \ge 4, n \ge 2$ [Be13].

17. Let K be a convex domain different from a parallelogram in $\mathcal{R}^2$. Then for all $n \ge 2$, one has $c(K,n,2) = \lfloor 3n - \sqrt{12n-3} \rfloor$. If K is a parallelogram, then $c(K,n,2) = \lfloor 4n - \sqrt{28n-12} \rfloor$ holds for all $n \ge 2$ [Br96]. On the other hand, if K is a convex body in $\mathcal{R}^d$, $d \ge 3$, then

$$c(K,n,d) \le \frac{H(K)}{2}n - \frac{1}{2^d \delta_T(K)^{\frac{d-1}{d}}}\sqrt[d]{\frac{\mathrm{iq}(B^d)}{\mathrm{iq}(K)}}\, n^{\frac{d-1}{d}} \le \frac{3^d-1}{2}n - \frac{\sqrt[d]{\omega_d}}{2^{d+1}}\, n^{\frac{d-1}{d}},$$

where $\omega_d = \frac{\pi^{\frac{d}{2}}}{\Gamma(\frac{d}{2}+1)}$ is the volume of the unit ball B^d [Be10].

18. Let $\mathcal{T}$ be an arbitrary normal tiling of $\mathcal{R}^3$. Then the average surface area of the cells in $\mathcal{T}$ is always at least $\frac{24}{\sqrt{3}}$: i.e., $\underline{s}(\mathcal{T}) \ge \frac{24}{\sqrt{3}} = 13.8564\ldots$ [Be13].

19. Let $T^d = \mathrm{conv}\{t_1, t_2, \ldots, t_{d+1}\}$ be a regular d-simplex of edge length 2 in $\mathcal{R}^d, d \ge 2$, and let $0 \le \lambda < \sqrt{\frac{2d}{d+1}} - 1$. Then $\bar{\delta}_d(\lambda) \le \frac{\mathrm{Vol}\left(T^d \cap \left(\cup_{i=1}^{d+1} t_i + (1+\lambda)B^d\right)\right)}{\mathrm{Vol}(T^d)} < 1$ holds [BeLá15].

Open Questions and Conjectures:

1. Determine the asymptotic behavior of $\delta(B^d)$ as $d \to +\infty$.

2. Determine the asymptotic behavior of $c(n,3)$ as $n \to +\infty$.

3. *Foam problem of unit ball packings*: If the Euclidean 3-space is partitioned into convex cells each containing a unit ball, how should the shapes of the cells be designed to minimize the average surface area of the cells? In particular, if $\mathcal{T}$ denotes the Voronoi tiling of an arbitrary unit ball packing in $\mathcal{R}^3$, then prove or disprove that $\underline{s}(\mathcal{T}) \ge 12\sqrt{2} = 16.9705\ldots$.

4. *Soft dodecahedral conjecture*: Let $D \subset \mathcal{R}^3$ be a regular dodecahedron circumscribed by the unit ball B^3. Then, for λ with $0 < \lambda < \sqrt{3}\tan\frac{\pi}{5} - 1 = 0.258408\ldots$, we set $\bar{\tau}_3(\lambda) = \frac{\mathrm{Vol}(D \cap (1+\lambda)B^3)}{\mathrm{Vol}(D)}$, where $\sqrt{3}\tan\frac{\pi}{5}$ is the circumradius of D. The *soft dodecahedral conjecture* asserts that if $0 < \lambda < \sqrt{3}\tan\frac{\pi}{5} - 1 = 0.258408\ldots$, then $\bar{\delta}_3(\lambda) \le \bar{\tau}_3(\lambda)$.

13.2.2 COVERING

Definitions:

A family $\mathcal{C} = \{K_i \mid i \in I\}$ of convex bodies in $\mathcal{R}^d$ forms a ***covering*** of $\mathcal{R}^d$ (that is, ***covers*** $\mathcal{R}^d$) if each point of $\mathcal{R}^d$ belongs to at least one convex body of $\mathcal{C}$.

The ***lower density*** and ***upper density*** of a covering $\mathcal{C}$ are

$$\underline{\nu}(\mathcal{C}) = \liminf_{R\to+\infty} \frac{\sum_{K_i\cap B_R\neq\emptyset} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)} \qquad \text{and} \qquad \overline{\nu}(\mathcal{C}) = \limsup_{R\to+\infty} \frac{\sum_{K_i\cap B_R\neq\emptyset} \mathrm{Vol}(K_i)}{\mathrm{Vol}(B_R)},$$

where B_R denotes the closed ball of radius R centered at the origin in $\mathcal{R}^d$.

If $\underline{\nu}(\mathcal{C}) = \overline{\nu}(\mathcal{C}) = \nu(\mathcal{C})$, then $\nu(\mathcal{C})$ is called the ***density*** of $\mathcal{C}$.

For a convex body $K \subseteq \mathcal{R}^d$, we define these quantities:

$\nu(K)$ = the smallest (lower) density of coverings of $\mathcal{R}^d$ by congruent copies of K;
$\nu_T(K)$ = the smallest (lower) density of coverings of $\mathcal{R}^d$ by translates of K;
$\nu_L(K)$ = the smallest (lower) density of coverings of $\mathcal{R}^d$ by lattice translates of K.

A ***homothety*** is an affine transformation of $\mathcal{R}^d$ of the form $x \mapsto t + \lambda x$, where $t \in \mathcal{R}^d$ and λ is a nonzero real number.

The image $t + \lambda K$ of a convex body K under a homothety is said to be its ***homothetic copy*** (or simply a ***homothet***). A homothetic copy is *positive* if $\lambda > 0$ and *negative* otherwise. Furthermore, a homothetic copy with $0 < \lambda < 1$ is called a ***smaller positive homothet***. Let $\alpha(K)$ denote the ***covering number*** of K, the minimum number of smaller positive homothets of K with a union containing K.

Given $0 < k < d$ define a ***k-codimensional cylinder*** C in $\mathcal{R}^d$ as a set which can be presented in the form $C = H + B$, where H is a k-dimensional linear subspace of $\mathcal{R}^d$ and B is a measurable set (called the base) in the orthogonal complement $H^\perp$ of H.

For a given convex body K and a k-codimensional cylinder $C = H + B$, we define the ***cross-sectional volume*** $\mathrm{crv}_K(C)$ of C with respect to K by

$$\mathrm{crv}_K(C) = \frac{\mathrm{Vol}_{d-k}(C \cap H^\perp)}{\mathrm{Vol}_{d-k}(P_{H^\perp}K)} = \frac{\mathrm{Vol}_{d-k}(P_{H^\perp}C)}{\mathrm{Vol}\ _{d-k}(P_{H^\perp}K)} = \frac{\mathrm{Vol}_{d-k}(B)}{\mathrm{Vol}\ _{d-k}(P_{H^\perp}K)},$$

where $P_{H^\perp} : \mathcal{R}^d \to H^\perp$ denotes the orthogonal projection of $\mathcal{R}^d$ onto $H^\perp$. Notice that for every invertible affine map $T : \mathcal{R}^d \to \mathcal{R}^d$ one has $\mathrm{crv}_K(C) = \mathrm{crv}_{TK}(TC)$.

Facts:

1. There are two major problems concerning covering:

- Given a convex body $K \subseteq \mathcal{R}^d$, find efficient coverings of $\mathcal{R}^d$ with congruent copies of K; that is, find coverings of $\mathcal{R}^d$ by congruent copies of K having "relatively small" density.
- Find a "good" lower bound for $\nu(K)$. (This is a highly nontrivial task for most of the convex bodies $K \subseteq \mathcal{R}^d$.)

2. If K is a convex body in $\mathcal{R}^d$, then

$$\nu(K) \le \nu_T(K) \le d(\ln d) + d(\ln\ln d) + 4d$$

and

$$\nu_T(K) \le \nu_L(K) \le d^{(\log_2 \log_2 d)+c} \quad \text{for some constant } c.$$

3. If B^d denotes the d-dimensional closed unit ball in $\mathcal{R}^d$, then

$$\nu(B^d) = \nu_T(B^d) \le \nu_L(B^d) \le cd(\ln d)^{\frac{1}{2}\log_2(2\pi e)}$$

for some constant c.

4. Take a regular simplex inscribed in a unit ball in $\mathcal{R}^d$ and draw unit balls around each vertex. Let τ_d be the ratio of the sum of the volumes of the portions of these balls lying in the regular simplex to the volume of the regular simplex. Then $\tau_d \le \nu(B^d)$.

5. $\tau_d \sim \frac{d}{e^{3/2}}$. (Thus, Facts 2 and 3 give strong estimates for $\nu(B^d)$. Moreover, for $d = 1$ and 2, the lower bound τ_d is sharp.)

6. The thinnest lattice covering of $\mathcal{R}^d$ by unit balls has been determined up to dimension 5 only. The following table lists the optimal lattices. See [CoSl93].

dimension	1	2	3	4	5
thinnest lattice covering	$\mathcal{Z}$	A_2	A_3^*	A_4^*	A_5^*

7. If K is a convex domain in $\mathcal{R}^2$, then $\alpha(K) \le 4$. If K is a convex body in $\mathcal{R}^3$, then $\alpha(K) \le 16$. Furthermore, if P is a convex polyhedron with affine symmetry in $\mathcal{R}^3$, then $\alpha(P) \le 8$ [Be10].

8. If K is a convex body in $\mathcal{R}^d, d \ge 2$, then $\alpha(K) \le \frac{\mathrm{Vol}(K-K)}{\mathrm{Vol}(K)}(d \ln d + d \ln\ln d + 5d + 1) \le \binom{2d}{d}(d \ln d + d \ln\ln d + 5d + 1)$. (Moreover, for sufficiently large d, $5d$ can be replaced by $4d$.) Furthermore, if $B[X] \subset \mathcal{R}^d, d \ge 3$ is an intersection of d-dimensional unit balls centered at the points of $X \subset \mathcal{R}^d$ having diameter $\mathrm{diam}(X) \le 1$, then $\alpha(B[X]) < 5d^{\frac{3}{2}}(4 + \ln d)\left(\frac{3}{2}\right)^{\frac{d}{2}}$ [Be13].

9. Let K be a convex body in $\mathcal{R}^d$. Let $C_1, \ldots, C_N$ be k-codimensional cylinders in $\mathcal{R}^d, 0 < k < d$, such that $K \subset \bigcup_{i=1}^N C_i$. Then $\sum_{i=1}^N \mathrm{crv}_K(C_i) \ge \frac{1}{\binom{d}{k}}$. Moreover, if K is an ellipsoid and $C_1, \ldots, C_N$ are 1-codimensional cylinders in $\mathcal{R}^d$ such that $K \subset \bigcup_{i=1}^N C_i$, then $\sum_{i=1}^N \mathrm{crv}_K(C_i) \ge 1$ [Be10].

10. The sum of the base areas of finitely many (1-codimensional) cylinders covering a 3-dimensional convex body is always at least one third of the minimum area 2-dimensional projection of the body [Be10].

11. If K is a centrally symmetric convex body and $C_1, \ldots, C_N$ are $(d-1)$-codimensional cylinders (i.e., planks) in $\mathcal{R}^d$ such that $K \subset \bigcup_{i=1}^N C_i$, then $\sum_{i=1}^N \mathrm{crv}_K(C_i) \ge 1$ [Ba91].

Open Questions and Conjectures:

1. *Hadwiger-Levi covering conjecture (1955)*: If K is an arbitrary convex body in $\mathcal{R}^d, d \ge 3$, then $\alpha(K) \le 2^d$.

2. *Bang's affine plank conjecture (1951)*: Let K be a convex body in $\mathcal{R}^d, d \ge 2$, and let $C_1, \ldots, C_N$ be $(d-1)$-codimensional cylinders (i.e., planks) in $\mathcal{R}^d$ such that $K \subset \bigcup_{i=1}^N C_i$. Then prove that $\sum_{i=1}^N \mathrm{crv}_K(C_i) \ge 1$.

3. *Bang's cylinder covering problem (1951)*: Prove or disprove that the sum of the base areas of finitely many (1-codimensional) cylinders covering a 3-dimensional convex body is at least half of the minimum area 2-dimensional projection of the body.

13.2.3 TILING

Only a "diagonal" view of the basic definitions and theorems of this area will be given. See [GrSh90] for additional material.

Definitions:

A ***tiling*** $\mathcal{T}$ of Euclidean d-space $\mathcal{R}^d$ is a countable family of closed topological d-cells of $\mathcal{R}^d$, the ***tiles*** of $\mathcal{T}$, which cover $\mathcal{R}^d$ without gaps and overlaps.

A ***monohedral tiling*** is a tiling $\mathcal{T}$ of $\mathcal{R}^d$ in which all tiles are congruent to one fixed tile T, the (metrical) ***prototile*** of $\mathcal{T}$. In this case, T ***admits*** the tiling $\mathcal{T}$.

A ***regular polygon*** is a polygon with all sides congruent and all interior angles equal.

A ***regular tiling*** is a monohedral tiling of the plane ($\mathcal{R}^2$) with a regular polygon as prototile.

A ***semiregular tiling*** is a tiling of the plane using n prototiles with the same numbers of polygons around each vertex.

A ***semiregular polyhedron*** is a convex polyhedron with each face a regular polygon, but where more than one regular polygon can be used as a face.

A tiling $\mathcal{T}$ of $\mathcal{R}^d$ by convex polytopes is ***normal*** if there exist positive real numbers r and R such that each tile contains a Euclidean ball of radius r and is contained in a Euclidean ball of radius R.

A ***face-to-face*** tiling is a tiling $\mathcal{T}$ by convex d-polytopes such that the intersection of any two tiles is a face of each tile, possibly the (improper) empty face. When $d = 2$, such a tiling is an ***edge-to-edge*** tiling.

A ***lattice tiling***, with lattice L, is a tiling $\mathcal{T}$ by translates of a single tile T such that the corresponding translation vectors form a d-dimensional lattice L in $\mathcal{R}^d$.

A Euclidean motion σ of $\mathcal{R}^d$ is a ***symmetry*** of a tiling $\mathcal{T}$ if σ maps (each tile of) $\mathcal{T}$ onto (a tile of) $\mathcal{T}$. The set of all symmetries of $\mathcal{T}$ (a group under composition) is the ***symmetry group*** $S(\mathcal{T})$ of $\mathcal{T}$.

A ***periodic tiling*** is a tiling $\mathcal{T}$ of $\mathcal{R}^d$ such that $S(\mathcal{T})$ contains translations in d linearly independent directions. A tiling $\mathcal{T}$ is ***nonperiodic*** if $S(\mathcal{T})$ contains no translation other than the identity.

An ***isohedral tiling*** is a tiling $\mathcal{T}$ such that $S(\mathcal{T})$ acts transitively on the tiles of $\mathcal{T}$.

An ***isogonal tiling*** is a tiling $\mathcal{T}$ such that $S(\mathcal{T})$ acts transitively on the vertices of $\mathcal{T}$.

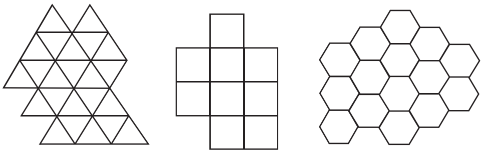
An ***isotoxal tiling*** is a tiling $\mathcal{T}$ such that $S(\mathcal{T})$ acts transitively on the edges of $\mathcal{T}$.

Let $\mathcal{T}$ and $\mathcal{T}'$ be tilings of $\mathcal{R}^d$ with symmetry groups $S(\mathcal{T})$ and $S(\mathcal{T}')$. Let $\Phi\colon \mathcal{R}^d \to \mathcal{R}^d$ be a homeomorphism that maps $\mathcal{T}$ onto $\mathcal{T}'$. Φ is ***compatible with a symmetry*** σ of $\mathcal{T}$ if there exists a symmetry σ' of $\mathcal{T}'$ such that $\sigma'\Phi = \Phi\sigma$. Φ is ***compatible with*** $S(\mathcal{T})$ if Φ is compatible with each σ in $S(\mathcal{T})$. The tilings $\mathcal{T}$ and $\mathcal{T}'$ of $\mathcal{R}^d$ are ***homeomeric***, or of the ***same homeomeric type***, if there exists a homeomorphism $\Phi\colon \mathcal{R}^d \to \mathcal{R}^d$ that maps $\mathcal{T}$ onto $\mathcal{T}'$ such that Φ is compatible with $S(\mathcal{T})$ and Φ^{-1} is compatible with $S(\mathcal{T}')$.

A prototile T in $\mathcal{R}^d$ is ***aperiodic*** if T admits a tiling of $\mathcal{R}^d$, yet all such tilings are nonperiodic. In general, a set S of prototiles in $\mathcal{R}^d$ is said to be ***aperiodic*** if S admits a tiling of $\mathcal{R}^d$, yet all such tilings are nonperiodic.

Facts:

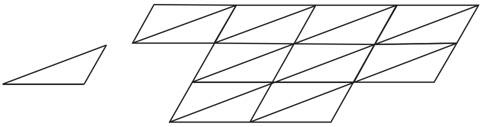
1. There are three monohedral edge-to-edge tilings of $\mathcal{R}^d$ with regular polygons; the prototile must be a triangle, a square, or a hexagon. These are illustrated in the following figure.



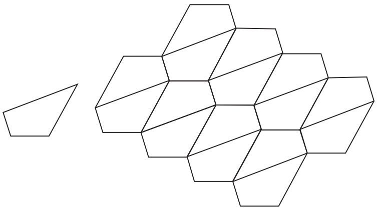
2. There are eight semiregular tilings of $\mathcal{R}^d$. These tilings use two or three prototiles.

3. Shapes that are not regular polygons [polyhedra] can be used in monohedral tilings of $\mathcal{R}^2$ [$\mathcal{R}^3$].

4. Any triangle can be used in a monohedral tiling of the plane. (Join two to form a parallelogram and tile a strip using these parallelograms. Repeat this process with parallel strips to tile the plane.) See the following figure.



5. Any quadrilateral can be used in a monohedral tiling of the plane. (Take a second copy of the quadrilateral and rotate it 180 degrees. Join the two to form a hexagon. Use the hexagons to tile the plane.) See the following figure.

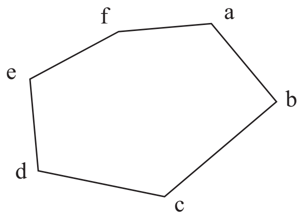


6. Any pentagon with a pair of parallel sides can be used in a monohedral tiling of the plane.

7. There are at least fourteen types of convex pentagons that can be used in a monohedral tiling of the plane. It is not known if there are more.

8. There are three types of convex hexagons that can be used in a monohedral tiling of the plane. Assume that the hexagon has vertices a, b, c, d, e, f in clockwise order, as shown in the following figure. The prototile must be of one of the following forms:

- sum of angles at a, b, c is 360°; length of $\{a, f\}$ = length of $\{c, d\}$;
- sum of angles at a, b, e is 360°; length of $\{a, f\}$ = length of $\{d, e\}$ and length of $\{b, c\}$ = length of $\{e, f\}$;
- angles at a, b, and c are each equal to 120°; length of $\{a, b\}$ = length of $\{a, f\}$, length of $\{c, b\}$ = length of $\{c, d\}$, and length of $\{e, d\}$ = length of $\{e, f\}$.



9. No convex polygon with more than six sides can be used as prototile in a monohedral tiling of $\mathcal{R}^2$.

10. Of the five regular polyhedra (tetrahedron, hexahedron (cube), octahedron, dodecahedron, icosahedron), only the tetrahedron and cube can be used as a prototile in a regular tiling of $\mathcal{R}^3$.

11. If $\mathcal{T}$ is a tiling of $\mathcal{R}^d$ with convex tiles, then each tile in $\mathcal{T}$ is a convex d-polyhedron.

12. If $\mathcal{T}$ is a tiling of $\mathcal{R}^d$ with compact convex tiles, then each tile in $\mathcal{T}$ is a convex d-polytope.

13. The following classification results have a long history. See [GrSh90].

- There exist precisely 11 distance edge-to-edge isogonal plane tilings, the tiles of which are convex regular polygons (called Archimedean tilings).
- There exist precisely 81 homeomeric types of normal isohedral plane tilings. Precisely 47 of these can be realized by a normal isohedral edge-to-edge tiling with convex polygonal tiles.
- There exist precisely 91 homeomeric types of normal isogonal plane tilings. Precisely 63 types can be realized by normal isogonal edge-to-edge tilings with convex polygonal tiles.
- There exist precisely 26 homeomeric types of normal isotoxal plane tilings. Precisely six types can be realized by a normal isotoxal edge-to-edge tiling with convex polygonal tiles.

14. Let T be a convex d-polytope. If T tiles $\mathcal{E}^d$ by translation, then T admits (uniquely) a face-to-face lattice tiling of $\mathcal{R}^d$. Such a tile T is called a *parallelotope*. This result is not true for nonconvex polytopes.

15. Several aperiodic sets have been found in the plane. Some of them, such as the Wang tiles and Penrose tiles, possess several highly interesting properties [GrSh90].

16. Progress has been made for aperiodic tilings in higher dimensions via dynamical systems [Ra95a].

Open Questions:

1. Extend the classification problems to higher dimensions. (At present, this looks hopeless.)

2. Classify all convex d-polytopes which are prototiles of monohedral tilings of $\mathcal{R}^d$. (This problem is not even solved for the plane.) However, under suitable restrictions the complexity of the problem changes. (See Fact 4.)

3. For $d \geq 5$, determine whether each d-parallelotope is a Voronoi cell (see §13.2.1) for some d-lattice. (This is known to be true for $1 \leq d \leq 4$.)

13.3 COMBINATORIAL GEOMETRY

This section studies geometric results involving combinatorics in the areas of convexity, incidences, distances, and colorings. In some cases the problems themselves have a combinatorial flavor, while in other cases their solution requires combinatorial tools.

13.3.1 CONVEXITY

In this subsection, questions of two different kinds are studied. Most of them belong to geometric transversal theory, a subject originating in Helly's theorem. Another group of problems grew out of the Erdős-Szekeres theorem, which turned out to be a starting point of Ramsey theory.

Definitions:

A subset C of d-dimensional Euclidean space (d-space) $\mathcal{R}^d$ is ***convex*** if the following is true: for any pair of points in C, the straight-line segment connecting them is entirely contained in C.

A convex set is ***strictly convex*** if its boundary contains no line segment.

A ***convex body*** is a compact (i.e., bounded and closed) convex set with nonempty interior.

A ***polytope*** is a bounded convex body that can be obtained as the intersection of finitely many closed half-spaces. (§13.1.1.)

A ***convex polygon*** is a polytope in the plane.

A ***vertex*** of a polytope P is a point $q \in P$, for which there is a hyperplane (§13.1.1) H such that $H \cap P = \{q\}$.

A point set is in ***convex position*** if it is the vertex set of a polytope.

The ***convex hull*** of a set $S \subseteq \mathcal{R}^d$ is the smallest convex set containing S.

A family $\mathcal{C} = \{C_1, C_2, \ldots\}$ of sets in d-space is said to be ***intersecting*** if all members of $\mathcal{C}$ have a point in common.

A set $T \subseteq \mathcal{R}^d$ is a ***transversal*** of a family $\mathcal{C}$ of sets if $T \cap C_i$ is nonempty for every i. If $\mathcal{C}$ has a k-element transversal ($|T| = k$), its members can be ***pierced*** by k points.

Two sequences $P = \{p_1, \ldots, p_n\}$ and $Q = \{q_1, \ldots, q_n\}$ of points in $\mathcal{R}^k$ have the same ***order type*** if, for all $1 \leq i_1 < i_2 < \cdots < i_{k+1} \leq n$, the orientations of the simplices induced by $\{p_{i_1}, \ldots, p_{i_{k+1}}\}$ and $\{q_{i_1}, \ldots, q_{i_{k+1}}\}$ are the same. This order type is ***nontrivial*** if P and Q are not contained in any hyperplane of $\mathcal{R}^k$.

A k-flat (an oriented k-dimensional plane) F intersects a sequence of d-dimensional convex bodies $\mathcal{C} = \{C_1, \ldots, C_n\}$ ***consistently*** with the above order type if there are $x_i \in F \cap C_i$ such that the sequences $X = \{x_1, \ldots, x_n\}$ and P have the same order type.

Facts:

1. The convex hull of a set S is the intersection of all convex sets containing S.

2. For any set $S \subset \mathcal{R}^d$ of finitely many points, not all of which lie in the same hyperplane, the convex hull of S is a polytope. In particular, if S has $d+1$ points, then its convex hull is a simplex whose vertices are the elements of S.

3. The convex hull of the vertex set of any convex polytope P is identical with P.

4. *Helly's theorem*: If a family $\mathcal{C}$ of at least $d+1$ convex bodies in $\mathcal{R}^d$ has the property that every $d+1$ of its members have a point in common, then $\mathcal{C}$ is intersecting (i.e., *all* its members have a point in common) [He23].

5. *Carathéodory's theorem*: If the convex hull of a set $S \subseteq \mathcal{R}^d$ contains a point p, then there exists a subset of S with at most $d+1$ elements whose convex hull contains p.

6. Let S be a compact set in $\mathcal{R}^d$ with the property that for every $(d+1)$-element subset $T \subset S$, there is a point $s \in S$ such that each segment connecting s to an element of T lies in S. Then S has a point such that every segment connecting it to an element of S is entirely contained in S [Kr46].

7. Any set of $(k-1)(d+1)+1$ points in $\mathcal{R}^d$ can be partitioned into k parts whose convex hulls have a point in common [Ra21], [Tv66].

8. Let $\mathcal{C}$ be any family of convex bodies in $\mathcal{R}^d$ with the property that the volume of the intersection of any $2d$ of them is at least 1. Then the volume of the intersection of all members of $\mathcal{C}$ is at least a positive constant depending only on d [BáKaPa82].

9. For any $\epsilon > 0$ and for any d there is a $\delta > 0$ satisfying the following condition: if $\mathcal{C}$ is a family of n $(> d+1)$ convex bodies in $\mathcal{R}^d$ having at least $\epsilon\binom{n}{d+1}$ intersecting $(d{+}1)$-tuples, then $\mathcal{C}$ has at least δn members with a point in common [Ka84].

10. For any $d < q \le p$, there exists $k = k(p,q,d)$ satisfying the following condition: if $\mathcal{C}$ is a family of convex bodies in $\mathcal{R}^d$ such that every subfamily of $\mathcal{C}$ of size p contains q members with a point in common, then $\mathcal{C}$ can be pierced by k points [AlKl92].

11. A sequence $\mathcal{C} = \{C_1, \ldots, C_n\}$ of convex bodies in $\mathcal{R}^d$ has a hyperplane transversal if and only if for some $0 \le k \le d-1$, there is a nontrivial k-dimensional order type of n points such that every $(k{+}2)$-member subfamily of $\mathcal{C}$ can be met by a suitable k-flat consistently with that order type [PoWe90].

12. If $\mathcal{S}_k$ is any family of k-dimensional linear subspaces of $\mathcal{R}^d$ with the property that any $\binom{k+l}{l}$ of them can be intersected by an l-dimensional subspace, then all members of $\mathcal{S}_k$ can be intersected by an l-dimensional subspace. (Two subspaces intersect each other if they have at least one point in common, different from the origin.)

13. Any set of five points in the plane, no three of which are on a line, has four elements in convex position.

14. *Erdős-Szekeres theorem*: For every $k > 2$, there exists a smallest integer $n(k)$ with the property that every set of at least $n(k)$ points in the plane, no three of which are on a line, contains k points in convex position. If $k = 3,4,5,6$, then $n(k) = 2^{k-2}+1$. (These are the only known values.) Furthermore, $2^{k-2}+1 \le n(k) \le \binom{2k-5}{k-2}$ [ErSz35], [TóVa98], and, asymptotically, $n(k) \le 2^{(1+o(1))k}$ [Su17].

Examples:

1. Let $S = \{(1,0,0),(0,1,0),(0,0,1)\}$. The convex hull of $S \subset \mathcal{R}^3$ is a triangular region, which is *not* a convex body in 3-space because its interior is empty.

2. Let $S = \{(0,0),(1,0),(0,1)\}$. The convex hull of $S \subset \mathcal{R}^2$ is a triangular region, which *is* a convex body (polygon) in the plane.

3. Let $S = \{(x,y) \mid 0 \le x \le 2,\ 0 \le y \le 2\}$ and $S' = \{(x,y) \mid 0 \le x \le 3,\ 0 \le y \le 3\}$. The family of all axis-parallel unit squares lying in S is intersecting because each of them contains the point $(1,1)$. The family of axis-parallel unit squares in S' can be pierced by four points: $(1,1),(1,2),(2,1),(2,2)$.

4. In the line, $\{1,3,4,2\}$ and $\{0,4,25,3\}$ have the same (1-dimensional) order type. The 3-dimensional closed unit balls centered at $(0,1,5),(0,0,9.6),(0,0,9.4),(1,0,7)$ are met by the z-axis consistently with the above order type, because these balls contain the points $(0,0,5)$, $(0,0,9)$, $(0,0,10)$, and $(0,0,7)$, respectively, and the order type of this sequence along the z-axis is the same as the 1-dimensional order type of $\{1,3,4,2\}$.

13.3.2 INCIDENCES

This subsection studies the structure (and number) of incidences between a set of points and a set of lines (or planes, spheres, etc.). The starting point of many investigations in this field was the Sylvester-Gallai theorem.

Definitions:

Given a point set P and a set L of lines (or k-flats, spheres, etc.) in Euclidean d-space $\mathcal{R}^d$, a point $p \in P$ and a line $l \in L$ are ***incident*** with each other, if $p \in l$.

Given a set L of lines in the plane, a point incident with precisely two elements of L is called an ***ordinary crossing***. Given a set of points $P \subseteq \mathcal{R}^d$, a hyperplane passing through precisely d elements of P is called an ***ordinary hyperplane*** (for $d = 2$, an ***ordinary line***).

Given a set of points P, a ***Motzkin hyperplane*** is a hyperplane h such that all but one element of $h \cap P$ lie in a $(d-2)$-flat.

A family Γ of curves in the plane has d ***degrees of freedom*** if there exists an integer s such that

- no two curves in Γ have more than s points in common;
- for any d points, there are at most d curves in Γ passing through all the points.

A family of ***pseudolines*** is a family of simple curves in the plane with the property that every two of them meet precisely once.

A family of ***pseudocircles*** is a family of simple closed curves in the plane with the property that every two of them meet in at most two points.

Facts:

1. *Sylvester-Gallai theorem*: Every finite set of points in the plane, not all of which are on a line, determines an ordinary line. In dual version: every finite set of straight lines in the plane, not all of which pass through the same point, determines an ordinary crossing.

2. For every finite set of points in Euclidean d-space, not all of which lie on a hyperplane, there exists a Motzkin hyperplane [Ha65], [Ha80].

3. Every set of n points in d-space, not all of which lie on a hyperplane, determine at least n distinct hyperplanes.

4. In 3-space, every set of n noncoplanar points determines at least $\frac{2n}{5}$ Motzkin hyperplanes.

5. If n is sufficiently large, then every set of n noncocircular points in the plane determines at least $\binom{n-1}{2}$ distinct circles, and this bound is best possible [El67].

6. Every set of n (>7) noncollinear points in the plane determines at least $\frac{6n}{13}$ ordinary lines. This bound is sharp for $n = 13$ and false for $n = 7$ [CsSa93].

7. If n is sufficiently large, then the number of ordinary lines is at least $n/2$ if n is even, and at least $3\lfloor n/4 \rfloor$ if n is odd [GrTa13]. This proves an old conjecture of Dirac and Motzkin.

8. There is a positive constant c such that every set of n points in the plane, not all on a line, has an element incident with at least cn connecting lines. Moreover, any set of n points in the plane, no more than $n - k$ of which are on the same line, determines at least $c'kn$ distinct connecting lines, for a suitable constant $c' > 0$. According to the $d = 2$ special case of Fact 4, due to de Bruijn-Erdős, for $k = 1$ the number of distinct connecting lines is at least n. For $k = 2$, the corresponding bound is $2n - 4$ (for $n \geq 10$) [Be83], [SzTr83].

9. Every set of n noncollinear points in the plane always determines at least $2\lfloor \frac{n}{2} \rfloor$ lines of different slopes. Furthermore, every set of n points in the plane, not all on a line, permits a spanning tree, all of whose $n - 1$ edges have different slopes [Un82], [Ja87].

10. The number of incidences between a set P of points and a set L of lines can be obtained by summing over all $l \in L$ the number of points in l belonging to P, or, equivalently, by summing over all $p \in P$ the number of lines in L passing through p.

11. Let Γ be a family of curves in the plane with d degrees of freedom. Then the maximum number of incidences between n points in the plane and m elements of Γ is

$$O(n^{d/(2d-1)}m^{(2d-2)/(2d-1)} + n + m)$$

(see [PaSh98]). From the most important special case, when Γ is the family of all straight lines ($d = 2$), it follows that for any set P of n points in the plane, the number of distinct straight lines containing at least k elements of P is $O(\frac{n^2}{k^3} + \frac{n}{k})$ [SzTr83]. This bound is asymptotically tight. The same result holds for pseudolines.

For $d > 2$, the above bound is probably not tight: slightly better results are known for the number of incidences between n points and a family Γ of m *algebraic* curves with bounded degree [ShShSo16].

12. The maximum number of incidences between n points and m spheres in $\mathcal{R}^3$ is

$$O(n^{\frac{4}{7}}m^{\frac{9}{7}}\beta(n,m) + n^2),$$

where $\beta(n,m) = o(\log(nm))$ is an extremely slowly growing function.

If no three spheres contain the same circle, then the following better bound is obtained:

$$O(n^{\frac{3}{4}}m^{\frac{3}{4}} + n + m).$$

Neither of these estimates is known to be asymptotically tight [ClEtal90], [Za13].

13. The maximum number of collinear triples determined by n points in the plane, no four of which are on a line, is at most $\frac{n^2}{6} - O(n)$ [BuGrSl79]. More precisely, if n is sufficiently large, the number of collinear triples is at most $\lfloor \frac{1}{6}n(n-3) \rfloor + 1$, and this bound is tight [GrTa13].

14. If $M(n)$ denotes the minimum number of different midpoints of the $\binom{n}{2}$ line segments determined by n points in convex position in the plane, then [ErFiFü91] showed

$$\binom{n}{2} - \lfloor \tfrac{n(n+1)(1-e^{-1/2})}{4} \rfloor \leq M(n) \leq \binom{n}{2} - \lfloor \tfrac{n^2-2n+12}{20} \rfloor.$$

Examples:

1. Let P be a set of seven points in the plane, consisting of the vertices, the centroid (the point of intersection of the medians), and the midpoints of all sides of an equilateral triangle. Then P determines three ordinary lines (the lines connecting the midpoints of two sides).

2. Let P be a $4k$-element set in the plane that can be obtained from the vertex set $\{v_1, v_2, \ldots, v_{2k}\}$ of a regular $2k$-gon by adding the intersection of the line at infinity with every line v_iv_j. Then the set P determines precisely $2k$ ordinary lines: every line connecting some v_i to the intersection point of $v_{i-1}v_{i+1}$ and the line at infinity ($1 \leq i \leq 2k$, the indices are taken modulo $2k$). (It can be achieved by a suitable projective transformation that no point of P is at infinity, and the number of ordinary lines remains $\frac{|P|}{2} = 2k$.)

3. Let P be a set of $n \geq 4$ points lying on two noncoplanar lines in 3-space so that there are at least two points on each line. Not all points of P are coplanar, but P does not determine any ordinary plane.

4. The family of all straight lines in the plane and the family of all unit circles both have two degrees of freedom. The family of all circles with arbitrary radii has three degrees of freedom. The family of the graphs of all polynomials of one variable and degree d has d degrees of freedom.

5. Let P be an $n^{\frac{1}{2}} \times n^{\frac{1}{2}}$ part of the integer grid; i.e.,

$$P = \{(i,j) \mid 1 \leq i \leq n^{\frac{1}{2}}, 1 \leq j \leq n^{\frac{1}{2}}\}.$$

Let $k = \left(\frac{cm}{n^{1/2}}\right)^{1/3} > 2$, where $c > 0$ is a sufficiently small constant. For every $1 \leq s < r \leq k$ and for every $1 \leq i \leq r, 1 \leq j \leq \frac{n^{1/2}}{2}$, consider the line passing through (i,j) and $(i+r, j+s)$. If c is sufficiently small, then the number of these lines is at most m. There is a constant $c' > 0$ such that the total number of incidences between these lines and the elements of P is at least $c'n^{\frac{2}{3}}m^{\frac{2}{3}}$. (See the case $d = 2$ of Fact 11.)

13.3.3 DISTANCES

The systematic study of the distribution of the $\binom{n}{2}$ distances determined by n points was initiated by Erdős. Given a set of n points $P = \{p_1, p_2, \ldots, p_n\}$, let $g(P)$ denote the number of distinct distances determined by P, and let $f(P)$ denote the number of times that the unit distance occurs between two elements of P. That is, $f(P)$ is the number of pairs $p_ip_j, i < j$, such that $|p_i - p_j| = 1$. In [Er46], Erdős raised the following general questions: What is the minimum of $g(P)$ and what is the maximum of $f(P)$ over all n-element subsets of Euclidean d-space or of any other fixed metric space?

Definitions:

For any point set P in a metric space, the ***unit distance graph*** of P is the graph $G(P)$ whose vertex set is P and two points (vertices) are connected by an edge if and only if their distance is 1.

Let P be a finite set of points in a metric space. If the distance between two points $p, q \in P$ is minimum, then p and q form a ***closest pair***.

A point $q \in P$ is a ***nearest neighbor*** of $p \in P$ if no point of P is closer to p than q.

A set P in a metric space is a ***separated set*** if the minimum distance between the points of P is at least 1.

The ***diameter*** of a finite set of points in a metric space is the maximum distance between two points of the set.

A point $q \in P$ is a ***farthest neighbor*** of $p \in P$ if no point of P is farther from p than q.

A set of points in the plane is said to be in ***general position*** if no three are on a line and no four on a circle.

Facts:

1. $f(P)$ is equal to the number of edges of $G(P)$.

2. If p and q form a closest pair in P, then q is a nearest neighbor of p and p is a nearest neighbor of q.

3. If the distance between p and q is equal to the diameter of P, then q is a farthest neighbor of p and p is a farthest neighbor of q.

4. The maximum number of times that the unit distance can occur among n points in the plane is $O(n^{4/3})$. *Conjecture*: the asymptotically best bound is $O(n^{1+c/\log\log n})$ [SpSzTr84].

5. The maximum number of times that the unit distance can occur in a separated set of $n \leq 3$ points is $\lfloor 3n - \sqrt{12n-3} \rfloor$ [Ha74].

6. The maximum number of times that the unit distance can occur in a set of n points in the plane with unit diameter is n [HoPa34].

7. For any set of $n > 3$ points in the plane, the total number of farthest neighbors of all elements is at most $3n-3$ if n is even, and at most $3n-4$ if n is odd. These bounds cannot be improved [EdSk89].

8. The maximum number of times that the unit distance can occur among n points in convex position in the plane is $O(n \log n)$. For $n > 15$, the best known lower bound is $2n-7$ [Fü90], [EdHa91].

9. In 2015 L. Guth and N. Katz showed that the minimum number of distinct distances determined by n points in the plane is $\Omega(n/\log n)$ (see [GuKa15]). It was conjectured by Erdős [Er46] that the best bound is $\Omega\big(\frac{n}{\sqrt{\log n}}\big)$.

10. The minimum number of distinct distances determined by $n > 3$ points in convex position in the plane is $\lfloor \frac{n}{2} \rfloor$ [Al63].

11. The minimum number of distinct distances determined by $n > 3$ points in the plane, no three of which are on a line, is at least $\lceil \frac{n-1}{3} \rceil$. *Conjecture*: the best possible bound is $\lfloor \frac{n}{2} \rfloor$.

12. The minimum number of distinct distances determined by n points in general position in the plane is $O(n^{1+c/\sqrt{\log n}})$, for some positive constant c. However, it is not known whether this function is superlinear in n [ErEtal93].

13. There are arbitrarily large noncollinear finite point sets in the plane such that all distances determined by them are integers, but there exists no infinite set with this property.

14. In an n-element planar point set, the maximum number of noncollinear triples that determine the same angle is $O(n^2 \log n)$, and this bound is asymptotically tight [PaSh90].

15. Let $f_3(n)$ denote the maximum number of times that the unit distance can occur among n points in $\mathcal{R}^3$. Then

$$\Omega(n^{\frac{4}{3}} \log\log n) \leq f_3(n) \leq n^{\frac{3}{2}},$$

where the lower bound was proved in [Er46] and the upper bound is a slight improvement of a result in [ClEtal90], obtained in [KaEtal12] and [Za13].

16. The maximum number of times that the unit distance can occur in a set of $n \geq 4$ points in $\mathcal{R}^3$ with unit diameter is $2n-2$ [Gr56].

17. If n is sufficiently large, then for any set of n points in $\mathcal{R}^3$, the total number of farthest neighbors of all elements is at most $\frac{n^2}{4}+\frac{3n}{2}+3$ if n is even, at most $\frac{n^2}{4}+\frac{3n}{2}+\frac{9}{4}$ if $n \equiv 1 \pmod 4$, and at most $\frac{n^2}{4}+\frac{3n}{2}+\frac{13}{4}$ if $n \equiv 3 \pmod 4$. These bounds cannot be improved [Cs96].

18. Let $f_d(n)$ denote the maximum number of times that the unit distance can occur among n points in $\mathcal{R}^d$. If $d \geq 4$ is even, then

$$f_d(n) = \tfrac{n^2}{2}\Big(1 - \tfrac{1}{\lfloor \frac{d}{2} \rfloor}\Big) + n - O(d).$$

If $d \geq 5$ is odd, then

$$f_d(n) = \tfrac{n^2}{2}\Big(1 - \tfrac{1}{\lfloor \frac{d}{2} \rfloor}\Big) + \Theta(n^{\frac{4}{3}}) \text{ [Er60], [ErPa90].}$$

19. Let $\Phi_d(n)$ denote the maximum of the total number of farthest neighbors of all points over all n-element sets in $\mathcal{R}^d$. For every $d \geq 4$,

$$\Phi_d(n) = n^2\Big(1 - \tfrac{1}{\lfloor \frac{d}{2} \rfloor} + o(1)\Big) \text{ [ErPa90].}$$

Examples:

1. Let P be the vertex set of a regular n-gon ($n > 3$) in the plane. Then $g(P)$, the number of distinct distances determined by P, is equal to $\lfloor \frac{n}{2} \rfloor$. The number of times that the diameter of P is realized is equal to n if n is odd, and $\frac{n}{2}$ if n is even.

2. Take a regular hexagon of side length k and partition it into $6k^2$ equilateral triangles with unit sides. Let P denote the union of the vertex sets of these triangles. Then P is a separated set, and $|P| = n = 3k^2+3k+1$. The number of times that the minimum (unit) distance occurs between two elements of P is $9k^2+3k = 3n - \sqrt{12n-3}$.

3. Let P denote an $n^{\frac{1}{2}} \times n^{\frac{1}{2}}$ part of the integer grid; i.e., let $P = \{(x,y) \mid 1 \leq x, y \leq n^{\frac{1}{2}}\}$. It follows from classical number-theoretic results that there exists an integer k ($\frac{n}{16} \leq k \leq \frac{n}{8}$) that can be written as the sum of two squares in $2n^{\frac{c}{\log\log n}}$ different ways, for a constant $c > 0$. Thus, for every $(x,y) \in P$, the number of points $(x',y') \in P$ satisfying $(x-x')^2+(y-y')^2 = k$ is at least $2n^{\frac{c}{\log\log n}}$. In other words, the distance $k^{\frac{1}{2}}$ occurs $n^{1+\frac{c}{\log\log n}}$ times among the elements. By proper scaling, an n-element point set P' is obtained in which the unit distance occurs $n^{1+\frac{c}{\log\log n}}$ times. That is, $f(P') = n^{1+\frac{c}{\log\log n}}$. It can also be shown that the number of distinct distances determined by P' satisfies $g(P') = g(P) = \frac{c'n}{\sqrt{\log n}}$ for a suitable positive constant c'.

4. *Lenz' construction*: Let $C_1, \ldots, C_{\lfloor \frac{d}{2} \rfloor}$ be circles of radius $\frac{1}{\sqrt{2}}$ centered at the origin of $\mathcal{R}^d$, and assume that the supporting planes of these circles are mutually orthogonal. Choose n_i points on C_i, where $n_i = \lfloor n / \lfloor \frac{d}{2} \rfloor \rfloor$ or $n_i = \lceil n / \lfloor \frac{d}{2} \rfloor \rceil$, so that $\sum_i n_i = n$. It is clear that any pair of points belonging to different circles C_i are at unit distance from each other. Hence, this point system determines at least

$$\tfrac{n^2}{2}\Big(1 - \tfrac{1}{\lfloor \frac{d}{2} \rfloor}\Big) + n - O(d)$$

unit distances.

5. Let p_1, p_2, p_3, p_4 be the vertices of a regular tetrahedron with side length 1 in $\mathcal{R}^3$. The locus of points in 3-space lying at unit distance from both p_1 and p_2 is a circle passing through p_3 and p_4. Choose distinct points $p_5, p_6, \ldots, p_n$ on the shorter arc of this circle between p_3 and p_4. An n-element point set in $\mathcal{R}^3$ is obtained with diameter 1 and in which the diameter occurs $2n-2$ times.

13.3.4 COLORING

One of the oldest problems in graph theory is the Four Color Problem (§8.6.4). This problem has attracted much interest among professional and amateur mathematicians, and inspired a lot of research about colorings, including Ramsey theory [GrRoSp90] and the study of chromatic numbers, polynomials, etc. In this section, some coloring problems are discussed in a geometric setting.

Definitions:

A ***coloring*** of a set with k colors is a partition of the set into k parts. Two points that belong to the same part are said to have the same color.

The ***chromatic number of a graph*** G is the minimum number of colors $\chi(G)$ needed to color the vertices of G so that no two adjacent vertices have the same color.

The ***chromatic number of a metric space*** is the chromatic number of the unit distance graph of the space; that is, the minimum number of colors needed to color all points of the space so that no two points of the same color are at unit distance.

The ***polychromatic number of a metric space*** is the minimum number of colors χ needed to color all points of the space so that for each color class C_i $(1 \leq i \leq \chi)$ there is a distance d_i with the property that no two points of this color are at distance d_i from each other.

A point set P in $\mathcal{R}^d$ is ***k-Ramsey*** if for any coloring of $\mathcal{R}^d$ with k colors, at least one of the color classes has a subset congruent to P. If for every k, there exists $d(k)$ such that P is k-Ramsey in $\mathcal{R}^{d(k)}$, then P is called ***Ramsey***.

A point set P' is called a ***homothetic copy*** (or a ***homothet***) of P, if P and P' are similar to each other and they are in parallel position.

Facts:

1. The minimum number of colors needed for coloring the plane so that no two points at unit distance receive the same color is at least 4 and at most 7. That is, the chromatic number of the plane is between 4 and 7 [JeTo95], [So09].

2. The following table contains the best known upper and lower bounds on the chromatic numbers of various metric spaces. ($S^{d-1}(r)$ denotes the sphere of radius r in d-space, where the distance between two points is the length of the chord connecting them.) See [So09].

space	*lower bound*	*upper bound*
line	2	2
plane	4	7
rational points of plane	2	2
3-space	6	15
rational points of $\mathcal{R}^3$	2	2
$S^2(r)$, $\frac{1}{2} \le r \le \frac{\sqrt{3-\sqrt{3}}}{2}$	3	4
$S^2(r)$, $\frac{\sqrt{3-\sqrt{3}}}{2} \le r \le \frac{1}{\sqrt{3}}$	3	5
$S^2(r)$, $r \ge \frac{1}{\sqrt{3}}$	4	7
$S^2\big(\frac{1}{\sqrt{2}}\big)$	4	4
rational points of $\mathcal{R}^4$	4	4
rational points of $\mathcal{R}^5$	8	$< \infty$
$\mathcal{R}^d$	$(1+o(1))(1.2)^d$	$(3+o(1))^d$
$S^{d-1}(r)$, $r \ge \frac{1}{2}$	d	$< \infty$

3. *Lower bound for the chromatic numbers of n-space*: The chromatic number of n-space is at least $n+2$ for $n \ge 2$ (D. Raiskii) [So09].

4. *Improved lower bounds for specific n:* The chromatic number of 3-space is at least 6 (O. Nechushtan), the chromatic number of 4-space is at least 7 (K. Cantwell), the chromatic number of 5-space is at least 9 (K. Cantwell), and the chromatic number of 6-space is at least 11 (J. Cibulka). See [So09].

5. *Lower bounds for chromatic numbers of Q_n for small n*: In 2008 J. Cibulka showed that $\chi(Q_5) \ge 8$ and $\chi(Q_7) \ge 15$. M. Mann and D. Cherkashin, A. Kulikov, and A. Raigorodskii [ChKuRa15] demonstrated that $\chi(Q_6) \ge 10$, $\chi(Q_8) \ge 16$, and $\chi(Q_9) \ge 22$, respectively.

6. The polychromatic number of the plane is at least 4 and at most 6 [So94].

7. For any finite d-dimensional point configuration P and for any coloring of d-space with finitely many colors, at least one of the color classes will contain a homothetic copy of P. The corresponding statement is false if "homothetic copy of P" is replaced by "translate of P".

8. A necessary condition for a finite set P to be Ramsey is that it be spherical; i.e., all its points lie on a sphere [GrRoSp90].

9. The following conditions are sufficient for a finite set P to be Ramsey:

- P is the vertex set of a right parallelepiped;
- P is the set of points in d-space with exactly k ($k < d$) nonzero coordinates having values $x_1, \ldots, x_k$ in this order, where $x_1, \ldots, x_k$ is an arbitrary sequence of nonzero reals;
- P is the vertex set of a regular n-gon;
- P is a subset of a Ramsey set;
- P is the Cartesian product of two Ramsey sets [FrRö86], [FrRö90].

10. It follows from the first two and the last two conditions of Fact 9 that all "triangles" are Ramsey. Moreover, given any nondegenerate point configuration ("simplex") S, there is a constant $c(S) > 1$ such that for every $k < c^d(S)$, S is k-Ramsey in d-space.

Examples:

1. Let G be a graph on the vertex set $\{v_1, \ldots, v_7\}$, whose edges are v_1v_2, v_1v_3, v_1v_4, v_1v_5, v_2v_3, v_2v_6, v_3v_6, v_4v_5, v_4v_7, v_5v_7, and v_6v_7. The chromatic number of G is 4.

2. The graph G of Example 1 can be embedded in the plane so that if two of its vertices are connected by an edge, then the corresponding points in the plane are at unit distance. In other words, G is a *subgraph* of the *unit distance graph* of the plane. (In every such imbedding, the points corresponding to $\{v_1, v_2, v_3, v_6\}$ and $\{v_1, v_4, v_5, v_7\}$ form two rhombi of side length 1 that share a vertex.) Hence, the chromatic number of the plane is at least 4.

3. Let P be a 2-element point set in Euclidean space. For every positive integer k, P is k-Ramsey in k-space. (To see this, consider a regular simplex in k-space, whose side length is equal to the distance between the elements of P. Any coloring of $\mathcal{R}^k$ induces a coloring of the vertices of this simplex and, by the pigeonhole principle, one can always find two vertices that get the same color. They form a 2-element set congruent to P. Thus, P is Ramsey.)

13.4 POLYHEDRA

This section presents basic properties of polyhedra, commonly known as (planar) solids. Any application such as geometric modeling that models the 3-dimensional world of objects must deal with polyhedra. Basic geometric and combinatorial properties of polyhedra as well as their convex decompositions and triangulations are discussed.

13.4.1 GEOMETRIC PROPERTIES OF POLYHEDRA

Definitions:

A ***(d-1)-dimensional plane*** is the solution set of the linear equation $a_1x_1 + a_2x_2 + \cdots + a_dx_d = a_{d+1}$, where $a_1, a_2, \ldots, a_{d+1}$ are constants and $x_1, \ldots, x_d$ are d variables.

A ***hyperplane*** in d-dimensional Euclidean space $\mathcal{R}^d$ is the set of all points on a $(d-1)$-dimensional plane.

A ***closed half-space*** in $\mathcal{R}^d$ is the set of all points on the hyperplane together with the points on one side of the same hyperplane.

A ***convex d-polyhedron*** is the intersection of a finite number of closed half-spaces in $\mathcal{R}^d$.

A ***nonconvex polyhedron*** is the union of a set of convex polyhedra such that the underlying space is connected and nonconvex.

A ***k-face***, part of the boundary of a polyhedron, lies on at least $d-k$ hyperplanes forming the boundary. In particular, 0-faces, 1-faces, and $(d-1)$-faces of a d-polyhedron are ***vertices***, ***edges***, and ***facets***, respectively.

A ***polytope*** (***d-polytope***) is a convex d-polyhedron that is contained in the interior of some d-dimensional cube: that is, a *bounded* convex d-polyhedron.

A d-polytope is ***regular*** if all its facets are regular $(d-1)$-polytopes that are combinatorially equivalent. A vertex is a regular 0-polytope.

Two polytopes P and Q are ***dual polytopes*** if there exists a one-to-one correspondence δ between the set of faces of P and Q such that two faces $f_1, f_2 \in P$ satisfy $f_1 \subset f_2$ if and only if $\delta(f_1) \supset \delta(f_2)$ in Q.

A ***manifold*** (***d-manifold***) is a topological space that is locally homeomorphic to $\mathcal{R}^d$ everywhere.

A ***manifold d-polyhedron*** is a polyhedron whose boundary is topologically the same as a $(d-1)$-manifold. That is, every point on the boundary of a manifold d-polyhedron has a small neighborhood that looks like $\mathcal{R}^d$.

A ***non-manifold d-polyhedron*** is a d-polyhedron whose boundary is not a manifold.

A manifold 3-polyhedron has ***genus*** g if its boundary is a 2-manifold with genus g. A 2-manifold surface has genus g if every set of $g+1$ circular cuts separate the surface, but not all sets of g circular cuts do.

Edges in a 3-polyhedron are ***reflex edges*** if the inner angle subtended by two faces meeting at that edge is greater than 180°.

Facts:

1. Every polytope has a dual polytope.

2. Every polytope is the convex hull of its vertices.

3. A k-face is an open set of dimension k.

4. *Curvature*: The curvature κ_v of a manifold 3-polyhedron at a vertex v is

$$\kappa_v = \tfrac{2\pi - \sum_i \theta_i}{2\pi},$$

where θ_i is the angle between two consecutive edges incident with v. Intuitively, curvature at a vertex measures its "sharpness".

5. *Gauss-Bonnet theorem*: $\sum\limits_v \kappa_v = 2 - 2g$.

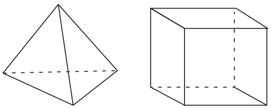
6. *Angle sums*: Let f be a face of a polytope P and let p be an interior point of f. The angle at f is measured as the fraction of P covered by a sufficiently small $(d-1)$-dimensional sphere centered at p. If α_k is the sum of angles at all k-dimensional faces, then

$$\sum_{k=0}^{d-1} (-1)^k \alpha_k = (-1)^{d-1} \text{ (\textit{Gram's formula}, [Gr67]).}$$

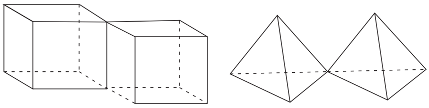
7. A 3-polyhedron is convex if and only if it does not have any reflex edges.

Examples:

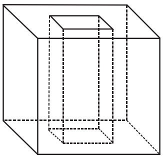
1. Tetrahedra and cubes are manifold 3-polyhedra with genus 0. These are displayed next.



2. Two cubes meeting at a single edge, or two tetrahedra meeting at a single vertex, form non-manifold 3-polyhedra. See the following figure.

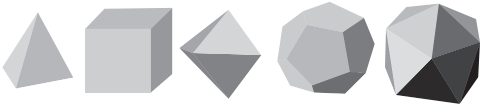


3. A cube has genus 0, but a cube with a cubical through-hole is a manifold 3-polyhedron with genus 1. This is illustrated in the following figure.



4. A cube and a octahedron (bipyramid) are dual to each other; a tetrahedron is dual to itself.

5. There are five regular polytopes in three dimensions: tetrahedron, cube (hexahedron), octahedron, dodecahedron, icosahedron. They are also called *Platonic solids*. See the following figure.



6. There is a circular cut for a toroidal surface that does not separate it, though any two circular cuts always separate it.

13.4.2 TRIANGULATIONS

A complex domain is decomposed into simple parts for computational simplicity in many applications. For example, in finite element methods often a domain is triangulated into simplices.

Definitions:

A ***simplex*** (***d-dimensional simplex*** or ***d-simplex***) is a d-polytope with $d+1$ vertices.

A ***triangulation*** of a d-polyhedron is a convex decomposition in which each convex piece of the decomposition is a d-simplex.

A polyhedron is ***triangulated with Steiner points*** if the vertex set of simplices in the triangulation is strictly a superset of the set of vertices of the polyhedron. This type of triangulation uses extra points (other than the vertices of the polyhedron) as vertices.

A triangulation of a polyhedron is a ***simplicial complex*** if for every two simplices σ_1, σ_2 in the triangulation, $\sigma_1 \cap \sigma_2$ is either empty or a face of both simplices.

A ***convex decomposition*** of a polyhedron is its partition into convex pieces that have disjoint interiors.

The ***aspect ratio of a simplex*** is the ratio of the radius of the circumscribing sphere to the radius of the inscribing sphere of the simplex.

The ***aspect ratio of a triangulation*** is the largest aspect ratio of a simplex in the triangulation.

Facts:

1. Every d-polytope can be triangulated without Steiner points.

2. Every d-polytope with n faces can be triangulated into $O(n)$ simplices in $O(n)$ time and space.

3. There are nonconvex 3-polyhedra that can't be triangulated without Steiner points.

4. The problem of deciding if a nonconvex 3-polyhedron can be triangulated without Steiner points or not is NP-complete [RuSe92].

5. The problem of decomposing a polyhedron into the minimum number of convex pieces is NP-hard.

6. Every polyhedron can be decomposed into disjoint convex pieces by repeatedly slicing the polyhedron through reflex edges [BaDe92], [Ch84].

7. There is a class of polyhedra with n edges, of which r are reflex, that requires at least $\Omega(n + r^2)$ convex pieces for its decomposition. These polyhedra have two sets of parallel edges which are created as reflex edges. Two such sets are placed on two hyperbolic paraboloids with an angle of almost 90° between them. These polyhedra require at least $\Omega(n + r^2)$ convex pieces for their decomposition [Ch84].

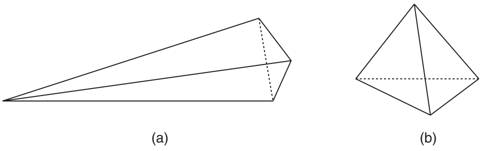
8. Every manifold 3-polyhedron can be triangulated into $O(n+r^2)$ tetrahedra in $O((n+r^2)\log r)$ time [ChPa90].

9. There exists a polynomial-time algorithm that produces a triangulation of any 3-polyhedron with an aspect ratio and size that are within a constant factor of the optimal [MiVa92].

Examples:

1. A triangle is a 2-simplex; a tetrahedron is a 3-simplex.

2. Part (a) of the following figure shows a tetrahedron with a bad aspect ratio; part (b) shows a tetrahedron with a good aspect ratio.



3. The Schönhardt polyhedron is a nonconvex 3-polyhedron that cannot be triangulated without Steiner points. This polyhedron can be constructed out of a prism whose base and top facets are equilateral triangles. Twist the top triangle, keeping the base fixed. This destroys the planarity of vertical facets. To maintain the planarity, triangulate these facets appropriately [RuSe92].

13.4.3 FACE NUMBERS

In many cases the complexity of algorithms dealing with polyhedra depends on the number of faces they contain. Therefore, combinatorial bounds on these numbers play a significant role in analyzing these algorithms.

Definitions:

A ***cyclic d-polytope*** is the convex hull of a set of n ($n \geq d+1$) points on the moment curve in $\mathcal{R}^d$, $x(t) = (t, t^2, \ldots, t^d)$.

A ***face vector*** of a d-polyhedron P is the d-dimensional vector $(f_0, f_1, \ldots, f_{d-1})$, where $f_i = f_i(P)$ is the number of i-dimensional faces of P.

A ***simplicial polytope*** is a polytope in which all faces are simplices.

Facts:

1. For $2k \leq d$, every k vertices of a cyclic polytope define a $(k-1)$-face.

2. *Euler's relation*: For any d-polytope, $\sum\limits_{i=0}^{d-1} (-1)^i f_i = 1 - (-1)^d$.

3. For a manifold 3-polyhedron with genus g, $\sum\limits_{i=0}^{2} (-1)^i f_i = 2 - 2g$.

4. The edges on the boundary of a manifold 3-polyhedron with genus 0 form a planar graph. By the property of planarity, the number of vertices, edges, and facets of such polyhedra are within a constant factor of each other.

5. *Dehn-Sommerville equations*: The face vectors of simplicial polytopes satisfy the following equations for $-1 \leq k \leq d-2$ with $f_{-1} = 1$:

$$E_d^k : \sum_{j=k}^{d-1} (-1)^j \binom{j+1}{k+1} f_j = (-1)^{d-1} f_k.$$

In particular, E_d^{-1} is Euler's relation.

6. *Upper bound theorem*: For any d-polytope P with n vertices, $f_i(P) = O(n^{\lfloor \frac{d}{2} \rfloor})$ for $1 \leq i \leq d-1$.

7. *Optimality of cyclic polytopes*: Cyclic polytopes achieve the upper bound since they have $\binom{n}{k} = \Omega(n^k)$ $(k-1)$-faces for $2k \leq d$. This implies that they have $\Omega(n^{\lfloor d/2 \rfloor})$ $\lfloor \frac{d}{2} \rfloor$-faces.

Examples:

1. The 3-dimensional cube ($d = 3$) has $f_0 = 8, f_1 = 12$, and $f_2 = 6$; thus, by Fact 2, $f_0 - f_1 + f_2 = 2$.

2. A 3-dimensional cube with a cubical through-hole ($g = 1$) has $f_0 = 16, f_1 = 24$, and $f_2 = 10$; thus, by Fact 3, $f_0 - f_1 + f_2 = 0$.

13.5 ALGORITHMS AND COMPLEXITY IN COMPUTATIONAL GEOMETRY

Computational geometry studies efficient algorithms for solving geometric problems and has applications in computer graphics, robotics, VLSI design, computer-aided design, pattern recognition, statistics, and other fields. The study of computational geometry uses concepts and results from classical geometry, topology, combinatorics, as well as standard techniques from design and analysis of computer algorithms. See [PrSh85] and [TóORGo17].

13.5.1 CONVEX HULLS

Finding efficient algorithms for the construction of convex hulls has been a central topic in computational geometry. Several efficient algorithms for constructing boundaries of convex hulls of sets of points in the plane have been developed.

Definition:

The ***convex hull*** of a set of points in $\mathcal{R}^d$ is the smallest convex set containing the points.

Algorithms:

1. *Finding boundaries of convex hulls by rotational sweeping*:

- *Graham Scan*: Given a set S of n points in the plane, Algorithm 1 scans the points rotationally around a fixed point and eliminates those that are not hull vertices. The remaining points are the vertices of the boundary of the convex hull of S. The running time of Graham Scan is $O(n \log n)$, which is dominated by the sorting of the points. The remaining steps take only linear time.

Algorithm 1: **Graham Scan.**

```
input: a finite set $S$ of points in the plane
output: the vertices of the boundary of the convex hull of $S$
$p_0$ := the point in $S$ with the minimum $y$-coordinate
sort remaining points by polar angle around $p_0$; append the point $p_0$ to the
    end of the sorted list; let the resulting list be $(p_1, p_2, \ldots, p_n)$, where $p_n = p_0$.
$H[1] := p_n$;  $H[2] := p_1$;  $j := 2$
for $i := 2$ to $n$
  while the path $\{H[j-1], H[j], p_i\}$ does not form a left turn
      $j := j - 1$
  $j := j + 1$
  $H[j] := p_i$
$\{H[1], H[2], \ldots, H[j]$ is the boundary of the convex hull$\}$
```

- *Jarvis' March*: Given a set S of n points in the plane, Jarvis' March algorithm constructs the boundary of the convex hull by "marching around" the outer perimeter of S. This method is also called "gift-wrapping". Jarvis' March runs in time $O(hn)$, where h is the number of vertices of the convex hull, which in the worst case is n.

2. *Divide-and-conquer algorithms*:

- *QuickHull*: This algorithm recursively constructs a chain on the boundary of the convex hull, connecting two hull vertices u and v. It first finds a hull vertex w on the chain (for example, w is the farthest point from the line $\overline{uv}$). Then the subchains connecting u and w, w and v, respectively, are constructed recursively and are concatenated [PrSh85]. QuickHull runs practically fast, but in the worst case the running time of QuickHull is $O(n^2)$.

- *MergeHull*: This algorithm first partitions the set S of points into two subsets S_1 and S_2 of equal size and then recursively constructs the boundaries of the convex hulls CH(S_1) and CH(S_2). Finally, CH(S_1) and CH(S_2) are "merged" into the convex hull of the set S [PrSh85].

  The boundary of the convex hull for S is the same as the boundary of the convex hull for the hull vertices of CH(S_1) and CH(S_2). Thus, to construct the boundary of CH(S), first sort the hull vertices of CH(S_1) and CH(S_2) (this sorting can be done in linear time), then apply the linear scan of Graham Scan to construct CH(S). Therefore, the boundary of the convex hull CH(S) can be constructed from CH(S_1) and CH(S_2) in linear time. The running time of MergeHull is $O(n \log n)$.

3. *Other methods*:

- *Incremental method*: The *incremental method* for constructing the boundary of the convex hull of a set of points in the plane adds one point at a time to an already constructed boundary of a convex hull. This method has time complexity $O(n \log n)$ [PrSh85]. An advantage of this method is that it can be generalized to construct boundaries of convex hulls in higher dimensions [Ed87].
- *Algorithm by Kirkpatrick and Siedel based on the prune-and-search method*: This algorithm partitions a given set of points in the plane into two linearly separable subsets of equal size, finds the two edges of the boundary of the convex hull that "bridge" these two subsets, and recursively constructs the subchains on the boundary of the convex hull between these two bridges. This method has time complexity $O(n \log h)$, where h is the number of vertices on the boundary of the convex hull [Ya90].

Facts:

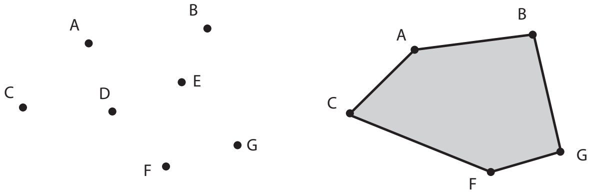
1. The problem of finding convex hulls is at least as hard as sorting. The lower bound $\Omega(n \log n)$ of sorting on comparison decision trees also applies to the convex hull problem. This lower bound $\Omega(n \log n)$ can be extended to a more general computation model, the bounded-degree algebraic decision trees.

2. An $O(n \log n)$ time algorithm for constructing the boundary of the convex hull of a set of points in $\mathcal{R}^3$ has been developed, which is a generalization of the MergeHull algorithm.

3. For dimension $d > 3$, the convex hull of n points in $\mathcal{R}^d$ can have up to $O(n^{\lfloor \frac{d}{2} \rfloor})$ faces. An algorithm based on the incremental method has been proposed to construct the convex hull for a set of n points in $\mathcal{R}^d$ in time $O(n^{\lfloor \frac{d+1}{2} \rfloor})$ [Ya90]. An optimal algorithm of time $O(n^{\lfloor \frac{d}{2} \rfloor})$ has been developed recently by Chazelle. (See the bibliography of [Mu94] for a reference.)

Examples:

1. The following figure shows a set S of 7 points in the plane and the convex hull of S.



2. The convex hull of the set $\{(0,0,0),\ (0,0,1),\ (0,1,0),\ (0,1,1),\ (1,0,0),\ (1,0,1),\ (1,1,0),\ (1,1,1)\}$ in $\mathcal{R}^3$ is the surface of the unit cube together with its interior.

13.5.2 TRIANGULATION ALGORITHMS

Triangulation plays an important role in many applications. On a triangulated planar straight-line graph, many problems can be solved more efficiently. Triangulation of a set of points arises in numerical interpolation of bivariate data and in the finite element method.

Definitions:

A ***planar straight-line graph*** (***PSLG***) is a planar graph such that each edge is a straight line.

A ***triangulation of a simple polygon*** P is an augmentation of P with nonintersecting diagonal edges connecting vertices of P such that in the resulting PSLG, every bounded face is a triangle.

A ***triangulation of a PSLG*** G is an augmentation of G with nonintersecting edges connecting vertices of G so that every point in the interior of the convex hull of G is contained in a face that is a triangle. In particular, the PSLG to be triangulated can be simply n discrete points in the plane.

A ***chain*** is a PSLG with vertices $v_1,\ldots,v_n$ and edges $\{v_1,v_2\},\{v_2,v_3\},\ldots,\{v_{n-1},v_n\}$.

A chain is ***monotone*** if there is a straight line L such that every line perpendicular to L intersects the chain in at most one point.

A simple polygon is ***monotone*** if its boundary can be decomposed into two monotone chains.

Two vertices v and u in a polygon are ***visible*** from each other if the open line segment $\overline{uv}$ is entirely in the interior of the polygon.

Facts:

1. Every simple polygon can be triangulated.

2. Every triangulation of a simple polygon with n vertices has $n-2$ triangles and $n-3$ diagonals.

3. Given a simple polygon with n vertices, there is a diagonal that divides the polygon into two polygons that have at most $\lceil \frac{2n}{3} \rceil + 1$ vertices.

4. For a history of triangulations, see [OR87].

5. Simple polygons can be triangulated in $O(n)$ time using an algorithm developed by Chazelle [Ch91].

6. PSLGs can be triangulated in $O(n\log n)$ time. (See the *triangulation of a general PSLG* algorithm — item 3 in the following list of algorithms.) This is optimal because a lower bound $\Omega(n\log n)$ has been derived for the time complexity of triangulation of a PSLG.

Algorithms:

1. *Triangulation of a monotone polygon*: A monotone polygon P can be triangulated in linear time based on the following greedy method. Observe that the monotone polygon P

is triangulated if nonintersecting edges are added so that no two vertices are visible from each other.

If necessary, rotate the polygon so that it is monotone with respect to the y-axis. Sort the vertices of P by decreasing y-coordinate. (This sorting can be done in linear time by merging the two monotone chains of P.) Move through the sorted list, and for a vertex v, examine each vertex u lower than v, in the sorted order, and add an edge between vertices v and u as long as u is visible from v. The edge addition process for the vertex v stops at a lower vertex that is not visible from v. Then move to the next vertex and perform the edge addition process. Note that once an edge is added between vertices v and u, then no vertices between v and u in the sorted list are visible from a vertex that is lower than u. Therefore, such vertices can be ignored in the later edge addition process. The edge addition process for all vertices can be performed in linear time if a stack is used to hold the sorted list.

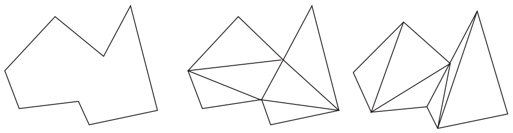
2. *Triangulation of a simple polygon*: Given a general simple polygon P, partition P in time $O(n \log n)$ into monotone polygons, then apply the previous linear-time algorithm to triangulate each monotone polygon. This gives a triangulation of a simple polygon in time $O(n \log n)$.

3. *Triangulation of a general PSLG*: To triangulate a general PSLG G, first add edges to G so that each face is a simple polygon (no nonconsecutive edges intersect), then apply Chazelle's linear-time algorithm (Fact 5) to triangulate each face.

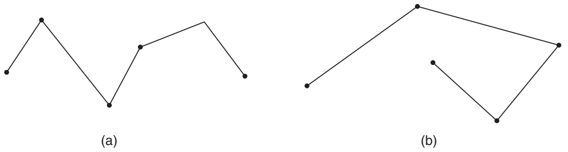
The complexity of Chazelle's algorithm can be avoided since there is an efficient algorithm that adds edges to a PSLG so that each face is a monotone polygon. To do this, observe that in a PSLG G every face is a monotone polygon if and only if each vertex (except the highest one) has a higher neighbor and each vertex (except the lowest one) has a lower neighbor. Thus, to make each face of G a monotone polygon, check each vertex of G and for those that do not have desired neighbors, add proper edges to them. This process can be accomplished in time $O(n \log n)$ using the plane sweeping method [PrSh85]. Now, the simpler linear-time algorithm for triangulating a monotone polygon (see item 1) is applied to triangulate each face.

Examples:

1. The following figure illustrates a simple polygon and two of its triangulations.



2. In part (a) of the following figure the chain is monotone (with respect to any horizontal line); the chain in part (b) is not monotone.



(a)

(b)

13.5.3 VORONOI DIAGRAMS AND DELAUNAY TRIANGULATIONS

Definitions:

Given a set $S = \{p_1, \ldots, p_n\}$ in $\mathcal{R}^d$, the ***Voronoi diagram*** $\mathrm{Vor}(S)$ of S is a partition of $\mathcal{R}^d$ into n convex polytopes (***Voronoi cells*** or ***Dirichlet cells***) $V(p_1), \ldots, V(p_n)$ such that the region $V(p_i)$ is the locus of points that are closer to p_i than to any other point in S.

Given the Voronoi diagram $\mathrm{Vor}(S)$ of a set $S = \{p_1, \ldots, p_n\}$ of points in the plane, the ***straight-line dual*** $D(S)$ of $\mathrm{Vor}(S)$ is a PSLG whose vertices are the points in S and in which two vertices p_i and p_j in $D(S)$ are connected if and only if the regions $V(p_i)$ and $V(p_j)$ share a common edge.

The PSLG $D(S)$ is a triangulation of the set S, called the ***Delaunay triangulation*** of S.

Facts:

1. The Voronoi diagram of a set of n points in the plane can be constructed in time $O(n \log n)$.

2. The Delaunay triangulation of a set S of points in the plane has the property that the circuit with the three vertices of a triangle of the triangulation on its boundary contains no other point of the set S. This property makes the Delaunay triangulation useful in interpolation applications.

3. The convex hull problem in the plane can be reduced in linear time to the Voronoi diagram problem in the plane: a point p in a set S is a hull vertex if and only if $V(p)$ is unbounded, and two hull vertices p_i and p_j are adjacent if and only if the two unbounded regions $V(p_i)$ and $V(p_j)$ share a common edge. Thus, the $O(n \log n)$ time algorithm for constructing Voronoi diagrams (Algorithm 2) is optimal.

4. The Voronoi diagram problem for n points in $\mathcal{R}^d$ can be reduced in linear time to the convex hull problem for n points in $\mathcal{R}^{d+1}$ [Ed87]. Thus, the Voronoi diagram of a set of n points in $\mathcal{R}^d$ can be constructed in time $O(n^{\lfloor (d+1)/2 \rfloor})$ based on the optimal algorithm for constructing the convex hull of a set of n points in $\mathcal{R}^{d+1}$.

Algorithms:

1. *Construction of Voronoi diagrams in the plane*: The Voronoi diagram of a set of points in $\mathcal{R}^2$ can be constructed using the divide-and-conquer method of Algorithm 2.

To efficiently partition a set S into a left subset and a right subset of equal size in each recursive construction, pre-sort the set S by x-coordinate. To merge the Voronoi diagrams $\mathrm{Vor}(S_L)$ and $\mathrm{Vor}(S_R)$ into the Voronoi diagram $\mathrm{Vor}(S)$, add the part of $\mathrm{Vor}(S)$ that is missing in $\mathrm{Vor}(S_L)$ and $\mathrm{Vor}(S_R)$ and then delete the part of $\mathrm{Vor}(S_L)$ and $\mathrm{Vor}(S_R)$ that does not appear in $\mathrm{Vor}(S)$.

Algorithm 2: **Construction of Voronoi diagrams.**

```
input: a set $S$ of points in the plane
output: the Voronoi diagram of $S$
if $|S| < 4$ then construct Vor($S$) directly and stop
else
```

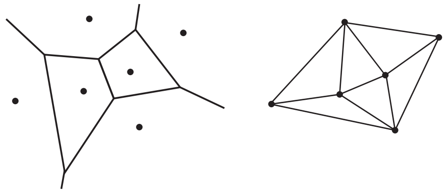
```
partition $S$ into two equal size subsets $S_L$ (left subset) and $S_R$ (right subset)
  separated by a vertical line
construct Vor($S_L$) and Vor($S_R$) recursively;
merge Vor($S_L$) and Vor($S_R$) into Vor($S$);
```

2. *Voronoi diagrams and geometric optimization problems*: An $O(n \log n)$ time optimal algorithm can be derived via the Voronoi diagram for the problem of finding for each point in a set S of n points in the plane the nearest point in S. This is so because each point p in S and its nearest neighbor correspond to two regions in Vor(S) that share a common edge. This also implies an $O(n \log n)$ time optimal algorithm for the problem of finding the closest pair in a set of n points in the plane.

The Voronoi diagram can be used to design an $O(n \log n)$ time optimal algorithm for constructing a Euclidean minimum spanning tree for a set S of n points in the plane because edges of any Euclidean minimum spanning tree must be contained in the Delaunay triangulation $D(S)$ of S. This algorithm implies an $O(n \log n)$ time approximation algorithm for the Euclidean traveling salesman problem which produces a traveling salesman tour of length at most twice the optimum.

Example:

1. The left half of the following figure illustrates a set of six points in the plane and the Voronoi diagram for the set. The right half shows the Delaunay triangulation of the set.



13.5.4 ARRANGEMENTS

Definition:

Given n lines in the plane, the ***arrangement*** of the lines in the plane is the PSLG whose vertices are the intersection points of the lines and whose edges connect consecutive intersection points on each line (it is assumed that all lines intersect at a common point at infinity).

Facts:

1. The arrangement of n lines in the plane partitions the plane into a collection of $O(n^2)$ faces, edges, and vertices.

2. The arrangement of n lines can be constructed in $O(n^2)$ time (Algorithm 3), which is optimal.

3. An arrangement can be represented by a *doubly-connected-edge-list* in which the edges incident with a vertex can be traversed in clockwise order in constant time per edge [PrSh85].

4. Applications of arrangements include finding the smallest-area triangle among n points, constructing Voronoi diagrams, and half-plane range query.

5. The arrangement of n hyperplanes in $\mathcal{R}^d$ can be defined similarly, which partitions $\mathcal{R}^d$ into $O(n^d)$ faces of dimension at most d.

6. Algorithm 3 can be generalized to construct the arrangement of n hyperplanes in $\mathcal{R}^d$ in $O(n^d)$ time, which is optimal [Ed87].

Algorithm:

1. *Constructing the arrangement of a set of lines*: Algorithm 3 constructs the arrangement $\mathcal{A}$ of a set H of n lines $L_1, \ldots, L_n$ in the plane by the incremental method.

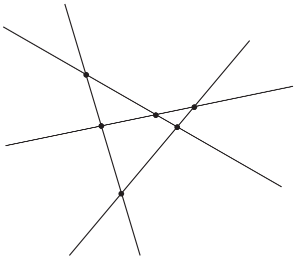
To traverse the faces of $\mathcal{A}$ that intersect the line L_i, start from a face F that has the point p_i on its boundary, and traverse the boundary of F until an edge e is encountered such that e intersects L_i at a point q. A new vertex q is introduced in $\mathcal{A}$ and the adjacencies of the two ends of the edge e are updated. Then reverse the traversing direction on the edge e and start traversing the face that shares the edge e with F, and so on. The total number of edges traversed in this process in order to insert the line L_i is bounded by $O(i)$ [Mu94].

Algorithm 3: **Incremental method for constructing the arrangement of a set H of n lines.**

```
input: a set $H$ of $n$ lines $L_1, L_2, \ldots, L_n$ in the plane
output: the arrangement $\mathcal{A}$ of the set $H$
$\mathcal{A} := L_1$;
for $i := 2$ to $n$
    find the intersection point $p_i$ of $L_i$ and $L_1$
    starting from $p_i$, traverse the faces of $\mathcal{A}$ that intersect $L_i$ and update the vertex
            set and edge set of $\mathcal{A}$
```

Example:

1. The following figure shows an arrangement of four lines in the plane. The graph has seven vertices (including the vertex at infinity), 16 edges (of which eight are unbounded), and 11 regions (of which eight are unbounded).



13.5.5 VISIBILITY

Visibility problems are concerned with determining what can be viewed from a given point (or points) in the plane or 3-dimensional space. See [OR87], [OR93], [Sh92].

Definitions:

The ***visibility problem*** is the problem of finding what is visible, given a configuration of objects and a viewpoint.

Given n nonintersecting line segments in the plane, the ***visibility graph*** is the graph whose vertices are the endpoints of the line segments, with two vertices adjacent if and only if they are visible from each other; i.e., there is an edge joining a and b if and only if the open line segment ab does not intersect any other line segments.

A ***star polygon*** is a polygon with an interior point p such that each point on the polygon is visible from p.

Facts:

1. Visibility problems have important applications in computer graphics and robotics and have served as motivation for research in computational geometry.

2. Constructing the visibility graph for a set of n nonintersecting line segments is a critical component of the shortest path problem in the plane. The visibility graph problem can be solved in optimal time $O(n^2)$ [Ya90].

3. *Art gallery theorems*: Given a simple polygon with n vertices,

- there is a set S of $\lfloor \frac{n}{3} \rfloor$ vertices of the polygon such that each point on or inside the polygon is visible from a point in S;
- there is a set S of $\lceil \frac{n}{3} \rceil$ points on the polygon such that each point on or outside the polygon is visible from a point in S;
- there is a set S of $\lceil \frac{n}{2} \rceil$ vertices of the polygon such that each point on, inside, or outside the polygon is visible from a point in S.

In each case the number given is the best possible.

Algorithms:

1. Given n line segments in the plane, compute the sequence of subsegments that are visible from the point $y = -\infty$, that is, by using parallel rays. The problem can be solved by a modified version of the plane sweeping algorithm for computing all intersection points of the line segments. The algorithm has worst-case time complexity $O(n^2 \log n)$.

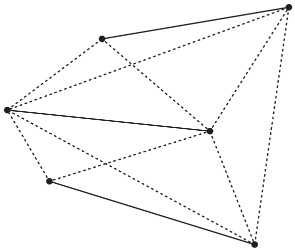
2. An alternative algorithm is based on the divide-and-conquer approach: arbitrarily partition the set of the n line segments into two equal size halves, solve both subproblems, and merge the results.

Note that the merging step amounts to computing the minimum of two piecewise (not necessarily continuous) linear functions, which can be easily done in time linear in the number of pieces if it is recursively assumed that the pieces are sorted by x-coordinate. For a set of n arbitrary line segments in the plane, in the worst case, the number of subsegments visible from the point $y = -\infty$ is bounded by $O(n\alpha(n))$ [Ya90], where $\alpha(n)$, the inverse of Ackermann's function (§1.3.2), is a monotonically increasing function that grows so slowly that for practical purposes it can be treated as a constant. Therefore, the merging step runs in time $O(n\alpha(n))$. Consequently, the time complexity of the algorithm based on the divide-and-conquer method is $O(n\alpha(n) \log n)$.

3. *Three-dimensional visibility*: Given a set of disjoint opaque polyhedra in $\mathcal{R}^3$, find the part of the set that is visible from the viewpoint $z = -\infty$ (that is, with parallel rays). The problem can be solved in time $O(n^2 \log n)$ by a modified plane sweeping algorithm for computing the intersection points of the line segments that are the projections of the edges of the polyhedra on the xy-plane. Optimal algorithms of time complexity $O(n^2)$ have been developed based on line arrangements [Do94], [Ya90].

Examples:

1. The following figure shows three line segments and the visibility graph with six vertices determined by the line segments. The edges of the visibility graph are shown as dotted lines.



2. *Surveillance problems*: A variety of problems require that "guards" be posted at points of a polygon so that corners and/or edges are visible. (See the art gallery theorems of Fact 3.)

3. *Hidden surface removal*: An important problem in computer graphics is the problem of finding (and removing) the portions of shapes in 3-dimensional space that are hidden from view, when the object is viewed from a given point. (See the three-dimensional visibility algorithm.)

13.6 GEOMETRIC DATA STRUCTURES AND SEARCHING

This section describes the use of data structures for searching, or querying, among a set S of geometric objects. For each of the following problems, there are algorithms that perform a single search in time proportional to n, the total complexity of all the geometric objects in S. These single-search algorithms use minimal data structures and minimal preprocessing time. When the application searches multiple times among the elements of the same set S, it becomes more efficient to preprocess the objects in S into a data structure that would allow a faster searching procedure.

This section presents four fundamental searching problems in computational geometry for which clever data structures reduce the search time to $O(\log_2^k n)$, where k is a small constant (often equal to 1 for problems in the plane and 3-dimensional space). This section covers only the static versions of these problems; that is, S never changes. The dynamic versions allow deletions from S and/or insertions into S in between queries. In the dynamic versions of the problem, in addition to polylogarithmic query time, the goal is to keep the update time polylogarithmic. The dynamic versions are, as a rule, much more difficult.

13.6.1 POINT LOCATION

Definition:

Let p be a point and S a subdivision of $\mathcal{R}^d$. (S can be a single geometric object, such as a polytope, or can be a general subdivision of $\mathcal{R}^d$.) The ***point location problem*** is the problem of determining which region of S contains p.

Examples:

1. Locate a point in the subdivision of the space induced by an *arrangement* of a set of hyperplanes. (See §13.5.4.)

2. Locate a point in a subdivision all of whose regions are convex (a *convex subdivision*). For example, an arrangement of hyperplanes is a convex subdivision.

3. Search for nearest neighbors in Voronoi diagrams. (See §13.5.3.)

4. Range searching. (See §13.6.2.)

5. Ray shooting. (See §13.6.3.)

Facts:

1. *Point location in straight-line subdivision using triangulation hierarchy*: Given an n-vertex triangulation $R' = (V', T')$, where V' is the set of vertices and T' is the set of triangles, an $(n+3)$-vertex *enclosed* triangulation $R = (V, T)$ is the triangulation R' together with the triangulation of the region between U and the convex hull of R', where $U = (V_U, T_U)$ is a triangle that contains R' in its interior. The *triangulation-hierarchy* of [Ki83] consists of a sequence of triangulations $\mathcal{R} = \langle R_1, R_2, \ldots, R_{c \log_2 n} \rangle$, where $R_1 = R$, $R_{c \log_2 n} = U$, and R_i is created from R_{i-1} as follows (see Example 1):

- remove from $V_{i-1} - V_U$ a set X of independent (that is, nonadjacent) vertices and remove from T_{i-1} the set Z of all triangles incident with any vertex in X: $V_i = V_{i-1} - X$, $T_i = T_{i-1} - Z$;
- retriangulate any polygons in $R_i = (V_i, T_i)$.

2. Algorithm 1 produces a hierarchy for planar subdivision. With minor modifications (for example, "triangles" become tetrahedrons), it can be used for subdivisions in $\mathcal{R}^3$. It can be proven that $|T_{c \log_2 n}| = 1$ for some constant c, and that $|\tau(t)|$ is a constant for every t.

3. Algorithm 1 runs in $O(n)$ time and produces a triangulation hierarchy that takes $O(n)$ space.

Algorithm 1: **Computing the triangulation hierarchy.**

```
input: planar straight-line subdivision $S$
output: triangulation hierarchy of $S$
compute triangulation $R'$ of $S$; compute enclosed triangulation $R$ of $R'$; choose a
    small constant $k$; $R_1 := R$; $i := 1$
while $|T_i| > 1$
  $i := i + 1$; $R_i := R_{i-1}$; mark all vertices in $V_i$ having degree $< k$
  while there exists some marked vertex $v$
    $P := (V_P, E_P)$ (polygon consisting of vertices adjacent to $v$; that is,
      $V_P := \{v_j \mid (v, v_j, v_k) \in T_i\}$; $E_P := \{(v_j, v_k) \mid (v, v_j, v_k) \in T_i\}$)
    remove $v$ from $V_i$; remove all the triangles incident with $v$ from $T_i$; that is,
      $T_{rem} := \{(v, v_j, v_k) \mid v_j \in V_P\}$; $T_i := T_i - T_{rem}$
    compute the triangulation $R_P$ of $P$
    for each triangle $t$ in $R_P$
      $\tau(t) :=$ the set of triangles in $T_{rem}$ that overlap with $t$
      create a pointer from $t$ to every triangle in $\tau(t)$
    unmark $v$ and any marked vertices in $V_P$
```

4. Algorithm 2 carries out point location, given a triangulation hierarchy, and takes $O(\log_2 n)$ time.

Algorithm 2: **Performing point location.**

```
input: a point $q$ and a triangulation hierarchy $\mathcal{R}$
output: triangle that contains $q$
check if $R_{c \log_2 n}$ contains $q$
$i := c \log_2 n - 1$; $t := U$
while $i \geq 1$
   determine the triangle $t'$ in $\tau(t)$ that contain $q$ using pointers from $t$ to $\tau(t)$
   $t := t'$; $i := i - 1$
```

5. The following table shows the complexity of various point location algorithms. The number m denotes the number of regions (or cells) in the subdivision S; n denotes the total combinatorial complexity of S.

dimension	*subdivision type*	*query time*	*space*	*preprocessing time*
2	convex subdivision	$O(\log_2 n)$	$O(n)$	$O(n)$
3	simple polytope	$O(\log_2 n)$	$O(n)$	$O(n)$
3	convex subdivision	$O(\log_2^2 n)$	$O(n \log_2^2 n)$	$O(n \log_2^2 n)$
d	arrangement of n hyperplanes	$O(\log_2 n)$	$O(n^d)$	$O(n^d)$
d	subdivision of m $(d{-}1)$-simplices with a total of n faces, $\epsilon > 0$	$O(\log_2^3 m)$	$O(m^{d-1+\epsilon} + n)$	$O(m^{d-1+\epsilon}$ $+ n \log_2 m)$

Example:

1. Part (a) of the figure seen on the next page shows triangulation R_1 of Fact 1 (the vertices that are removed from R_1 are circled). Part (b) shows triangulation R_2 (dotted lines are edges in retriangulation). Part (c) gives a list of the pointers from triangles in R_2 to triangles in R_1.

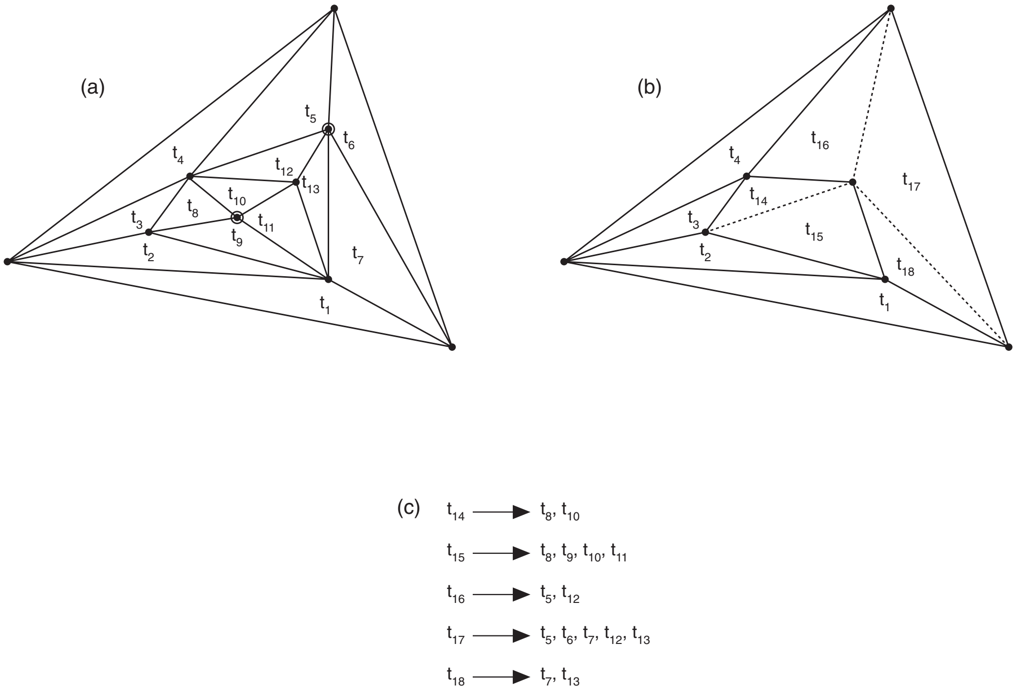
13.6.2 RANGE SEARCHING

Definitions:

The ***range counting problem*** is the problem of counting the number of points in a given set $S \subseteq \mathcal{R}^d$ that lie in a given query range q.

The ***range reporting problem*** is the problem of determining all points in a given set $S \subseteq \mathcal{R}^d$ that lie in a given query range q.

The ***range emptiness problem*** is the problem of determining if a given query range q contains any points from a given set $S \subseteq \mathcal{R}^d$.



Facts:

1. The following table gives information on various range searching algorithms. The integer n is the number of points in S; ϵ is an arbitrarily small positive constant. When the query is reporting, the query time has an additive factor of k, which is the size of the output.

dim	*range type*	*query time*	*space*	*preprocessing time*
2	orthogonal	$O(\log_2 n)$	$O(n \log_2^{2+\epsilon} n)$	$O(n \log_2 n)$
2	convex polygon	$O(\sqrt{n} \log_2 n)$	$O(n)$	$O(n^{1+\epsilon})$
2	convex polytope	$O(n^{2/3} \log_2^2 n)$	$O(n \log_2 n)$	$O(n^{1+\epsilon})$
d	convex polytope for $n \leq m \leq n^d$	$O(\log_2^{d+1} n)$ $O(n^{1-1/d})$ $O((n/m^{1/d}) \log_2^{d+1} n)$	$O(n^d)$ $O(n)$ $O(m^{1+\epsilon})$	$O(n^d (\log_2 n)^\epsilon)$ $O(n^{1+\epsilon})$ $O(m^{1+\epsilon})$
d	half-space for $n \leq m \leq n^d$	$O(\log_2 n)$ $O(n/m^{1/d})$	$O(n^d / \log_2^d n)$ $O(m)$	$O(n^d / \log_2^{d-\epsilon} n)$ $O(n^{1+\epsilon} + m(\log_2 n)^\epsilon)$

2. The following table gives information on various range reporting algorithms.

				preprocessing
dim	*range type*	*query time*	*space*	*time*
2	half-plane fixed-radius circle	$O(\log_2 n + k)$	$O(n)$	$O(n \log_2 n)$
2	orthogonal	$O(\log_2 n + k)$	$O(n \log_2^{\epsilon} n)$	$O(n \log_2 n)$
3	half-space	$O(\log_2 n + k)$	$O(n \log_2 n)$	$O(n \log_2^3 n \log_2 \log_2 n)$
d	half-space $n \le m \le n^{\lfloor \frac{d}{2} \rfloor}$	$O(\log_2 n + k)$ $O(n^{1-1/\lfloor \frac{d}{2} \rfloor+\epsilon}+k)$ $O(\frac{n}{m^{1/d}} \log_2 n+k)$	$O(n^{\lfloor \frac{d}{2} \rfloor+\epsilon})$ $O(n)$ $O(m^{1+\epsilon})$	$O(n^{\lfloor \frac{d}{2} \rfloor+\epsilon})$ $O(n)$ $O(m^{1+\epsilon})$
d	orthogonal	$O(\log_2^{d-1} n + k)$ $O(dn^{1-\frac{1}{d}} + k)$	$O(\frac{n \log_2^{d-1} n}{\log_2 \log_2 n})$ $O(dn)$	$O(n \log_2^{d-1} n)$ $O(dn \log_2 n)$

3. Orthogonal range searching in $\mathcal{R}^2$ can be carried out using range trees.

4. The *range tree* is defined recursively by Algorithm 3. Each node stores a subset of points organized into a threaded binary search tree by the y-coordinates of the points. The left child contains half the parent's points, in particular those with lesser x-coordinates; the right child contains the other half of the parents' points with greater x-coordinates.

Each node also stores the range of x-coordinates of its points. For simplicity, all coordinates of all points are assumed to be distinct. It is also assumed that all points of $S = \{(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)\}$ have been presorted by their x-coordinate so that $x_1 < x_2 < \cdots < x_n$.

5. The running time of Algorithm 3 is $O(n \log_2^2 n)$ and the space taken by the range tree is $O(n \log_2 n)$. The running time can be improved by a $\log_2 n$ factor. Essentially the same procedure can be used to build range trees in any dimension.

```
Algorithm 3:  Computing the range tree.
  procedure RangeTree($S = \{(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)\}$: set of points,
        $T$: pointer to root of a range tree)
  if $S = \emptyset$ then return
  else store the interval $[x_1, x_n]$ in $T.int$
     store $BinarySearchTree(S)$ in $T.y$
     $RangeTree(\{(x_1, y_1), \ldots, (x_{\frac{n}{2}}, y_{\frac{n}{2}})\}, T.left\_child)$
     $RangeTree(\{(x_{\frac{n}{2}+1}, y_{\frac{n}{2}+1}), \ldots, (x_n, y_n)\}, T.right\_child)$

  procedure BinarySearchTree($S' = \{(x_1, y_1), \ldots, (x_n, y_n)\}$: set of points)
  sort the points of $S'$ by $y$-coordinate so that $y_1 < y_2 < \cdots < y_n$
  create a threaded balanced binary search tree $B$ for $S'$:
     store point $(x_i, y_i)$ in the $i$th leftmost leaf $\ell_i$
     $\ell_i.next := \ell_{i+1}$  {connect the leaves into a linked list}
     $\ell_i.key := y_i$
     for each node $v$, $v.key := \min\{\ell_i.key \mid \ell_i \in subtree(v.right\_child)\}$
```

```
**Algorithm 4**: **Orthogonal range reporting using range trees**
  procedure $OrthoRangeSearching(q = [x_1, x_2] \times [y_1, y_2]$: rectangle in the plane,
      $T$: pointer to root of range tree)
  if $T = NIL$ then return
  else if $T.int \subseteq [x_1, x_2]$ then $SearchAll(T.y, [y_1, y_2])$
  if $[x_1, x_2] \cap \in T.left\_child.int \neq \emptyset$ then
    $OrthoRangeSearching(q, T.left\_child)$
  if $[x_1, x_2] \cap \in T.right\_child.int \neq \emptyset$ then
    $OrthoRangeSearching(q, T.right\_child)$

  procedure $SearchAll(v$: pointer to root of binary tree, $[y_1, y_2]$: query interval)
  while $v$ is not a leaf
    if $y_1 < v.key$ then $v = v.left\_child$
    else $v := v.right\_child$
  if $v.key < y_1$ then $v = v.next$
  while $v \neq NIL$ and $v.key < y_2$
    output point stored at $v$
    $v := v.next$
```

6. Orthogonal range reporting proceeds as follows down the range tree. If the range of the current node x is a subset of the x range of the query, then all the points in the node's binary search tree with y-coordinate in the y range of the query are output. If the x range of the query overlaps the x range of the left child, then the algorithm proceeds recursively to the left child. If the x range of the query overlaps the x range of the right child, then the algorithm proceeds recursively to the right child.

7. Algorithm 4 takes $O(\log_2^2 n + k)$ time, where k is the number of reported points. This running time can be improved to $O(\log_2 n + k)$.

Examples:

1. *Orthogonal range search*: The query range q is a Cartesian product of intervals on different coordinate axes.

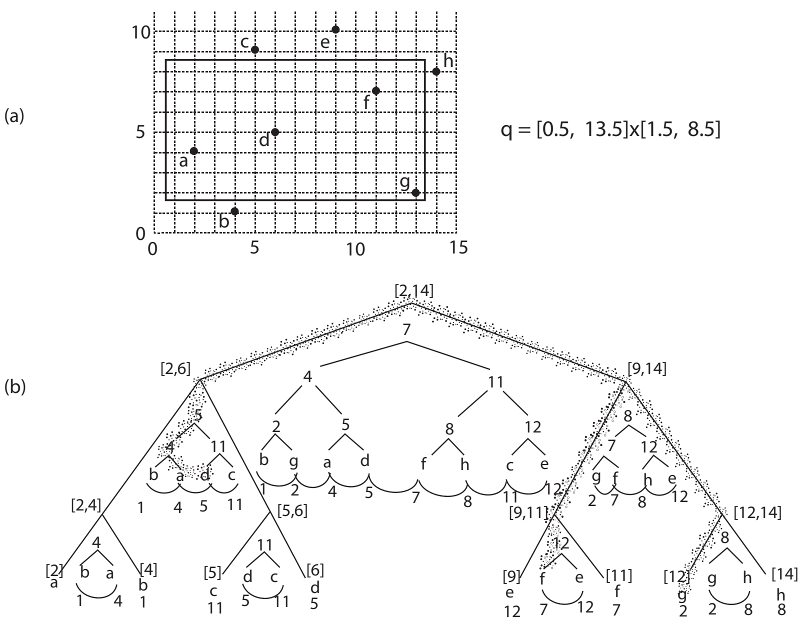
2. *Bounded distance search*: The query range q is a sphere in $\mathcal{R}^d$.

3. Other typical search domains are half-spaces and simplices.

4. *Machine learning*: Points are labeled as positive or negative examples of a concept, and range query determines the relative number of positive and negative examples in the range (thus enabling the range to be classified as either a positive or negative example of the concept).

5. *Multikey searching in databases*: Records identified by a d-tuple of keys can be viewed as a point in $\mathcal{R}^d$, and the range query on records corresponds to an orthogonal range query.

6. Part (a) of the following figure shows a set of eight points in $\mathcal{R}^2$: $a, b, \ldots, h$ and a query range q. Part (b) shows the associated range tree.



13.6.3 RAY SHOOTING AND LINES IN SPACE

Definitions:

A ***ray*** r is a half-line that is directed away from its endpoint; that is, it satisfies the equation $r = p + \lambda\vec{v}$, $\lambda \geq 0$, where p is the ***starting point*** of r and $\vec{v}$ is the ***direction*** of r.

Given a set S of geometric objects in $\mathcal{R}^d$ and a query ray r, the ***ray shooting problem*** is the problem of determining the first object in S that is hit by r, that is, the object $s \in S$ whose intersection with r is closer to p than the intersection between r and any other object in S.

A polyhedron is ***axis-parallel*** if each of its edges is parallel to a coordinate axis.

Facts:

1. Applications of ray shooting include hidden surface removal, visibility questions and ray tracing in computer graphics, and computing shortest paths in the presence of obstacles in robotics.

2. The following table gives information on various ray shooting algorithms.

		query		*preprocess-*
dim	*subdivision type*	*time*	*space*	*ing time*
2	simple polygon	$O(\log_2 n)$	$O(n)$	$O(n)$
2	line segments	$O(\log_2 n)$ $O(\sqrt{n}\log_2 n)$	$O(n^2\alpha^2(n))$ $O(n\log_2^2 n)$	$O(n^2\alpha^2(n))$ $O(n\log_2^2 n)$
3, fix p	axis-parallel polyhedra	$O(\log_2 n)$	$O(n\log_2 n)$	$O(n\log_2 n)$
3, fix p	polyhedra for any $\epsilon > 0$, $n \le m \le n^2$	$O(\log_2 n)$ $O(n^{1+\epsilon}/\sqrt{m})$	$O(n^2\alpha(n))$ $O(m^{1+\epsilon})$	$O(n^2\alpha(n))$ $O(m^{1+\epsilon})$
3, fix $\vec{v}$	axis-parallel polyhedra for any $\epsilon > 0$	$O(\log_2 n\ \times$ $(\log_2\log_2 n)^2)$ $O(\log_2 n)$	$O(n\log_2 n)$ $O(n^{1+\epsilon})$	$\tilde{O}(n\log_2^2 n)$ $O(n^{1+\epsilon})$
3, fix $\vec{v}$	polyhedra for any $\epsilon > 0$, $n \le m \le n^3$	$O(\log_2 n)$ $O(n^{1+\epsilon}/m^{1/3})$	$O(n^{3+\epsilon})$ $O(m^{1+\epsilon})$	$O(n^{3+\epsilon})$ $O(m^{1+\epsilon})$
3	axis-parallel polyhedra	$O(\log_2 n)$	$O(n^{2+\epsilon})$	$O(n^{2+\epsilon})$
3	polyhedra	$O(\log_2 n)$	$O(n^{4+\epsilon})$	$\tilde{O}(n^{4+\epsilon})$

Algorithm:

1. *Ray shooting from a fixed point among planar nonintersecting segments*: For simplicity, assume that the fixed point p in the plane is at the origin. Define two relations using the same notation: for two points q_j and q_k, $q_j \prec q_k$ if q_j makes a smaller polar angle with respect to the origin than does q_k; for two nonintersecting segments s_j and s_k, $s_j \prec s_k$ if for every ray r that starts at the origin and crosses both s_j and s_k, r crosses s_j before crossing s_k. Segment (q_j, q_k) *starts* at q_j and *ends* at q_k if $q_j \prec q_k$. A *null* segment is denoted s_∞; that is, a query ray hitting s_∞ does not intersect any of the given segments.

Algorithm 5, *VisibilityMap*, creates an array $\mathcal{I}$ of nonoverlapping angle intervals, sorted by their polar angle, with the property that consecutive entries in $\mathcal{I}$ have different "smallest" segments according to the "$\prec$" relation.

This algorithm uses a technique called sweep-plane: the algorithm sweeps the polar coordinates originating at p with a ray, stopping the sweep-ray at all the angles where the sweep-ray intersects a segment endpoint. The set S' stores all the segments intersected by the current sweep-ray; S' is organized as a binary search tree ordered by the "$\prec$" relation on the segments. When the sweep-ray encounters a segment endpoint that starts a segment, the segment is added to S'; when the sweep-ray encounters a segment endpoint that ends a segment, the segment is removed from S'. At every stop of the sweep-ray, if the smallest (under the "$\prec$" relation) segment of S' is different from the sweep-ray's last stop, a new interval is added to $\mathcal{I}$. See Example 3.

Algorithm 5, *VisibilityMap*, takes $O(n\log_2 n)$ time and can be used for ray shooting among simple polygons. The visibility map consists of array $\mathcal{I}$ and takes $O(n)$ space. The problem is harder if the segments are allowed to intersect.

Algorithm 6, *RayShoot*, takes $O(\log_2 n)$ time.

Algorithm 5: **Computing visibility map.**

```
procedure $VisibilityMap$($p$: fixed origin point, $S$: set of $n$ segments)
sort endpoints of all segments by their polar angles so that $q_1 \prec q_2 \prec \cdots \prec q_{2n}$
$no\_of\_intervals := 0$; $S' := \langle s_\infty \rangle$
{$S'$ is a binary search tree containing segments ordered by the "$\prec$" relation}
for $i = 1$ to $2n$
   $first :=$ the "smallest" (under the "$\prec$" relation) segment in $S'$
   if $q_i$ starts a segment $s_j$ then insert $s_j$ into $S'$
   if $q_i$ ends a segment $s_j$ then remove $s_j$ from $S'$
   if $first \neq$ smallest segment in $S'$ then
      $no\_of\_intervals := no\_of\_intervals + 1$
      $\mathcal{I}[no\_of\_intervals].angle :=$ polar angle of $q_i$
      $\mathcal{I}[no\_of\_intervals].name :=$ the smallest segment in $S'$
```

Algorithm 6: **Ray shooting using the visibility map.**

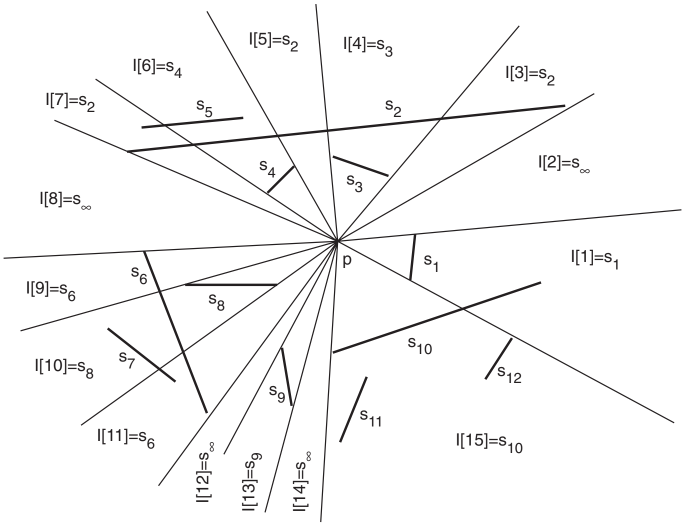
```
procedure $RayShoot$($r = (p, \vec{v})$: query ray, $\mathcal{I}$: visibility map)
consider $\vec{v}$ as a polar angle
do a binary search among $\mathcal{I}[*].angle$ to find the segment $\mathcal{I}[k].name$ such that
   $\mathcal{I}[k].angle \le \vec{v}$ and $\mathcal{I}[k+1].angle > \vec{v}$
```

Examples:

1. S can be a single object, such as a simple polygon in the plane.

2. S can be a collection of objects, such as a set of polyhedra in 3-dimensional space.

3. The following figure illustrates the sweep-plane technique, with rays originating from point p. The thick lines in this figure are the segments in S and the thin lines are the boundaries between intervals in the visibility map for S. The intervals are labeled by their names.



13.7 COMPUTATIONAL TECHNIQUES

This section describes some techniques used in the design of geometric algorithms.

13.7.1 PARALLEL ALGORITHMS

The goal of parallel computing is to solve problems faster than would be possible on a sequential machine — through the use of parallel algorithms. The complexity of a parallel algorithm is given in terms of its *time* and the number of *processors* used [Já92]. The *work* of a parallel algorithm is bounded above by the *processor-time product*, the product of the number of processors and the time.

Definitions:

A ***parallel algorithm*** is an algorithm that concurrently uses more than one processing element during its execution.

A ***parallel machine*** is a computer that can execute multiple operations concurrently.

A ***parallel random access machine*** (***PRAM***) is a synchronous machine in which each processor is a sequential RAM and processors communicate using a shared memory. Depending upon whether concurrent accesses are allowed to the shared memory cells, a PRAM is either ***exclusive read*** (***ER***) or ***concurrent read*** (***CR***), and either ***exclusive write*** (***EW***) or ***concurrent write*** (***CW***).

Facts:

1. *Parallel divide-and-conquer*: Parallel algorithms can be obtained using the *divide-and-conquer* paradigm. The subproblems resulting from the divide phase are solved in parallel, and the combining phase of the algorithm is parallelized. In traditional divide-and-conquer algorithms, the problem is partitioned into two subproblems.

2. *Many-way divide-and-conquer*: Sometimes faster parallel algorithms can be obtained by partitioning the original problem into multiple, smaller subproblems, often referred to as *many-way divide-and-conquer* [Já92]. The solution to the original problem is obtained from the solutions to the subproblems.

3. *Cascading divide-and-conquer*: Some divide-and-conquer algorithms can be speeded up by pipelining (cascading) the work performed in the recursive applications as follows. Consider a binary tree representing the solutions to the recursive computations of the original divide-and-conquer algorithm, where leaves represent terminal subproblems. To obtain a faster algorithm, information is passed from a child to its parent before the solution to the child's subproblem is completely known. The parent then does some precomputation so that the solution to its problem can be computed as soon as the solutions of both of its children's problems are available. Typically, the information passed from a child to its parent is a constant sized sample of the child's current state. Often, such algorithms run in time proportional to the height of the recursion tree.

4. Cole first used pipelining to design a work-optimal $O(\log n)$ time parallel version of merge sort. Atallah, Cole, and Goodrich used this strategy to solve several geometric problems including the 3-dimensional maxima problem and computing the visibility of a polygon from a point [AtGo93].

Algorithms:

1. *Using parallel divide-and-conquer to compute the convex hull $CH(S)$ of a set S of n points in the plane*: In Algorithm 1 the points in S are presorted by x-coordinate so that the division in the second step can be accomplished in constant time. The sorting takes $O(\log n)$ time using $O(n \log n)$ work [Já92]. The tangents needed in the third step can be computed in constant time using $|S_L| + |S_R|$ processors on a CREW PRAM [AtGo93]. Thus, as there are $O(\log n)$ recursive calls, Algorithm 1 runs in $O(\log n)$ time using $O(n \log n)$ work, which is both worst-case work-optimal and time-optimal for the CREW PRAM.

```
Algorithm 1: ConvexHull($S$: a set presorted by $x$-coordinate).
  if $|S| \leq 3$ then construct $CH(S)$ directly
  else
    partition $S$ into two subsets of equal size, $S_L$ (the left subset) and $S_R$ (the
        right subset), which are separated by a vertical line
    in parallel, recursively construct $CH(S_L)$ and $CH(S_R)$
    construct $CH(S)$ from $CH(S_L)$, $CH(S_R)$, and common tangents between them
```

2. *Computing the convex hull of a 3-dimensional point set*: The convex hull of a 3-dimensional point set can be computed using a two-way divide-and-conquer algorithm similar to Algorithm 1. The running time of this algorithm is $O(\log^2 n)$ because the combining in the last step of Algorithm 1 takes $O(\log n)$ time since it is more complex than in the planar case. However, a faster algorithm can be designed using many-way divide-and-conquer. The point set is partitioned into $O(n^{\frac{1}{2}})$ groups, each of size $O(n^{\frac{1}{2}})$, and then, even though the combining still takes $O(\log n)$ time, a total time of $O(\log n)$ can be obtained.

13.7.2 RANDOMIZED ALGORITHMS

Randomization is a powerful technique that has been used in algorithms for many geometric problems.

Definition:

A ***randomized algorithm*** is an algorithm that makes random choices during its execution.

Facts:

1. Randomized algorithms are often faster, simpler, and easier to generalize to higher dimensions than deterministic algorithms.

2. For many problems, efficient algorithms can be obtained by processing the input objects in a particular order or by grouping them into equal-sized subsets. Although significant computation may be required to exactly determine an appropriate order or a good partition into subsets, in many cases simple random choices can be used instead.

3. *Randomized incremental methods*: One of the simplest ways to construct a geometric structure is incrementally. In an incremental construction algorithm, the input objects are inserted one at a time and the current structure is updated after each addition. The desired structure is obtained after all input objects have been inserted. Although the cost of some updates could be very large, in many cases it can be shown that if the objects are inserted in *random order*, then the amount of work for each update is expected to be small and the expected running time of the algorithm will be small as well. Thus, the expectation of the running time depends not on the input distribution but on the ratio of good to bad insertion sequences.

4. The power of randomization in incremental algorithms was first noted by Clarkson and Shor, and by Mulmuley. Randomized incremental algorithms have been proposed for constructing many geometric structures including convex hulls, Delaunay triangulations, trapezoidal decompositions, and Voronoi diagrams [Mu94].

5. *Randomized divide-and-conquer*: In randomized divide-and-conquer a random subset of the input is used to partition the original problem into subproblems. Then, as in any divide-and-conquer algorithm, the subproblems are solved, perhaps recursively, and their solutions are combined to obtain the solution to the original problem. Ideally, the partition produces subproblems of nearly equal size and the sum of the subproblem sizes roughly equals the input size. This ideal can almost be achieved for many geometric problems. For example, with probability at least $\frac{1}{2}$, $O(r)$ subproblems of size $O(\frac{n \log r}{r})$ can often be obtained, where n is the number of input objects and r is the size of the random subset.

6. The fact that a random sample of the input items can often be used to produce subproblems of almost equal size was first shown by Clarkson, and by Haussler and Welzl. Randomized divide-and-conquer algorithms are known for many geometric problems including answering closest-point queries, constructing arrangements, triangulating point sets, and constructing convex hulls [Mu94].

Examples:

1. *Incrementally constructing the intersection of a set H of n halfplanes in the plane*: First, a random permutation $(h_1, h_2, \ldots, h_n)$ of H is formed. Let I_i denote the intersection of halfplanes h_1 through h_i. During the ith iteration of the algorithm, I_i is computed from I_{i-1} by removing the portion of I_{i-1} that is not contained in h_i.

To make this update easier, a vertex of the current intersection I_{i-1} that is not contained in h_j is maintained, for all $j \geq i$; such a vertex is said to *conflict* with h_j. Given a conflicting vertex v for h_i, the portion of I_{i-1} that must be removed is determined by traversing its boundary in both directions from v until reaching vertices that are contained in h_i. Since I_n has size $O(n)$, the amortized cost of each update is $O(1)$ and the algorithm spends a total of $O(n)$ time updating the intersection. After I_i is computed, the conflicting vertex for h_j is updated, for all $j > i$. It can be shown that the total cost of maintaining the conflicting vertices in the algorithm is $O(n \log n)$.

2. *Using randomized divide-and-conquer to construct the intersection $I(S)$ of a set S of n halfplanes, each of which contains the origin*: See Algorithm 2. In Step 2, the intersection of the halfplanes in the sample is used to create $O(r)$ triangles, each of which corresponds to a subproblem. For technical reasons, the region corresponding to each subproblem should have constant descriptive complexity.

Often, this condition is achieved by triangulating the resulting structure. Next, the input is distributed to the subproblems. Usually, this is done by finding the objects that intersect, or *conflict* with, a subproblem's region.

Then, the subproblems are solved, recursively if desired, and their solutions are combined to form the solution to the original problem. In the intersection algorithm the final solution is obtained by "gluing" the subproblem solutions together.

If r is some suitably chosen constant, then Algorithm 2 runs in expected time $O(n \log n)$.

```
Algorithm 2: Intersect($S$: a set of $n$ halfplanes).
  $R :=$ a random sample of size $r$ chosen from $S$.
  compute the intersection $I(R)$ and triangulate it by connecting each vertex of
      $I(R)$ to the origin to obtain $T(R)$
  for each triangle $t \in T(R)$, determine its conflict list $c(t)$ (the set of halfplanes
      in $S$ whose bounding lines intersect $t$)
  for each triangle $t \in T(R)$, compute the intersection of the halfplanes in $c(t)$ re-
      stricted to $t$ {This may be done recursively}
```

13.7.3 PARAMETRIC SEARCH

Definition:

Parametric search is an algorithmic technique for solving optimization problems by using an algorithm for solving an associated decision problem as a subroutine.

Algorithm:

1. Parametric search is a powerful algorithmic technique that can be applied to a diverse range of optimization problems. It is best explained in terms of an abstract optimization problem. Consider two versions of this problem:

- a *search problem* P, which can be parametrized by some real, nonnegative value t and whose solution is a value t^* that satisfies the optimization criteria;
- a *decision problem* $D(t)$, whose input includes a real, nonnegative value t and whose solution is either YES or NO.

In parametric search, the search problem P is solved using an algorithm A_s for the decision problem $D(t)$. In order to apply parametric search, the points corresponding to YES answers for $D(t)$ must form a connected, possibly unbounded, interval in $[0, \infty)$. Then, assuming that $D(0) =$ YES, the search problem P is to find the largest value of t for which $D(t) =$ YES.

The basic idea of parametric search is to use A_s to find t^*. This is done by simulating A_s, but using a variable (parameter) instead of a value for t. Assume that A_s can detect if $t = t^*$, and that the computation in A_s consists of comparisons, each of which tests the sign of a bounded degree polynomial in t and in the original input. During each comparison in the simulation:

- the roots of the appropriate polynomial are computed,
- A_s is run on each root,
- t^* is located between two consecutive roots.

Thus, each comparison in the simulation reduces the interval known to contain t^*, which is originally $[0, \infty)$.

Facts:

1. In most geometric applications it can be shown that at some point the simulation will test a root that is equal to t^*.

2. If T_s denotes the worst-case running time of A_s, the total cost of the parametric search is $O(T_s^2)$ since there are $O(T_s)$ operations in the simulation of A_s, and each comparison operation in this simulation takes $O(T_s)$ time.

3. With a parallel algorithm A_p to solve the decision problem $D(t)$, the (sequential) parametric search can be done faster. Suppose that A_p runs in T_p parallel time steps using p processors. Then, A_p performs at most p *independent* comparison operations during each parallel time step. The parametric search simulates A_p sequentially as follows. To simulate a parallel time step of A_p:

- compute the $O(p)$ roots of the at most p bounded degree polynomials corresponding to independent comparisons in the parallel time step;
- sort these roots;
- use a binary search to locate t^* between two consecutive roots. (The sequential algorithm A_s is used to evaluate the roots during the binary search.)

The cost of simulating each parallel time step is $O(p \log p + T_s \log p)$, and the total cost of the parametric search is $O(T_p(p \log p + T_s \log p))$.

4. Parametric search was originally proposed by Megiddo. It has been used for many geometric problems including ray shooting, slope selection, and computing the diameter of a 3-dimensional point set [Mu94].

Example:

1. *Answering ray shooting queries in a convex polytope Q*: In the search problem P, a ray r is given originating at a point p contained in Q, and the face of Q hit by r needs to be found. The decision problem $D(t)$ is the *polytope membership problem*: given a point t, determine if t lies in Q. The value t^* sought by the parametric search is the point where r intersects Q. The ray shooting problem can be solved in $O(\log^2 n)$ time by parametric search [Mu94] (since, given an appropriate data structure, the polytope membership problem can be solved sequentially in $O(\log n)$ time).

13.7.4 FINITE PRECISION

Geometric algorithms are usually designed assuming the *real random access machine* model of computation. In this model, values can be arbitrarily long real numbers, and all standard operations such as $+, -, \times$, and $\div$ can be performed in unit time regardless of operand length. In reality, however, computers have finite precision and can only approximate real numbers. Several techniques have been suggested for dealing with this problem [Fo93].

Facts:

1. *Algorithms directly designed for a discrete domain*: This approach can dramatically increase the complexity of the algorithm and has not gained wide use.

2. *Floating point numbers*: Floating point numbers provide a convenient and efficient way to approximate real numbers. Unfortunately, naively rounding numbers in geometric algorithms can create serious problems such as topological inversions. There are cases when floating point arithmetic can safely be used. For example, for certain inputs the result of the floating point operation will be unambiguous. Some algorithms have been shown to be sufficiently stable using floating point arithmetic. However, no general method is known for designing stable algorithms.

3. *Exact arithmetic*: In exact arithmetic, numbers are represented by vectors of integers and all primitive operations are guaranteed to give correct answers. Integer arithmetic is sufficient for many geometric algorithms since symbolic or algebraic numbers are rarely needed, and in many cases homogeneous coordinates can remove the need for rational numbers. However, since exact representations can have large bit complexity, exact arithmetic can be expensive — typically increasing the cost of arithmetic operations by an order of magnitude. This cost can be decreased somewhat by optimizing the expressions and computations involving exact arithmetic.

4. *A combination of floating point and exact arithmetic*: First, the operation is performed using floating point arithmetic. Then, if the result is ambiguous, an exact computation is performed.

5. *Adaptive-precision arithmetic*: In adaptive-precision arithmetic each number is approximated by an interval whose endpoints require lower precision. If the exact computation using the approximation is ambiguous, the method iterates using smaller and smaller intervals with higher precision endpoints.

6. Although no clear consensus has been reached, a combination of the above strategies may yield the best results.

13.7.5 DEGENERACY AVOIDANCE

To simplify exposition by reducing the number of cases that must be considered, many geometric algorithms assume that the input is in *general position*. The general position assumption depends on the problem. For example, in problems involving planar point sets, the assumption might be that no two points have the same x-coordinate, that no three points lie on the same line, or that no four points lie on the same circle.

Definitions:

A set of objects is in ***general position*** if the objects satisfy certain specified conditions.

A set of input objects that violates the general position assumption is ***degenerate***.

Facts:

1. *Perturbation*: Several schemes have been proposed that apply small perturbations to transform the input so that it does not contain degeneracies [Fo93]. The object of perturbation schemes is to allow the design of simpler algorithms which may validly assume the input is in general position.

Algorithms using perturbation schemes may not always produce correct output. For example, in a convex hull algorithm, points on the boundary could potentially be perturbed into the interior of the polytope and vice versa. Also, perturbation schemes can affect, perhaps adversely, *output-sensitive* algorithms whose running times depend on the size of the output they produce.

2. *Deal with degeneracies directly*: Algorithms that deal with degeneracies in a problem specific manner have been designed for problems such as triangulating point sets. Although this approach is not as general and usually leads to more complex algorithms than those employing perturbation schemes, it can provide superior performance.

3. *Symbolically perturbing the coordinates of each input point (Edelsbrunner, Mücke)*: This is done by adding to each coordinate a suitable power of a small, positive real number represented by a symbolic parameter ϵ. Then, since values are now polynomials in ϵ, the arithmetic operations in the algorithm are replaced by polynomial arithmetic operations. Geometric primitives are implemented symbolically, typically by evaluating a sequence of determinants. Assuming that the dimension of the problem is fixed, this scheme increases the running time of the algorithm by at most a constant factor. However, the overhead incurred can in fact be quite large.

13.8 APPLICATIONS OF GEOMETRY

Geometry overlays the entire computing spectrum, having applications in almost every area of science and engineering, including astrophysics, molecular biology, mechanical design, fluid mechanics, computer graphics, computer vision, geographic information systems, robotics, multimedia, and mechanical engineering.

The growing availability of large geometric databases is a major driver of the increase in applications. GIS mapping databases containing most of the world's roads enable route planning applications. Airborne LIDAR creates terrain elevation databases. That enables observer visibility computation, with applications ranging from radio tower siting to visual nuisance mitigation. Laser scanners produce 3D point clouds recording the surfaces of objects from buildings down to sculptures and even people. The ensuing applications include deducing the structure of those objects' surfaces.

13.8.1 MATHEMATICAL PROGRAMMING

Definition:

Mathematical programming is the large-scale optimization of an objective function (such as cost) of many variables subject to constraints, such as supplies and capacities.

Facts:

1. Mathematical programming includes both *linear programming* (continuous, integer, and network) and *nonlinear programming* (quadratic, convex, general continuous, and general integer).

2. Applications include transportation planning and transshipment, factory production scheduling, and even determining a least-cost but adequate diet.

3. A *modeling language*, such as AMPL, is often used in applications [FoGaKe93].

Example:

1. *Linear programming in low dimensions*: This is a special case of linear programming since there are algorithms whose time is linear in the number of constraints but exponential in the number of dimensions.

Application:

1. Find the *smallest enclosing ball* of a set of points or a set of balls in arbitrary dimension [We91]. This uses a randomized incremental algorithm employing the move-to-front heuristic.

13.8.2 POLYHEDRAL COMBINATORICS

Polyhedra have been important to geometry since the classification of regular polyhedra in classical times.

Fact:

1. The following are some of the many possible operations that can be performed on polygons and polyhedra:

- *Boolean operations*, such as intersection, union, and difference;
- *point location* of new query points in a preprocessed set of polygons, which may partition a larger region;
- *range search* of a preprocessed set of points to find those inside a new query polygon;
- *decomposition* (or *triangulation*) of a polygon into triangles or a polyhedron into tetrahedra (§13.4.2). A simple n-gon is always decomposable into $n-2$ triangles, in linear time, and all triangulations have exactly $n-2$ triangles. However, some polyhedra in $\mathcal{R}^3$ cannot be partitioned intro tetrahedra without additional Steiner points. Also, different triangulations of the same polyhedron may have different numbers of tetrahedra.

Applications:

1. *Aperiodic tilings and quasicrystals*: Tilings (in the plane) and crystallography (in 3-dimensional space) are classic applications of polygons and polyhedra. A recent development is the study of aperiodic (Penrose) tilings [Ga77] and quasicrystals [Ap94]. These are locally but not globally symmetric under 5-fold rotations, quasi-periodic with respect to translations, and self-similar. The 1991 Nobel Prize in Chemistry was awarded for the discovery of actual quasicrystals:

- `http://www.nobelprize.org/nobel_prizes/chemistry/laureates/2011/`

Large-scale symmetries, such as 5-fold, that are impossible in traditional crystallography, can be visible with X-ray diffraction. Tilings can be constructed by projecting simple objects from, say, $\mathcal{R}^5$. One application is the surface reinforcement of soft metals.

2. *Error-correcting codes*: Some error-correcting codes can be visualized with polytopes as follows. Assume that the goal is k-bit symbols, where any error of up to b bits can be detected. The possible symbols are some of the 2^k vertices of the hypercube in k-dimensional space. The set of symbols must contain no two symbols less than $b+1$ distance apart, where the metric is the number of different bits. If errors of up to c bits are to be correctable, then no two symbols can be closer than $2c+1$.

Similarly, in quantum computing, a *quantum error-correcting code* can be designed using Clifford groups and binary orthogonal geometry [CaEtal97].

13.8.3 COMPUTATIONAL CONVEXITY

Definitions:

An ***$\mathcal{H}$-polytope*** is a polytope defined as the intersection of m half-spaces in $\mathcal{R}^n$.

A ***$\mathcal{V}$-polytope*** is a polytope defined as the convex hull of m points in $\mathcal{R}^n$.

A ***zonotope*** is the vector (Minkowski) sum of a finite number of line segments.

Computational convexity is the study of high-dimensional convex bodies.

An ***oracle*** is an algorithm that gives information about a convex body.

Facts:

1. Computational complexity is related to linear programming, polyhedral combinatorics, and the algorithmetic theory of polytopes and convex bodies.

2. In contrast to computational geometry, computational complexity considers convex structures in normed vector spaces of finite but not restricted dimension. If the body under consideration is more complex than a polytope or zonotope, it may be represented as an oracle. Here the body is a black-box, and all information about it, such as membership, is supplied by calls to the oracle function. Typical algorithms involve *volume computation*, either deterministically, or by *Monte Carlo* methods, perhaps after decomposition into simpler bodies, such as simplices.

3. When the dimension n is fixed, the volume of $\mathcal{V}$-polytopes and $\mathcal{H}$-polytopes can be computed in polynomial time.

4. There does not exist a polynomial-space algorithm for the exact computation of the volume of $\mathcal{H}$-polytopes (where n is part of the input).

5. Additional information on computational convexity can be found at

- `http://dimacs.rutgers.edu/TechnicalReports/TechReports/1994/94-31.ps`

13.8.4 MOTION PLANNING IN ROBOTICS

In Computer Assisted Manufacturing, both the tools and the parts being assembled must often be moved around each other in a cluttered environment. Their motion should be planned to avoid collisions, and then to minimize cost.

Definition:

A ***Davenport-Schinzel sequence*** of order s over an alphabet of size n, or $DS(n,s)$, is a sequence of characters such that:

- no two consecutive characters are the same;
- for any pair of characters, a and b, there is no alternating subsequence of length $s+2$ of the form $\ldots a \ldots b \ldots a \ldots b \ldots$.

Facts:

1. Practical general motion, *path planning*, is solvable with Davenport-Schinzel sequences [ShAg95]. Upper bounds on $\lambda_s(n)$, the length of the longest $DS(n,s)$, determine upper bounds on the complexity of the lower envelopes of certain functions.

For example, given n points in the plane that are moving with positions that are polynomials of degree s in time, the number of times that the closest pair of points can change is $\lambda_{2s}(\binom{n}{2})$.

2. Visibility graphs (§13.5.5) are useful in finding a shortest path between two points in the plane, in the presence of obstacles.

3. The problem of moving a finite object in the presence of obstacles may also be mapped into a *configuration space* (or *C-space*) problem of moving a corresponding point in a higher dimension. If translational and rotational motion in 2-dimensional (respectively 3-dimensional) is allowed, then the C-space is 3-dimensional (respectively 6-dimensional).

4. Articulated objects, multiple simultaneous motion, and robot hands also increase the number of degrees of freedom.

5. Current problems:

- *representation* of objects, since although planar, faceted models are simpler, the objects should be algebraic surfaces, and even if they are planar, in C-space their corresponding versions will be curved;
- *grasping*, or placing a minimal number of fingers to constrain the object's motion;
- *sequence planning* of the assembly of a collection of parts;
- *autonomous navigation* of robots in unstructured environments.

13.8.5 CONVEX HULL APPLICATIONS

Facts:

1. The convex hull (§13.5.1) is related to the Voronoi diagram (§13.5.3) since a convex hull problem in $\mathcal{R}^k$ is trivially reducible to a Voronoi diagram problem in $\mathcal{R}^k$, and a Voronoi diagram problem in $\mathcal{R}^k$ is reducible to a convex hull problem in $\mathcal{R}^{k+1}$.

2. The definition of convex hull is not constructive, in that it does not lead to a method for finding the convex hull. Nevertheless, there are many constructive algorithms and implementations. One common implementation is *QuickHull* (§13.5.1), a general dimension code for computing convex hulls, Delaunay triangulations, Voronoi vertices, furthest-site Voronoi vertices, and half-space intersections [BaDoHu96].

3. *Alpha-shapes* are a useful generalization of convex hulls [Ed05]. An intuitive definition is as follows. For a given α, form a surface by rolling around the given point set with a sphere of radius α, then smooth out the curved regions. The specification $\alpha = \infty$ gives the convex hull of the point set. The smaller the value of α, the more closely the original points are followed. One application is inferring a surface from a 3D point set. A good introduction to the topic is found at

- `http://graphics.stanford.edu/courses/cs268-16-fall/Handouts/AlphaShapes/as_fisher.pdf`

Examples:

1. *Mathematics*:

- determining the principal components of spectral data;
- studying circuits of matroids that form a Hilbert base;
- studying the neighbors of the origin in the $\mathcal{R}^8$ lattice.

2. *Biology and medicine*:

- classifying molecules by their biological activity;
- determining the shapes of left ventricles for electrical analysis of the heart.

3. *Engineering*:

- computing support structures for objects in layered manufacturing in rapid prototyping [StBrEa95]. By supporting overhanging material, these structures prevent the object from toppling while partially built.
- designing nonlinear controllers for controlling vibration;
- finding invariant sets for delta-sigma modulators;
- classifying handwritten digits;
- analyzing the training sets for a multilayer perceptron model;
- determining the operating characteristics of process equipment;
- navigating robots;
- creating 6-dimensional wrench spaces to measure the stability of robot grasps;
- building micromagnetic models with irregular grain structures;
- building geographical information systems;
- simulating a spatial database system to evaluate spatial tesselations for indexing;
- producing virtual reality systems;
- performing discrete simulations of incompressible viscous fluids using vortex methods;
- modeling subduction zones of tectonic plates and studying fluid flow and crystal deformation;
- computing 3-dimensional unstructured meshes for computational fluid dynamics.

13.8.6 NEAREST NEIGHBOR

Variants of the problem of finding the nearest pair of a set of points have applications in fields from handwriting recognition to astrophysics.

Facts:

1. *Fixed search set, varying query point*: A fixed set $\mathcal{P}$ of n points in $\mathcal{R}^d$ is preprocessed so that the closest point $p \in \mathcal{P}$ can be found for each query point q. The search time per query can range from $\log n$ (if $d = 2$) to $n^{\frac{d}{2}}$ (for large d). The Voronoi diagram is commonly used in low dimensions. However, because of the Voronoi diagram's complexity in higher dimensions, hierarchical search structures, bucketing, and probabilistic methods perhaps returning approximate answers are common.

2. *Moving points*: The points in $\mathcal{P}$ may be moving and the close pairs of points over time is of interest.

Examples:

1. Fixed search sets, varying query point:

- *Character recognition in document processing*: Each representative character is defined by a vector of features. Each new, unknown character must be mapped to the closest representative character in feature space.
- *Color map optimization in computer graphics*: Many frame buffers allow only the 256 colors in the current color map to be displayed simultaneously, from a palette of 2^{24} possible colors. Thus, each color in a new image must be mapped to the closest color in the color map. A related problem is the problem of determining what colors to use in the color map.

- *Clustering algorithms for speech and image compression in multimedia systems*: As in the color map problem, a large number of points must be quantized down to a smaller set.

2. Moving points:

- *Simulation of star motion in astrophysics*: Calculating the gravitational attraction between every pair of stars is too costly, so only close pairs are individually calculated. Otherwise the stars are grouped, and the attraction between close groups is calculated. The groups may themselves be grouped hierarchically.
- *Molecular modeling*: In molecular modeling, close pairs of atoms will be subject to van der Waals forces.
- *Air traffic control*: Air traffic controllers wish to know about pairs of aircraft closer than a minimum safe distance. Here the metric is nonuniform; small vertical separations are more tolerable than small horizontal separations.
- During path planning in robotics and numerically controlled machining, unintended close pairs of objects must also be avoided.

13.8.7 COMPUTER GRAPHICS

Computer graphics may be divided into *modeling* of surfaces, and *simulation* of the models. The latter includes *rendering* a scene and its light sources to generate synthetic imagery with respect to some viewpoint. Rendering involves *visibility*, or determining which parts of the surfaces are visible, and *shading* them according to some lighting model.

Definitions:

Anti-aliasing refers to filtering out high-frequency spatial components of a signal, to prevent artifacts, or aliases, from appearing in the output image. In graphics, a high frequency may be an object whose image is smaller than one pixel or a sharp edge of an object.

A ***GUI*** (***graphical user interface***) is a mechanism that allows a user to interactively control a computer program with a bitmapped display by using a mouse or pointer to select menu items, move sliders or valuators, and so on. The keyboard is only occasionally used. A GUI contrasts with typing the program name followed by options on a command line, or by preparing a text file of commands for the program. A GUI is easier and more intuitive to use, but can slow down an expert user.

Examples:

1. *Visibility*: Visibility algorithms may be *object-space*, where the visible parts of each object are determined, or *image-space*, where the color of each pixel in the frame buffer is determined. The latter is often simpler, but the output has less meaning, since it is not referred back to the original objects. Techniques include *ray tracing* and *radiosity*.

- *Ray tracing*: Ray tracing extends a line from viewpoint through each pixel of the frame buffer until the first intersecting object. If that surface is a mirror, then the line is reflected from the surface and continues in a different direction until it hits another object (or leaves the scene). If the object is glass, then both a reflecting and a refracting line are continued, with their colors to be combined according to Fresnel's law.

One geometry problem here is that of *sampling for subpixel averaging*. The goal is to color a square pixel of a frame buffer according to the fraction of its area occupied by each visible object. Given a line diagonally crossing a pixel, the fraction of the pixel covered by that face must be obtained for anti-aliasing. If the edges of two faces intersect in this pixel, each face cannot be handled independently, for example with an anti-aliased Bresehnam algorithm. If this is done badly, then it is very obvious in the final image as a possible fringe of a different color around the border of the object [Mi96].

The solution is to pick a small set of points in the pixel (typically 9, 16, or 64 points), determine which visible object projects to each point, and combine those colors. The problem is then to select a set of sampling points in the pixel, such that given a subset region, the number of points in it approximates its area. Four possible methods, from worst to best, are to

- ◇ pick the points independently and uniform randomly;
- ◇ use a nonrandom uniform distribution;
- ◇ start with the above distribution, then jitter the points, or perturb each one slightly;
- ◇ use simulated annealing to improve the point distribution.

- *Radiosity*: Radiosity partitions the scene into facets, computes a *form factor* of how much light from each facet will impinge on each other, and solves a system of linear equations to determine each facet's brightness. This models diffuse lighting particularly well.
- *Windowing systems*: Another visibility problem is designing the appropriate data structure for representing the windows in a GUI, so that the window that is in front at any particular pixel location can be determined, in order to receive the input focus.
- *Radio wave propagation*: The transmission of radio waves, as from cellular telephones, which are reflected and absorbed by building contents, is another application of visibility [Fo96].

2. *Computer vision*: Applications of geometry to vision include *model-based recognition* (or *pattern matching*), and *reconstruction or recovery of 3-D structure* from 2-D images, such as stereopsis, and structure from motion. In recognition, a model of an object is transformed into a sensor-based coordinate system and the transformation must be recovered. In reconstruction, the object must be determined from multiple projections.

3. *Medical image shape reconstruction*: Various medical imaging methods, such as computer tomography, produce data in the form of successive parallel slices through the body. The basic step in reconstructing the 3-dimensional object from these slices in order to view it involves joining the corresponding vertices and edges of two polygons in parallel planes by triangles to form a simple polyhedron. However, there exists a pair of polygons that cannot be so joined [GiORSu96].

13.8.8 MECHANICAL ENGINEERING DESIGN AND MANUFACTURING

Geometry is very applicable in CAD/CAM, such as in the design and manufacture of automobile bodies and parts, aircraft fuselages and parts such as turbine blades, and ship hulls and propellers. The current leading edge of CAD/CAM is ***additive manufacturing***, also known as ***3D printing***.

Examples:

1. *Representations*: How should mechanical parts be represented? One problem is that geometric descriptions are verbose compared to 2-dimensional descriptions, such as draftings, since those assume certain things that the users will fill in as needed, but which must be explicit in the geometric description. Currently, it is possible to additively manufacture objects that cannot be represented so that their properties can be analyzed. The problem is objects containing lattices with billions of cells and nonhomogeneous (graded) materials. See George Allen's comments in

- `http://www.3dcadworld.com/why-cad-is-hard-geometric-problems/`
- `http://www.cs.technion.ac.il/gdm2014/Presentations/GDM2014_allen.pdf`

Possible representation methods include the following:

- *constructive solid geometry*: Primitive objects, such as cylinders and blocks, are combined with the regularized Boolean operators union, intersection, and difference.
- *faceted boundary representation*: The object is a polyhedron with a boundary of planar faces.
- *exact boundary representation*: The object is defined by boundary "faces", but now each face can be curved, such as a NURBS (Non-Uniform Rational B-Spline), or an implicit piecewise quadric, Dupin cyclide (a quartic surface that is good for blending two quadric surfaces), or supercyclide.

The possible methods can be evaluated with the following criteria:

- *robustness* against numerical errors;
- *elegance*;
- *accuracy* in representing complex, curved, shapes, especially blends between the two surfaces at the intersection of two components;
- *ease* of explicitly obtaining geometry such as the boundary;
- *efficiency* when implemented on GPUs, which prefer simple, regular, representations.

2. *Mesh generation*: A *mesh* is the partition of a polyhedron into, typically, tetrahedra or hexahedra to facilitate finite element modeling. A good mesher conforms to constraints, can change scale over a short distance, has no unnecessary long thin elements, and has fewer elements when possible. In some applications, periodic *remeshing* is required.

If the elements are tetrahedra, then a Delaunay criterion that the circumsphere of each tetrahedron contains no other vertices may be used. However, this is inappropriate in certain cases, such as just exterior to an airfoil, where a (hexahedral) element may have an aspect ratio of 100,000:1. This raises numerical computation issues.

Applications of meshing outside mechanical design include *computational fluid dynamics*, *contouring* in GIS, *terrain databases* for real-time simulations, and Delaunay applications in general. Some mesh generation and additive manufacturing programs include the following.

- *Triangle*, a 2-dimensional quality mesh generator and Delaunay triangulator. Triangle generates exact Delaunay triangulations, constrained Delaunay triangulations, conforming Delaunay triangulations, Voronoi diagrams, and triangular meshes. The latter can be generated with no small or large angles, and are thus suitable for finite element analysis.

`https://www.cs.cmu.edu/~quake/triangle.html`

- *TetGen*, a quality tetrahedral mesh generator and a 3D Delaunay triangulator.

  `http://wias-berlin.de/software/tetgen/`

- *MeshLab* is an open-source system for processing and editing 3D triangular meshes. It provides a set of tools for editing, cleaning, healing, inspecting, rendering, texturing, and converting meshes. It offers features for processing raw data produced by 3D digitization tools/devices and for preparing models for 3D printing.

  `http://www.meshlab.net/`

- *ImplicitCAD* is an open-source, programmatic CAD environment.

  `http://www.implicitcad.org/`

- *Autodesk Netfabb* is an excellent commercial product with a comprehensive range of connected tools, including design optimization and printing.

  `https://www.netfabb.com/`

- *Slic3r* is a widely used free open and flexible toolchain for 3D printers. It introduced many features such as multiple extruders, brim, microlayering, bridge detection, command line slicing, variable layer heights, sequential printing (one object at time), honeycomb infill, mesh cutting, object splitting into parts, AMF support, avoiding crossing perimeters, and distinct extrusion widths.

  `http://slic3r.org/`

3. *Minimizing workpiece setup in numerically controlled (NC) machining*: In 4- and 5-axis numerically controlled machining, in order to machine all the faces, the workpiece must be repeatedly dismounted, recalibrated, and remounted. This setup can take much more time than the actual machining. Minimizing the number of setups by maximizing the number of faces that can be machined in one setup is a visibility problem harder than finding an optimal set of observers to cover some geographic terrain. Exact solutions are NP-hard; approximate solutions use geometric duality, topological sweeping, and efficient construction and searching of polygon arrangements on a sphere.

4. *Dimensional tolerancing*: *Tolerancing* refers to formally modeling the relationships between mechanical function and geometric form while assigning and analyzing dimensional tolerances to ensure that parts assemble interchangeably [SrVo93]. A tolerance may be specified *parametrically*, as a variation in a parameter, such as the width of a rectangle, or as a *zone* that the object's boundary must remain in. The latter is more general but must be restricted to prohibit pathologies, such as the object's boundary being not connected.

Tolerance synthesis attempts to optimize the tolerances to minimize the manufacturing cost of an object, considering that, while large tolerances are cheaper to manufacture, the resulting product may function poorly [Sk96].

Unsolved Problems:

The following problems are perpetually on the list of those needing more research.

1. *Blending* between two surfaces in mechanical design, especially at the ends of the blend, where these surfaces meet others. (A *blending surface* smooths the intersection of two surfaces by being tangent to them, each along a curve.)

2. *Variational design* of a class of objects subject to constraints. Well-designed constraint systems may have multiple solutions; the space must be searched for the correct one. Labeling derivative entities, such as the edge resulting from the intersection of two inputs, is an issue partly because this edge may not exist for some parameter values.

3. Generally *formalizing the semantics* of solid modeling [Ho96].

4. Updating *simplifying assumptions*, such as the linearity of random access memory, and points being in general position, which were useful in the past, but which cause problems now.

5. *Accounting for dependencies* between geometric primitives, and *maintaining topological consistency*.

6. Designing *robust algorithms* when not only is there numerical roundoff during the computation, but also the input data are imprecise, for example, with faces not meeting properly.

7. Better *3-dimensional anti-aliasing* to remove crevices and similar database errors before *rapid prototyping*.

8. There still remains a need for many features in geometry implementations, such as more *geometric primitives* at all levels, *default visualization or animation* easily callable for each data structure, more *rapid prototyping* with visualization, a *visual debugger* for geometric software, including changing objects online, and generally *more interactivity*, not just data-driven programs.

13.8.9 LAYOUT PROBLEMS

The efficient layout of objects has wide-ranging applications in geometry.

Examples:

1. *Textile part layout*: The clothing industry cuts parts from stock material after performing a tight, nonoverlapping, layout of the parts, in order to minimize the costs of expensive material. Often, because the cloth is not rotationally symmetric, the parts may be translated, but not rotated. Therefore, geometric algorithms for minimizing the overlap of translating polygons are necessary. Since this problem is PSPACE-hard, heuristics must be used [Da95], [LiMi95].

2. *VSLI layout*: Both laying out circuits and analyzing the layouts represent important problems. The masks and materials of a VLSI integrated circuit design are typically represented as rectangles, mostly isothetic, although 45 degrees or more general angles of inclination for the edges are becoming common. The rectangles of different layers may overlap. One integrated circuit may be 50MB of data before its hierarchical data structure is flattened, or 2GB after. For further details, see [WeHa11].

Geometry problems include the following.

- *design rule verification*: It is necessary to check that objects are separated by the proper distances and that average metal densities are appropriate for the fabrication process.
- *polygon simplification*: A design described by a complex set of polygons may perhaps be optimized into a smaller set of isothetic polygons (with only horizontal and vertical sides), such that the symmetric difference from the original design is as small as possible.

- *logic verification*: The electrical *circuit* is determined by the graph extracted from the adjacency information of the rectangles, and whether it matches the original logic design is determined. A subproblem is determining *devices* (*transistors*), which occur when rectangles of two particular different layers overlap.
- *capacitance*: This depends on the closeness of the component rectangles, which might be overlapping or separated, representing two conductors.
- *PPC* (Process Proximity Correction): This means to correct the effect that, when *etching* a circuit, a rectangle's edges are displaced outward, possibly causing it to come too close to another rectangle, and change the circuit.

13.8.10 GRAPH DRAWING AND VISUALIZATION

The classic field of *graph drawing and visualization* (see [KaWa01], [Ta14], and [TaTo95]) aims automatically to display a graph, emphasizing fundamental properties such as symmetry while minimizing the ratio between longest and shortest edges, number of edge crossings, etc. Applications include advanced GUIs, visualization systems, databases, showing the interactions of individuals and groups in sociology, illustrating connections between components in software engineering, and visualization of biological networks, including phylogenetic trees, metabolic networks, protein-protein interaction networks, and gene regulatory networks.

Facts:

1. Graph G can be drawn as the 1-skeleton of a convex polytope in $\mathcal{R}^3$ if and only if G is planar and 3-connected (Steinitz). See [Gr67].

2. Given a 3-connected planar graph, the graph can be drawn as a convex polyhedron in $\mathcal{R}^3$ using $O(n)$ volume while requiring the vertices to be at least unit distance apart, which allows them to be visually distinguished. This can be done in $O(n^{1.5})$ time [ChGoTa96].

3. A special language GraphML is available for representing graphs and drawings of these graphs.

4. Three of the most widely used software systems for constructing graph drawings are the Open Graph Drawing Framework (OGDF), the GDTookit, and the Public Implementation of a Graph Algorithm Library and Editor PIGALE, available at

- `http://www.ogdf.net`
- `http://www.dia.uniroma3.it/~gdt`
- `http://pigale.sourceforge.net`

5. There are a variety of hardware and software systems available for visualization of 3-dimensional graph drawings. See [La01] and the conference sites

- `http://algo.math.ntua.gr/~gd2016/`
- `http://www.diagrams-conference.org/2016/`

13.8.11 GEOGRAPHIC INFORMATION SYSTEMS

A *map* (§8.6.4) is a planar graph. Minimally, it contains *vertices*, *edges*, and *polygons*. However, a sequence of consecutive edges and 2-vertices is often called a *chain* (or *polyline*), and its interior vertices *points*. For example, if each polygon is one nation, then the southern border of Canada with the USA is one chain.

Definition:

A ***geographic information system*** (***GIS***) is an information system designed to capture, store, manipulate, analyze, and display spatial or geographically-referenced data.

Facts:

Typical simple geometric operations are given in Facts 1–6. More complex ones are given in Facts 7–9.

1. *Projecting data from one map projection to another, and determining the appropriate projection*: Since the earth is not a developable surface, no projection meets all the following criteria simultaneously: *equal-area*, *equidistant* (preserving distances from one central point to every other point), *conformal* (preserving all angles), and *azimuthal* (correctly showing the compass angle from one central point to every other point). Since a projection that meets any one criterion exactly is quite bad in the others, the most useful projections tend to be compromises, such as the recent *Robinson projection* [Da95].

2. *Rubber-sheeting*, or nonlinear stretching, to align a map with calibration points, and for *edge joining* of adjacent map sheets or databases, which may have slightly different coordinate systems.

3. *Generalizing* or reducing the number of points in a chain while preserving certain error properties.

4. *Topological cleanup* so that edges that are supposed to meet at one vertex do so, the boundary of each polygon is a closed sequence of vertices and polylines, adjacency information is correct, and so on.

5. Choice of the correct *data structure*. Should elevation data be represented in a *gridded* form (as an array of elevations) or should a *triangulated irregular network* (TIN) be used (the surface is partitioned into triangles)?

6. *Zone of influence calculation*: For example, find all the national monuments within ten miles of the highway.

7. *Overlaying*: Overlaying two maps to produce a third, where one polygon of the overlay map will be those points that are all from the same two polygons of the two input maps is one of the most complex operations in a GIS. If only the *area* or other mass property of the overlay polygons is desired, then it is not necessary completely to find the overlay polygons first; it is sufficient to find the set of vertices and their neighborhoods of each overlay polygon [FrEtal94].

8. *Name placement*: Consider a cartographic map containing point features such as cities, line features such as rivers, and area features such as states. The *name placement* problem involves locating the features' names so as to maximize readability and aesthetics [FrAh84]. Efficient solutions become more important as various mapping packages now produce maps on demand. The techniques also extend to *labelling CAD drawings*, such as piping layouts and wiring diagrams.

9. *Viewsheds and visibility indices*: Consider a terrain database, and an observer and target, both of which may be some distance above the terrain. The observer can see the target if and only if a line between them does not intersect the terrain. Note that if they are at different heights above the terrain, then this relation is not necessarily commutative.

The (not necessarily connected) polygon of possible targets visible by a particular observer is his *viewshed*. The viewshed's area is the observer's *visibility index*. In order to site observers optimally, the visibility index for each possible observer in the database may be required. Calculating this exactly for an $n \times n$ gridded database takes time $O(n^5)$ so sampling techniques are used [FrRa94].

Implementations:

1. *GRASS GIS*, also known as GRASS (Geographic Resources Analysis Support System), is a free and open-source Geographic Information System (GIS) software suite widely used used for geospatial data management and analysis, image processing, graphics and maps production, spatial modeling, and visualization.

- `https://grass.osgeo.org/`

2. *The Open Source Geospatial Foundation* (OSGeo) was created to support the collaborative development of open-source geospatial software and to promote its widespread use.

- `http://www.osgeo.org/`

13.8.12 GEOMETRIC CONSTRAINT SOLVING

Applications of geometric constraint solving include mechanical engineering, molecular modeling, geometric theorem proving, and surveying.

Definition:

Geometric constraint solving is the problem of locating a set of geometric elements given a set of constraints among them.

Fact:

1. The problem may be under-constrained, with an infinite number of solutions, or over-constrained, with no solutions without some relaxation.

Examples:

1. A *receptor* is a rigid cavity in a protein, which is the center of activity for some reaction. A *ligand* is a small molecule that may bind at a receptor. The activity level of a drug may depend on how the ligand fits the receptor, which is made more complicated by the protein molecule's bending.

2. In CAD/CAM, there may be constraints such as the specification that opposite sides of a feature must be parallel. For example, commercial systems like Pro/Engineer allow the user to freehand-sketch a part, and then apply constraints such as right angles, to snap the drawing to fit. Then the user is required to add more constraints until the part is well constrained.

3. *Molecular modeling*: There is often a lock-and-key relationship between a flexible protein molecule's receptor and the ligand that it binds. In addition to geometrically matching the fitted shapes, the surface potentials of the molecules is also important. This fitting problem, called *molecular docking*, is important in *computer-aided drug design*. Generally, a heuristic strategy is used to move the molecules to achieve no overlap between the two molecules while maximizing their contact area [IePa95].

13.8.13 IMPLEMENTATIONS

One major application of geometry is in implementations of geometric software packages, either as *class libraries* and *subroutine packages* callable from user programs, or as *stand-alone systems*, which the user prepares input data files for and directs with either input command files or a GUI. These implementations are useful both for creating or modeling geometric objects and for visualizing them. This section describes some implementations of general usefulness across several applications.

Definitions:

In an object-oriented computer language, a ***class library*** is a set of new data types (classes) and operations on them, activated by sending a message to an ***object***, or data item. (For example, a plane object may respond to a message to rotate itself. The internal representation of an object is private, and it may be accessed only by sending it a message.)

In C++, class libraries often use ***template metaprogramming***. Here, class templates are expanded at compile time into code that often runs much more efficiently than traditional subroutine libraries. This trades off compilation time for execution time, especially for complicated classes with efficient specialized cases. For example, consider a matrix that is known at compile time to be of size 3×3, which is common in geometric applications. Here, specialized code is generated for any loop iterating over the rows of the matrix, probably using loop unrolling. Even better, expressions with several matrix operations chained together become code with no temporary matrix storage allocations, and with all the code located together in one routine and available for global optimization.

Example libraries:

1. *Boost.Geometry* (also known as the Generic Geometry Library, GGL) is a part of the collection of Boost C++ Libraries. It defines concepts, primitives, and algorithms for solving geometry problems.

- `http://www.boost.org/doc/libs/1_63_0/libs/geometry/doc/html/geometry/introduction.html`

Boost.Geometry contains a dimension-agnostic, coordinate-system-agnostic and scalable kernel, based on concepts, meta-functions, and tag dispatching. Supported algorithms include area, length, perimeter, centroid, convex hull, intersection (clipping), within (point in polygon), distance, envelope (bounding box), simplify, and transform. Boost.Geometry can be used wherever geometry plays a role, such as in mapping and GIS, game development, computer graphics and widgets, robotics, and astronomy. However, the development has been mostly GIS-oriented.

2. *Computational Geometry Algorithms Library* (CGAL) is a software project that provides access to efficient and reliable geometric algorithms in the form of a C++ library. CGAL is used in various areas needing geometric computation, such as geographic information systems, computer aided design, molecular biology, medical imaging, computer graphics, and robotics.

The library offers data structures and algorithms like triangulations, Voronoi diagrams, Boolean operations on polygons and polyhedra, point set processing, arrangements of curves, surface and volume mesh generation, geometry processing, alpha shapes, convex hull algorithms, shape analysis, AABB and KD trees, among others.

CGAL is a massive project that started in 1996 as a consortium of several existing projects. It was originally funded by the European Union's information technologies program ESPRIT.

- `http://www.cgal.org/`

3. *Geogram* is a C++ programming library of geometric algorithms, with efficient graphics for surfacic and volumetric meshes.

- `http://homepages.loria.fr/BLevy/GEOGRAM/`

Example stand-alone systems:

1. *Wolfram|Alpha* is an engine for carrying out dynamic computations, searching for answers, and providing knowledge, based on the *Mathematica* system. Alpha can answer questions such as "How many baseballs fit in a Boeing 747?", where the answer makes a reasonable assumption about the packing density, and states it. More technical questions, such as intersecting lines, computing properties of polytopes, and drawing fractals, are also possible.

- `https://www.wolframalpha.com/about.html`
- `https://www.wolfram.com/mathematica/`

2. *Blender* is a free and open-source 3D creation suite. It supports modeling, rigging, animation, simulation, rendering, compositing and motion tracking, video editing, and game creation.

- `https://www.blender.org/`

3. Several very efficient geometry and GIS programs for processing large datasets are available at

- `www.ecse.rpi.edu/Homepages/wrf/Software`

Here is a sampling of the supported software:

- *PinMesh* is a very fast algorithm with the facility to preprocess a polyhedral mesh in order to perform 3D point location queries [MaEtal16].
- *TiledVS* allows one to efficiently compute terrain viewsheds on large raster terrains using small amounts of real memory with a custom virtual memory manager [FeEtal16].
- *UPLAN* is an efficient algorithm for path planning on road networks having polygonal constraints [MaEtal15b].
- *EMFlow* and *RWFlood* efficiently compute hydrography (water flow) on very large (50000×50000) terrains containing basins [GoEtal15]; the novel component was to raise the ocean and compute how it flowed over sills to flood interior basins.
- *EPUG-Overlay* allows one to compute the overlay of two GIS maps (plane graphs) in parallel using rational numbers, with the ability to process maps with tens of millions of vertices and hundreds of thousands of polygons in a few minutes [MaEtal15a].
- *NearptD* is a very fast parallel nearest neighbor algorithm and implementation, which has processed 10^7 points in E^6 and $184 \cdot 10^6$ points in E^3.

CODING THEORY

Alfred J. Menezes
Paul C. van Oorschot
David Joyner and
Tony Shaska

INTRODUCTION

This chapter deals with techniques for the efficient and reliable transmission of data over communications channels that may be subject to non-malicious errors. The general topic areas related to these techniques are information theory and coding theory. Information theory is concerned with the mathematical theory of communication, and includes the study of redundancy and the underlying limits of communications channels. Coding theory, in its broadest sense, deals with the translation between source data representations and the corresponding representative symbols used to transmit source data over a communications channel, or store this data. Error-correcting coding is the part of coding theory that adds systematic redundancy to messages to allow transmission errors not only to be detected, but also to be corrected.

GLOSSARY

AG code (***algebraic geometry code***): a code defined in terms of the divisors of an algebraic curve.

analog channel: a channel that is continuous in amplitude and time.

BCH code: a code arising from a special family of cyclic codes.

binary symmetric channel (***BSC***): a memoryless channel with binary input and output alphabets, and fixed probability p that a symbol is transmitted incorrectly.

burst error: a vector whose only nonzero entries are among a string of successive components, the first and last of which are nonzero.

capacity of a channel: a measure of the ability of a channel to transmit information reliably.

check symbols: the positions in a codeword that provide redundancy.

code: a map from the set of words to the set of all finite strings of elements in a designated alphabet.

codeword: a string produced when a code is applied to a word.

coding theory: the subject concerned with the translation between source data representations and the corresponding representative symbols used to transmit source data over a communications channel.

complete maximum likelihood decoding (***CMLD***): the decoding scheme that decodes a received n-tuple to the unique codeword of minimum distance from this n-tuple, if such a codeword exists. Otherwise, the scheme arbitrarily decodes the n-tuple to one of the codewords closest to this n-tuple.

convolutional code: a code in which the encoder has memory, so that an n-tuple produced by the encoder not only depends on the message k-tuple u, but also on some message k-tuples produced prior to u.

coset: the set $C + x = \{c + x \mid c \in C\}$ determined by a word x, given a code C.

coset leader: a coset member of smallest Hamming weight.

cyclic code: a linear code in which every cyclic shift of a codeword is also a codeword.

data compression: the transformation of data into a representation which is more compact yet maintains the information content of the original data.

dual code (of a code): the orthogonal complement of the code.

entropy: a measure of the amount of information provided by an observation of a random variable.

equivalent codes: codes for which there is a fixed permutation of the coordinate positions which transform one code to the other.

erasure: a transmission error whose position is known, but whose transmission symbol for that position is not.

error-correction coding: coding that adds systematic redundancy to messages to allow transmission errors to be detected and corrected.

error-detection coding: coding that adds systematic redundancy to messages to allow transmission errors to be detected (but not necessarily corrected).

extended code: the code obtained by adding a parity check symbol to each codeword of a code.

generator matrix for a code: a matrix whose rows form a basis for that code.

generator polynomial: a monic polynomial of least degree in a cyclic code.

Golay code: a particular perfect code.

Hamming code: a perfect single-error correcting code.

Hamming distance between two n-tuples: the number of coordinate positions in which they differ.

Hamming distance of a code: the smallest Hamming distance over all pairs of distinct codewords in that code.

Hamming weight of an n-tuple: the number of nonzero coordinates.

incomplete maximum likelihood decoding (***IMLD***): the decoding scheme that decodes a received n-tuple to a unique codeword such that the distance between the n-tuple and the codeword is minimum if such a codeword exists. If no such codeword exists, then the scheme reports that errors have been detected, but no correction is possible.

information symbols: the positions within a codeword that provide information on the message sent.

information theory: the mathematical theory of communication concerned with both the study of redundancy and the underlying limits of communication channels.

linear code: a subspace of the set of n-tuples with entries from a finite field.

list decoding: a decoding algorithm which outputs a list of possible codewords "near" the received word, one of which is correct.

low-density parity check code: a linear code whose parity check matrix contains relatively few nonzero elements.

memoryless source: a source for which the probability of a particular word being emitted at any point in time is fixed.

message: a finite string of source words.

minimum error probability decoding (***MED***): the decoding scheme that decodes a received n-tuple r to a codeword c for which the conditional probability $Pr(c$ is sent $\mid r$ is received), $c \in C$, is largest.

nonlinear code: a code which lacks the structure of a vector space over a finite field.

Nordstrom-Robinson code: a special nonlinear code.

parity check bit: a bit added to a bit string so that the total number of 1s in the extended string is even.

parity check matrix (for a code): a generator matrix for the dual code of the code.

perfect code: a code of distance d for which every word is within distance $t = \lfloor \frac{d-1}{2} \rfloor$ of some codeword.

Preparata code: a code from an infinite family of nonlinear codes that have efficient encoding and decoding algorithms.

punctured code: the code obtained by removing any column of a generator matrix of a linear code.

qubit (***quantum bit***): the analog in quantum computation of a bit in classical computation.

Reed-Muller code: a code from a particular family of linear codes.

Reed-Solomon code: a linear code from a special family of BCH codes.

self-dual code: a linear code that is equal to its dual code.

self-orthogonal code: a linear code that is contained in its dual code.

shortened code: the set of all codewords in a linear code which are 0 in a fixed coordinate position with that position deleted.

stabilizer code: a device used to help construct quantum codes from some classical codes.

syndrome (of a word x): the vector xH^T, where H is a parity check matrix for a linear code C.

systematic code: a linear code that has a generator matrix of the form $[I_k \mid A]$ (alternatively, of the form $[A \mid I_k]$).

turbo code: a special type of code built using convolutional codes and an interleaver which permutes the original bits before sending them to the second encoder.

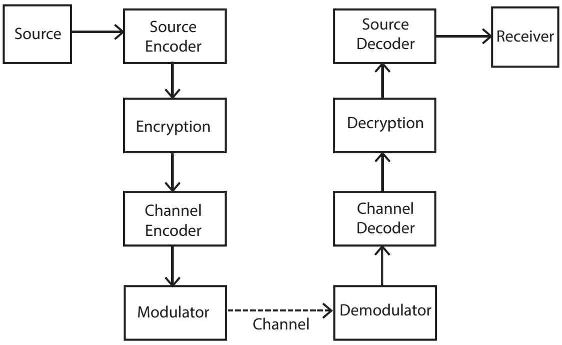
uniquely decodable code: a code for which every string of symbols is the image of at most one message.

14.1 COMMUNICATION SYSTEMS AND INFORMATION THEORY

14.1.1 BASIC CONCEPTS

Definitions:

A ***communication system***, as illustrated in the following figure, is modeled as a data source providing either continuous or discrete output, a ***source encoder*** transforming source data into binary digits (***bits***), a ***channel encoder***, and a channel.



In many communication systems the channel is ***analog***, that is, continuous in amplitude and time, in which case a modulator/demodulator (***modem***) is required to transform between analog channel data and discrete encoder/decoder data.

The ***source encoder***, the aim of which is to minimize the number of bits required to represent source data while still allowing subsequent reconstruction, typically includes ***data compression*** to remove unnecessary redundancy.

The objective of the ***channel encoder*** is to maximize the rate at which information can be reliably conveyed by the channel, in the presence of disruptive channel noise.

Coding theory is the study of the translation between source data representations and the corresponding representative symbols (coded data) used to transmit source data over a communication channel.

Error-correction coding, located in the channel encoder, adds systematic redundancy to messages to allow transmission errors not only to be detected but also to be corrected.

14.1.2 ENTROPY

Definitions:

Information theory is concerned with a mathematical theory of communication and includes the study of redundancy and the underlying limits of communication channels.

Let X be a random variable that takes on a finite set of values $x_1, x_2, \ldots, x_n$ with probability $Pr(X = x_i) = p_i$, where $0 \leq p_i \leq 1$ for each i, $1 \leq i \leq n$, and $\sum_{i=1}^{n} p_i = 1$. Also, let Y be a random variable that takes on a finite set of values.

The ***entropy*** (or ***uncertainty***) of X is defined to be $H(X) = -\sum_{i=1}^{n} p_i \log_2 p_i$, where $p_i \log_2 p_i = 0$ if $p_i = 0$.

The ***joint entropy of X and Y*** is defined to be

$$H(X,Y) = -\sum_{x,y} Pr(X{=}x, Y{=}y) \log_2 Pr(X{=}x, Y{=}y).$$

If X and Y are random variables, the ***conditional entropy of X given Y = y*** is

$$H(X \mid Y{=}y) = -\sum_{x} Pr(X{=}x \mid Y{=}y) \log_2 Pr(X{=}x \mid Y{=}y).$$

The ***conditional entropy of X given Y*** (or the ***equivocation of Y about X***) is $H(X \mid Y) = -\sum_{y} Pr(Y{=}y)\, H(X \mid Y{=}y)$. (The summation indices x and y range over all values of X and Y, respectively.)

Facts:

1. Useful books that cover information theory include [Ha80], [HaHaJo97], [Mc77], and [We98].

2. Information theory provides a theoretical basis for many results in error-correcting codes and cryptography, and provides theoretical bounds useful as metrics for evaluating conjectures in both areas.

3. The entropy of X is a measure of the amount of information provided by an observation of X.

4. The entropy of X is also useful for approximating the number of bits required to encode the elements of X.

5. If X and Y are random variables, then

- $0 \le H(X) \le \log_2 n$;
- $H(X) = 0$ if and only if $p_i = 1$ for some i, and $p_j = 0$ for all $j \ne i$ (that is, there is no uncertainty of the result);
- $H(X) = \log_2 n$ if and only if $p_i = \frac{1}{n}$ for each i, $1 \le i \le n$ (that is, all outcomes are equally likely);
- $H(X,Y) \le H(X) + H(Y)$;
- $H(X,Y) = H(X) + H(Y)$ if and only if X and Y are independent.

6. The quantity $H(X \mid Y)$ measures the amount of uncertainty remaining about X after Y has been observed.

7. If X and Y are random variables, then

- $H(X \mid Y) \ge 0$;
- $H(X \mid X) = 0$;
- $H(X,Y) = H(Y) + H(X \mid Y)$;
- $H(X \mid Y) \le H(X)$;
- $H(X \mid Y) = H(X)$ if and only if X and Y are independent.

Examples:

1. If X is the random variable on the set $\{x_1, x_2, x_3, x_4\}$ with $p_1 = 0.4$, $p_2 = 0.3$, $p_3 = 0.2$, and $p_4 = 0.1$, then the entropy of X is

$$H(X) = -(0.4 \log_2 0.4 + 0.3 \log_2 0.3 + 0.2 \log_2 0.2 + 0.1 \log_2 0.1) \approx 1.84644.$$

2. If X is the random variable on the same set $\{x_1, x_2, x_3, x_4\}$ with $p_1 = p_2 = p_3 = p_4 = \frac{1}{4}$, then the entropy of X is

$$H(X) = -4(\tfrac{1}{4}\log_2 \tfrac{1}{4}) = 2.$$

This situation, with equal probability outcomes, achieves the maximum entropy $\log_2 n = \log_2 4 = 2$.

14.1.3 THE NOISELESS CODING THEOREM

Definitions:

A ***source*** is a stream of ***words*** from a set $W = \{w_1, w_2, \ldots, w_M\}$.

Let X_i denote the ith word produced by a source. The source is said to be ***memoryless*** if for each word $w_j \in W$, the probability $Pr(X_i = w_j) = p_j$ is independent of i, that is, the X_i are independent and identically distributed random variables.

The ***entropy*** of a memoryless source is $H = -\sum_{j=1}^{M} p_j \log_2 p_j$.

A ***code*** is a map f from W to A^*, the set of all finite strings of elements of A where A is a finite set called the ***alphabet***.

For each source word $w_j \in W$, the string $f(w_j)$ is a ***codeword***.

The ***length*** of the codeword $f(w_j)$, denoted $|f(w_j)|$, is the number of symbols in the string.

A ***message*** is any finite string of source words. If $m = v_1v_2\ldots v_r$ is a message, then its encoding is obtained by concatenation: $f(m) = f(v_1)f(v_2)\ldots f(v_r)$.

The ***average length*** of a code f is $\sum_{j=1}^{M} p_j|f(w_j)|$.

A code is ***uniquely decodable*** if every string from A^* is the image of at most one message.

A ***prefix code*** is a code such that there do not exist distinct words w_i and w_j such that $f(w_i)$ is an initial segment, or prefix, of $f(w_j)$.

Facts:

1. Prefix codes are uniquely decodable.

2. Prefix codes have the advantage of being *instantaneous*. That is, they can be decoded online without looking at future codewords.

3. *Kraft's inequality*: A prefix code $f\colon W \to A^*$ with codeword length $|f(w_i)| = l_i$ for $i = 1, 2, \ldots, M$ exists if and only if $\sum_{j=1}^{M} n^{-l_j} \le 1$, where n is the size of the alphabet A.

4. *Macmillan's inequality*: If a uniquely decodable code $f\colon W \to A^*$ with codeword lengths $l_1, l_2, \ldots, l_M$ exists, then $\sum_{j=1}^{M} n^{-l_j} \le 1$, where n is the size of the alphabet A.

5. A uniquely decodable code with prescribed word lengths exists if and only if a prefix code with the same word lengths exists. As a result, attention can be restricted to prefix codes.

6. *Shannon's noiseless coding theorem*: For a memoryless source of entropy H, any uniquely decodable code for the source into an alphabet of size n must have average length at least $\frac{H}{\log_2 n}$. Moreover, there exists such a code having average length less than $1 + \frac{H}{\log_2 n}$.

7. For a memoryless source, a prefix code with smallest possible average length can be constructed by the Huffman coding algorithm. (See §9.1.2.)

Examples:

1. The code that maps the letters A, B, C, D to 1, 01, 001, 0001, respectively, is a prefix code on this set of four letters.

2. The code that maps the letters A, B, C, D to 11, 111, 11111, 111111, respectively, is not a prefix code since the code for A forms the first part of the code for B (and for the codes for C and D as well). It is also not uniquely decodable since a bit string can correspond to more than one string of the letters A, B, C, D. For example, 11111 corresponds to AB, BA, and C.

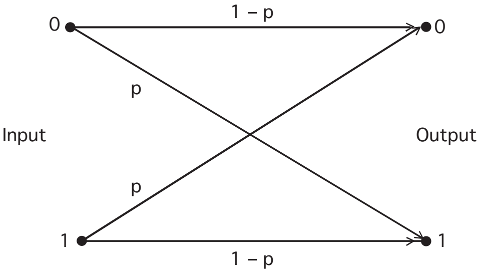
14.1.4 CHANNELS AND CHANNEL CAPACITY

Definitions:

A ***channel*** is a medium that accepts strings of symbols from a finite alphabet $A = \{a_1, \ldots, a_n\}$ and produces strings of symbols from a finite alphabet $B = \{b_1, \ldots, b_m\}$.

Let X_i denote the ith input symbol and let Y_i denote the ith output symbol. The channel is said to be ***memoryless*** if the probability $Pr(Y_i = b_j \mid X_i = a_k) = p_{jk}$ (for $1 \le j \le m$ and $1 \le k \le n$) is independent of i.

A ***binary symmetric channel*** (***BSC***) is a memoryless channel with input and output alphabets $\{0, 1\}$, and probability p that a symbol is transmitted incorrectly. The probability p is called the *symbol error probability* of the channel. See the following figure.



A ***q-ary symmetric channel*** is a memoryless channel with input and output alphabets each of size q and such that the probability that an error occurs on symbol transmission is a constant p. Furthermore, if an error does occur then each of the $q-1$ symbols different from the correct symbol is equally likely to be received.

The ***capacity*** of a binary symmetric channel with symbol error probability p is $C(p) = 1 + p\log_2 p + (1-p)\log_2(1-p)$.

Facts:

1. The capacity of a communications channel is a (unitless) measure of its ability to transmit information reliably.

2. The capacity of a BSC with symbol error probability p is a monotone decreasing function of p for $0 \le p \le \frac{1}{2}$, with $1 \ge C(p) \ge 0$. Moreover, $C(0) = 1$ and $C(\frac{1}{2}) = 0$.

Example:

1. The capacity of a BSC with symbol error probability 0.01 is given by

$$C(0.01) = 1 + 0.01 \log_2(0.01) + 0.99 \log_2(0.99) \approx 0.92.$$

14.2 BASICS OF CODING THEORY

Coding theory is the subject devoted to the theory of error-correcting codes. Error-correcting codes were invented to correct errors over unreliable transmission links. With digital communications and digital storage media ubiquitous in the modern world, error-correcting codes have grown in importance. Advances in error-correcting codes have made it possible to transmit information across the solar system using weak transmitters and to store data robustly on storage media so that it is resistant to damage, such as scratches on a compact disk.

Error-correcting codes work by encoding data as strings of symbols, such as bit strings, that contain redundant information that helps identify which codeword may have been sent when a string of symbols, potentially different from the string sent, is received. Coding theory is an active research area, with new and better codes being devised at a steady pace.

14.2.1 FUNDAMENTAL CONCEPTS

Definitions:

Let A be any finite set (called an *alphabet*), and let A^n denote the set of all n-tuples with entries in A. A ***block code*** of length n containing M ***codewords*** over the alphabet A is a subset of A^n of size M. Such a block code is called an ***(n, M)-code*** over A.

The ***Hamming distance*** $d(x, y)$ between two n-tuples x and $y \in A^n$ is the number of entries in which they differ.

Let C be an (n, M)-code over A. The ***Hamming distance of C*** is the smallest Hamming distance over all pairs of distinct codewords in C. If C has Hamming distance d, then C is sometimes referred to as an ***(n, M, d)-code***.

The ***information rate*** (or ***rate***) of an (n, M)-code over an alphabet of size q is $R = \frac{\log_q M}{n}$.

Suppose that a codeword c from a block code is transmitted and r is received. The ***error vector*** is $e = r - c$ (formed by componentwise subtraction). The ***number of errors*** is the number of nonzero components in e.

A code is said to ***detect*** t errors if the decoder is capable of detecting any pattern of t or fewer errors per codeword that may be introduced by the channel.

A code is said to ***correct*** t errors if the decoder is capable of correcting any pattern of t or fewer errors per codeword that may be introduced by the channel.

Suppose that a codeword c from a block code is transmitted and r is received. An ***erasure*** is a coordinate within r which is unknown.

A code is said to be ***t-erasure correcting*** if the decoder is capable of correcting any pattern which contains at most t erasures.

A ***burst error*** of length t is a vector whose only nonzero entries are among a string of successive entries, considered cyclically or non-cyclically, the first and last of which are nonzero.

A code is said to be ***t-cyclic burst error correcting*** if the decoder is capable of correcting any pattern which is a cyclic burst of length t.

If C_1 and C_2 are two (n, M)-codes over an alphabet A, then C_1 and C_2 are said to be ***equivalent codes*** if there is a fixed permutation of the coordinate positions which transform one code to the other.

The ***parity check bit*** of a bit string is 0 if there is an even number of bits in the string and is 1 if there is an odd number of bits in the string.

Facts:

1. Richard Hamming wrote one of the pioneering papers of coding theory in 1948, published in [Ha50].

2. Lester Hill, around the time of his paper [Hi27] from the 1920s, wrote an unpublished paper entitled "The checking of the accuracy of transmittal of telegraphic communications by means of operations in finite algebraic fields" [ToChJo12]. In this paper, Hill introduced a very special class of BCH codes for the purpose of error detection.

3. Some of the many introductory-level books in coding theory are [Ba97], [Bi05], [GuRuSu15], [JoKi11], [Mo05], [Pr92], [Ro06], [Ro96], and [Ye08]. For more extensive treatments, see [Be15], [Bl03], [JoZi15], [LiCo04], [Ma03], [NeRaSl06], [PeWe72], [PlHuBr98], [TsVl91], [TsVlNo07], [vL99], and especially [HuPl03] and [MaSl77], which contain extensive bibliographies.

4. The Error Correcting Codes (ECC) home page provides free software implementing several important error-correcting codes:

- `http://www.eccpage.com`

5. The main objective of coding theory is the design of codes such that

- an efficient algorithm is known for encoding messages;
- an efficient algorithm is known for decoding;
- the error-correcting capability of the code is high;
- the information rate of the code is high.

6. For applications in which a two-way communications channel is available (for example, a telephone circuit), it is sometimes economical to use error detection and retransmission upon error, in a so-called *automatic repeat request* (ARQ) strategy, rather than so-called *forward error correction* (FEC) techniques capable of actually correcting errors at the cost of more complex decoding equipment. This is not an option when the communications channel is effectively one-way or unperturbed source data is not available for retransmission (for example in CD-ROM storage and deep-space communications systems).

7. For any n-tuples $x, y, z \in A^n$, the Hamming distance satisfies

- $d(x, y) \geq 0$ with equality if and only if $x = y$;
- $d(x, y) = d(y, x)$;

- $d(x,y) + d(y,z) \geq d(x,z)$.

8. The information rate R of a block code measures the fraction of information of the code which is non-redundant; the information rate R satisfies the inequality $0 < R \leq 1$.

9. When a word r is received, the decoder must make some decision. This decision may be one of the following:

- no errors have occurred; accept r as a codeword;
- errors have occurred; correct r to a codeword c;
- errors have occurred; no correction is possible.

10. Let C be an (n, M, d)-code.

- If used only for error detection, C can detect $d-1$ errors.
- If used for error correction, C can correct $\lfloor \frac{d-1}{2} \rfloor$ errors.
- If used for erasure correction, C can correct $d-1$ erasures.

11. Let C be an (n, M, d)-code, and let $s, t, u \geq 0$.

- If $d \geq 2s + t + 1$, then C can simultaneously correct s errors and detect $s + t$ errors.
- If $d \geq 2s + t + 1$, then C can simultaneously correct s errors and t erasures.
- If $d \geq 2s + t + u + 1$, then C can simultaneously correct s errors and t erasures and detect $s + u$ errors.

12. Equivalent codes have the same distance, and hence the same error-correcting capabilities.

13. Adding a parity check bit to a bit string of length n produces a bit string of length $n + 1$ with an even number of 0s.

14. Different families of error-correcting codes have been, and continue to be, designed to meet the particular requirements of applications. One type of requirement is the ability to correct specific types of errors. For many applications, it is sufficient to assume that errors in different positions occur independently of each other. This assumption follows immediately when using a memoryless channel.

15. In other applications, errors may not be independent of each other. For example, when signals are sent over radio channels, including those from deep space, interference can produce errors in a run of bits. Similarly, damage to storage media, such as a compact disk, can produce errors that come in clusters. These types of errors may be better modeled using burst errors and are better handled by cyclic codes (§14.4.1), in particular Reed-Solomon codes (§14.4.4), interleaved Reed-Solomon codes (see [HuPl03] for more information), and fire codes (see [Bl03]).

Examples:

1. The code produced by adding a parity check bit to each bit string of length n can detect a single error. (It detects an odd number of errors, but not an even number of errors; no error correction is possible using this code.) For example, suppose the bit string 0111 is received where the code word sent is a bit string of length three with a parity check bit added. Since 0111 contains three 1s, it cannot be a codeword. Hence, an error was made in transmission. This error cannot be corrected. To see this, note that if exactly one bit error was made in the transmission, any of the codewords 0110, 0101, 0011, and 1111 could have been sent.

2. $C = \{0100011, 1010101, 1101111\}$ is a $(7, 3, 3)$-code over the binary alphabet. Note that $d = 3$ is the minimum Hamming distance between codewords (namely, the first and third codewords). The information rate of C is $R = \frac{\log_2 3}{7} \approx 0.226$.

3. The *binary repetition code* of length n is the code $C = \{00\ldots0, 11\ldots1\}$. The code has distance n, and so can correct $\lfloor \frac{n-1}{2} \rfloor$ errors. If used only for error detection, then C can detect $n-1$ errors. Although the error-correcting capabilities of C are very good, its information rate $R = \frac{1}{n}$ is very poor.

14.2.2 MAXIMUM LIKELIHOOD DECODING

Definitions:

Suppose C is an (n, M, d)-code. Different decoding schemes can be used to recover a codeword from a transmitted bit string received with possible errors. These schemes include

- ***Minimum Error Probability Decoding*** (***MED***): If an n-tuple r is received, then correct r to a codeword c for which the conditional probability $Pr(c \text{ is sent} \mid r \text{ is received})$, $c \in C$, is largest.
- ***Incomplete Maximum Likelihood Decoding*** (***IMLD***): If an n-tuple r is received, and there is a unique codeword $c \in C$ such that $d(r, c)$ is a minimum, then correct r to c. If no such c exists, then report that errors have been detected, but no correction is possible.
- ***Complete Maximum Likelihood Decoding*** (***CMLD***): If an n-tuple r is received, and there is a unique codeword $c \in C$ such that $d(r, c)$ is a minimum, then correct r to c. Otherwise, arbitrarily select one of the codewords $c \in C$ that is the closest to r, and correct r to c.

Facts:

1. For any fixed probability distribution of the source messages, the probability of a decoding error, given that an n-tuple r is received, is minimized by MED among all decoding schemes.

2. MED has the disadvantage that the decoding algorithm depends on the probability distribution of the source messages. The decoding strategy that is used in practice is CMLD.

3. Suppose that the probability that a symbol is transmitted incorrectly in a q-ary symmetric channel is p, where $0 < p < \frac{q-1}{q}$. Let r be a received word and $c_1, c_2 \in C$ with $d(c_1, r) = d_1$ and $d(c_2, r) = d_2$. Let $Pr(r \mid c)$ denote the probability that r is received, given that c was sent. Then $Pr(r \mid c_1) \leq Pr(r \mid c_2)$ if and only if $d_1 \geq d_2$.

4. CMLD chooses a codeword c for which the conditional probability $Pr(r \text{ is received} \mid c \text{ is sent})$, $c \in C$, is largest.

5. If all source messages are equally likely, then CMLD performs in exactly the same way as MED.

Examples:

1. For the binary symmetric channel, Maximum Likelihood Decoding agrees with Nearest Neighbor Decoding (where a received word v is corrected to the codeword c closest to it in the Hamming distance).

2. $C = \{010101, 101010, 111111\}$ is a $(6, 3, 3)$-code over the binary alphabet. The code is transmitted over a binary symmetric channel. The received word $v = 011111$ has respective distances $2, 4, 1$ to the three codewords of C and so is corrected to the codeword $c = 111111$ using Maximum Likelihood Decoding.

14.2.3 THE NOISY CHANNEL CODING THEOREM

Definitions:

Let C be an (n, M)-code, where each word occurs with equal probability. Let r_i be the probability of making an incorrect decision using complete maximum likelihood decoding given that the ith codeword was transmitted. The ***error probability*** of the code C is $P_C = \frac{1}{M}\sum_{j=1}^{M} r_j$.

Let parameters n and M be fixed. Define $P^*(n, M, p)$ to be the smallest error probability P_C of any (n, M)-code using a BSC with symbol error probability p.

Facts:

1. *Shannon's noisy channel coding theorem*: Let $C(p)$ denote the capacity of a BSC with symbol error probability p, and define the quantity $M_n = 2^{\lfloor Rn \rfloor}$. If $0 < R < C(p)$, then $P^*(n, M_n, p) \to 0$ as $n \to \infty$.

2. By Shannon's noisy channel coding theorem, arbitrarily reliable communication with a fixed information rate is possible on a channel provided that the information rate is less than the channel capacity. Unfortunately, all known proofs of the theorem are nonconstructive and do not give bounds on word lengths. So the good codes promised by the theorem may have extremely large word lengths.

14.3 LINEAR CODES

Linear codes are an important type of codes with a particular type of structure. In particular, a linear code is a code that is a subspace of a finite-dimensional vector space over a finite field. The main advantages of using linear codes arise from the efficient procedures for correcting errors. These procedures are based on matrix computations that can be carried out easily and rapidly.

14.3.1 INTRODUCTION

Definitions:

Let $GF(q)^n$ denote the vector space of all n-tuples having components from the finite field $GF(q)$ (§5.6.3). The elements of $GF(q)^n$ are called *vectors* or *words*.

An ***[n, k]-linear code*** C over $GF(q)$ is a k-dimensional subspace of $GF(q)^n$ over $GF(q)$. More precisely, C is a ***linear block code***, but the qualification "block" is generally omitted. The code C is referred to as an ***[n, k, d]-code***, where n is the ***length*** of the code, k is the ***dimension*** of the subspace, and d is the ***distance***.

The ***Hamming weight*** of a word $v \in GF(q)^n$ is the number of nonzero coordinates in v.

Let C be an $[n,k]$-code over $GF(q)$. A ***generator matrix*** G for C is a $k \times n$ matrix with entries from $GF(q)$ whose rows form a basis for C.

If an $[n,k]$-code C has a generator matrix of the form $G = [I_k \,|\, A]$, then C is called a ***systematic code***, and the generator matrix G is said to be in ***standard form***.

The first k positions within a systematic $[n,k]$-code are referred to as the ***information symbols*** for the code. The last $n-k$ positions are referred to as the ***check symbols***.

Let $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ be two vectors in $GF(q)^n$. The ***inner product*** of x and y is the field element $x \circ y = \sum_{i=1}^{n} x_i y_i$. If $x \circ y = 0$, x and y are ***orthogonal***.

Let C be an $[n,k]$-code over $GF(q)$. The ***orthogonal complement*** of C, denoted $C^\perp$ (read "C perp"), is the set of vectors orthogonal to every vector in C:

$$C^\perp = \{x \in GF(q)^n \mid x \circ y = 0 \text{ for all } y \in C\}.$$

$C^\perp$ is usually called the ***dual code*** of C.

A ***parity check matrix*** for an $[n,k]$-code C is a generator matrix for $C^\perp$.

A linear code C is ***self-orthogonal*** if $C \subseteq C^\perp$. It is ***self-dual*** if $C = C^\perp$.

Facts:

1. Both [HuPl03] and [MaSl77] are excellent books on linear codes.

2. Square parentheses (used to denote an $[n,k]$-code or an $[n,k,d]$-code) denote that a code is linear, while round brackets (used to denote an (n,M)-code or an (n,M,d)-code as defined in §14.2.1) are used for all codes, linear or not.

3. An $[n,k]$-code over $GF(q)$, the finite field of q elements, is an (n,q^k)-block code.

4. The information rate of an $[n,k]$-code is $R = \frac{k}{n}$.

5. The distance of a linear code C is the minimum Hamming weight of a nonzero vector in C.

6. A linear code is often described by a generator matrix.

7. If G is a generator matrix for a code, then any matrix obtained from G by applying a sequence of elementary row operations is also a generator matrix for that code.

8. Let C be an $[n,k]$-code over $GF(q)$. Then there exists an equivalent systematic code C' with generator matrix $[I_k \,|\, A]$, where I_k is the $k \times k$ identity matrix, and A is a $k \times (n-k)$ matrix with entries from $GF(q)$.

9. If G is a generator matrix for an $[n,k]$-code C, then $C = \{mG \mid m \in GF(q)^k\}$. The source messages can be taken to be the elements of $GF(q)^k$, and hence encoding is simply multiplication by G. Systematic codes are advantageous because if G is in standard form and $c = mG$ is the codeword corresponding to a message m, then the first k components of c are identically m.

10. Within a systematic code, the information symbols provide information about the message while the check symbols provide the redundancy which makes error correction possible.

11. If C is an $[n,k]$-code over $GF(q)$, then $C^\perp$ is an $[n,n-k]$-code over $GF(q)$.

12. If C is an $[n,k]$-code over $GF(q)$, then the dual code of $C^\perp$ is C itself.

13. There are many important special types and families of linear codes, including Hamming codes (§14.3.4), Golay codes (§14.5.2), Reed-Muller codes (§14.3.5), and cyclic codes (§14.4.1). Among cyclic codes, BCH codes form an important class (§14.4.3) and among BCH codes there is an important class of codes known as Reed-Solomon codes (§14.4.4).

14. Reed-Muller codes were used by the Mariner 9 spacecraft on its mission to Mars. A Golay code was used by the Voyager 2 on its mission to Jupiter and Saturn. A Reed-Solomon code was used by the Voyager 2 on its mission to Uranus. (See §15.9 in [HuPl03] for more details on these applications.)

15. Algorithm 1 uses linear algebra to construct a parity check matrix for a linear code from a generator matrix.

```
Algorithm 1: Constructing a parity check matrix $H$ from a generator
        matrix $G$.
  $G'$ := the reduced row echelon form of $G$ {use elementary row operations}
  $A$ := the $k \times (n-k)$ matrix obtained from $G'$ by deleting the (pivot) leading
         columns of $G'$
  $H$ := the $(n-k) \times n$ matrix $H$ obtained by placing, in order, the rows of $-A$ in
         the columns of $H$ which correspond to the leading columns of $G'$, and
         placing in the remaining $n-k$ columns of $H$, in order, the columns of the
         $(n-k) \times (n-k)$ identity matrix $I_{n-k}$
```

16. *Parity check matrices*: Let C be an $[n,k]$-code over $GF(q)$ with a generator matrix G, and let H be a parity check matrix for C.

- A vector $x \in GF(q)^n$ belongs to C if and only if $xH^T = 0$; it follows that $GH^T = 0$.
- If $G = [I_k \,|\, A]$ is a generator matrix for C, then $H = [-A^T \,|\, I_{n-k}]$ is a parity check matrix for C.
- C has distance at least s if and only if every set of $s-1$ columns of H are linearly independent over $GF(q)$; in other words, the distance of C is equal to the smallest number of columns of H that are linearly dependent over $GF(q)$.

17. Let C be an $[n,k]$-code with generator matrix G. C is self-orthogonal if and only if $GG^T = 0$.

18. Let C be an $[n,k]$-code with generator matrix G. C is self-dual if and only if it is self-orthogonal and $k = \frac{n}{2}$ (and hence n is even).

19. A *low-density parity check matrix (LDPC)* is a linear code whose parity check matrix has relatively few nonzero elements.

Examples:

1. Let C be a binary $[7,4]$-code with generator matrix

$$G = \begin{pmatrix} 0 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 0 & 1 & 1 & 1 \end{pmatrix}.$$

Elementary row operations yield the reduced row echelon form of G:

$$G' = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

The leading columns of G' are columns 1, 3, 5, and 7, giving

$$A = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

Hence, the following parity check matrix is obtained

$$H = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 1 & 0 \end{pmatrix}.$$

2. The *extended Hamming code* of order 3 is a binary $[8,4,4]$-code with generator matrix

$$G = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 \end{pmatrix}.$$

The code is self-dual since $GG^T = 0$.

14.3.2 SYNDROME DECODING

Syndrome decoding is a general decoding technique for linear codes that is useful if the information rate of the code is high. Let C be an $[n,k,d]$-code over $GF(q)$ with parity check matrix H.

Definitions:

For any $x \in GF(q)^n$, the ***coset*** of C determined by x is the set $C + x = \{c + x \mid c \in C\}$.

For any $x \in GF(q)^n$, the ***syndrome*** of x is the vector xH^T.

A ***coset leader*** of a coset of C is one of the coset members of smallest weight.

Facts:

1. The coset determined by 0 is C.

2. For all $x \in GF(q)^n$, $x \in C + x$.

3. For all $x, y \in GF(q)^n$, if $y \in C + x$, then $C + y = C + x$, that is, each word in a coset determines that coset.

4. The cosets of C partition $GF(q)^n$ into q^{n-k} cosets, each of size q^k.

5. A syndrome is a vector of length $n - k$.

6. Two vectors x_1 and $x_2 \in GF(q)^n$ are in the same coset of C if and only if they have the same syndrome, that is, $x_1H^T = x_2H^T$.

7. A vector $x \in GF(q)^n$ is a codeword if and only if its syndrome is 0.

8. Suppose that a codeword c is transmitted and r is received. If $e = r - c$, then $rH^T = eH^T$, which means that the error vector is in the same coset as the received word. By maximum likelihood decoding, the decoder should choose a vector of smallest weight in this coset as the error vector.

9. The fact that there is a one-to-one correspondence between syndromes and coset leaders leads to *syndrome decoding*, a decoding algorithm for linear codes, which is described as Algorithm 2.

```
Algorithm 2: Syndrome decoding for linear codes.
precomputation: set up a one-to-one correspondence between coset leaders and
    syndromes; let $r$ be a received word and $H$ the parity check matrix
compute the syndrome $s = rH^T$ of $r$
find the coset leader $e$ associated with $s$
correct $r$ to $r - e$
```

Example:

1. Consider the binary $[5, 2]$-code C with generator matrix

$$G = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 & 1 \end{pmatrix}$$

and parity check matrix

$$H = \begin{pmatrix} 0 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 1 \end{pmatrix}.$$

The eight cosets of C are

$$\begin{array}{ll} \{00000, 10001, 01111, 11110\} & \{10000, 00001, 11111, 01110\} \\ \{01000, 11001, 00111, 10110\} & \{00100, 10101, 01011, 11010\} \\ \{00010, 10011, 01101, 11100\} & \{11000, 01001, 10111, 00110\} \\ \{10100, 00101, 11011, 01010\} & \{01100, 11101, 00011, 10010\}. \end{array}$$

The following is a list of coset leaders and their syndromes:

coset leader	00000	10000	01000	00100	00010	11000	10100	01100
syndrome	000	001	111	100	010	110	101	011

If the word $r = 01101$ is received, compute the syndrome $01101 \cdot H^T = 010$, which corresponds to a coset leader $e = 00010$. Hence, r is corrected to $r - e = 01111$.

14.3.3 CONSTRUCTING NEW CODES FROM OLD

There are several methods for modifying a linear code to produce a new linear code. Some of these methods are extending a code, puncturing a code, and shortening a code.

Definitions:

If C is a linear code of length n over the field $GF(q)$, then the ***extended code*** $\overline{C}$ of C is $\overline{C} = \{(c_1, c_2, \ldots, c_n, c_{n+1}) \mid (c_1, c_2, \ldots, c_n) \in C,\ \sum_{i=1}^{n+1} c_i = 0\}$. The symbol c_{n+1} is called the ***overall parity check symbol***.

If C is a linear code over $GF(q)$, the code obtained by removing any column of a generator matrix of C is called a ***punctured*** C, denoted C^*.

If C is a linear code of length n, a ***shortened code*** C' of C is a linear code of length $n-1$ which equals the set of all codewords in C having 0 in a fixed coordinate position, with that position deleted.

Facts:

1. If C is an $[n, k, d]$-code over $GF(q)$ with generator matrix G and parity check matrix H, then

- $\overline{C}$ is an $[n+1, k, \overline{d}]$-code over $GF(q)$;
- if C is a binary code, then $\overline{d} = \begin{cases} d, & \text{if } d \text{ is even} \\ d+1, & \text{if } d \text{ is odd;} \end{cases}$
- a generator matrix for $\overline{C}$ is $\overline{G}$, which is obtained by adding a column to G in such a way that the sum of the elements of each row of $\overline{G}$ is 0;
- a parity check matrix for $\overline{C}$ is $\overline{H}$, where $\overline{H} = \begin{pmatrix} 1 & 1 & 1 & 1 & \cdots & 1 \\ & & & & & 0 \\ & & H & & & 0 \\ & & & & & \vdots \\ & & & & & 0 \end{pmatrix}$.

2. Puncturing a code is the reverse process to extending a code.

3. If C is an $[n, k, d]$-code over $GF(q)$, then C^* is a linear code over $GF(q)$ of length $n-1$, dimension k or $k-1$, and distance d or $d-1$.

4. If C is an $[n, k, d]$-code over $GF(q)$, $k \geq 2$, and C has at least one codeword for which the deleted position has a nonzero entry, then C' is an $[n-1, k-1, d']$-code over $GF(q)$, with $d' \geq d$.

14.3.4 HAMMING CODES

Definition:

A ***Hamming code*** of order r over F_q, denoted $H_r(q)$, is an $[n, k]$-code where $n = \frac{q^r-1}{q-1}$ and $k = n - r$, with a parity check matrix whose columns are nonzero and such that no two columns are scalar multiples of each other.

Facts:

1. A decoding algorithm for Hamming codes is shown in Algorithm 3.

2. In the binary case ($q = 2$), the Hamming code $H_r(2)$ has a parity check matrix whose columns consist of all nonzero binary vectors of length r, each used exactly once.

3. $H_r(q)$ has distance 3, and so is a 1-error correcting code.

4. Any two binary Hamming codes of order r are equivalent.

5. $H_r(q)$ is a perfect code (§14.5.2).

```
Algorithm 3: Decoding algorithm for Hamming codes.
  $H$ := a parity check matrix for a Hamming code $H_r(q)$
  $r$ := a received word
  compute the syndrome $s = rH^T$ of $r$
  if $s = 0$ then accept $r$ as the transmitted word
  else
    compare $s^T$ with the columns of $H$
    if $s^T = \alpha h_i$ (where $h_i$ is the $i$th column of $H$) and $\alpha \in F_q$ then
      the error vector $e$ is the vector with $\alpha$ in position $i$ and 0s elsewhere
      correct $r$ to $c = r - e$
```

Example:

1. Consider $H_3(2)$, the binary Hamming code of order 3. The code has length $n = 7$ and dimension $k = 4$, and a parity check matrix is

$$H = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix}.$$

If the received word is $r = 1011101$, compute the syndrome $s = 1011101 \cdot H^T = 001$, which is the third column of H. Hence $e = 0010000$, and correct r to 1001101.

14.3.5 REED-MULLER CODES

Definition:

A ***first-order Reed-Muller code***, denoted $R(1, m)$, is the binary $[2^m, m+1]$-code whose generator matrix is formed by adding a single row entirely of 1s to the $m \times 2^m$ submatrix whose columns consist of all binary m-tuples.

A ***kth-order Reed-Muller code***, denoted $R(k, m)$, is the binary $[2^m, s]$-code where $s = \sum_{i=0}^{k} \binom{m}{k}$ whose generator matrix consists of a single row entirely of 1s and the rows of the submatrices $B_1, \ldots, B_k$ which have the following form. B_1 is the $m \times 2^m$ matrix whose columns are all distinct binary m-tuples and B_i for $i = 2, \ldots, k$ is the $\binom{m}{i} \times 2^m$ matrix where each row is formed from an i-subset of the rows of B_1 by making an entry 1 if and only if the corresponding entries in each member of the i-subset is 1.

Facts:

1. A first-order Reed-Muller code $R(1, m)$ has weight 2^{m-1}.

2. In practice, the columns in the generator matrix of a first-order Reed-Muller code are listed according to a *proper ordering*. This may be seen as normal lexigraphic order of 0-1 strings, but from right to left. Alternatively, it may be seen as the natural order of the integers in little-endian binary representation. The matrix in Example 1 shows this ordering.

3. First-order Reed-Muller codes can be decoded using Algorithm 4.

```
Algorithm 4: Decoding algorithm for first-order Reed-Muller codes.
  $H_{2^m}$ := a Hadamard matrix of order $2^m$ in standard form
  $G$ := a generator matrix for the Reed-Muller code
  $r := (r_0, \ldots, r_{2^m-1})$ a received word
  compute the vector $R := (R_0, \ldots, R_{2^m-1})$ where $R_i = (-1)^{r_i}$
  compute the vector $\hat{R} := RH_{2^m}$
  let $\hat{R} = (\hat{R}_0, \ldots, \hat{R}_{2^m-1})$; find a component $\hat{R}_j$ with maximum magnitude
  suppose $j$ has the binary representation $j = \sum_{i=1}^{m} j_i 2^{i-1}$ with $j_i \in \{0,1\}$
  if $\hat{R}_j > 0$ then decode $r$ to $\sum_{i=1}^{m} j_i \vec{v}_i$ where $\vec{v}_i$ is the $i$th row of $G$ (discounting
    the row of 1s)
  if $\hat{R}_j \leq 0$ then decode $r$ to $\vec{1} + \sum_{i=1}^{m} j_i \vec{v}_i$ where $\vec{v}_i$ is the $i$th row of $G$ (discounting
    the row of 1s)
```

4. In Algorithm 4, the computation of RH_{2^m} can be speeded up by using a *Fast Hadamard Transform*.

5. The first-order Reed-Muller code $R(1,5)$ was used to transmit photographs from the Mariner 9 spacecraft. It had good error-correcting capabilities of correcting 7 errors and detecting 8. However, it had a very low information rate and relatively few codewords.

6. The kth order Reed-Muller code may also be viewed as a subspace of the vector space V of linear functionals $f : GF(2)^m \to GF(2)$. By considering linear functionals as polynomials in $x_1, \ldots, x_n$, the set of the characteristic functionals $\chi_u = \prod_{i=1}^{m}(x_i + 1 + u_i)$ for all $u = (u_1, \ldots, u_m)$ forms a basis for V. Note that χ_u has the property that $\chi_u(u) = 1$ but $\chi_u(v) = 0$ for all $v \neq u$. The kth-order Reed-Muller code is the subspace of functionals of total degree at most k. A bijection can be explicitly defined between this representation and the ordinary representation by taking $f \mapsto (c_0, \ldots, c_{2^m-1})$ if $f = \sum_{i=0}^{2^m-1} c_i \chi_{u_i}$ where u_i is the m-tuple representing the binary value of i.

7. The kth-order Reed-Muller code can also be represented as the code whose generator matrix is the incidence matrix between the points and the $(m-k)$-flats of an affine geometry of dimension m over $GF(2)$.

Examples:

1. Consider the first-order Reed-Muller code $R(1,3)$. This code has length $n = 8$, dimension $k = 4$, and distance $d = 4$. Using the proper ordering, the generator matrix for $R(1,3)$ is

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}.$$

2. Suppose the vector $r = (1,0,1,1,0,1,1,0)$ is received. Then we can compute $R = (-1,1,-1,-1,1,-1,-1,1)$. Multiplying R by the Hadamard matrix

$$H_8 = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{pmatrix}$$

gives us the vector $\hat{R} = (-2, -2, 2, 2, -2, -2, 2, -6)$. The component $\hat{R}_7 = -6$ has largest magnitude. Since $7 = 1{+}(1)2^1{+}1(2^2)$, and $\hat{R}_7 < 0$, we decode r to $c = (1, 0, 0, 1, 0, 1, 1, 0)$.

3. The second-order Reed-Muller code $R(2, 3)$ would have $n = 8$, $k = 7$, and $d = 2$. It would have generator matrix

$$G = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}.$$

14.3.6 WEIGHT ENUMERATORS

Definitions:

Let C be an (n, M)-code and let A_i be the number of codewords of weight i in C, for $i = 0, 1, \ldots, n$. The vector $(A_0, A_1, \ldots, A_n)$ is called the ***weight distribution*** of C.

Let C be an $[n, k]$-code over $GF(q)$ with weight distribution $(A_0, A_1, \ldots, A_n)$. The ***weight enumerator*** of C is defined to be the polynomial $W_C(z) = \sum_{i=0}^{n} A_i z^i$.

Facts:

1. Let C be an $[n, k]$-code over $GF(q)$, and let the symbol error probability on the q-ary symmetric channel be p. If C is used only for error detection, then the probability of an error going undetected is $\sum_{i=0}^{n} A_i \big(\frac{p}{q-1}\big)^i (1-p)^{n-i}$.

2. *MacWilliams' identity*: Let C be an $[n, k]$-code over $GF(q)$ with dual code $C^{\perp}$. Then

$$W_{C^{\perp}}(z) = \tfrac{1}{q^k}\,[1 + (q-1)z]^n\, W_C\big(\tfrac{1-z}{1+(q-1)z}\big).$$

Examples:

1. The weight distribution of a binary Hamming code of length n satisfies the recurrence $A_0 = 1, A_1 = 0,$

$$(i+1)A_{i+1} + A_i + (n-i+1)A_{i-1} = \tbinom{n}{i}, \quad i \geq 1.$$

2. The weight enumerator of the Golay code (§14.5.2) is

$$1 + 253z^7 + 506z^8 + 1288z^{11} + 1288z^{12} + 506z^{15} + 253z^{16} + z^{23}.$$

14.4 CYCLIC CODES

Cyclic codes are an important type of linear code which have an additional algebraic structure imposed upon them. They are not only subspaces of finite-dimensional vector spaces, but ideals within a special type of polynomial ring. This additional structure enables the use of shifting and polynomial multiplication in addition to ordinary vector addition. One of the main advantages of cyclic codes is their ability to correct errors which occur in bursts.

14.4.1 INTRODUCTION

Definitions:

A linear code C of length n is ***cyclic*** if whenever $(a_0, a_1, a_2, \ldots, a_{n-1})$ is a codeword in C, then the cyclic shift $(a_{n-1}, a_0, a_1, \ldots, a_{n-2})$ is also a codeword in C.

Let $g(x)$ be a polynomial in $GF(q)[x]/(x^n - 1)$. The ideal generated by $g(x)$, namely $\{a(x)g(x) \mid a(x) \in GF(q)[x]/(x^n - 1)\}$, is called the ***code generated*** by $g(x)$ and is denoted $\langle g(x)\rangle$.

Let C be a nonzero cyclic code in $GF(q)[x]/(x^n - 1)$. A monic polynomial $g(x)$ of least degree in C is called a ***generator polynomial*** of C.

The polynomial $h(x) = \dfrac{x^n - 1}{g(x)}$ is called the ***check polynomial*** of C.

Let H be a parity check matrix for a cyclic code. If r is a received word, the ***syndrome polynomial*** of r is the polynomial $s(x)$ corresponding to the syndrome $s = rH^T$.

Facts:

1. The study of cyclic codes is facilitated by the attachment of some additional algebraic structure to the vector space $GF(q)^n$.

2. If the vector $(a_0, a_1, a_2, \ldots, a_{n-1})$ in $GF(q)^n$ is identified with the polynomial $a_0 + a_1x + a_2x^2 + \cdots + a_{n-1}x^{n-1}$, then

- the ring $GF(q)[x]/(x^n - 1)$ can be viewed as a vector space over $GF(q)$;
- the vector spaces $GF(q)^n$ and $GF(q)[x]/(x^n - 1)$ are isomorphic;
- multiplication of a polynomial in $GF(q)[x]/(x^n - 1)$ by x corresponds to a cyclic shift of the corresponding vector;
- a linear code C in the vector space $GF(q)^n$ is cyclic if and only if C is an ideal in the ring $GF(q)[x]/(x^n - 1)$.

3. An ideal may contain many elements which will generate the ideal. One of these generators is singled out as *the* generator.

4. If $g(x)$ is a generator polynomial of a cyclic code C, then $g(x)$ generates C; that is, $\langle g(x)\rangle = C$.

5. The following are consequences of the fact that the ring $GF(q)[x]/(x^n - 1)$ is a principal ideal domain (i.e., each ideal is generated by a monic polynomial, called the generator polynomial). Here C is a nonzero cyclic code in $GF(q)[x]/(x^n - 1)$ with generator polynomial $g(x)$.

- The generator polynomial of C is unique.

- $g(x)$ divides $x^n - 1$ in $GF(q)[x]$.

- If the degree of $g(x)$ is $n-k$, that is, $g(x) = g_0 + g_1x + g_2x^2 + \cdots + g_{n-k}x^{n-k}$ (and $g_{n-k} = 1$), then a basis for C is $\{g(x), xg(x), x^2g(x), \ldots, x^{k-1}g(x)\}$; hence C has dimension k and a generator matrix for C is

$$\begin{pmatrix} g_0 & g_1 & g_2 & \cdots & \cdots & g_{n-k} & 0 & 0 & \cdots & 0 \\ 0 & g_0 & g_1 & \cdots & \cdots & g_{n-k-1} & g_{n-k} & 0 & \cdots & 0 \\ 0 & 0 & g_0 & \cdots & \cdots & g_{n-k-2} & g_{n-k-1} & g_{n-k} & \cdots & 0 \\ \vdots & \vdots & & \ddots & & & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & g_0 & \cdots & & \cdots & & g_{n-k} \end{pmatrix}.$$

6. Any $c(x) \in C$ can be written uniquely as $c(x) = f(x)g(x)$ in the ring $GF(q)[x]$, where $f(x) \in GF(q)[x]$ has degree less than k. Hence, encoding a message polynomial $f(x)$ consists simply of polynomial multiplication by $g(x)$.

7. The dual code $C^{\perp}$ is also cyclic.

8. Let $h(x) = h_0 + h_1x + h_2x^2 + \cdots + h_kx^k = \dfrac{x^n - 1}{g(x)}$ be in $GF(q)[x]$. Then the *reciprocal polynomial* $h^*(x) = x^k h(\frac{1}{x})$ of $h(x)$ is a generator of $C^{\perp}$. (In fact, $(\frac{1}{h_0})h^*(x)$ is the generator polynomial of $C^{\perp}$.) Hence, a parity check matrix for C is

$$\begin{pmatrix} h_k & h_{k-1} & h_{k-2} & \cdots & \cdots & h_0 & 0 & 0 & \cdots & 0 \\ 0 & h_k & h_{k-1} & \cdots & \cdots & h_1 & h_0 & 0 & \cdots & 0 \\ 0 & 0 & h_k & \cdots & \cdots & h_2 & h_1 & h_0 & \cdots & 0 \\ \vdots & \vdots & & \ddots & & & \ddots & \ddots & \ddots & \\ 0 & 0 & \cdots & 0 & h_k & \cdots & & \cdots & & h_0 \end{pmatrix}.$$

9. A cyclic code of length n over $GF(q)$ is characterized by its generator polynomial.

10. There is a one-to-one correspondence between cyclic codes in $GF(q)^n$ and monic polynomials in $GF(q)[x]$ which divide $x^n - 1$.

11. The following table gives the complete factorization of $x^n - 1$ over $GF(2)$ for some small values of odd n, $1 \leq n \leq 31$.

n	*factorization of* $x^n - 1$ *over* $GF(2)$
1	$1 + x$
3	$(1+x)(1+x+x^2)$
5	$(1+x)(1+x+x^2+x^3+x^4)$
7	$(1+x)(1+x+x^3)(1+x^2+x^3)$
9	$(1+x)(1+x+x^2)(1+x^3+x^6)$
11	$(1+x)(1+x+x^2+\cdots+x^{10})$
13	$(1+x)(1+x+x^2+\cdots+x^{12})$
15	$(1+x)(1+x+x^2)(1+x+x^2+x^3+x^4)(1+x+x^4)(1+x^3+x^4)$
17	$(1+x)(1+x+x^2+x^4+x^6+x^7+x^8)(1+x^3+x^4+x^5+x^8)$
19	$(1+x)(1+x+x^2+\cdots+x^{18})$
21	$(1+x)(1+x+x^2)(1+x^2+x^3)(1+x+x^3)(1+x^2+x^4+x^5+x^6)\cdot$ $\cdot(1+x+x^2+x^4+x^6)$
23	$(1+x)(1+x+x^5+x^6+x^7+x^9+x^{11})(1+x^2+x^4+x^5+x^6+x^{10}+x^{11})$
25	$(1+x)(1+x+x^2+x^3+x^4)(1+x^5+x^{10}+x^{15}+x^{20})$
27	$(1+x)(1+x+x^2)(1+x^3+x^6)(1+x^9+x^{18})$
29	$(1+x)(1+x+x^2+\cdots+x^{28})$
31	$(1+x)(1+x^2+x^5)(1+x^3+x^5)(1+x+x^2+x^3+x^5)(1+x+x^2+x^4+x^5)\cdot$ $\cdot(1+x+x^3+x^4+x^5)(1+x^2+x^3+x^4+x^5)$

12. If C is an $[n,k]$-cyclic code generated by $g(x)$, then another parity check matrix for C is the matrix H whose ith column is x^i **mod** $g(x)$, for $i = 0, 1, \ldots, n-1$.

13. If $r(x)$ is the polynomial corresponding to the received word r, then the syndrome polynomial of r is simply $s(x) = r(x)$ **mod** $g(x)$.

14. A cyclic code can correct cyclic burst errors of length t if and only if all cyclic burst errors of length t or less have different syndrome polynomials. Algorithm 1 shows how burst errors can be corrected. In the algorithm, $g(x)$ is the generator polynomial for an $[n,k]$-cyclic code which can correct burst errors of length t.

Algorithm 1: **Decoding algorithm using burst error correction in cyclic codes.**

```
suppose a codeword $c$ is transmitted and $r$ is received
for $i = 0$ to $n-1$
   compute the syndrome polynomial $s_i(x) = x^i r(x)$ mod $g(x)$
   if $s_i$ has a (non-cyclic) burst of length $t$ or less then
      compute the error polynomial $e(x) = x^{n-i} s_i(x)$
      correct $r(x)$ to $c(x) = r(x) - e(x)$
      break
received word cannot be decoded
```

Examples:

1. Over $GF(2)$, the factorization of $x^7 - 1$ is $x^7 - 1 = (1+x)(1+x+x^3)(1+x^2+x^3)$. The monic divisors of $x^7 - 1$ are

$$\begin{aligned}
g_1(x) &= 1\\
g_2(x) &= 1 + x\\
g_3(x) &= 1 + x + x^3\\
g_4(x) &= 1 + x^2 + x^3\\
g_5(x) &= (1 + x)(1 + x + x^3) = 1 + x^2 + x^3 + x^4\\
g_6(x) &= (1 + x)(1 + x^2 + x^3) = 1 + x + x^2 + x^4\\
g_7(x) &= (1 + x + x^3)(1 + x^2 + x^3) = 1 + x + x^2 + x^3 + x^4 + x^5 + x^6\\
g_8(x) &= 1 + x^7
\end{aligned}$$

The polynomial $g_5(x)$ generates the binary $[7, 3]$-cyclic code

$$C = \{0000000, 1011100, 0101110, 0010111, 1001011, 1100101, 1110010, 0111001\}.$$

A generator matrix for C is

$$G = \begin{pmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0\\ 0 & 1 & 0 & 1 & 1 & 1 & 0\\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix}.$$

A parity check matrix for C is

$$H = \begin{pmatrix} 1 & 1 & 0 & 1 & 0 & 0 & 0\\ 0 & 1 & 1 & 0 & 1 & 0 & 0\\ 0 & 0 & 1 & 1 & 0 & 1 & 0\\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{pmatrix}.$$

2. The cyclic code in Example 1 has distance $d = 4$ and so can correct 1 error, but is also a 2-cyclic burst error correcting code. Suppose the the word $r = 1110100$ is received. Running Algorithm 1 yields the results

i	$s_i(x)$	s_i
0	$x + x^3$	0101
1	$1 + x^3$	1001
2	$1 + x + x^2 + x^3$	1111
3	$1 + x$	1100

The syndrome is a (non-cyclic) burst of length 2. The error polynomial is $e(x) = x^{7-3}s_3(x) = x^4 + x^5$. The received word r is decoded to the codeword $c = r - e = 1110100 - 0000110 = 1110010$.

14.4.2 INTERLEAVING

Definitions:

Let C be an $[n,k]$-code and consider s codewords $c_i = (c_{i,1}, c_{i,2}, \dots, c_{i,n}) \in C$. Place these codewords in a matrix as follows.

$$\begin{pmatrix} c_{1,1} & c_{1,2} & \cdots & c_{1,n} \\ c_{2,1} & c_{2,2} & \cdots & c_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ c_{s,1} & c_{s,2} & \cdots & c_{s,n} \end{pmatrix}.$$

The word $(c_{1,1}, c_{2,1}, \dots, c_{s,1}, c_{1,2}, c_{2,2}, \dots, c_{s,2}, \dots, c_{1,n}, c_{2,n}, \dots, c_{s,n})$ obtained by expanding the matrix entry-by-entry column-wise is said to be made by ***interleaving*** the s codewords together.

The $[ns, ks]$-code C^* obtained by interleaving all possible s-tuples of codewords from C is said to have been created by ***interleaving C to a depth of s***.

Suppose instead of interleaving the codewords, we use the entries in each column of the above matrix as information symbols within an $[m, s]$-code $\hat{C}$. The result would be a sequence of codewords from $\hat{C}$. This process is referred to as ***cross-interleaving*** C and $\hat{C}$.

Facts:

1. If an $[n,k]$-code C has distance d, then the code C^* obtained by interleaving C to a depth of s has distance ds.

2. If an $[n,k]$-code C can correct cyclic burst errors of length t, then the code C^* obtained by interleaving C to a depth of s can correct cyclic bursts of length st.

3. Suppose G is a generator matrix for an $[n,k]$-code C and let C^* be the code obtained by interleaving C to a depth of s. A generator matrix G^* for C^* can be constructed by interleaving each of the k rows of G separately with $s-1$ copies of the zero codeword in each of the s possible ways. The resulting ks vectors would form the rows of G^*.

4. If C is a cyclic code with generator polynomial $g(x)$, then C^*, the code obtained interleaving C to a depth of s, is also cyclic and its generator polynomial is $g(x^s)$.

5. In practice, after cross-interleaving C and $\hat{C}$, the resulting codewords in $\hat{C}$ are often interleaved themselves to some specified depth.

Examples:

1. Let C be the binary $[7,4]$-code with generator matrix

$$G = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}.$$

Interleaving the three codewords 1000111, 1010100, and 0111000 would produce the interleaved codeword 110 001 011 001 110 100 100.

2. Suppose that we wish to cross-interleave the three codewords from Example 1 with the binary $[6,3]$-code with generator matrix

$$G = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 & 1 \\ 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}.$$

Using each group of three symbols as information symbols, we get the seven new codewords 110100, 001110, 011101, 001110, 110100, 100111, and 100111. In practice, we can now interleave these codewords to a desired depth.

14.4.3 BCH CODES

Definitions:

Let β be a primitive nth root of unity in an extension field of $GF(q)$. Let $g(x)$ be the least common multiple of the minimal polynomials over $GF(q)$ of $\beta^a, \beta^{a+1}, \ldots, \beta^{a+\delta-2}$ where a is an integer. The cyclic code of length n over $GF(q)$ with generator polynomial $g(x)$ is called a ***BCH code*** (after its discoverers: R. C. Bose, D. Ray-Chaudhuri, and A. Hocquenghem) with ***designed distance*** δ.

If $a = 1$ in the definition of a BCH code, the code is called ***narrow-sense***. If $n = q^m - 1$ for some positive integer m (that is, β is primitive in $GF(q^m)$), the code is ***primitive***.

Facts:

1. BCH codes are special types of cyclic codes, discovered by A. Hocquenghem in 1959 and independently by R. C. Bose and D. K. Ray-Chaudhuri in 1960.

2. *BCH bound*: Let C be a BCH code over $GF(q)$ with designed distance δ. Then C has distance at least δ.

3. Algorithm 2 is one method for decoding BCH codes. In the algorithm, let $g(x)$ be a generator polynomial for a BCH code over $GF(q)$ of designed distance δ and length n. Hence $g(x) = \text{lcm}\{m_i(x) \mid a \le i \le a+\delta-2\}$, where $m_i(x)$ is the minimal polynomial of β^i over $GF(q)$, and β is a primitive nth root of unity in an extension field $GF(q^m)$.

Algorithm 2: **Decoding algorithm for BCH codes.**

```
suppose a codeword $c$ is transmitted and $r$ is received
compute $S_j = r(\beta^{a+j})$ for $j = 0, 1, \ldots, \delta-2$ and form the polynomial $S(z) = \sum_{j=0}^{\delta-2} S_j z^j$
use the extended Euclidean algorithm to calculate the greatest common divisor
    of $S(z)$ and $z^{\delta-1}$ in the ring $GF(q^m)[z]$; stop as soon as the remainder $r_i(z)$
    has degree $< \frac{\delta-1}{2}$; this yields polynomials $s_i(z)$ and $t_i(z)$ such that
    $s_i(z)z^{\delta-1} + t_i(z)S(z) = r_i(z)$; $\sigma(z) := t_i(z)$; $w(z) := r_i(z)$
find $B$, the set of roots of $\sigma(z)$ in $GF(q^m)$
for each $\gamma \in B$, set $E_\gamma = \frac{-\gamma^{-1}w(\gamma)}{\sigma'(\gamma)}$, where $\sigma'(z)$ denotes the formal derivative
    of $\sigma(z)$
the error vector is $e = (e_0, e_1, \ldots, e_{n-1})$, where $e_i = \begin{cases} 0, & \text{if } \beta^{-i} \notin B, \\ E_\gamma, & \text{if } \beta^{-i} = \gamma \in B \end{cases}$
decode $r$ to $r - e$
```

4. In Algorithm 2 the roots comprising B will lie in the subgroup of $GF(q^m)^*$ generated by β.

5. If it is assumed that the number of errors is $l \leq \lfloor \frac{\delta-1}{2} \rfloor$, then the decoding in Algorithm 2 is correct.

6. There are more efficient ways of obtaining $\sigma(z)$ and $w(z)$ than by using the Euclidean algorithm; for example, by using the Berlekamp-Massey algorithm (see §5.4.2 in [HuPl03]).

7. There exists an analogue to Algorithm 2 for decoding BCH codes in which both errors and erasures occur. See Chapter 5 of [HuPl03] for a description and references.

Examples:

1. Consider the finite field $GF(3^3)$ generated by a root α of the primitive polynomial $f(x) = 1 + 2x^2 + x^3 \in GF(3)[x]$. A table of powers of α is given in the following table.

i	α^i	i	α^i	i	α^i
0	1	9	$2+2\alpha+2\alpha^2$	18	$1+\alpha$
1	α	10	$1+2\alpha+\alpha^2$	19	$\alpha+\alpha^2$
2	α^2	11	$2+\alpha$	20	$2+2\alpha^2$
3	$2+\alpha^2$	12	$2\alpha+\alpha^2$	21	$1+2\alpha+2\alpha^2$
4	$2+2\alpha+\alpha^2$	13	2	22	$1+\alpha+\alpha^2$
5	$2+2\alpha$	14	2α	23	$2+\alpha+2\alpha^2$
6	$2\alpha+2\alpha^2$	15	$2\alpha^2$	24	$1+2\alpha$
7	$1+\alpha^2$	16	$1+2\alpha^2$	25	$\alpha+2\alpha^2$
8	$2+\alpha+\alpha^2$	17	$1+\alpha+2\alpha^2$		

The element $\beta = \alpha^2$ is a primitive 13th root of unity in $GF(3^3)$. If $m_i(x)$ denotes the minimal polynomial of β^i over $GF(3)$, then

$$\begin{aligned} m_0(x) &= 2 + x \\ m_1(x) &= 2 + 2x + 2x^2 + x^3 \\ m_2(x) &= 2 + 2x + x^3 \\ m_4(x) &= 2 + x + 2x^2 + x^3 \\ m_7(x) &= 2 + x^2 + x^3. \end{aligned}$$

Since $m_1(x) = m_3(x)$, the polynomial

$$g(x) = \text{lcm}(m_0(x), m_1(x), m_2(x), m_3(x)) = m_0(x)m_1(x)m_2(x)$$

has among its roots the elements β^0, β^1, β^2, and β^3. Hence $g(x)$ is a generator polynomial for a BCH code over F_3 of designed distance $\delta = 5$ and length $n = 13$.

2. Using the BCH code in Example 1, suppose that the decoder received the word $r = (220\ 021\ 110\ 2110)$. The following steps follow Algorithm 2 to decode r:

- Compute $S_0 = r(\beta^0) = 1$, $S_1 = r(\beta^1) = \alpha^{14}$, $S_2 = r(\beta^2) = \alpha^{23}$, and $S_3 = r(\beta^3) = \alpha^{16}$. This gives $S(z) = 1 + \alpha^{14}z + \alpha^{23}z^2 + \alpha^{16}z^3$.

- Applying the extended Euclidean algorithm in $GF(3^3)[z]$ to $S(z)$ and z^4 yields

i	$s_i(z)$	$t_i(z)$	$r_i(z)$	$\deg r_i(z)$
-1	1	0	z^4	4
0	0	1	$1+\alpha^{14}z+\alpha^{23}z^2+\alpha^{16}z^3$	3
1	1	$\alpha^{17}+\alpha^{23}z$	$\alpha^{17}+\alpha^{16}z+\alpha^{13}z^2$	2
2	$\alpha^3+\alpha^{16}z$	$\alpha^{15}+\alpha^3z+\alpha^{13}z^2$	$\alpha^{15}+\alpha^{16}z$	1

  Stop, since $\deg(r_2(z)) < \frac{\delta-1}{2} = 2$. Hence, $\sigma(z) = \alpha^{15}+\alpha^3z+\alpha^{13}z^2$ and $w(z) = \alpha^{15}+\alpha^{16}z$.
- By trying all possibilities, obtain the set $B = \{\beta^5, \beta^9\}$ of roots of $\sigma(z)$.
- Compute $E_{\beta^5} = -\beta^{-5}\frac{w(\beta^5)}{\sigma'(\beta^5)} = 2$ and $E_{\beta^9} = -\beta^{-9}\frac{w(\beta^9)}{\sigma'(\beta^9)} = 2$.
- Hence, the error vector is $e = (000\ 020\ 002\ 0000)$ and the word r is decoded to $(220\ 001\ 111\ 2110)$.

14.4.4 REED-SOLOMON CODES

Definition:

A ***Reed-Solomon*** (***RS***) code C is a primitive BCH code of length $n = q-1$ over $GF(q)$. If C has dimension k then we call C an $[n,k]$-RS code.

Facts:

1. Reed-Solomon codes are special types of BCH codes, and hence they have the same encoding and decoding algorithms.

2. Reed-Solomon codes are important because, for a fixed n and k, no linear code can have greater distance.

3. Reed-Solomon codes are useful for correcting burst errors. (A *binary burst* of length b is a bit string whose only nonzero entries are among b successive components, the first and last of which are nonzero.)

4. A Reed-Solomon code was used to encode the data transmissions from the Voyager 2 spacecraft during its encounter with Uranus in January, 1986.

5. If C is an $[n,k]$-RS code over $GF(q)$ with designed distance δ, then the generator polynomial for C has the form $g(x) = (x-\beta^a)(x-\beta^{a+1})\dots(x-\beta^{a+\delta-2})$, where β is a primitive element of $GF(q)$.

6. If C is an $[n,k]$-RS code over $GF(q)$ with designed distance δ, then the distance of C is exactly $\delta = n-k+1$.

7. A *generalized* $[n,k]$*-Reed-Solomon code* consists of all the codewords having the form $(f(\alpha_1),\dots,f(\alpha_n))$ for all polynomials $f \in GF(q)[x]$ of degree $< k$ where $\alpha_1,\dots,\alpha_n$ are fixed distinct elements from $GF(q)$. Codewords are sometimes represented as polynomials in $GF(q)[x]$ of degree $< k$.

8. Generalized Reed-Solomon codes can be decoded by a *curve-fitting* algorithm proposed by Sudan. This algorithm gives a way of decoding generalized RS-codes beyond the normal error-correction capabilities of an RS-code. It uses a method called *list decoding*, which produces a list of possible candidates to which the transmitted codeword should correspond. An excellent introduction to list decoding can be found in [Gu04].

9. It is possible to associate codewords within an RS-code to their polynomial representatives in a generalized RS-code. Suppose $c = (c_1, \dots, c_n)$ is a codeword in an RS-code such that the c_is are distinct. Setting $\alpha_i = c_i$ gives the association. A polynomial f in the general representation can be converted to an n-tuple by evaluating it at the n elements c_i. An n-tuple $(\hat{c}_1, \dots, \hat{c}_n)$ can be converted to a polynomial f of degree $< k$ by applying Lagrange interpolation given the relations $\hat{c}_i = f(c_i)$.

10. Error correction in compact disks (developed by Philips and Sony) uses a code known as the Cross-Interleaved Reed-Solomon Code (CIRC). The CIRC code is obtained by cross-interleaving two Reed-Solomon codes, one a $[28, 24]$-RS code and the other a $[32, 28]$-RS code.

Examples:

1. Consider the finite field $GF(5)$ generated by $\beta = 2$. Then $g(x) = (x - \beta)(x - \beta^2) = (x - 2)(x - 4) = x^2 + 4x + 3$ generates a $[4, 2]$-RS code over $GF(5)$ with distance $\delta = 4$.

2. The code in Example 1 may be considered as a generalized RS-code by considering all polynomials of degree < 2 over $GF(q)$ and using the fixed elements $(1, 2, 4, 3)$. Using this representation, the codeword $(1, 2, 4, 3)$ is associated with the polynomial x while the codeword $(0, 4, 2, 3)$ is associated with the polynomial $1 + 4x$.

14.4.5 CODES FROM INCIDENCE MATRICES OF GRAPHS

Definition:

For any prime p, consider the row span C over $GF(p)$ of the $|V| \times |E|$ incidence matrix of a connected graph $\Gamma = (V, E)$. This class of codes arising from incidence matrices of graphs has been investigated by a number of researchers, for example, Dankelmann, Key, and Rodrigues [DaKeRo13].

Recall an incidence structure $D = (P, B, J)$, with point set P, block set B, and incidence J, is a ***t*-(v, k, λ) design** if $|P| = v$, every block $b \in B$ is incident with precisely k points, and every t distinct points are together incident with precisely λ blocks. The ***code $C_F(D)$ of the design D over the finite field F*** is the space spanned by the incidence vectors of the blocks over F.

An ***edge cut*** of a connected graph Γ is a set $S \subset E$ such that $\Gamma - S = (V, E - S)$ is disconnected. The ***edge connectivity*** $\lambda(\Gamma)$ is the minimum cardinality of an edge cut. The minimum and maximum degrees of the vertices of Γ are denoted by $\delta(\Gamma)$ and $\Delta(\Gamma)$.

If $\lambda(\Gamma) = \delta(\Gamma)$ and, in addition, the only edge sets of cardinality $\lambda(\Gamma)$ whose removal disconnects Γ are the sets of edges incident with a vertex of degree $\delta(\Gamma)$, then Γ is called ***super-λ***.

Let $\Gamma = (V, E)$ be a connected graph and let G be an incidence matrix for Γ. Denote by $C_p(G)$ the row-span of G over $GF(p)$. Note that $C_2(G)$ is also known as the ***cut space*** of Γ.

Facts:

1. We have $\dim(C_2(G)) = |V| - 1$. For odd p, $\dim(C_p(G)) = |V|$ if Γ has a closed path of odd length (i.e., if Γ is not bipartite), and $\dim(C_p(G)) = |V| - 1$ if Γ has no closed path of odd length (i.e., if Γ is bipartite).

2. Let $\Gamma = (V, E)$ be a connected graph and let G be a $|V| \times |E|$ incidence matrix for Γ. Then

- $C_2(G)$ is a $[|E|, |V|-1, \lambda(\Gamma)]_2$-code;
- if Γ is super-λ, then $C_2(G)$ is a $[|E|, |V|-1, \delta(\Gamma)]_2$-code, and the minimum words are the rows of G of weight $\delta(\Gamma)$.

3. Let $\Gamma = (V, E)$ be a connected bipartite graph and let G be a $|V| \times |E|$ incidence matrix for Γ. Then

1. $C_p(G)$ is a $[|E|, |V|-1, \lambda(\Gamma)]_p$-code;

2. if Γ is super-λ, then $C_p(G)$ is a $[|E|, |V|-1, \delta(\Gamma)]_p$-code, and the minimum words are the nonzero scalar multiples of the rows of G of weight $\delta(\Gamma)$.

Examples:

1. Let $\Gamma = K_5$ denote the complete graph on five vertices and let G be an incidence matrix for Γ. Then $C_2(G)$ is a $[10, 4, 4]$-code and its dual is a $[10, 6, 3]$-code.

2. Let $\Gamma = K_7$ denote the complete graph on seven vertices and let G be an incidence matrix for Γ. Then $C_2(G)$ is a $[21, 6, 6]$-code and its dual is a $[21, 15, 3]$-code.

14.5 BOUNDS FOR CODES

How many codewords can a code have if its codewords are n-tuples of elements of $GF(q)$ and it has distance d? Although this is a difficult question for all but special sets of values of n, q, and d, there are several different useful bounds on M, the number of codewords in the code. There are also special types of codes, called perfect codes, that achieve the maximum number of codewords possible, given values of n, q, and d.

14.5.1 CONSTRAINTS ON CODE PARAMETERS

Definitions:

Let $A_q(n, d)$ be the maximum M for which there exists an (n, M, d)-code over $GF(q)$. A code that achieves this bound is called ***optimal***.

Let $V_q(n, d)$ be the number of words in $GF(q)^n$ that have distance at most d from a fixed word.

An $[n, k, d]$-code for which $k = n - d + 1$ is called a ***maximum distance separable*** (***MDS*** code), or an ***$[n, k]$-MDS code***.

Facts:

1. Little is known about $A_q(n, d)$ except for some specific values of q, n, and d.

2. For all $n \geq 1$, $A_q(n, 1) = q^n$ and $A_q(n, n) = q$.

3. For all $n \geq 2$, $A_q(n, d) \leq qA_q(n-1, d)$.

4. If d is even, then $A_2(n, d) = A_2(n-1, d-1)$.

5. $V_q(n, d) = \sum_{i=0}^{d} \binom{n}{i} (q-1)^i$.

6. *Hamming bound* (or *sphere-packing bound*): If $t = \lfloor \frac{d-1}{2} \rfloor$, then $A_q(n, d) \leq \frac{q^n}{V_q(n,t)}$.

7. *Singleton bound*: $A_q(n, d) \leq q^{n-d+1}$. Hence, for any $[n, k, d]$-code over $GF(q)$, $k \leq n - d + 1$.

8. *Manin result*: There exists a continuous decreasing function $\alpha_q : [0,1] \to [0,1]$ such that

- α_q is strictly decreasing on $[0, \frac{q-1}{q}]$;
- $\alpha_q(0) = 1$;
- if $\frac{q-1}{q} \leq x \leq 1$, then $\alpha_q(x) = 0$;
- The set Σ_q of all accumulation points of sequences $(d_C/n_C, k_C/n_C)$, with C a linear code over $GF(q)$, is given by

  $$\Sigma_q = \{(\delta, R) \in [0,1]^2 \mid 0 \leq R \leq \alpha_q(\delta)\}.$$

  The Singleton bound, for example, gives an upper estimate for $\alpha_q(\delta)$.

9. *Gilbert-Varshamov bound*:

- $A_q(n,d) \geq \frac{q^n}{V_q(n,d-1)}$;
- if $V_q(n-1, d-2) < q^{n-k}$, then there exists an $[n,k,d]$-linear code over $GF(q)$; thus, if k is the largest integer for which this inequality holds, then $A_q(n,d) \geq q^k$.

10. *Asymptotic Gilbert-Varshamov bound*:

$$\alpha_q(x) \geq 1 - x\log_q(q-1) - x\log_q(x) - (1-x)\log_q(1-x).$$

In other words, for each fixed $\epsilon > 0$, there exists an $[n,k,d]$-code C (which may depend on ϵ) with

$$R(C) \geq 1 - \delta(C)\log_q(q-1) - \delta(C)\log_q(\delta(C)) - (1-\delta(C))\log_q(1-\delta(C)) - \epsilon.$$

11. For thirty years, the asymptotic version of the Gilbert-Varshamov bound was believed to be the best possible lower bound for good codes. In 1982, using some sophisticated ideas from algebraic geometry, it was proved that the Gilbert-Varshamov bound can be improved. A good survey of these results appears in [TsVl91], [TsVlNo07].

12. Let C be an $[n,k]$-MDS code. If G is a generator matrix for C, then any k columns of G are linearly independent.

13. If C is an $[n,k]$-MDS code, then $C^\perp$ is also an MDS code.

14. *Johnson bound*: If $d = 2t+1$, then

$$A_2(n,d) \leq \frac{2^n}{\sum\limits_{i=0}^{t}\binom{n}{i} + \frac{1}{\lfloor\frac{n}{t+1}\rfloor}\binom{n}{t}\left(\frac{n-t}{t+1} - \lfloor\frac{n-t}{t+1}\rfloor\right)}.$$

This is an improvement of the Hamming bound (Fact 6) for binary codes.

Examples:

1. The $[13, 10, 3]$ Hamming code over $GF(3)$ meets the Singleton bound.

2. The Reed-Solomon codes are MDS codes.

14.5.2 PERFECT CODES

Definitions:

An (n, M, d)-code over $GF(q)$ is said to be ***perfect*** if it meets the Hamming bound, that is, $M = \frac{q^n}{V_q(n,t)}$, where $t = \lfloor \frac{d-1}{2} \rfloor$.

The ***binary Golay code*** is a $[23, 12, 7]$-code over $GF(2)$ with generator matrix $G = [I_{12} \mid A]$, where

$$A = \begin{pmatrix} 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}.$$

The ***ternary Golay code*** is an $[11, 6, 5]$-code over $F_3 = \{0, 1, 2\}$ with generator matrix $G = [I_6 \mid B]$, where

$$B = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 2 & 1 \\ 1 & 0 & 1 & 2 & 2 \\ 2 & 1 & 0 & 1 & 2 \\ 2 & 2 & 1 & 0 & 1 \\ 1 & 2 & 2 & 1 & 0 \end{pmatrix}.$$

Facts:

1. A necessary condition for a code to be perfect is that d be odd.

2. The binary Golay code is a perfect code.

3. The extended binary Golay code is a $[24, 12, 8]$-code that is self-dual.

4. The ternary Golay code is a perfect code.

5. The set of all perfect codes over $GF(q)$, determined in 1973 by A. Tietäväinen, consists of the following:

- the linear code consisting of all words in $GF(q)^n$;
- the binary repetition codes of odd lengths;
- the Hamming codes and all codes with the same parameters as them;
- the binary Golay code and all codes equivalent to it;
- the ternary Golay code and all codes equivalent to it.

6. There do exist perfect codes with the same parameters as the Hamming codes, but which are not equivalent to them.

Examples:

1. The extended binary Golay code is a $[24, 12, 8]$-code that is self-dual.

2. The binary Hamming $[7, 4, 3]$ code is perfect.

14.6 NONLINEAR CODES

Although linear codes are studied and used extensively, there are several important types of nonlinear codes. In particular, there are nonlinear codes with efficient encoding and decoding algorithms, as well as nonlinear codes that are important for theoretical reasons.

14.6.1 NORDSTROM-ROBINSON CODE

Definitions:

Permute the coordinates of the extended binary Golay code so that one of the weight 8 codewords is $1111111100\ldots0$, and call this new code C'. For each of the 8-bit words $00000000, 10000001, 01000001, 00100001, 00010001, 00001001, 00000101, 00000011$, there are exactly 32 codewords in C' that begin with that word. The ***extended Nordstrom-Robinson code*** is the code whose codewords are obtained from these 256 words by deleting the first 8 coordinate positions. The ***Nordstrom-Robinson code*** is obtained by puncturing the last digit of the extended Nordstrom-Robinson code.

Facts:

1. The extended Nordstrom-Robinson code is a binary $(16, 256, 6)$-nonlinear code.

2. The Nordstrom-Robinson code is a binary $(15, 256, 5)$-nonlinear code.

3. The Johnson bound (§14.5.1, Fact 14) yields $A_2(15, 5) \leq 256$, and hence it follows that $A_2(15, 5) = 256$. On the other hand, it has been proved that no linear code of length 15 and distance 5 has more codewords than the binary 2-error correcting BCH code, which has 128.

14.6.2 PREPARATA CODES

Definitions:

The ***Preparata codes*** are an infinite family of nonlinear codes that have efficient encoding and decoding algorithms. Let β be a primitive element of $GF(2)^m$, and label the elements of $GF(2)^m$ as $\alpha_i = \beta^i$, $0 \leq i \leq 2^m - 2$, and $\alpha_{2^m-1} = 0$. For a subset $X \subseteq GF(2)^m$, let $\chi(X)$ denote the characteristic vector of X; that is, $\chi(X)$ is a binary vector of length 2^m whose ith coordinate is 1 if $\alpha_i \in X$ and is 0 otherwise, for each $0 \leq i \leq 2^m - 1$.

If $m \geq 3$ is odd, the ***extended Preparata code*** $\overline{P}(m)$ is the set of words of the form $(\chi(X), \chi(Y))$, where X and Y are subsets of $GF(2)^m$ such that

- $|X|$ and $|Y|$ are even;
- $\sum_{x\in X} x = \sum_{y\in Y} y$;

- $\sum_{x \in X} x^3 + \left(\sum_{x \in X} x\right)^3 = \sum_{y \in Y} y^3$.

The ***Preparata code*** $P(m)$ is obtained from $\overline{P}(m)$ by puncturing the coordinate corresponding to the field element 0 in the first half of each codeword.

Facts:

1. If $m \geq 3$ is odd, then $\overline{P}(m)$ is a binary nonlinear code with parameters $n = 2^{m+1}$, $M = 2^{2^{m+1}-2m-2}$, $d = 6$.

2. If $m \geq 3$ is odd, then $P(m)$ is a binary nonlinear code with parameters $n = 2^{m+1} - 1$, $M = 2^{2^{m+1}-2m-2}$, $d = 5$.

3. $P(3)$ is the same as the Nordstrom-Robinson code.

4. The Preparata codes can be viewed as linear codes over $\mathcal{Z}_4$.

14.7 CONVOLUTIONAL CODES

Convolutional codes are a powerful class of error-correcting codes. They work differently than block codes do. Instead of grouping message symbols into blocks for encoding, check digits are interwoven within streams of information symbols. Convolutional codes can be considered to have memory, since n symbols of information are encoded using these n symbols and previous information symbols.

14.7.1 BACKGROUND

Definitions:

The figure in §14.1.1 can be used to distinguish two approaches to decoding. For a ***hard decision decoder***, the demodulator maps received coded data symbols into the set of transmitted data symbols (for example, 0 and 1). In contrast, the demodulator of ***soft decision decoders*** may pass extra information to the decoder (for example, three bits of information for each received channel data symbol, indicating the degree of confidence in its being a 0 or a 1).

Facts:

1. Convolutional codes were introduced by P. Elias in 1955, and are widely used in practice today.

2. Convolutional codes are used extensively in radio and satellite links and have been used by NASA for deep-space missions since the late 1970s.

3. There are linear codes that differ from block codes in that the codewords do not have constant length.

4. Convolutional codes also differ from block codes in that the n-tuple produced by an encoder depends not only on the message k-tuple u, but also on some message k-tuples produced prior to u; that is, the encoder has memory.

5. Soft decision decoding typically allows performance improvements.

6. Hard and soft decision techniques can be used in both block and convolutional codes, although soft decision techniques can typically be used to greater advantage in convolutional codes.

7. Theoretical results, particularly with respect to BCH codes, position block codes as superior to convolutional codes.

8. The minimum distances of BCH codes are typically much larger than the corresponding free distances (§14.7.3) of comparable convolutional codes.

9. Decoding techniques for block codes are generally applicable only to q-ary (or binary) symmetric channels, which are an appropriate model for only a relatively small fraction of channels that arise in practice.

10. Efficient decoding of BCH codes requires hard-decision decoding, which suffers information loss relative to soft-decision strategies, precipitating a performance penalty. The resulting performance of the BCH decoder is significantly inferior to that for a comparable convolutional code, despite the BCH codes being inherently more powerful. Consequently, convolutional codes are used in a majority of practical applications, due to their relative simplicity and performance, and the large number of communication channels which benefit from soft decoding techniques.

11. A recently developed class of codes, known as *turbo codes*, are built using convolutional codes. The basic idea behind a turbo encoder is to combine two simple convolutional encoders. Input to the encoder is a block of bits. The two constituent encoders generate parity bits and the information bits are sent unchanged. The key innovation is an interleaver, which permutes the original information bits before they are provided as input to the second encoder. The permutation causes input sequences which produce low-weight codewords for one encoder to generally produce high-weight codewords for the other encoder. See [HeWi99] for information on turbo codes.

Example:

1. In the simplest version of soft decision decoding, known as the *binary erasure channel* (and usually classified as a hard-decision technique), the demodulator output is one of three values: 0, 1, or "erasure" (indicating that neither a 0 nor a 1 was clearly recognized).

14.7.2 SHIFT REGISTERS

Definitions:

An ***m*-stage shift register** is a hardware device that consists of m **delay elements** (or ***flip-flops***), each having one input and one output, and a clock which controls the movement of data. During each unit of time, the following operations are performed:

- a new input bit and the contents of some of the delay elements are added modulo 2 to form the output bit;
- the content of each delay element (with the exception of the last delay element) is shifted one position to the right;
- the new input bit is fed into the first delay element.

The ***generator*** of an m-stage shift register is a polynomial $g(x) = 1 + g_1x + g_2x^2 + \cdots + g_mx^m \in GF(2)[x]$, where $g_i = 1$ if the contents of the ith delay element are involved in the modulo 2 sum that produces the output, and $g_i = 0$ otherwise.

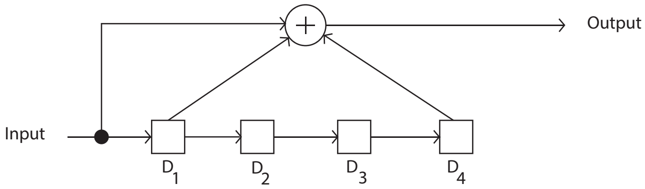
Facts:

1. Assume that the initial contents of a shift register are all 0s. Suppose that a shift register has generator $g(x)$. Let the input stream $u_0, u_1, u_2, \ldots$ be described by the formal power series $u(x) = u_0 + u_1x + u_2x^2 + \cdots$ over $GF(2)$. (If the input stream is finite of length t, let $u_i = 0$ for $i \geq t$.) Similarly, let the output stream $c_0, c_1, c_2, \ldots$ be described by the formal power series $c(x) = c_0 + c_1x + c_2x^2 + \cdots$ over $GF(2)$. Then $c(x) = u(x)g(x)$.

2. In some applications, some of the delay elements are added modulo 2 to the input element. This type of register is referred to as a *linear feedback shift register* (LFSR).

Examples:

1. *Shift-example*: Suppose that the delay elements of the 4-stage shift register in the following figure initially contain all 0s.



If the input stream to the register is 11011010 (from left to right), the updated contents of the delay elements and the output bits are summarized in the following table:

time	*input*	D_1	D_2	D_3	D_4	*output*
0	–	0	0	0	0	–
1	1	1	0	0	0	1
2	1	1	1	0	0	0
3	0	0	1	1	0	1
4	1	1	0	1	1	1
5	1	1	1	0	1	1
6	0	0	1	1	0	0
7	1	1	0	1	1	1
8	0	0	1	0	1	0

2. The generator of the shift register in Example 1 is $g(x) = 1 + x + x^4$.

14.7.3 ENCODING

Note: Throughout this subsection assume that the initial contents of a shift register are all 0s.

Definitions:

An ***(n, 1, m)-convolutional code*** with generators $g_1(x), g_2(x), \ldots, g_n(x) \in GF(2)[x]$ ($m = \max(\deg g_i(x))$) contains all codewords of the form $c(x) = (c_1(x), c_2(x), \ldots, c_n(x))$, where $c_i(x) = u(x)g_i(x)$, and $u(x) = u_0 + u_1x + u_2x^2 + \cdots$ represents the input stream. The ***system memory*** of the code is m.

A convolutional code is ***catastrophic*** if a finite number of channel errors can cause an infinite number of decoding errors.

The ***rate*** of an (n, k, m)-convolutional code is $\frac{k}{n}$.

The ***free distance*** d_{free} of a convolutional code is the minimum weight of all nonzero output streams.

A ***Recursive Systematic Convolutional*** (***RSC***) ***code*** is a convolutional code which allows some of the output bits to to be fed back into the input to make the code *systematic* in the sense that the data bits within a codeword come before the redundancy bits.

Facts:

1. A convolutional code is linear.

2. Convolutional codes are not block codes since the codewords have infinite length. They are, however, similar to block codes, and in fact can be viewed as block codes over certain infinite fields.

3. An $(n, 1, m)$-convolutional code can be described by a single shift register with n outputs, where $c_i(x)$ is the output of the single-output shift register with generator $g_i(x)$ when $u(x)$ is the input. In practice, $c_1(x), c_2(x), \ldots, c_n(x)$ are interleaved to produce one output stream.

4. Let C be an $(n, 1, m)$-convolutional code with generators $g_1(x), g_2(x), \ldots, g_n(x)$. Let $G(x) = \sum_{i=1}^{n} x^{i-1} g_i(x^n)$. If the message is $u(x)$, then the corresponding interleaved codeword is $\overline{c}(x) = G(x)u(x^n)$.

5. The *Viterbi algorithm* is a maximum likelihood decoding algorithm for convolutional codes [LiCo04]. For an algebraic treatment of convolutional codes, see [Pi88].

6. If $\gcd(g_1(x), g_2(x), \ldots, g_n(x)) = 1$ in $GF(2)[x]$, then C is not catastrophic.

7. An (n, k, m)-convolutional code can be described by k multi-output shift registers, each of maximum length m. The message is divided into k streams, each stream being the input to one of the k shift registers. There are n output streams, each formed using some or all of the shift registers.

8. The free distance of a convolutional code is a measure of the error-correcting capability of the code, and is a concept analogous to the distance of a block code.

9. In contrast to block codes, there are few algebraic constructions known for convolutional codes.

10. The convolutional codes used in practice are usually those found by a computer search designed to maximize the free distance among all encoders with fixed parameters n, k, and m. The following table lists the best codes with a rate of $\frac{1}{2}$ ($n = 2$, $k = 1$). The polynomials $g_1(x)$ and $g_2(x)$ are represented by their coefficients, listed from low order to high order.

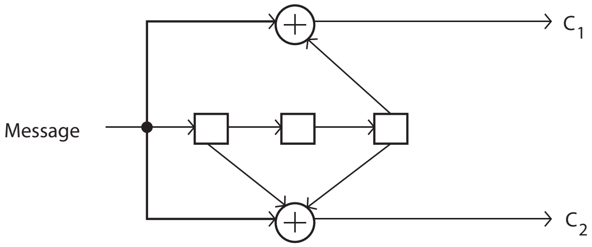
m	$g_1(x)$	$g_2(x)$	d_{free}
2	101	111	5
3	1101	1111	6
4	10011	11101	7
5	110101	101111	8
6	1011011	1111001	10
7	11100101	10011111	10
8	101110001	111101011	12
9	1001110111	1101100101	12
10	10011011101	11110110001	14
11	100011011101	101111010011	15
12	1000101011011	1111110110001	16

11. While a convolutional code is constructed with a shift register, an RSC is constructed with an LFSR.

12. An RSC code can be shown to be equivalent to a convolutional code. But because they are systematic, data bits can be sent directly to the output. This is generally referred to as the *data stream*. The redundancy bits, meanwhile, are processed through the LFSR. This is generally referred to as the *parity stream*.

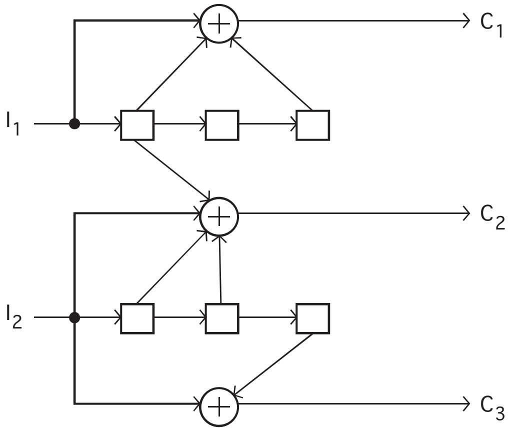
Examples:

1. Consider the $(2, 1, 3)$-convolutional code with generators $g_1(x) = 1 + x^3$ and $g_2(x) = 1 + x + x^3$. The code can be described by the shift register of the following figure. The message $u(x) = 1 + x^3 + x^4$, corresponding to the bit string 10011, gets encoded to $c(x) = (u(x)g_1(x), u(x)g_2(x)) = (1 + x^4 + x^6 + x^7, 1 + x + x^5 + x^6 + x^7)$, or in interleaved form to $\overline{c} = 11\ 01\ 00\ 00\ 10\ 01\ 11\ 11\ 00\ 00\ 00\ \ldots$.



2. Suppose that the input stream contains an infinite number of 1s, and the output stream has only finitely many 1s. If the channel introduces errors precisely in the positions of these 1s, then the resulting all-zero output stream will be decoded by the receiver to $m(x) = 0$.

3. The following figure is a shift register encoder for a $(3, 2, 3)$-convolutional code C.



If the input stream is $u = 1011101101$, it is first divided using alternating bits into two streams $I_1 = 11110$ and $I_2 = 01011$. The three output streams are $c_1 = 10010$, $c_2 = 00011$ and $c_3 = 01010$, and the interleaved output is $\overline{c} = 100\ 001\ 000\ 111\ 010$.

14.7.4 TURBO CODES

Definitions:

A ***turbo code*** is the code formed by ***parallel concatenation*** of two RSC codes whose output consists of the following three streams:

- the data stream;
- the parity stream from the first RSC;
- the parity stream from the second RSC where the input data stream, within each input block of a given length m, has been permuted.

Facts:

1. The permutation involved in the input stream for the second RSC code is usually taken to be pseudorandom in practice. When this is the case, any nonzero input will produce a parity stream with large Hamming weight in at least one of the two RSCs.

2. Turbo codes (along with LDPC) are the codes which are closest to achieving Shannon's noiseless coding theorem.

3. If the input stream consists of blocks of length m and the parity streams output blocks of length n_1 and n_2 respectively, then turbo codes have a rate of $m/(m+n_1+n_2)$.

4. In order to increase the rate of a turbo code, some of the elements in the output stream may be deleted. This is known as *puncturing* the code. When decoding, these symbols are reconstructed using a soft-decision decoder.

5. Turbo codes generally suffer from low rates as well as high encoding and decoding complexity.

6. Turbo codes were initially used in deep-space applications, 3G telephony, and wireless standards.

14.8 QUANTUM ERROR-CORRECTING CODES

14.8.1 QUANTUM CODES

Let $q = p^n$, for some prime p. Let $\mathcal{H}$ be the q-dimensional Hilbert space (i.e., a q-dimensional complex linear space).

Definitions:

A ***quantum system*** is given by the tensor product space $V := \mathcal{H}^{\otimes n} = \mathcal{H} \otimes \mathcal{H} \otimes \cdots \otimes \mathcal{H}$. An element of V is called a ***quantum state*** and denoted by $|\psi\rangle$ and a ***quantum code*** Q is a q^k-dimensional subspace of V. A quantum state $|\psi\rangle \in Q$ of k particles is transmitted over a noisy channel and we then receive a quantum state $|\bar{\psi}\rangle \in V$ of n particles.

Let $q = 2$. A ***qubit*** is the short form for quantum bit and the analog of a bit in classical computation. The possible states of a quantum bit are the states of the vector space $\mathcal{C}^2$. The standard basis of this state space is denoted $|0\rangle = \binom{1}{0}$, $|1\rangle = \binom{0}{1}$. The general state of a qubit is a linear combination $|\psi\rangle = \alpha\,|0\rangle + \beta\,|1\rangle$, with $\alpha,\ \beta \in \mathcal{C}$ and $|\alpha|^2 + |\beta|^2 = 1$. For $q > 2$ the analogue of qubits is ***qudits***.

The ***Pauli group*** for $\mathcal{H}$ is defined as

$$G = \langle X^i Z^j \mid i, j \in \mathcal{F}_q \rangle,$$

where

$$X = \begin{pmatrix} 0 & 0 & \cdots & 0 & 1 \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & \omega_p & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \omega_p^{p-1} \end{pmatrix}.$$

The ***Pauli group*** on V of length n is the tensor product of the Pauli group on single qubits:

$$G_n = \langle U_1 \otimes \cdots \otimes U_n \mid U_i \in G \ \text{ for } i = 1, \ldots, n \rangle.$$

As usual, we will call the elements of G_n ***operators*** in G_n.

Stabilizer codes are helpful devices that make possible construction of quantum codes from classical codes. Let V denote the qubit state space and let G_n be the Pauli group on n qubits. Let $H \leq G_n$ and denote by V_H the subspace of V fixed by H:

$$V_H = \{v \in V \mid gv = v, \forall g \in G_n\}.$$

Subsequently we assume that H is abelian and $-I \notin H$. The subspace V_H is called the ***stabilizer code*** $C(H)$ of H.

Since it suffices to look at a set of generators, we can represent a stabilizer code in an easier way. A ***generator matrix*** $\mathcal{G}$ of a stabilizer code is an $l \times 2n$ matrix $\mathcal{G}(X|Z)$, where the first n components represent the X errors and the second n components represent the Z errors.

For an operator $E \in G_n$, we denote its adjoint by $E^\dagger$ and for any subgroup $H \leq G_n$, its normalizer will be denoted $N(H)$; see [Sh08] for details.

The ***weight*** wt of an operator $U_1 \otimes \cdots \otimes U_n$ is the number of elements U_i that are not equal to the identity.

Facts:

1. V_H is non-trivial if and only if H is abelian and $-I \notin H$.

2. Let $\{E_i\}$ be a set of operators in G_n such that $E_j^\dagger E_k \notin N(H) \setminus H$ for all j and k. Then $\{E_j\}$ is a correctable set of errors for the code $C(H)$. For a proof, see [AsKn01].

3. Let H be an abelian subgroup of G_n. If a state $|\psi\rangle$ is in the $+1$ eigenspace of a set of generators $\{g_1, \ldots, g_l\}$ of H, it is an eigenstate of all elements in H.

4. The generator matrix defines an $[[n, k, d]]$ quantum error-correcting code with $k = n - l$.

5. Let $E \in G_n$ be an error operator. Then

- if $E \in H$, then E is a codeword;
- if $E \in G_n \backslash N(H)$, then the error is detectable and can be corrected with the most likely error principle;

- if $E \in N(H)\backslash H$, then the error cannot be detected and therefore is not correctable.

6. Fact 5 allows us to introduce the distance of a stabilizer code. The *distance* d of a quantum stabilizer code C is the minimum weight of all normalizer elements that are not in the stabilizer:

$$d = \min\{wt(x) \mid x \in N(H)\backslash H\}.$$

7. The stabilizer code of the normalizer $N(H)$ is equal to the dual code $C^{\perp_s}$ with respect to the symplectic inner product $\langle\, , \rangle$. Consequently

$$d = \min\{wt(x) \mid x \in C^{\perp_s}\backslash C\}.$$

8. Quantum codes can be constructed from classical codes [AsKn01]. Specifically, let $C \subset F_q^{2n}$ be an $(n+k)$-dimensional subspace such that $C^{\perp_s} \subset C$. Then there exists a quantum code $Q \subset \mathcal{H}^{\otimes n}$ of dimension q^k and minimum distance $d = \dim C \setminus C^{\perp_s}$.

14.8.2 QUANTUM ALGEBRAIC GEOMETRY CODES

Definitions:

Let $F/\mathcal{F}_q$ be an algebraic function field in one variable. Let $P_1, \dots, P_n$ be places of degree 1 and let $D = P_1 + \cdots + P_n$. Furthermore let G be a divisor with $\text{supp}(G) \cap \text{supp}(D) = \emptyset$. Then the ***Goppa code*** (respectively ***AG code***) $C_{\mathcal{L}} \subseteq \mathcal{F}_q^n$ is defined by

$$C_{\mathcal{L}}(D, G) = \{(f(P_1), \dots, f(P_n)) \mid f \in \mathcal{L}(G)\} \subseteq \mathcal{F}_q^n.$$

Define the following linear ***evaluation map***

$$\varphi : \ \mathcal{L}(G) \to \mathcal{F}_q^n$$

$$f \mapsto (f(P_1), \dots, f(P_n)).$$

Facts:

1. The Goppa code is given by $C_{\mathcal{L}}(D, G) = \varphi(\mathcal{L}(G))$.

2. The code $C_{\mathcal{L}}(D, G)$ is a linear $[n, k, d]$-code with parameters

$$k = \dim G - \dim(G - D), \quad d \geq n - \deg G =: d_{des}.$$

The parameter d_{des} is called the *designed distance* of the Goppa code. See [ElSh11], [Sh08], [TsVl91], and [TsVlNo07] for details.

3. Assume $\deg G < n$ and let g be the genus of $F/\mathcal{F}_q$. Then the following hold [St93].

- $\varphi : \mathcal{L}(G) \to C_{\mathcal{L}}(D, G)$ is injective and $C_{\mathcal{L}}(D, G)$ is an $[n, k, d]$-code with

$$\begin{aligned} k &= \dim G \geq \deg G + 1 - g \\ d &\geq n - \deg G. \end{aligned}$$

- If in addition $2g - 2 < \deg G < n$, then

$$k = \deg G + 1 - g.$$

- If $(f_1, \ldots, f_k)$ is a basis of $\mathcal{L}(G)$, then a generator matrix for $C_{\mathcal{L}}(D, G)$ is

$$M = \begin{pmatrix} f_1(P_1) & \cdots & f_1(P_n) \\ \vdots & & \vdots \\ f_k(P_1) & \cdots & f_k(P_n) \end{pmatrix}.$$

4. Let $D = P_1 + \cdots + P_n$ be a divisor, where the P_is are places of degree 1 of an algebraic function field $F/\mathcal{F}_q$. Furthermore let G be a divisor with $\text{supp}(G) \cap \text{supp}(D) = \emptyset$ and define the code $C_\Omega(D, G)$ by

$$C_\Omega(D, G) = \{(\text{res}_{P_1}(\omega), \ldots, \text{res}_{P_n}(\omega) \mid \omega \in \Omega_F(G - D)\} \subseteq \mathcal{F}_q^n,$$

where $\text{res}_{P_i}(w)$ is the residue of w at P_i. In other words, if $t \in F$ is a P_i-prime element and $w \in F$ has a P_i-adic expansion $w = \sum_{j=n}^{\infty} a_j t^j$ with $n \in \mathcal{Z}$ and $a_j \in \mathcal{F}$, then $\text{res}_{P_i}(w) = a_{-1}$. Then the code $C_\Omega(D, G)$, where D and G are as above, has the following properties:

- $C_{\mathcal{L}}(D, G)^\perp = C_\Omega(D, G)$;
- $C_\Omega(D, G) = a \cdot C_{\mathcal{L}}(D, H)$ with $H = D - G + (\eta)$ where η is a differential, $v_{P_i}(\eta) = -1$ for $i = 1, \ldots, n$, and $a = (\text{res}_{P_1}(\eta), \ldots, \text{res}_{P_n}(\eta)$;
- $C_{\mathcal{L}}(D, G)^\perp = a \cdot C_{\mathcal{L}}(D, H)$.

5. One can use differentials with special properties to help construct a self-orthogonal code [St93, Prop. VII.1.2]. Namely, let x and y be elements of F such that $v_{P_i}(y) = 1$, $v_{P_i}(x) = 0$, and $x(P_i) = 1$ for $i = 1, \ldots, n$. Then the differential $\eta = x \cdot \frac{dy}{y}$ satisfies $v_{P_i}(\eta) = -1$ and $\text{res}_{P_i}(\eta) = 1$ for $i = 1, \ldots, n$.

CRYPTOGRAPHY

Charles C. Y. Lam, Chapter Editor

This chapter is a major extension and update of the sections on cryptography in the first edition written by Alfred J. Menezes and Paul C. van Oorshot.

INTRODUCTION

The history of protecting the secrecy of information goes back to ancient times. For example, the ancient Romans used a secret code to send messages that could not be read by their enemies. The evolution of secret codes ties with the historical development of human intelligence and improvements in technology.

In modern times, there is a constant need to protect information from unauthorized access and from malicious actions. The field of cryptography is devoted to methods that offer such protection. Sending secret messages, authenticating messages, distributing secret keys, sharing secrets, electronic cash, and electronic voting are only some of the applications addressed by modern cryptography.

Symmetric key cryptography and public key cryptography are the two major classes of cryptography. Since prehistoric times, encryption conducted between two parties can be seen as a communication mechanism with a secret key shared between two communicating parties, where the knowledge of the encryption key implies the knowledge of the corresponding decryption key. In the 1970s, through the demonstration of a practical method by Whitfield Diffie and Martin Hellman, and an independent classified discovery within Britain's GCHQ (Government Communications Headquarters), public key cryptography came to life. The discovery led to constructions of many new products that are used in the digital age.

The study of cryptography spans various fields from mathematics, computer science, and engineering, to non-science areas such as business and law. The goal of mathematical cryptography is to ensure the security of the most fundamental cryptographic components.

GLOSSARY

active adversary: an adversary that threatens the integrity or authentication of stored or transmitted data.

adaptive chosen-ciphertext attack security (***CCA2***): given the challenge ciphertext C in CCA1 security, the attacker can continue the decryption requests adaptively, except for C itself, and is unable to recover the plaintext.

advanced encryption standard (***AES***): a 128-bit block cipher adopted as a standard in the United States and widely used for commercial applications.

affine cipher: a cipher that encrypts $x \in \mathcal{Z}_{26}$ by sending it to $ax+b$ mod 26, using the key (a, b), where $a, b \in Z_{26}$ and $\gcd(a, b) = 1$.

attribute-based encryption: a public key encryption scheme where the user's secret key and the ciphertext both depend on attributes such as membership and position title.

authentication: corroboration that a party, or the origin of data, is as claimed.

bitcoin: a widely-used cryptocurrency.

bitcoin mining: a process in ensuring data integrity in bitcoin transactions that requires a search of a nonce that produces a desired hash result.

block cipher: a cipher that breaks up the plaintext into blocks of a fixed length and encrypts each block via a secret bijective transformation.

Caesar cipher: a cipher that shifts each letter forward three positions in the alphabet, wrapping the letters at the end of the alphabet around to the beginning letters. (Sometimes, all shift ciphers are called Caesar ciphers.)

certification authority (***CA***): a trusted authority that verifies the identity and RSA public key of a party, and signs the data.

chosen-ciphertext attack: an attack in which the adversary has some chosen ciphertext and its corresponding plaintext.

chosen-plaintext attack: an attack in which the adversary has some chosen plaintext and its corresponding ciphertext.

cipher: an encryption scheme.

cipher block chaining (***CBC***) ***mode***: a mode of operation of an n-bit block cipher in which plaintext is processed n bits at a time, an initialization block is used, and to encrypt each successive n-bit block the bitwise XOR of the block with the encrypted version of the previous block is formed and the resulting n-bit block is encrypted by the block cipher.

cipher feedback (***CFB***) ***mode***: a mode of operation of an n-bit block cipher in which plaintext is processed t bits at a time, $1 \leq t \leq n$, and in which the ciphertext depends on the current block and previous blocks.

ciphertext: encrypted plaintext.

ciphertext-only attack: an attack in which the adversary has possession of some ciphertext and nothing else.

ciphertext space: the set of all possible ciphertexts.

cloud computing: an internet-based model for shared computing resources and data.

computational security: the amount of computational effort required by the best currently-known attacks to defeat a system.

conference key distribution: a mechanism whereby a trusted authority assigns a piece of secret data to each user so that any desired group of users can compute a common secret key.

confidentiality: preventing protected data from becoming available in an intelligible form to unauthorized parties.

counter mode: a mode of operation of a n-bit block cipher in which the secret keystream is formed by encrypting an incremental counter initialized by an initial value (IV).

Cramer-Shoup cryptosystem: a public key cryptosystem based on the decisional Diffie-Hellman problem.

cryptanalysis: the use of mathematical, statistical, and other techniques to defeat cryptographic protection mechanisms, including plaintext from ciphertext without knowledge of the key.

cryptocurrency: a class of digital cash for which cryptography is used in secure transactions and in the creation of additional currency.

cryptographic primitive: a basic algorithm used to build cryptographic protocols.

cryptographic protocol: a protocol that performs security functions and applies cryptographic primitives.

cryptography: the science and study of protecting data from malicious or unauthorized actions, including access to, manipulation, impersonation, and forgery.

cryptology: the study of both cryptography and cryptanalysis. (Note that "cryptography" is often used in place of "cryptology".)

cryptosystem (or ***cryptographic system***): a system composed of a space of plaintext messages, a space of ciphertext messages, a key space, and families of enciphering and deciphering functions indexed with the keys.

data encryption standard (***DES***): a 64-bit block cipher adopted as a standard in the United States and which is widely used for commercial applications.

data integrity: the assurance that data has not been subjected to unauthorized manipulation, possibly including assurances regarding uniqueness and timeliness.

data origin authentication: corroboration that the origin of data is as claimed.

decryption: the process of recovering plaintext from ciphertext with knowledge of the key.

differential analysis: an attack on symmetric key ciphers that distinguishes the right key from wrong guesses by observing the statistical distribution of differences in the input plaintext and differences in the output ciphertext.

digital cash: a digital equivalent of cash that achieves all the functionality and security (and more) of physical cash.

digital signature: the digital analogue of a handwritten signature, in the form of a value dependent on some secret known only to the signer and on the message being signed.

digital signature algorithm (***DSA***): a digital signature scheme adopted as a United States standard and which is widely used for commercial applications.

digram cipher: a cipher that replaces pairs of plaintext characters (*digrams*) with other digrams.

electronic code book (***ECB***) ***mode***: a mode of operation of an n-bit block cipher in which plaintext is encrypted n bits at a time.

electronic voting: a mechanism to provide accurate, auditable, fast, and secure voting over a communications network.

ElGamal cryptosystem: a public key cryptosystem based on the discrete logarithm problem.

elliptic curve cryptosystem: a public key cryptosystem based on the elliptic curve discrete logarithm problem.

encryption: the process of mapping plaintext to ciphertext designed to render data unintelligible to all but the intended recipient.

Enigma machine: a rotor-based encryption machine developed before World War II and used extensively by the German military during the war with modifications.

entity authentication: corroboration that a party's identity is as claimed.

Feistel cipher: a block cipher structure introduced by Horst Feistel of IBM in the 1970s and used in the construction of many ciphers.

frequency analysis: a technique to analyze a classical cipher by studying the frequency of letters or groups of letters in a ciphertext.

Goldwasser-Micali cryptosystem: the first provably secure public key cryptosystem.

hash function: a function that maps arbitrary length bit strings to small fixed length outputs that is easy to compute and has preimage resistance, weak collision resistance, and/or strong collision resistance.

Hill cipher: a matrix-based cipher using an invertible $n \times n$ matrix A over $\mathcal{Z}_{26}$ as its key, which encrypts plaintext by splitting it into blocks of size n and then sending the plaintext block $m = (m_1, m_2, \ldots, m_n)'$ as the m-tuple Am.

homomorphic encryption: an encryption mechanism that allows certain computations to be carried out on ciphertext in such a way that decryption of the result yields the same quantity as obtained by performing the computations on the original plaintext.

identity-based encryption: a public key cryptosystem that uses an arbitrary string, such as email address or name, as the public key.

Kerckhoff's assumption: the statement that the security of a system should rest entirely in the secret key—the adversary is assumed to have complete knowledge of the rest of the cryptographic mechanism(s).

key: a secret number or other significant information which parametrizes an encryption or decryption algorithm.

key exchange (or ***key agreement***): a mechanism that allows two parties to securely share a secret key so that no one else can obtain a copy.

key schedule: an algorithm that derives a series of subkeys from an input key used for encryption rounds in a symmetric key encryption scheme.

keyspace: the set of all possible keys of a cryptosystem.

keystream generator: an algorithm to generate an infinitely long stream of characters to be used as keys starting with a secret seed value.

known-plaintext attack: an attack in which the adversary has some plaintext and its corresponding ciphertext.

linear cryptanalysis: an attack on symmetric key ciphers that distinguishes the right key from wrong key guesses by observing the linear approximation of input plaintext bits and output ciphertext bits.

linear feedback shift register (***LFSR***): a shift register whose input is characterized by a linear recursive function of the output.

message authentication code (***MAC***): a keyed function $F_K(\cdot)$ acting on messages m such that when m and $F_K(m)$ are transmitted, the intended recipient will be assured of the authenticity of m.

message space: the set of all possible plaintexts.

non-adaptive chosen-ciphertext attack security (***CCA1***): an attacker that can inquire multiple times the plaintext for any adaptively chosen ciphertext, yet is unable to recover the plaintext for a new challenge ciphertext C.

nonce: a pseudorandom number generated for one-time use.

non-repudiation: the ability to ensure that a party to a communication cannot deny the authenticity of their signature or the sending of a message that they originated.

NTRU cryptosystem: a lattice-based public key cryptosystem.

oblivious transfer: a protocol in which one party has a set of bit strings as input and the other party can choose a string to be transferred but the first party cannot determine which string this is.

one-time pad: a stream cipher in which the secret key has length equal to that of the plaintext and is used only once for encryption.

output feedback (***OFB***) ***mode***: a mode of operation of an n-bit block cipher in which a message is split into blocks of t bits for processing, $1 \leq t \leq n$, and in which error propagation is avoided.

Paillier cryptosystem: a public key cryptosystem based on the intractability of computing n-th residue classes.

passive adversary: an adversary that does not interrupt, alter, or insert any transmitted or stored data.

perfect secrecy (or ***unconditional security***): a security criteria in which an adversary is assumed to have unlimited computational resources.

plaintext: a message to be encrypted.

polyalphabetic substitution cipher: a family of monoalphabetic substitution ciphers using different substitution mappings in various locations of the plaintext.

polygram substitution cipher: a cipher that substitutes groups of characters with other groups of characters.

probabilistic encryption: an encryption scheme that involves the use of randomness in the encryption algorithm, so that the same message is encrypted into different ciphertexts when different randomness parameters are chosen.

product cipher: a combination of two or more simpler ciphers.

provable security: security in which the difficulty of defeating the method is essentially as difficult as solving a well-known, supposedly difficult problem.

public key certificate: data that binds together a party's identification and public key.

public key system: a cryptosystem in which each user has a pair of encryption (public) and decryption (private) keys.

quantum attack: an attack on cryptographic primitives using quantum computing methods.

quantum cryptography: cryptographic methods employing the science of quantum mechanical properties.

round function: a subroutine in a symmetric key encryption scheme that is run multiple times to obtain the ciphertext.

RSA cryptosystem: a public key cryptosystem in which encryption is based on modular exponentiation with a modulus that is the product of two large primes, and is based on the difficulty of factoring the product of two large primes and the ease of generating large primes.

scytale: an ancient encryption device that writes on a piece of parchment wrapped around a cylinder.

secret sharing: a mechanism that allows a group of users to share a secret such that any group with more than a threshold number of them can recover the secret, whereas fewer members are unable to obtain any information about the secret.

***secure hash algorithm* (*SHA*)**: a family of cryptographic hash functions adopted as a standard in the United States and widely used for commercial applications.

secure multiparty computation: a protocol π such that, given n parties $P_1, \ldots, P_n$ where each P_i has a private input x_i, π realizes a function $f(x_1, \ldots, x_n) = (o_1, \ldots, o_n)$ such that P_i obtains the output o_i, $i = 1, \ldots, n$.

self-synchronizing stream cipher: a stream cipher capable of re-establishing proper decryption automatically after loss of synchronization, with at most a fixed number of plaintexts unrecoverable.

shift cipher: a cipher that replaces each plaintext letter by the letter shifted a fixed number of positions in the alphabet, with letters at the end of the alphabet shifted to the beginning of the alphabet.

steganography: the art of concealing the existence of data without the transformation of data.

substitution cipher: a cipher that replaces each plaintext character by a fixed substitute according to a permutation of the alphabet.

stream cipher: a symmetric key cipher that encrypts individual characters of a plaintext message using a keystream generator and a family of encryption functions indexed by keys.

symmetric key system: a cryptosystem in which knowing the encryption function corresponding to a key allows a user to easily determine the corresponding decryption function.

synchronous stream cipher: a stream cipher in which the keystream is generated independently of the message.

transposition cipher: a cipher that divides plaintext into blocks of a fixed size and rearranges the characters in each block according to a fixed permutation.

unconditional security (or ***perfect secrecy)***: a security criteria for which an adversary is assumed to have unlimited computational resources.

Vernam cipher: a one-time pad.

Vigenère cipher: a cipher with a t-tuple $(k_1, \ldots, k_t)$ as its key that encrypts plaintext messages in blocks of size t so that the ith letter in a block is shifted k_i positions in the alphabet, modulo 26.

15.1 BASICS OF CRYPTOGRAPHY

The word cryptography comes from Greek words that translate as “hidden writing”. Until the mid 20th century, these Greek words completely described the subject, when all activities were devoted to making messages secret, to recovering secret messages, and to preventing unauthorized attempts to find original messages from secret messages. However, during the last fifty years, cryptography has expanded to cover all aspects of protecting data from a wide range of malicious activities. A particular vocabulary now describes different parts of cryptography, the processes of making messages secret and recovering these messages, and attacks on secret messages.

15.1.1 BASIC CONCEPTS

Definitions:

Cryptography is the science and study of protecting data from malicious or unauthorized actions, including access to, manipulation, impersonation, and forgery.

Cryptanalysis is the use of mathematical, statistical, and other techniques to defeat cryptographic protection mechanisms.

Cryptology is the study of both cryptography and cryptanalysis, although "cryptography" is often used in place of "cryptology".

Steganography is the art of concealing the existence of data without transforming the data.

A ***cipher*** is a method whereby a message in some source language (the ***plaintext***) is transformed by a mapping, called an ***encryption*** algorithm, to yield an output, called the ***ciphertext***, which is unintelligible to all but an authorized recipient.

A recipient of an encrypted message is able to recover the plaintext from the ciphertext by use of a corresponding ***decryption*** algorithm.

A ***key*** is a secret number or other significant information which parametrizes an encryption or decryption algorithm.

The ***message space*** (or ***plaintext space***) $\mathcal{M}$ is the set of all possible plaintexts, the ***ciphertext space*** $\mathcal{C}$ consists of all possible ciphertexts, and the ***keyspace*** $\mathcal{K}$ consists of all possible keys.

An ***encryption algorithm*** E is a family of mappings parametrized by a key $k \in \mathcal{K}$, such that each value k defines a mapping $E_k \in \mathcal{E}$, where $\mathcal{E}$ is the set of all invertible mappings from $\mathcal{M}$ to $\mathcal{C}$. A specific plaintext message m is mapped by E_k to a ciphertext $c = E_k(m)$.

The set $\mathcal{D}$ of ***decryption algorithms*** consists of all invertible mappings from $\mathcal{C}$ back to $\mathcal{M}$, such that for each encryption key $k \in \mathcal{K}$, there is some mapping $D \in \mathcal{D}$ such that $D_{f(k)}(E_k(m)) = m$ for all $m \in \mathcal{M}$, where $f(k)$ is some key dependent on k and $D_{f(k)}$ is the decryption algorithm corresponding to the decryption key $f(k)$. For so-called ***symmetric key*** systems, this decryption key $f(k)$ is equal to k itself.

A ***cryptographic primitive*** is a basic algorithm used to build cryptographic protocols. Hash functions and encryption schemes are examples of cryptographic primitives.

A ***cryptosystem*** is a five-tuple $(\mathcal{M}, \mathcal{C}, \mathcal{K}, \mathcal{E}, \mathcal{D})$ consisting of the following:

- a set of possible plaintexts $\mathcal{M}$;
- a set of possible ciphertexts $\mathcal{C}$;
- a set of possible keys $\mathcal{K}$;

- a family of encryption algorithms $\mathcal{E}$ and the corresponding family of decryption rules $\mathcal{D}$, parametrized by the keyspace $\mathcal{K}$.

Probabilistic encryption involves the use of randomness in the encryption algorithm, so that the same message is encrypted into different ciphertexts when different randomness parameters are chosen.

Confidentiality means preventing confidential data from being available in an intelligible form to unauthorized parties.

Detection of data manipulation by unauthorized parties (including alteration, insertion, deletion, substitution, delay, and replay) is called ***data integrity***; it should be noted that encryption alone does not guarantee data integrity.

Authentication is corroboration that a party's identity is as claimed (***entity authentication***), or that the origin of data is as claimed (***data origin authentication***); related to this is the assurance that data has not been subjected to unauthorized manipulation (cf. data integrity), possibly including assurances regarding uniqueness and timeliness.

The provision for the resolution of disputes related to digital signatures is called ***non-repudiation***. Digital signatures can be used as the basis of authorization of certain actions. Disputes may occasionally arise subsequently due to either false denials (***repudiated*** signatures) or fraudulent claims (***forged*** signatures).

A ***digital signature*** is intended to be the digital analogue of a handwritten signature; it should be a number dependent on some secret known only to the signer, and, additionally, on the content of the message being signed.

Facts:

1. Many excellent books on cryptography are available. Those new to the subject can consult [Bu13], [DeKn15], [Ma03], [PaPe09], and [TrWa06]. Books with more historical content include [MevOVa10] and [Sc07]. Textbooks with comprehensive coverage at a more advanced level are [KaLi14] and [St05].

2. Cryptography differs from steganography in that while the former involves use of techniques to secure data (for example, codes and ciphers), the latter involves the use of techniques which obscure the existence of data itself (for example, invisible ink, secret compartments, and the use of subliminal channels).

3. Cryptographic mechanisms can be used to support a number of fundamental security services, including confidentiality, data integrity, authentication, and non-repudiation.

4. The traditional objectives of confidentiality and authentication (although not both required in all cases) lead to the following requirements for a cryptosystem:

- *Fundamental requirement.* (To maintain secrecy of key) it should be infeasible for an adversary to deduce the key k given one or more plaintext-ciphertext pairs (m, c);
- *Confidentiality requirement.* (To maintain confidentiality) it should be infeasible for an adversary to deduce the plaintext m corresponding to any given ciphertext c;
- *Authentication requirement.* (To prevent forgery or substitution) it should be infeasible for an adversary to deduce a ciphertext c' corresponding to any message m' of his choosing, or corresponding to any other (meaningful) message m.

15.1.2 SECURITY OF CRYPTOSYSTEMS

Definitions:

Adversaries are either ***passive*** or ***active***. Passive adversaries are a threat to confidentiality; they do not interrupt, alter, or insert any transmitted or stored data. Active adversaries additionally threaten integrity and authentication.

There are many models under which one can assume a cryptanalyst is able to attack a cryptographic system. The following types of attack can be hypothesized for increasingly powerful adversaries:

- ***ciphertext-only***: the adversary has possession only of some ciphertext;
- ***known-plaintext***: the adversary has some plaintext and its corresponding ciphertext;
- ***chosen-plaintext***: the adversary has some plaintext of his choosing and its corresponding ciphertext;
- ***chosen-ciphertext***: the adversary has some ciphertext of his choosing and its corresponding plaintext.

The most stringent measure of the security of a cryptographic algorithm is ***unconditional security***, where an adversary is assumed to have unlimited computational resources, and the question is whether there is enough information available to defeat the system. Unconditional security for encryption systems is called ***perfect secrecy***.

To measure an adversary's uncertainty in the key after observing n ciphertext characters C, Shannon defined the ***key equivocation function*** $Q(n) = H(K|C_1C_2 \ldots C_n)$, the conditional entropy (§14.1.2) of the key K given the ciphertext messages $C_1, C_2, \ldots, C_n$; this measures the amount of uncertainty that remains in the key K after observing the ciphertexts $C_1, C_2, \ldots, C_n$. Shannon defined the ***unicity distance*** of the cipher to be the first value $n = n_0$ for which $Q(n) \approx 0$.

A cryptographic method is said to be ***provably secure*** if the difficulty of defeating it can be shown to be essentially as difficult as (that is, polynomially equivalent to) solving a well-known and *supposedly* difficult (typically number-theoretic) problem, such as integer factorization or the computation of discrete logarithms. (Thus, "provable" here means provable subject to as yet unproved assumptions.)

A proposed technique is said to be ***computationally secure*** if the (perceived) level of computation required to defeat it exceeds, by a comfortable margin, the computational resources of the hypothesized adversary.

Facts:

1. It is a standard cryptographic assumption that an adversary will have access to ciphertext.

2. *Kerckhoff's assumption*: The security of a system should rest entirely in the secret key — the adversary is assumed to have complete knowledge of the rest of the cryptographic mechanism(s).

3. In determining whether the security of a particular cryptosystem is adequate for a particular application, the powers and resources of the anticipated adversary must be taken into account. Potential adversaries may have powers ranging from minimal to unlimited.

4. The security of a cryptographic algorithm can be measured according to several different metrics, including unconditional security, provable security, and computational security.

5. Let M, C, and K be random variables ranging over the message space $\mathcal{M}$, ciphertext space $\mathcal{C}$, and keyspace $\mathcal{K}$. Unconditional security for encryption systems can be specified by the condition $H(M|C) = H(M)$; that is, the uncertainty in the plaintext, after observing the ciphertext, is equal to the a priori uncertainty about the plaintext — observation of the ciphertext provides no information (whatsoever) to an adversary.

6. A necessary condition for an encryption scheme to be unconditionally secure is that the key should be at least as long as the plaintext. The one-time pad (§15.3.5) is an example of an unconditionally secure encryption algorithm.

7. In general, encryption schemes do not offer perfect secrecy, and each ciphertext character observed decreases the uncertainty in the encryption key k used.

8. Let n_0 be the unicity distance of a cipher. After observing n_0 characters, the key uncertainty is zero, meaning an information-theoretic adversary can narrow the set of possible keys down to a single candidate, thus defeating the cipher.

9. The computational security measures the amount of computational effort required, by the best currently-known attacks, to defeat a system.

15.2 CLASSICAL CRYPTOGRAPHY

The ancient Greeks and Romans were known to use cryptography. Some of the earliest uses of ciphers include the *Scytale* and the *Caesar cipher*. While all of the systems are now considered insecure, they provide insights into the evolution of cryptography.

The approaches in cryptography and cryptanalysis became more systematic in the 19th century. With the development of electromechanical devices, encryption machines were introduced after World War I. The Enigma machine was one of the most famous encryption machines used in World War II. The ciphers up to this point were all restricted to the encryption of individual characters, or groups of characters in the plaintext.

The invention of transistors after World War II led to the computer age where plaintext messages were no longer encoded in pure characters in a specific language. Encryption methods have taken on a much more mathematical approach since then.

Definitions:

Let $\mathcal{P} = \mathcal{C} = \mathcal{Z}_n$ be the plaintext and the ciphertext character set for some integer n. Let $K \in \mathcal{Z}_n$. The encryption-decryption pair e_K, d_K defined by

$$\begin{aligned} e_K(x) &= x + K \bmod n, \\ d_K(y) &= y - K \bmod n \end{aligned}$$

is a ***shift cipher***.

Suppose the plaintext and the ciphertext character set $\mathcal{A}$ are the same. A ***simple*** (***monoalphabetic***) ***substitution cipher*** is a permutation π over $\mathcal{A}$, where the message is mapped one character at a time. Decryption is done by applying π^{-1} to the ciphertext.

Given the alphabet of size n, the ***affine cipher*** uses the encryption function $e_{a,b}(x) = ax + b \bmod n$, where $\gcd(a, n) = 1$.

A ***digram cipher*** replaces pairs of plaintext characters (digrams) with other digrams.

A ***polygram substitution cipher*** involves substituting groups of characters with other groups of characters.

Let t be a positive integer. Let π be a permutation on $\{1, 2, \ldots, t\}$. For a plaintext $m = (m_1, m_2, \ldots, m_t)$, the ***permutation cipher*** maps m to $e_\pi(m_1, m_2, \ldots, m_t) = (m_{\pi(1)}, m_{\pi(2)}, \ldots, m_{\pi(t)})$.

A ***polyalphabetic substitution cipher*** is a family of monoalphabetic substitution ciphers using different substitution mappings at various locations of the plaintext.

A ***simple Vigenère cipher*** of period t over an n-character alphabet has a key $k_1k_2 \ldots k_t$, where encryption of plaintext $m = m_1m_2m_3 \ldots$ to ciphertext $c = c_1c_2c_3 \ldots$ is specified by $c_i = m_i + k_i \bmod n$. The key is reused every t characters (that is, the index i of k is taken modulo t). The cipher is an example of a polyalphabetic substitution cipher.

Let m be an n-character message in vector form $m = (m_1, m_2, \ldots, m_n)'$. The ***Hill cipher*** (1929) is an n-gram substitution cipher defined by an invertible $n \times n$ matrix A over $\mathcal{Z}_{26}$ as the key, with encryption $c = Am$. Decryption is therefore $m = A^{-1}c$.

Facts:

1. For a plaintext character set $\mathcal{Z}_n$, there are n distinct shift ciphers. That is, the size of the keyspace is n.

2. The shift cipher can be easily compromised using *exhaustive key search*, by trying all keys K, $0 \leq K \leq n-1$, until meaningful text appears.

3. The *Caesar Cipher*, purportedly used by Julius Caesar, is a shift cipher with $K = 3$.

4. In the English language with 26 characters, there are $26! \approx 4 \times 10^{26}$ possible monoalphabetic substitution ciphers, making exhaustive search infeasible.

5. The monoalphabetic substitution cipher can be broken easily by *frequency analysis*, which makes use of statistical properties of letters in the English language.

6. The affine cipher is a polygram substitution cipher.

7. Al-Kindi, an Arab mathematician, published around AD 800 the book *Risalah fi Istikhraj al-Mu'amma* on cryptography. The book was the first publication that described cryptanalytic techniques, including frequency analysis.

8. Ibn al-Durayhim (AD 1312–1361) gave detailed descriptions of eight ciphers, including substitution and transposition ciphers (see *Scytale*, Fact 15).

9. The first polyalphabetic substitution cipher was invented by Leon Battista Alberti circa 1467.

10. Cryptography was widely employed across Europe during and after the Renaissance. One of the most famous stories involved the use of cryptanalysis by Sir Francis Walsingham, leading to the execution of Mary, Queen of Scots.

11. In the English alphabet of 26 characters, there are 26^2 digrams, and thus there are $(26^2)!$ possible keys in the digram cipher.

12. The *Playfair Cipher* (1854) is a digram cipher where an alphabet of 25 letters is arranged in a 5×5 array. In the English alphabet, this can be done by either equating I and J, or omitting Q or X to reduce the number of letters from 26 to 25. Encryption is done by encrypting pairs of plaintext letters as follows:

- If the two letters are in different rows and columns in the table, then the two letters form two corners of a rectangle, and are replaced by the letters representing the other two corners of the rectangle, where the first encrypted letter is in the same column as the first letter of the plaintext.
- If the two letters are in the same row, then each letter is replaced by the letter to the immediate right in the table, where a wrap around to the first column occurs when needed.
- If the two letters are in the same column, then each letter is replaced by the letter immediately below it. The cipher defeats basic frequency analysis, but is easily broken by analysis of frequencies of pairs of letters.

13. The Hill Cipher can be easily broken by a known-plaintext attack through solving a system of linear equations.

14. The permutation cipher keeps the plaintext characters unchanged, and uses a permutation to alter the positions of the characters in the plaintext.

15. The *Scytale* was used by the Greeks, especially by the Spartans, during military campaigns. To operate, a piece of parchment is wrapped around a cylinder. The message is then written on the parchment. The recipient wraps the parchment on a cylinder of the exact specification to retrieve the message. The ciphertext is a result of a special case of permutation cipher called *transposition cipher* due to the regular reordering of plaintext characters.

16. Two approaches for the cryptanalysis of the Vigenère cipher are the *Kasiski test*, based on finding repeated strings in cipher text, and the *index of coincidence*, which examines the probability that two letters in the ciphertext are the same.

- Kasiski (1863), and independently Babbage in 1846 who kept it as a military secret, discovered that repeated strings in the plaintext that are apart by multiples of the length of the key are encrypted in the same way. Therefore, by examining repeated patterns, candidate key lengths k can be deduced. Suppose k is the actual key length, let $c = c_1c_2c_3\ldots c_{nk}$ be the ciphertext, and let

$$\begin{aligned}
\mathbf{c}_1 &= c_1c_{k+1}c_{2k+1}\cdots c_{(n-1)k+1},\\
\mathbf{c}_2 &= c_2c_{k+2}c_{2k+2}\cdots c_{(n-1)k+2},\\
&\vdots\\
\mathbf{c}_k &= c_kc_{2k}c_{3k}\cdots c_{nk}.
\end{aligned}$$

  Since every kth character is encrypted using the same method, each $\mathbf{c}_i$ should have a letter frequency distribution similar to regular English text.

- *Index of coincidence* (Friedman, 1920). Suppose $\mathbf{c} = c_1c_2\ldots c_n$ is a ciphertext of n characters. The index of coincidence $E_I(\mathbf{c})$ is the probability that two random elements of $\mathbf{c}$ are identical. In regular English text, the probability is approximately 0.065, whereas for a completely random string, the probability is approximately 0.038. The method involves organizing the ciphertext in a manner similar to the Kasiski test and measures the index of coincidence for each string $\mathbf{c}_i$. The correct key length guess should reveal index of coincidence values similar to those of English text.

17. The *Jefferson disk*, a polyalphabetic substitution cipher invented by Thomas Jefferson in 1795, uses rotating disks. A solid cylinder of length 6 inches is sliced into 36 disks. Each disk is numbered, where the 26 letters of the alphabet are inscribed on the disk around the edge in a distinct and random ordering. Each disk has a hole in the middle that allows them to be stacked and mounted on an axle. Encryption is done in blocks of 36 letters. To encrypt, each of the 36 wheels is rotated individually to align the message in one row. Then, any of the other 25 rows can be used as the ciphertext. To decrypt, the recipient arranges the cylinders in the agreed-upon order, aligns the ciphertext in one row, then checks the other 25 rows until meaningful message appears. Since there are 36 disks, the total number of possible orderings is $36! \approx 3.72 \times 10^{41}$.

18. A *rotor machine* is a design for mechanical automation of polyalphabetic substitution ciphers. It consists of a number of wired wheels called rotors. Each rotor has connectors on each face of the wheel, wired internally so that an individual rotor represents a fixed monoalphabetic substitution cipher by mapping a character at its input face to another one at its output face. A plaintext character input to the first rotor generates an output that serves as an input to the second rotor. This process continues until the ciphertext character outputs from the last rotor.

- When the rotors are fixed, the combination of rotors produces only a monoalphabetic substitution cipher.
- The rotors are designed to move with each plaintext character encipherment. This results in a polyalphabetic substitution cipher. A basic design mechanism involves rotating one step of the first rotor until it completes a single revolution, then the second rotor will move one step, and so on.
- The encryption key includes the order of the rotors and their respective positions.
- The first rotor machine was built by Dutch naval officers Theo A. van Hengel and R. P. C. Spengler in 1915. Independent inventions have also been attributed to E. H. Hebern, A. G. Damm, H. A. Koch, and A. Scherbius.
- E. H. Hebern founded the Hebern Electric Code, Inc. in 1921 to become the first U.S. cipher machine company. The company went bankrupt in 1926.
- A. Scherbius filed a rotor machine patent in 1918. Scherbius later designed and marketed the *Enigma machine*.
- Scherbius developed the Enigma machine in successive versions. The company Chiffriermaschinen AG was set up in 1923 to produce and market these machines. The initial Model A (1923) was replaced by Model B (1925). In 1926, a reflector and indicator lamps were introduced in Model C. In 1927, Enigma D, with improvements that allowed wheels to be interchangeable, received wide commercial success.
- The Enigma machine as used in World War II consists of versions of similar design with a choice of wheels, and other enhancements such as plugboards to increase the complexity of cryptanalysis.
- Alan Turing, who worked at the British Government Code and Cypher School (GC&CS) at Bletchley Park during the war, provided many of the ideas that led to the construction of the Bombe machine for the cryptanalysis of the Enigma.

19. Many other codes were used in World War II. Some notable ones include the American *Codetalkers* using Native American languages as a basis for a substitution cipher, the British *Typex* which is an adaptation of the Enigma machine, and the German *Fish cipher* [Tu00], similar to the Enigma, but only used between the German High Command and Army Group commanders in the field.

20. Some references on the history of classical cryptography include *The Code Book* [Si00], *The Codebreakers* [Ka96], *Handbook of Applied Cryptography* [MevOVa10], and *Introduction to Cryptography with Coding Theory* [TrWa06].

Examples:

1. The shift cipher can be used on any alphabet by a proper mapping from the alphabet to some $\mathcal{Z}_n$. In English, we can map $A \leftrightarrow 0$, $B \leftrightarrow 1$, …, $Z \leftrightarrow 25$ over $\mathcal{Z}_{26}$. For example, with key $K = 4$, the word "QUIZ" is encoded to $(16, 20, 8, 25)$, and is encrypted to $(20, 24, 12, 3)$, or "UYMD".

2. A permutation cipher of the English alphabet such as

```
plaintext  abcdefghijklmnopqrstuvwxyz
ciphertext UXJAGRDEYLNKOPBCTWVQMIHFZS
```

maps the word "king" to "NYPD".

3. Let $A = 0$, $B = 1$, $C = 2, \ldots$ Consider the affine cipher $e_{3,14}(x) = 3x + 14 \bmod 26$. Then the word "QUEEN" is encrypted to "KWAAB".

4. Consider the permutation cipher on nine symbols $\pi = (135)(86)(2497)$, where the symbols indicate the positions of characters in the message. The word "XYLOPHONE" is then encrypted to "POXYLNEHO".

5. Using the mapping $A \leftrightarrow 0, B \leftrightarrow 1, C \leftrightarrow 2, \ldots, Z \leftrightarrow 25$, the Vigenère cipher with key "MIKE" encrypts the message "SENDMORETROOPS" to "EMXHYWBIFZYSBA".

15.3 MODERN PRIVATE KEY CRYPTOSYSTEMS

Classical encryption can be performed by hand (e.g., Caesar cipher) or by mechanical means (e.g., Enigma cipher). Modern ciphers refer to ciphers invented since the 1970s which rely upon the power of modern computers. For the most commonly used modern private key cryptosystems, plaintext messages and ciphertext messages are bit strings of a specified length. These cryptosystems are designed so that encryption and decryption can be carried out rapidly using complicated functions that are designed to be resistant to attack. This section covers the basic principles of such cryptosystems and provides information about the most widely used private key systems of today and of the past three decades.

15.3.1 BLOCK CIPHERS

Definitions:

A ***block cipher*** breaks up the plaintext into blocks of a fixed length and encrypts each block via a secret bijective transformation.

The secret bijective transform of a block cipher is defined by a ***key schedule*** and a ***round function***. The key schedule expands the secret key K into r distinct roundkeys $K_1, K_2, ..., K_r$. To perform encryption, the round function (denoted by ϕ) is iteratively applied r times on the plaintext x_0 and the roundkeys K_i to produce the ciphertext x_r.

$$\begin{array}{rcl} Keyschedule(K) & \mapsto & K_1, K_2, K_3, \ldots, K_r \\ x_0 & = & Plaintext \\ x_1 & = & \phi(K_1, x_0) \\ x_2 & = & \phi(K_2, x_1) \\ x_3 & = & \phi(K_3, x_2) \\ & \ldots & \\ x_r & = & \phi(K_r, x_{r-1}) \\ Ciphertext & = & x_r. \end{array}$$

r is called the ***number of rounds of the block cipher*** and is carefully chosen to ensure sufficient security without sacrificing throughput.

The round function ϕ mixes the intermediate text with the roundkeys by performing the following transformations in sequence:

- ***Substitution/Confusion:*** To provide (local) nonlinearity. This is usually realized by several 4-bit or 8-bit nonlinear substitution tables (also called ***S-boxes***) acting in parallel.
- ***Permutation/Diffusion:*** To spread the nonlinear effect across the whole block. This is usually realized by a bit permutation or a linear matrix product over $GF(2)$.

A ***product cipher*** combines two or more simpler ciphers (transformations) such that the resulting cipher is more secure than its components. Thus a block cipher can be seen as a product cipher which combines many simpler transformations (where confusion and diffusion are alternately applied over many rounds) to perform encryption.

Facts:

1. The *substitution cipher* is an example of a block cipher where the plaintext is broken up into individual English alphabets and each alphabet is encrypted through a secret substitution table.

2. Modern block ciphers encrypt block sizes of 64 bits or 128 bits.

3. It is not possible to represent the secret bijection of modern block sizes by a single substitution table. Thus modern block ciphers are instantiated by a sequence of simpler substitution tables and permutation transforms which mixes the plaintext with the secret key to produce a ciphertext.

4. Some prominent examples of block ciphers include the Data Encryption Standard (DES, §15.3.2) [Fi77] and the Advanced Encryption Standard (AES, §15.3.3) [DaRi13].

5. The product cipher was introduced by Claude Shannon in his paper "Communication theory of secrecy systems" in 1949.

15.3.2 FEISTEL CIPHERS

Definitions:

The ***Feistel cipher*** is a block cipher structure introduced by Horst Feistel of IBM in the 1970s. It is used to construct many ciphers including the Data Encryption Standard (DES).

The ***round function of a Feistel cipher*** (denoted by ϕ_K) divides the input into two equal halves (L, R) and is defined by

$$\phi_K(L, R) = (R, L \oplus F(K, R)),$$

where K is the roundkey and F is a function mapping the right half R and the roundkey K to be XORed with the left half L. For an r-round Feistel cipher, a swap is performed on the left and right halves of the final output to produce the ciphertext, that is,

$$E_K(P) = swap(\phi_{K_r} \circ \cdots \circ \phi_{K_2} \circ \phi_{K_1}(P)).$$

where $swap(L, R) = (R, L)$ for equal halves (L, R).

Facts:

1. One advantage of the Feistel cipher is that it is an *involution*. That is, the encryption circuit can be re-used for decryption when the roundkeys are fed in reverse order. Thus it saves implementation resources as only one copy of the cipher needs to be implemented for both encryption and decryption.

2. One of the earliest and most well-known Feistel ciphers is the *Data Encryption Standard* (DES), proposed in 1977 [Fi77]. DES resulted from an IBM submission to a 1974 request by the U.S. National Bureau of Standards (NBS) (which has now become the National Institute of Standards and Technology, NIST) soliciting encryption algorithms for the protection of computer data.

3. The early success of DES made Feistel a well-researched structure with many more secure Feistel ciphers being designed later. Some examples include the ciphers KASUMI [Ca05], Camellia [AoEtal00], its parallelizable variant p-Camellia [YaKhPo13], and the finalists MARS and Twofish of the AES competition [Ae97] (see §15.3.3). These ciphers still make use of the basic Feistel structure but use more secure components, larger keylength and blocklength, or use a larger number of rounds.

4. The basic Feistel cipher with two sub-blocks has also been extended to generalized Feistel structures with four sub-blocks. They include the ciphers Skipjack [Sk98], CLEFIA [ShEtal07], SMS4 [DiLe08], its parallelizable variant p-SMS4 [YaKhPo13], and the finalist RC6 of the AES competition [Ae97] (see §15.3.3). For illustrative purposes, we can illustrate the round function of SMS4 as an example of a generalized Feistel structure:

$$\phi_K(A, B, C, D) = (B, C, D, A \oplus F(K, B \oplus C \oplus D)).$$

5. DES was used by the U.S. government to protect binary coded data during transmission and storage in computer systems and networks. It was also used by the banking industry and businesses to protect financial transactions for commercial data security. DES and its more secure variant Triple-DES (which encrypts the plaintext three times using a longer key) were also part of the SSH/TLS suite of ciphers to protect internet traffic.

6. A high-level description of DES is the following:

- DES processes plaintext blocks of 64 bits and produces ciphertext blocks of 64 bits. The encryption mapping E_K is parameterized by a secret 56-bit key K. Since decryption requires that the mapping be invertible, E_K is a bijection.
- Encryption of each 64-bit block proceeds in sixteen stages or rounds. The 56-bit key K is used to create sixteen 48-bit subkeys K_i, one for each round.
- Within each round, eight fixed, carefully selected 6-to-4 bit substitution mappings (S-boxes) S_i, collectively denoted S, are used.

- The initial 64-bit plaintext is divided into two 32-bit halves, L_0 and R_0. Each round is functionally equivalent, taking 32-bit inputs L_{i-1} and R_{i-1} from the previous round and producing outputs L_i and R_i for $1 \leq i \leq 16$, according to

  $$L_i = R_{i-1},\ R_i = L_{i-1} \oplus F(R_{i-1}, K_i),\ F(R_{i-1}, K_i) = P(S(E(R_{i-1} \oplus K_i))).$$

  Here E is a fixed expansion permutation mapping 32 bits to 48 bits (all bits are used once, some are taken twice), and P is another fixed permutation on 32-bits. An initial permutation (IP) precedes the first round, and its inverse is applied following the last round.
- Decryption makes use of the same algorithm and same key, except the subkeys are applied to the internal rounds in the reverse order.

7. DES was used by financial institutions through the 1990s, but in the late 1990s it became apparent that it is not sufficiently secure. With advancements in computing technologies, brute force search of the DES keyspace became cheaper and easier (as outlined in Facts 8–10). Furthermore, several methods, known as Differential Cryptanalysis and Linear Cryptanalysis (see Facts 11–12), were discovered and were shown to be more efficient than brute force.

8. The keylength of DES (56 bits) is too short. The original proposal for DES had a keylength of 64 bits. But later, eight bits of the secret key were converted to parity bits making the equivalent keylength 56 bits. The complexity of exhaustive search is 2^{56} and this was already criticized early on by researchers to be insufficient protection against brute force search. Diffie and Hellman postulated in 1977 that a custom machine consisting of 10^6 custom VLSI chips costing $20,000,000 could search the entire DES keyspace in about one day.

9. In 1998, the Electronic Frontier Foundation built a dedicated DES Cracker machine (DEEP CRACK) costing $250,000 which could find a DES key in 56 hours [De98].

10. In 2006, re-configurable parallelized hardware called COPACOBANA was built to break ciphers with keylengths up to 64 bits, including DES [GüEtal08]. It takes longer to find a DES key (on average 8.7 days) but is much cheaper at $10,000. With the advancement in computing technologies, brute force search on DES became faster, cheaper, and easier.

11. *Differential Cryptanalysis* (DC) is an attack on DES that distinguishes the right key from wrong key guesses by observing the statistical distribution of differences in the input plaintext and differences in the output ciphertext. It can recover the secret key with 2^{47} chosen plaintext-ciphertext pairs [BiSh91], which is faster than exhaustive search. However, the enormous volume of chosen plaintext-ciphertext pairs required diminishes the value of this attack.

12. *Linear Cryptanalysis* (LC) on DES distinguishes the right key from wrong key guesses by observing the linear approximation of input plaintext bits and output ciphertext bits. It can recover the key with 2^{43} known plaintext-ciphertext pairs [Ma93], which is faster than exhaustive search. Similar to DC, even though plaintext-ciphertext pairs are not required to be chosen, the enormous volume of pairs required still diminishes the value of this attack.

13. Differential and linear cryptanalysis on DES can be thwarted by changing keys before the required number of plaintext-ciphertext pairs needed for cryptanalysis is transmitted. For example, we can change the key after every 2^{32} ciphertexts are transmitted.

14. The short keylength of DES allows for practical key recovery with just a few plaintext-ciphertext pairs. One countermeasure to the short keylength of DES is to use

Triple-DES which encrypts the plaintext three times with longer keys. In the following description, K_1, K_2, K_3 are 56-bit keys, PT is the plaintext, and CT is the ciphertext.

- Two-Key Triple-DES (112-bit secret key):

$$CT = DES_{K_1}(DES^{-1}_{K_2}(DES_{K_1}(PT))).$$

- Three-Key Triple-DES (168-bit secret key):

$$CT = DES_{K_3}(DES^{-1}_{K_2}(DES_{K_1}(PT))).$$

Note that the decryption function DES^{-1} is used for the second pass to allow for backward compatibility with single-key DES. This is because DES with single-key K can be defined as two-key Triple-DES with key $(K_1, K_2) = (K, K)$ or three-key Triple-DES with key $(K_1, K_2, K_3) = (K, K, K)$.

15. Another way to counter the short keylength of DES is to use DES-X. It is defined as

$$CT = DES_{K_2}(PT \oplus K_1) \oplus K_3,$$

where PT and CT are the plaintext and ciphertext, K_2 is a 56-bit DES key, and K_1 and K_3 are 64-bit keys to mask the input and output of DES. The total keylength for DES-X is 184 bits.

16. *Meet-in-the-middle* (MITM) attacks can be applied to Triple-DES and DES-X to reduce the complexity of brute force search, but their security is still better than DES. Two-key triple DES can be attacked with 2^{32} known plaintexts, 2^{88} time complexity, and 2^{56} memory [vOWi90]. Three-key Triple-DES can be attacked with three known plaintexts, 2^{112} time complexity, and 2^{56} memory [MevOVa10]. The equivalent keylength of DES-X is shown to be 88 bits under a distinguishing attack with 2^{30} known plaintexts [KiRo01]. See [MevOVa10] for a summary of various MITM attacks on Triple-DES and [KiRo01] for a proof of the security of DES-X against MITM.

17. Although Triple-DES and DES-X are considered to be secure, neither has sufficiently high throughput to be used for modern applications. Because of this, in 1997 NIST launched a competition for a new encryption standard, to be named the Advanced Encryption Standard (AES).

15.3.3 THE ADVANCED ENCRYPTION STANDARD (AES)

In 1997, NIST organized a competition to choose a replacement for DES called the *Advanced Encryption Standard* (AES) [Ae97]. The competition called for ciphers with a 128-bit blocklength and keylengths of 128, 192, and 256 bits, secure against known attacks including differential and linear cryptanalysis, and which provided excellent performance when implemented in hardware and software.

The process of determining which of the 15 submissions provided the best trade-off between security and performance took three years. Finally, in 2000 the winner was declared to be *Rijndael*, the submission of the Belgian cryptographers Joan Daemen and Vincent Rijmen. After winning the competition, the name AES replaced their original name Rijndael.

Definitions:

The ***AES cipher*** takes in a 128-bit plaintext and three possible keylengths of 128, 192, and 256 bits. The ***internal state*** can be viewed as a 4-by-4 array of bytes which is first filled with the 128-bit plaintext. A ***key schedule*** expands the secret key of 128, 192, or 256 bits into 11, 13, and 15 roundkeys, respectively. A ***prewhitening roundkey*** is XORed to the plaintext and then the round function is repeatedly applied for $R =$ 10, 12, or 14 times for AES-128, AES-192, or AES-256. Each round of AES uses these operations:

- **SubBytes:** Every byte is nonlinearly transformed by a ***Substitution Box*** (***S-Box***). The S-Box is affine equivalent to the power function x^{254} on GF(2^8); x^{254} is the multiplicative inverse of x when $x \neq 0$, and 0 when $x = 0$. The finite field representation for GF(2^8) is given by GF(2)$[a]/(f(a))$, where $f(a) = a^8 + a^4 + a^3 + a + 1$ is an irreducible polynomial.
- **ShiftRows:** The ShiftRows operation shifts row r of the AES state array by $r-1$ bytes to the left.
- **MixColumns:** The MixColumns operation multiplies each column of the state array by a right circulant matrix over GF(2^8). The first row of the matrix is given by $(a, a+1, 1, 1)$ where GF(2^8) is also defined by GF(2)$[a]/(f(a))$, where $f(a) = a^8 + a^4 + a^3 + a + 1$.
- **AddRoundKey:** This operation XORs the ith subkey k_i to the ith round.

Facts:

1. A complete description of DES can be found in [DaRi13].

2. The AES cipher execution framework is shown in Algorithm 1.

Algorithm 1: **AES cipher algorithm.**

```
input: $R$, plaintext
output: ciphertext
state := plaintext
AddRoundKey(state, $k_0$)
for $i = 1$ to $R - 1$
    SubBytes(state)
    ShiftRows(state)
    MixColumns(state)
    AddRoundKey(state, $k_i$)
SubBytes(state)
ShiftRows(state)
AddRoundKey(state, $k_R$)
ciphertext := state
```

3. The final round transformation does not have the MixColumns operation.

4. After adoption of AES as the new international block cipher standard by NIST, many banks and financial institutions migrated their encryption algorithm from DES to AES.

5. AES is also used by the IPSec (Internet Protocol Security) standard to protect IP communications. Other applications include TLS/SSH encryption for internet security and WPA/WPA2 encryption for Wifi Protection Access.

6. The NSA also stipulated AES as part of its suite B algorithms to protect both unclassified and most classified information for the U.S. government.

7. AES is based on the concept of a Substitution Permutation Network (SPN). An SPN starts with a roundkey XOR layer followed by an S-Box substitution layer that provides confusion, followed by a diffusion layer designed to spread the local S-box effect to the entire block.

8. The SubBytes operation in AES has the lowest differential and linear probabilities which defend AES against differential [BiSh91] and linear [Ma93] cryptanalysis (two attacks which broke DES). The AES SubBytes is a special case of a power function x^k on GF(2^n); see [Ca10b] for other power functions with good cryptographic properties.

9. The MixColumns matrix is a 4×4 Maximal Distance Separable (MDS) matrix over GF(2^8). These matrices have optimal branch number 5. The *branch number* of a matrix is the minimum number of nonzero bytes in the input and output, when ranged among all nonzero inputs. The maximal possible branch number for an $n \times n$ matrix is $n + 1$, in which case the matrix will be called an *MDS matrix*. An MDS matrix ensures a high number of active S-boxes in a block cipher to prevent differential and linear cryptanalysis.

10. In general, an $n \times n$ MDS matrix over GF(2^k) can be formed by reducing the generator matrix of a $[2n, n, n+1]$-MDS code over GF(2^k) to standard form $[I|A]$. Then A will be an MDS matrix.

11. An equivalent formulation for an $n \times n$ MDS matrix A is that every submatrix of A must be nonsingular. In particular, this means that all entries of an MDS matrix have to be nonzero.

12. The AES ShiftRows is an example of an *optimal diffusion* structure [DaRi13]. It spreads the effect of MixColumns across the whole 128-bit state and amplifies the diffusion effect of MixColumns from five active S-boxes every two rounds to 25 active S-boxes every four rounds. This gives very strong protection against DC and LC, where the differential and linear characteristic probability over four rounds of AES is already 2^{-150}, rendering both attacks infeasible [DaRi13].

13. Due to the algebraic nature of the components used by AES, it is possible to embed the AES cipher into a bigger cipher BES (Big Encryption System) such that BES can be expressed as a simple set of linear and quadratic equations over $GF(2^8)$ [MuRo02].

14. It was claimed that the XSL (eXtreme Sparse Linearization) attack [CoPi02] can then be applied on the BES equations to break AES with complexity 2^{100}. However, it was shown in [LiKh07] that there were too many linearly dependent equations in the XSL attack on BES for it to work. Despite this, there may be some other way to solve the simple set of equations produced by the BES embedding.

15. As of 2016, the most successful attacks on AES are the related-key differential cryptanalysis [BiKhNi09] and biclique attacks [BoKhRe11]. However, they are still not yet practical.

- Related-key differential cryptanalysis (RK-DC) is a differential attack where not just the plaintext, but also the secret key has a nonzero input difference. If the key difference is chosen carefully, then there is a higher chance to find a good differential path such that during the AddRoundKey operation, the roundkey differences cancel the intermediate state differences to result in fewer active bytes. RK-DC can reduce the attack complexity on AES-256 from 2^{256} to 2^{130} but needs 2^{35} related keys, which are extremely unlikely to be available in most practical applications, except perhaps when AES-256 is used in a hash function mode of operation.

- The biclique attack is a variant of the meet-in-the-middle attack (MITM) that uses a biclique structure to extend the number of rounds that can be attacked by MITM. The attack on AES-128, 192, and 256 has complexity $2^{126.1}$, $2^{189.7}$, and $2^{254.4}$, respectively. Although they are the best single-key attacks on AES, their complexity is too close to exhaustive search to be practical.

16. For applications that use AES-256 in a hash function mode of operation, the key schedule needs to be strengthened to resist related-key differential attacks. Such work has been carried out in [Ni10] and [ChEtal11], where the main cipher remains intact but the key schedule is modified so that high probability related-key differential paths, crucial for a successful attack, cannot be found.

15.3.4 MODES OF OPERATION

With large messages, it is necessary to break up the message into smaller blocks for encryption. Therefore, to use block ciphers, there is a need to employ an encryption mode of operation such that messages can be broken up in blocks, and encrypted in sequence. Various modes are introduced with distinct benefits.

Definitions:

An ***initial vector*** (***IV***) is a random value generated and sent in the clear with the ciphertext in some block cipher modes.

The ***Electronic Code Book*** (***ECB***) ***mode*** encrypts the plaintext block by block:

$$c_r = E_K(m_r),$$

for $1 \le r \le l$.

In the ***Cipher Block Chaining*** (***CBC***) ***mode***, the previous ciphertext block is XORed to the current plaintext block before encryption:

$$c_1 = E_K(m_1 \oplus IV),\ c_r = E_K(m_r \oplus c_{r-1}),$$

for $2 \le r \le l$.

The ***Output FeedBack*** (***OFB***) ***mode*** is a stream cipher mode where the IV is repeatedly encrypted, and the most significant t bits of the output blocks form the secret keystream to be XORed to the plaintext m_r to form the ciphertext c_r:

$$s_0 = E_K(IV),\ s_r = E_K(s_{r-1}),\ c_r = m_r \oplus MSB_t(s_{r-1}),$$

for $1 \le r \le l$.

The ***Cipher FeedBack*** (***CFB***) ***mode*** is a variant of the OFB mode. The ciphertext is still formed by XORing the plaintext to the secret internal state. However, the secret internal state evolution is formed by repeatedly encrypting a concatenation of the previous secret state shifted left by t bits and the ciphertext:

$$s_0 = IV,\ s_r = (s_{r-1} \ll t) \oplus c_{r-1},\ c_r = m_r \oplus MSB_t(E_K(s_{r-1})),$$

for $1 \le r \le l$.

Like the OFB mode, the ***Counter Mode*** is one where the secret keystream is formed by encrypting an incremental counter initialized by IV:

$$c_r = m_r \oplus E_K(IV + r - 1),$$

for $1 \le r \le l$.

Facts:

1. ECB is not secure because the same plaintext blocks are mapped to the same ciphertext blocks. For example, if we want to encrypt the pixels of a secret treasure map, it only maps the natural color of a map to different secret colors, but the outline and secret locations would still be visible. That is why we need other modes of operation that conceal the relationship between plaintext blocks.

2. *Error propagation.* Counter mode and OFB have 1-bit propagation, i.e., a 1-bit error in the ciphertext during transmission causes a 1-bit error in the plaintext after decryption. CBC and CFB have 1-bit plus 1-block propagation, i.e., a 1-bit error in the ciphertext causes a 1-bit error in the corresponding plaintext block and a 1-block error in the subsequent block after decryption [Dw01].

3. *Performance.* CBC needs more resources to implement because it needs both encryption and decryption, whereas OFB, CFB, and counter mode just need encryption. Counter mode is faster than the other three modes because it can be parallelized. CFB allows for t-bit block slip recovery.

4. *Security against IV misuse.* If IV is repeated, counter mode and OFB are totally broken because the same keystream KS would be repeated for two different encryptions and we have

$$CT = PT \oplus KS \text{ and } CT' = PT' \oplus KS \Rightarrow CT \oplus CT' = PT \oplus PT'.$$

Thus the plaintext XOR relation can be deduced from the ciphertext. This weakness only affects the first block of CFB. CBC is not affected as different plaintexts will give different ciphertexts even when the IV is repeated. Thus many software implementations use CBC mode because software random number generation is less reliable and IV could repeat. However, it is important to protect the integrity of the IV in CBC mode, or else an adversary can selectively manipulate the first message block by manipulating the bits of the IV. This situation may be avoided by encrypting the IV.

5. Counter mode is combined with message authentication functions CMAC and GMAC to form the CCM and GCM authenticated encryption modes, respectively [Dw04], [Dw07].

15.3.5 STREAM CIPHERS

Definitions:

A ***keystream*** is a stream of secret random characters that are combined with the plaintext to form the ciphertext.

A ***stream cipher*** is a symmetric key cipher that encrypts individual characters of a plaintext message, or small units. It is defined by a keystream generator and an encryption rule.

The ***keystream generator*** takes in a short secret seed (usually the secret key K) and expands it into an infinitely long stream of keystream characters, i.e., $Key\_Gen(K) = z_1, z_2, z_3, \ldots$.

The ***encryption rule*** $e_z(x)$ defines how the plaintext character x_i is combined with the keystream character z_i. There is a corresponding decryption rule $d_z(x)$ such that $d_z(e_z(x)) = x$.

The ***one-time pad*** is a stream cipher where the secret key is of bitlength equal to the plaintext and never re-used for encryption. Thus there is no need for a keystream generator as the keystream Z is just the secret key K. The encryption rule is $e_z(x) = x \oplus z$. The decryption rule is $d_z(y) = y \oplus z$.

A ***synchronous stream cipher*** is a stream cipher in which the keystream is generated independently of the message.

A ***self-synchronizing stream cipher*** is a stream cipher capable of re-establishing proper decryption automatically after loss of synchronization, with only a fixed number of plaintexts unrecoverable.

Many stream ciphers use ***Linear Feedback Shift Registers*** (***LFSR***) in their construction (see §14.7.2). An n-word LFSR is defined over a finite field F with an initial state $(s_0, s_1, \ldots, s_{n-1})$, $s_i \in F$, and a feedback relation

$$s_{i+n} = c_{i+n-1}s_{i+n-1} + c_{i+n-2}s_{i+n-2} + \cdots + c_i s_i,\ i \geq 0.$$

In stream cipher applications, the LFSR is usually defined over the finite field $F = GF(2)$ or $GF(2^m)$.

Facts:

1. The one-time pad can be proven to be unconditionally secure but it suffers the drawback that a large quantity of keying material has to be pre-shared to encrypt long messages. Thus in practice, stream ciphers usually generate a long unpredictable keystream from a short key to be XORed with the plaintext for encryption.

2. An important advantage of stream ciphers is that they are lighter and faster than block ciphers in hardware implementations. This is because stream ciphers process smaller chunks of data, and thus need fewer resources to store and process the intermediate states. They also have smaller error propagation (than certain block cipher modes such as CFB, CBC) where a one-character error in the ciphertext only causes a one-character error in the plaintext.

3. When the encryption rule is $e_z(x) = x \oplus z$, it is insecure to use the same keystream z_i to encrypt two different plaintext streams x_i and x'_i. This is because the ciphertext streams will be $c_i = x_i \oplus z_i$ and $c'_i = x'_i \oplus z_i$. And this allows the adversary to deduce the plaintext relation $x_i \oplus x'_i$ from the ciphertext relation $c_i \oplus c'_i$ because they are equal.

4. To prevent the repeated keystream weakness, an initialization vector IV is mixed into the key generation and sent in the clear to the receiver for decryption. Now even when the sender uses the same secret key K to encrypt two sessions, he can mix it with two distinct initial vectors IV, IV' to produce distinct keystreams $Key\_Gen(K, IV) = z_1, z_2, z_3, \ldots$ and $Key\_Gen(K, IV') = z'_1, z'_2, z'_3, \ldots$.

5. Care must be taken not to repeat the initial vector IV when using stream ciphers or else it is completely broken. It is also not that easy to convert a stream cipher to an authenticated encryption (AE) scheme, whereas numerous AE modes of operation for block ciphers such as CCM, GCM, OCB exist.

6. The Vigenère cipher can be seen as a stream cipher. The keystream generator is a cyclical repetition of the secret key:

$$Key\_Gen(k_1, k_2, \ldots, k_s) = k_1, k_2, \ldots, k_s, k_1, k_2, \ldots, k_s, \ldots.$$

The encryption rule is $e_z(x) = x + z \pmod{26}$, where the English alphabet $A, B, \ldots, Z$ is mapped to $0, 1, \ldots, 25$.

7. Another stream cipher that works on the English alphabet is the autokey cipher. The keystream generator only uses the secret key once in the beginning and then the plaintext is appended to it. If the plaintext stream is $m_1, m_2, \ldots, m_n$, then the keystream is

$$Key\_Gen(k_1, k_2, \ldots, k_s) = k_1, k_2, \ldots, k_s, m_1, m_2, \ldots, m_{n-s}.$$

The English alphabet is encoded as in the Vigenère cipher and the encryption rule is $e_z(x) = x + z \pmod{26}$.

8. On modern computers, the plaintext characters used are binary bits and the encryption rule is usually the XOR operation $e_z(x) = x \oplus z$. Most of the complexity and security of the cipher is provided by the keystream generation.

9. Early stream ciphers from the 1950s were based on Linear Feedback Shift Registers (LFSRs). A straightforward way to encrypt is to use an LFSR to expand a short key into a long keystream and XOR it to the plaintext.

10. The LFSR structure, however, is insecure as the cryptosystem is linear and can be easily broken by Gaussian elimination, or more efficiently by the Berlekamp-Massey algorithm (even when the LFSR feedback taps are secret) [Ma69]. The Berlekamp-Massey algorithm is derived from the Berlekamp-Welch algorithm for decoding BCH codes.

11. To be more secure, the LFSR output can be filtered by a nonlinear Boolean function in one of two configurations [Ru12]:

- *Combinatorial Generator.* This stream cipher consists of n LFSRs and a nonlinear Boolean function $f(x)$ mapping n bits to 1 bit. At each clock cycle, 1 bit is extracted from each LFSR to make up an n-bit input vector, which is passed through the Boolean function $f(x)$ to produce 1 output keystream bit. The keystream is XORed with the plaintext to form the ciphertext.
- *Filter Function Generator.* This stream cipher consists of one LFSR and one Boolean function $f(x)$ mapping n bits to 1 bit. At each clock cycle, n bits are extracted from the LFSR and passed as input to the Boolean function $f(x)$ to produce 1 output keystream bit. The keystream is XORed with the plaintext to form the ciphertext.

12. The combinatorial and filter function generator stream ciphers are secure against traditional attacks such as correlation attack, divide and conquer attack, and linear span attack if the filter function $f(x)$ is chosen to have the following good cryptographic properties:

- *Balance.* The Boolean function $f(x)$ has an equal number of 0s and 1s in its output. This is to prevent the keystream from having any bias which might leak information about the plaintext.
- *Low Linear Bias.* We want the linear bias of $f(x)$ given by

  $$\epsilon = |\, Pr(f(x) = l(x)) - \tfrac{1}{2}|$$

  to be low for all linear functions $l(x)$. This is to defend against fast correlation attacks which make use of soft decoding techniques from LDPC (low-density parity-check), convolutional, and turbo codes [AgEtal12] to recover the stream cipher secret state. See §14.3 and §14.7.
- *High Correlation Immunity.* This property requires $f(x)$ to have linear bias $\epsilon = 0$ for all linear approximations with few linear terms. This is to defend against divide and conquer correlation attacks on combinatorial generators [Ca10a].

- *High Algebraic Degree.* We need $f(x)$ to have high algebraic degree, i.e., its Boolean expression involves monomials that are products of many variables. This is to defend against algebraic attacks and the Berlekamp-Massey attack on keystreams with low linear complexity. Furthermore, for additional resistance to algebraic attacks, we also require $f(x)$ to have high algebraic immunity (explained below).

13. It was believed that stream ciphers with high algebraic degree are not susceptible to algebraic attacks. However, the fast algebraic attack invented in 2003 managed to break such ciphers [Co03], [CoMe03].

14. *Algebraic Attack on Stream Ciphers.* The algebraic attack from [CoMe03] works on the filter function $f(x)$ in stream ciphers. The attack finds low degree Boolean functions $g(x)$ such that $f(x)g(x)$ also has low degree. Then the keystream equation $f(L_t(s)) = z_t$, which may have high degree, will be transformed to the low degree equation

$$f(L_t(s))g(L_t(s)) = z_t g(L_t(s)).$$

This low degree equation can be solved by algebraic methods such as linearization, eXtreme Linearization (XL), or Gröbner basis finding algorithms.

15. *Algebraic Immunity.* To resist the algebraic attacks from [CoMe03] and [Co03] on stream ciphers, we need $f(x)$ to have *high algebraic immunity*. That means we want all Boolean functions $g(x)$ such that $g(x)f(x) = 0$ for all x and all functions $g(x)$ such that $g(x)(f(x) + 1) = 0$ for all x to have high algebraic degree.

16. Some practical applications of stream ciphers include the following:

- *SNOW 3G* stream cipher for UEA2/UIA2 telecommunications encryption. The SNOW cipher takes in a 128-bit key and a 128-bit initialization vector IV. It is a filter function generator that maintains its secret state in a 16-word LFSR defined over GF(2^{32}). The nonlinear combiner is a finite state machine that consists of three 32-bit registers that make use of the AES SubBytes and MixColumns operations for computation. It builds on the success of AES by retaining some of the good cryptographic properties of AES components but aims to be faster by computing each 32-bit word with fewer clock cycles. As of 2015, there is one published analysis on SNOW 3G which shows some related key distinguishing properties [KiYo11], but is not a break of the cipher.
- *RC4* stream cipher for WEP encryption to protect WiFi traffic. The RC4 cipher takes in variable length keys between 40 to 2048 bits. It maintains a key dependent secret permutation table on 256 bytes, which is iteratively updated by a pseudorandom generation algorithm to produce a keystream of secret bytes. This is XORed with the plaintext to produce the ciphertext. The original specification of RC4 is only defined based on a secret key with no initialization vector IV. However, the usage in WEP requires a fresh IV for every packet transmitted. The WEP designers used RC4 with a 128-bit key, where a 24-bit IV is concatenated with a 104-bit secret key. However, the weak design of this key schedule enabled Fluhrer, Mantin, and Shamir to launch a related-key attack (same 104-bit secret key but different 24-bit chosen IVs) on WEP encryption to recover the secret key in practical time [FlMaSh01].
- *E0* stream cipher for Bluetooth encryption. The E0 stream cipher takes in a 128-bit key, 48-bit Bluetooth address, and a 26-bit master counter. These are used to initialize four LFSRs of lengths 25, 31, 33, 39 bits and a finite state machine (FSM) that consists of two pairs of 2-bit delay elements. At each clock cycle, 1

bit is taken from the FSM and each of the four LFSRs to be XORed to form a keystream bit. This is then XORed with the plaintext to form the ciphertext. The best attack on E0 to date is a conditional correlation attack by Lu, Meier, and Vaudenay [LuMeVa05]. It uses the first 24 bits of $2^{23.8}$ frames (each frame is 2745 bits long) to recover the secret key with 2^{38} complexity.

- *A5/1* stream cipher for GSM encryption. The A5/1 stream cipher takes in a 64-bit key and a 22-bit frame number, which are used to initialize three LFSRs of lengths 19, 22, and 23 bits. The LFSRs are clocked in a stop-and-go fashion based on majority logic. One clocking bit is taken from each LFSR and a majority vote is computed. If the clocking bit of an LFSR agrees with the majority bit, that LFSR is clocked. Thus at each clock cycle, either two or three LFSRs are clocked. The short 64-bit key length of A5/1 makes it vulnerable to brute force attack based on just a few frames of known plaintext, e.g., by using the COPACOBANA search engine [GüEtal08]. With more known plaintext, there are faster attacks such as the correlation attack by Maximov et al. [MaJoBa04], where A5/1 can be broken in less than one minute based on a few seconds of conversation.

17. The emergence of algebraic attacks and other prominent breaks on stream cipher standards such as A5/1 and A5/2 (used in GSM encryption) prompted the call for better design/standardization of stream ciphers [Es04]. This prompted the call for a stream cipher competition ESTREAM, organized by EU-ECRYPT, to develop secure stream cipher standards.

18. The ESTREAM competition was held by EU-ECRYPT from 2005 to 2008 [RoBi08]. The stream cipher entries fall under two profiles: profile 1 for high throughput software (faster than AES) and profile 2 for lightweight hardware implementations in constrained devices. There were 34 submissions of which seven were chosen to be stream cipher standards after scrutiny by the international cryptographic community.

19. The OFB and counter modes of a block cipher expand the secret key into a long keystream (independently of the plaintext) by repeated applications of the block cipher. Thus they are examples of synchronous stream ciphers.

20. The CFB mode of a block cipher is an example of a self-synchronizing stream cipher. CFB mode with t-bit feedback can recover from a bit slip of t bits. That is, when t consecutive bits of data are lost during transmission, the ciphertext will decrypt incorrectly for b/t iterations, where b is the blocklength, and then resume correct decryption after the misaligned content is completely flushed from the block cipher input register.

Examples:

1. Consider an autokey cipher with secret key "iloveyou"$= \{8, 11, 14, 21, 4, 24, 14, 20\}$. It maps the plaintext "todayisagoodday"$= \{19, 14, 3, 0, 24, 8, 18, 0, 6, 14, 14, 3, 3, 0, 24\}$ as follows:

$$\begin{array}{rcl} \text{plaintext} & : & 19, 14, 3, 0, 24, 8, 18, 0, 6, 14, 14, 3, 3, 0, 24 \\ \text{keystream} & : & 8, 11, 14, 21, 4, 24, 14, 20, 19, 14, 3, 0, 24, 8, 18 \\ \text{ciphertext} & : & 1, 25, 17, 21, 2, 6, 6, 20, 25, 2, 17, 3, 1, 8, 16. \end{array}$$

The keystream is formed by appending the plaintext after the key and the ciphertext is formed by adding the plaintext to the keystream modulo 26. The ciphertext converted to the alphabet is "bzrvcgguzcrdbiq".

2. Consider a simple 9-bit LFSR cipher over $GF(2)$ defined by the feedback relation $s_{i+9} = s_{i+4} + s_i$. Suppose the secret key is 011001010 and the plaintext is the 16-bit string 1100111010110111. To perform encryption, the secret key is expanded to a 16-bit keystream 0110010100011010. It is then XORed to the plaintext to form the ciphertext 1010101110101101.

3. One example of the algebraic attack of [CoMe03] is on the *Toyocrypt* cipher. The cipher is a nonlinear filter function generator where a 128-bit LFSR is filtered by a 128-bit Boolean function defined by

$$f(s_0, s_1, \ldots, s_{127}) = s_{127} + \textstyle\sum_{i=0}^{62} s_i s_{\alpha(i)} + s_{10}s_{23}s_{32}s_{42}+$$

$$s_2s_9s_{12}s_{18}s_{20}s_{23}s_{25}s_{26}s_{28}s_{33}s_{38}s_{41}s_{42}s_{51}s_{53}s_{59} + \textstyle\prod_{i=0}^{62} s_i,$$

where $\alpha(i)$ is a permutation of the indices $i \in \{63, 64, \ldots, 125\}$. This filter function is not easy to attack directly with an algebraic attack because its degree is 63, which is high.

However, when $f(s)$ is multiplied by the linear polynomial $g(s) = s_{23} + 1$, we see that $f(s)g(s)$ becomes a cubic polynomial

$$f(s)g(s) = s_{127}(s_{23} + 1) + \textstyle\sum_{i=0}^{62} s_i s_{\alpha(i)}(s_{23} + 1).$$

This is because the last three monomials of $f(s)$ disappear when multiplied by $(s_{23} + 1)$, as s_{23} appears in them and $s_{23}^2 = s_{23}$ for Boolean variables. In this way, the degree of the keystream equation is reduced from 63 to 3. By performing a linearization attack (treating each monomial as a new variable), one can solve the resulting linear system for the key in $2^{51.6}$ time using $2^{17.4}$ keystream bits. In [Co03], an improvement is made to this attack where the keystream independent part of the linearized equations is preprocessed by the Berlekamp-Massey algorithm and stored in memory, leading to a faster online attack. There was a further enhancement [ZhEtal09] to the algebraic attacks of [CoMe03] and [Co03] by considering the attack in the re-synchronization scenario, which results in further reduction of the attack complexity to a few seconds on a PC to recover the secret key under four resynchronizations, each producing 128 keystream bits.

15.4 HASH FUNCTIONS

Conventional hash functions in non-cryptographic applications are commonly used to map data of arbitrary size to a fixed size. Cryptographic hash functions require additional properties and are used for the purposes of data integrity and message authentication.

15.4.1 BASIC CONCEPTS

Definitions:

A ***hash function*** h maps arbitrary length bit strings to small fixed length (for example, 128-bit or 512-bit) outputs called ***hash-values***.

A ***collision*** is a pair of distinct bit strings mapped to the same output by a hash function.

A hash function is ***preimage-resistant*** if given any y in the range of h (for which a corresponding input is not known), it is computationally infeasible to find any preimage x^* such that $h(x^*) = y$.

A hash function is ***weak collision-resistant*** if given any one input x, it is computationally infeasible to find a second preimage $x^* \neq x$ such that $h(x) = h(x^*)$.

A hash function is ***strong collision-resistant*** if it is computationally infeasible to find any two distinct inputs x and x^* such that $h(x) = h(x^*)$.

A ***one-way hash function*** (***OWHF***) is a function h that maps arbitrary length inputs to fixed length outputs, and has the properties of preimage-resistance and weak collision-resistance.

A ***collision-resistant hash function*** (***CRHF***) is a function h that maps arbitrary length inputs to fixed length outputs, and has the property of strong collision-resistance.

An n-bit hash function is said to have ***ideal security*** if the following properties hold:

- Given a hash output, producing both a preimage and a second preimage given a first, requires approximately 2^n operations;
- Producing a collision requires approximately $2^{n/2}$ operations.

Facts:

1. The basic idea is that a hash-value serves as a compact representative image (sometimes called a *digital fingerprint* or *message digest*) of the input string, and can be used as if it were uniquely identifiable with that string.

2. The problem of checking the integrity of the potentially large original input is reduced to verifying that of a small, fixed-size hash-value.

3. A hash-value should be uniquely identifiable with a single input *in practice*, and collisions should be *computationally difficult* to find.

4. While the utility of hash functions is widespread, the most common cryptographic uses are with digital signatures and for data integrity.

5. Regarding digital signatures, long messages are typically hashed first, and then the hash-value is signed rather than signing individual blocks of the original message. Advantages of this oversigning the individual blocks of the original message directly include efficiency with respect to both time and space.

6. Regarding data integrity, hash functions together with appropriate additional techniques can be used to verify the integrity of data. Specific integrity applications include virus protection and software distribution.

7. MACs (§15.6.2) are a special class of hash functions which take in addition to message input a secret key as a second input, allowing for the verification of both data integrity and data origin authentication.

8. Given a hash function h and an input x, $h(x)$ should be easy to compute.

9. The complete specification of h is usually assumed to be publicly available.

10. Collision-resistance is required for applications such as digital signatures and data integrity. Otherwise an adversary might find two messages x and x' that have the same hash-value, obtain a signature on x, and claim it as a signature on x'.

11. Depending on the intended application and the susceptibility of the environment to certain attacks, weak or strong collision-resistance may be required.

12. There are no known instances of functions that have been proven to be one-way, that is, for which it can be *proven* (without assumptions) that finding a preimage is difficult. However, it would be most surprising if such functions indeed did not exist. All instances of “one-way functions” given to date should thus properly be qualified as “conjectured” or “candidate” one-way functions.

13. Particular hash functions differ in the nature of the compression function and preprocessing of the input.

14. A typical usage for data integrity is as follows:

- The hash-value corresponding to a particular input is computed at some point in time;
- The integrity of this hash-value is then protected in some manner;
- At a subsequent point in time, to verify the input data has not been altered, the hash-value is recomputed, using purportedly the same input, and compared for equality with the original hash-value.

15.4.2 CONSTRUCTION AND METHODS

In general, hash functions are built by processing small blocks of data iteratively. Two common construction methods account for the majority of existing secure hash functions.

Facts:

1. *Merkle-Damgård construction*: Most hash functions process fixed-size blocks of the input iteratively as follows:

- A prespecified starting value or *initializing value* (IV) is defined.
- The hash input $x = x_1 x_2 \dots x_t$ of arbitrary finite length is divided into fixed-length n-bit blocks x_i. This preprocessing typically involves appending extra bits (*padding*) as necessary to extend the input to an overall bit length that is a multiple of the blocklength n. The padding also often includes a partial block indicating the bit length of the unpadded input.
- Each block x_i is then used as input to a simpler hash function f, called an m-bit *compression function*, which computes a new intermediate result of some fixed bit length m as a function of the previous m-bit intermediate result (initially the IV) and the block x_i. Letting H_i denote the partial result after the ith stage, the hash $h(x)$ of an input $x = x_1 x_2 \dots x_t$ is defined as follows:

$$H_0 = IV; \qquad H_i = f(H_{i-1}, x_i),\ 1 \le i \le t; \qquad h(x) = H_t.$$

- H_{i-1} serves as the *chaining variable* between stages $i-1$ and i.

2. *Matyas-Meyer-Oseas construction*: This construction works with any block cipher such as AES. Let E be an n-bit block cipher parameterized by a symmetric key k. Let g be a function that maps an n-bit string to a key k suitable for E. Fix an initial value IV. The following algorithm is then an n-bit hash function which, given any input string x, outputs an n-bit hash $h(x)$:

- Divide x into n-bit blocks and pad if necessary by some method such that all blocks are complete, yielding a padded message of t n-bit blocks $x_1 x_2 \dots x_t$;
- Define $h(x) = H_t$, where

$$H_0 = IV; \quad H_i = E_{g(H_{i-1})}(x_i) \oplus x_i,\ \ 1 \le i \le t.$$

This is believed to be a one-way hash function requiring 2^n operations to find a preimage, and $2^{n/2}$ operations to find a collision. For underlying ciphers, such as DES, which have relatively small blocklength (for example, with blocks of no more than 64 bits), this is not a collision-resistant hash function since 2^{32} operations is well within current computational capability.

15.4.3 FAMILIES OF HASH FUNCTIONS

Families of unkeyed hash functions were introduced over the years as cryptographic primitives. These functions were updated in response to increases in computational power, new attacks, as well as industrial needs.

Facts:

1. The *MD Message-Digest Algorithm Family* was proposed by Rivest et al. *MD2* was proposed in 1989 [Ka92]. The input is in blocks of 128 bits with an output size of the same length. MD2 is considered historic. In CVE-2009-2409 [Cv09], security updates were issued to disable MD2 in Firefox, GnuTLS before 2.6.4 and 2.7.4, OpenSSL 0.9.8 through 0.9.8k, and other products that support MD2 with X.509 certificates.

2. *MD4* was an update in 1990 [Ri92]. The input block size is 512 bits with an output size of 128 bits. As of 2011, MD4 was considered "historic" [TuCh11].

3. *MD5* was proposed in 1992 as a replacement of MD4. The algorithm follows a Merkle-Damgård construction with the same input and output parameters as MD4. In 2013, Xie, Liu, and Feng demonstrated a collision attack in 2^{18} operations [XiLiFe13]. It is advised that MD5 not be used [Vu08].

4. *MD6* was first published in 2008 [Ri08] by Rivest et al. as a proposal for the NIST SHA-3 competition. It uses a Merkle tree-like structure to make use of parallel computation of hashes for long inputs. MD6 did not advance to the second round of the competition.

5. The *Secure Hash Algorithm* (SHA) is a family of hash functions published by NIST.

6. *SHA-0*, published in 1993, produces a hash of 160 bits with inputs in 512-bit blocks. The algorithm follows a Merkle-Damgård construction. It was quickly withdrawn and replaced by SHA-1 in 1995. In 2008, Manuel and Peyrin [MaPe08] showed that a SHA-0 collision can be found in $2^{33.6}$ operations.

7. *SHA-1* has the same input and output parameters as SHA-0, and follows a Merkle-Damgård construction. In 2005, Wang et al. [WaYu05] presented a collision attack with complexity 2^{63}. In 2011, NIST [BaRo11] declared that "SHA-1 shall not be used for digital signature generation after December 31, 2013."

8. A SHA-1 collision was demonstrated in 2017 with a complexity of $2^{63.1}$, or 100 GPU years, at a cost of $110,000 by researchers at CWI Amsterdam and Google Research [StEtal17].

9. *SHA-2*, published in 2001, is itself a family of six hash functions with various input/output sizes. These functions follow a Merkle-Damgård construction with a Davies-Meyer compression function. SHA-224 and SHA-256 have block sizes of 512 bits and output a digest (hash value) of 224 and 256 bits, respectively, in 64 rounds. SHA-384, SHA-512, SHA-512/224, and SHA-512/256 have block sizes of 1024 bits and output digests of size 384, 512, 224, and 256 bits, respectively in 80 rounds. Reduced-rounds attacks were found in 2012 [BiEtal11], [KhReSa12].

10. *SHA-3* is a result of a NIST call for an alternative to SHA-2. Submissions were accepted until the end of 2008. The standard was ultimately released in August 2015 [Fi15]. The algorithm uses a sponge construction [BeEtal07]. SHA3-224, SHA3-256, SHA3-384, SHA3-512 have block sizes of 1152, 1088, 832, 576 and output digests of size 224, 256, 384, and 512, respectively.

15.5 PUBLIC KEY CRYPTOGRAPHY

The invention of public key cryptography in the 1970s significantly changed the field of cryptography. As a result, many security services can now be realized. In a private key system, the encryption and decryption keys are the same, or the knowledge of the encryption key implies an easy derivation of the decryption key. On the other hand, in a public key cryptosystem there is a *public key* portion and a *private key* portion. The public key is not kept secret and allows everyone to use it to encrypt messages to the owner of the private key. The private key is known only to the receiver and is used for decryption of the ciphertext.

A number of public key cryptosystems were proposed in the past 40 years. Soon after their appearance, cryptanalysts worked hard to break them. Most systems were broken quickly. Those that have withstood sustained attacks are generally believed to meet the security requirements of a public key cryptosystem. However, researchers still continue to look for ways to break them and sometimes succeed quite a while after the systems were first proposed. In the following, we introduce the significant systems that have survived existing attacks and appeared hard to break, and that are also reasonably efficient.

15.5.1 INTRODUCTION TO PUBLIC KEY CRYPTOSYSTEMS

Definitions:

Let E_p and D_s be the encryption and decryption algorithms in a public key cryptosystem with a ***public key*** p and a ***private key*** s, respectively. To encrypt plaintext M, one can generate the ciphertext $C = E_p(M)$. Upon receiving ciphertext C, the receiver, using the private key s, decrypts by evaluating $M' = D_s(C)$. Given the public key p, it should be hard to compute the private key s.

Non-adaptive chosen-ciphertext attack security (***CCA1***): an attacker that can inquire multiple times the plaintext for any adaptively chosen ciphertext is unable to recover the plaintext for a new challenge ciphertext C. Here non-adaptivity means that no query is based on C (i.e., no decryption query is allowed after C is given).

Adaptive chosen-ciphertext attack security (***CCA2***): given the challenge ciphertext C in CCA1 security, the attacker can continue the decryption requests adaptively, except for C itself, and is unable to recover the plaintext.

Facts:

1. The invention of public key cryptography is credited to Diffie and Hellman [DiHe76]. However, it was first conceived in 1970 by James H. Ellis in secret work at the U.K.'s Government Communications Headquarters (GCHQ). This earlier discovery was not made public until 1997.

2. In 1978 Ron Rivest, Adi Shamir, and Leonard Adleman invented the first public key cryptosystem that has withstood attack, the RSA cryptosystem (see §15.5.2). However, in 1997 it was revealed that in 1973 Clifford Cocks discovered the equivalent of the RSA cryptosystem in secret work at the GCHQ.

3. For a cryptosystem to be useful, it is necessary that $M' = M$. In addition, given the ciphertext C and public key p, it should be hard to derive the plaintext M. That is, the cryptosystem should be resistant to *ciphertext-only attack*.

4. CCA2 is a desired property, but can be difficult to achieve in practice.

5. Since the late 1970s many different public key cryptosystems have been developed. The mostly widely used are the RSA cryptosystem (§15.5.2), the ElGamal cryptosystem (§15.5.3), and the elliptic curve cryptosystem (§15.5.4). Other important public key cryptosystems are the NTRU cryptosystem (§15.5.5), the Cramer-Shoup cryptosystem (§15.5.6), the Paillier cryptosystem (§15.5.7), the Goldwasser-Micali probabilistic cryptosystem (§15.5.8), identity-based encryption (§15.5.9), and attribute-based encryption (§15.5.10).

6. It will be possible to quickly break many, but not all, public key cryptosystems once quantum computing becomes practical. This is noted in the coverage of the public key cryptosystems in this section.

15.5.2 RSA CRYPTOSYSTEM

The RSA cryptosystem is the best known and most widely used public key cryptosystem for secure data transmission. Its suitability as a public key cryptosystem is based on the difficulty of factoring large integers compared with the ease of finding large primes.

Facts:

1. *Key Generation.*

- Randomly select two large and distinct primes p and q. Compute $n = pq$ and $\phi(n) = (p-1)(q-1)$.
- Select an arbitrary value e with $1 < e < \phi(n)$ so that $\gcd(e, \phi(n)) = 1$.
- Compute d with $1 < d < \phi(n)$ such that $ed \equiv 1 \pmod{\phi(n)}$.
- The public key is (n, e) and the private key is d.

2. *Encryption.* To encrypt a plaintext $M \in \{0, 1, \ldots, n-1\}$, compute $C = M^e \bmod n$.

3. *Decryption.* To decrypt M from C, compute $M = C^d \bmod n$.

4. The correctness of RSA follows from elementary number theory, in particular from Euler's theorem (see §4.3.1).

5. Some computational notes:

- The public exponent e should be coprime with $\phi(n) = (p-1)(q-1)$ and can be checked using the Euclidean algorithm (see §4.2.2).
- The secret exponent d can be computed from $(e, \phi(n))$ using the extended Euclidean algorithm (see §4.2.2).
- To compute $M^e \bmod n$ and $C^d \bmod n$, many fast modular exponentiation algorithms such as the square-and-multiply algorithm are available [MevOVa10].

6. The hardness of factoring is the security basis of RSA. Some particular concerns with the choice of parameters are the following:

- When $|p - q|$ is small, n will suffer from Fermat factoring attack.
- When $|p - q| < n^{1/4}$, Coppersmith [Co97] presented an attack to factor n.
- If $p - 1$ or $q - 1$ has small factors only, then n can be factored using Pollard's $p - 1$ algorithm [Po74]; when $p + 1$ or $q + 1$ has small factors only, then n can be factored using Williams' $p + 1$ algorithm [Wi82].

7. One might attempt to use a small d for better decryption efficiency. However, this usage is vulnerable to the factoring attacks by Wiener [Wi90], Boneh and Durfee [BoDu99], and Howgrave-Graham and Seifert [HoSe99]. Hinek and Lam [HiLa10] showed that in practice, three instances of RSA encryption are sufficient to factor n when $d < n^{0.33}$ with at least 93% success rate. Therefore, it is advisable not to use small d.

8. Due to the nature of factoring algorithms, p and q need to be of similar size to keep the system secure.

9. *RSA assumption and factoring assumption.*

- Security against ciphertext-only attack requires that it be hard to derive M from C and (n, e). This is known as the *RSA assumption*.
- Given n, if one can find p and q, then one can easily compute d from (n, e). So the security of RSA needs the assumption that it is hard to factor n. This is known as the *factoring assumption*, and is stronger than the RSA assumption.

10. Under a generic computation model over the ring $\mathcal{Z}_n$, the factoring assumption is equivalent to the RSA assumption [AgMa09]. This gives evidence for the widely accepted belief that they are equivalent in the normal computation model.

11. Under the RSA assumption, RSA is secure against ciphertext-only attack. However, it is not CCA2 secure due to its multiplicative property.

12. To generate the keys e and d, one must first generate two primes p and q of similar bitlengths. There are several efficient probabilistic primality tests available, such as the Miller-Rabin test and the Solovay-Strassen test (§4.4).

13. There are several general purpose factoring algorithms. See §4.5 for details.

14. In 1991, RSA Laboratories began the *RSA Factoring Challenge* to stimulate research in factoring products of two large primes. One goal of this challenge has been to provide guidance as to the minimum recommended size of an *RSA modulus* $n = pq$.

15. As of 2016, the largest factored RSA modulus n has bitlength 768 (RSA-768). Therefore, the choice of n needs to be significantly larger. Currently, a 2048-bit (617 decimal digits) modulus is recommended for general applications and a 3072-bit (925 decimal digits) modulus for high-security applications.

16. If quantum computers are developed, RSA will be completely broken, since the factoring problem can be efficiently solved on quantum computers. However, building such computers does not seem realistic in the near future.

17. An important application of RSA is the *digital envelope*. A digital envelope is a framework for data encryption, in which the data is encrypted under a secret key using a symmetric key cryptosystem such as AES, while this secret key is encrypted using a public key cryptosystem, such as RSA. The details are described in PKCS #7 [Ka98]. A well-known application of the digital envelope is Pretty Good Privacy (PGP), a system for email security.

18. An important use of the RSA system is to guarantee the authenticity of a message using a *digital signature*. See §15.6.1 for details.

Examples:

1. Suppose that $p = 53$ and $q = 83$, so that $n = 53 \cdot 83 = 4399$ and $\phi(n) = (53 - 1)(83 - 1) = 4624$, and further suppose that $e = 23$. Then $(n, e) = (4399, 23)$ is a valid public key for RSA because $\gcd(\phi(n), e) = \gcd(4624, 23) = 1$, as can be verified using the Euclidean algorithm. Using the extended Euclidean algorithm, it can be shown that $23^{-1} \bmod 4624 = 927$. Hence, the exponent in the private key corresponding to the public key $(4399, 23)$ is $d = 927$. (Note that for practical use, the primes p and q need to be hundreds of digits long.)

2. In Example 1, to encrypt $M = 19$, compute $C = M^e \bmod n = 2556$. In order to decrypt $C = 2556$, compute $M = C^d \bmod n = 19$.

15.5.3 ELGAMAL CRYPTOSYSTEM

The ElGamal cryptosystem is developed from the Diffie-Hellman key-exchange protocol. The system can be defined over any cyclic group. Its security is based on both the discrete logarithm problem and the computational Diffie-Hellman problem.

Facts:

1. The ElGamal cryptosystem was invented by Taher ElGamal [El85] in 1985.

2. *Key Generation.*

- Let p be a large prime. Let g be a generator of the multiplicative group $\mathcal{Z}_p^*$.
- Randomly select d with $1 \leq d \leq p-2$, and compute $h = g^d \bmod p$.
- The public key is (p, g, h) and the private key is d.

3. *Encryption.* To encrypt a plaintext $M \in \langle g \rangle$, randomly select k with $1 \leq k \leq p-2$ and then compute $X = g^k \bmod p$ and $Y = Mh^k \bmod p$. The ciphertext is $C = (X, Y)$.

4. *Decryption.* To decrypt (X, Y), the receiver computes $M' = YX^{-d} \bmod p$.

5. The correctness of the algorithm follows from the fact that $YM^{-1} = h^k = g^{kd} = X^d$.

6. Given p, g, and h, if one can determine the private key d, then the ciphertext can be decrypted. Thus, the security of ElGamal encryption depends on the hardness of finding d from (p, g, h). This is called the *Discrete Logarithm Problem* (DLP).

7. The ciphertext-only security of ElGamal encryption requires that it be hard to determine $Z = h^k \bmod p$ from (p, g, h, X). This is called the *Computational Diffie-Hellman Problem* (CDHP). It is widely believed that the CDHP can only be solved by first solving the DLP.

8. The assumption that the DLP is hard does not hold in every finite cyclic group. For instance, the DLP is easy in the additive group $\mathcal{Z}_n$.

9. The DLP is insecure under a quantum attack.

Examples:

1. Let $p = 3767$ and choose $g = 7$. Let $d = 15$. Then $h = 7^{15} \bmod 3767 = 3467$. The public key is $(p, g, h) = (3767, 7, 3467)$ and the private key is $d = 15$. Note that in practice, the parameters should be larger.

2. In Example 1, to encrypt message $M = 125$, choose a random value $k = 87$, compute $X = 7^{87} \bmod 3767 = 3113$ and $Y = Mh^k \bmod 3767 = 125 \cdot 3467^{87} \bmod 3767 = 2379$. Thus, the ciphertext is $(3113, 2379)$. To decrypt the ciphertext $(3113, 2379)$, compute $M' = YX^{-d} \bmod 3767 = 2379 \cdot 3113^{-15} \bmod 3767 = 2379 \cdot 464 \bmod 3767 = 125$.

15.5.4 ELLIPTIC CURVE CRYPTOSYSTEM

The elliptic curve cryptosystem is a adaptation of the ElGamal cryptosystem over a group of elliptic curves over a finite field. A significant advantage of this system is that it requires a significantly smaller key size compared to other systems in order to achieve the same level of computational security.

Facts:

1. Elliptic curve cryptography (ECC) is the elliptic curve analogue of discrete logarithm cryptography. It was invented by Neal Koblitz [Ko87] and Victor Miller [Mi85] in 1985. (See §4.11 for the basics of elliptic curve group operations.)

2. *Key Generation.*

- Select a large prime p and elliptic curve group $E(\mathcal{F}_p)$.
- Let P be a point of prime order n in $E(\mathcal{F}_p)$ and randomly select an integer d, $1 \le d \le n-1$. Compute $Q = dP$.
- The public key is (p, E, n, P, Q) and the secret key is d.

3. *Encryption.* To encrypt message $M \in \langle P \rangle$, select a random integer k from $[1, n-1]$; the ciphertext is $C = (C_1, C_2) = (kP, M + kQ)$.

4. *Decryption.* To decrypt (C_1, C_2), compute $M = C_2 - dC_1$.

5. Decryption is correct because $C_2 - dC_1 = M + kQ - dkP = M + k(dP) - dkP = M$.

6. There are a number of standards on the use of elliptic curve cryptography, covering the choice of curves and various implementation issues.

- ANSI X9.62 (2005) specifies Elliptic Curve Digital Signature Algorithm (ECDSA). The standard includes methods and criteria for public and private key generation, and procedural controls required for the secure use of the algorithm with these keys.
- ANSI X9.63 (2011) specifies key agreement and key transport schemes using elliptic curves for use in symmetric schemes.
- IEEE P1363 (2000, 2004) includes key agreement, signature, and encryption schemes.
- NIST FIPS 186-4 (2013), the Digital Signature Standard (DSS) specifies DSA, RSA, and ECDSA.
- NSA Suite B (2005) includes a set of cryptographic algorithms proposed by the National Security Agency (NSA). Included are ECDSA and Elliptic Curve Diffie-Hellman Key Agreement (ECDH). In 2015, NSA announced preliminary plans for a future transition to quantum-resistant algorithms.

7. The security of ECC is based on the difficulty of the *Elliptic Curve Discrete Logarithm Problem* (ECDLP): namely, given point $P \in E(\mathcal{F}_q)$ of prime order n and a point $Q \in \langle P \rangle$, find an integer ℓ such that $Q = \ell P$.

- Using Pollard's rho attack. the ECDLP can be solved in $\sqrt{n}$ time.
- The index-calculus attack, which normally applies to the discrete logarithm problem over a finite field, is not generally applicable to the ECDLP.
- In special cases, one can compute an isomorphism from $\langle P \rangle$ to a cyclic group G, where the discrete logarithm problem can be solved by algorithms running in subexponential or faster time. The following attacks have been discovered:

- *Prime-field-anomalous curve.* A curve E of prime order p defined over $\mathcal{F}_p$ is isomorphic to the additive group $\mathcal{F}_p^+$. The attack was found in 1998 [Se98], [Sm99], [TaEtal98].
- *Weil and Tate pairing attacks.* When E is defined over $\mathcal{F}_q$ and $\gcd(n, q) = 1$, there is an isomorphism between E and the multiplicative subgroup of order n of $\mathcal{F}_{q^k}^*$ of some extension field $\mathcal{F}_{q^k}$. However, k is very large in general and so the attack is easily circumvented.
- *Weil descent.* This attack reduces the ECDLP in an elliptic curve defined over a binary field $\mathcal{F}_{2^m}$ to the discrete logarithm problem in the Jacobian of a hyperelliptic curve defined over a proper subfield of $\mathcal{F}_{2^m}$. Thus far, the attack is effective only in certain elliptic curves over $\mathcal{F}_{2^m}$ where m is composite. Therefore, for cryptographic purposes, curves defined over $\mathcal{F}_{2^m}$ where m is composite should be avoided [Fr01], [GaHeSm02], [JaMeSt01], [MaMeTe02], [MeQu01], [MeTe06], [MeTeWe04].

8. Since ECC is based on the elliptic curve discrete logarithm problem, ECC is insecure against quantum attacks.

Examples:

1. Let $p = 23$ and consider $E(\mathcal{F}_{23}) : y^2 = x^3 + x + 1$. Let $P = (3, 10)$ and $d = 3$. Then $Q = 2P + P = (7, 12) + (3, 10) = (-4, 5)$.

2. In Example 1, to encrypt $M = (9, 7)$, choose $k = 2$, whence $C_1 = kP = (7, 12)$ and $C_2 = kQ + M = 2(7, 12) + (9, 7) = (-6, 3) + (9, 7) = (3, 13)$. To decrypt $(C_1, C_2) = ((7, 12), (3, 13))$, compute $dC_1 = 3(7, 12) = (-6, 3)$. Thus, $C_2 - dC_1 = (3, 13) - (-6, 3) = (3, 13) + (-6, 20) = (9, 7) = M$.

15.5.5 NTRU CRYPTOSYSTEM

NTRU is a cryptosystem based on lattices. It is one of the very few cryptosystems that is currently resistant to quantum attacks.

Facts:

1. NTRU is a lattice-based public key cryptosystem proposed by J. Hoffstein, J. Pipher, and J. Silverman in 1996.

2. For a prime N, let $R = \mathcal{Z}[x]/(x^N - 1)$. Let $F(x), G(x) \in R$ with $F(x) = \sum_{i=0}^{N-1} F_i x^i$ and $G(x) = \sum_{j=0}^{N-1} G_j x^j$. Then multiplication $\odot$ in R can be implemented as $F(x) \odot G(x) = H(x) = \sum_{k=0}^{N-1} H_k x^k$, where $H_k = \sum_{i+j=k \bmod N} F_i G_j$.

3. *Key Generation.*

- Select a large prime N, and coprime integers p and q with $q \gg p$.
- Choose random polynomials $f(x), g(x) \in R$ with coefficients in $\{-1, 0, 1\}$. Compute $f_p(x), f_q(x)$ such that $f(x) \odot f_p(x) = 1 \bmod p$ and $f(x) \odot f_q(x) = 1 \bmod q$.
- Define $h(x) = pf_q(x) \odot g(x) \bmod q$. Then the public key is (N, p, q, h) and the private key is $(f(x), f_p(x))$.

4. *Encryption.* Consider message $m(x) \in R$ with coefficients in $\{-1, 0, 1\}$. Generate a random polynomial $r(x) \in R$ with small coefficients (relative to q) and compute $c(x) = r(x) \odot h(x) + m(x) \bmod q$. The ciphertext is $c(x)$.

5. *Decryption.* To decrypt ciphertext $c(x)$, the receiver computes $A(x) = f(x) \odot c(x) \bmod q$ so that the coefficients of $A(x)$ are in $[-q/2, q/2]$. Recover the plaintext $m'(x) = f_p(x) \odot A(x) \bmod p$.

6. The correctness of the decryption can be demonstrated as follows. Notice that

$$A(x) = f(x) \odot r(x) \odot (pf_q \odot g(x)) + f(x) \odot m(x) \bmod q.$$

Simplifying, we have $A(x) = pr(x) \odot g(x) + f(x) \odot m(x) \bmod q$. Since p and the coefficients of $r(x), f(x), g(x), m(x)$ are small relative to q, it holds that $A(x) = pr(x) \odot g(x) + f(x) \odot m(x)$. Hence, $m'(x) = f_p(x) \cdot A(x) \bmod p = f_p(x) \odot f(x) \odot m(x) \bmod p = m(x)$.

7. The security of NTRU relies on the difficulty of finding $f_q(x)$ and $g(x)$ from $h(x)$.

8. NTRU security is based on the hardness of the *Shortest Vector Problem* (SVP), finding the shortest vector in a lattice.

9. Currently, the most powerful attack on NTRU is the Lenstra-Lenstra-Lovász (LLL) algorithm. However, the attack can be prevented when the security parameters are sufficiently large.

10. NTRU is not known to be compromised by any quantum algorithm. This is an advantage over the RSA, ElGamal, and ECC schemes.

Example:

1. Let $N = 11$, $p = 3$, $q = 31$, $f(x) = x^8 - x^7 + x^3 + x - 1$, $g(x) = x^3 - x + 1$. We have $f_q(x) = 8x^{10} + 11x^9 + 20x^8 + 10x^7 + 28x^6 + 26x^5 + 30x^3 + 17x^2 + 11x + 26$ and $f_p(x) = 2x^{10} + 2x^9 + 2x^8 + x^6 + 2x^4 + x^3 + x^2 + 2$. Thus, $h(x) = pf_q(x) \odot g(x) \bmod q = 21x^{10} + 26x^9 + 15x^8 + 8x^7 + 3x^6 + 5x^5 + 5x^4 + 24x^3 + 11x^2 + 19x + 21$. The public key is (N, p, q, h) and the private key is $(f(x), f_p(x))$.

2. In Example 1, to encrypt the message $m(x) = x^{10} - x^9 + x^8 + x + 1$, choose a random polynomial $r(x) = x^9 + x^8 + x + 1$ and compute the ciphertext $c(x) = r(x) \odot h(x) + m(x) \bmod q = 16x^{10} + 18x^9 + 4x^8 + 27x^7 + 18x^6 + 2x^5 + 9x^4 + 12x^3 + 9x^2 + 8x + 16$. To decrypt $c(x)$, compute $A(x) = f(x) \odot c(x) \bmod q = -5x^{10} + 3x^9 + 2x^8 - 2x^6 + 2x^5 + 3x^4 + 4x^3 - x^2 + 2x + 7$. Thus, $m'(x) = f_p(x) \odot A(x) \bmod p = x^{10} - x^9 + x^8 + x + 1 = m(x)$.

15.5.6 CRAMER-SHOUP CRYPTOSYSTEM

The Cramer-Shoup cryptosystem is an extension of the ElGamal cryptosystem. It is the first practical scheme that is proven to be CCA2 secure without random oracles.

Facts:

1. The first practical CCA2-secure public key cryptosystem was proposed by R. Cramer and V. Shoup [CrSh98] in 1998.

2. The security is based on the *Decisional Diffie-Hellman* (DDH) assumption: it is hard to distinguish (g, h, g^x, h^x) from (g, h, g^x, h^y), where $g, h \in \mathcal{Z}_p^*$ have large prime order q and x, y are randomly selected from $\mathcal{Z}_q$.

3. *Key Generation.*

- Let p be a large prime. Let $\mathcal{G}$ be a subgroup of $\mathcal{Z}_p^*$ of large prime order q. (All arithmetic in $\mathcal{G}$ is performed modulo p.) Randomly select generators $g_1, g_2 \in \mathcal{G}$. Let H be a hash function.
- Randomly select $x_1, x_2, y_1, y_2, z \in \mathcal{Z}_q$ and compute $c = g_1^{x_1} g_2^{x_2}$, $d = g_1^{y_1} g_2^{y_2}$, $h = g_1^z$.

- The public key is $(p, g_1, g_2, c, d, h, H)$ and the private key is (x_1, x_2, y_1, y_2, z).

4. *Encryption.* To encrypt the plaintext $m \in \mathcal{G}$, choose a random $r \in \mathcal{Z}_q$ and compute $u_1 = g_1^r,\ u_2 = g_2^r,\ e = mh^r,\ \alpha = H(u_1, u_2, e),\ v = c^r d^{r\alpha}$. The ciphertext is (u_1, u_2, e, v).

5. *Decryption.* To decrypt the ciphertext (u_1, u_2, e, v), the receiver first computes $\alpha = H(u_1, u_2, e)$ and verifies whether $v = u_1^{x_1+y_1\alpha} u_2^{x_2+y_2\alpha}$. If the verification fails, he rejects; otherwise, he outputs $m' = e/u_1^z$.

6. The verification of the decryption step follows, since $u_1^{x_1+y_1\alpha} u_2^{x_2+y_2\alpha} = u_1^{x_1} u_2^{x_2} \cdot (u_1^{y_1} u_2^{y_2})^\alpha = c^r d^{r\alpha} = v$ and $e = mh^r = mg_1^{zr} = mu_1^z$.

7. CCA2 security is attained because to pass the verification the encrypter has to construct u_1, u_2, v that are consistent with a single r. To achieve this, he needs to know r (hence the plaintext e/h^r). Thus, the decryption requests in a CCA2 attack are not useful.

8. *Plaintext Awareness* (PA) refers to the property that one must know the underlying plaintext when creating a ciphertext. This property is useful to guarantee some privacy properties such as deniability. The plaintext awareness of this scheme was shown in [De06]. The PA property of more general schemes appeared in [JiWa10].

9. The Cramer-Shoup cryptosystem has CCA2 security, but it assumes DDH. This assumption does not hold under quantum attacks.

10. It is important to verify that u_1, u_2, e, v have prime order q. Otherwise, the scheme may be vulnerable to attacks in some circumstances.

Examples:

1. Let $p = 23$, $g_1 = 4$, $g_2 = 9$. Let $x_1 = 2$, $x_2 = 3$, $y_1 = 5$, $y_2 = 6$, $z = 7$. Compute $c = g_1^{x_1} g_2^{x_2} = 3$, $d = g_1^{y_1} g_2^{y_2} = 13$, $h = g_1^z = 8$. Then the public key is $(p, g_1, g_2, c, d, h) = (23, 4, 9, 3, 13, 8)$ and the private key is $(x_1, x_2, y_1, y_2, z) = (2, 3, 5, 6, 7)$.

2. In Example 1, to encrypt the message $M = 5$, select the random value $r = 8$ and compute $u_1 = g_1^r = 9$, $u_2 = g_2^r = 13$, $e = mh^r = 20$. Suppose $\alpha = H(u_1, u_2, e) = 9$ and so $v = c^r d^{r\alpha} = 13$. Thus, the ciphertext is $(u_1, u_2, e, v) = (9, 13, 20, 13)$. To decrypt the ciphertext $(9, 13, 20, 13)$, note that $u_1^{x_1+y_1\alpha} u_2^{x_2+y_2\alpha} = 13$, which is consistent with v. Decryption proceeds by evaluating $m = e/u_1^z = 20/9^7 = 5$.

15.5.7 PAILLIER CRYPTOSYSTEM

The Paillier cryptosystem is an encryption system that has been proposed as a primitive in electronic voting and cloud computing.

Facts:

1. The system was proposed by P. Paillier in 1999 [Pa99].

2. The security is based on the intractability of computing nth residue classes.

3. *Key Generation.*

- Randomly select two large primes p, q of similar size so that $\gcd(pq, (p-1)(q-1)) = 1$. Let $n = pq$ and $\lambda = (p-1)(q-1)$.
- Randomly select $g \in \mathcal{Z}_{n^2}^*$ such that the order of g is a multiple of n. This can be checked by determining if $\gcd(L(g^\lambda \bmod n^2), n) = 1$, where $L(x) = \frac{x-1}{n}$.
- The public key is (n, g) and the private key is (p, q).

4. *Encryption.* To encrypt the message $m \in \mathcal{Z}_n$, randomly select $r \in \mathcal{Z}_n^*$. Compute the ciphertext $c = g^m \cdot r^n \bmod n^2$.

5. *Decryption.* To decrypt the ciphertext $c \in \mathcal{Z}_{n^2}$, compute

$$m' = \frac{L(c^\lambda \bmod n^2)}{L(g^\lambda \bmod n^2)} \bmod n.$$

6. The correctness of the algorithm makes use of the fact that the order of g is a multiple of n in $\mathcal{Z}_{n^2}^*$, together with using the binomial theorem on $(1+n)^x \bmod n^2$. Details can be found in [Pa99].

7. The ciphertext is double the size of the message. This is a considerable practical disadvantage.

8. The system is *additively homomorphic* (§15.6.4).

9. The Paillier cryptosystem is not secure under a quantum attack.

Examples:

1. Let $p = 149, q = 179$. Then $n = pq = 26671$, $\lambda = (p-1)(q-1) = 26344$. Choose $g = 5$. Note that $\gcd(L(g^\lambda \bmod n^2), n) = \gcd(1213, 26671) = 1$. The public key is therefore $(n, g) = (26671, 5)$ and the private key is $(p, q) = (149, 179)$.

2. In Example 1, let the message be $m = 67$. Randomly choose $r = 81$. The ciphertext is $c = g^m \cdot r^n \bmod n^2 = 5^{67} \cdot 81^{26671} \bmod 26671^2 = 577656191$.

3. To decrypt the ciphertext 577656191, compute

$$m' = \frac{L(577656191^{26344} \bmod 26671^2)}{L(5^{26344} \bmod 26671^2)} \bmod 26671 = \frac{1258}{1213} \bmod 26671 = 67.$$

Note that the denominator above was calculated in Example 1 during the key setup stage.

15.5.8 GOLDWASSER-MICALI CRYPTOSYSTEM

The Goldwasser-Micali scheme is a probabilistic public key cryptosystem that is also the first provably secure system.

Facts:

1. The system was proposed by S. Goldwasser and S. Micali in 1982 [GoMi82].

2. The security is based on the intractability of the *Quadratic Residuosity Problem.* Namely, let $n \geq 3$ be an odd composite integer and let J_n be the set of all $a \in \mathcal{Z}_n^*$ having Jacobi symbol 1. Given $b \in J_n$, determine whether or not b is a quadratic residue modulo n.

3. *Key Generation.*

- Randomly select two large primes p and q of roughly the same size. Compute $n = pq$.
- Select $y \in \mathcal{Z}_n$ such that the *Legendre symbol* $\left(\frac{y}{p}\right) = \left(\frac{y}{q}\right) = -1$, so that the Jacobi symbol $\left(\frac{y}{n}\right) = 1$.
- The public key is (n, y) and the private key is (p, q).

4. *Encryption.* Let the message m be represented as a binary string $m = m_1 m_2 \dots m_t$.

- For each bit m_i, randomly select $x_i \in \mathcal{Z}_n^*$. If $m_i = 1$, then compute $c_i = yx_i^2 \bmod n$; otherwise, compute $c_i = x_i^2 \bmod n$.
- The ciphertext is $c = (c_1, c_2, \dots, c_t)$.

5. *Decryption.* To decrypt the ciphertext $c = (c_1, c_2, \dots, c_t)$,

- For each c_i, decide whether it is a quadratic residue modulo n by evaluating the Legendre symbol $e_i = \left(\frac{c_i}{p}\right)$. If $e_i = 1$, then set $m_i' = 0$. Otherwise, set $m_i' = 1$.
- The decrypted message is $m' = m_1' m_2' \dots m_t'$.

6. *Correctness.* When $m_i = 0$, c_i is a quadratic residue modulo n. However, when $m_i = 1$, c_i is a pseudosquare modulo n and is revealed when computing the Legendre symbol modulo p.

7. The system is insecure under a quantum attack due to the ability to factorize n.

8. The system was developed to demonstrate a provably secure system. Similar to the Paillier system in §15.5.7, message expansion is a practical drawback, in this case with expansion by a factor of $\log_2 n$.

15.5.9 IDENTITY-BASED ENCRYPTION

Identity-based encryption uses some unique information about the identity of a user as the public key, thus eliminating the need to manage public key certificates. It uses some central authority to distribute the secret key to the user.

Facts:

1. Identity-based encryption (IBE) is a public key cryptosystem that uses an arbitrary string (e.g., email address or name) as the public key. It was first proposed by A. Shamir [Sh84b] in 1984. The motivation of this system is to remove the task of managing public key certificates. The first fully functional construction was proposed by D. Boneh and M. Franklin [BoFr01] in 2001.

2. Let G_1 and G_2 be multiplicatively-written cyclic groups of prime order p. A bilinear pairing $\hat{e}$ on (G_1, G_2) is an efficiently computable map $\hat{e} : G_1 \times G_1 \to G_2$ satisfying

- *Bilinearity:* $\forall g, h \in G_1$, $\forall a, b \in \mathcal{Z}_p$, $\hat{e}(g^a, h^b) = \hat{e}(g, h)^{ab}$; and
- *Non-degeneracy:* $\hat{e}(g, h) = 1$ implies that $g = 1$ or $h = 1$.

3. *Key Generation.* The system generator determines p, G_1, G_2, $\hat{e}$, chooses a generator g of G_1, chooses two hash functions $G : \{0,1\}^* \to \{0,1\}^n$ and $H : \{0,1\}^* \to G_1$, a random $s \in \mathcal{Z}_p$, and sets $P_{pub} = g^s$. The system parameters are

$$(p, g, G_1, G_2, \hat{e}, G, H, P_{pub}).$$

The system master key is s.

4. *Extract.* For any identity ID, the system generates its private key as $d_{\mathsf{ID}} = H(\mathsf{ID})^s$.

5. *Encryption.* To encrypt $M \in \{0,1\}^n$ under identity ID, randomly select $r \in \mathcal{Z}_p$ and compute the ciphertext as

$$(C_1, C_2) = \big(g^r,\ M \oplus G[\hat{e}(H(\mathsf{ID})^r, P_{pub})]\big).$$

6. *Decryption.* To decrypt (C_1, C_2) for identity ID, compute

$$M' = C_2 \oplus G[\hat{e}(d_{\mathsf{ID}}, C_1)].$$

7. The correctness of this scheme can be easily seen. In the encryption step,

$$\hat{e}(H(\mathsf{ID})^r, P_{pub}) = \hat{e}(H(\mathsf{ID}), g)^{rs} = \hat{e}(H(\mathsf{ID})^s, g^r) = \hat{e}(d_{\mathsf{ID}}, C_1),$$

where the last value is the quantity evaluated in the decryption step.

8. Security relies on the *Computational Bilinear Diffie-Hellman* (CBDH) assumption: given (g^a, g^b, g^c), it is hard to compute $\hat{e}(g, g)^{abc}$. If this assumption does not hold, then from g^r, $P_{pub} = g^s$ and $H(\mathsf{ID}) = g^w$ (for unknown w), an attacker can compute $\hat{e}(g, g)^{rsw}$ which is $\hat{e}(H(\mathsf{ID})^r, P_{pub})$. This can then be used to recover M.

9. The Boneh-Franklin scheme assumes that the output of hash functions G and H is random so that no information about the input can be deduced from the output. Such idealized hash functions are called *random oracles*.

10. Although this assumption is reasonable in practice, it is known that security in the random oracle model does not necessarily hold when the random oracle is replaced by a concrete hash function.

11. CCA2-secure IBE without random oracles was constructed by Boneh and Boyen [BoBo04].

12. The Boneh-Franklin scheme is not secure against an adaptive chosen ciphertext (CCA2) attack. Given the ciphertext (C_1, C_2), one can easily deduce the ciphertext for the message $M \oplus 1$. However, the scheme can be converted to a CCA2-secure scheme by a Fujisaki-Okamoto transformation [FuOk99].

13. Although IBE can eliminate the need to certify public keys, it still does not remove the need for public key management. For instance, if a user's private key is leaked, an official revocation is still needed.

14. Just as with RSA, ElGamal, and elliptic curve schemes, the Boneh-Franklin scheme is broken quickly using quantum computers.

15.5.10 ATTRIBUTE-BASED ENCRYPTION

While identity-based encryption uses one unique informational item about a user as the public key, attribute-based encryption uses multiple attributes of a user to determine access to decryption.

Facts:

1. Attribute-based encryption is a type of public key encryption where the user's secret key and the ciphertext both depend on attributes.

- *Attribute examples:* membership, position title, age, color, height.
- *Motivation:* one can decrypt a ciphertext only if the attributes for the secret key satisfy the attribute constraints embedded in the ciphertext.
- *Example:* to decrypt a ciphertext for the female professors of a mathematics department, the decryption key needs to contain attributes of "female", "professor", and "mathematics department".

- *Collusion-resistant security:* if an attacker collects many keys, then he can decrypt a ciphertext only if one of these keys satisfies the attribute restriction of the ciphertext. In the previous example, a female student and a male mathematics professor cannot jointly decrypt the ciphertext.
- *Application:* in cloud access control, encrypted data is stored in a cloud server. A user who retrieves a ciphertext can decrypt it if and only if he has a key satisfying the encryption policy.

2. The concept of attribute-based encryption was first proposed by Sahai and Waters [SaWa05] and by Goyal et al. [GoEtal06]. In the former, a ciphertext can be decrypted if and only if the number of common attributes embedded in the decryption key and the ciphertext is greater than or equal to a threshold. The latter generalized the scheme: a ciphertext can be decrypted if and only if the attributes in the ciphertext satisfy the access structure embedded in the key.

3. The following are some basic notions:

- Let $e : G_1 \times G_1 \to G_2$ be a bilinear pairing, where G_1 and G_2 are multiplicatively-written groups of prime order p.
- The universe of attributes is the set $\{1, \ldots, n\}$. Each user u has a subset of attributes $\mathcal{A}_u \subseteq \{1, \ldots, n\}$.
- A ciphertext C is prepared using an attribute set $\mathcal{B}$; user u can decrypt C only if $|\mathcal{A}_u \cap \mathcal{B}| \geq d$ for a fixed threshold d.
- *Lagrange interpolation.* For a polynomial $q(x) \in \mathcal{Z}_p[x]$ of degree $d-1$ and a set $\mathcal{S} \subseteq \mathcal{Z}_p - \{0\}$ of size d, we have $q(0) = \sum_{i \in \mathcal{S}} q(i)\lambda_i$, where $\lambda_i = \prod_{j \in \mathcal{S}\setminus\{i\}} \frac{j}{j-i}$.

4. The Sahai-Waters attribute-based encryption scheme [SaWa05] is described in the following facts.

5. *System Setup.* The system manager selects $p, G_1, G_2, \hat{e}$ and a generator g of G_1. Then he selects $t_1, \ldots, t_n, y$ randomly from $\mathcal{Z}_p$ and defines $h_1 = g^{t_1}$, $h_2 = g^{t_2}, \ldots, h_n = g^{t_n}$, $Y = e(g,g)^y$. The system parameters are $(p, G_1, G_2, \hat{e}, h_1, \ldots, h_n, Y)$ and the master key is $(t_1, \ldots, t_n, y)$.

6. *User Key Generation.* For user u, randomly select a polynomial $q(x) \in \mathcal{Z}_p[x]$ such that $q(0) = y$. For each $i \in \mathcal{A}_u$, compute $D_i = g^{\frac{q(i)}{t_i}}$. Then the private key for u is $\{D_i\}_{i \in \mathcal{A}_u}$.

7. *Encryption.* To encrypt $m \in G_2$ with attribute set $\mathcal{B}$, the sender randomly selects $s \in \mathcal{Z}_p$ and computes the ciphertext

$$(\mathcal{B}, C_0, \{C_i\}_{i \in \mathcal{B}}) = (\mathcal{B}, mY^s, \{h_i^s\}_{i \in \mathcal{B}}).$$

8. *Decryption.* To decrypt a ciphertext $(\mathcal{B}, C_0, \{C_i\}_{i \in \mathcal{B}})$ for user u where $|\mathcal{A}_u \cap \mathcal{B}| \geq d$, user u finds a subset $\mathcal{S} \subseteq \mathcal{A}_u \cap \mathcal{B}$ of size d and computes

$$m' = \frac{C_0}{\prod_{i \in \mathcal{S}} \hat{e}(D_i, C_i)^{\lambda_i}}.$$

9. The correctness of the decryption is immediate. Note that $C_0 = mY^s$. The denominator in the decryption step can be simplified as follows:

$$\prod_{i \in \mathcal{S}} \hat{e}(D_i, C_i)^{\lambda_i} = \prod_{i \in \mathcal{S}} \hat{e}(g^{\frac{q(i)}{t_i}}, g^{st_i})^{\lambda_i} = \hat{e}(g,g)^{s \sum_{i \in \mathcal{S}} q(i)\lambda_i} = \hat{e}(g,g)^{sq(0)} = Y^s.$$

10. The idea behind security is the following. To decrypt m, one needs to compute Y^s. If $|\mathcal{A}_u \cap \mathcal{B}| < d$, user u does not have sufficiently many shares to recover $q(0) = y$ in the exponentiation $[e^s(g,g)]^{q(0)} = Y^s$ (due to s in Y^s, the recovery $Y^{s'}$ in other ciphertexts will be useless). Hence, decryption will be infeasible. Any two users u_1, u_2 will have different polynomials $q_1(x), q_2(x)$ when generating their private keys. Hence, it is not productive for them to collude.

11. Security relies on the *Decisional Bilinear Diffie-Hellman* (DBDH) assumption, which states that it is hard to distinguish $(g, g^a, g^b, g^c, \hat{e}(g,g)^{abc})$ from $(g, g^a, g^b, g^c, \hat{e}(g,g)^r)$, where a, b, c, r are uniformly random in $\mathcal{Z}_p$. This assumption does not hold under quantum attacks.

15.6 CRYPTOGRAPHIC MECHANISMS

The cryptosystems described in the previous sections work with several core cryptographic applications that provide immediate, basic services in communications security. These core products are often components in high-level applications.

15.6.1 DIGITAL SIGNATURE

The notion of digital signature was invented by W. Diffie and M. Hellman in 1976. The authors conjectured about the existence of the mechanism. The use of a digital signature is to demonstrate the authenticity of an electronic document. The first practical algorithm was demonstrated through the RSA digital signature scheme.

Definitions:

A ***digital signature*** is an electronic analogue of traditional handwritten signatures.

When using public key methods, a digital signature has a private ***signing key*** s for a signer and a public ***verification key*** v for a verifier. The signing procedure is described by a signing algorithm S and the verification procedure is described by a verification algorithm V.

A signature scheme is secure against a ***public key only attack*** if no attacker can forge a signature only with V.

A signature scheme is secure against a ***known-message attack*** if an attacker cannot forge a signature of a new message after given some messages and their corresponding signatures.

A signature scheme is secure against a ***chosen-message attack*** if an attacker cannot forge a signature of a new message when he adaptively chooses arbitrary messages and receives their corresponding signatures.

Facts:

1. Signatures must be verifiable in the sense that, should a dispute arise as to whether a party signed a document (caused by either a lying signer trying to *repudiate* a signature it did create, or a fraudulent claimant), an unbiased third party can resolve the matter equitably, without requiring access to the signer's secret information (private key).

2. Most of today's digital signature algorithms employ techniques from public key cryptography. It is possible to use symmetric key cryptography to achieve this goal, but it requires the use of a trusted third party, or new keying materials for each signature.

3. A secure digital signature should be resistant to the three types of attacks: public key only attack, known-message attack, and chosen-message attack.

4. There is a digital signature scheme for each of the public key schemes given in §15.5. There are also other approaches as described in this section.

5. *RSA signature scheme.* The plain RSA signature scheme is dual to the RSA public key cryptosystem.

- *Key generation.* The signing key is d, and the verification key is (n, e), which are generated in the same manner as in RSA encryption.
- *Signing.* To sign a message $m \in \mathcal{Z}_n$, the signer computes the signature as $sig = m^d \bmod n$.
- *Verifying.* To verify the signature sig, check if $sig^e \equiv m \pmod{n}$.

6. Given an arbitrary message m, since d is unknown, it is hard to forge the signature $m^d \bmod n$. However, it is easy to forge a signature for some messages. For instance, sig is a valid signature of message $sig^e \bmod n$ since $(sig^e)^d \equiv sig \pmod{n}$.

7. To avoid this forging attack, one should first hash the message m. That is, if $H : \{0,1\}^* \to \{0, \ldots, n-1\}$ is a hash function, the actual signature of m is defined as $sig = H(m)^d \bmod n$. The verification is modified accordingly. Assuming that H is a random oracle and that the RSA assumption holds, the hashed RSA signature is proven secure against chosen-message attacks.

8. The *ElGamal digital signature scheme* is a randomized signature algorithm that generates digital signatures on binary messages with arbitraty length. It requires a hash function $h : \{0,1\}^* \to \mathcal{Z}_p$, where p is a large prime number.

- *Key Generation.* As in the ElGamal cryptosystem, the public key is (p, g, h) and the private key is d.
- *Signing.* To sign a message $m \in \{0,1\}^*$, the signer randomly selects k with $1 \le k \le p-2$ with $\gcd(k, p-1) = 1$, and then computes $X = g^k \bmod p$ and $s = k^{-1}(h(m) - dX) \bmod p - 1$. The signature is (X, s).
- *Verifying.* To verify the signature (X, s), compute $v_1 = h^X \cdot X^s \bmod p$ and $v_2 = g^{h(m)} \bmod p$. Accept the signature if and only if $v_1 = v_2$.

9. The correctness of the ElGamal signature algorithm can be easily seen since $ks \equiv h(m) - dX \pmod{p-1}$. That is, $h(m) \equiv dX + ks \pmod{p-1}$ so that $v_2 \equiv g^{h(m)} \equiv g^{dX+ks} \equiv (g^d)^X \cdot (g^k)^s \equiv h^X \cdot X^s \equiv v_1 \pmod{p-1}$.

10. The security of the ElGamal scheme is based on the discrete logarithm assumption in $\langle g \rangle$.

11. The *Digital Signature Algorithm* (DSA) was adopted in 1994 by the U.S. government as a signature standard [Fi13]. It is a variant of the ElGamal signature scheme and is described as follows:

- *Setup.* The system generator selects a large prime p of bitlength at least 3072 such that $p-1$ has a 256-bit prime factor q. It also selects an element $g \in \mathcal{Z}_p^*$ of order q.
- *Key generation.* Select x from $\mathcal{Z}_q$ randomly and compute $h = g^x \bmod p$. The signing key is x and the verification key is (p, q, g, h).

- *Signing.* To sign a message m with signing key x, the signer randomly selects k from $\mathcal{Z}_q$ and computes

  $$r = (g^k \bmod p) \bmod q \quad \text{and} \quad s = k^{-1}(H(m) + xr) \bmod q.$$

  The signature of m is (r, s).

- *Verifying.* To verify a signed message $(m, (r, s))$, let $w = s^{-1} \bmod q$. Check that

  $$r \overset{?}{=} [(g^{H(m)}h^r)^w \bmod p] \bmod q.$$

  If the equality holds, the signature is accepted; otherwise, it is rejected.

12. The correctness of the signature can be easily seen since

$$(g^{H(m)}h^r)^w \equiv g^{(H(m)+rx)w} \equiv g^k \pmod{p}.$$

13. The security of DSA is based on the discrete logarithm assumption in $\langle g\rangle$.

14. An adaptation of elliptic curve cryptography to DSA is described in ANSI X9.62 as the *Elliptic Curve Digital Signature Algorithm* (ECDSA).

15. The short signature scheme known as *BLS signature* was proposed by D. Boneh, B. Lynn, and H. Shacham [BoLySh04]. The scheme is built using a bilinear pairing.

Namely, let G_1 and G_2 be multiplicatively-written cyclic groups of prime order p. Let g be a generator of G_1 and let $\hat{e} : G_1 \times G_1 \to G_2$ be a bilinear pairing (see §15.5.9). The BLS scheme is specified as follows:

- *Setup.* The system generator selects p, G_1, G_2, g and a hash function $H : \{0,1\}^* \to G_1$.
- *Key generation.* Select $x \in \mathcal{Z}_q$ randomly and compute $h = g^x$. The verification key is (G_1, G_2, p, g, h) and the signing key is x.
- *Signing.* To sign a message m, the signer computes $\sigma = H(m)^x$.
- *Verifying.* To verify the signed message (m, σ), a verifier checks if $\hat{e}(\sigma, g) \overset{?}{=} \hat{e}(H(m), h)$. If equality holds, the signature is accepted; otherwise, it is rejected.

16. The correctness of the BLS signature follows from bilinearity of $\hat{e}$.

17. It was proven in [BoLySh04] that BLS is secure against chosen-message attack, assuming that H is a random function and that the CDH assumption in G_1 holds.

Examples:

1. *RSA Signature.* Using the RSA key pair $(n, e) = (4399, 23)$ and $d = 927$, to sign the message $m = 19$, compute $sig = m^d \bmod n = 19^{927} \bmod 4399 = 4155$. To verify the signature $sig = 4155$, compute $sig^e \equiv 4155^{23} \equiv 19 \equiv m \pmod{4399}$.

2. *ElGamal Signature.* Let the ElGamal parameters be $(p, g, h) = (3767, 7, 3467)$ and $d = 15$. Suppose we need to sign the message m where $h(m) = 125$. Randomly choose the value $k = 87$. Note that $\gcd(87, 3766) = 1$. Compute $X = 7^{87} \bmod 3767 = 3113$ and $s = k^{-1}(h(m) - dX) \bmod p - 1 = 87^{-1}(125 - 15 \cdot 3113) \bmod 3766 = 3274$. The signature is $(3113, 3274)$. To verify, compute $v_1 = h^X \cdot X^s \bmod p = 3467^{3113} \cdot 3113^{3274} \bmod 3767 = 3030$, and $v_2 = g^{h(m)} \bmod p = 7^{125} \bmod 3767 = 3030$. Note that $v_1 = v_2$.

3. *DSA Key Setup.* Let $p = 15464731$. Since $p - 1 = 15464730 = 2 \cdot 3 \cdot 5 \cdot 17 \cdot 30323$, let $q = 30323$. Note that 2 is a generator of $\mathcal{Z}_p^*$. Then $g = 2^{2 \cdot 3 \cdot 5 \cdot 17} = 2241624$ has order q. Consider $x = 5$. Then $h = g^x \bmod p = 6922386$. The signing key is $x = 5$ and the verification key is $(p, q, g, h) = (15464731, 30323, 2241624, 6922386)$. Note that DSA parameters have much larger specified bitlength.

4. *DSA Signing.* Suppose the message m has hash value $H(m) = 10628$. The signer randomly selects $k = 14 \in \mathcal{Z}_q$ and computes $r = (g^k \bmod p) \bmod q = 5120962 \bmod q = 26698$ and $s = k^{-1}(H(m) + xr) \bmod q = 14626$. The signature for m is $(r, s) = (26698, 14626)$.

5. *DSA Verification.* To verify the signed message m having the signature $(r, s) = (26698, 14626)$, evaluate $w = s^{-1} \bmod q = 18375$. Then $[(g^{H(m)}h^r)^w \bmod p] \bmod q = 5120962 \bmod q = 26698 = r$.

15.6.2 MESSAGE AUTHENTICATION CODE

Message authentication code, also called keyed hash function, is a cryptographic primitive that protects the authenticity and integrity of a message.

Definitions:

A ***message authentication code*** (MAC) scheme is a keyed function $F_K(\cdot)$ acting on messages m such that when m and $F_K(m)$ are transmitted, the intended recipient will be assured of the authenticity of m.

If a computationally bounded attacker has obtained the MACs of n messages of its choice but still cannot forge the MAC of a new message with probability ϵ, the system is called an ***(n, ϵ)-secure MAC***.

If ϵ is negligible, and n and the runtime of an attacker are polynomially bounded, then the MAC scheme is ***existentially unforgeable***.

A ***universal$_2$ hash function*** from S to V is a keyed hash function H_K such that for any pair of distinct inputs x, y, $H_K(x) = H_K(y)$ holds for at most $\frac{1}{|V|}$ of all possible keys.

Facts:

1. In a MAC scheme, the sender and the receiver share the secret key K. This primitive was introduced by E. Gilbert, F. MacWilliams, and N. Sloane [GiMaSl74].

2. The security notion for MAC schemes is similar to that of digital signature schemes. An attacker may request the MACs of some messages of its choosing, and its objective is to forge the MAC of some new message.

3. *Onetime MAC.* Let p be a large prime and let the key $K = (a, b)$ be chosen randomly from $\mathcal{Z}_p^2$. Consider the MAC scheme $F_{a,b}(x) = ax + b \mod p$, where $a, b \in \mathcal{Z}_p$.

- It is immediate that this scheme is $(1, 1/p)$-secure.
- This is a special case of a universal$_2$ hash function used as a MAC by Wegman and Carter [WeCa81].

4. *HMAC.* This is a message authentication code proposed in 1996 by M. Bellare, R. Canetti, and H. Krawczyk [BeCaKr96]. It is standardized as FIPS PUB 198-1.

Let $\text{HMAC}_K(m) = H\big((K \oplus \mathit{opad}) || H((K \oplus \mathit{ipad}) || m)\big)$, with H an iterated hash function (e.g., MD5, SHA-1, SHA-256), K is the secret key, *opad* is the constant 0x5c5c5c...5c5c, and *ipad* is the constant 0x363636...3636 such that *opad* and *ipad* have the same length as K.

5. *CBC-MAC.* This is a message authentication code obtained from the CBC encryption mode. The construction is as follows. Let $K = (K_1, K_2)$ be the secret key and let (E, D) be a block cipher of blocklength ℓ.

- Suppose m is the message to be authenticated. The sender divides m into ℓ-bit blocks $m_1||m_2||\ldots||m_t$.
- Set $V_0 = 0$. For $i = 0, \ldots, t$, compute $V_i = E_{K_1}(V_{i-1} \oplus m_i)$.
- Define the MAC of m to be $E_{K_2}(V_t)$.

6. The plain CBC-MAC is simply V_t. However, this construction is not secure. Indeed, given the MAC σ of $m_1||m_2||\ldots||m_t$ and the MAC σ' of $m_1'||m_2'|||\ldots||m_s'$, one can compute $m_1'' = V_t \oplus m_1'$. Then the MAC of

$$m_1||\ldots||m_t||m_1''||m_2'||m_3'||\ldots||m_s'$$

is σ', which follows from the fact $m_1'' \oplus \sigma = 0 \oplus m_1'$.

7. An alternative patch to the plain CBC-MAC is to prepend the length of m to the input. The problem with this variant is that the message length must be known before the processing begins.

15.6.3 KEY EXCHANGE

Two communicating parties wishing to exchange messages using symmetric key encryption must first establish an encryption key. Key exchange is a mechanism that allows two parties to securely share a secret key so that no one else can obtain a copy.

Facts:

1. A shared key is required whenever a symmetric key system is used. When a key is used for just one communcations session, such a key is called a *session key*.

2. The idea of key exchange in the modern era originated in the landmark Diffie-Hellman paper [DiHe76].

3. Generally, key exchange is assumed to take place over a public channel, therefore, any key exchange protocol must assume that all messages are available to any person including the adversary. The ultimate goal of the adversary is to compromise the secret key shared between communicating parties.

4. The security model describes what information the adversary can obtain and what actions it can take. Two types of security are considered: *passive security* and *active security*. In *passive security*, an adversary can observe messages transmitted over the channel but cannot modify them. In *active security*, an adversary can modify, delete, and replay messages transmitted over the channel. In both cases, the goal is to compute the key shared between the legitimate communicating parties.

5. *Diffie-Hellman key exchange.* Malcolm J. Williamson of GCHQ came up with the Diffie-Hellman key exchange in 1974. His work was unknown to the public until its declassification in 1997.

Sender (A) and Receiver (B) agree on large primes p and q, where q divides $p - 1$, and an element g of order q in $\mathcal{Z}_p^*$. The steps of this protocol are as follows:

- A selects x randomly, where $1 \leq x \leq q - 1$, and sends g^x to B.
- Upon receiving g^x, B selects a random value y, $1 \leq y \leq q - 1$, and sends g^y to A. Then B computes the shared key as $sk = (g^x)^y = g^{xy}$.
- Upon receiving g^y, A computes the shared key as $sk = (g^y)^x = g^{xy}$.

6. The protocol is passively secure if the Computational Diffie-Hellman (CDH) assumption holds. That is, it is computationally infeasible to compute g^{xy} from g^x and g^y. However, the protocol is not actively secure.

7. Nonetheless, the Diffie-Hellman key agreement protocol serves as a basic mechanism for constructing actively-secure key establishment protocols.

8. The *Internet Key Exchange* (IKE) protocol [HaCa98] is used in IPsec standards. Its security against active attacks has been proven by R. Canetti and H. Krawczyk [CaKr02].

Let p, q be large primes with $q \mid p-1$ and let g be an element of order q in $\mathcal{Z}_p^*$. Suppose (Sig, Ver) is a signature scheme and let MAC be a message authentication code. Let $F_K(\cdot) : \{0,1\}^* \to \{0,1\}^{2\lambda}$ be a keyed function (called a *pseudorandom function*) whose outputs appear random to an attacker who does not know K. The steps of this protocol are the following:

- *Setup.* Each user i generates a signing key s_i and verification key v_i of (Sig, Ver). Then s_i is the private key and v_i is the public key for user i.
- *Protocol.* The key exchange between user i and user r proceeds as follows:
  - ◇ User i selects a random $x, 1 \le x \le q-1$, and sends g^x and a session-id s to user r.
  - ◇ User r selects a random $y, 1 \le y \le q-1$, computes $(k_0, k_1) = F_{g^{xy}}(0)$, and sends
  $$(s, g^y, Sig_{s_r}(1||s||g^x||g^y), \mathrm{MAC}_{k_1}(1||s||r)) = (s, \beta, \sigma, \tau)$$
  to user i.
  - ◇ Upon receiving (s, β, σ, τ), user i computes $(k_0', k_1') = F_{\beta^x}(0)$ and verifies that $Ver_{v_r}(\sigma) = 1$ and $\tau = \mathrm{MAC}_{k_1'}(1||s||r)$. If the verification passes, user i defines k_0' as the shared key and sends
  $$(s, Sig_{s_i}(0||s||g^y||g^x), \mathrm{MAC}_{k_1'}(0||s||i)) = (s, \sigma', \tau')$$
  to user r; otherwise, user i rejects.
  - ◇ Upon receiving (s, σ', τ'), user r verifies that σ' and τ' are valid. If so, user r accepts k_0 as the shared key; otherwise, user r rejects.

9. The IKE protocol is essentially an authenticated variant of the Diffie-Hellman key exchange.

10. The protocol guarantees that g^y and g^x originated from the legitimate parties. g^y and g^x are cryptographically bound in σ' and σ to guarantee that both parties see the same (g^y, g^x).

11. The purpose of the session id s is to prevent attacks that combine data from different sessions.

12. The MAC is used to ensure that the other party has indeed computed the session key. This is called *explicit authentication.*

13. *Password-based key exchange.* Passwords are probably the most popular mechanism for access control. Naturally, key exchange using a password as the user's long-term secret is useful.

14. M. Bellare, D. Pointcheval, and P. Rogaway [BePoRo00] proposed a provably secure password-based key exchange protocol that is based on the encrypted key exchange (EKE) technique of Bellovin and Merritt [BeMe92].

Let π be a password shared between Alice and Bob. Let p, q be large primes with $q \mid p-1$, and let g be an element of order q in $\mathcal{Z}_p^*$. Let $E_\pi(\cdot) : G \to G$ be a symmetric key encryption scheme with decryption algorithm $D_\pi(\cdot)$, and let H be a hash function. The steps for the password-based key exchange protocol are as follows:

- Party A selects x randomly from $\mathcal{Z}_q$ and sends $(A, E_\pi(g^x)) = (A, \beta)$ to party B.
- On receiving (A, β), B recovers $g^x = D_\pi(\beta)$, randomly selects $y \in \mathcal{Z}_q$, defines $k = H(A, B, g^x, g^y, g^{xy})$, and sends $(B, E_\pi(g^y), H(k, 1)) = (B, \gamma, \tau_1)$ to A.
- On receiving (B, γ, τ_1), A recovers $g^y = D_\pi(\gamma)$, computes $k = H(A, B, g^x, g^y, g^{xy})$, and checks if $\tau_1 = H(k, 1)$. If yes, then A sends $\tau_2 = H(k, 2)$ to B and defines the session key to be $sk = H(k, 0)$; otherwise, A rejects.
- On receiving τ_2, B verifies that $\tau_2 = H(k, 2)$. If yes, A defines the session key to be $sk = H(k, 0)$; otherwise, B rejects.

15. This protocol is actively secure. The security proof relies on the assumption that H is a random oracle and E is an ideal cipher. Researchers have made progress towards removing such assumptions (see [GeLi03], [GrKa10], [JiGo04], [KaOsYu01]).

15.6.4 HOMOMORPHIC ENCRYPTION

Homomorphic encryption is an encryption mechanism that allows certain computations to be carried out on ciphertext in such a way that decryption of the result yields the same quantity as would be obtained if the computations were performed on the original plaintext.

Definition:

An encryption scheme is ***additively homomorphic*** if the ciphertext of $m_1 + m_2$ can be obtained from ciphertexts of m_1 and m_2.

An encryption scheme is ***multiplicatively homomorphic*** if the ciphertext of $m_1 m_2$ can be obtained from ciphertexts of m_1 and m_2.

An encryption scheme is ***fully homomorphic*** if it is both multiplicatively and additively homomorphic.

Facts:

1. *RSA cryptosystem is multiplicatively homomorphic.* Given ciphertexts $c_1 = m_1^e \bmod n$ and $c_2 = m_2^e \bmod n$, the ciphertext of $m = m_1 \cdot m_2 \bmod n$ is $c = c_1 \cdot c_2 \bmod n$. However, RSA is not additively homomorphic.

2. *ElGamal cryptosystem is multiplicatively homomorphic.* Given ciphertexts $c_1 = (g^r, m_1 h^r)$ and $c_2 = (g^s, m_2 h^s)$, the ciphertext of $m = m_1 \cdot m_2$ is $c = (g^{r+s}, m_1 m_2 h^{r+s})$. ElGamal is not additively homomorphic.

3. *Paillier cryptosystem is additively homomorphic.* Given ciphertexts $c_1 = g^{m_1} r_1^n$ and $c_2 = g^{m_2} r_2^n$, then $c_1 c_2 = g^{m_1+m_2}(r_1 r_2)^n$.

4. It had long been an open question whether a fully homomorphic public key encryption cryptosystem existed. The existence of such a public key cryptosystem would be important because when such a cryptosystem is used, any computation can be formulated as a circuit of addition and multiplication operations, whereby a third party can compute any function of arbitrary ciphertexts.

5. In 2009, C. Gentry solved this open question by constructing the first fully homomorphic public key cryptosystem using lattice-based cryptography [Ge09]. Although this solved the open question, his system is far too slow to be practical.

6. An application of fully homomorphic encryption is *cloud computing* (§15.7.3).

7. All currently studied fully homomorphic cryptosystems are public key based.

8. In 2010, a second fully homomorphic cryptosystem using integer-based cryptography was developed by M. van Dijk, C. Gentry, S. Halevi, and V. Vaikuntanathan [vDEtal10]. Like Gentry's original cryptosystem, this approach is also impractical.

9. After the development of the first two fully homomorphic cryptosystems, the search for a practical fully homomorphic cryptosystem continued. Much progress has been made with the development of a second generation of fully homomorphic cryptosystems, but as of 2017 work remains before there is a fully homomorphic cryptosystem that can be used in real-world applications.

10. In commercial applications, it may be desirable to chain certain services together while keeping the secrecy of the data intact. Homomorphic encryption can be used to achieve privacy where information is processed in the encrypted form.

Example:

1. Homomorphic encryption can be used in health care where digital patient data from multiple sources can be stored securely while computations are being performed without violating a patient's right to confidentiality.

15.6.5 SECRET SHARING

Secret sharing is a mechanism that allows a group of users to share a secret such that a sufficient number of them can recover the secret whereas an insufficient number of users is unable to obtain any information about the secret.

Definition:

In a ***(t, n)*-secret sharing** scheme, each of n users receives a ***share*** of a secret s so that any t or more of them can recover s, but any group of fewer than t parties cannot determine any information about s.

Facts:

1. Secret sharing was independently invented by Shamir [Sh79] and Blakley [Bl79].

2. *Shamir's secret sharing scheme.* Let p be a prime; the secret is $s \in \mathcal{F}_p$.

- *Sharing.* The dealer chooses a random polynomial $f(x)$ of degree $t-1$ with constant term s. That is, $f(x) = a_0 + a_1x + \cdots + a_{t-1}x^{t-1}$ where a_i for $i \geq 1$ is uniformly random over $\mathcal{F}_p$ and $a_0 = s$. The share for party i is $s_i = f(i)$.
- *Recovery.* When at least t parties wish to recover the secret s, they jointly do the following
  - ◇ Choose some arbitrary t parties $i_1, \ldots, i_t$ from the set of colluders.
  - ◇ Since $s_{i_j} = f(i_j)$ for $j = 1, \ldots, t$, they use Lagrange interpolation to obtain

$$f(x) = \textstyle\sum_{j=1}^{t} s_j \frac{\prod_{1\leq k\leq t, k\neq j}(x-i_k)}{\prod_{1\leq k\leq t, k\neq j}(i_j-i_k)}.$$

They then recover

$$s = f(0) = \textstyle\sum_{j=1}^{t} s_j \frac{\prod_{1\leq k\leq t, k\neq j} i_k}{\prod_{1\leq k\leq t, k\neq j}(i_k-i_j)}.$$

- *Security.* If fewer than t parties (say, parties $1, \dots, t-1$) wish to recover s, they can form
$$s_j = a_0 + a_1 j + \cdots + a_{t-1} j^{t-1}, \ j = 1, \dots, t-1.$$
Notice that $(s_1, \dots, s_t)$ uniquely recovers $(a_0, \dots, a_{t-1})$ and vice versa. Hence, $(s_1, \dots, s_t)$ is in 1-1 correspondence with $(a_0, \dots, a_{t-1})$. Since the latter is uniformly random over $\mathcal{F}_p^t$, so too is the former. Hence, given $(s_1, \dots, s_{t-1})$, a_0 is uniformly random over $\mathcal{F}_p$ due to the randomness of s_t, and thus $(s_1, \dots, s_{t-1})$ reveals nothing about s.

3. When $t = n$, an (n, n)-secret sharing is one where any n parties can recover the secret while the absence of one or more parties will leak no information about s. In this case, a simpler scheme exists whereby the dealer chooses $n-1$ random shares $s_1, \dots, s_{n-1}$ and defines the share $s_n = s - s_1 - \cdots - s_{n-1} \bmod p$.

4. *Blakley's secret sharing scheme.* The scheme uses a t-dimensional projective space $PG(t, \mathcal{F}_q)$. Let the secret be a random point $P \in PG(t, \mathcal{F}_q)$. The scheme is described as follows:

- *Sharing.* To share a secret $P \in PG(t, \mathcal{F}_q)$ among n users, the dealer randomly chooses n hyperplanes that contain P. Each user receives one of these hyperplanes as his share.
- *Recovery.* If any $v \geq t$ users want to recover P, t of the users are selected to combine their shares to form t linear equations, the solution of which determines P.
- *Correctness.* In the recovery, the t equations must be linearly independent in order to recover P. This can be satisfied with high probability when n is not too large while q is large.
- *Security.* Any set of fewer than t users can only form a linear system with fewer than t equations. This determines a proper subspace of $PG(t, \mathcal{F}_q)$, but cannot determine P.

5. Compared to Shamir's scheme, the Blakley sharing scheme is not perfectly secure. That is, fewer than t users can still obtain some information about the secret P compared to randomly guessing P. The correctness also does not hold with probability 1 as there is a nonzero probability that some subset of fewer than t shares (i.e., hyperplanes) can linearly generate another particular share.

Examples:

1. Shares of a missile launching code can be given to a list of 12 generals, where at least five of them need to collaborate to reveal the launch code.

2. A private company can use secret sharing to protect unauthorized fund transfers over a certain threshold by giving shares of the authorization code to multiple members of management.

15.6.6 CONFERENCE KEY DISTRIBUTION

Among the members of a group of users, there may be a need for a subgroup to perform secure communications. Conference key distribution was invented to achieve this purpose.

Definitions:

A ***conference key distribution*** scheme is a mechanism whereby a trusted authority assigns a piece of secret data to each user so that any desired group of users can compute a common secret key (called a ***group key***).

If a group of users compute their group key interactively, then the scheme is called an ***interactive key distribution*** (*key agreement* or *group key exchange*); otherwise it is called a ***non-interactive key distribution*** (or *key pre-distribution*).

If the total number of users is n, then a *non-interactive conference distribution scheme* (see Fact 2) secure against t colluding users is called ***(n, t)-secure***.

If the scheme is secure against computationally unbounded attackers, then it is called ***unconditionally secure***; otherwise, it is called ***computationally secure***.

Facts:

1. Diffie-Hellman key exchange is an interactive key distribution scheme for a group of size two.

2. In a non-interactive scenario, security requires that colluding users should not be able to compute a group key when none of the colluding users is a group member.

- To ensure that an efficient construction is possible, the number of colluding users is usually bounded by a threshold t.

3. In an interactive scenario, security is more complex, and considers both passive attack and active attacks. An attacker can corrupt a number of users, and thereby obtain the secret data of these users.

- In a passive attack, an attacker can only observe the transmitted messages.
- In an active attack, an attacker can impersonate legitimate users and modify messages sent by users.
- In both cases, the attacker's objective is to learn a conference key that he is not supposed to know.

4. *Blom non-interactive key distribution.* Blom [Bl84] proposed a non-interactive conference key distribution scheme without public key components. His scheme is for subgroups of size two and is secure against a collusion of size k. Suppose there are n users.

- *Key setup.* The key setup for users is based on the $(k+1)$-by-n generator matrix G of an $(n, k+1)$-MDS code over a finite field $\mathcal{F}_q$. Let D be a $(k+1) \times (k+1)$ purely random but symmetric matrix over $\mathcal{F}_q$. Then the secret key K_i for user i is defined as the ith column of DG.
- *Conference key computation.* The conference key k_{ij} for users i and j is the entry (i, j) of the square matrix $(DG)^T G = G^T DG$. This is the inner product of the ith column of DG and the jth column of G. User i can compute k_{ij} since i possesses K_i and G is public. On the other hand, user j can compute k_{ij} as the inner product of the ith column of G and the jth column of DG.
- *Security.* Blom's scheme is secure against a collusion of size k. The colluders possess k columns of DG. However, since G is the generator matrix of an $(n, k+1)$-MDS code, any $k+1$ columns of G are linearly independent. This independence does not change by left multiplying with a full-ranked square matrix D (ignoring the negligible probability that rank$(D) < k+1$). Hence, K_i is independent of any collusion of size k.

5. *Polynomial interpolation non-interactive key distribution.* Blundo et al. [BlEtal98] extended Blom's scheme for conferences of arbitrary size t. Their scheme is based on polynomial representations. For security against collusions of size k, their scheme is described as follows:

- *Key setup.* Let σ denote an arbitrary permutation over $\{1, \ldots, t\}$. Then define

  $$P(x_1, \ldots, x_t) = \textstyle\sum_{0 \le j_1 \le \cdots \le j_t \le k} a_{j_1 \cdots j_t} \sum_{\sigma} x_{\sigma(1)}^{j_1} \cdots x_{\sigma(t)}^{j_t},$$

  where $a_{j_1 \cdots j_t}$ is uniformly random over the finite field $\mathcal{F}_q$. Note that $P(x_1, \ldots, x_t)$ is symmetric. The secret key for user i is defined as $K_i = P(i, x_2, \ldots, x_t)$ for $i = 1, \ldots, n$.

- *Conference key computation.* The conference key for a group $G = \{i_1, \ldots, i_t\}$ is $k_G = P(i_1, \ldots, i_t)$. User i_ℓ can compute $k_G = P(i_\ell, i_1, \ldots, i_{\ell-1}, i_{\ell+1}, \ldots, i_t)$. The scheme works because $(\ell, 1, \ldots, \ell - 1, \ell + 1, \ldots, t)$ is a permutation of $(1, \ldots, t)$ and $P(x_1, \ldots, x_t)$ is symmetric.

- *Security.* (n, k)-security requires that any collusion group $\{i_1^*, \ldots, i_k^*\} \subset \{1, \ldots, n\}$ is unable to compute a conference key k_G, when no member in G colluded.
  - ◇ Suppose $G = \{i_1, \ldots, i_t\}$. Let $P_0(x_1, \ldots, x_t)$ be any symmetric polynomial of degree $\le k$ such that $P_0(i_u^*, x_2, \ldots, x_t) = K_{i_u^*}$ for $u = 1, \ldots, k$.
  - ◇ In addition, note that $A(x_1, \ldots, x_t) = \prod_{j=1}^{k} \prod_{v=1}^{t} (x_v - i_j^*)$ is symmetric with degree k and satisfies $A(i_j^*, x_2, \ldots, x_t) = 0$.
  - ◇ Then, for any $\alpha \in \mathcal{F}_q$, $P_0(x_1, \ldots, x_t) + \alpha A(x_1, \ldots, x_t)$ can serve as a candidate of $P(x_1, \ldots, x_t)$ (in view of colluders $\{i_1^*, \ldots, i_k^*\}$), because when evaluated at i_j^*, it yields the result $K_{i_j^*}$.
  - ◇ However, it has a conference key $P_0(i_1, \ldots, i_t) + \alpha \prod_{j=1}^{k} \prod_{v=1}^{t} (i_v - i_j^*)$ for G, which is uniformly random over $\mathcal{F}_q$ (due to the randomness of α) as $i_v \ne i_j^*$. Thus, the colluders have no information about k_G.

6. *Fiat-Naor scheme.* Fiat and Naor [FiNa93] proposed a non-interactive key distribution scheme. This scheme is designed for n users $\{1, \ldots, n\}$ and is unconditionally secure against w colluders.

- *Key setup.* Let $P_1, \ldots, P_\nu$ be all the subsets of $\{1, \ldots, n\}$ of size at least $n-w$. Note that $\nu = \sum_{i=0}^{w} \binom{n}{i}$. Associate each P_i with a random key k_{P_i}. The secret key for user j is $K_j = \{k_{P_i} \mid j \in P_i,\ i = 1, \ldots, \nu\}$. Thus, K_j has size $\sum_{i=0}^{w} \binom{n-1}{i}$.

- *Conference key computation.* For any group $G \subseteq \{1, \ldots, n\}$, the conference key is $k_G = \sum_{i: G \subseteq P_i} k_{P_i}$. Since every member $j \in G$ knows k_{P_i} for any P_i containing G, user j can compute k_G.

- *Security.* The Fiat-Naor scheme is secure against w colluders.
  - ◇ Suppose the colluders are $\{i_1, \ldots, i_w\}$. Then, for any G not containing any colluders, $k_G = \sum_{j: G \subseteq P_j} k_{P_j}$ is independent of $\{K_{i_1}, \ldots, K_{i_w}\}$.
  - ◇ Notice that there exists t such that $P_t = \{1, \ldots, n\} - \{i_1, \ldots, i_w\}$ and hence k_{P_t} is independent of the keys of colluders. Since $i_j \notin G$ for any j, $G \subseteq P_t$. Thus, k_{P_t} appears in the sum of k_G. So k_G is independent of the keys of colluders.

7. *Tripartite key distribution from pairing.* Joux [Jo00] presented a one-round computationally secure key distribution scheme for groups of size three. It is based on a bilinear pairing $\hat{e} : G_1 \times G_1 \to G_2$, where G_1, G_2 are groups of prime order p.

- *Key setup.* Let $g \in G_1$ be a generator. Then each user i randomly selects a_i, $1 \leq a_i \leq q-1$, as its private key and publishes $Q_i = g^{a_i}$ as its public key.
- *Conference key computation.* For any group $\{i, j, \ell\}$, the conference key is $k_{\{i,j,\ell\}} = \hat{e}(g,g)^{a_i a_j a_\ell}$. User i can compute this key using a_i as $\hat{e}(Q_j, Q_\ell)^{a_i} = \hat{e}(g,g)^{a_i a_j a_\ell}$.
- *Security.* The security of Joux's scheme requires the *Computational Bilinear Diffie-Hellman* (CBDH) assumption.

8. *Burmester-Desmedt interactive key distribution scheme.* Burmester and Desmedt [BuDe94] proposed an interactive key distribution scheme. Their scheme is a generalization of the Diffie-Hellman key exchange to the multiparty setting. It provides a way to compute the conference key for an entire group of users. However, it is insecure when used to compute a group key for a proper subgroup using the same key setup.

Let p and q be large primes with $q \mid p-1$. Let $g \in \mathcal{Z}_p^*$ be an element of order q.

- *Key setup.* For $i = 0, \ldots, n-1$, user i randomly selects a secret key a_i, $1 \leq a_i \leq q-1$, and publishes the public key $A_i = g^{a_i}$.
- *Conference key computation.* User i computes $X_i = (A_{i+1}/A_{i-1})^{a_i}$ and broadcasts X_i to group members, where index arithmetic is performed modulo n when necessary. The group key is defined as $k = g^{a_0 a_1 + \cdots + a_{n-2} a_{n-1} + a_{n-1} a_0}$. For any user j, notice that $A_{i-1}^{\ell a_i} X_i^{\ell - 1} = g^{a_{i-1} a_i} \times A_{i+1}^{(\ell-1) a_i}$ for each i. Therefore, user j can compute k by computing

$$\begin{aligned}
& A_{j-1}^{a_j n} X_{j+1}^{n-1} X_{j+2}^{n-2} \cdots X_{j-2}^{1} \qquad (6) \\
& \quad = g^{a_{j-1} a_j} \times A_j^{a_{j+1}(n-1)} X_{j+2}^{n-2} \cdots X_{j-2}^{1} \\
& \quad = g^{a_{j-1} a_j + a_j a_{j+1}} \times A_{j+1}^{a_{j+2}(n-2)} X_{j+3}^{n-3} \cdots X_{j-2}^{1} \\
& \quad \vdots \\
& \quad = g^{a_{j-1} a_j + a_j a_{j+1} + \cdots + a_{j-2} a_{j-1}} = g^{a_0 a_1 + \cdots + a_{n-1} a_0}.
\end{aligned}$$

- *Security.* The Burmester-Desmedt scheme is secure against a passive outsider attack. The attacker knows all of $X_1, A_1, \ldots, X_{n-1}, A_{n-1}$.
  - ◇ In a passive attack, the attacker cannot compute $g^{a_0 a_1 + \cdots + a_{n-1} a_0}$. Otherwise, from Eq. (6), the attacker can compute $A_{j-1}^{a_j} = g^{a_{j-1} a_j}$. Since $A_1, \ldots, A_{n-1}$ is computationally independent of $g^{a_0 a_1}, \ldots, g^{a_{n-1} a_0}$ and hence is computationally independent of $g^{a_{j-1} a_j}, X_1, \ldots, X_{n-1}$, the attacker must compute $g^{a_{j-1} a_j}$ solely based on $X_1, \ldots, X_{n-1}$. However, this is impossible because they are statistically independent.
  - ◇ Since conference key distribution is usually used to help a subgroup derive a conference key, one might think that the Burmester-Desmedt scheme can also do the same as key derivation is completely compatible with any subgroup. However, once a user i is involved in a group key computation for a group (say, $\{1, \ldots, n\}$), user i can compute $A_{j-1}^{a_j}$ using the group key and Eq. (6). Then user i can compute the conference key of any group that involves users $j-1$ and j (and not including user i).

15.6.7 OBLIVIOUS TRANSFER

There are a variety of reasons why someone may wish to send one of many pieces of information to a receiver without knowing which piece has been transferred. This task can be done using what is known as oblivious transfer.

Definitions:

Oblivious transfer (***OT***) is a protocol in which Alice has a set of bit strings as her input and Bob can choose only one string to be transferred to him and Alice cannot determine which string this is.

When Alice's set has k elements, the protocol is called $\boldsymbol{OT_1^k}$.

In a ***k-out-of-n oblivious transfer***, Alice has a set of n bit strings as her input, where Bob chooses k strings to be transferred.

Facts:

1. Oblivious transfer originated in Rabin's work [Ra81], where he described a method to send a message m from Alice to Bob with a success probability of $\frac{1}{2}$, while Alice does not know if Bob received the message or not.

- Alice generates RSA parameters p, q, n, e, d, and sends n, e, m^e to Bob.
- Bob chooses a random value $x \in \mathcal{Z}_n^*$ and evaluates $c = x^2 \bmod n$. Note that since $x \in \mathcal{Z}_n^*$, there are four square roots of $c \bmod n$. He sends c to Alice.
- With the knowledge of p, q, Alice finds a square root y of c easily, and sends y to Bob.
- If y is not x or $-x$, then Bob can factor n by evaluating $\gcd(x - y, n)$, and thus solve for d to recover m. Otherwise, Bob cannot recover m from m^e. Since there are four square roots, Bob recovers m with probability $\frac{1}{2}$.

2. A key requirement of oblivious transfer is that Alice cannot learn which element Bob has chosen while Bob cannot learn any information about the remaining elements in the set.

3. Three constructions of Naor et al. [NaPi01], [NaPi05] are the simplest among all provably secure OT schemes.

4. The *one-out-of-two oblivious transfer protocol* (OT_1^2) is due to Naor and Pinkas [NaPi01].

5. Alice has two messages M_0, M_1. Bob has a bit σ and wishes to learn M_σ. The protocol proceeds as follows:

- Let p, q be large primes with $q \mid p - 1$ and let $g \in \mathcal{Z}_p^*$ be an element of order q.

  Bob randomly selects $a, b, r \in \mathcal{Z}_q$ and sends $A = g^a$, $B = g^b$, $C_\sigma = g^{ab}$, and $C_{1-\sigma} = g^r$ to Alice.
- Alice verifies that $C_0 \neq C_1$. Then she randomly selects $s_0, s_1, t_0, t_1 \in \mathcal{Z}_q$, and computes and sends

  $$W_0 = (A^{s_0} g^{t_0}, M_0 C_0^{s_0} B^{t_0}),\ W_1 = (A^{s_1} g^{t_1}, M_1 C_1^{s_1} B^{t_1})$$

  to Bob.
- Upon receiving $W_0 = (\alpha_0, \beta_0)$ and $W_1 = (\alpha_1, \beta_1)$, Bob computes $M_\sigma = \beta_\sigma / \alpha_\sigma^b$.

6. *Correctness.* Notice that $C_\sigma = A^b$. Thus, $(A^{s_\sigma} g^{t_\sigma})^b = C_\sigma^{s_\sigma} B^{t_\sigma}$ and $M_\sigma = \beta_\sigma / \alpha_\sigma^b$.

7. *Alice's privacy.* Since $C_0 \neq C_1$, $C_{\bar\sigma}$ is not the Diffie-Hellman value corresponding to (A, B), where $\bar\sigma = 1 - \sigma$. Therefore, $\frac{r}{a} \neq \frac{b}{1}$. Thus, $C_{\bar\sigma}^{s_{\bar\sigma}} B^{t_{\bar\sigma}}$ is independent of $A^{t_{\bar\sigma}} g^{t_{\bar\sigma}}$. That is, $M_{\bar\sigma}$ is independent of Alice's knowledge.

8. The Decisional Diffie-Hellman (DDH) assumption states that it is hard to distinguish (g^a, g^b, g^{ab}) from (g^a, g^b, g^r), when a, b, r are randomly selected.

9. *Bob's privacy.* σ is computationally independent of Alice's knowledge (A, B, C_0, C_1) since distinguishing C_0 from C_1 given (A, B) is the DDH problem.

10. *One-out-of-many oblivious transfer* (OT_1^k). The OT_1^k extension of the OT_1^2 protocol originated in [NaPi01]. Suppose Alice has messages $M_0, \ldots, M_{k-1}$, and Bob has an index $I \in \{0, \ldots, k-1\}$ and wishes to learn M_I. The protocol proceeds as follows:

- Let p, q be large primes with $q \mid p-1$ and let $g \in \mathcal{Z}_p^*$ be an element of order q. Bob randomly selects $a, b, r_j \in \mathcal{Z}_q$ for $j \neq I$ and computes $A = g^a, B = g^b, C_I = g^{ab}, C_j = g^{r_j}, \forall j \neq I$. Finally, he sends $(A, B, C_0, \ldots, C_{k-1})$ to Alice.
- Alice verifies $C_i \neq C_j$ for $i \neq j$. Then she computes and sends
$$W_i = (A^{s_i} g^{t_i}, M_i C_i^{s_i} B^{t_i}),\ \forall i = 0, \ldots, k-1$$
to Bob, where s_i, t_i are randomly selected from $\mathcal{Z}_q$.
- Upon receiving $W_i = (\alpha_i, \beta_i)$, $i = 0, \ldots, k-1$, Bob computes $M_I = \beta_I / \alpha_I^b$.

11. Correctness and privacy analyses for Alice and Bob are similar to OT_1^2 in Fact 10.

12. *OT_1^k from a general setup assumption.* This construction of OT_1^k is due to Naor and Pinkas [NaPi05]. The scheme, built from an OT_1^2 protocol and a one-way function, is described in the following facts.

13. Let $F_K(\cdot)$ be a *pseudorandom function*, i.e., a keyed function such that without the knowledge of K, one cannot distinguish outputs of $F_K(\cdot)$ from random values, even if one can adaptively learn the outputs of many other inputs. Pseudorandom functions can be constructed from one-way functions.

14. Suppose Alice has input $(M_0, \ldots, M_{2^\ell - 1})$ and Bob has an index I and wishes to learn M_I. Let $a_0 \cdots a_{\ell-1}$ be the binary representation of I. The protocol proceeds as follows:

- Alice prepares ℓ pairs of secret keys for function F: (K_i^0, K_i^1), $i = 0, \ldots, \ell - 1$. For each $0 \leq J \leq 2^\ell - 1$, let the binary representation of J be $j_0 \cdots j_{\ell-1}$. Alice computes $C_J = M_J \oplus \left(\oplus_{i=0}^{\ell-1} F_{K_i^{j_i}}(J)\right)$ and sends $(C_0, \ldots, C_{2^\ell - 1})$ to Bob.
- For each $i = 0, \ldots, \ell - 1$, Alice and Bob jointly execute OT_1^2: Alice has input (K_i^0, K_i^1) and Bob has a_i as input. As a result, for each i, Bob learns $K_i^{a_i}$.
- Bob computes $M_I = C_I \oplus F_{K_i^{a_i}}(I)$.

15. *Correctness.* As $I = a_0 \cdots a_{\ell-1}$, it follows that $C_I = M_I \oplus \left(\oplus_{i=0}^{\ell} F_{K_i^{a_i}}(I)\right)$ by definition of C_I.

16. *Alice's privacy.* Notice that $F_{K_i^b}(0), \ldots, F_{K_i^b}(2^\ell - 1)$ are computationally independent for any i and bit b when K_i^b is not given. In the OT_1^2 protocol, for each i, Bob can learn at most one of K_i^0, K_i^1 (assume it is a_i). Then, for any $J \neq I = a_0 \cdots a_{2^\ell - 1}$, there exists at least one i, $j_i \neq a_i$, and hence $K_i^{j_i}$ is not learned by Bob. Thus C_J is computationally independent of Bob's view, and therefore Bob cannot learn M_J for any $J \neq I$.

17. *Bob's privacy.* Bob uses I only in the execution of OT_1^2 for each i. That is, he inputs a_i. However, by Bob's privacy in OT_1^2, Alice learns nothing about a_i. Thus, Bob's privacy is guaranteed.

15.6.8 SECURE MULTIPARTY COMPUTATION

Definition:

A ***secure multiparty computation*** is a protocol π such that given n parties $P_1, \ldots, P_n$, where each P_i has a private input x_i, π realizes a function $f(x_1, \ldots, x_n) = (o_1, \ldots, o_n)$ such that P_i obtains the output o_i, $i = 1, \ldots, n$.

Facts:

1. The requirements of secure multiparty computation include

- *Correctness.* After jointly executing π, each P_i should obtain o_i in $f(x_1, \ldots, x_n)$.
- *Security.* After executing π, P_i cannot obtain any information about $(x_1, \ldots, x_n)$ beyond (o_i, x_i). That is, besides the protocol output o_i and input x_i, P_i cannot learn anything from the messages he sees during the execution of π.

2. A set of parties $A \subseteq \{P_1, \ldots, P_n\}$ might collude and are called *corrupted parties.* Security requires that they cannot obtain anything from the execution of π beyond $\{(o_i, x_i)\}_{P_i \in A}$.

3. *Semi-honest vs. malicious security.* In *semi-honest security*, corrupted parties faithfully follow the specification of π during the execution and their goal is to determine some information about the inputs of honest parties. In *malicious security*, corrupted parties may arbitrarily deviate from the specification of π and might send inconsistent messages in order to obtain information about the inputs of honest parties.

4. *Randomized function vs. deterministic function.* The function value is a random variable for any randomized function $f(x_1, \ldots, x_n)$. However, the randomness parameter of each party can be included in the input. That is, if P_i uses randomness parameter r_i, then his input can be considered to be $x_i|r_i$. The function f then becomes deterministic. Thus, we only need to consider deterministic functions.

5. *Function represented by a circuit.* Any (vector) Boolean function $f(x_1, \ldots, x_n)$ can be represented using a set of basic logic gates. For example, {AND, OR, NOT} is a complete set for this purpose, and so is {NAND}.

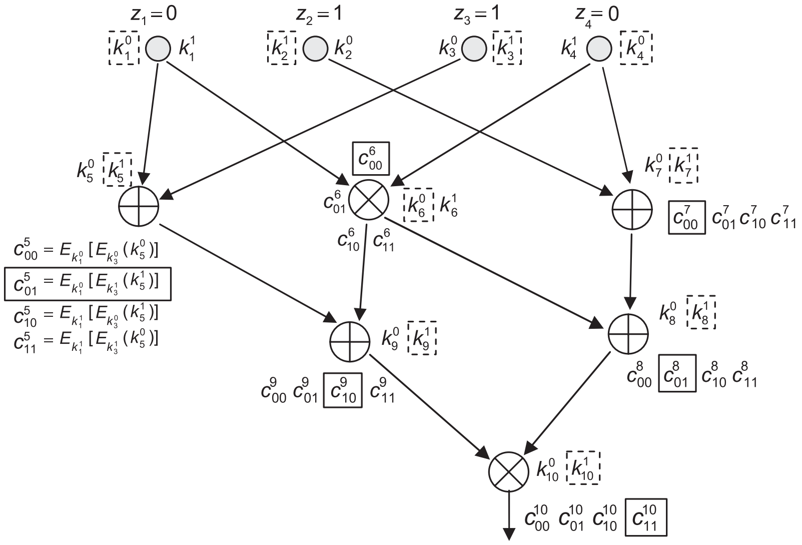
6. The origins of secure multiparty computation stem from *Yao's millionaires' problem* [Ya82], in which two millionaires Alice and Bob wish to find out who is richer without revealing their wealth.

7. *Garbled circuit.* Let C be a Boolean circuit realizing the function to be computed. For simplicity, assume the circuit consists of XOR and AND gates. Assume the circuit inputs are $z_1, \ldots, z_m$. A gate has two inputs and an output. The input of a gate comes from a circuit input or an output of another gate. A circuit input or a gate is called a *node.* We label all nodes from 1 to N for some integer N. For each node i, select a pair of random keys (k_i^0, k_i^1). Let (E, D) be a symmetric encryption scheme. For a gate node s, assume its inputs come from nodes i and j. Then we associate this gate with the ciphertext table as follows.

- Let $g : \{0,1\} \times \{0,1\} \to \{0,1\}$ be a gate function for gate s. Define

$$c^s_{0,0} = E_{k^0_i}(E_{k^0_j}(k_s^{g(0,0)})), \qquad c^s_{0,1} = E_{k^0_i}(E_{k^1_j}(k_s^{g(0,1)}))$$
$$c^s_{1,0} = E_{k^1_i}(E_{k^0_j}(k_s^{g(1,0)})), \qquad c^s_{1,1} = E_{k^1_i}(E_{k^1_j}(k_s^{g(1,1)})).$$

A circuit with a ciphertext table at each gate is called a *garbled circuit*. The following figure provides an example.



$z_1 = 0$
k_1^0
k_1^1
$z_2 = 1$
k_2^1
k_2^0
$z_3 = 1$
k_3^0
k_3^1
$z_4 = 0$
k_4^1
k_4^0
k_5^0
k_5^1
$c_{00}^5 = E_{k_1^0}[E_{k_3^0}(k_5^0)]$
$c_{01}^5 = E_{k_1^0}[E_{k_3^1}(k_5^1)]$
$c_{10}^5 = E_{k_1^1}[E_{k_3^0}(k_5^1)]$
$c_{11}^5 = E_{k_1^1}[E_{k_3^1}(k_5^0)]$
c_{00}^6
c_{01}^6
k_6^0
k_6^1
c_{10}^6 c_{11}^6
k_7^0
k_7^1
c_{00}^7 c_{01}^7 c_{10}^7 c_{11}^7
k_8^0
k_8^1
c_{00}^8 c_{01}^8 c_{10}^8 c_{11}^8
k_9^0
k_9^1
c_{00}^9 c_{01}^9 c_{10}^9 c_{11}^9
k_{10}^0
k_{10}^1
c_{00}^{10} c_{01}^{10} c_{10}^{10} c_{11}^{10}

Note that for any input (α, β) of gate s, $c^s_{\alpha,\beta}$ is a double encryption of one of the random keys at this gate that corresponds to its output bit $g(\alpha,\beta)$. Then, given (k_i^α, k_j^β) and $\{c^s_{00}, c^s_{01}, c^s_{10}, c^s_{11}\}$ (in a random order), we can compute $k_s^{g(\alpha,\beta)}$ using the fact that $D_{k_j^\beta}(D_{k_i^\alpha}(c_{\alpha',\beta'}))$ equals $k_s^{g(\alpha,\beta)}$ if $(\alpha', \beta') = (\alpha, \beta)$ and equals $\perp$ (meaning a decryption error) otherwise.

- Anyone who is given $k_1^{z_1}, \ldots, k_m^{z_m}$ (but not the z_is) can evaluate the garbled circuit in a gate-by-gate manner and finally obtain the key $k_N^{C(z_1,\ldots,z_m)}$ (assume that node N is the last gate to be evaluated in C).
- From $k_N^{C(z_1,\ldots,z_m)}$, one cannot obtain $C(z_1, \ldots, z_m)$. But given k_N^0 and k_N^1, one can determine it.

8. *Yao's two-party computation protocol.* Suppose that the parties 1 and 2 have inputs $(x_1, \ldots, x_n)$ and $(y_1, \ldots, y_n)$, respectively, where $x_i, y_i \in \{0, 1\}$. The protocol proceeds as follows:

- Party 1 takes a pair of secret keys (k_i^0, k_i^1) for each node i in circuit C for $i = 1, \ldots, N$, where N is the total number of nodes in C.
- For each gate s, party 1 computes a table $c^s_{00}, c^s_{01}, c^s_{10}, c^s_{11}$ and shuffles them randomly. This generates a garbled circuit of C.
- Party 1 sends $G(C)$ and $k_1^{x_1}, \ldots, k_n^{x_n}$ (assuming the input nodes of party 1 are $1, \ldots, n$) to party 2.
- At this moment, party 2 needs to further obtain $k_{n+1}^{y_1}, \ldots, k_{2n}^{y_n}$ in order to decrypt the ciphertext table for each gate and finally obtain $k_N^{C(x_1,\ldots,x_n,y_1,\ldots,y_n)}$.

- Toward this end, let the input nodes for party 2 be $n+1,\dots,2n$. For each $i=1,\dots,n$, party 1 with input (k^0_{n+i},k^1_{n+i}) and party 2 with input y_i jointly execute a 1-out-of-2 oblivious transfer to send $k^{y_i}_{n+i}$ to party 2.
- Upon receiving $k^{x_i}_i$ and $k^{y_i}_{n+i}$ for $i=1,\dots,n$, party 2 evaluates the garbled circuit of C and obtains $k_N^{C(x_1,\dots,x_n,y_1,\dots,y_n)}$ (assuming gate N is the final gate to be evaluated in C), and sends it to party 1.
- Party 1 obtains $C(x_1,\dots,x_n,y_1,\dots,y_n)$ by comparing $k_N^{C(x_1,\dots,x_n,y_1,\dots,y_n)}$ (from party 2) with k^0_N and k^1_N, and sends the output to party 2.

9. *Passive security of party 1.* Notice that $k^{x_i}_i$ is independent of x_i. Thus, prior to the final output from party 1, the input $x_1,\dots,x_N$ is independent of the messages seen by party 2. Thus, during the entire protocol, party 2 can only obtain information about $(x_1,\dots,x_n)$ through $C(x_1,\dots,x_n,y_1,\dots,y_n)$.

10. *Passive security of party 2.* Party 1 obtains $y_1,\dots,y_n$ only through the 1-out-of-2 oblivious transfers and $C(x_1,\dots,x_n,y_1,\dots,y_n)$ in the final step. However, by the security of oblivious transfers, party 1 obtains no knowledge about $y_1,\dots,y_n$. Hence, the obtained information is covered by $C(x_1,\dots,x_n,y_1,\dots,y_n)$.

11. *GMW multiparty computation protocol* was invented by Goldreich, Micali, and Wigderson [GoMiWi87].

Consider circuit C with NOT and AND gates. For $i=1,\dots,m$, suppose party i has input $\mathbf{x}_i=(x_{i1},\dots,x_{in})\in\{0,1\}^n$. The protocol proceeds as follows:

- Each party i shares input bit $x_{i\ell}$ with all parties. Specifically, he generates uniformly random bits $x^j_{i\ell}$ so that $\sum_{j=1}^m x^j_{i\ell}=x_{i\ell}$ and sends $\{x^j_{i\ell}\}_{\ell=1}^n$ to party j *in private*. Thus, each party j obtains a share $x^j_{i\ell}$ for each input bit $x_{i\ell}$.
- All parties jointly evaluate the gates in C in a top-down manner, where only the top gates are attached to the input wires of C. If the input(s) of a gate g is shared among all parties, then g is evaluated, with the result shared among all parties as follows:
  - ◇ if g is a NOT gate with input z, then by assumption, z is shared among all parties. Assume party i obtains a share z_i. Then, party 1 flips z_1 and all other parties keep their shares unchanged. Since $\bar{z}_1+z_2+\cdots+z_m=\bar{z}$, the NOT gate is evaluated with sharing.
  - ◇ if g is an AND gate with inputs x,y, then by assumption, x,y are shared and party i holds the share x_i,y_i for x,y, respectively. The parties want to jointly compute $z=x\cdot y$ with sharing $z=z_1+\cdots+z_m$. Notice that

$$\left(\textstyle\sum_{i=1}^m x_i\right)\left(\textstyle\sum_{i=1}^m y_i\right)=\textstyle\sum_{i=1}^m x_iy_i+\sum_{1\le i<j\le m}(x_iy_j+x_jy_i). \qquad (7)$$

Since party i owns x_i,y_i, he can compute x_iy_i locally and define it as z_{ii}. Then $(x_iy_j+x_jy_i)$ can be jointly computed by parties i and j with sharing $z_{ij}+z_{ji}=(x_iy_j+x_jy_i)$ via OT^4_1 as follows:

> Party i selects z_{ij} uniformly randomly and tries to help party j derive z_{ji}. Notice that $z_{ji}=z_{ij}$ for $x_jy_j=00$; $z_{ji}=z_{ij}+y_i$ for $x_jy_j=10$; $z_{ji}=z_{ij}+x_i$ for $x_jy_j=01$; $z_{ji}=z_{ij}+x_i+y_i$ for $x_jy_j=11$. Then party 1 with input $(z_{ij},z_{ij}+y_i,z_{ij}+x_i,z_{ij}+y_i+x_i)$ and party 2 with input (x_j,y_j) execute OT^4_1, thereby allowing party 2 to obliviously obtain $z_{ji}=z_{ij}+(x_iy_j+x_jy_i)$.

Finally, each party i defines $z_i=\sum_{j=1}^m z_{ij}$. This yields a shared evaluation of $x\cdot y$.

- After evaluating all gates of C, each party i obtains a share o_i^j for party j's output gate. Then, all parties send their shares $o_i^j, i = 1, \ldots, m$ to party j. Party j obtains his circuit output $o^j = \sum_{i=1}^m o_i^j$.

12. *Correctness.* For each gate g, the sharing for its output is achieved. As seen in the previous fact, each gate is computed correctly. Consequently, C is properly evaluated.

13. *Privacy of party i.* We need to guarantee that x_i is not leaked beyond $C(x_1, \ldots, x_m)$.

- Evaluating each gate does not leak any information. Namely, if g is a NOT gate, this is true because each output share is computed locally only. If g is an AND gate, x_i is not leaked in any sense. Recall that the inputs are used only in OT_1^4, whereas OT_1^4 does not leak any information beyond $z_{ji} = z_{ij} + (x_i y_j + x_j y_i)$. Further, since z_{ij} is selected by party i in a uniform random manner, x_i is independent of z_{ji}.
- In the output stage, party i obtains o_j^i from every party j, whereas the $o_j^i, j = 1, \ldots, m$, are jointly uniformly random subject to $o^i = \sum_{j=1}^m o_j^i$. Thus, it does not leak more than o^i. The privacy of party i is achieved.

15.7 HIGH-LEVEL APPLICATIONS OF CRYPTOGRAPHY

The cryptosystems and cryptographic mechanisms described earlier in this chapter are often components of high-level applications. In this section, three important high-level applications are described: digital cash, electronic voting, and secure cloud computing.

15.7.1 DIGITAL CASH

Digital cash aims to achieve all the functionality and security (and more) of paper cash in an electronic world.

Definitions:

According to the European Banking Authority, ***virtual currency*** is “a digital representation of value that is neither issued by a central bank or a public authority, nor necessarily attached to a fiat currency, but is accepted by natural or legal persons as a means of payment and can be transferred, stored, or traded electronically”. Cryptography is not necessarily used in the framework.

Cryptocurrency is a class of unregulated digital cash in which cryptography is used in secure transactions and in the creation of additional currency.

A ***nonce*** is a pseudorandom number generated for one-time use.

Facts:

1. The following are some desirable properties of digital cash suggested in the literature [Ch83], [ChFiNa90], [Wa97]:

- *Anonymity.* Transactions should be anonymous to third parties.

- *Peer-to-peer transactions.* Transactions do not need to involve a trusted third party, nor a central clearance system.
- *Offline.* Transactions can be conducted offline.
- *Proof of payment.* Payment schemes should provide proof of payment.
- *Fraud detection.* There is the ability to determine fraud, such as double spending.
- *Protection from theft.* A stop payment occurs if cash is stolen.

2. Much of the research in digital cash involves two issues: maintaining anonymity and preventing double spending. Bitcoin is one recent and high-profile digital cash system.

3. *Bitcoin* is a cryptocurrency invented in 2008 by an unknown person under the alias of Satoshi Nakamoto. In 2009, the system was released as open-source software.

4. The legal status of bitcoin varies from country to country, from being purely illegal to unregulated, and to being considered as a commodity.

5. General information on bitcoin:

- The main cryptographic primitives used are ECDSA and SHA-256.
- Bitcoin is a peer-to-peer version of electronic cash. No financial institution is involved in any transaction.
- An electronic coin is defined to be a chain of digital signatures.
- A timestamp server mechanism is used to verify a chain of transactions. A *block* is a chain of transactions together with information from a previously verified block and a nonce with predefined properties.
- As the chain of transactions grows, the electronic coin takes up memory. A Merkle tree-like structure is used to reduce the space required.
- The hash function SHA-256 is used extensively both for signing the hash of transactions and for providing proof-of-work (see Fact 8) to prevent fraud. ECDSA is used for the signing of the hash.
- Bitcoin does not provide anonymity since all transactions are recorded in a public chain. However, anonymity can be partially achieved by keeping public keys anonymous.
- As of November 2016, bitcoin had a market capitalization of US $11 billion.

6. The operations of the bitcoin network follow six steps:

- Every new transaction is broadcast to all nodes.
- Each node then collects new transactions into a block by concatenating the transactions.
- Each node competes to find a proof-of-work (see Fact 8) for its block.
- A node that finds a proof-of-work broadcasts the block to all nodes.
- Nodes accept the block when all transactions are verified and not already spent.
- Nodes accept the block by working on creating the next block in the chain, using the hash of the previous block to begin a new block.

7. In a transaction from user A to user B, user A combines the previous transaction and B's public key, and signs its hash using A's signing key. The result is then transmitted to B and publicly announced. Any other user can verify the transaction by verifying A's signature.

8. To further reinforce integrity of data, a timestamp mechanism is used to hash a chain of transactions as proof of existence of data. The timestamp server uses a *proof-of-work* system: the timestamp requires the hashing of the previous timestamp hash, together with a nonce and a chain of transactions, resulting in a *block*; the choice of nonce is restricted such that when hashed, the result must begin with a required number of zero bits. This process is called *mining*.

9. It is possible that two timestamps on the same set of transactions can be produced at similar times. In this case, the longest block chain is recognized. In the case that there is a tie, then it is broken when the next proof-of-work is found for one of the chains.

10. Since proof-of-work requires computing power from contributors, there is an incentive in the form of new bitcoins that are offered to those who provided the proof-of-work service.

11. *Bitcoin security.*

- The proof-of-work system is used to prevent fraud. As with any cryptographically secure hash function, the amount of time (work) required to find a nonce doubles with each additional required zero bit.
- Double spending is avoided by recording the series of transactions which is available to all users.
- For a malicious user to nullify a past transaction, the attacker must re-do the proof-of-work of the block, all subsequent blocks, and surpass the work of the honest nodes. The probability of being able to accomplish this diminishes exponentially as more blocks are added.
- Bitcoin can be proven to be secure when there are more honest nodes than malicious nodes.
- The bitcoin wallet, which is a file that contains a collection of private signing keys for use in transactions, is not encrypted by default, and is vulnerable to theft.

15.7.2 ELECTRONIC VOTING

Electronic voting was developed to fulfill a need for an accurate, auditable, fast and secure voting system. Suggested voting systems include polling place electronic voting and remote internet voting [Jo], [Mo00].

Definitions:

Electronic voting is voting using electronic means to assist in vote casting or counting votes.

Blinding is a technique wherein a supplier can provide a service to a client without knowing the actual content of the input or the output. In the case of voting, a voter uses the technique to conceal the vote, which is then submitted to an administrator for signing. The voter reveals the vote anonymously at a later stage.

Facts:

1. Some cryptographically-relevant criteria for an electronic voting system include the following [Mo00]:

- *Eligibility and Authentication.* Only registered voters can vote.
- *Uniqueness.* Participants can vote at most once.

- *Accuracy.* Votes should be recorded correctly.
- *Integrity.* The system prevents votes from being modified, forged, or deleted.
- *Verifiability and Auditability.* The system has the ability to verify that votes are accounted for, with reliable and authentic election records.
- *Reliability.* The system should work despite numerous failures.
- *Secrecy and Non-Coercibility.* No one should be able to determine how an individual voted. Voters should not be able to prove how they voted.

2. *Blind Signatures Based Voting* (Fujioka-Okamoto-Ohta). This voting scheme was published in 1993 [FuOkOh92]. It uses *blind signatures*, where an administrator signs the concealed vote submitted by the voter. The scheme consists of six major steps: preparation, administration, voting, collecting, opening, and counting.

- *Preparation.* A voter fills in a ballot using a key k, attaches a random ID string to the ballot, and blinds the vote using a blinding technique. The voter then sends the blinded vote to the administrator.
- *Administration.* The administrator, after verifying the validity of the voter, signs the blinded vote and sends it back to the voter.
- *Voting.* The voter unblinds the signature and sends the administrator-signed anonymous ballot to the collector.
- *Collecting.* The collector checks the administrator's signature and enters the encrypted vote into a list.
- *Opening.* The voter checks if the ballot is in the list and sends key k through an anonymous channel.
- *Counting.* The collector opens the vote using key k.

3. The scheme is proven to satisfy eligibility and authentication, uniqueness, accuracy, integrity, verifiability, and secrecy.

4. *Cryptographic Counter Based Voting* (Katz-Myers-Ostrovsky). A cryptographic n-counter is a triple of algorithms (G, D, T), with n different counting states, such that using any public key cryptosystem, we have

- G is a probabilistic key generation algorithm, where a k-bit input generates a public key-private key pair (pk, sk) and a string s_0. The secret key implicitly defines an associated set of states S_{sk}, where $s_0 \in S_{sk}$. The states represent the count.
- D is the deterministic decryption algorithm that takes in secret key sk and a string s, and outputs an integer $i \in \mathcal{Z}_n$ if $s \in S_{sk}$. Otherwise, D outputs *contradiction.*
- T is a probabilistic algorithm known as the *transition algorithm.* It takes the public key pk, string s, and an integer $i \in \mathcal{Z}_n$, and outputs string s'.

5. A high-level voting protocol is described in the following steps. Assume that there are n voters, where voters are voting in sequence.

- *Setup.* The authorities run the key generation algorithm, and then announce the public key pk and the initial string s_0 to all voters.
- *Voting.* The collector carries the current total. Let s_i be the counter after the ith vote. For the $(i+1)$st vote, the voter takes the current counter s_i, public key pk, the desired vote, and updates the state to s_{i+1} using the transition function.

- *Tally.* The authorities decrypt the last counter.

6. A simple voting protocol where a voter's choice is limited to $\{0, 1\}$ is illustrated using quadratic residuosity in [KaMyOs01]. The scheme is proven to satisfy secrecy, reliability, and verifiability.

7. In a *mix-net voting scheme* [BoGo02], [ChPe92], [JaJuRi02], voters submit signed, encrypted votes. A sequence of independent authorities called *mixers* shuffle the votes and perform further encryption. After a chain of mixers has performed the operations, the shuffled votes are completely decrypted. Due to the secret shuffling, the votes become anonymous, thus protecting secrecy. A method of providing shuffle-and-decrypt proofs also provides verifiability.

8. The Paillier cryptosystem [Pa99], a homomorphic encryption system (§15.6.4) that satisfies $E(m_1)E(m_2) = E(m_1 + m_2)$, can be used in voting where encrypted votes are multiplied and then decrypted to reveal the total tally [BaEtal01].

15.7.3 SECURE CLOUD COMPUTING

Cloud computing emerged from the development of high-speed, high-capacity networks and low-cost computers. The proliferation of computer technology has enabled sharing of computing and data resources across the internet. This shared resources model enables businesses and researchers to avoid expensive initial infrastructure costs, and it maximizes the use of computational resources across a network.

Definition:

Cloud computing is an internet-based model that allows shared computing resources and data to electronic devices on demand. The goal is to enable ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources that can be rapidly provisioned and released with minimal management effort or service provider interaction [MeGr11].

Facts:

1. Since resources are shared, it is essential that confidentiality and auditability are provided throughout the service [ArEtal10].

2. In the interest of data privacy, cryptographic separation is needed in which computations and data are concealed in such a way that they appear intangible to the outsider [Ry13], [SuKa11], [ZiLe12]. One can store the encrypted data on a cloud server and the cloud server can run operations such as keyword search, or perform arithmetic on the data, without decrypting the data. This mechanism eliminates the need to download data from the cloud, thereby reducing security risk.

3. One solution to protect data privacy in cloud computing is through the use of homomorphic encryption [TeHaGh12], [TeHa14]; see §15.6.4. Paillier [Pa99] and Goldwasser-Micali [GoMi82] cryptosystems can be used in applications where the operation is addition. However, both systems involve message expansion and thus have a practical disadvantage. The RSA and ElGamal systems can be used for multiplication requests.

DISCRETE OPTIMIZATION

INTRODUCTION

This chapter discusses various topics in discrete optimization, especially those that arise in applying operations research techniques to applied problems. A fundamental tool is linear programming and its extensions to problems in which certain variables must assume integer values. These techniques are useful in devising solution techniques for a variety of problems in which a given resource must be optimally utilized subject to constraints. The chapter also presents several metaheuristic approaches for approximate solution of difficult discrete optimization problems.

GLOSSARY

active constraint: an inequality satisfied with equality by a given vector.

balanced matrix: a 0-1 matrix having no square submatrix of odd order with exactly two 1s in each row and column.

basic feasible solution (of an LP): a basic solution that is also a feasible solution.

basic solution (of an LP): a solution obtained by setting certain *nonbasic* variables to zero and solving for the remaining *basic* variables.

bid language: a format for communicating lists of combinatorial bids.

bin packing problem: an optimization problem in which a given set of items is to be packed using the fewest number of bins.

bounded LP: a linear programming problem having a finite optimal solution.

capacitated location problem: a location problem in which bounds are placed on the amount of demand that can be handled by individual facilities.

p-center: a set of p locations for facilities that minimizes the maximum distance from any demand point to its closest facility.

characteristic function: a mapping from the set of all coalitions to the nonnegative real numbers.

characteristic-function game: a model for distributing a cooperative benefit fairly among players when the concept of fairness is based on the bargaining strengths of coalitions that could form if the players had not already agreed to cooperate.

coalition: any subset of the players in a game.

combinatorial auction: a situation in which multiple items are auctioned, and each bidder can submit several bids (each of which may contain several items).

complete information: a situation arising when a game's structure is known to all players.

convex hull: the smallest convex set containing a given set of points.

convex set: a set containing the line segment joining any two of its points.

CPM model: a deterministic activity net with strict precedence among the activities.

critical path: a sequence of activities that determines the completion time of a project.

criticality index: the probability that a given path (activity) is (lies on) a critical path of a project.

cutting plane: a constraint that can be added to an existing set of constraints without excluding any feasible integer solution.

decision variables: the unknowns in an optimization problem.

demand point: a point in a metric space that is a source of demand for the service provided by the facilities.

deterministic activity net: a directed network in which all the parameters (such as duration, resource requirements, precedence) are known deterministically.

dual LP: a minimization LP problem associated with a given maximization LP problem.

equilibrium: a strategy combination from which no player has a unilateral incentive to depart.

facility: a place where a service (or product) is provided.

facility location: a point in a metric space where a facility is located.

feasible direction: a direction that preserves feasibility in a sufficiently small neighborhood of a given feasible solution.

feasible LP: an LP with a nonempty feasible region.

feasible region: the set of all feasible solutions to a given LP.

feasible solution: a vector that satisfies the given set of constraints.

fixed point (of a function f): a point x such that $f(x) = x$.

float: in a deterministic activity net, a measure of the flexibility available in scheduling an activity without delaying the project completion time.

forward auction: an auction with several buyers and one seller.

frequency-based memory: used in TS to expand the current neighborhood and examine unvisited regions.

c-game: a characteristic-function game.

GAN model: a probabilistic activity net with conditional progress and probabilistic realization of activities.

general position: a set of points $x_1, x_2, \ldots, x_{p+1} \in \mathcal{R}^n$ such that the vectors $x_2 - x_1$, $x_3 - x_1, \ldots, x_{p+1} - x_1$ are linearly independent.

GERT model: a probabilistic activity net with exclusive-or branching.

goal programming (GP) problem: an LP having multiple objective functions.

improving direction: a feasible direction that improves the objective function value.

imputation: a distribution among players of the cooperative benefit in a c-game.

infeasible LP: an LP with an empty feasible region.

integer programming (***IP***) ***problem***: a linear programming problem in which some of the decision variables are required to be integers.

interior point method: a technique for solving an LP that iteratively moves through the interior of the feasible region.

knapsack problem: an optimization problem in which items are to be selected to maximize the total benefit without exceeding the capacity of the knapsack.

linear programming (***LP***) ***problem***: an optimization problem involving the selection of decision variables that optimize a given linear function and that satisfy linear inequality constraints.

location problem: an optimization problem in which p facilities are to be established to minimize the cost of meeting known demands arising from n locations.

LP relaxation: the linear programming problem obtained by dropping the integrality requirements of an IP.

p-median: a set of p locations for facilities that minimizes the total (transportation) cost of satisfying all demands.

metric space: a set of points on which a distance function has been defined.

mixed strategy: a probability distribution over a set of pure strategies.

move: an operation that modifies a given solution x to obtain a "nearby" solution x' to an optimization problem.

neighbor (of a solution $\boldsymbol{x}$): another solution x' to an optimization problem reached by a valid move from x.

neighborhood (of a solution $\boldsymbol{x}$): the set of all neighbors of x.

neighborhood search algorithm: an iterative algorithm that begins with a solution to an optimization problem and iteratively moves to an improving solution if one exists.

noncooperative game: a mathematical model of strategic behavior in the absence of binding agreements.

normalized characteristic function: a mapping from the set of all coalitions to $[0, 1]$.

nucleolus: a c-game solution concept based on minimizing the dissatisfaction of the most dissatisfied coalitions.

objective function: the function associated with a given optimization problem that is to be maximized or minimized.

optimal solution: a feasible solution to an optimization problem achieving the largest (or perhaps smallest) value of the objective function.

packing: a subset of items from a given list that can be placed in a bin of specified capacity.

path relinking: a search strategy in TS that chooses moves from initiating solutions that incorporate attributes of guiding solutions.

payoff function: a mapping from the set of feasible strategy combinations to $\mathcal{R}^n$, where n is the number of players.

perfect information: a situation arising when the history of a game is known to all players.

PERT model: a probabilistic activity net with strict precedence and activity durations that are known only in probability.

pivot: a move from a given basic solution of an LP to one differing in only one active constraint.

players: a collection of interacting decisionmakers.

polyhedron: the set of points satisfying a given finite set of linear inequalities.

probabilistic activity net: a directed network in which some or all of the parameters, including the realization of the activities, are probabilistically known.

pure strategy: a plan of action available to a player.

recency-based memory: used in TS to obtain a modified neighborhood that excludes (makes tabu) recently visited solutions.

reduced cost: the unit change in the objective function incurred by increasing the value of a given decision variable.

redundant constraint: a constraint that can be removed from a given set of constraints without changing the set of feasible solutions.

set cover: a family of subsets such that each of a specified list of elements is contained in at least one subset.

set covering problem: an optimization problem in which a minimum cost set cover is needed.

set partition: a family of subsets such that each of a specified list of elements is contained in exactly one subset.

set partitioning problem: an optimization problem in which a minimum cost set partition is needed.

Shapley value: a c-game solution concept based on players' marginal worths to coalitions on joining, assuming all orders of formation are equally likely.

p-simplex: the convex hull of a collection of $p+1$ points in general position.

simplex method: a technique for solving an LP that moves from vertex to neighboring vertex along the boundary of the feasible region.

simplicial subdivision (of a simplex): a decomposition of the simplex into a collection of simplices that intersect only along entire common faces.

slack variables: the components of $b - Ax^*$ where x^* is a feasible solution to an LP with constraints $Ax \leq b$, $x \geq 0$.

solution: an equilibrium or set of equilibria in a noncooperative game, or an imputation or set of imputations in a c-game.

strategic behavior: behavior such that the outcome of an individual's actions depends on actions yet to be taken by others.

strategic oscillation: a search strategy in TS that repeatedly approaches and crosses the feasibility boundary from different directions.

strategy combination: a vector of strategies, one for each player.

tableau: a table storing all information pertinent to a given basic solution for an LP.

tabu search (***TS***): a metaheuristic solution methodology that employs adaptive memory and responsive exploration of the solution space.

tabu tenure: the number of iterations that an attribute remains tabu-active in TS, thus preventing the revisiting of recently examined solutions.

totally unimodular matrix: a 0-1 matrix such that every square submatrix has determinant 0, $+1$, or -1.

unbounded LP: a linear programming problem that is not bounded.

variable-depth neighborhood search algorithm: a neighborhood search algorithm that moves to a new solution in a neighborhood of variable depth at each iteration.

very large-scale neighborhood: a neighborhood that has very large size with respect to the problem input.

very large-scale neighborhood search algorithm: a neighborhood search algorithm that selects from a very large-scale neighborhood at each iteration.

vertex (of a feasible region): given a feasible region S, a point $x \in S \subseteq \mathcal{R}^n$ defined by the intersection of exactly n linearly independent constraints.

Vickrey-Clarke-Groves (***VCG***) ***mechanism***: an efficient auction mechanism in which each bidder has an incentive to be honest about his/her valuation of the items.

winner determination problem: the problem of finding a set of winning bids to maximize total monetary value in an auction.

16.1 LINEAR PROGRAMMING

Linear programming (LP) involves the optimization of a linear function under linear inequality constraints. Applications of this model are widespread, including problems arising in marketing, finance, inventory, capital budgeting, computer science, transportation, and production. Algorithms are available that, in practice, solve LP problems efficiently.

16.1.1 BASIC CONCEPTS

Definitions:

A ***linear programming*** (***LP***) ***problem*** is an optimization problem that can be written

$$\begin{aligned} \text{maximize:} \quad & cx \\ \text{subject to:} \quad & \widetilde{A}x \le \widetilde{b} \end{aligned} \tag{1}$$

where $\widetilde{A}$ is a given $q \times n$ matrix, c is a given row vector of length n, and $\widetilde{b}$ is a given column vector of length q. The ***decision variables*** of problem (1) are represented by the column vector x of length n.

A ***feasible solution*** is a vector x satisfying $\widetilde{A}x \le \widetilde{b}$. The ***feasible region*** is the subset of all feasible solutions in $\mathcal{R}^n$. If no feasible solution exists (so that the feasible region is empty), the LP problem is ***infeasible***; otherwise it is ***feasible***.

Each of the q inequalities in $\widetilde{A}x \le \widetilde{b}$ is a ***constraint***. A constraint is ***redundant*** if removing it from (1) doesn't change the feasible region.

For a feasible solution x, the function $z = cx$ is the ***objective function***, with cx the ***objective value*** of x. When the objective value $z^* = cx^*$ is also maximum, then the feasible x^* is an ***optimal*** solution. If the objective value can be made arbitrarily large over the feasible region, the LP problem is ***unbounded***. Otherwise it is ***bounded***.

A vector y is a ***feasible direction*** at x^* if there is some $\tau > 0$ such that $\widetilde{A}(x^* + \lambda y) \le \widetilde{b}$ for all $0 \le \lambda \le \tau$. If $cy > 0$ also holds, then y is an ***improving direction***.

A constraint of the system $\widetilde{A}x \le \widetilde{b}$ that is satisfied with equality by a feasible solution x^* is ***active*** at x^*.

A set of constraints $\{a_i x \le b_i \mid i = 1, 2, \ldots, k\}$ is ***linearly independent*** if the vectors $\{a_1, a_2, \ldots, a_k\}$ are linearly independent (see §6.1.3).

A ***vertex*** is a feasible solution with n linearly independent active constraints. A vertex with more than n active constraints is ***degenerate***. An LP problem with a degenerate vertex is ***degenerate***.

A set S is ***convex*** if the line segment joining any two of its points is contained in S: i.e., $\lambda x + (1 - \lambda)y \in S$ holds for all $x, y \in S$ and $0 \le \lambda \le 1$.

Let L be the line segment connecting the two vertices x^1 and x^2. Then x^1 and x^2 are ***adjacent*** if for all points $y \ne x^1, x^2$ on L and all feasible y^1 and y^2, the only way y can equal $\frac{1}{2}y^1 + \frac{1}{2}y^2$ is if y^1 and y^2 are also on L. In this case, L is an ***edge***.

Facts:

1. Linear programming models arise in a wide variety of applications, which typically involve the allocation of scarce resources in the best possible way. A sample of such application areas, with reference sources, is given in the following table.

application	*references*
production scheduling and inventory control	[Ch83], [Ga85]
tanker scheduling	[BaJaSh90]
airline scheduling	[Ga85]
cutting stock problems	[BaJaSh90], [Ch83]

approximation of data	[Ch83]
matrix games	[Ch83]
blending problems	[BaJaSh90]
petroleum refining	[Ga85]
capital budgeting	[BaJaSh90]
military operations	[Ga85]
land use planning	[Ga85]
agriculture	[Ga85]
banking and finance	[Ga85]
environmental economics	[Ga85]
health care	[Ga85]
marketing	[Ga85]
public policy	[Ga85]

2. The general concepts of linear programming were first developed by G. B. Dantzig in 1947 in connection with military planning problems for the U.S. Air Force. Earlier, in 1939, L. V. Kantorovich formulated and solved a particular type of LP problem in production planning.

3. The term "linear programming" conveys its historical origins and purpose: it is a mathematical model involving *linear* constraints and a *linear* objective function, used for the optimal planning (*programming*) of operations.

4. Form (1) of an LP naturally occurs in the selection of levels for production activities that maximize profit subject to constraints on the utilization of the given resources.

5. These transformations on an LP do not change feasible (or optimal) solutions:

- *constraints*: change the sense of an inequality by multiplying both sides by -1; or replace $a_i x = b_i$ with $a_i x \leq b_i$ and $-a_i x \leq -b_i$; or replace $a_i x \leq b_i$ with $a_i x + s_i = b_i$ and $s_i \geq 0$;
- *variables*: for x_j unrestricted, set $x_j := x'_j - x''_j$ with $x'_j, x''_j \geq 0$; or for $x_j \leq 0$, set $x_j := -x'_j$ with $x'_j \geq 0$;
- *objective function*: change a minimization (maximization) problem to a maximization (minimization) problem by setting $c := -c$.

6. *Farkas' lemma*: Suppose $\widetilde{A}$ is a $q \times n$ matrix and c is an n-row vector. Then the following are equivalent:

- $cy \geq 0$ for all $y \in \mathcal{R}^n$ such that $\widetilde{A}y \geq 0$;
- there exists some $u \in \mathcal{R}^q$ such that $u \geq 0$, $c = u\widetilde{A}$.

This result is important in establishing the optimality conditions for linear programming problems; it can also be applied to show the existence (and uniqueness) of solutions to linear models of economic exchange and stationary distributions in finite Markov chains (§7.7). (J. Farkas, 1847–1930)

7. A feasible solution with an improving direction cannot be optimal for (1).

8. A feasible solution with no improving direction is always optimal for (1).

9. If a feasible solution to (1) has an improving direction y and if $\widetilde{A}y \leq 0$ then the LP problem is unbounded.

10. Each LP problem is either infeasible, unbounded, or has an optimal solution. This need not be the case for nonlinear optimization problems.

11. Form (1) of an LP is helpful for understanding the geometric properties of an LP.

12. For algorithmic purposes the following form, form (2), of an LP is preferred:

$$\begin{aligned} \text{maximize: } & cx \\ \text{subject to: } & Ax \leq b \\ & \ \ x \geq 0. \end{aligned} \tag{2}$$

Here A is an $m \times n$ matrix.

13. The most general form of an LP problem is

$$\begin{aligned} \text{maximize (or minimize): } & dx_1 + ex_2 + fx_3 \\ \text{subject to: } & Ax_1 + Bx_2 + Cx_3 \leq a \\ & Dx_1 + Ex_2 + Fx_3 \geq b \\ & Gx_1 + Hx_2 + Kx_3 = c \\ & x_1 \geq 0,\ x_2 \leq 0,\ x_3 \text{ unrestricted.} \end{aligned}$$

In this formulation A, B, C, D, E, F, G, H, and K are matrices; a, b, and c are column vectors; and d, e, and f are row vectors.

14. The feasible region of an LP problem is a convex set.

15. *Equivalence of forms*: The general form in Fact 13 is equivalent to both form (1) and form (2) in the following sense: any of these three forms can be transformed into another using the operations of Fact 5. Each form possesses the same set of feasible (or optimal) solutions.

16. An excellent glossary of linear programming terms, as well as concepts in general mathematical optimization, can be found at

- `http://glossary.computing.society.informs.org/ver2/mpgwiki/`

17. A comprehensive introduction to building linear programming models and a discussion of various applications are found in Williams [Wi13].

Examples:

1. *Feed mix*: A manufacturer produces a special feed for farm animals. To ensure that the feed is nutritionally balanced, each bag of feed must supply at least 1250 mg of Vitamin A, 250 mg of Vitamin B, 900 mg of Vitamin C, and 232.5 mg of Vitamin D. Three different grains $(1, 2, 3)$ are blended to create the final product. Each ounce of Grain 1 supplies 2, 1, 5, 0.6 mg of Vitamins A, B, C, D, respectively. Each ounce of Grain 2 provides 3, 1, 3, 0.25 mg of Vitamins A, B, C, D, while each ounce of Grain 3 provides 7, 1 mg of Vitamins A, D. The costs (per ounce) of the constituent grains are 41, 35, and 96 cents for Grains 1, 2, and 3, respectively.

The manufacturer wants to determine the minimum cost mix of grains that satisfies all four nutritional requirements. If x_i is the number of ounces of Grain i that are blended in the final product, then the manufacturer's problem is modeled by the following LP:

$$\begin{aligned} \text{minimize:}\quad & 0.41x_1 + 0.35x_2 + 0.96x_3 \\ \text{subject to:}\quad & 2x_1 + 3x_2 + 7x_3 \ge 1250 \\ & x_1 + x_2 \ge 250 \\ & 5x_1 + 3x_2 \ge 900 \\ & 0.6x_1 + 0.25x_2 + x_3 \ge 232.5 \\ & x_1,\ x_2,\ x_3 \ge 0. \end{aligned}$$

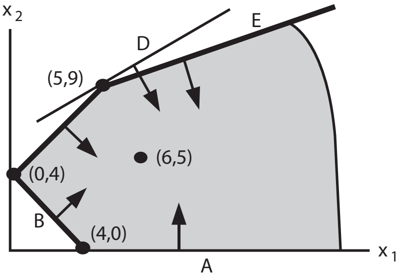
Each constraint in this LP corresponds to a nutritional requirement. It turns out that the optimal solution to the LP is $x_1^* = 200.1$, $x_2^* = 49.9$, $x_3^* = 100.01$ with $z^* = 195.5$. Note that the amount of Vitamin C supplied by this solution is in excess of 900 mg, while the other vitamins are supplied in exactly the minimum amounts.

2. The LP in Example 1 is not in either form (1) or form (2). However, using Fact 5 it can be transformed into form (2), giving the equivalent representation

$$\begin{aligned} \text{maximize:}\quad & -0.41x_1 - 0.35x_2 - 0.96x_3 \\ \text{subject to:}\quad & -2x_1 - 3x_2 - 7x_3 \le -1250 \\ & -x_1 - x_2 \le -250 \\ & -5x_1 - \ 3x_2 \le -900 \\ & -0.6x_1 - 0.25x_2 - x_3 \le -232.5 \\ & x_1,\ x_2,\ x_3 \ge 0. \end{aligned}$$

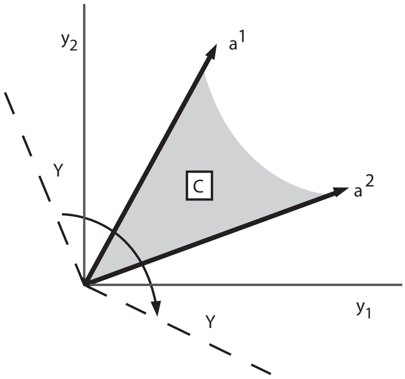
3. The following figure shows the feasible region of the LP problem

$$\begin{array}{lll} \text{maximize:} & -x_1 & \\ \text{subject to:} & -x_2 \le 0 & \text{(A)} \\ & -x_1 - x_2 \le -4 & \text{(B)} \\ & -x_1 + x_2 \le 4 & \text{(C)} \\ & -3x_1 + 5x_2 \le 30 & \text{(D)} \\ & -x_1 + 3x_2 \le 22 & \text{(E)} \end{array}$$



This LP has $n = 2$ decision variables x_1, x_2 and it has the vertices $(4, 0)$, $(0, 4)$, and $(5, 9)$. Vertex $(x_1, x_2) = (0, 4)$ is the optimal solution, achieving the maximum objective value $z = 0$. Thus, the LP is bounded, even though its feasible region is not bounded. Constraint (D) is redundant, since dropping it doesn't change the feasible region. Vertex $(5, 9)$ is degenerate, since $3 > n$ constraints are active at this vertex. All vectors are feasible directions at $(6, 5)$. At vertex $(5, 9)$, the direction $(1, -1)$ is feasible, but the direction $(1, 1)$ is not. Vertices $(0, 4)$ and $(5, 9)$ are adjacent, as are $(4, 0)$ and $(0, 4)$.

4. *Farkas' lemma*: The row vectors a^1, a^2 of $\widetilde{A} = \begin{pmatrix} 2 & 4 \\ 5 & 2 \end{pmatrix}$ are shown in the next figure.



The set $Y = \{y \mid \widetilde{A}y \ge 0\}$ is the region bounded by the two dashed lines. Notice that if $c = u\widetilde{A}$ for some $u \ge 0$ then c must lie in the cone C bounded by the vectors a^1 and a^2. Geometrically, any $c \in C$ makes an acute angle with every $y \in Y$, hence $cy \ge 0$. Conversely, any c making an acute angle with every $y \in Y$ must be in C.

5. Fact 10 is illustrated using the following LP problem:

$$\begin{array}{rl} \text{maximize:} & -x_1 - x_2 \\ \text{subject to:} & -2x_1 + x_2 \le -1 \\ & -x_1 - 2x_2 \le -2 \\ & x_1,\ x_2 \ge 0\,. \end{array}$$

This LP has the optimal solution $(x_1^*, x_2^*) = (\frac{4}{5}, \frac{3}{5})$. Suppose the objective function is changed to $z = x_1 - x_2$. Then $(x_1, x_2) = (a, 0)$ is feasible for $a \ge 2$ with objective value a. Thus z can be made arbitrarily large and the LP is unbounded. On the other hand, if the second constraint is changed to $4x_1 - x_2 \le -1$, the feasible region is empty and the LP is infeasible.

6. *Product mix*: A company manufactures n types of a product, using m shops. Type j requires a_{ij} machine-hours in shop i. There is a limitation of b_i machine-hours for shop i and the sale of each type j unit brings the company a profit c_j. The optimization problem facing the company is given by an LP problem in form (2). Namely, if x_j is the number of units produced of type j, then the optimization problem is

$$\begin{array}{rl} \text{maximize:} & \sum\limits_{j=1}^{n} c_j x_j \\ \text{subject to:} & \sum\limits_{j=1}^{n} a_{ij} x_j \le b_i, \qquad i = 1, \ldots, m \\ & x_j \ge 0, \qquad j = 1, \ldots, n. \end{array}$$

7. *Transportation*: A product stored at m warehouses needs to be shipped to satisfy demands at n markets. Warehouse i has a supply of s_i units of the product, and market j has a demand of d_j units. The cost of shipping a unit of product from warehouse i to market j is c_{ij}. The problem is to determine the number of units x_{ij} to ship from warehouse i to market j in order to satisfy all demands while minimizing cost:

$$\begin{array}{rl} \text{maximize:} & \sum\limits_{i=1}^{m} \sum\limits_{j=1}^{n} c_{ij} x_{ij} \\ \text{subject to:} & \sum\limits_{j=1}^{n} x_{ij} \le s_i, \qquad i = 1, \ldots, m \\ & \sum\limits_{i=1}^{m} x_{ij} = d_j, \qquad j = 1, \ldots, n \\ & x_{ij} \ge 0, \qquad i = 1, \ldots, m,\ j = 1, \ldots, n. \end{array}$$

This is an LP in the form specified by Fact 13. Using the transformations in Fact 5, this optimization problem can alternatively be expressed as an LP in the form (1).

16.1.2 TABLEAUS

Definitions:

Suppose that an LP is expressed in form (2) of §16.1.1, with A an $m \times n$ matrix. A ***tableau*** is any table $\begin{array}{c|c} u & z \\ \hline D & f \end{array}$ with the following properties:

- D is an $m \times (m+n)$ matrix with entries d_{tj}; z is a real number; u is an $(m+n)$-row vector; and f is an m-column vector.

- Associated with the tableau is a partition Σ_B, Σ_N of the integers $1, \ldots, m+n$. The set Σ_B, with cardinality m, is the ***basic set*** and Σ_N is the ***nonbasic set***.
- For every row index $t = 1, \ldots, m$, there is a column of D equal to zero in all coordinates except for the tth coordinate, which equals 1. The index of this column is $\varphi(t)$ where φ is a function from $\{1, \ldots, m\}$ to Σ_B associated with the tableau.
- $\begin{array}{c|c} u & z \\ \hline D & f \end{array}$ can be obtained from $\begin{array}{cc|c} -c & 0 & 0 \\ \hline A & I & b \end{array}$ (where $\Sigma_B = \{n+1, \ldots, m+n\}$ and $\varphi(t) = n+t$, $t = 1, \ldots, m$) by performing the following ***pivot*** operation a finite number of times:

  P1. choose a row index $t^* \in \{1, \ldots, m\}$ and a column index $j^* \in \Sigma_N$ with $d_{t^*j^*} \neq 0$;
  P2. multiply row t^* by $1/(d_{t^*j^*})$;
  P3. add appropriate multiples of row t^* to all other rows to make $u_{j^*} = 0$ and to make $d_{tj^*} = 0$ for all $t \neq t^*$;
  P4. remove j^* from Σ_N and place it in Σ_B; remove $\varphi(t^*)$ from Σ_B and place it in Σ_N; set $\varphi(t^*) = j^*$.

In the pivot operation, $\varphi(t^*)$, before replacement, is the index of the ***leaving variable*** and j^* is the index of the ***entering variable***.

The set of variables $\{x_i \mid i \in \Sigma_B\}$ are the ***basic variables*** and the remaining variables are the ***nonbasic variables***.

A ***basic solution*** is a vector x^* with its basic variables defined by $x_i^* = f_t$ where $t = \varphi^{-1}(i)$; its nonbasic variables have $x_i^* = 0$. If $f \geq 0$ then x^* is a ***basic feasible solution*** (***BFS***).

The ***basis matrix*** B is the $m \times m$ matrix consisting of the columns of $[A \;\; I\,]$ corresponding to the basic variables; the ***nonbasis matrix*** N is the $m \times n$ matrix corresponding to the nonbasic variables. Let c_B $[c_N]$ denote the vector of basic [nonbasic] components of c. Let x_B $[x_N]$ denote the vector of basic [nonbasic] components of x.

The ***reduced cost*** of nonbasic variable x_j is the negative of u_j in the associated tableau.

The ***slack variables*** are given by $(x_{n+1}, x_{n+2}, \ldots, x_{n+m}) = b - Ax$.

Facts:

1. Every BFS of (2) corresponds to a vertex of (1), with $q = m+n$, $\widetilde{A} = \begin{bmatrix} A \\ -I \end{bmatrix}$, $\widetilde{b} = \begin{bmatrix} b \\ 0 \end{bmatrix}$.

2. In the absence of degeneracy the correspondence in Fact 1 is one-to-one; otherwise it is many-to-one.

3. Every LP problem (2) with an optimal solution has an optimal solution that is a vertex. Since the number of vertices is finite, LP problems are combinatorial in nature; that is, an LP can be solved in theory by enumerating its vertices and then selecting one with maximum objective value.

4. Let x^* be a BFS of (2). All information pertinent to x^* is contained in its tableau which (after possibly permuting the first $m+n$ columns) is

$$\begin{array}{cc|c} 0 & c_B B^{-1} N - c_N & c_B B^{-1} b \\ \hline I & B^{-1} N & B^{-1} b \end{array}.$$

Here $c_B B^{-1} b$ is the objective value z of x^*. The value of the basic variable x_i^* is the tth component of $B^{-1}b$, where $i = \varphi(t)$. Every nonbasic variable has value 0.

5. A tableau expresses the set of equations below, called a *dictionary* [Ch83]:

$$\begin{aligned} x_B &= B^{-1}b - B^{-1}Nx_N \\ z &= c_B B^{-1} b + (c_N - c_B B^{-1} N) x_N. \end{aligned}$$

6. The reduced costs of the nonbasic variables are given by the vector $c_N - c_B B^{-1} N$. Basic variables have zero reduced cost.

7. Column i of B^{-1} is identical to d^{m+i}, the column of D associated with the slack variable x_{n+i}.

Examples:

1. When slack variables x_4, x_5, x_6 are added to the LP

$$\begin{aligned} \text{maximize:}\quad & 3x_1 + 4x_2 + 4x_3 \\ \text{subject to:}\quad & 3x_1 - x_3 \le 5 \\ & -9x_1 + 4x_2 + 3x_3 \le 12 \\ & -6x_1 + 2x_2 + 4x_3 \le 2 \\ & x_1, x_2, x_3 \ge 0 \end{aligned}$$

the following equivalent LP is formed:

$$\begin{aligned} \text{maximize:}\quad & 3x_1 + 4x_2 + 4x_3 + 0x_4 + 0x_5 + 0x_6 \\ \text{subject to:}\quad & 3x_1 - x_3 + x_4 = 5 \\ & -9x_1 + 4x_2 + 3x_3 + x_5 = 12 \\ & -6x_1 + 2x_2 + 4x_3 + x_6 = 2 \\ & x_1, x_2, \ldots, x_6 \ge 0. \end{aligned}$$

The associated tableau, with $\Sigma_B = \{4, 5, 6\}$ and $\Sigma_N = \{1, 2, 3\}$, is then

-3	-4	-4	0	0	0	0
3	0	-1	1	0	0	5
-9	4	3	0	1	0	12
-6	2	4	0	0	1	2

Here $\varphi(1) = 4$, $\varphi(2) = 5$, $\varphi(3) = 6$. The basic variables are $x_4 = 5$, $x_5 = 12$, $x_6 = 2$ and the nonbasic variables are $x_1 = 0$, $x_2 = 0$, $x_3 = 0$. The basic feasible solution associated with this tableau is $x = (0, 0, 0, 5, 12, 2)^T$ with objective value $z = 0$. The nonbasic variables x_1, x_2, x_3 have reduced costs $3, 4, 4$, respectively.

2. A pivot is now performed on the tableau in Example 1 using $t^* = 3$ and $j^* = 2$, so the entering variable is x_2 and the leaving variable is x_6. The resulting tableau (a) follows, where $\Sigma_B = \{2, 4, 5\}$ and $\varphi(1) = 4$, $\varphi(2) = 5$, $\varphi(3) = 2$. The corresponding BFS is $x = (0, 1, 0, 5, 8, 0)^T$ with objective value $z = 4$. If a pivot is performed on (a) using $t^* = 1$ and $j^* = 1$, then tableau (b) results. Here $\varphi(1) = 1$, $\varphi(2) = 5$, $\varphi(3) = 2$ and the new BFS is $x = (\frac{5}{3}, 6, 0, 0, 3, 0)^T$ with objective value $z = 29$.

tableau (a)

-15	0	4	0	0	2	4
3	0	-1	1	0	0	75
3	0	-5	0	1	-2	8
-3	1	2	0	0	$\frac{1}{2}$	1

tableau (b)

0	0	-1	5	0	2	29
1	0	$-\frac{1}{3}$	$\frac{1}{3}$	0	0	$\frac{5}{3}$
0	0	-4	-1	1	-2	3
0	1	1	1	0	$\frac{1}{2}$	6

For tableau (b), the basis matrix B corresponds to columns $1, 5, 2$ of $[A\ \ I\,]$, namely $B = \begin{pmatrix} 3 & 0 & 0 \\ -9 & 1 & 4 \\ -6 & 0 & 2 \end{pmatrix}$. From Fact 7, the inverse matrix $B^{-1} = \begin{pmatrix} \frac{1}{3} & 0 & 0 \\ -1 & 1 & -2 \\ 1 & 0 & \frac{1}{2} \end{pmatrix}$ consists of columns $4, 5, 6$ in tableau (b).

16.1.3 SIMPLEX METHOD

The simplex method is in practice remarkably efficient and it is widely used for solving LP problems. The solution idea dates back to J. B. J. Fourier (1768–1830); it was developed and popularized in 1947 by G. B. Dantzig (1914–2005). This section presents two descriptions of the same algorithm: the first is geometrically intuitive, the second is closer to its actual implementation.

Facts:

1. *Simplex algorithm I*: This method (Algorithm 1) solves a linear programming problem in form (1) of §16.1.1. Assuming that an initial vertex is known, this algorithm travels from vertex to vertex along improving edges until an optimal vertex is reached or an unboundedness condition is detected. In Algorithm 1, the rows of $\widetilde{A}$ are denoted $a_1, a_2, \ldots, a_q$ and $\widetilde{b}$ has the corresponding components $b_1, b_2, \ldots, b_q$.

```
Algorithm 1: Simplex algorithm — form (1).
  input: LP in form (1), initial vertex $x_0$
  output: an optimal vertex or an indication of unboundedness
  $k := 0$
  find a subsystem $Bx \le r$ of (1) consisting of $n$ linearly independent constraints
      active at $x_k$
  $S :=$ list containing the indices of these active constraints
  {Main loop}
  if $u \equiv cB^{-1} \ge 0$ then $x_k$ is an optimal solution — stop
  else {an improving direction}
    $i^* :=$ the smallest index such that $u_{i^*} < 0$
    $y :=$ column $i^*$ of $-B^{-1}$
    if $\widetilde{A}y \le 0$ then the LP problem is unbounded — stop
    else {move to next vertex (possibly same as last)}
      $j^* :=$ smallest index $j$ attaining minimum $\lambda \equiv \min\{\frac{b_j - a_j x_k}{a_j y} \mid j \notin S,\ a_j y > 0\}$
      $x_{k+1} := x_k + \lambda y$
      $S[i^*] := j^*$; update $B$
      $k := k + 1$
  {Continue with next iteration of main loop}
```

2. *Simplex algorithm II*: This method (Algorithm 2) solves a linear programming problem in form (2) of §16.1.1, assuming that $b \ge 0$. It proceeds by successively identifying nonbasic variables having positive reduced cost and pivoting them into the current basis in a way that maintains a basic feasible solution (BFS).

```
Algorithm 2: Simplex algorithm — form (2).
  input: LP in form (2), with $b \geq 0$
  output: an optimal BFS or an indication of unboundedness
  begin with the initial tableau: $\begin{array}{cc|c} -c & 0 & 0 \\ \hline A & I & b \end{array}$, where $\Sigma_B = \{n+1, \ldots, m+n\}$
      and $\varphi(t) = n + t,\ t = 1, \ldots, m$
  $x_0 := (x_B, x_N)$ where $x_B = b \geq 0$ and $x_N = 0$
  $k := 0$
  {Main loop}
  if $u_j \geq 0$ for all $j \in \Sigma_N$ then $x_k$ is an optimal solution — stop
  else {select entering variable}
    $j^* :=$ the smallest index with $u_{j^*} < 0$
    if $d_{tj^*} \leq 0$ for $t = 1, \ldots, m$ then the LP is unbounded — stop
    else
      $t^* :=$ an index $t$ achieving the minimum
              $\min\{\frac{f_t}{d_{tj^*}} \mid t = 1, \ldots, m;\ d_{tj^*} > 0\}$
        (if there are several such $t^*$, make $\varphi(t^*)$ as small as possible)
      do a pivot with entering index $j^*$, leaving index $\varphi(t^*)$
      set component $\varphi(t)$ of $x_{k+1}$ to $f_t$ for $t = 1, \ldots, m$ and the remaining components of $x_{k+1}$ to zero
      $k := k + 1$
  {Continue with next iteration of main loop}
```

3. There are examples for which Algorithm 1 requires exponential running time, and similarly for Algorithm 2.

4. In practice the number of iterations of Algorithms 1 and 2 is proportional to the number of constraints m and grows slowly with the number of variables n.

5. There is a one-to-one correspondence between the vertex x_k of Algorithm 1 and the BFS x_k of Algorithm 2, when $\widetilde{A}$ is set to $\begin{bmatrix} A \\ -I \end{bmatrix}$ and $\widetilde{b}$ is set to $\begin{bmatrix} b \\ 0 \end{bmatrix}$.

6. Interchanging a basic and a nonbasic variable in Algorithm 2 corresponds to interchanging a nonactive and an active constraint in Algorithm 1.

7. In the absence of degeneracy, the objective value strictly increases at each step (in both algorithms). The method of breaking ties by choosing the smallest index prevents *cycling* and ensures termination in finite time. In practice, though, cycling is rare and other rules are used.

8. When a vertex is not known in Algorithm 1 (when $b \not\geq 0$ in Algorithm 2) a preliminary LP problem, *Phase I*, can be solved to get an initial vertex (a starting tableau).

9. The *revised simplex method* is a variation of Algorithm 2. Instead of maintaining the entire tableau at each step only B^{-1} is kept. Columns of $[\,A \;\; I\,]$ are brought in from storage as needed to find j^* and t^*. This method is good for sparse matrices A with many columns.

10. LP problems can be submitted online for solution using the NEOS server at

- `http://www.neos-server.org/neos`

11. A survey of software packages for solving linear programming problems is described in [Fo15]. Virtually all of these products run on PCs. In many cases, the LP solvers are linked to more general modeling packages that provide a single environment for carrying out the formulation, solution, and analysis of LP problems.

12. Many software packages are available to model and to solve LP problems.

–The AMPL and GAMS modeling languages are described at

- `http://www.ampl.com`
- `http://www.gams.com`

–Solver software (LINDO API and MATLAB) can be found at

- `http://www.lindo.com`
- `http://www.mathworks.com/products/optimization`

–Integrated solver and modeling environments are described at

- `http://www.aimms.com`
- `http://optimization-suite.coin-or.org`
- `http://www.cplex.com`
- `http://www.gurobi.com`
- `http://www.lindo.com`

Examples:

1. The LP in Example 1 of §16.1.2 can be placed in the form (1) with

$$\widetilde{A} = \begin{pmatrix} 3 & 0 & -1 \\ -9 & 4 & 3 \\ -6 & 2 & 4 \\ -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad \widetilde{b} = \begin{pmatrix} 5 \\ 12 \\ 2 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \quad c = (3\ \ 4\ \ 4).$$

If $x_0 = (0,1,0)^T$ then constraints $3,4,6$ are active at x_0 and $S = [3,4,6]$. Thus

$$B = \begin{pmatrix} -6 & 2 & 4 \\ -1 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad B^{-1} = \begin{pmatrix} 0 & -1 & 0 \\ \frac{1}{2} & -3 & 2 \\ 0 & 0 & -1 \end{pmatrix}, \quad u = cB^{-1} = (2\ \ -15\ \ 4).$$

Here $i^* = 2$, $y = (1,3,0)^T$, $\widetilde{A}y = (3,3,0,-1,-3,0)^T$, and $\widetilde{b} - \widetilde{A}x_0 = (5,8,0,0,1,0)$. Then $\lambda = \min\{\frac{5}{3}, \frac{8}{3}\} = \frac{5}{3}$ and $j^* = 1$. The new vertex is $x_1 = x_0 + \lambda y = (\frac{5}{3}, 6, 0)^T$ and S is updated to $S = [3,1,6]$, so B now contains rows $3,1,6$ of $\widetilde{A}$. Additional iterations of Algorithm 1 can then be carried out using the updated S and B.

2. The same LP can alternatively be solved using Algorithm 2. For illustration, suppose that the tableau (a) from Example 2 (§16.1.2) is given, corresponding to the BFS $x_1 = (0,1,0,5,8,0)^T$ and $\Sigma_B = \{2,4,5\}$. Here $u = (-15,0,4,0,0,2)$ and $j^* = 1$ is chosen. The minimum ratio test gives $\min\{\frac{5}{3}, \frac{8}{3}\} = \frac{5}{3}$ and $t^* = 1$. The next pivot produces tableau (b) in Example 2 (§16.1.2), with $\Sigma_B = \{1,2,5\}$ and $x_2 = (\frac{5}{3}, 6, 0, 0, 3, 0)^T$. Here $u = (0,0,-1,5,0,2)$ so a further pivot is performed using $j^* = 3$ and $t^* = 3$, giving the tableau below. Since $u \geq 0$ the BFS $x_3 = (\frac{11}{3}, 0, 6, 0, 27, 0)^T$ is an optimal solution to the LP, with optimal objective value $z^* = 35$.

$$\begin{array}{cccccc|c}
0 & 1 & 0 & 6 & 0 & \frac{5}{2} & 35 \\
\hline
1 & \frac{1}{3} & 0 & \frac{2}{3} & 0 & \frac{1}{6} & \frac{11}{3} \\
0 & 4 & 0 & 3 & 1 & 0 & 27 \\
0 & 1 & 1 & 1 & 0 & \frac{1}{2} & 6
\end{array}$$

16.1.4 INTERIOR POINT METHODS

There are numerous interior point methods for solving LP problems. In contrast to the simplex method, which proceeds from vertex to vertex along edges of the feasible region, these methods move through the interior of the feasible region. In particular this section discusses N. Karmarkar's "projective scaling" algorithm (1984).

Definitions:

The ***norm*** of $x \in \mathcal{R}^n$ is given by $\|x\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}$. (See §6.1.4.)

Let e denote the row vector of n 1s.

The LP problem

$$\begin{aligned}
\text{minimize: } \quad & z = cx \\
\text{subject to: } \quad & Ax = 0 \\
& ex = 1 \\
& x \geq 0
\end{aligned} \tag{3}$$

is in ***standard form*** for Karmarkar's method if $\frac{1}{n}\,e$ is a feasible vector and if the optimal objective value is $z^* = 0$.

The $n \times n$ diagonal matrix $\text{diag}(x_1, x_2, \ldots, x_n)$ has diagonal entries $x_1, x_2, \ldots, x_n$. (See §6.3.1.)

The ***unit simplex*** in n dimensions is $S_n = \{x \in \mathcal{R}^n \mid ex = 1,\ x \geq 0\}$.

If $\overline{x}$ is feasible to (3), Karmarkar's ***centering transformation*** $T_{\overline{x}} : S_n \to S_n$ is

$$T_{\overline{x}}(x) = \frac{\text{diag}(\overline{x})^{-1} x}{e\ \text{diag}(\overline{x})^{-1} x}.$$

The ***projection*** of a vector v onto the subspace $X \equiv \{x \in \mathcal{R}^n \mid \widetilde{A}x = 0\}$ is the unique vector $p \in X$ for which $(v - p)^T x = 0$ for all $x \in X$. (See §6.1.4.)

Karmarkar's ***potential function*** for (3) is $f(x) = \sum\limits_{j=1}^{n} \ln\left(\frac{cx}{x_j}\right)$.

Facts:

1. Any LP problem can be transformed into form (3); see [BaJaSh90], [Sc86] for details.

2. The centering transformation $T_{\overline{x}}$ is one-to-one and onto.

3. The inverse of the centering transformation is

$$T_{\overline{x}}^{-1}(y) = \frac{\text{diag}(\overline{x})\, y}{e\ \text{diag}(\overline{x})\, y}\ .$$

4. The transformation $T_{\overline{x}}$ places $\overline{x}$ at the center of the transformed unit simplex: $T_{\overline{x}}(\overline{x}) = \frac{1}{n}\,e$.

5. The transformation $T_{\overline{x}}$ maps the feasible region of (3) to

$$Y = \{y \in \mathcal{R}^n \mid A\,\mathrm{diag}(\overline{x})\,y = 0,\; ey = 1,\; y \geq 0\}.$$

6. $W = \{w \in \mathcal{R}^n \mid A\,\mathrm{diag}(\overline{x})\,w = 0,\; ew = 0,\; w \geq 0\}$ is the set of all feasible directions for Y.

7. The projection of v onto W is $[I - P^T(PP^T)^{-1}P]v$, where $P = \begin{pmatrix} A\,\mathrm{diag}(\overline{x}) \\ 1\;1\;\cdots\;1 \end{pmatrix}$.

8. *Karmarkar's algorithm*: This method (Algorithm 3) moves through the interior of the feasible region of (3), transforming the problem at each iteration to place the current point at the "center" of the transformed region.

```
Algorithm 3:  Karmarkar's method.
  input: LP in form (3)
  output: an optimal solution to (3)
  $x_0 := \frac{e}{n}$
  $k := 0$
  {Main loop}
  {Test for optimality within $\epsilon$}
  if $cx_k < \epsilon$ then stop
  else {find new point $y$ in transformed unit simplex}
    $P := \begin{pmatrix} A\,\mathrm{diag}(x_k) \\ 1\;1\;\cdots\;1 \end{pmatrix}$
    $c_P := [I - P^T(PP^T)^{-1}P]\,\mathrm{diag}(x_k)\,c^T$
    $y_k := \frac{e}{n} - \left(\frac{\theta}{\sqrt{n(n-1)}}\right)\frac{c_P}{\|c_P\|}$
    {find new feasible point in the original space}
    $x_{k+1} := T_{x_k}^{-1}(y_k)$
    $k := k + 1$
  {Continue with next iteration of main loop}
```

9. In Algorithm 3, $\epsilon > 0$ is a fixed tolerance chosen arbitrarily small. The parameter θ is a constant, $0 < \theta < 1$, associated with convergence of the algorithm. The value $\theta = \frac{1}{4}$ ensures the convergence of Algorithm 3.

10. There is a positive constant δ with $f(x_k) - f(x_{k+1}) \geq \delta$ for all iterations k of Karmarkar's method. To ensure this inequality $\mathrm{diag}(x_k)\,c$, rather than c, is projected onto the space of feasible directions W.

11. For large problems, Karmarkar's method requires many fewer iterations than does the simplex method.

12. Letting L be the maximum number of bits needed to represent any number associated with the LP problem, the running time of Karmarkar's algorithm is *polynomial*, namely $O(n^{3.5}L^2)$.

13. The earliest polynomial-time algorithm for LP problems is the ellipsoid method, proposed by L. G. Khachian in 1979. (See [Ch83], [Sc86].)

14. The ellipsoid method has worst-case complexity $O(n^6L^2)$, where L is defined in Fact 12. Because its calculations require high precision, this method is very inefficient in practice.

15. Karmarkar's polynomial-time algorithm was announced in 1984 and it has proven to be seriously competitive with the simplex method. Typically, Karmarkar's algorithm reduces the objective function by fairly significant amounts at the early iterations, often converging within 50 iterations regardless of the problem size.

16. More efficient interior point methods have been developed and have proven to be competitive with, and often superior to, the best simplex packages, especially for large LP problems [RoTeVi10], [Wr87].

17. LP problems can be submitted online for solution by several solvers that implement interior-point methods using the NEOS server at

- `http://www.neos-server.org/neos`

18. The LP solver packages mentioned in Fact 12 of §16.1.3 all support solution by interior point algorithms.

Example:

1. In the following LP the vector $x = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})^T$ is feasible and the problem has the optimal objective value $z^* = 0$, achieved for $x^* = (0, \frac{2}{3}, \frac{1}{3})^T$.

$$\begin{aligned} \text{minimize: } & x_1 \\ \text{subject to: } & x_1 + x_2 - 2x_3 = 0 \\ & x_1 + x_2 + x_3 = 1 \\ & x_1, x_2, x_3 \geq 0. \end{aligned}$$

Karmarkar's algorithm is started with $x_0 = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})^T$, yielding $cx_0 = \frac{1}{3}$. For illustrative purposes the value $\theta = 0.9$ is used throughout. Since $A = (1\ 1\ {-2})$ the matrix $P = \begin{pmatrix} \frac{1}{3} & \frac{1}{3} & -\frac{2}{3} \\ 1 & 1 & 1 \end{pmatrix}$, giving $c_P = (\frac{1}{6}, -\frac{1}{6}, 0)$ and $y_0 = (0.0735, 0.5931, 0.3333)^T = x_1$. The new objective value is $cx_1 = 0.0735$. Additional iterations of Algorithm 3 are tabulated in the following table, showing convergence to the optimal $x^* = (0, \frac{2}{3}, \frac{1}{3})^T$ after just a few iterations.

k	0	1	2	3	4
x_k	$\begin{pmatrix} 0.3333 \\ 0.3333 \\ 0.3333 \end{pmatrix}$	$\begin{pmatrix} 0.0735 \\ 0.5931 \\ 0.3333 \end{pmatrix}$	$\begin{pmatrix} 0.0056 \\ 0.6611 \\ 0.3333 \end{pmatrix}$	$\begin{pmatrix} 0.0004 \\ 0.6663 \\ 0.3333 \end{pmatrix}$	$\begin{pmatrix} 0.0000 \\ 0.6666 \\ 0.3333 \end{pmatrix}$
y_k	$\begin{pmatrix} 0.0735 \\ 0.5931 \\ 0.3333 \end{pmatrix}$	$\begin{pmatrix} 0.0349 \\ 0.5087 \\ 0.4564 \end{pmatrix}$	$\begin{pmatrix} 0.0333 \\ 0.4852 \\ 0.4814 \end{pmatrix}$	$\begin{pmatrix} 0.0333 \\ 0.4835 \\ 0.4832 \end{pmatrix}$	$\begin{pmatrix} 0.0333 \\ 0.4833 \\ 0.4833 \end{pmatrix}$
cx_k	0.3333	0.0735	0.0056	0.0004	0.0000

16.1.5 DUALITY

Associated with every LP problem is its dual problem, which is important in devising alternative solution procedures for the original LP. The dual also provides useful information for conducting postoptimality analyses on the given LP.

Definitions:

Associated with every LP problem is another LP problem, its ***dual***. The original problem is called the ***primal***.

The dual of an LP in form (2)

$$\begin{aligned} \text{maximize: } & cx \\ \text{subject to: } & Ax \le b \\ & x \ge 0 \end{aligned}$$

is defined to be the LP

$$\begin{aligned} \text{minimize: } & ub \\ \text{subject to: } & uA \ge c \\ & u \ge 0. \end{aligned} \tag{4}$$

The components $u_1, u_2, \ldots, u_m$ of u are the ***dual variables***.

Facts:

1. To find the dual of an arbitrary LP problem either transform it (§16.1.1, Fact 5) into form (2) or use the following table:

primal	*dual*
maximization problem	minimization problem
unrestricted variable	equality constraint
nonnegative variable	$\ge$ constraint
nonpositive variable	$\le$ constraint
equality constraint	unrestricted variable
$\le$ constraint	nonnegative variable
$\ge$ constraint	nonpositive variable

2. The dual of the dual LP is the primal LP.

3. *Weak duality theorem*: For any feasible solution x to the primal and any feasible solution u to the dual $cx \le ub$.

4. *Strong duality theorem*: If x^* is an optimal solution to (2) then there exists an optimal solution u^* for (4) and $cx^* = u^*b$.

5. A given primal LP and its associated dual LP can only produce certain combinations of outcomes, as specified in the following table. For example, if one problem is unbounded then the other must be infeasible.

primal	*dual*
optimal	optimal
infeasible	unbounded
unbounded	infeasible
infeasible	infeasible

6. Let x^* be an optimal BFS of the primal LP (2), with the corresponding tableau $\begin{array}{c|c} u & z \\ \hline D & f \end{array}$. Then u is an optimal BFS of the dual LP (4).

7. *Complementary slackness*: An optimal dual (primal) variable u_i^* (x_j^*) can be nonzero only if it corresponds to a primal (dual) constraint active at x^* (u^*).

8. *Economic interpretation*: Suppose in the LP (2) that b_i is the amount of resource i available to a firm maximizing its profit. Then the optimal dual variable u_i^* is the price the firm should be willing to pay (over and above its market price) for an extra unit of resource i.

9. *Dual simplex algorithm*: This approach (Algorithm 4) can be used when a basic solution for (2) is known that is not necessarily feasible but which has nonnegative reduced costs (i.e., it is a *dual feasible* basic solution). The main idea of the algorithm is to start with the dual feasible basic solution and to maintain dual feasibility at each pivot. An optimal BFS is found once primal feasibility is achieved.

```
Algorithm 4: Dual simplex algorithm.
  input: LP in form (2), dual feasible basic solution $x_0$
  output: an optimal BFS or an indication of infeasibility
  associate with $x_0 = (x_B, x_N) = (f, 0)$ the tableau $\begin{array}{c|c} u & z \\ \hline D & f \end{array}$, where $u \geq 0$
  $k := 0$
  {Main loop}
  {Optimality test}
  if $f \geq 0$ then $x_k$ is an optimal solution — stop
  else
    $t^*$ := the smallest index with $f_{t^*} < 0$
    if $d_{t^*j} \geq 0$ for all $j$ then the LP is infeasible — stop
    else
      $j^*$ := the smallest index attaining the maximum
            $\max\{\frac{u_j}{d_{t^*j}} \mid j = 1, \ldots, m+n; d_{t^*j} < 0\}$
      do a pivot with entering index $j^*$, leaving index $\varphi(t^*)$
      set component $\varphi(t)$ of $x_{k+1}$ to $f_t$ for $t = 1, \ldots, m$ and the remaining
            components of $x_{k+1}$ to zero
      $k := k + 1$
  {Continue with next iteration of main loop}
```

10. The dual simplex method was devised in 1954 by C. E. Lemke (1920–2004).

11. C++ code that implements the dual simplex algorithm can be found at

- `http://www.codeforge.com/article/214515`

Examples:

1. Using the table of Fact 1, the dual of

$$\begin{aligned} \text{maximize:} \quad & 5x_1 - 7x_2 \\ \text{subject to:} \quad & x_1 + 3x_2 - x_3 + x_4 \leq -1 \\ & 2x_1 + x_2 - 4x_3 - x_4 \geq 3 \\ & x_1 + x_2 - 3x_3 + 2x_4 = 2 \\ & x_2 \geq 0,\ x_4 \leq 0,\ x_1, x_3 \text{ unrestricted} \end{aligned}$$

is

$$\begin{array}{rl} \text{minimize:} & -u_1+3u_2+2u_3 \\ \text{subject to:} & u_1+2u_2+u_3=5 \\ & 3u_1+u_2+u_3\geq -7 \\ & -u_1-4u_2-3u_3=0 \\ & u_1-u_2+2u_3\leq 0 \\ & u_1\geq 0,\ u_2\leq 0,\ u_3 \text{ unrestricted.} \end{array}$$

2. The LP of §16.1.2, Example 1 has the dual

$$\begin{array}{rl} \text{minimize:} & 5u_1+12u_2+2u_3 \\ \text{subject to:} & 3u_1-9u_2-6u_3\geq 3 \\ & 4u_2+2u_3\geq 4 \\ & -u_1+3u_2+4u_3\geq 4 \\ & u_1,u_2,u_3\geq 0\,. \end{array}$$

The optimal solution to the primal LP (see §16.1.3, Example 2) is $x^*=(\frac{11}{3},0,6)^T$ with optimal objective value $z^*=35$. The associated tableau has $u=(0,1,0,6,0,\frac{5}{2})$. The optimal dual variables for (4) are recovered from the reduced costs of the slack variables x_4, x_5, and x_6, so that $u^*=(6,0,\frac{5}{2})$. As guaranteed by Fact 4, the optimal dual objective value $5u_1^*+12u_2^*+2u_3^*=30+5=35=z^*$. The complementary slackness conditions in Fact 7 hold here: the second primal constraint holds with strict inequality ($x_5^*=27>0$), so the second dual variable $u_2^*=0$; also, the second dual constraint holds with strict inequality ($u_5^*=1>0$), so the second primal variable $x_2^*=0$.

3. Using the transformations in Fact 5 of §16.1.1, the LP problem

$$\begin{array}{rl} \text{minimize:} & 2x_1+3x_2+4x_3 \\ \text{subject to:} & 2x_1-x_2+3x_3\geq 4 \\ & x_1+2x_2+x_3\geq 3 \\ & x_1,x_2,x_3\geq 0 \end{array}$$

can be written in form (2), with the corresponding tableau (a) below. Since $u\geq 0$ the current solution $x_4=-4$, $x_5=-3$ is dual feasible but not primal feasible. Algorithm 4 can then be applied, giving $t^*=1$ and $j^*=1$. The variable x_4 leaves the basis and the variable x_1 enters, giving tableau (b) and the new basic but not feasible solution $x=(2,0,0,0,-1)^T$ with $z=4$. One additional dual simplex pivot achieves primal feasibility and produces the optimal solution $x^*=(\frac{11}{5},\frac{2}{5},0,0,0)^T$ with $z^*=\frac{28}{5}$.

tableau (a)

2	3	4	0	0	0
−2	1	−3	1	0	−4
−1	−2	−1	0	1	−3

tableau (b)

0	4	1	1	0	−4
1	$-\frac{1}{2}$	$\frac{3}{2}$	$-\frac{1}{2}$	0	2
0	$-\frac{5}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$	1	−1

16.1.6 SENSITIVITY ANALYSIS

Since the data to an LP are often estimates or can vary over time, the analysis of many problems requires studying the behavior of the optimal LP solution to changes in the input data. This form of sensitivity analysis typically uses the solution of the original LP as a starting point for solving the altered LP.

Definitions:

The ***original tableau*** for the LP problem (2) is $\begin{array}{cc|c} -c & 0 & 0 \\ \hline A & I & b \end{array}$.

The ***final tableau*** for the optimal basic solution x^* (possibly after a permutation of the columns $1, \ldots, m+n$) is

$$\begin{array}{c|c} u & z \\ \hline D & f \end{array} = \begin{array}{cc|c} 0 & c_B B^{-1}N - c_N & c_B B^{-1}b \\ \hline I & B^{-1}N & B^{-1}b \end{array}.$$

Row 0 of a tableau refers to the row u of associated dual variables.

A tableau is ***suboptimal*** if some entries of row 0 are negative. A tableau is ***infeasible*** if some entries of column f are negative.

Let a^j be the column of $[A \;\; I\,]$ associated with variable x_j and let d^j be the column of D associated with variable x_j.

Facts:

1. The formulas in Table 1 show how to construct an updated tableau $\mathcal{T}'$ from the final tableau $\mathcal{T}$ of an LP problem:

- if $\mathcal{T}'$ is suboptimal, reoptimize using the simplex method starting with $\mathcal{T}'$;
- if $\mathcal{T}'$ is infeasible, reoptimize using the dual simplex method starting with $\mathcal{T}'$;
- otherwise, $\mathcal{T}'$ corresponds to an optimal BFS for the altered problem.

Table 1: Formulas for constructing the updated tableau $\mathcal{T}'$.

change in *LP data*	*possible changes* *in tableau*	*tableau updates*
change in c_s, s nonbasic: $c_s := c_s + \Delta$	only entry s of row 0 can change	$u_s := u_s - \Delta$
change in c_s, s basic: $c_s := c_s + \Delta$	row 0 and z can change	update c_B $u_j := c_B B^{-1} a^j - c_j$, j nonbasic $z := c_B B^{-1} b$
change in b_r: $b_r := b_r + \Delta$	decision variables and z can change	$f := f + \Delta(d^{n+r})$ update b $z := c_B B^{-1} b$
change nonbasic column s: $a^s := \widetilde{a}^s$ $c_s := \widetilde{c}_s$	tableau column s and u_s can change	update a^s and c_s $u_s := c_B B^{-1} a^s - c_s$ $d^s := B^{-1} a^s$
add a new column a^ℓ with cost c_ℓ	new tableau column ℓ and new u_ℓ	$u_\ell := c_B B^{-1} a^\ell - c_\ell$ $d^\ell := B^{-1} a^\ell$

2. *Ranging*: Table 2 shows how to calculate the (maximal) ranges over which the current basis B remains optimal. In the “range” column of Table 2, b and c_B refer to entries of $\mathcal{T}$, rather than $\mathcal{T}'$.

3. When b_i is changed within the allowable range (Table 2), the change in the objective value is $-\Delta$ times the reduced cost of the slack variable associated with row i.

4. To add a new constraint $a_\ell x \leq b_\ell$ to the original LP do the following:

- add a new (identity) column to the tableau corresponding to the slack variable of the new constraint;
- add a new row ℓ to the tableau corresponding to the new constraint;
- for each basic j with $d_{\ell j} \neq 0$, multiply row $i = \varphi^{-1}(j)$ by $-d_{\ell j}$ and add to row ℓ;
- if the updated $f_\ell < 0$ use the dual simplex method to reoptimize.

5. For changes in more than one component of c, or in more than one right-hand side b, use the "100% *rule*":

- *objective function changes*: If all changes occur in variables j with $u_j > 0$, the current solution remains optimal as long as each c_j is within its allowable range (Table 2). Otherwise, let Δc_j be the change to c_j. If $\Delta c_j \geq 0$ set $r_j := \frac{\Delta c_j}{\Delta_U}$, else set $r_j := -\frac{\Delta c_j}{\Delta_L}$, where Δ_U, Δ_L are computed from Table 2. If $\sum r_j \leq 1$, the current solution remains optimal (if not, the rule tells nothing).
- *right-hand side changes*: If all changes are in constraints not active at x^*, the current basis remains optimal as long as each b_i is within its allowable range (Table 2). Otherwise, let Δb_i be the change to b_i. If $\Delta b_i \geq 0$ set $r_i := \frac{\Delta b_i}{\Delta_U}$, else set $r_i := -\frac{\Delta b_i}{\Delta_L}$, where Δ_U, Δ_L are computed from Table 2. If $\sum r_i \leq 1$, the current solution remains optimal (if not, the rule tells nothing).

Table 2: Ranges over which current basis is optimal.

change in LP data	*range*
change in c_s, s nonbasic: $c_s := c_s + \Delta$	$\Delta \leq u_s$
change in c_s, s basic: $c_s := c_s + \Delta$	$\Delta_L \leq \Delta \leq \Delta_U$, where $p = s$th row of B^{-1} $\Delta_L = \max\{\frac{c_j - c_B B^{-1} a^j}{pa^j} \mid pa^j > 0,\ j \text{ nonbasic}\}$ $\Delta_U = \min\{\frac{c_j - c_B B^{-1} a^j}{pa^j} \mid pa^j < 0,\ j \text{ nonbasic}\}$
change in b_r: $b_r := b_r + \Delta$	$\Delta_L \leq \Delta \leq \Delta_U$, where $q = r$th column of B^{-1} $\Delta_L = \max\{\frac{-(B^{-1}b)_i}{q_i} \mid q_i > 0\}$ $\Delta_U = \min\{\frac{-(B^{-1}b)_i}{q_i} \mid q_i < 0\}$

Examples:

1. The LP problem

$$\begin{array}{rl} \text{maximize:} & 3x_1 + 4x_2 + 4x_3 \\ \text{subject to:} & 3x_1 - x_3 \leq 5 \\ & -9x_1 + 4x_2 + 3x_3 \leq 12 \\ & -6x_1 + 2x_2 + 4x_3 \leq 2 \\ & x_1, x_2, x_3 \geq 0 \end{array}$$

has the final tableau $\mathcal{T}$

$$\begin{array}{cccccc|c} 0 & 1 & 0 & 6 & 0 & \frac{5}{2} & 35 \\ \hline 1 & \frac{1}{3} & 0 & \frac{2}{3} & 0 & \frac{1}{6} & \frac{11}{3} \\ 0 & 4 & 0 & 3 & 1 & 0 & 27 \\ 0 & 1 & 1 & 1 & 0 & \frac{1}{2} & 6 \end{array}$$

corresponding to the optimal BFS $x^* = (\frac{11}{3}, 0, 6, 0, 27, 0)^T$ with $z^* = 35$. The associated basis matrix B contains columns $1, 5, 3$ and the inverse basis matrix is B^{-1}, where

$$B = \begin{pmatrix} 3 & 0 & -1 \\ -9 & 1 & 3 \\ -6 & 0 & 4 \end{pmatrix}, \qquad B^{-1} = \begin{pmatrix} \frac{2}{3} & 0 & \frac{1}{6} \\ 3 & 1 & 0 \\ 1 & 0 & \frac{1}{2} \end{pmatrix}.$$

If the nonbasic objective coefficient c_2 is changed to $4 + \Delta$, the current BFS remains optimal for $\Delta \le u_2 = 1$, that is, for $c_2 \le 5$. If the basic objective coefficient c_1 is changed to $3 + \Delta$, then $p = (\frac{2}{3}, 0, \frac{1}{6})$ and $\Delta_L = \max\{\frac{-1}{1/3}, \frac{-6}{2/3}, \frac{-5/2}{1/6}\} = -3$. This gives $-3 \le \Delta$, so the current BFS remains optimal over the range $c_1 \ge 0$. If, however, c_3 is changed to the value 2, meaning $\Delta = -2$, the current basis with $\Sigma_B = \{1, 5, 3\}$ will no longer be optimal. Using Table 2 the vector c_B is updated to $c_B = (3, 0, 2)$ and the nonbasic u_j are computed as $u_2 = -1$, $u_4 = 4$, $u_6 = \frac{3}{2}$. The updated $u = (0, -1, 0, 4, 0, \frac{3}{2})$ and $z = 23$ are inserted in tableau $\mathcal{T}$. Since $u_2 < 0$ a simplex pivot with $j^* = 2$ and $t^* = 3$ is performed, leading to the new optimal solution $x^* = (\frac{5}{3}, 6, 0, 0, 3, 0)^T$ with $z^* = 29$.

2. Suppose that the right-hand side b_1 in the original LP of Example 1 is changed to $b_1 = 3$, corresponding to the change $\Delta = -2$. From Table 1 f is updated to $(\frac{11}{3}, 27, 6)^T - 2(\frac{2}{3}, 3, 1)^T = (\frac{7}{3}, 21, 4)^T$, giving the optimal BFS $x^* = (\frac{7}{3}, 0, 4, 0, 21, 0)^T$. Since $b = (3, 12, 2)^T$ the objective value found from Table 1 is $z = 23$. Notice that the change in objective value is $\Delta z = 23 - 35 = -12$, which is the same as $-\Delta$ times the reduced cost $-u_4$ of x_4: namely, $-12 = 2 \cdot (-6)$. To determine the range of variation of b_1 so that the basis defined by $\Sigma_B = \{1, 5, 3\}$ remains unchanged, Table 2 is used. Here $q = (\frac{2}{3}, 3, 1)^T$ and $\Delta_L = \max\{-\frac{11/3}{2/3}, -\frac{27}{3}, -\frac{6}{1}\} = -\frac{11}{2}$. Thus $-\frac{11}{2} \le \Delta$ so that the current basis is optimal for $b_1 \ge -\frac{1}{2}$.

3. If the new constraint $3x_1 + 2x_2 - x_3 \le 4$ is added to the LP in Example 1, the (previous) optimal solution $x^* = (\frac{11}{3}, 0, 6, 0, 27, 0)^T$ is no longer feasible. Using Fact 4, a new row and column are added to the tableau $\mathcal{T}$, giving tableau (a) below. By adding (-3) times row 1 and $+1$ times row 3 to the last row, a new tableau (b) is produced corresponding to the basic set $\Sigma_B = \{1, 5, 3, 7\}$. Since $b_4 < 0$ the dual simplex algorithm is then used with $t^* = 4$ and $j^* = 4$, producing a new tableau that is primal feasible, with the new optimal BFS $(3, 0, 5, 1, 24, 0, 0)^T$ and objective value 29.

tableau (a)

0	1	0	6	0	$\frac{5}{2}$	0	35
1	$\frac{1}{3}$	0	$\frac{2}{3}$	0	$\frac{1}{6}$	0	$\frac{11}{3}$
0	4	0	3	1	0	0	27
0	1	1	1	0	$\frac{1}{2}$	0	6
3	2	-1	0	0	0	1	4

tableau (b)

0	1	0	6	0	$\frac{5}{2}$	0	35
1	$\frac{1}{3}$	0	$\frac{2}{3}$	0	$\frac{1}{6}$	0	$\frac{11}{3}$
0	4	0	3	1	0	0	27
0	1	1	1	0	$\frac{1}{2}$	0	6
0	2	0	-1	0	0	1	-1

4. One example of the practical use of sensitivity analysis occurred in the airline industry. When the price of aviation fuel was relatively high, and varied by airport location, a linear programming model was successfully used to determine an optimal strategy for refueling aircraft. The key idea is that it might be more economical to take on extra fuel at an enroute stop if the fuel cost savings for the remainder of the flight are greater than the extra fuel burned because of the excess weight of additional fuel. A linear programming model of this situation ended up saving millions of dollars annually. An important feature was providing pilots with *ranges* of fuel prices for each airport location, with associated optimal policies for taking on extra fuel based on the cost range.

5. Another example of the beneficial use of sensitivity analysis occurred in a 1997 study to assess the effectiveness of mandatory minimum-length sentences for reducing drug use. One finding of the study was that the longer sentences become more effective than conventional enforcement only when it costs more than \$30,000 to arrest a drug dealer. Thus, rather than producing a single optimal policy, this study identified conditions (parameter ranges) under which each alternative policy is to be preferred.

16.1.7 GOAL PROGRAMMING

Goal programming refers to a multicriteria decision-making problem in which a given LP problem can have multiple objectives or goals. This technique is useful when it is impossible to satisfy all goals simultaneously. For example, a model for optimizing the operation of an oil refinery might seek not only to minimize production cost, but also to reduce the amount of imported crude oil and the amount of oil having a high sulfur content. In another instance, the routing of hazardous waste might consider minimizing not only the total distance traveled but also the number of residents living within ten miles of the selected route.

Definitions:

A ***goal programming*** (***GP***) ***problem*** has linear constraints that can be written

$$\begin{aligned} Ax &\le b \\ Hx + \widetilde{x} - \overline{x} &= h \\ x \ge 0,\ \widetilde{x} \ge 0,\ \overline{x} &\ge 0 \end{aligned}$$

and objective functions

$$\begin{aligned} G_1 :&\quad \text{minimize } z_1 = c_1\widetilde{x}_1 + d_1\overline{x}_1 \\ G_2 :&\quad \text{minimize } z_2 = c_2\widetilde{x}_2 + d_2\overline{x}_2 \\ &\qquad\vdots \\ G_\ell :&\quad \text{minimize } z_\ell = c_\ell\widetilde{x}_\ell + d_\ell\overline{x}_\ell \end{aligned}$$

where A is an $m \times n$ matrix and H is an $\ell \times n$ matrix.

The value h_k is the ***target value*** of the kth goal. Goal k is ***satisfied*** if $(Hx)_k = h_k$ holds for a given vector x of ***decision variables***.

The variables $\widetilde{x}$ are the ***underachievement variables*** while the variables $\overline{x}$ are the ***overachievement variables***.

Facts:

1. In a GP problem, the aim is to find decision variables that approximately satisfy the given goals, which is achieved by jointly minimizing the magnitudes of the underachievement and overachievement variables.

2. Assuming $c_k > 0$ and $d_k > 0$, then goal k is satisfied by making $z_k = 0$.

3. If all c_t and d_t are positive then for each $k = 1, \dots, \ell$ at most one of $\widetilde{x}_k, \overline{x}_k$ will be positive in an optimal solution.

4. One important case of a GP problem has $c_k = d_k = 1$ for $k = 1, \dots, \ell$, making the objective to (approximately) satisfy all constraints $Hx = h$.

5. When the relative importance of $G_1, \ldots, G_\ell$ is known precisely, an ordinary LP can be used with the objective function being a weighted sum of $z_1, \ldots, z_\ell$.

6. *Preemptive goal programming*: Here the goals are prioritized $G_1 \gg G_2 \gg \cdots \gg G_\ell$, meaning that goal G_1 is the most important and goal G_ℓ is the least important. Solutions are sought that satisfy the most important goal. Among all such solutions, those are retained that best satisfy the second highest goal, and so forth.

7. *Goal programming simplex method*: The simplex method (§16.1.3, Algorithm 2) can be extended to preemptive GP (minimization) problems, with the following modifications:

- ℓ "objective rows" are maintained in the tableau instead of just one.
- Let i^* be the highest-priority index with $z_{i^*} > 0$ for which there exists a nonbasic j^* with $u^{i^*}_{j^*} > 0$ and with $u^i_{j^*} \geq 0$ for any (higher-priority) objective row $i < i^*$. If there is no such i^*, stop; else pick j^* corresponding to the most positive $u^{i^*}_{j^*}$.
- All ℓ objective rows are updated when a pivot is performed.
- At completion, if the solution fails to satisfy all goals, then every nonbasic variable that would decrease the objective value z_i if it entered the basis, would increase $z_{i'}$ for some higher-priority goal $G_{i'}$, $i' < i$.

8. An optimization package (LiPS) that implements goal programming can be found at

- `http://sourceforge.net/projects/lipside/`

16.1.8 INTEGER PROGRAMMING

Integer programming problems are LPs in which some of the variables are constrained to be integers. Such problems more accurately model a wide range of application areas, including capital budgeting, facility location, manufacturing, scheduling, logical inference, physics, engineering design, environmental economics, and VLSI circuit design. However, integer programming problems are much more difficult to solve than LPs.

Definitions:

Let $\mathcal{Z}^n$ $[\mathcal{Z}^n_+]$ denote the set of all n-vectors with all components integers [nonnegative integers], and let $\mathcal{R}^n$ $[\mathcal{R}^n_+]$ denote the set of all n-vectors with all components real numbers [nonnegative real numbers].

A ***pure integer programming*** (***IP***) ***problem*** is an optimization problem of the form

$$\begin{aligned} \text{maximize:} \quad & z_{IP} = cx \\ \text{subject to:} \quad & Ax \leq b \\ & x \in \mathcal{Z}^n_+ \end{aligned} \tag{5}$$

where A is an $m \times n$ matrix, b is an m-column vector, and c is an n-row vector.

A ***0-1 IP problem*** is an IP with each $x_j \in \{0, 1\}$.

A ***mixed integer programming*** (***MIP***) ***problem*** is of the form

$$\begin{aligned} \text{maximize:} \quad & z_{MIP} = cx + hy \\ \text{subject to:} \quad & Ax + Gy \leq b \\ & x \in \mathcal{Z}^n_+,\ y \in \mathcal{R}^p_+ \end{aligned}$$

where A is an $m \times n$ matrix, G is an $m \times p$ matrix, b is an m-column vector, c is an n-row vector, and h is a p-row vector.

For IP problem (5), the ***feasible region*** is $S \equiv \{x \in \mathcal{Z}_+^n \mid Ax \leq b\}$.

A ***polyhedron*** is a set of points in $\mathcal{R}^n$ satisfying a finite set of linear inequalities.

If X is a finite set of points in $\mathcal{R}^n$, the ***convex hull*** of X is

$$\mathit{conv}\,(X) \equiv \{\textstyle\sum \lambda_i x_i \mid x_i \in X,\ \sum \lambda_i = 1,\ \lambda_i \geq 0\}.$$

The ***LP relaxation*** of (5) is the linear programming problem

$$\begin{aligned} \text{maximize:}\quad & z_{LP} = cx \\ \text{subject to:}\quad & Ax \leq b \\ & x \geq 0. \end{aligned} \tag{6}$$

More generally, a ***relaxation*** of (5) is any problem $\max\{cx \mid x \in T\}$, where $S \subset T$.

The problem $\max\{cx \mid \bar{A}x \leq \bar{b},\ x \in \mathcal{Z}_+^n\}$ is a ***formulation*** for (5) if it contains exactly the same set of feasible integral points as (5). If the feasible region of the LP relaxation of one formulation is strictly contained in another, the first is a ***tighter*** formulation.

Suppose $\widetilde{x}$ is a feasible solution to (6) but not to (5). A ***cutting plane*** is any inequality $\pi x \leq \pi_0$ satisfied by all points in $\mathit{conv}\,(S)$ but not by $\widetilde{x}$.

A family $\mathcal{S}$ of subsets of S is a ***separation*** of S if $\bigcup_{S_k \in \mathcal{S}} S_k = S$; a separation is usually a partition of the set S.

A ***lower bound*** $\underline{z}$ for z_{IP} is an underestimate of z_{IP}.

Facts:

1. $z_{IP} \leq z_{LP}$. More generally, any relaxation of (5) has an optimal objective value at least as large as z_{IP}.

2. If x' is feasible to (5) then $z' = cx'$ satisfies $z' \leq z_{IP}$.

3. The feasible region of an LP problem is a polyhedron, and every polyhedron is the feasible region of some LP problem.

4. The set $\mathit{conv}\,(S)$ is a polyhedron, so there is an LP problem $\max\{cx \mid \widetilde{A}x \leq \widetilde{b},\ x \geq 0\}$ with the feasible region $\mathit{conv}\,(S)$.

5. An optimal solution to the LP in Fact 4 is an optimal solution to (5). However, finding all necessary constraints, called *facets*, of this LP is extremely difficult.

6. IP is an NP-hard optimization problem (§17.5.2). Consequently, such problems are harder to solve in practice than LPs. The inherent complexity of solving IPs stems from the nonconvexity of their feasible region, which makes it difficult to verify the optimality of a proposed optimal solution in an efficient manner.

7. Formulation of an IP is critical: achieving problem tightness is more important than reducing the number of constraints or variables appearing in the formulation.

8. An excellent introduction to building integer linear programming models is found in Williams [Wi13].

9. Solution techniques for (5) usually involve some preliminary operations that improve the formulation, called *preprocessing*, followed by an iterative use of heuristics to quickly find feasible solutions.

10. Popular solution techniques for solving (5) include cutting plane methods (Fact 11), branch-and-bound techniques (Fact 13), and (hybrid) branch-and-cut methods.

11. *Cutting plane method*: This approach (Algorithm 5) proceeds by first finding an optimal solution $\overline{x}$ to a relaxation R of the original problem (5). If $\overline{x}$ is not optimal, a cutting plane is added to the constraints of the current relaxation and the new LP is then solved. This process is repeated until an optimal solution is found.

Algorithm 5: **Cutting plane algorithm for (5).**

```
input: IP in form (5)
output: an optimal solution $x^*$ with objective value $z^*$
let $R$ be the LP relaxation: $\max\{cx \mid Ax \le b,\ x \ge 0\}$
{Main loop}
optimally solve problem $R$, obtaining $\overline{x}$
if $\overline{x} \in \mathcal{Z}^n_+$ then stop with $x^* := \overline{x}$ and $z^* := c\overline{x}$
else
  find a cutting plane $\pi x \le \pi_0$ with $\pi\overline{x} > \pi_0$ and $\pi x \le \pi_0$ for all feasible
      solutions of (5)
  modify $R$ by adding the constraint $\pi x \le \pi_0$
{Continue with next iteration of main loop}
```

12. General methods for finding cutting planes for IP or MIP problems are relatively slow. Cutting plane algorithms using facets for specific classes of IP problems are better, since facets make the "deepest" cuts.

13. *Branch-and-bound method*: This approach (Algorithm 6) decomposes the original problem P into subproblems or *nodes* by breaking S into subsets. Each subproblem P_j is implicitly investigated (and possibly discarded) until an optimal one is found. In this algorithm z_j^* is the optimal value of problem P_j, $\overline{z_j}$ is the optimal value of the relaxation R_j of P_j, and $\underline{z_j}$ is the best known lower bound for z_j^*.

Algorithm 6: **Branch-and-bound algorithm for (5).**

```
input: IP in form (5)
output: an optimal solution $x_0$ with objective value $\underline{z_0}$
let $P$ be the problem: $\max\{cx \mid x \in S\}$
$P_0 := P$; $S_0 := S$; $\underline{z_0} := -\infty$; $\overline{z_0} := +\infty$
put $P_0$ on the list of live nodes
{Branching}
  if no live node exists then go to {termination}
  else select a live node $P_j$
{Bounding}
  solve a relaxation $R_j$ of $P_j$
  if $R_j$ is infeasible then discard $P_j$ and go to {branching}
  if $\overline{z_j} = +\infty$ then go to {separation}
{$\overline{z_j}$ is finite}
  if $\overline{z_j} \le \underline{z_0}$ then discard node $P_j$ and go to {branching}
  if $\overline{z_j} = \underline{z_j}$ then update $\underline{z_0} := \max\{\underline{z_0}, \underline{z_j}\}$ and discard any node $P_i$ for
        which $\overline{z_i} \leq \underline{z_0}$
{Separation}
  choose a separation $\mathcal{S}_j^*$ of $S_j$ forming new live nodes and go to {branching}
{Termination}
  if $\underline{z_0} = -\infty$ then problem (5) is infeasible
  if $\underline{z_0}$ is finite then $\underline{z_0}$ is the optimal objective value and the associated $x_0$ is
        an optimal solution
```

14. In Algorithm 6 the optimal value $\overline{z_j}$ of relaxation R_j is an upper bound for z_j^*. Also $\underline{z_0}$ is the objective value for the best known feasible solution to (5).

15. LP relaxations are often used in the bounding portion of Algorithm 6.

16. There are specializations of Algorithm 6 for 0-1 IP problems and for MIP problems.

17. Branch-and-bound tends to be a computationally expensive solution method. Usually it is applied only when other methods appear to be stalling.

18. In the survey [Fo15] of linear programming software, many of the packages listed will handle IP problems as well. When available, these extensions to binary and/or integer-valued variables are indicated by the survey.

19. Several software packages that solve IP and MIP problems can be found at

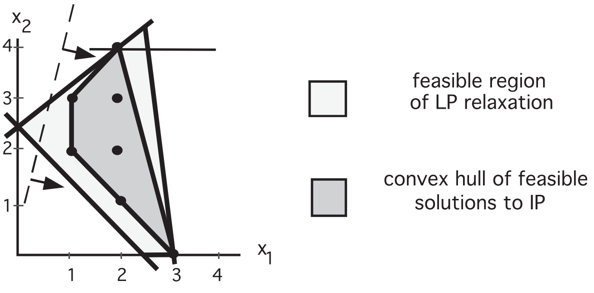
- `http://www.aimms.com`
- `http://optimization-suite.coin-or.org`
- `http://www.cplex.com`
- `http://www.gurobi.com`
- `http://www.lindo.com`
- `www.mathworks.com/products/optimization`

Examples:

1. The next figure shows the convex hull of feasible solutions to the IP

$$\begin{array}{rl}
\text{maximize:} & -x_1 + \frac{1}{2}x_2 \\
\text{subject to:} & x_2 \leq 4 \\
& -x_1 - x_2 \leq -\frac{5}{2} \\
& 8x_1 + x_2 \leq 24 \\
& -3x_1 + 4x_2 \leq 10 \\
& x_1,\ x_2 \geq 0 \\
& x_1,\, x_2 \text{ integers.}
\end{array}$$

Here $S = \{(1,2),(1,3),(2,1),(2,2),(2,3),(2,4),(3,0)\}$. The optimal solution occurs at $(1,3)$, with $z_{IP} = \frac{1}{2}$. The feasible region of the LP relaxation is also shown, with the optimal LP value $z_{LP} = \frac{5}{4}$ attained at $(0, \frac{5}{2})$; a cutting plane is depicted by the dashed line.



x2
4
3
2
1
1
2
3
4
x1
feasible region of LP relaxation
convex hull of feasible solutions to IP

For this problem, *conv* (S) is defined by the following constraints:

$$\begin{aligned} -x_1 - x_2 &\le -3 \\ -x_1 + x_2 &\le 2 \\ -x_1 + &\le -1 \\ 4x_1 + x_2 &\le 12 \\ x_2 &\le 4 \\ x_1,\ x_2 &\ge 0. \end{aligned}$$

All of these constraints are facets except for $x_2 \le 4$ and the nonnegativity constraints, which are redundant.

2. The following IP has the feasible region $S = \{(0,0),(1,1),(2,2),(3,3),(4,4)\}$ and the optimal solution occurs at $(4,4)$ with $z_{IP} = 8$:

$$\begin{aligned} \text{maximize:}\quad & x_1 + x_2 \\ \text{subject to:}\quad & 2x_1 - 2x_2 \le 1 \\ & -7x_1 + 8x_2 \le 4 \\ & x_1,\ x_2 \ge 0 \\ & x_1,\ x_2 \text{ integers.} \end{aligned}$$

The LP relaxation has a feasible region defined by vertices $(0,0)$, $(\frac{1}{2},0)$, $(0,\frac{1}{2})$, $(8,\frac{15}{2})$, so its optimal solution occurs at $(8,\frac{15}{2})$ with $z_{LP} = \frac{31}{2}$. Consequently, the LP solution is a poor approximation to the optimal IP solution. Moreover, simply rounding the LP solution gives either $(8,7)$ or $(8,8)$, both of which are infeasible to the given IP problem.

3. The following IP can be solved using Algorithm 6:

$$\begin{aligned} \text{maximize:}\quad & 3x_1 + 3x_2 - 8x_3 \\ \text{subject to:}\quad & -3x_1 + 6x_2 + 7x_3 \le 8 \\ & 6x_1 - 3x_2 + 7x_3 \le 8 \\ & x_1,\ x_2,\ x_3 \ge 0 \\ & x_1,\ x_2,\ x_3 \text{ integers.} \end{aligned}$$

The initial problem P_0 has an LP relaxation R_0 that is obtained by removing the integer restrictions; solving this LP gives $x = (2.667, 2.667, 0)$ with $z = 16$. A separation is achieved by creating the two subproblems P_1 and P_2; the constraint $x_1 \le 2$ is appended to P_0, creating P_1, while the constraint $x_1 \ge 3$ is appended to P_0, creating P_2. Now the live nodes are P_1 and P_2. Solving the LP relaxation R_1 gives $x = (2, 2.333, 0)$ with $z = 13$. New subproblems P_3 and P_4 are obtained from P_1 by appending the constraints $x_2 \le 2$ and $x_2 \ge 3$, respectively. Now the live nodes are subproblems P_2, P_3, P_4. The

LP relaxation R_2 of P_2 is infeasible, as is the LP relaxation R_4 of P_4. Solving the LP relaxation R_3 gives the feasible integer solution $x = (2, 2, 0)$ with $z = 12$. Since there are no more live nodes, this represents the optimal solution to the stated problem.

4. *Fixed-charge problem*: Find optimal levels of n activities to satisfy m constraints while minimizing total cost. Each activity j has per unit cost c_j. In addition, there is a startup cost d_j for certain undertaken activities j.

This problem can be modeled as a MIP problem, with a real variable x_j for the level of each activity j. If activity j has a startup cost, introduce the additional 0-1 variable y_j, equal to 1 when $x_j > 0$ and 0 otherwise. For example, this condition can be enforced by imposing the constraints $M_j y_j \geq x_j$, $y_j \in \{0, 1\}$, where M_j is a known upper bound on the value of x_j. The objective is then to minimize $z = cx + dy$.

5. *Queens problem*: On an $n \times n$ chessboard, the task is to place as many nontaking queens as possible.

This problem can be formulated as a 0-1 IP problem, having binary variables x_{ij}. Here $x_{ij} = 1$ if and only if a queen is placed in row i and column j of the chessboard. The objective function is to maximize $z = \sum_i \sum_j x_{ij}$ and there is a constraint for each row, column, and diagonal of the chessboard. Such a constraint has the form $\sum_{(i,j) \in S} x_{ij} \leq 1$, where S is the set of entries in the row, column, or diagonal. For example, one optimal solution of this IP for the 7×7 chessboard is the assignment $x_{16} = x_{24} = x_{37} = x_{41} = x_{53} = x_{65} = x_{72} = 1$, with all other $x_{ij} = 0$.

16.2 LOCATION THEORY

Location theory is concerned with locating a fixed number of facilities at points in some space. The facilities provide a service (or product) to the customers whose locations and levels of demand (for the service) are known. The object is to find locations for the facilities to optimize some specified criterion, e.g., the cost of providing the service. Interest in location theory has grown very rapidly because of its variety of applications to such fields as operations research, city planning, geography, economics, electrical engineering, and computer science.

16.2.1 p-MEDIAN AND p-CENTER PROBLEMS

Definitions:

A ***metric space*** is a space S consisting of a set of points with a real-valued function $d(x, y)$ defined on all pairs of points $x, y \in S$ with the following properties (§6.1.4):

- $d(x, y) = d(y, x) \geq 0$ for all $x, y \in S$;
- $d(x, y) = 0$ if and only if $x = y$;
- $d(x, z) \leq d(x, y) + d(y, z)$ for all $x, y, z \in S$.

The value $d(x, y)$ is called the ***distance*** between points $x, y \in S$.

There are p facilities that are to be located at some set $X_p = \{x_1, x_2, \ldots, x_p\}$ of p points in the (metric) space S. The elements of X_p are the ***facility locations***.

The facilities are to provide a service to the customers whose positions are given by a set $V = \{v_1, v_2, \ldots, v_n\}$ of n points in S. The points in V are the ***demand points*** and the level of ***demand*** at $v_i \in V$ is given by $w(v_i) \geq 0$.

For $x \in S$ and $X_p \subseteq S$, let $d(x, X_p)$ be the minimum distance from x to a point of X_p: $d(x, X_p) = \min\limits_{x_i \in X_p} \{d(x, x_i)\}$.

Suppose X_p is a candidate set of points in S for locating the p facilities. The following two objective functions are defined on $X_p \subseteq S$:

- $F(X_p) = \sum\limits_{i=1}^{n} w(v_i) d(v_i, X_p)$;
- $H(X_p) = \max\limits_{1 \leq i \leq n} \{w(v_i) d(v_i, X_p)\}$.

The set $X_p^m \subseteq S$ is a ***p*-*median*** if $F(X_p^m) \leq F(X_p)$ for all possible $X_p \subseteq S$.

The set $X_p^c \subseteq S$ is a ***p*-*center*** if $H(X_p^c) \leq H(X_p)$ for all possible $X_p \subseteq S$.

Facts:

1. It is customary to assume that the demand at v_i is satisfied by its closest facility. Then $w(v_i)d(v_i, X_p)$ indicates the total (transportation) cost associated with having the demand at $v_i \in S$ satisfied by its closest facility in the candidate set X_p.

2. $F(X_p)$ represents the total transportation cost of satisfying the demands if the facilities are located at X_p.

3. $H(X_p)$ represents the cost (or unfairness) associated with a farthest demand point not being in close proximity to any facility.

4. A p-median formulation is designed for locating p facilities in a manner that minimizes the average cost of serving the customers.

5. A p-center formulation is designed for locating p emergency facilities (e.g., police, fire, and ambulance services), in which the maximum time to respond to an emergency is to be made as small as possible.

6. The p-median and p-center problems are only interesting if $p < n$; otherwise, it is possible to locate at least one facility at each demand point, thereby reducing $F(X_p)$ or $H(X_p)$ to 0.

Examples:

1. Suppose that a single warehouse is to be located in a way to service n retail outlets at minimum cost. Here $w(v_i)$ is the number of shipments made per week to the outlet at location v_i. This can be modeled as a 1-median problem, since the objective is to locate the single warehouse to minimize the total distance traveled by delivery vehicles.

2. A new police station is to be located within a portion of a city to serve residents of that area. Neighborhoods in that area can be taken as the demand points, and locating the police station can be formulated as a 1-center problem. Here, the maximum distance from the source of an emergency is critical so the police station should be located to minimize the maximum distance from a neighborhood. The weights at each demand point might be taken to be equal, or in some situations differing weights could signify conversion factors that translate distance into some other measure such as the value of residents' time.

3. *Statistics*: Suppose that n given data values $x_1, x_2, \ldots, x_n$ are viewed as points placed along the real line. If the distance between points x_i and x_j is their absolute difference $|x_i - x_j|$, then a 1-median of this set of points (unweighted customer locations) is a point (facility) $\hat{x}$ that minimizes $\sum_{i=1}^{n} |x_i - \hat{x}|$. In fact, $\hat{x}$ corresponds to a *median* of the n data values. If the distance between points x_i and x_j is their squared difference $(x_i - x_j)^2$, then a 1-median is a point $\bar{x}$ minimizing $\sum_{i=1}^{n}(x_i - \bar{x})^2$, which is precisely the *mean* of the n data values. Alternatively, for either distance measure the 1-center of this set of points turns out to correspond to the *midrange* of the dataset: namely, the 1-center is the point located halfway between the largest and the smallest data values.

16.2.2 p-MEDIANS AND p-CENTERS ON NETWORKS

Definitions:

A ***network*** is a weighted graph $G = (V, E)$ with vertex set $V = \{v_1, v_2, \ldots, v_n\}$ and edge set E, where $m = |E|$; see §8.1.1.

The ***weight*** of vertex $v \in V$ represents the demand at v and is denoted by $w(v) \geq 0$.

The ***length*** of edge $e \in E$ represents the cost of travel (or distance) across e and is denoted by $\ell(e) > 0$. Each edge is assumed to be a line segment joining its end vertices.

A ***point on a network*** G is any point along any edge of G. The precise location of the point x on edge $e = (u, v)$ is indicated by the distance of x from u or v.

If x and y are any two points on G, the ***distance*** $d(x, y)$ is the length of a shortest path between x and y in G, where the length of a path is the sum of the lengths of the edges (or partial edges) in the path.

Facts:

1. Network G with the above definition of distance constitutes a metric space (§16.2.1).

2. *p-median theorem*: Given a positive integer p and a network $G = (V, E)$, there exists a set of p vertices $V_p \subseteq V$ such that $F(V_p) \leq F(X_p)$ for all possible sets X_p of p points on G. That is, a p-median can always be found that consists entirely of vertices.

3. A p-median of a network G can be found by a finite search through all possible $\binom{n}{p}$ choices of p vertices out of n. This is still a formidable task, but if p is a small number (say $p < 5$) it is certainly manageable.

4. The p-median theorem also holds if the cost of satisfying the demand at $v_i \in V$ is $f_i(d(v_i, X_p))$, instead of $w(v_i) \cdot d(v_i, X_p)$, provided that $f_i \colon \mathcal{R}^+ \to \mathcal{R}^+$ is a concave nondecreasing function for all $i = 1, 2, \ldots, n$. ($\mathcal{R}^+$ denotes the set of nonnegative real numbers.) In this case, the objective function for the p-median problem becomes $F(X_p) = \sum_{i=1}^{n} f_i(d(v_i, X_p))$.

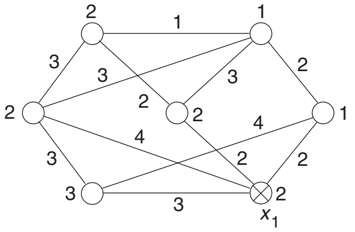
5. Each point x of a p-center X_p^c of network $G = (V, E)$ is a point on some edge e such that for some pair of distinct vertices u and $v \in V$, $w(u)d(u, x) = w(v)d(v, x)$; i.e., the point x is the "center" of a shortest path from u to v in G that passes through edge e.

6. There are at most n^2 predetermined choices of points on each edge of G that could be potential points in X_p^c; thus there are n^2m predetermined choices for points in X_p^c.

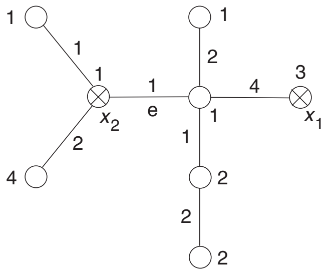
7. A p-center X_p^c of network G can be found by examining all possible $\binom{n^2m}{p}$ choices of p points out of n^2m. Even for small values of p, this is a formidable task.

Examples:

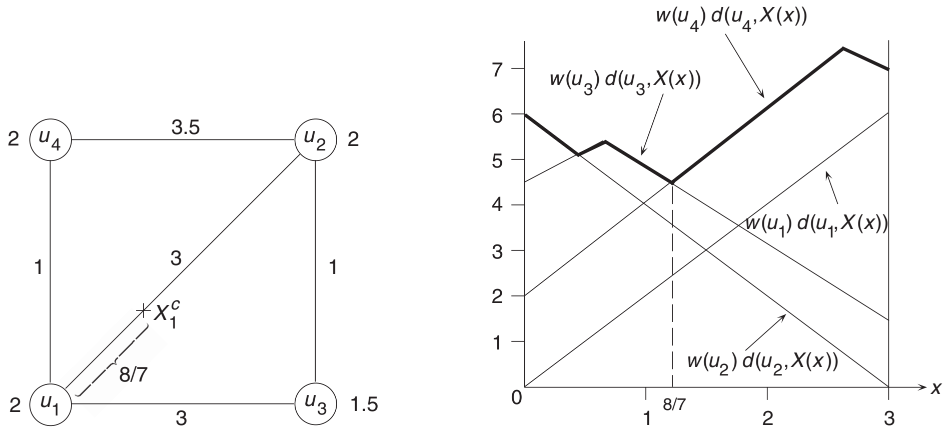
1. In the following network the levels of demand are given at the vertices and the lengths of the edges are shown on the edges. The 1-median of this network is at the vertex labeled x_1. The total transportation cost is $F(\{x_1\}) = 35$.



2. A tree network T is shown in the following figure, with the vertex demands and edge lengths displayed. A 2-median of T is the set of vertices $X_2 = \{x_1, x_2\}$, with total transportation cost $F(X_2) = 25$. If x_1 is kept fixed and t is an arbitrary point along edge e, then $\{x_1, t\}$ also constitutes a 2-median of T. This is consistent with Fact 2, which only states that there is a p-median that is a subset of V, not that every p-median occurs in this way.



3. A 1-center X_1^C is found for the network shown in the left portion of the following figure. For illustration, suppose that the 1-center is along the edge (u_1, u_2), thereby limiting the search to candidate points on this edge. Let $X(x)$ be an arbitrary point along edge (u_1, u_2), parametrized by the scalar $x = d(u_1, X(x))$. Note that $x \in [0, 3]$ with $X(0) = u_1$ and $X(3) = u_2$.



The right portion of the figure shows plots of $w(u_i)d(u_i, X(x))$ as a function of x for $i = 1, 2, \ldots, 4$. The plot of $D(x) \equiv \max_{1 \leq i \leq 4} w(u_i)d(u_i, X(x))$ is highlighted in bold and $D(x)$ assumes its minimum value when $x = \frac{8}{7}$. The 1-center of the network in part (a) is then located along edge (u_1, u_2) a distance of $\frac{8}{7}$ from u_1. Note that for this value of x, $w(u_4)d(u_4, X(x)) = w(u_3)d(u_3, X(x))$, consistent with Fact 5. In general, X_1^c of a network is not necessarily a unique point; however, here X_1^c is unique and $H(X_1^c) = \frac{30}{7}$.

4. Transportation planners are trying to decide where to locate a single school bus stop along a major highway. Situated along a one-mile stretch of the highway are eight communities. The table below gives the number of school-age students in each community who ride the bus on a daily basis. The distance of each community from the westernmost edge of the one-mile stretch of highway is also shown.

community	1	2	3	4	5	6	7	8
# students	9	4	8	11	5	3	5	11
distance (mi)	0.0	0.2	0.3	0.4	0.6	0.7	0.9	1.0

The data of this problem can be represented by an undirected path (§8.1.3) with each vertex v corresponding to a community and $w(v)$ being the number of students from that community riding the bus. Edges join adjacent communities and have a length given by the difference in distance entries from the table. To minimize the total (weighted) distance traveled by the students, a 1-median is sought. By Fact 2, only vertex locations need to be considered. For example, situating the bus stop at vertex 3 incurs a cost of $F(\{3\}) = 9(0.3) + 4(0.1) + 8(0) + 11(0.1) + 5(0.3) + 3(0.4) + 5(0.6) + 11(0.7) = 17.6$. The minimum cost is incurred for vertex 4, with $F(\{4\}) = 16.2$, so that the bus stop should be located at community 4.

16.2.3 ALGORITHMS FOR LOCATION ON NETWORKS

Algorithms for finding p-medians and p-centers of a network G can be devised that are feasible for small values of p. For general p, however, there are no efficient methods known for arbitrary networks G. Specialized (and efficient) algorithms are available when G is a tree.

Definitions:

Let T be a tree (§9.1.1) with vertex weights $w(v)$.

If T' is a subnetwork of T, define the ***total weight*** of T' by $W(T') = \sum_{v \in V(T')} w(v)$.

For $v \in V(T)$, let $T_{v1}, T_{v2}, \ldots, T_{vd(v)}$ be the components of $T - v$, where $d(v)$ is the degree (§8.1.1) of vertex v. Define $M_v = \max_{1 \leq i \leq d(v)} \{W(T_{vi})\}$.

A ***leaf vertex*** of T is a vertex of degree 1.

Facts:

1. For a network $G = (V, E)$ with n vertices and m edges, the p-median and p-center problems can be solved in $O(n^{p+1})$ and $O(m^p n^p \log^2 n)$ time, respectively [Ta88].

2. Bhattacharya and Shi [BhSh14] provide an improved algorithm for solving the p-center problem with worst-case complexity $O(m^p n^{p/2} 2^{\log^* n} \log n)$ when $p \geq 3$, where $\log^* n$ denotes the iterated logarithm of n. When $p = 2$, the algorithm's running time is improved to $O(m^2 n \log^2 n)$.

3. If p is an independent input variable (i.e., p could grow with n), then both the p-center and p-median problems are NP-hard [KaHa79a], [KaHa79b]. Thus it is highly unlikely that an algorithm will be found with running time polynomial in n, m, and p.

4. Considerable success has been reported in solving large p-median problems using heuristic methods that do not necessarily guarantee optimal solutions. A survey of various heuristic approaches as well as multiobjective extensions is presented in [DaMa15].

5. Exact and heuristic algorithms for variants of the p-center problem are reviewed in [CaLaYa15].

6. Algorithms of complexities $O(n^2p)$ and $O(n \log n)$ for the p-median and p-center problems on tree networks have been reported by Tamir [Ta96] and by Frederickson and Johnson [MiFr90, Chapter 7].

7. Vertex u is a 1-median of a tree network T if and only if $M_u \leq \frac{1}{2}W(T)$.

8. *1-median of a tree*: This algorithm (Algorithm 1) is based on Fact 7. The main idea is to repeatedly remove a leaf vertex, confining the problem to a smaller tree T'.

Algorithm 1: **1-median of a tree.**

```
input: tree $T$
output: 1-median $\widetilde{v}$
$T' := T$; $W_0 := \sum_{v \in V(T')} w(v)$; $W(v) := w(v)$ for each $v \in V(T')$
{Main loop}
**if** $T'$ consists of a single vertex $\widetilde{v}$ **then** stop
**else**
  $\widetilde{v} :=$ a leaf vertex of $T'$
  **if** $W(\widetilde{v}) \geq \frac{1}{2}W_0$ **then** stop
  **else**
    $u :=$ the vertex adjacent to $\widetilde{v}$ in $T'$
    $W(u) := W(u) + W(\widetilde{v})$
    $T' := T' - \widetilde{v}$
{Continue with next iteration of main loop}
```

9. Algorithm 1 can be implemented to run in $O(n)$ time.

10. Let T be a tree network with $w(v) = c$ for all $v \in V(T)$. Then the 1-center of T is the unique middle point of a longest path in T.

11. Select any vertex v_0 in a tree network T. Let v_1 be a farthest vertex from v_0, and let v_2 be a farthest vertex from v_1. Then the path from v_1 to v_2 is a longest path in T.

12. *1-center of a tree*: This algorithm (Algorithm 2) applies to "unweighted" trees, in which there are identical weights at each vertex. It is based on Facts 10 and 11.

Algorithm 2: **1-center of an unweighted tree.**

```
input: tree $T$ with $w(v) = c$ for all $v \in V(T)$
output: 1-center $x$
find a longest path $P$ in $T$ (using Fact 11)
let $u_1$ and $u_2$ be the end vertices of $P$
find the middle point of this path: i.e., the point $x$ such that $d(x, u_1) = d(x, u_2)$
```

13. Algorithm 2 can be implemented to run in $O(n)$ time.

Examples:

1. Suppose that the vertices of the tree T in Example 2 of §16.2.2 are labeled $v_1, v_2, \ldots, v_8$ in order from top to bottom and left to right at each height. Algorithm 1 can be applied to find the 1-median of T. First, the leaf vertex v_1 is selected and since $W(v_1) = 1$ is less than $\frac{1}{2}W_0 = \frac{15}{2}$, its weight is added to vertex v_3. The following table shows the progress of the algorithm, which eventually identifies vertex v_4 as the 1-median of T. As guaranteed by Fact 7, $M_{v_4} = \max\{6, 1, 3, 4\} \leq \frac{15}{2}$.

		$W(v_i)$							
iteration	$\widetilde{v}$	1	2	3	4	5	6	7	8
0		1	1	1	1	3	4	2	2
1	v_1	–	1	2	1	3	4	2	2
2	v_2	–	–	2	2	3	4	2	2
3	v_5	–	–	2	5	–	4	2	2
4	v_6	–	–	6	5	–	–	2	2
5	v_3	–	–	–	11	–	–	2	2

2. Consider the tree T used in Example 1 whose vertices are labeled as in that example. Algorithm 2 can be applied to find the 1-center of T, with all vertex weights being 1. First, select v_1 and find a farthest vertex from it, namely v_5. A farthest vertex from v_5 is then v_8, giving a longest path $P = [v_5, v_4, v_7, v_8]$ in T. The midpoint x of P, located $\frac{1}{2}$ unit from v_4 along edge (v_4, v_5), is then the 1-center of T. If instead the longest path $Q = [v_6, v_3, v_4, v_5]$ in T had been identified, then the same midpoint x would be found.

16.2.4 CAPACITATED LOCATION PROBLEMS

Definitions:

Let $X_p = \{x_1, \ldots, x_p\}$ be a set of locations for p facilities in the metric space S with n demand points $V = \{v_1, \ldots, v_n\} \subseteq S$ where $w(v_i) \geq 0$ is the demand at $v_i \in V$.

For each $v_i \in V$ and $x_j \in X_p$, let $w(v_i, x_j)$ be the portion of the demand at v_i satisfied by the facility at x_j.

Let $W(x_j)$ be the sum of the demands satisfied by (or allocated to) the facility at x_j. In a ***capacitated location problem***, upper (and/or lower) bounds are placed on $W(x_j)$.

Given the positive integer p and positive constant α, two versions of the ***capacitated p-median*** (***CPM***) ***problem*** in network $G = (V, E)$ are defined:

(a) Find a set of locations X_p such that $F(X_p) = \sum_{v_i \in V} w(v_i) d(v_i, X_p)$ is minimized subject to $W(x_j) \leq \alpha$ for all $x_j \in X_p$. Here it is assumed that the demands are satisfied by their closest facility, and in the case of ties, a demand, say at v, may be allocated in an arbitrary way among the closest facilities to v.

(b) Find X_p and $\{w(v_i, x_j) \mid v_i \in V \text{ and } x_j \in X_p\}$ to minimize

$$\sum_{j=1}^{p} \sum_{i=1}^{n} w(v_i, x_j) d(v_i, x_j)$$

subject to

$$\sum_{i=1}^{n} w(v_i, x_j) \le \alpha, \quad j = 1, 2, \ldots, p$$
$$\sum_{j=1}^{p} w(v_i, x_j) = w(v_i), \quad i = 1, 2, \ldots, n.$$

Facts:

1. Capacitated facility location problems occur in several applied settings, including

- the location of manufacturing plants (with limited output) to serve customers;
- the location of landfills (with limited capacity), which receive solid waste from the members of a community;
- the location of concentrators in a telecommunication network, where each concentrator bundles messages received from individual users and can handle only a certain amount of total message traffic.

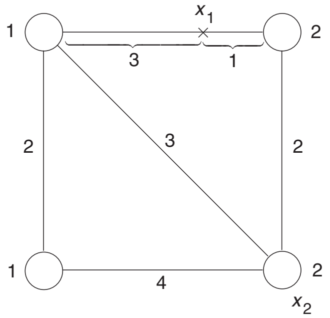
2. Version (a) of CPM may not have a solution if α is too small.

3. If α is sufficiently large in version (a) and CPM has a solution, there may not exist a solution consisting entirely of vertices of G. See Example 1.

4. Version (b) of the CPM has a solution consisting entirely of vertices of G. This was shown by J. Levy; see [HaMi79].

Examples:

1. Suppose $p = 2$ and $\alpha = 3$ in the following network G. A solution to version (a) of the CPM problem consists of the points $X_2 = \{x_1, x_2\}$ with $W(x_1) = W(x_2) = 3$ and $F(X_2) = 9$. It is easy to see that the choice of any two vertices for X_2 would violate the allocation constraint to one facility.



2. If $p = 2$ and $\alpha = 3$ for the network G given in Example 1, then version (b) of the CPM problem has a solution containing only vertices of G. Suppose that the top two vertices in the figure are v_1 and v_2 (from left to right) and the bottom two vertices are v_3 and v_4. Then $X_2 = \{v_1, v_2\}$ is an optimal solution, where all the demand $w(v_3) = 1$ is allocated to v_1 whereas the demand $w(v_4) = 2$ is equally split between v_1 and v_2. (Here, not all demand from v_4 is sent to its closest facility v_2.) In this solution, $W(v_1) = W(v_2) = 3$ and $F(X_2) = 7$.

16.2.5 FACILITIES IN THE PLANE

The p-median and p-center problems can be defined in the plane $\mathcal{R}^2$. Several measures of distance are commonly considered for these location problems in the plane.

Definitions:

Let $x = (x_1, x_2)$ and $y = (y_1, y_2)$ be points of $S = \mathcal{R}^2$.

The ***Euclidean*** (ℓ_2) ***distance*** between x and y is $d(x, y) = [(x_1 - y_1)^2 + (x_2 - y_2)^2]^{1/2}$.

The ***rectilinear*** (ℓ_1) ***distance*** between x and y is $d(x, y) = |x_1 - y_1| + |x_2 - y_2|$.

The (***generalized***) ***Weber problem*** is the p-median problem in $\mathcal{R}^2$ with the ℓ_2 measure of distance.

The ***unweighted Euclidean 1-center problem*** is the 1-center problem in $\mathcal{R}^2$ with the ℓ_2 measure of distance and with $w(v_i) = c$ for all $v_i \in V$.

Facts:

1. No polynomial-time algorithm for the Weber problem, even when $p = 1$, has been discovered. The history of this problem, and generalizations, are discussed in [We93].

2. In practice, an iterative method due to Weiszfeld [We37], [WePl09] has been shown to be highly successful for the Weber problem with $p = 1$.

3. Further information on the Weiszfeld algorithm and extensions can be found in [Pl11]. Recent algorithmic improvements are discussed in [Dr15] and [RoVa13].

4. The p-median and p-center problems in $\mathcal{R}^2$ with either ℓ_1 or ℓ_2 as the measure of distance have been proven to be NP-hard if p is an input variable [MeSu84].

5. The unweighted Euclidean 1-center problem is equivalent to finding the center of the smallest (radius) circle that encloses all points in V.

6. The following table provides a summary of time complexity results of the best known algorithms for location problems in the plane [Me83], [MeSu84].

	p arbitrary	$p = 1$
p-median	NP-hard if p is an input variable under ℓ_1 or ℓ_2 unknown complexity if p is fixed	unknown complexity under ℓ_1 or ℓ_2
p-center	NP-hard if p is an input variable under ℓ_1 or ℓ_2 unknown complexity for fixed $p > 1$	$O(n \log^2 n)$ under ℓ_2 $O(n)$ under ℓ_2 in the unweighted case $O(n)$ under ℓ_1 for both the weighted and unweighted cases

7. A unified treatment of location problems in Euclidean space studies the *ordered median location problem*, which generalizes both the p-median and p-center problems [BlPuEl14], [NiPu05].

Examples:

1. The floor plan of a factory contains existing machines A, B, C at the coordinate locations $a = (0, 4)$, $b = (2, 0)$, $c = (5, 2)$. A new central storeroom, to house materials needed by the machines, is to be placed at some location $x = (x_1, x_2)$ on the factory floor. Because the aisles of the factory floor run north-south and east-west, transportation between the storeroom and the machines must take place along these perpendicular directions. For example, the distance between the storeroom and the machine C is $|x_1 - 5| + |x_2 - 2|$. Management wants to locate the storeroom so that the weighted sum of distances between the new storeroom and each machine is minimized, taking into account that the demand for material by machine A is twice the demand by machine B, and demand for material by machine C is three times that by machine B. This is a weighted 1-median problem in the plane with the ℓ_1 measure of distance. The point $(3, 2)$ is an optimal location for the storeroom. In fact, for any $2 \le u \le 5$ the point $(u, 2)$ is also an optimal location.

2. Suppose that the ℓ_2 distance measure is used instead in Example 1. Then a weighted 1-median is a location $x = (x_1, x_2)$ that minimizes

$$2\sqrt{x_1^2 + (x_2 - 4)^2} + \sqrt{(x_1 - 2)^2 + x_2^2} + 3\sqrt{(x_1 - 5)^2 + (x_2 - 2)^2}.$$

The minimizing point in this case is $(5, 2)$, which is the *unique* optimal location for the storeroom. On the other hand, if the demands for material are the same for all three machines, then the unweighted 1-median occurs at the unique location $(2.427, 1.403)$.

16.2.6 OBNOXIOUS FACILITIES

In the preceding subsections, it has been assumed that the consumers at v_i wish to be as close as possible to a facility. That is, the facilities are desirable. In contrast, this subsection discusses location problems where the facilities are undesirable or obnoxious.

Definitions:

For $v_i \in V$, $w(v_i)d(v_i, X_p)$ represents the ***utility*** (in contrast to cost) associated with having an obnoxious facility located at distance $d(v_i, X_p)$ from v_i.

The following two ***obnoxious facility location problems*** are defined:

(a) find $X_p \subseteq S$ to maximize $F(X_p) = \sum_{i=1}^{n} w(v_i)d(v_i, X_p)$;

(b) find $X_p \subseteq S$ to maximize $G(X_p) = \min_{1\le i\le n} w(v_i)d(v_i, X_p)$.

If space S is a network $G = (V, E)$, for each edge $e = (u, v) \in E$, let $x(e) = x$ be the point on e such that $w(u)d(u, x) = w(v)d(v, x) \equiv w(e)$.

Facts:

1. If S is a network, problem (a) may not have a solution that is a subset of vertices (see Example 2).

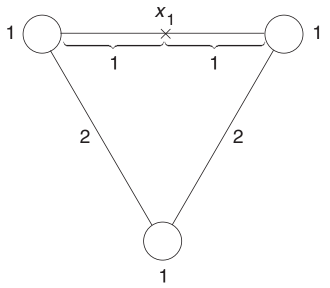
2. Suppose S is a network G with $w(v_i) > 0$ for all $v_i \in V$; further assume that at most one point of X_p can be on any particular edge. Renumber the m edges of G so that $w(e_1) \ge w(e_2) \ge \cdots \ge w(e_m)$. Then $x(e_1), x(e_2), \ldots, x(e_p)$ is a solution to problem (b).

3. Additional results on this subject can be found in [BrCh89].

Examples:

1. In the location of obnoxious facilities, the distance to a closest facility is to be made as large as possible. This type of problem arises in siting nuclear power plants, sewage treatment facilities, and landfills, for example.

2. In the following network, an optimal solution $X_1 = \{x_1\}$ to problem (a) when $p = 1$ is the midpoint of any edge, with $F(X_1) = 5$. However, if the facility is located at any vertex v then $F(\{v\}) = 4$.



16.2.7 EQUITABLE LOCATIONS

The p-median problem is a widely used model for locating public or private facilities. However, it may leave some demand points (communities) too far from their closest facility and thus might be perceived as inequitable. To remedy this situation, the p-median problem can be modified in several ways.

Definitions:

Suppose S is a metric space, $V \subseteq S$, $w(v_i) \geq 0$ for all $v_i \in V$, and p is a positive integer.

Let $w'(v_i) = w(v_i)/\sum_{j=1}^{n} w(v_j)$ and define $F'(X_p) = \sum_{i=1}^{n} w'(v_i)d(v_i, X_p)$, $Z(X_p) = \sum_{i=1}^{n} w'(v_i)[d(v_i, X_p) - F'(X_p)]^2$.

The following three ***equitable facility location problems*** are defined:

(a) given a constant β, find a set of p points $X_p \subseteq S$ to minimize

$$F(X_p) = \textstyle\sum_{i=1}^{n} w(v_i)d(v_i, X_p)$$

subject to

$$d(v_i, X_p) \leq \beta, \quad \text{for all } v_i \in V;$$

(b) given a constant α, $0 < \alpha < 1$, find a set of p points $X_p \subseteq S$ to minimize $\alpha F(X_p) + (1 - \alpha)H(X_p)$;

(c) find $X_p \subseteq S$ to minimize $Z(X_p)$.

Facts:

1. Since the objective function in (b) is a linear combination of the objective functions for the p-median and p-center problems, the solution X_p^* is called a *centdian*.

2. $F'(X_p) = F(X_p)/\sum_{j=1}^{n} w(v_j)$ is the mean distance to the consumers given that the facilities are located at X_p.

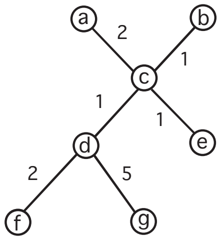
3. $Z(X_p)$ is the variance of the distance to the consumers given that the facilities are located at X_p.

4. Additional results are discussed in [HaMi79], [Ma86].

5. Other models that introduce equity criteria for facility location models are discussed in [Og09].

Example:

1. The following figure shows a tree network T on vertices $a, b, \ldots, g$, with the edge lengths displayed. Suppose that all vertex weights are 1. Then the 1-median of T is located at vertex c, while the 1-center of T is located at the point x one unit from vertex d along (d, g). These locations can be calculated using Algorithms 1 and 2 from §16.2.3. It can be verified that the centdian of T is at point x for $0 \leq \alpha \leq \frac{1}{6}$, at vertex d for $\frac{1}{6} \leq \alpha \leq \frac{1}{2}$, and at vertex c for $\frac{1}{2} \leq \alpha \leq 1$.



16.3 PACKING AND COVERING

Many practical problems can be formulated as either packing or covering problems. In packing problems, known activities are given each of which requires several resources for its completion. The problem is to select a most valuable set of activities to undertake without using any common resources. Such a problem arises, for example, in scheduling as many computational activities as possible on a set of machines (resources) that cannot be used simultaneously for more than one activity. In covering problems, a specified set of tasks must be performed, and the objective is to minimize the resources required to perform the tasks. For example, a number of delivery trucks (resources) operating on overlapping geographical routes need to be dispatched to pick up items at customer locations (tasks). The fewest number of trucks are to be sent so that each customer location is "covered" by at least one of the dispatched trucks. Both exact and heuristic solution algorithms for packing and covering problems are discussed in this section.

16.3.1 KNAPSACKS

The knapsack problem arises when a single critical resource is to be optimally allocated among a variety of options. Specifically, there are available a number of items, each of which consumes a known amount of the resource and contributes a known benefit. Items are to be selected to maximize the total benefit without exceeding the given amount of the resource. Knapsack problems arise in many practical situations involving cutting stock, cargo loading, and capital budgeting.

Definitions:

Let $N = \{1, 2, \ldots, n\}$ be a given set of n ***items***. Utilizing item j consumes (requires) $a_j > 0$ units of the given resource and confers the benefit $c_j > 0$.

The ***knapsack problem*** (***KP***) is the following 0-1 integer linear programming problem:

$$\begin{aligned}\text{maximize:}\quad & \sum_{j\in N} c_j x_j\\ \text{subject to:}\quad & \sum_{j\in N} a_j x_j \le b\\ & x_j \in \{0,1\}.\end{aligned}\tag{1}$$

It is assumed that $a_j \le b$ for all $j \in N$. Let $z(b)$ denote the optimal objective value in (1) for a given integer b.

The ***LP relaxation*** (§16.1.8) of (1) is the linear programming problem:

$$\begin{aligned}\text{maximize:}\quad & \sum_{j\in N} c_j x_j\\ \text{subject to:}\quad & \sum_{j\in N} a_j x_j \le b\\ & 0 \le x_j \le 1.\end{aligned}\tag{2}$$

Let z_{LP} denote the optimal objective value to the LP relaxation (2).

Let N^1 and N^0 be the set of variables taking values 1 and 0, respectively, in the optimal solution to (2). Let λ^* be the dual variable (§16.1.5) associated with the knapsack inequality in the optimal solution to (2).

A ***cover*** is a set $S \subseteq N$ such that $\sum_{j\in S} a_j > b$. The cover S is ***minimal*** if no proper subset of S is a cover.

A ***branch-and-bound tree*** for KP is a tree T whose nodes correspond to subproblems obtained by fixing certain variables of (1) to either 0 or 1. The ***root*** of T corresponds to the original problem (1).

A node t of T is specified by its ***level*** $k = 0, 1, \ldots, n$ and the index set $N_t \subseteq \{1, \ldots, k\}$ of variables currently fixed to 1.

Associated with the set N_t is the current benefit $z_t = \sum_{j\in N_t} c_j$ and the available amount of resource $b_t = b - \sum_{j\in N_t} a_j$.

Facts:

1. Formulation (1) is a 0-1 integer linear programming problem with a single (knapsack) constraint. It expresses the optimization problem in which a subset of the n items is to be selected to maximize the total benefit without exceeding the available amount of the given resource (the capacity of the knapsack).

2. KP is an NP-hard optimization problem (§17.5.2).

3. KP can be solved in polynomial time for fixed b.

4. Given a rational $\epsilon > 0$, a 0-1 vector x^* can be found satisfying $\sum_{j\in N} a_j x_j^* \le b$ and $\sum_{j\in N} c_j x_j^* \ge (1-\epsilon) z(b)$ in time polynomially bounded by $\frac{1}{\epsilon}$ and by the sizes of $a = (a_1, \ldots, a_n)$, $c = (c_1, \ldots, c_n)$, and b.

5. If the coefficients a_j can be ordered such that each coefficient is an integer multiple of the previous one, then KP can be solved in polynomial time.

6. If $a_{j-1} \ge a_j + \cdots + a_n$ holds for $j = 2, \ldots, n$ then KP can be solved in polynomial time.

7. *Greedy heuristic*: This heuristic (Algorithm 1) for the KP processes the variables x_j in nonincreasing order of $\frac{c_j}{a_j}$, making each variable equal to 1 if possible.

```
Algorithm 1: Greedy heuristic for the KP.
  input: KP with $\frac{c_1}{a_1} \geq \frac{c_2}{a_2} \geq \cdots \geq \frac{c_n}{a_n}$
  output: feasible solution $x = (x_1, x_2, \ldots, x_n)$
  for $k := 1$ to $n$
    $x_k := 1$
    if $\sum_{j=1}^{k} a_j x_j > b$ then $x_k := 0$
```

8. Suppose z_H is the objective value for the solution x produced by Algorithm 1. Then $z(b) \geq z_H \geq \frac{1}{2} z(b)$.

9. Algorithm 1 is most effective if the coefficients a_j are small relative to b.

10. The LP relaxation (2) can be solved explicitly by filling the knapsack in turn with items j in order of nonincreasing $\frac{c_j}{a_j}$, ignoring the integer restriction. The solution x obtained has at most one fractional component.

11. *Core heuristic*: This heuristic (Algorithm 2) for the KP first solves the LP relaxation (2) as in Fact 10, in which at most one variable x_k can be fractional. A smaller knapsack problem is then solved, by setting to 0 any variable x_j with index j sufficiently greater than k and by setting to 1 any variable x_j with index j sufficiently smaller than k.

```
Algorithm 2: Core heuristic for the KP.
  input: KP with $\frac{c_1}{a_1} \geq \frac{c_2}{a_2} \geq \cdots \geq \frac{c_n}{a_n}$
  output: feasible solution $x = (x_1, x_2, \ldots, x_n)$
  {Solve LP relaxation}
    find the smallest value $k$ such that $\sum_{j=1}^{k} a_j \geq b$
  {Solve restricted KP}
    select any $r > 0$
    $x_j := 1$ for $j \leq k - r$
    $x_j := 0$ for $j \geq k + r$
    solve to optimality the smaller knapsack problem:
      maximize   $\sum_{j=k-r+1}^{k+r-1} c_j x_j$
      subject to $\sum_{j=k-r+1}^{k+r-1} a_j x_j \leq b - \sum_{j=1}^{k-r} a_j$
                 $x_j \in \{0, 1\}$
```

12. Algorithm 2 is effective if the number of variables n is large since values of r between 10 and 25 give very good approximations in most cases. For further details see [BaZe80].

13. $z(b) \leq z_{LP}$.

14. If z^l is the objective value of a feasible solution to (1), then $z^l \leq z(b)$.

15. Node t of the branch-and-bound tree T corresponds to a subproblem having a nonempty set of feasible solutions if and only if $b_t \geq 0$. When this holds, z_t is a lower bound for $z(b)$.

16. An upper bound on the objective value over the subproblem corresponding to node t is $z_t^u = \lfloor z_t^* \rfloor$, where $z_t^* = z_t + \max\{\sum_{j=k+1}^{n} c_j x_j \mid \sum_{j=k+1}^{n} a_j x_j \leq b_t,\ 0 \leq x_j \leq 1\}$.

17. *Implicit enumeration*: This is an exact technique based on the branch-and-bound method (§16.1.8). It is implemented using a branch-and-bound tree T, with the following specifications:

- The initial tree T consists of the root t, with lower bound z^l on $z(b)$ obtained using the greedy heuristic. An upper bound for node t is $z_t^u = z_{LP}$.
- If $z_t^u \le z^l$, then node t is discarded since it cannot provide a better solution.
- If $z_t^u > z^l$, there are three cases (where node t is at level k of T):
  - ◇ $a_{k+1} < b_t$: If $k+1 < n$, create a new node with $x_{k+1} = 1$. If $k+1 = n$ an optimal solution for node t has $x_n = 1$. Since this solution is feasible for KP, set $z^l = z_t^u$ and discard node t.
  - ◇ $a_{k+1} = b_t$: An optimal solution for node t (and a feasible solution for KP) is obtained by setting $x_{k+1} = 1$ and $x_j = 0$ for $j > k+1$. Set $z^l = z_t^u$ and discard node t.
  - ◇ $a_{k+1} > b_t$: Discard the (infeasible) node with $x_{k+1} = 1$ and create a new node with $x_{k+1} = 0$.
- To backtrack from node t let $N_t = \{j_1, \ldots, j_r\} \subseteq \{1, \ldots, k\}$ with $j_1 < \cdots < j_r$. If $k \notin N_t$ retreat to level j_r and set $x_{j_r} = 0$. If $k = j_r$ retreat to level j_{r-1} and set $x_{j_{r-1}} = 0$.

18. *Variable fixing*: Given z_{LP}, z^l, N^1, N^0, and λ^*, the following tests can be used to fix variables and reduce the size of the knapsack problem:

- If $k \in N^1$ and $z_{LP} - (c_k - \lambda^* a_k) \le z^l$, then fix $x_k = 1$.
- If $k \in N^0$ and $z_{LP} + (c_k - \lambda^* a_k) \le z^l$, then fix $x_k = 0$.
- Given $k \in N^1$ define

$$z_{LP}^k = \sum_{j \in N^1 - \{k\}} c_j \ + \ \max\Big\{ \sum_{j \in N - N^1} c_j x_j \ \Big| \ \sum_{j \in N - N^1} a_j x_j \le b, \ 0 \le x_j \le 1 \Big\}.$$

  If $z_{LP}^k \le z^l$, then x_k can be fixed to 1.
- Given $k \in N^0$ define

$$z_{LP}^k = \ c_k \ + \ \max\Big\{ \sum_{j \in N - N^0} c_j x_j \ \Big| \ \sum_{j \in N - N^0} a_j x_j \le b - a_k, \ 0 \le x_j \le 1 \Big\}.$$

  If $z_{LP}^k \le z^l$, then x_k can be fixed to 0.

19. *Minimal cover inequality*: If S is a minimal cover then each feasible solution x to KP satisfies $\sum_{j \in S} x_j \le |S| - 1$.

20. *Lifted minimal cover inequality*: The minimal cover inequality can be further strengthened. Without loss of generality, assume that $a_1 \ge a_2 \ge \cdots \ge a_n$ and $S = \{j_1 < j_2 < \cdots < j_r\}$. Let $\mu_h = \sum_{k=1}^h a_{j_k}$ for $h = 1, \ldots, r$ and define $\lambda = \mu_r - b \ge 1$. Then each feasible solution x to KP satisfies $\sum_{j \in N-S} \alpha_j x_j + \sum_{j \in S} x_j \le |S| - 1$, where

- if $\mu_h \le a_j \le \mu_{h+1} - \lambda$ then $\alpha_j = h$;
- if $\mu_{h+1} - \lambda + 1 \le a_j \le \mu_{h+1} - 1$ then (a) $\alpha_j \in \{h, h+1\}$, and (b) there is at least one lifted minimal cover inequality with $\alpha_j = h+1$.

21. Computer codes for solving knapsack problems can be found at

- `http://www.diku.dk/~pisinger/codes.html`

22. Further details on the material in this section are available in [KePfPi04], [NeWo88], and [Sc86].

23. Algorithms for the multidimensional 0-1 knapsack problem are discussed in [FrHa05].

Examples:

1. *Investment problem*: An investor has \$50,000 to place in any combination of five available investments $(1, 2, 3, 4, 5)$. All investments have the same maturity but are issued in different denominations and have different (one-year) yields, as shown in the table.

investment	1	2	3	4	5
denomination (\$)	10,000	20,000	30,000	10,000	20,000
yield (%)	20	14	18	9	13

Let variable $x_j = 1$ if Investment j is selected and $x_j = 0$ if it is not. The interest earned for Investment 1 is $(0.20)10{,}000 = 2{,}000$; the values of the other investments are found similarly. Then the investor's problem is the knapsack problem

$$\begin{aligned} \text{maximize:}\quad & 2{,}000x_1 + 2{,}800x_2 + 5{,}400x_3 + 900x_4 + 2{,}600x_5 \\ \text{subject to:}\quad & 10{,}000x_1 + 20{,}000x_2 + 30{,}000x_3 + 10{,}000x_4 + 20{,}000x_5 \le 50{,}000 \end{aligned}$$

which has the optimal solution $x_1 = x_3 = x_4 = 1$, $x_2 = x_5 = 0$ with maximum interest of \$8,300.

2. Consider the knapsack problem in 0-1 variables x

$$\begin{aligned} \text{maximize:}\quad & 30x_1 + 8x_2 + 16x_3 + 20x_4 + 12x_5 + 9x_6 + 5x_7 + 3x_8 \\ \text{subject to:}\quad & 10x_1 + 3x_2 + 7x_3 + 9x_4 + 6x_5 + 5x_6 + 3x_7 + 2x_8 \le 27. \end{aligned}$$

Here the variables x_j are indexed in nonincreasing order of $\frac{c_j}{a_j}$. The optimal solution to the LP relaxation (2) is $x_1 = x_2 = x_3 = 1$, $x_4 = \frac{7}{9}$, $x_j = 0$ otherwise, with $z_{LP} = 69\frac{5}{9}$. The greedy heuristic (Algorithm 1) gives the feasible solution $x_1 = x_2 = x_3 = x_5 = 1$, $x_j = 0$ otherwise, with $z_H = 66$. Using $r = 3$, the core heuristic gives $x_1 = x_2 = x_4 = x_6 = 1$, $x_j = 0$ otherwise. This solution is optimal, with objective value 67.

3. Consider the knapsack problem in 0-1 variables x

$$\begin{aligned} \text{maximize:}\quad & x_1 + x_2 + x_3 + x_4 + x_5 + x_6 \\ \text{subject to:}\quad & 10x_1 + 8x_2 + 4x_3 + 3x_4 + 3x_5 + 2x_6 \le 11. \end{aligned}$$

The set $S = \{3, 4, 5, 6\}$ is a minimal cover which gives the lifted minimal cover inequality $3x_1 + 2x_2 + x_3 + x_4 + x_5 + x_6 \le 3$. Adding this inequality and solving the resulting linear program gives $x_4 = x_5 = x_6 = 1$, $x_j = 0$ otherwise. This solution is optimal.

4. *General knapsack problem*: The general (or unbounded) knapsack problem allows the decision variables x_j to be any nonnegative integers, not just 0 and 1. For example, an individual can select any number of a given item to pack in a knapsack, subject to the given weight restriction.

16.3.2 BIN PACKING

Minimizing the number of copies of a resource required to perform a specified set of tasks can be formulated as a bin packing problem. It is assumed that no such task can be split between two different units of the resource. For example, this type of problem arises in allocating a set of customer loads to (identical) trucks, with no load being split between two trucks. Also, the scheduling of heterogeneous tasks on identical machines can be viewed as a bin packing problem. Namely, find the fewest number of machines of capacity C such that each task is executed on one of the machines and the total capacity of jobs assigned to any machine does not exceed C.

Definitions:

The positive integer C denotes the ***bin capacity***.

Let $L = (p_1, p_2, \ldots, p_n)$ be a list of n ***items***, where item p_i has an integer ***size*** $s(p_i) \leq C$.

A subset $P \subseteq L$ is a ***packing*** if $\sum_{p_i \in P} s(p_i) \leq C$.

The ***gap*** of a packing P is given by the quantity $C - \sum_{p_i \in P} s(p_i)$.

The ***bin packing problem*** is the problem of finding the minimum number of bins (each of capacity C) needed to pack all items so that the gap in each bin is nonnegative. The minimum number of bins needed for the list L is denoted $b^*(L)$.

Facts:

1. The bin packing problem is an NP-hard optimization problem (§17.5.2).

2. *First fit (FF) method*: In this heuristic algorithm, item p_i $(i = 1, 2, \ldots, n)$ is placed in the first bin into which it fits. A new bin is started only when p_i will not fit into any nonempty bin.

3. Let $b^{FF}(L)$ denote the number of bins produced by the FF algorithm for a list L. Then $b^{FF}(L) \leq \min\{\lceil \frac{17}{10} b^*(L) \rceil,\ 1.75 b^*(L)\}$.

4. *First fit decreasing (FFD) method*: In this heuristic algorithm, the items are first ordered by decreasing size so that $s(p_1) \geq s(p_2) \geq \cdots \geq s(p_n)$. Then the FF algorithm is applied to the reordered list.

5. Let $b^{FFD}(L)$ denote the number of bins produced by the FFD algorithm for a list L. Then $b^{FFD}(L) \leq \min\{\frac{11}{9} b^*(L) + 3,\ 1.5 b^*(L)\}$.

6. If all item sizes are of the form $C(\frac{1}{k})^j$, $j \geq 0$, for some fixed positive integer k, then $b^{FFD}(L) = b^*(L)$.

7. If the item sizes are uniformly distributed on $[0, a]$ with $0 < a \leq \frac{C}{2}$, then asymptotically $\frac{b^{FFD}(L)}{b^*(L)} \to 1$.

8. *Modified first fit decreasing (MFFD) method*: This heuristic method (Algorithm 3) produces a packing using relatively few bins. After the initial phase of packing the largest sized items L_A, let an "A-bin" denote one containing only a single item from L_A.

Algorithm 3: MFFD algorithm for bin packing.

```
input: list $L$, bin capacity $C$
output: a packing of $L$
partition $L$ into the three sublists  $L_A = \{p_i \mid s(p_i) \in (\frac{1}{3}C, C]\}$,
     $L_D = \{p_i \mid s(p_i) \in (\frac{11}{71}C, \frac{1}{3}C]\}$, $L_X = \{p_i \mid s(p_i) \in (0, \frac{11}{71}C]\}$
pack the sublist $L_A$ using the FFD algorithm.
{Pack as much of $L_D$ into $A$-bins as possible}
  1. let bin $B_j$ be the $A$-bin with the currently largest gap; if the two smallest
       unpacked items in $L_D$ will not fit together in $B_j$, go to 4
  2. place the smallest unpacked item $p_i$ from $L_D$ in $B_j$
  3. let $p_k$ be the largest unpacked item in $L_D$ that will now fit in $B_j$; place $p_k$
       in $B_j$ and go to 1
  4. combine the unpacked portion of $L_D$ with $L_X$ and add these items to the
       packing using FFD
```

9. Let $b^{MFFD}(L)$ denote the number of bins produced by the MFFD algorithm for a list L. Then asymptotically, as $b^*(L)$ gets large, $b^{MFFD}(L) \leq 1.183b^*(L)$.

10. *Best fit (BF) method*: In this heuristic algorithm, item p_i is placed in the bin into which it will fit with the smallest gap left over. Ties are broken in favor of the lowest indexed bin.

11. *Best fit decreasing (BFD) method*: In this heuristic algorithm, the items are first ordered so that $s(p_1) \geq s(p_2) \geq \cdots \geq s(p_n)$. Then the BF algorithm is applied to the reordered list.

12. Asymptotic worst-case bounds for BF [BFD] are the same as those for FF [FFD]. In practice the BF version performs somewhat better.

13. For a fixed number of d different item sizes, the bin packing problem can be solved in polynomial time [GoRo14].

14. Further details on the material covered in this section are found in [CoEtal13] and [CoGaJo84].

Examples:

1. Television commercials are to be assigned to station breaks. This is a bin packing problem where the duration of each station break is C and the duration of each commercial is $s(p_i)$.

2. Material such as cable, lumber, or pipe is supplied in a standard length C. Demands for pieces of the material are for arbitrary lengths $s(p_i)$ not exceeding C. The objective is to use the minimum number of standard lengths to supply a given list of required pieces. This is also a bin packing problem.

3. A set of independent tasks with known execution times $s(p_i)$ are to be executed on a collection of identical processors. Determining the minimum number of processors needed to complete all tasks by the deadline C is a bin packing problem.

4. Consider the list $L = (4, \ldots, 4, 7, \ldots, 7, 8, \ldots, 8, 13, \ldots, 13)$, consisting of twelve 4s and six each of 7s, 8s, and 13s. Each bin has capacity $C = 24$. Either FF (or BF) when applied to L results in a packing with twelve bins: two bins are packed as $(4, 4, 4, 4, 4, 4)$, two as $(7, 7, 7)$, two as $(8, 8, 8)$, and six as (13).

5. If FFD (or BFD) is applied to the list in Example 4, a packing with ten bins results: six bins are packed as $(13, 8)$, two as $(7, 7, 7)$, and two as $(4, 4, 4, 4, 4, 4)$.

6. If MFFD is applied to the list in Example 4, then L_A contains the six 13s and L_D contains the remaining items. Packing L_A using FFD results in six A-bins, each containing a single 13 and having gap 11. Steps 1–3 of Algorithm 3 result in six bins packed as $(13, 7, 4)$, and Step 4 yields two bins packed as $(8, 8, 8)$ and one bin packed as $(4, 4, 4, 4, 4, 4)$. This is an optimal solution since all nine bins are completely packed.

16.3.3 SET COVERING AND PARTITIONING

Set covering or set partitioning problems arise when a specified set of tasks must be performed while minimizing the cost of resources used. Such problems arise in scheduling fleets of vehicles or aircraft, locating fire stations in an urban area, political redistricting, and fault testing of electronic circuits.

Definitions:

Let e denote the column vector of all 1s.

Let $A = (a_{ij})$ be a 0-1 ***incidence matrix*** and let $c = (c_j)$ be a row vector of ***costs***.

The set $A_j = \{i \mid a_{ij} = 1\}$ contains all rows ***covered*** by column j.

The ***set covering*** (***SC***) ***problem*** is the 0-1 integer linear programming problem

$$\begin{aligned} \text{minimize:} \quad & cx \\ \text{subject to:} \quad & Ax \geq e \\ & x_j \in \{0,1\}. \end{aligned}$$

Let v^* be the optimal objective value to this problem.

The ***set partitioning*** (***SP***) ***problem*** has the same form as the set covering problem except the constraints are $Ax = e$.

The ***LP relaxation*** of SC or SP is obtained by replacing the constraints $x_j \in \{0,1\}$ by $0 \leq x_j \leq 1$. Let v_{LP} be the optimal objective value to the LP relaxation.

The matrix A is ***totally unimodular*** if the determinant of every square submatrix of A is 0, +1, or −1.

The matrix A is ***balanced*** if A has no square submatrix of odd order, containing exactly two 1s in each row and column.

The matrix A is in ***canonical block form*** if, by reordering, its columns can be partitioned into t nonempty subsets $B_1, \ldots, B_t$ such that for each block B_j there is some row i of A with $a_{ik} = 1$ for all $k \in B_j$ and $a_{ik} = 0$ for $k \in \cup_{l=j+1}^{t} B_l$. The rows of A are then ordered so that the row defining B_j becomes the jth row for $j = 1, \ldots, t$.

Facts:

1. Formulation SC expresses the problem of selecting a set of columns (sets) that together cover all rows (elements) at minimum cost. In formulation SP, the covering sets are required to be disjoint.

2. Both SC and SP are NP-hard optimization problems (§17.5.2).

3. Checking whether a set partitioning problem is feasible is NP-hard.

4. In many instances (including bin packing, graph partitioning, and vehicle routing) the LP relaxation of the set covering (partitioning) formulation of the problem is known to give solutions very close to optimality.

5. For the bin packing and vehicle routing problems (see Examples 2–3) $v^* \leq \frac{4}{3}\lceil v_{LP} \rceil$.

6. If A is totally unimodular or balanced, then the polyhedra $\{x \mid Ax \geq e,\ 0 \leq x_j \leq 1\}$ and $\{x \mid Ax = e,\ 0 \leq x_j \leq 1\}$ have only integer extreme points (vertices). In this case, SC and SP can be solved in polynomial time using linear programming.

7. Checking whether a given matrix A is totally unimodular or balanced can be done in polynomial time.

8. Every 0-1 matrix that is totally unimodular is also balanced. The converse, however, is not true (see Example 4).

9. The matrix A is totally unimodular if and only if each collection of columns of A can be split into two parts so that the sum of the columns in one part minus the sum of the columns in the other part is a vector with entries 0, +1, −1.

10. *Greedy heuristic*: This heuristic (Algorithm 4) for the set covering problem successively chooses columns that have smallest cost per covered row.

Algorithm 4: **Greedy heuristic for the set covering problem.**

```
input: 0-1 $m \times n$ matrix $A$, costs $c$
output: feasible set cover $x$
$M^1 := \{1, 2, \ldots, m\}$; $N^1 := \{1, 2, \ldots, n\}$; $k := 1$
{Main loop}
select $j^k \in N^k$ to minimize $\frac{c_j}{|A_j \cap M^k|}$
$N^{k+1} := N^k - \{j^k\}$
obtain $M^{k+1}$ from $M^k$ by deleting all rows containing a 1 in column $j^k$
if $M^{k+1} = \emptyset$ then $x_j := 1$ for $j \notin N^{k+1}$ and $x_j := 0$ otherwise
else $k := k + 1$
{Continue with next iteration of main loop}
```

11. *Randomized greedy heuristic*: This heuristic for the set covering problem is similar to Algorithm 4 except that at iteration k the column $j^k \in N^k$ is selected at random from among columns j satisfying $\frac{c_j}{|A_j \cap M^k|} \leq (1 + \alpha) \min\{\frac{c_r}{|A_r \cap M^k|} \mid r \in N^k\}$, where $\alpha \geq 0$.

12. Whereas Algorithm 4 is run only once, the randomized greedy heuristic is repeated several times and the best solution is selected.

13. *Implicit enumeration*: This exact approach (Algorithm 5) for SP works well for dense matrices. In this algorithm, S is the index set of the variables fixed at 1, z is the associated objective value, and R is the set of rows satisfied by S. Also z^* denotes the objective value of the best feasible solution found so far.

Algorithm 5: **Implicit enumeration method for SP.**

```
input: 0-1 matrix $A$, costs $c$
output: optimal set of columns $S$ (if any)
place $A$ in canonical block form with blocks $B_j$
order the columns within $B_j$ by nondecreasing $c_t / \sum_i a_{it}$
$S := \emptyset$; $R := \emptyset$; $z := 0$, $z^* := \infty$
1. $r := \min\{i \mid i \notin R\}$; set a marker in the first column of $B_r$
2. examine all columns of $B_r$ in order starting from the marked column
   if column $j$ is found with $a_{ij} = 0$ for all $i \in R$ and $z + c_j < z^*$ then go to 3
   if $B_r$ is exhausted then go to 4
3. $S := S \cup \{j\}$; $R := R \cup \{i \mid a_{ij} = 1\}$; $z := z + c_j$
   if all rows are included in $R$ then $z^* := z$ and go to 4 else go to 1
4. if $S = \emptyset$ then terminate with the best solution found (if any)
   else let $k :=$ the last index included in $S$
        $S := S - \{k\}$; update $z$ and $R$
        $B_r :=$ the block to which column $k$ belongs
        move the marker in $B_r$ forward by one column and go to 2
```

14. Other implicit enumeration approaches to set partitioning and set covering are discussed in [BaPa76].

15. *Cutting plane methods*: Cutting plane methods (§16.1.8) have been used successfully to solve large set partitioning and set covering problems. For details regarding an implementation used to solve crew scheduling problems see [HoPa93].

16. Further details on the material in this section can be found in [GaNe72], [Ho97], [KoVy12], [NeWo88], and [Sc86].

Examples:

1. *Crew scheduling problem*: An airline must cover a given set of flight segments with crews. There are specified work rules that restrict the assignment of crews to flights. The objective is to cover all flights at minimum total cost. The rows of the matrix A correspond to the flights that an airline has to cover. The columns of A are the incidence vectors of flight "rotations": sequences of flight segments for each flight that begin and end at individual base locations and that conform to all applicable work rules. The objective is to minimize crew costs. This problem can be formulated as either a set covering or set partitioning problem.

2. *Bin packing*: The bin packing problem (§16.3.2) can be formulated as a set partitioning problem. The rows of the matrix A correspond to the items and the columns are incidence vectors of any feasible packing of items to a bin. The cost of each variable is 1 if the number of bins is to be minimized. In general, a weighted version can also be formulated where different bins have different costs.

3. *Vehicle routing*: Given are a set of customers and the quantity that is to be supplied to each from a warehouse. A fleet of trucks of a specified capacity is available. The objective is to service all the customers at minimum cost. The rows of the matrix A correspond to the customers and the columns are incidence vectors of feasible assignments of customers to trucks (a bin packing problem). The cost of each variable is the cost of the corresponding assignment of customers to the truck. This problem can be formulated as either a set covering or set partitioning problem.

4. The following matrix A is not totally unimodular, since $\det(A) = -2$. This can also be seen using Fact 9. If A has columns C_j then $(C_1 + C_2) - (C_3 + C_4) = (0, 2, 0, 0)^T$ has an entry greater than one in absolute value. However, A is a balanced matrix.

$$A = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix}$$

5. There are four requests R_1, R_2, R_3, R_4 for information stored in a database, which is composed of five large files $\{1, 2, 3, 4, 5\}$. Request R_1 can be fulfilled by retrieving files 1, 3, or 4; request R_2 by retrieving files 2 or 3; request R_3 by retrieving files 1 or 5; and request R_4 by retrieving files 4 or 5. The lengths of the files are $7, 3, 12, 7, 6$ (gigabytes), respectively, and the time to retrieve each file is proportional to its length. Filling all requests in the minimum amount of time is then a set covering problem, with costs $c = (7, 3, 12, 7, 6)$ and incidence matrix

$$A = \begin{pmatrix} 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 \end{pmatrix}.$$

Applying the greedy heuristic (Algorithm 4) produces $j^1 = 2$, $j^2 = 5$, and $j^3 = 1$, giving $x = (1, 1, 0, 0, 1)$ with total cost 16. This is an optimal solution to the SC problem.

16.4 ACTIVITY NETS

Activity nets are important tools in the planning, scheduling, and control of projects. In particular, the CPM (Critical Path Method) and PERT (Program Evaluation and Review Technique) models are widely used in the management of large projects, such as those occurring in construction, shipbuilding, aerospace, computer system design, urban planning, marketing, and accounting.

16.4.1 DETERMINISTIC ACTIVITY NETS

The scheduling of large complex projects can be aided by modeling as a directed network of activities having known durations and resource requirements, with the network structure defining the activity precedences. The commonly used critical path method is described as well as extensions that address constrained resources, financial considerations, and project compression.

Definitions:

A ***project*** is defined by a set of ***activities*** that are related by ***precedence*** relations. An ***activity*** consumes time and resources to accomplish, whereas a ***dummy activity*** consumes neither.

Activity u (strictly) ***precedes*** activity v, written $u \prec v$, if activity u must be completed before activity v can be initiated.

A project can be represented using a directed acyclic network G (§8.3.4).

In the ***activity-on-node*** (***AoN***) representation of a project, the network G contains a ***node*** for each activity and the ***arcs*** of G represent the precedence relations between nodes (activities).

In the ***activity-on-arc*** (***AoA***) representation of a project, the network G contains an ***arc*** for each activity and the ***nodes*** of G represent certain ***events***. Precedence relations are described by the network arcs, possibly requiring the use of ***dummy arcs*** (dummy activities). In the AoA representation, the network is assumed to have no multiple arcs joining the same pair of nodes, so an activity can be unambiguously referred to by (i, j) for some nodes i and j, with the corresponding activity ***duration*** being a_{ij}.

Network G is a ***deterministic activity net*** if the precedence relations and the parameters associated with the activities are known deterministically. Such a network is also referred to as a ***Critical Path Method*** (***CPM***) ***model***.

An ***initial node*** of G has no entering directed arcs; a ***terminal node*** has no exiting directed arcs.

Generalized precedence relations (***GPRs***) relax the necessity of a strict precedence between activities. They can be specified in the form of certain lead or lags between a pair of activities, commonly by ***start-to-start***, ***finish-to-finish***, ***start-to-finish***, and ***finish-to-start*** relations.

The ***optimal project compression problem*** is that of achieving a target project completion time with least cost, or alternatively minimizing the duration of the project subject to a specified budget constraint.

The complex interaction between the required resources and the duration of an activity is assumed to be given by the functional relationship $c_a = \phi(y_a)$, where y_a is the duration of activity a, $\ell_a \le y_a \le u_a$, and c_a is its cost. The upper limit u_a is the ***normal*** duration and the lower limit ℓ_a is the ***crash*** duration of activity a.

Facts:

1. The CPM model arose out of the need to solve industrial scheduling problems; the original work was jointly sponsored by Dupont and Sperry-Rand in the late 1950s.

2. In the AoA representation, the network can be assumed to have a single initial node and a single terminal node. These conditions can in general be guaranteed, possibly through the introduction of dummy arcs.

3. Suppose that the AoA representation of a network has n nodes, with initial node 1 and terminal node n. Then the nodes can always be renumbered (*topologically sorted*) such that each arc leads from a smaller numbered node to a larger numbered one. (See §8.3.4.)

4. In the AoA representation, the *earliest time* of realization of node j, written $t_j(E)$, is determined recursively from $t_j(E) = \max_{i\in B(j)}\{t_i(E) + a_{ij}\}$ and $t_1(E) = 0$, where $B(j)$ is the set of nodes immediately preceding node j.

5. Suppose the time of realization of node n is specified as $t_n(L) \ge t_n(E)$. The *latest time* of realization of node i, written $t_i(L)$, is determined recursively from $t_i(L) = \min_{j\in A(i)}\{t_j(L) - a_{ij}\}$, where $A(i)$ is the set of nodes immediately succeeding node i.

6. $t_j(L) \ge t_j(E)$ holds for any node j. The difference $t_j(L) - t_j(E) \ge 0$ is called the *node slack* for j.

7. For each activity (i, j) there are four *activity floats* corresponding to the differences $t_j(X) - t_i(Y) - a_{ij}$, where $X, Y \in \{E, L\}$:

- *total float*: $TF(i, j) = t_j(L) - t_i(E) - a_{ij}$;
- *safety float*: $SF(i, j) = t_j(L) - t_i(L) - a_{ij}$;
- *free float*: $FF(i, j) = t_j(E) - t_i(E) - a_{ij}$;
- *interference float*: $IF(i, j) = t_j(E) - t_i(L) - a_{ij}$.

8. $TF(i, j)$, $SF(i, j)$, and $FF(i, j)$ are always nonnegative, whereas $IF(i, j)$ can be negative, indicating infeasibility of realization under the specified conditions (all activities succeeding node j are accomplished as early as possible and all activities preceding node i are accomplished as late as possible).

9. A *critical* activity (i, j) has total float $TF(i, j) = 0$. If $t_n(L) = t_n(E)$, then the set of critical activities contains at least one path from node 1 to node n, which represents a longest path in the network from node 1 to node n. Such a path is called a *critical path* (CP).

10. Floats play an important role in both resource allocation and activity scheduling, since floats give a measure of the flexibility in scheduling activities during project execution without delaying the project completion time.

11. The problems of optimal resource allocation and activity scheduling subject to the known precedence constraints are NP-hard optimization problems (§17.5.2).

12. Practical solutions to optimal resource allocation and activity scheduling problems are based on heuristics. Virtually all heuristics used in practice rely on ranking the activities according to their float (TF, SF, FF, IF).

13. The measure TF is the only float in the AoA mode that is representation-invariant; this measure is the same in both modes of representation and in all AoA models of the same project.

14. The SF, FF, IF measures are representation-dependent: they do indeed depend on the structure of the AoA and they may also vary from their AoN values.

15. A simple redefinition of $t_i(E)$ for nodes i with all outgoing arcs dummy and $t_j(L)$ for nodes j with all incoming arcs dummy reestablishes the invariance of the activity floats to the mode of representation [ElKa90].

16. A plethora of "off-the-shelf" project planning and control software packages for PCs are currently available [DeHe90], [KoPa01]. The review [DeHe90] also outlines criteria against which a software package should be judged.

17. An extensive listing of commercial and noncommercial software for project planning can be found at

- https://wikipedia.org/wiki/Comparison_of_project_management_software

18. GPRs afford the flexibility of modeling relations that are present among activities in many practical situations, gained at a price in computational effort and interpretation of results. The concepts of criticality and float of an activity take on a new meaning, since activities may be "compressed" (speeded up) or "expanded" (slowed down) from their "normal" durations [ElKa92].

19. Considerations of resource availabilities are important in project planning and its dynamic control. The most common planning criteria are

- minimization of the project duration;
- smoothing of resource usage;
- minimization of the maximum resource utilization;
- minimization of the cost of resource usage;
- maximization of the present value of the project.

20. In the presence of limited resources, the "critical path" may no longer be a "path", in the sense of a connected chain of activities. What emerges is the concept of a *critical sequence* of activities [El77], which need not form a connected chain in the network. (See Example 4.)

21. The scheduling of activities related by arbitrary precedence relations subject to resource availabilities is an NP-hard problem. Consequently, such problems are typically approached by integer programming techniques (§16.1.8) or heuristics (e.g., simulated annealing, tabu search, genetic algorithms, neural nets).

22. The book [SlWe89] discusses project scheduling under constrained resources; in particular, Chapter 5 of Part I evaluates various heuristics that have been proposed. Also [HeDeDe98] gives a review of recent contributions to this area.

23. Typically, resources are available in one or several units or may be acquired at a cost. Mathematical models (large-scale integer linear programs) abound for the minimization of the project duration [El77]. Various branch-and-bound approaches have been proposed for these models [DeHe92], [Sp94].

24. Heuristic procedures, let alone optimization algorithms, for activity scheduling under the other criteria mentioned in Fact 19 are not generally available.

25. In the CPM model of activity networks there is little problem in defining the cost of an activity, and subsequently the cost of the project.

26. Generally, there are two streams of cash flow (from the contractor's point of view): an *in-stream* representing payments to the contractor by the owner, and an *out-stream* representing payments by the contractor in the execution of the activities.

27. From the owner's point of view there is only one stream of cash flows: namely, payments to the contractor for work accomplished. Given a particular schedule for the activities, the two streams of cash flow can be easily obtained. The problem is then scheduling activities to maximize the net present value (NPV) of the project.

28. Issues concerning the NPV of a project are equally important to those interested in bidding on a proposed project and those who are committed to carry out an already agreed-upon project. Succinctly stated, the problem is to determine the dates of the deliverables in order to maximize the NPV.

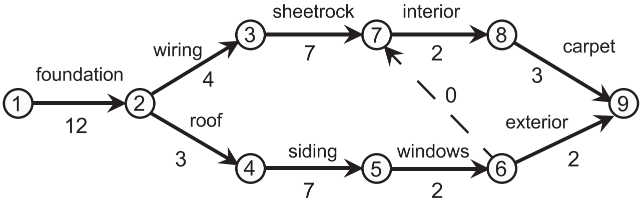
29. Suppose that the function $\phi(y_a)$ is nonincreasing over the interval $[\ell_a, u_a]$. Reference [El77] gives a treatment of linear, convex, concave, and discrete functions, while [ElKa92] discusses the case in which $\phi(y_a)$ is piecewise linear and convex over the interval $[\ell_a, u_a]$.

Examples:

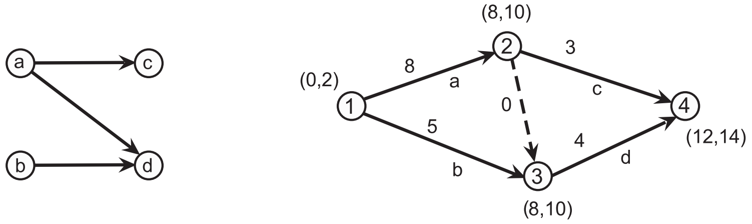
1. *Construction planning*: The construction of a house involves carrying out the nine activities listed in the following table. Their durations and (immediate) predecessor activities are also indicated.

activity	*duration (days)*	*predecessors*
foundation/frame	12	—
wiring/plumbing	4	foundation/frame
sheetrock	7	wiring/plumbing
interior paint	2	sheetrock, windows
carpet	3	interior paint
roof	3	foundation/frame
siding	7	roof
windows	2	siding
exterior paint	2	windows

An AoA representation of this project is shown in the following figure. It is necessary to use a dummy activity to ensure that the given precedences are faithfully depicted. The nodes have been numbered in topological order, with node 1 the initial node and node 9 the terminal node. The longest path from node 1 to node 9 is $[1, 2, 4, 5, 6, 7, 8, 9]$ with length 29, corresponding to a project completion time of 29 days.



2. A project is composed of the four activities a, b, c, d with precedence relations $a \prec c$, $a \prec d$, and $b \prec d$. The AoN representation of this project is shown in part (a) of the following figure. The AoA representation is shown in part (b) of the figure, where the nodes have been numbered in topological order (Fact 3). The dummy activity joining nodes 2 and 3 is needed to maintain the integrity of the precedence relations. Activity durations are indicated on the arcs of part (b) of the figure.

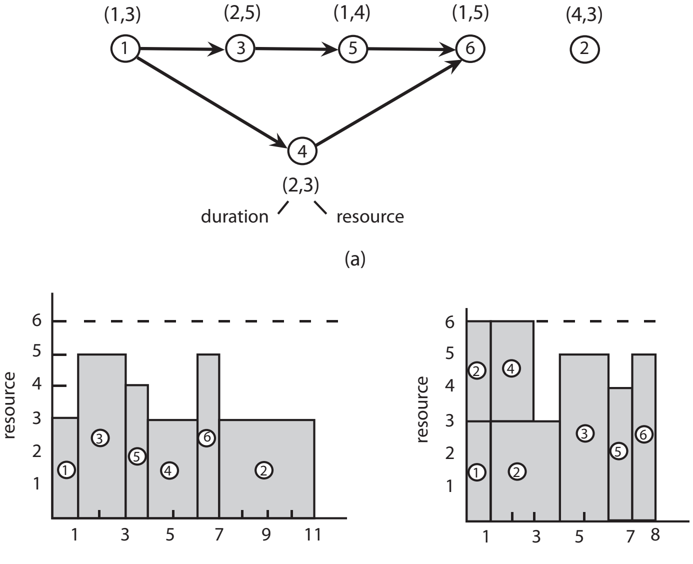


(a) (b)

3. The earliest and latest event times $t_j(E), t_j(L)$ are shown next to each node j in part (b) of the figure of Example 2, where $t_4(L) = 14$, which is 2 units more than $t_4(E) = 12$. Here all nodes have the same slack of 2, which provides no information on the various activity floats, given in the following table. Since $TF(i,j) > 0$ for all activities (i,j), there are no critical activities and no critical path, since a small delay in any activity will not delay the completion time of the project. The critical path can be determined if instead $t_4(L) = t_4(E) = 12$. Then the critical path is given by $[1,2,3,4]$.

activity	TF	SF	FF	IF
$(1,2)$	2	0	0	-2
$(1,3)$	5	3	3	1
$(2,4)$	3	1	1	-1
$(3,4)$	2	0	0	-2

4. The following figure gives a project with six activities in AoN representation. There is a single resource, with availability of 6 units. The duration of each activity and the required quantity of the resource are indicated next to each activity (node).



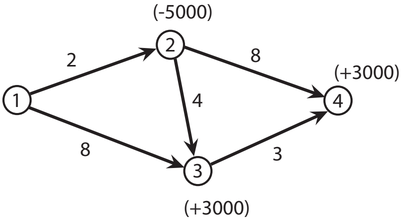
(a)

(b) (c)

The CP (based solely on durations) is $[1,3,5,6]$ of duration 5. If the integrity of the CP is maintained as long as possible, then activity 4 must be inserted before activity 6 (thus breaking the continuity of the CP), which is then followed by activity 2, as shown in part

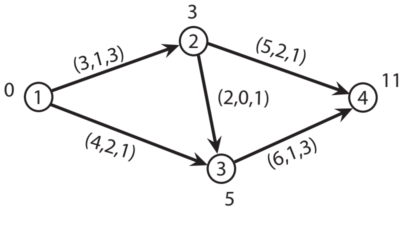
(b) of the figure. The total duration of the project under this schedule is 11 time units. Now consider the schedule shown in part (c) of the figure, in which the CP is split after activity 1; the total duration of the project is thereby reduced to only 8 time units.

5. The project of the following figure is shown in AoA mode, with the duration of each activity written beside each arc. The payment shown next to a node is the income accrued (if positive) or expense incurred (if negative) at the time of realization of that event (node). The CP is $[1, 3, 4]$ with duration 11. Ignoring the time value of money (i.e., assuming a discount factor $\beta = 0$) gives 1,000 as the estimate of project profit. Assuming a discount factor $\beta = 0.99$ and that activities are done as early as possible to maintain the CP, the estimate of project profitability shrinks to $-5{,}000(.99)^2 + 3{,}000(.99)^8 + 3{,}000(.99)^{11} = 553.75$.



Now suppose that the schedule of activities is modified as follows: delay activity $(1, 2)$ to complete at time $t_2 = 4$ (instead of 2); do activity $(1, 3)$ as early as possible to complete at time $t_3 = 8$; and do activity $(2, 4)$ as early as possible (after the realization of node 2) to complete at time $t_4 = 12$. Then the project profitability increases to $-5{,}000(.99)^4 + 3{,}000(.99)^8 + 3{,}000(.99)^{12} = 624.41$. Note that the increase in project profitability comes as a consequence of ignoring the CP, and in fact delaying the project beyond its normal duration.

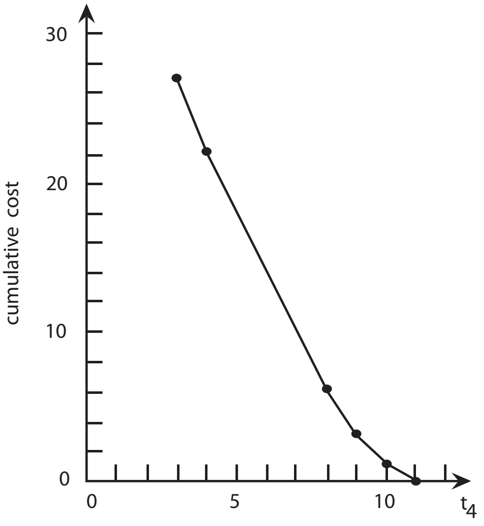
6. A project involving five activities is shown in the following figure in AoA mode. Each activity (arc) a is labeled with (u_a, ℓ_a, k_a) where k_a is the marginal cost of reducing duration from the normal time u_a. Next to each node j is its earliest time of realization $t_j(E)$ under normal activity durations.



The next table summarizes the breakpoints of the resulting piecewise linear cost function.

breakpoint	*duration* (t_4)	*marginal cost*	*cumulative cost*
1	11	1	0
2	10	2	1
3	9	3	3
4	8	4	6
5	4	5	22
6	3	∞	27

The function itself is shown in the following figure. With the complete cost function in hand it is easy to answer various questions. For example, the least additional cost required to reduce the project duration from its normal value 11 to 7 is seen to be 10. Alternatively, if 6 additional units of money are available, then the maximum reduction achievable in the project duration is 3 units of time (from 11 to 8).



16.4.2 PROBABILISTIC ACTIVITY NETS

The CPM model can be extended to incorporate uncertainty or randomness. If the durations of activities are random variables, then the network is a PERT (Program Evaluation and Review Technique) model. Alternatively, the very undertaking of an activity may be determined by chance and this consideration has led to the development of GAN (Generalized Activity Network) models.

Definitions:

A ***probabilistic activity net*** is a directed network in which some or all of the parameters, including the realization of the activities, are probabilistically known.

In a ***PERT model***, activity durations are random variables. The duration of activity a has expected value μ_a and variance σ_a^2.

Let $P(\tau)$ be the probability that the project is completed by time τ.

The ***criticality index*** of a path Q in the network is the probability that Q is a critical path in any realization of the project.

The ***criticality index*** of an activity a is the probability that a lies on a critical path in any realization of the project.

A ***GAN model*** is a probabilistic activity net with conditional progress and probabilistic realization of activities.

If X is a standard normal deviate (§7.3.1), then its (cumulative) distribution function is denoted by $\Phi(x) = Pr(X \leq x)$.

Facts:

1. The original PERT model evolved in the late 1950s from the U.S. Navy's efforts to plan and accelerate the Polaris submarine missile project.

2. A detailed account of the original PERT model, its analysis, and the criticisms levied against it is found in [El77, Chapter 3].

3. Estimation of the exact probability distribution function (pdf) of the project duration is an extremely difficult problem due to the nonindependence of the paths leading from the initial node to the terminal node.

4. The original PERT model suggested substituting μ_a for each activity duration and then proceeding with the standard CPM calculations to determine a critical path Q^* in the resulting deterministic network.

5. The pdf of the duration of the project can then be approximated using a normal distribution having mean $\widehat{\mu}_{Q^*} = \sum_{a \in Q^*} \mu_a$ and variance $\widehat{\sigma}^2_{Q^*} = \sum_{a \in Q^*} \sigma^2_a$. The normal approximation increases in validity as the number of activities in the path Q^* increases.

6. The probability $P(\tau)$ of project completion by time τ can be approximated using $\widehat{P}(\tau) = \Phi((\tau - \widehat{\mu}_{Q^*})/\widehat{\sigma}_{Q^*})$.

7. The value $\widehat{\mu}_{Q^*}$ always underestimates the exact mean project duration (often, seriously). No equivalent statement can be made about the variance estimate $\widehat{\sigma}^2_{Q^*}$ except that it is often a gross approximation of the exact variance.

8. PERT analysis goes one step further and uses an approximation to the expected value and the variance of each activity, based on the assumption that each activity duration follows a beta distribution (§7.3.1). In particular, the variance is approximated by $\frac{1}{36}(\text{range})^2$. These additional assumptions render the procedure even more suspect.

9. An immediate consequence of randomness in the activity durations is that (virtually) any path can be the CP in some realization of the project. Thus, the criticality index of a path and the criticality index of an activity are more meaningful concepts. See [Wi92] for a critique of the latter.

10. In general, it is extremely difficult to determine the exact values of the criticality indices analytically. Monte Carlo sampling is typically used to estimate these values [BaCoPr95].

11. Since the early days of PERT, significant strides have been made in estimating the various parameters in the PERT model. The approaches can be classified into the categories of *exact*, *approximating*, and *bounding* procedures. See [El89], [Ka92].

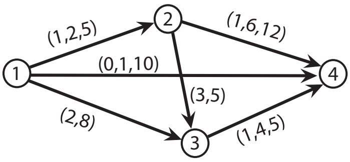
12. The concept of a *uniformly directed cutset* has been used to evaluate some common network performance criteria under the assumption of exponentially distributed activity durations [KuAd86]. Attempts to extend the concept to applications in optimal resource allocation have had limited success thus far.

13. The restriction of GANs to "exclusive-or" type nodes renders the network a graphical representation of a *semi-Markov process*. The resulting *GERT* (Graphical Evaluation and Review Technique) model has been expanded into SLAM II, an extremely powerful discrete event simulation language.

14. The analysis of stochastic activity nets with exclusive-or type nodes (*STEOR-nets*) is thoroughly discussed in [Ne90].

Examples:

1. The following figure shows a project with six activities whose durations are random variables that assume discrete values with equal probabilities. For example, activity $(1, 2)$ has duration 1, 2, or 5 with probability $\frac{1}{3}$ each.



The exact distribution of project completion time (secured by complete enumeration of the 324 realizations) is shown in the following table, from which it is seen that the true mean project duration is $\mu = 12.315$ and the true standard deviation is $\sigma = 2.5735$. The probability that the project duration is no more than 12 time units is $P(12) = 0.4815$. The PERT estimates of these same parameters, based on the deterministic critical path $[1, 2, 3, 4]$, are $\widehat{\mu}_{Q^*} = 10$, $\widehat{\sigma}_{Q^*} = 1$, and $\widehat{P}(12) = 0.9772$.

duration (t_4)	*frequency*	*relative frequency*
17	36	0.1111
15	12	0.0370
14	48	0.1481
13	72	0.2222
12	42	0.1296
11	30	0.0926
10	36	0.1111
9	28	0.0864
8	10	0.0309
7	6	0.0185
6	2	0.0062
5	2	0.0062
	324	1.0000

2. The paths from initial node 1 to terminal node 4 for the project in the figure of Example 1 are $Q_1 = [1, 2, 4]$, $Q_2 = [1, 2, 3, 4]$, $Q_3 = [1, 4]$, $Q_4 = [1, 3, 4]$. The following table lists the frequency and relative frequency that each path Q_i, or combination of paths, is a critical path. The path criticality indices are then easily determined from this table. For example, the criticality index of Q_1 is 0.3951 $(= 0.3457 + 0.0309 + 0.0185)$, and of Q_4 is 0.2592 $(= 0.1975 + 0.0185 + 0.0432)$. The criticality index of each activity can be easily determined from the criticality indices of the paths. For instance, the criticality index of activity $(1, 2)$, which lies on paths Q_1 and Q_2, is 0.7284 $(= 1 - 0.0741 - 0.1975)$.

t_4	Q_1	Q_2	Q_3	Q_4	Q_1, Q_2	Q_1, Q_4	Q_2, Q_3	Q_2, Q_4

16.4.3 COMPLEXITY ISSUES

Facts:

1. The AoN representation of a project is essentially unique.

2. The AoA representation is not unique because of the necessity to introduce dummy activities (e.g., to maintain the integrity of the precedence relations).

3. Construction of the AoA representation can be carried out with different objectives in mind: to minimize the number of nodes, to minimize the number of dummy activities, or to minimize the *complexity index* of the resulting AoA network [MiKaSt93].

4. Analytical solutions to optimization problems for project networks often proceed by conditioning upon certain activities, and then removing the conditioning through either enumeration or multiple integration. Minimizing the computing effort then involves minimizing the number of activities on which such conditioning takes place.

5. If the network is series-parallel then no conditioning is required and its analysis is straightforward, though it may be computationally demanding.

6. If the network is not series-parallel, then the minimum number of activities for conditioning can be secured by the optimal node reduction procedure of [BeKaSt92], which has polynomial complexity.

7. Patterson [Pa83] collected a set of 110 standard test problems, useful for comparing alternative solution procedures. These problems have been supplanted by a more recent sets of test problems [KaSpDr92], [KoSp97]. Benchmark problems for resource-constrained project scheduling problems are available at

- `http://www.om-db.wi.tum.de/psplib/library.html`

8. Several measures of the complexity of a project network were proposed in the 1960s, with questionable validity. The significance of the complexity index [BeKaSt92] in accounting for the difficulty in analysis is discussed in [DeHe96].

16.5 GAME THEORY

Games, mathematical models of conflict or bargaining, can be classified in three ways: by mood of play (noncooperative or cooperative), by field of application (e.g., biology or economics), and by mathematical structure (e.g., discrete, continuous, or differential). Correspondingly, game theory is a vast and diverse subject with different traditions in each of many specialties. This section discusses discrete games, in which finitely many strategies are available to finitely many players. Combinatorial and other games form largely separate disciplines to which appropriate references appear in §16.5.4.

16.5.1 NONCOOPERATIVE GAMES

This section discusses noncooperative games involving a finite number of players. Collusion among the players is not allowed in these types of games. Such games can model a wide variety of situations, as indicated in §16.5.4.

Definitions:

An n-player game Γ in ***extensive form*** consists of

- a set $\{1,\ldots,n\}\cup\{0\}$ of n decisionmakers (or ***players***) augmented by a fictitious player, called 0 (or ***chance***), whose actions are random;
- a tree, in which each nonterminal vertex represents a decision point for some player, whose possible actions correspond to arcs emanating from the vertex;
- a ***payoff function*** that assigns an n-vector to each terminal vertex;
- a partition of the nonterminal vertices into $n+1$ vertex sets, one for each player and for chance;
- a subpartition of each player's vertex set into subsets (***information sets***), such that no vertex follows another in the same subset and all vertices in a subset are followed by the same number of arcs;
- a probability distribution on arcs emanating from any chance vertex.

A ***subgame*** of Γ is a game whose tree is a subtree of the tree for Γ. A subgame is ***proper*** if the information set that contains its root contains no other vertices.

A game is ***finite*** if its tree is finite.

A game has ***perfect*** information if all information sets contain a single vertex; otherwise, it has ***imperfect*** information.

A game has ***complete*** information if all players know the entire extensive form including all terminal payoffs; otherwise it has ***incomplete*** information.

A ***pure strategy*** is a function that maps each of a player's information sets to an emanating arc.

An n-person game in ***normal*** (or ***strategic***) ***form*** consists of a set $N=\{1,2,\ldots,n\}$ of players, a set S_k of possible pure strategies for each $k\in N$, and a payoff function $f=(f_1,f_2,\ldots,f_n)$ that assigns $f_k(w)$ to Player k for every pure strategy combination $w=(w^1,w^2,\ldots,w^n)$, where $w^k\in S_k$. Payoffs are computed by taking expected values over distributions associated with chance vertices in the corresponding extensive form.

Let $D \subseteq S_1 \times S_2 \times \cdots \times S_n$ be the set of all possible pure strategy combinations w.

Let $w \,||\, \overline{w}^k$ denote the joint pure strategy combination that is identical to w except for the strategy of Player k:

$$w \,||\, \overline{w}^k = (w^1, \ldots, w^{k-1}, \overline{w}^k, w^{k+1}, \ldots, w^n).$$

$w^* \in D$ is a ***Nash equilibrium pure strategy combination*** (or simply ***equilibrium***) if, for every $k \in N$, $f_k(w^*) \geq f_k(w^* \,||\, \overline{w}^k)$ holds for all $\overline{w}^k \in S_k$. (John F. Nash, 1928–2015) Let E denote the set of all such equilibria.

For $k \in N$ define the function m_k that minimizes $f_k(w)$ over components of w that k does not control:

$$m_k(w^k) = \min_{\{\overline{w} \,|\, \overline{w}^k = w^k\}} f_k(\overline{w}).$$

If $\widetilde{w}^k$ maximizes $m_k(w^k)$, then $\widetilde{w}^k$ is a ***max-min strategy*** for k and $\widetilde{f}_k = m_k(\widetilde{w}^k)$ is the corresponding ***max-min payoff***.

Let $D^* = \{w \in D \mid f_k(w) \geq \widetilde{f}_k \text{ for all } k \in N\}$.

The strategy combination w is ***individually rational*** for all players if $w \in D^*$.

The combination $w \in D$ is ***group rational*** (or ***Pareto-optimal***) if no $\overline{w} \in D$ exists such that $f_k(\overline{w}) \geq f_k(w)$ for all $k \in N$ and $f_i(\overline{w}) > f_i(w)$ for some $i \in N$.

Let P denote the set of all Pareto-optimal w. The set $P^* = P \cap D^*$ is the ***bargaining set*** and each $w \in P^*$ is a ***cooperative*** strategy combination.

An equilibrium is ***subgame perfect*** if its restriction to any proper subgame is also an equilibrium. Let E_S denote the set of subgame perfect equilibria.

Facts:

1. Information sets are constructed so that in making a decision a player knows the identity of the information set, but not the particular vertex of the set at which the decision is being made.

2. At an equilibrium $w^* \in D$, no $k \in N$ has a unilateral incentive to depart from $(w^*)^k$ if each $j \in N$, $j \neq k$, holds fast to $(w^*)^j$.

3. $w \,||\, w^k = w$.

4. Different equilibria can yield identical outcomes.

5. The bargaining set can also be defined with "threat" strategies in lieu of max-min (or "security") strategies as criteria of individual rationality. Context determines which definition is apt.

6. If E is a singleton, or if all elements of E yield the same outcome (see Example 7), then the game is usually regarded as solved.

7. In general, however, E may either be empty or yield a multiplicity of outcomes (see Example 8).

8. A sufficient condition for $E \neq \emptyset$ in a finite game is that information be perfect (although E need not be computable by all players unless information is also complete). The above condition is not necessary; see Examples 7 and 8.

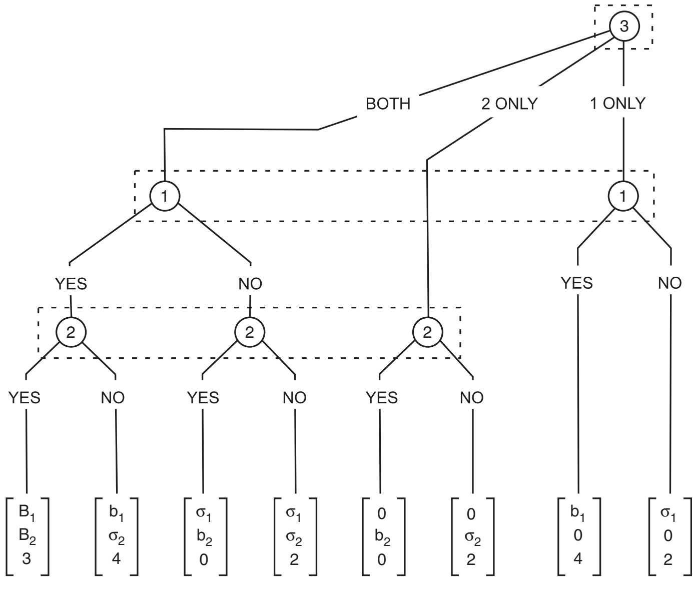
9. If E yields a multiplicity of outcomes, then an equilibrium selection criterion is necessary. One criterion is to reduce E to $E \cap P^*$, thus preferring cooperative equilibria (of a noncooperative game) to noncooperative equilibria. Another criterion is to reduce E to $E \cap E_S$.

10. Rationales for the above criteria are discussed in [Me93]. Other equilibrium selection criteria are discussed in [Fr90] and [My91].

11. The equilibrium selection problem is one of the important unsolved problems of game theory; see [BiKiTa93].

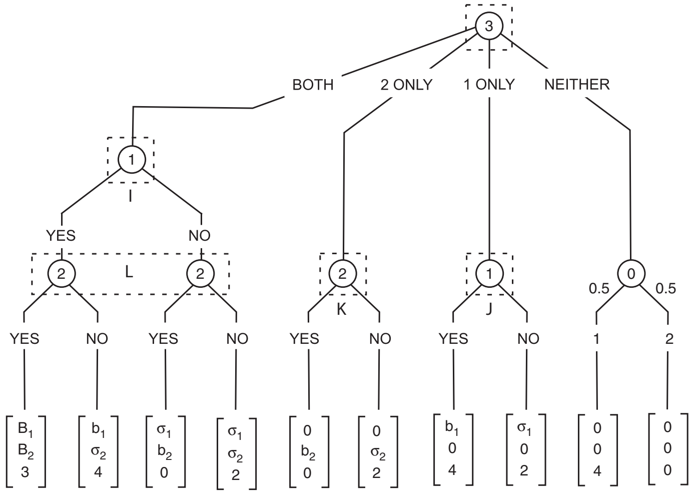
Examples:

1. A university (Player 3) must offer a faculty position to either or both of two individuals, a distinguished researcher (Player 1) and a younger colleague in the same area (Player 2), each of whom can say either YES or NO to an offer but cannot communicate with the other. The payoff to Player $i = 1, 2$ (in well-being) is σ_i (> 0) for an offer, b_i $(> \sigma_i)$ for an appointment, and B_i $(> b_i)$ if both are appointed. To the university, hiring Player 1 alone is worth 4 (in prestige); but hiring both merits 3, hiring neither is worth 2, and hiring Player 2 alone merits zero, because appointing Player 2 prevents the appointment of another distinguished researcher. The university hides from each candidate whether it has made an offer to the other. The extensive form of this game is shown in the following figure. Each player has a single information set (denoted by a rectangle). There are no chance vertices and no proper subgames. The payoffs to Players 1, 2, and 3 are indicated by the 3-vector at each terminal vertex of the tree.



2. Suppose in Example 1 that the university now reveals to whom it has made an offer. Also, the university need not offer the position to either candidate this year, in which case a single individual is appointed next year and chance decides with equal probability which current candidate the appointee matches in caliber, giving the university a payoff of $0.5(4) + 0.5(0) = 2$. The extensive form of this game is shown in the following figure. Player 1 has information sets I, J; Player 2 has information sets K, L. There is a single chance vertex. Information sets I, J, K each contain the root of a proper subgame.

3. The figures of Examples 1 and 2 are finite games of imperfect information since in both cases Player 2 has an information set with more than one vertex. Each game has incomplete information if players know only their own terminal payoffs.



4. In the figure of Example 2, Player 2 can say YES or NO at each of K or L. Hence Player 2 has four possible strategies: YKNL (yes if K, no if L), NKYL, an unconditional YES, and an unconditional NO. Likewise, Player 1 has four strategies: YINJ, NIYJ, YES, and NO.

5. The following table depicts the strategic form of the figure of Example 1 as a 3-dimensional array. The strategy sets are $S_1 = \{\text{YES, NO}\}$, $S_2 = \{\text{YES, NO}\}$, and $S_3 = \{\text{BOTH, 1 ONLY, 2 ONLY}\}$. The payoff function is defined by $f_1(\text{YES, NO, 1 ONLY}) = b_1$, $f_2(\text{NO, NO, 2 ONLY}) = \sigma_2$, $f_3(\text{YES, YES, BOTH}) = 3$, etc. Player 1's strategies correspond to rows, Player 2's strategies correspond to columns, and Player 3's strategies correspond to arrays.

$$\begin{array}{ccc} & \text{YES} & \text{NO} \\ \text{YES} & \begin{bmatrix} B_1 \\ B_2 \\ 3 \end{bmatrix} & \begin{bmatrix} b_1 \\ \sigma_2 \\ 4 \end{bmatrix} \\ \text{NO} & \begin{bmatrix} \sigma_1 \\ b_2 \\ 0 \end{bmatrix} & \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ 2 \end{bmatrix} \\ & \multicolumn{2}{c}{\text{BOTH}} \end{array} \qquad \begin{array}{ccc} & \text{YES} & \text{NO} \\ \text{YES} & \begin{bmatrix} b_1 \\ 0 \\ 4 \end{bmatrix} & \begin{bmatrix} b_1 \\ 0 \\ 4 \end{bmatrix} \\ \text{NO} & \begin{bmatrix} \sigma_1 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} \sigma_1 \\ 0 \\ 2 \end{bmatrix} \\ & \multicolumn{2}{c}{\text{1 ONLY}} \end{array} \qquad \begin{array}{ccc} & \text{YES} & \text{NO} \\ \text{YES} & \begin{bmatrix} 0 \\ b_2 \\ 0 \end{bmatrix} & \begin{bmatrix} 0 \\ \sigma_2 \\ 2 \end{bmatrix} \\ \text{NO} & \begin{bmatrix} 0 \\ b_2 \\ 0 \end{bmatrix} & \begin{bmatrix} 0 \\ \sigma_2 \\ 2 \end{bmatrix} \\ & \multicolumn{2}{c}{\text{2 ONLY}} \end{array}$$

6. The following table depicts the strategic form of the figure of Example 2 as a 3-dimensional array. Player 1's strategies correspond to rows, Player 2's strategies correspond to columns, and Player 3's strategies correspond to arrays. The strategy sets now are $S_1 = \{\text{YES, YINJ, NIYJ, NO}\}$, $S_2 = \{\text{YES, YKNL, NKYL, NO}\}$, and $S_3 = \{\text{BOTH, 1 ONLY, 2 ONLY, NEITHER}\}$. The sets S_1, S_2 contain more strategies than in Example 5 because Players 1 and 2 have better information: the game is less imperfect. The payoff to Player 3 from NEITHER is an expectation over arcs emanating from the game's single chance vertex.

$$\begin{array}{ccccc}
 & \text{YES} & \text{YKNL} & \text{NKYL} & \text{NO} \\
\text{YES} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} \\
\text{YINJ} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} \\
\text{NIYJ} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} \\
\text{NO} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix} & \begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix}
\end{array}$$

NEITHER

7. {YES, YES, 1 ONLY} and {YES, NO, 1 ONLY} are the equilibria of Example 1; both yield the same outcome, namely, Player 1 is hired without an offer to Player 2.

8. Example 2 has 14 equilibria: namely, (YINJ, YES, BOTH), (YINJ, NKYL, BOTH), and all strategy combinations of the form (YES, $\cdot$, 1 ONLY), (NIYJ, $\cdot$, 1 ONLY), or (NO, $\cdot$, NEITHER), where $\cdot$ denotes any of the four strategies of Player 2. Eight of these 14 equilibria correspond to the equilibrium outcome of Example 1, whereas the other six correspond to two different outcomes.

9. For Example 1, $m_3(\text{BOTH}) = 0 = m_3(\text{2 ONLY})$ and $m_3(\text{1 ONLY}) = 2$, implying $\widetilde{w}^3 = \text{1 ONLY}$ and $\widetilde{f}_3 = 2$. For $k \leq 2$, $m_k(\text{YES}) = 0 = m_k(\text{NO})$, implying $\widetilde{f}_k = 0$. So $D^* = D - \{(\text{YES, YES, 2 ONLY}), (\text{NO, YES, 2 ONLY}), (\text{NO, YES, BOTH})\}$.

10. For Example 1, $P = \{(\text{YES, YES, BOTH}), (\text{YES, NO, BOTH})\} = P^*$.

11. In Example 2, the equilibria (YINJ, YES, BOTH) and (YINJ, NKYL, BOTH) are not subgame perfect because in the subgame beginning at J they would require Player 1 to say NO, which would be irrational. (Player 1's threat to say NO, unless Player 3 makes an offer to BOTH, is not credible because Player 3 has a first mover advantage.)

12. While reducing E to $E \cap P^*$ eliminates equilibria of the form (NO, $\cdot$, NEITHER) in Example 2, it is also possible that E and P are disjoint (as in Example 1).

13. While reducing E to $E \cap E_S$ eliminates equilibria of the form (YINJ, YES, BOTH) and (YINJ, NKYL, BOTH) in Example 2, it is also possible that $E = E_S$ (as in Example 1, where there are no proper subgames).

16.5.2 MATRIX AND BIMATRIX GAMES

This subsection discusses two-player noncooperative games. Such games can be represented in normal form by a pair of matrices.

Definitions:

Suppose $S_1 = \{1, \ldots, r\}$ and $S_2 = \{1, \ldots, s\}$.

The $r \times s$ ***payoff matrices*** $A = (a_{ij})$ and $B = (b_{ij})$, with $a_{ij} = f_1(i,j)$ and $b_{ij} = f_2(i,j)$, define a ***bimatrix game***.

The game is ***zero-sum*** if $a_{ij} + b_{ij} = 0$ for all $i \in S_1$, $j \in S_2$. The game is ***symmetric*** if $r = s$ and $B = A^T$. In either case, the game is completely determined by A and is called a ***matrix game***.

For Player 1, $i \in S_1$ is ***dominated*** by $i' \in S_1$ if $a_{i'j} \geq a_{ij}$ for all $j \in S_2$, with strict inequality for at least one j. For Player 2, $j \in S_2$ is dominated by $j' \in S_2$ if $b_{ij'} \geq b_{ij}$ for all $i \in S_1$ with strict inequality for at least one i.

Let e_k denote the k-dimensional vector in which every entry is 1, and let X_k denote the $(k-1)$-dimensional ***unit simplex*** $X_k = \{(x_1, \ldots, x_k) \mid xe_k = 1,\ x \geq 0\}$.

A ***mixed strategy*** for Player 1 is a vector $p = (p_1, \ldots, p_r) \in X_r$, where p_i is the probability that Player 1 selects $i \in S_1$. Similarly, a mixed strategy for Player 2 is $q = (q_1, \ldots, q_s) \in X_s$, where q_j is the probability that Player 2 selects $j \in S_2$.

In a ***mixed strategy combination*** $(p,q) \in X_r \times X_s$, the expected payoffs to Players 1 and 2, respectively, are given by $\phi_1(p,q) = pAq^T$ and $\phi_2(p,q) = pBq^T$.

The pair $(p^*, q^*) \in X_r \times X_s$ is a ***Nash equilibrium mixed strategy combination***, or simply an ***equilibrium in mixed strategies***, if $\phi_1(p^*, q^*) \geq \phi_1(p, q^*)$ for all $p \in X_r$ and $\phi_2(p^*, q^*) \geq \phi_2(p^*, q)$ for all $q \in X_s$. If the game is zero-sum, then p^* is called an ***optimal strategy*** for Player 1 and q^* is called an optimal strategy for Player 2.

Facts:

1. Every bimatrix game has at least one equilibrium in mixed strategies.

2. All equilibria in mixed strategies of a zero-sum game yield the same expected payoffs, v to Player 1 and $-v$ to Player 2; v is known as the *value* of the game.

3. The value v of a zero-sum game and a pair (p^*, q^*) of optimal strategies can always be computed by solving a dual pair of linear programming (LP) problems (§16.1). The primal LP problem finds p to maximize v subject to $A^T p \geq v1_s$, $p \in X_r$, whereas the dual LP problem finds q to minimize v subject to $Aq \leq v1_r$, $q \in X_s$.

4. Player 1 can achieve the value v of a zero-sum game with a mixed strategy that attaches zero probability to any dominated pure strategy. Likewise, Player 2 can achieve value $-v$ by playing dominated pure strategies with zero probability.

5. Graphical methods can be used to compute efficiently all equilibria of zero-sum games where $r = 2$ or $s = 2$, or of matrix games (of either type) where $r = s = 3$; see [Dr81], [Ow13], and [Pe08]. There is no general method for computing all equilibria.

6. The definition of mixed strategy and the existence of equilibria are readily extended to n-player games. This result was one of the fundamental contributions to game theory for which John Nash was awarded the 1994 Nobel Prize in Economic Science.

Examples:

1. Two advertising agencies are involved in a campaign to promote competing beverages. The payoffs of various promotional strategies are shown in the following table.

	j	1	2
i		old	new
1	old	0	−2
2	new	−2	−1
3	diet	3	−3

The promotional strategies for the first agency are: stress the old formula, advertise a new formula, or advertise a diet drink. The second agency has the possible strategies: stress the old formula, or advertise a new formula. The payoffs in this case indicate the net change in millions of sales gained (by Advertiser 1). For example, if the first agency promotes a diet drink while the other agency promotes the old formula, three million more drinks will be sold. On the other hand, if the other agency happens to promote the new formula, then the first agency will end up losing three million unit sales to the second agency.

2. An investor has just taken possession of jewels worth \$45,000 and must store them for the night in one of two locations (A, B). The safe in location A is relatively secure, with a probability $\frac{1}{15}$ of being opened by a thief. The safe at location B is not as secure as the safe at location A, and has a probability $\frac{1}{5}$ of being opened. A notorious thief is aware of the jewels, but doesn't know where they will be stored. Nor is it possible for the thief to visit both locations in one evening. This is a (symmetric) zero-sum game between the investor (Player 1), who selects where to keep the jewels and the thief (Player 2), who decides which safe to try. If the investor puts the jewels in the most secure location (A) and the jewel thief goes to this location, the expected loss in this case is $\frac{1}{15}(-45{,}000) + \frac{14}{15}(0) = -3{,}000$. The other entries of the payoff matrix in the following table are computed similarly, and are expressed in thousands of dollars (to the investor).

	j	1	2
i		old	new
		A	B
1	A	−3	0
2	B	0	−9

No pure strategy combination is a Nash equilibrium, since it is always tempting for one player to defect from the current strategy. However, there is a Nash equilibrium mixed strategy combination: $p^* = (\frac{3}{4}, \frac{1}{4}) = q^*$, with value $v = -\$2{,}250$ to the investor. The mixed strategy p^* is found by solving the following linear program, in which Player 1 wants to find the largest value of v so that he is guaranteed to receive at least v (regardless of what Player 2 does). The associated optimal dual LP solution gives q^*.

$$\begin{array}{rl} \text{maximize:} & v \\ \text{subject to:} & -3p_1 + 0p_2 \geq v \\ & 0p_1 - 9p_2 \geq v \\ & p_1 + p_2 = 1 \\ & p_1, p_2 \geq 0 \end{array}$$

3. The zero-sum game of *chump* is played between two camels, a dromedary (Player 1) and a bactrian (Player 2). Player k must simultaneously flash F_k humps and guess that its opponent will flash G_k. Possible strategies (F_k, G_k) satisfy $0 \leq F_1, G_2 \leq 1$ and $0 \leq F_2, G_1 \leq 2$. If both players are right or wrong, then the game is a draw; if one is wrong and the other is right, then the first pays $F_1 + F_2$ piasters to the second. The following table shows the strategy sets and corresponding payoffs a_{ij} to Player 1.

	j		1	2	3	4	5
i		$(0,0)$	$(0,1)$	$(1,0)$	$(1,1)$	$(2,0)$	$(2,1)$
	$(0,0)$	0	0	−1	0	−2	0
1	$(0,1)$	0	0	0	1	−2	0
2	$(0,2)$	0	0	−1	0	0	2
3	$(1,0)$	1	0	0	−2	0	−3
4	$(1,1)$	0	−1	2	0	0	−3
5	$(1,2)$	0	−1	0	−2	3	0

The first row and column can be deleted from the full payoff matrix because $(0,0)$ is dominated by $(0,1)$ for both players (Fact 4). Thus it suffices to analyze the reduced payoff matrix in which $r = s = 5$. The value of the game is $-\frac{4}{21}$ for Player 1 ($\frac{4}{21}$ for Player 2). Optimal strategies $p^* = (\frac{2}{21}, \frac{4}{7}, \frac{1}{7}, \frac{4}{21}, 0)$ and $q^* = (\frac{4}{7}, \frac{4}{21}, \frac{2}{21}, \frac{1}{7}, 0)$ are found by linear programming (Fact 3). Note that strategies $i = 5$ and $j = 5$ have zero probability at this equilibrium, despite being undominated.

4. The symmetric game of *four ways* [Me01] is played by two left-turning motorists who arrive simultaneously from opposite directions at a 4-way junction. Each has three pure strategies: the first is to go, the second to wait, and the third a conditional strategy of going only if the other appears to be waiting. It takes 2 seconds for one motorist to cross the junction while the other waits. If initially both either go or wait, then both motorists incur an extra "posturing" delay of either 3 or 2 seconds, respectively. Also, the one who ultimately waits is equally likely to be either player. For example, $a_{11} = 0.5 \times (-3 - 2) + 0.5 \times (-3) = -4$ and $a_{22} = 0.5 \times (-2 - 2) + 0.5 \times (-2) = -3$. This game has the payoff matrix

$$\begin{pmatrix} -4 & 0 & 0 \\ -2 & -3 & -2 \\ -2 & 0 & -4 \end{pmatrix}.$$

There are infinitely many equilibria in mixed strategies; these are described in the following table, where $0 \leq a \leq 1$ and $\frac{1}{2} \leq b \leq 1$.

p^*	q^*
$(1, 0, 0)$	$(0, a, 1-a)$
$(0, a, 1-a)$	$(1, 0, 0)$
$(0, 1, 0)$	$(b, 0, 1-b)$
$(b, 0, 1-b)$	$(0, 1, 0)$
$\frac{1}{11}(6, 2, 3)$	$\frac{1}{11}(6, 2, 3)$

16.5.3 CHARACTERISTIC-FUNCTION GAMES

When there exists a binding agreement among all players to cooperate, attention shifts from strategies to the bargaining strengths of coalitions. These strengths are assumed to be measured in terms of a freely transferable benefit (e.g., money or time) and players are assumed to seek a fair distribution of the total benefit available. Also, without loss of generality, the benefit of cooperation will be taken as the savings in costs.

Definitions:

A ***coalition*** is a subset S of $N = \{1, \dots, n\}$; equivalently, $S \in 2^N$.

The ***cost*** associated with coalition S is denoted $c(S)$.

Let $\mathcal{R}^+$ denote the set of nonnegative reals. The ***characteristic function*** $\overline{\nu}\colon 2^N \to \mathcal{R}^+$ assigns to each S its cooperative benefit, using $\overline{\nu}(S) = \max\{0, \sum_{i \in S} c(\{i\}) - c(S)\}$.

A ***characteristic-function game***, or ***c-game***, is the pair $\Gamma = (N, \overline{\nu})$.

The game Γ is ***inessential*** if $\overline{\nu}(N) = 0$. If $\overline{\nu}(N) > 0$ then the game is ***essential***, with ***normalized characteristic function*** $\nu\colon 2^N \to [0, 1]$ defined by $\nu(S) = \frac{\overline{\nu}(S)}{\overline{\nu}(N)}$.

The game Γ is ***convex*** if $\nu(S \cup T) \geq \nu(S) + \nu(T) - \nu(S \cap T)$ for all $S, T \in 2^N$.

Let $X = X_n$ be the $(n-1)$-dimensional unit simplex (§16.5.2). Any $x \in X$ is called an ***imputation***; it allocates x_i of the total normalized benefit $\nu(N) = 1$ to Player i. An imputation is ***unreasonable*** if it allocates more to some $i \in N$ than the maximum that i could contribute to any coalition $T - \{i\}$ by joining it.

The ***reasonable set*** is $X_{RS} = \{x \in X \mid x_i \leq \max_T [\nu(T) - \nu(T - \{i\})]$ for all $i \in N\}$.

For any $x \in X$ and $S \in 2^N$, the ***excess*** of coalition S at x is $e(S, x) = \nu(S) - \sum_{i \in S} x_i$.

The ***core*** of Γ is $C = \{x \in X \mid e(S, x) \leq 0$ for all $S \in 2^N\}$.

The ***marginal worth*** of Player i to the coalition $T - \{i\}$ is $\nu(T) - \nu(T - \{i\})$.

The ***Shapley value*** of a c-game is the imputation $x^S = (x_1^S, x_2^S, \dots, x_n^S)$ defined by $x_i^S = \frac{1}{n!} \sum_{T \in \Pi^i} (|T| - 1)!\,(n - |T|)!\,(\nu(T) - \nu(T - \{i\}))$, where $\Pi^i = \{T \in 2^N \mid T \supseteq \{i\}\}$.

Facts:

1. An imputation is both individually rational and group rational (see §16.5.1).

2. Convexity is a sufficient (but not necessary) condition for the core to exist.

3. If $C \neq \emptyset$ then $C \subseteq X_{RS}$.

4. If C contains a single imputation, then the c-game is usually regarded as solved.

5. In general, C may either be empty (see Example 1) or contain infinitely many imputations (see Example 2).

6. If C contains infinitely many imputations, then there are several ways to single one out as the solution to the c-game. One approach is to define a "center" of C, which leads to the important concept of the *nucleolus* [Me01].

7. Every c-game solution concept assumes that players have agreed to enter coalition N. If its order of formation were known, players could be allocated their marginal worths; in general, however, this order of formation (and hence marginal worth) is a random variable.

8. If all orders of formation of N are equally likely, then the probability that Player i enters N by joining the coalition $T - \{i\}$ is $\frac{(|T|-1)!(n-|T|)!}{n!}$.

9. The Shapley value distinguishes a single imputation as the solution of a c-game by allocating to players the expected values of their marginal worths, based on the assumption that all orders of formation of N are equally likely.

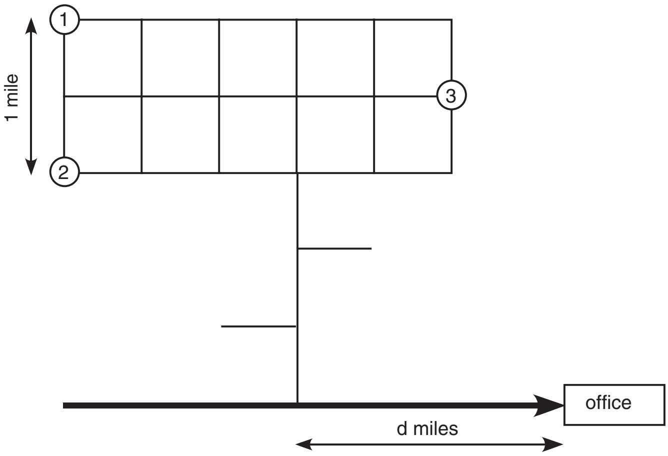
10. $x^S \in X_{RS}$.

11. $x^S \in C$ if Γ is convex.

Examples:

1. In the c-game *log-hauling* [Me01], three lone drivers of pickup trucks discover a pile of 150 logs too heavy for any one to lift. Players 1, 2, and 3 can haul up to 45, 60, and 75 logs, respectively. Thus $\overline{\nu}(\{1,2\}) = 105$, $\overline{\nu}(\{1,3\}) = 120$, $\overline{\nu}(\{2,3\}) = 135$, and $\overline{\nu}(\{1,2,3\}) = 150$ so that $\nu(\{1,2\}) = \frac{7}{10}$, $\nu(\{1,3\}) = \frac{4}{5}$, and $\nu(\{2,3\}) = \frac{9}{10}$. This c-game is not convex; for example, if $S = \{1,2\}$ and $T = \{2,3\}$, then $1 = \nu(S \cup T) < \nu(S) + \nu(T) - \nu(S \cap T) = \frac{8}{5}$. Also, $C = \emptyset$.

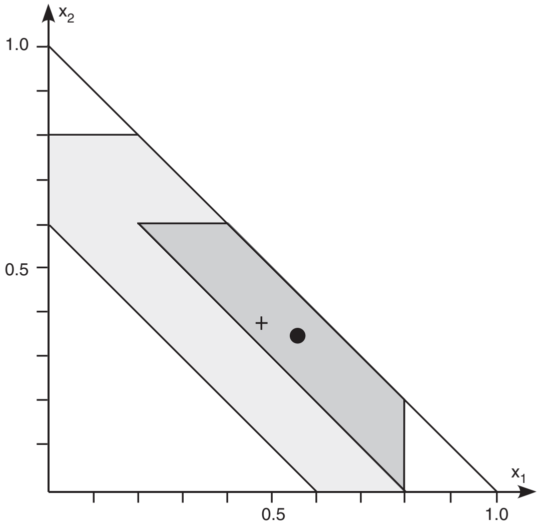
2. The c-game *car pool* [Me01] is played by three co-workers whose office is d miles from their residential neighborhood, shown in the following figure.



Driving to work costs $\$k$ per mile, and the shortest route is always used. The benefit of cooperation is car pool savings, giving the characteristic function displayed in the following table.

S	$c(S)$	$\overline{\nu}(S)$	$\nu(S)$	$e(S,x)$ *for* $d=1$
$\emptyset$	0	0	0	0
$\{1\}$	$(4+d)k$	0	0	$-x_1$
$\{2\}$	$(3+d)k$	0	0	$-x_2$
$\{3\}$	$(3+d)k$	0	0	x_1+x_2-1
$\{1,2\}$	$(4+d)k$	$(3+d)k$	$\frac{3+d}{3+2d}$	$\frac{4}{5}-x_1-x_2$
$\{1,3\}$	$(6+d)k$	$(1+d)k$	$\frac{1+d}{3+2d}$	$x_2-\frac{3}{5}$
$\{2,3\}$	$(6+d)k$	dk	$\frac{d}{3+2d}$	$x_1-\frac{4}{5}$
$\{1,2,3\}$	$(7+d)k$	$(3+2d)k$	1	0

Because $x_3 = 1 - x_1 - x_2$ (≥ 0), a set of imputations is determined by its projection onto $x_3 = 0$. In these terms, for $d = 1$, X is the largest triangle in the following figure, X_{RS} is the shaded hexagon, and C is the shaded quadrilateral. Here $C \subset X_{RS} \subset X$ because the c-game is convex (for all $d \geq 0$).



3. For the c-game in Example 2, it is easy enough to locate a center for C; see the figure for Example 2, where the nucleolus is marked by a dot.

4. In Example 1, the six possible formation orders of N are 123, 132, 213, 231, 312, 321. Thus, the Shapley value is the imputation $x^S = (\frac{17}{60}, \frac{1}{3}, \frac{23}{60})$; see the following table.

i	$T \in \Pi^i$	$\nu(T) - \nu(T - \{i\})$	*probability i enters N by joining $T - \{i\}$*	x_i^S
1	$\{1\}$	0	$\frac{1}{3}$	$\frac{17}{60}$
	$\{1,2\}$	$\frac{7}{10}$	$\frac{1}{6}$	
	$\{1,3\}$	$\frac{4}{5}$	$\frac{1}{6}$	
	$\{1,2,3\}$	$\frac{1}{10}$	$\frac{1}{3}$	
2	$\{2\}$	0	$\frac{1}{3}$	$\frac{1}{3}$
	$\{1,2\}$	$\frac{7}{10}$	$\frac{1}{6}$	
	$\{2,3\}$	$\frac{9}{10}$	$\frac{1}{6}$	
	$\{1,2,3\}$	$\frac{1}{5}$	$\frac{1}{3}$	
3	$\{3\}$	0	$\frac{1}{3}$	$\frac{23}{60}$
	$\{1,3\}$	$\frac{4}{5}$	$\frac{1}{6}$	
	$\{2,3\}$	$\frac{9}{10}$	$\frac{1}{6}$	
	$\{1,2,3\}$	$\frac{3}{10}$	$\frac{1}{3}$	

5. By a calculation very similar to that laid out in the table of Example 4, the Shapley value for Example 2 is the imputation $x^S = (\frac{7}{15}, \frac{11}{30}, \frac{1}{6})$. Because the c-game is convex, $x^S \in C$. This is illustrated in the previous figure, where x^S is marked by a cross.

16.5.4 APPLICATIONS

Discrete (noncooperative or characteristic-function) games have numerous applications and merge with other categories of games not examined here. The references in the following table provide sources for the definitions, concepts, and applications of such games. This table also lists some representative areas of application of game theory.

category and references	*selected applications*	*remarks*
characteristic function games [GoGaFi10], [Me93], [Me01], [Ow13], [Pe08], [Wa88]	airport landing fees, voting, water resources	utility is usually assumed to be transferable: in essence, players value benefits identically
classical game theory [LuRa57], [vNMo53]	microeconomics, parlor games	economic (as opposed to evolutionary) game theory
combinatorial games [AlNoWo07], [Gu91]	chess, go, nim, other parlor games	two players; complete, perfect information; no chance moves; zero-sum
continuous games [Dr81], [Fr90]	duels, military combat, oligopoly theory	a discrete game with mixed strategies is a special case of a continuous game
cooperative games in strategic form (as opposed to c-games) [Fr90], [Me01], [Pe08]	wage bargaining, motoring behavior	agreements among players are binding
differential games [BaHa94], [DoEtal00], [Me93]	resource management	extension of optimal control theory

category and references	*selected applications*	*remarks*
economic game theory [Fr90], [GoGaFi10], [My91]	microeconomics	equilibria are the result of rational thought processes
evolutionary game theory [BrRy13], [Cr03], [Ma82], [Me01], [Sa10], [Si10]	animal behavior	equilibria are the result of natural selection or equivalent populational processes
iterated games [Fr90], [Me01], [Si10]	rationality of cooperation	often infinitely many iterations
resource games [Me93]	fisheries, forestry, water resources	discrete, continuous, and differerential games are all used
symmetric matrix games [BrRy13], [Cr03], [Ma82], [Me01], [Sa10], [Si10]	evolutionary game theory	dynamical systems theory provides a rationale for strategic equilibrium
zero-sum matrix games [Dr81], [Pe08]	military science	

16.6 SPERNER'S LEMMA AND FIXED POINTS

A fixed point of a function from a set X to itself is a point of X that is mapped into itself. Brouwer (1912) proved that every continuous mapping f on the unit ball has a fixed point. Sperner (1928) gave an elegant proof of Brouwer's fixed-point theorem using a combinatorial lemma known today as Sperner's lemma. This lemma has a number of applications to economics, nonlinear programming, and game theory.

16.6.1 SPERNER'S LEMMA

Sperner's lemma is a combinatorial result applicable to certain triangulations of a p-dimensional convex set, in which the vertices of the triangulation are given labels from $\{1, 2, \ldots, p+1\}$.

Definitions:

The $p+1$ points $x_1, x_2, \ldots, x_{p+1} \in \mathcal{R}^n$ are said to be in ***general position*** if the vectors $x_2 - x_1, x_3 - x_1, \ldots, x_{p+1} - x_1$ are linearly independent (§6.1.3).

The set $C \subseteq \mathcal{R}^n$ is ***convex*** if for all $x, y \in C$ and $0 \leq \lambda \leq 1$, $\lambda x + (1-\lambda)y \in C$.

The ***convex hull*** of a finite set of points $v_1, \ldots, v_{p+1} \in \mathcal{R}^n$ is the set $\langle v_1, \ldots, v_{p+1} \rangle = \big\{ \sum\limits_{i=1}^{p+1} \lambda_i v_i \mid \sum\limits_{i=1}^{p+1} \lambda_i = 1, \, \lambda_i \geq 0 \big\}$.

A ***p-simplex*** σ is the convex hull of $p+1$ points $x_1, \ldots, x_{p+1} \in \mathcal{R}^n$ in general position.

The ***vertices*** of the p-simplex $\sigma = \langle x_1, \ldots, x_{p+1} \rangle$ are the points $x_1, \ldots, x_{p+1}$. The ***face*** $\tau = \langle x_{j_1}, \ldots, x_{j_k} \rangle$ of σ is the simplex spanned by the subset $\{x_{j_1}, \ldots, x_{j_k}\}$ of $\{x_1, \ldots, x_{p+1}\}$. Write $\tau \prec \sigma$ when τ is a face of σ.

A ***simplicial complex*** K is a collection of simplices satisfying

- if $\sigma \in K$ and $\tau \prec \sigma$ then $\tau \in K$;
- if $\sigma, \tau \in K$ intersect, their intersection is a face of each.

The ***p-skeleton*** of a simplicial complex K is the set of all simplices of dimension p or less. The 0-skeleton is the ***vertex set***, denoted $V(K)$.

A ***simplicial subdivision*** $\mathcal{F}$ of a simplex σ is a collection of simplices $\{\tau_j \mid 1 \leq j \leq m\}$ satisfying

- $\sigma = \bigcup_{j=1}^{m} \tau_j$;
- the intersection of any two τ_j is either empty or a face of each.

A simplicial subdivision $\mathcal{F}'$ of a simplicial complex $\mathcal{K}$ is a ***refinement*** of the simplicial subdivision $\mathcal{F}$ of $\mathcal{K}$ if every simplex of $\mathcal{F}$ is a union of simplices of $\mathcal{F}'$.

Given a simplicial subdivision $\mathcal{F}$ of the p-simplex $\sigma = \langle x_1, \ldots, x_{p+1} \rangle$, a ***proper labeling*** of $\mathcal{F}$ is a mapping $\ell \colon V(\mathcal{F}) \to \{1, 2, \ldots, p+1\}$ satisfying

- $\ell(x_m) = m$ for $m = 1, \ldots, p+1$;
- if vertex v lies on a face $\langle x_{k_1}, \ldots, x_{k_q} \rangle$ of σ, then $\ell(v) \in \{k_1, \ldots, k_q\}$.

Here $\{1, 2, \ldots, p+1\}$ is the ***label set***, and if $\ell(v) = k$ then v ***receives the label*** k.

A ***distinguished simplex*** is a p-simplex that receives all $p+1$ labels 1 through $p+1$.

Facts:

1. The convex hull $\langle v_1, \ldots, v_{p+1} \rangle$ is the intersection of all convex sets containing the points $v_1, \ldots, v_{p+1}$.

2. The dimension of any p-simplex is p.

3. A p-simplex contains $2^{p+1} - 1$ simplices of dimension p or less.

4. *Sperner's lemma* (1928): Every properly labeled subdivision of a simplex σ has an odd number of distinguished simplices. (E. Sperner, 1906–1980)

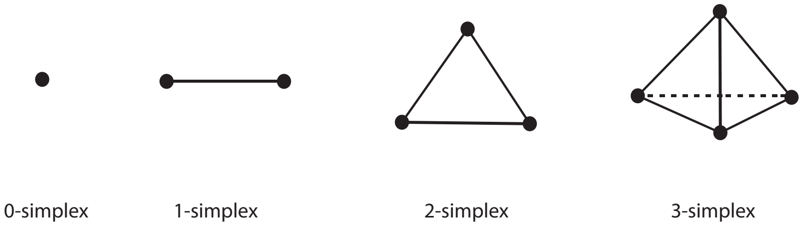
5. Algorithm 1 gives a method for finding a distinguished triangle in a properly labeled subdivision of a triangle T. Each iteration of the outer loop starts at a distinguished 1-simplex and traces out a path, terminating either at a distinguished 2-simplex or at an outer edge of T.

```
Algorithm 1: Distinguished simplex of a 2-simplex.
  input: properly labeled subdivision of triangle $T$
  output: a distinguished triangle of $T$
  {Outer loop}
    find a distinguished 1-simplex $\tau$ along the bottom of $T$
    {Inner loop}
    repeat
      if the unique triangle containing $\tau$ is distinguished then stop
      else proceed to a neighboring triangle whose common edge is distinguished
    until either a distinguished triangle is found or the search leads to the bottom
        edge of $T$
  continue outer loop with a new distinguished 1-simplex $\tau$
```

6. Since there is an odd number of distinguished 1-simplices along the bottom of T (Fact 4) and since each "failed" outer loop iteration produces a path joining two such distinguished 1-simplices, Algorithm 1 must eventually produce a path terminating at a distinguished 2-simplex.

Examples:

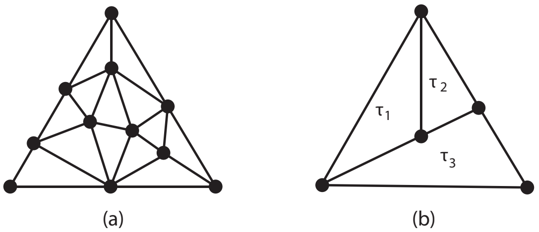
1. A 0-simplex is a point, a 1-simplex is a line segment, and a 2-simplex is a triangle (interior included). A 3-simplex includes the vertices, edges, faces, and interior of a tetrahedron. See the following figure.



0-simplex 1-simplex 2-simplex 3-simplex

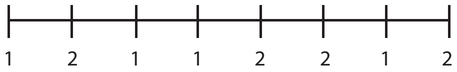
2. The 0-skeleton of a simplex σ is its vertex set; the 1-skeleton of σ is the edge set of σ including their endpoints; if σ is a 3-simplex, the 2-skeleton is the union of the faces of σ.

3. Part (a) of the following figure shows a simplicial subdivision of a 2-simplex. The subdivision in part (b) of the figure is not simplicial because $\tau_1 \cap \tau_3$ is not a face of the simplex τ_3.

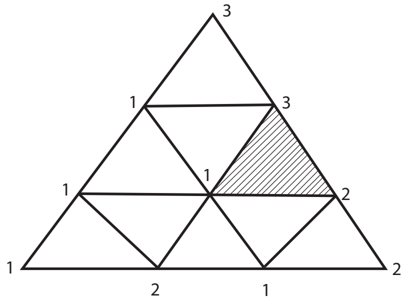


(a) (b)

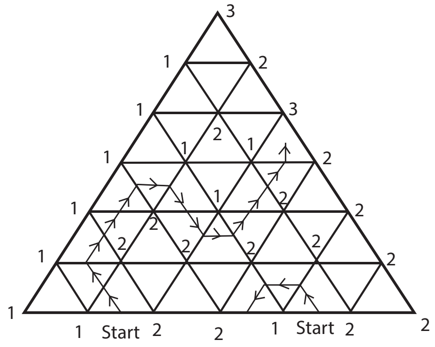
4. The following figure shows a proper labeling of a simplicial subdivision of a 1-simplex. A distinguished 1-simplex is a subinterval that receives both the labels 1 and 2. In this example, there are five such 1-simplices, an odd number (as guaranteed by Fact 4).



5. The following figure shows a proper labeling of a simplicial subdivision of a 2-simplex. There is one distinguished 2-simplex, receiving all three labels, which is shown shaded in the figure. If the vertex in the interior of the triangle is instead labeled 3, then there will be three distinguished 2-simplices, still an odd number.



6. Several possible paths from executing Algorithm 1 are displayed in the following figure. The rightmost path terminates in a bottom edge, while the leftmost path leads to a distinguished triangle. Note that there are three distinguished triangles in this example, an odd number as required by Sperner's lemma.



16.6.2 FIXED-POINT THEOREMS

Fixed-point theorems have applicability to a number of problems in economics, as well as to game theory and optimization.

Definitions:

The point $x \in B$ is a ***fixed point*** of the mapping $f\colon B \to B$ if $f(x) = x$.

The mapping f defined on a subset X of a normed space B is a ***contraction*** if there is some $0 \le \beta < 1$ such that $\|f(x) - f(y)\| \le \beta\|x - y\|$ for all $x, y \in X$.

The function F is a ***set mapping*** on X if $F(x)$ is a nonempty subset of X for all $x \in X$.

The set mapping F is ***convex*** if $F(x)$ is a convex subset of X for all $x \in X$.

Facts:

1. Fixed-point theorems can be used to demonstrate the existence of economic equilibria, solutions to a system of nonlinear equations, and Nash equilibria in two-person nonzero-sum games.

2. *Brouwer's fixed-point theorem* I: Every continuous mapping $f\colon \sigma \to \sigma$ where σ is a p-simplex has a fixed point. (L. E. J. Brouwer, 1881–1966)

3. For a simplex $\sigma = \langle x_1, x_2, \ldots, x_{p+1}\rangle$ and a continuous mapping $f\colon \sigma \to \sigma$, let $f(\sum_{k=1}^{p+1} \lambda_k x_k) = \sum_{k=1}^{p+1} \mu_k x_k$. Then $\sum_{k=1}^{p+1} \mu_k = \sum_{k=1}^{p+1} \lambda_k = 1$.

4. Relative to the mapping $f\colon \sigma \to \sigma$, define $T_j = \{\sum_{k=1}^{p+1} \lambda_k x_k \mid \mu_j \le \lambda_j\}$. Then a fixed point of f is any point belonging to $\bigcap_{j=1}^{p+1} T_j$.

5. Suppose an interior vertex v of a subdivision $\mathcal{F}$ of σ is labeled with j provided that $v \in T_j$, and suppose a vertex v belonging to a face $\langle x_{k_1}, x_{k_2}, \ldots, x_{k_t}\rangle$ is labeled with any one of the labels $k_1, k_2 \ldots, k_t$. Then a fixed point of f occurs in a distinguished simplex of σ.

6. Algorithm 2, based on Sperner's lemma (§16.6.1), produces a sequence of points converging to a fixed point of a p-simplex σ.

Algorithm 2: **Fixed point of a p-simplex.**

```
input: function $f$ defined on a $p$-simplex $\sigma$
output: fixed point $x^* \in \sigma$
construct a sequence of subdivisions $\{\mathcal{F}_n \mid n \ge 1\}$ such that $\mathcal{F}_{n+1}$ refines $\mathcal{F}_n$
label the vertex set of $\mathcal{F}_n$ as in Fact 5
for each subdivision $\mathcal{F}_n$ find a distinguished simplex $\tau_n$
$\bigcap \tau_n$ contains the desired fixed point $x^*$
```

7. *Brouwer's fixed-point theorem* II: Every continuous mapping from a convex compact set $B \subseteq \mathcal{R}^n$ into itself has a fixed point.

8. *Contraction mapping theorem*: Every contraction $f\colon X \to X$ has a fixed point. The fixed point is the limit of the sequence $\{f(x_n) \mid n \ge 0\}$, where x_0 is an arbitrary element of X and $x_{n+1} = f(x_n)$.

9. *Kakutani's fixed-point theorem*: Let $X \subseteq \mathcal{R}^n$ be a convex compact set and suppose that F is a convex mapping on X. If the graph $\{(x, y) \mid y \in F(x)\} \subseteq \mathcal{R}^{2n}$ is closed, then there exists a point $x^* \in X$ such that $x^* \in F(x^*)$.

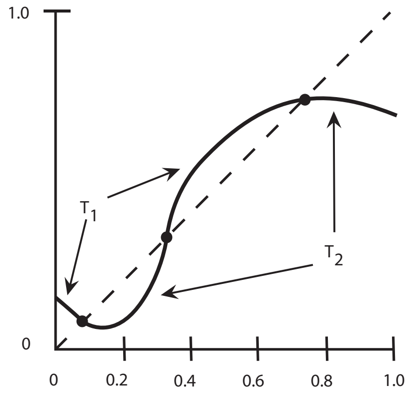
10. *Schauder's fixed-point theorem*: Every continuous mapping f on a convex compact subset X in a normed space B has a fixed point.

11. Reference [Bo89] gives applications of fixed-point theorems to determining market equilibria, maximal elements of binary relations, solutions to complementarity problems, as well as solutions to various types of games (cooperative and noncooperative).

Examples:

1. The real-valued function $f(x) = 1 - x$ is a mapping from the 1-simplex $\sigma = [0, 1]$ to itself. It is not a contraction since $|f(x) - f(y)| = |(1 - x) - (1 - y)| = 1 \cdot |x - y|$ holds for all $x, y \in \sigma$ so $\beta \ge 1$. The function f has a fixed point at $x = \frac{1}{2}$. However, the iterative procedure in Fact 8 will not generally locate this fixed point. For example, using $x_0 = \frac{1}{4}$ produces the sequence $x_1 = f(x_0) = \frac{3}{4}$, $x_2 = f(x_1) = \frac{1}{4}$, $x_3 = f(x_2) = \frac{3}{4}$, and so forth, with no limiting value.

2. The following figure shows a real-valued function $f\colon \sigma \to \sigma$ defined over the 1-simplex $\sigma = [0, 1]$. This function has three fixed points, identified by the intersection of the graph of f with the dashed line $y = x$. The sets T_j of Fact 4 relative to $x_1 = 0$, $x_2 = 1$ are also indicated in the figure, and it is verified that $T_1 \cap T_2$ contains the three fixed points of f. A subdivision of σ into five subintervals is shown in the figure. Using Fact 5, the associated vertices (at $x = 0.0, 0.2, 0.4, 0.6, 0.8, 1.0$) receive the labels $1, 2, 1, 1, 2, 2$ respectively, and so there are three distinguished simplices (each containing a fixed point).



3. The real-valued function $f(x) = \frac{1}{4+x^2}$ is a mapping from $\mathcal{R}$ to itself. It can also be shown to be a contraction mapping with $\beta = \frac{1}{16} < 1$. If the iterative procedure in Fact 8 is applied using $x_0 = 1$, then $x_1 = 0.2$, $x_2 = 0.24752$, $x_3 = 0.24623$, $x_4 = 0.24627$, and $x_5 = 0.24627$, yielding the (approximate) fixed point $x^* = 0.24627$.

4. *Perron's theorem*: This theorem (§6.5.5), which assures that every positive matrix has a positive eigenvalue-eigenvector pair, can be proved using the fixed-point theorem in Fact 2. Let $A = (a_{ij})$ be an $n \times n$ matrix, with all $a_{ij} > 0$. The set $\sigma = \{x \in \mathcal{R}^n \mid \sum_{k=1}^{n} x_k = 1,\ x_k \geq 0\}$ is an $(n-1)$-simplex, and the continuous function defined by $f(x) = \frac{Ax}{\|Ax\|_1}$ maps σ into itself. (Here $\|w\|_1$ is the l_1 norm of vector w; see §6.4.5.) By Fact 2, f has a fixed point $\bar{x}$, so that $A\bar{x} = \|A\bar{x}\|_1\bar{x}$. Since at least one component of $\bar{x}$ is positive and A is positive, the vector $A\bar{x}$ has positive components. It then follows that the eigenvalue $\|A\bar{x}\|_1$ is positive and that the corresponding eigenvector $\bar{x}$ has all positive components.

16.7 COMBINATORIAL AUCTIONS

A combinatorial auction (CA) describes a market with several items for sale in which bidders make bids on combinations of items rather than individual items. The specified combination is either won in its entirety or the bid is not accepted. Although initially proposed in 1982 by Rassenti, Smith, and Bulfin [RaSmBu82], the widespread use of CAs in a variety of real-world settings began only later, in the early 21st century. The most prominent CAs have occurred in industrial procurement and in the sale of radio spectrum licenses to telecommunication companies (with individual auctions in some instances generating billions of dollars in revenue). The following subsections discuss basic concepts as well as four issues arising in combinatorial auctions: winner determination, bid language, incentive compatibility, and demand revelation. A few suggested exercises are included sporadically.

16.7.1 BASIC CONCEPTS

Definitions:

A ***combinatorial auction*** (***CA***) describes a situation in which multiple items are auctioned, and each bidder can submit several bids (each may contain several items). The set of ***bidders*** is $I = \{1, 2, \ldots, i, \ldots, |I|\}$, the set of ***bids*** is $J = \{1, 2, \ldots, j, \ldots, |J|\}$, and the set of ***items*** for sale is $K = \{1, 2, \ldots, k, \ldots, |K|\}$. In addition, there is a fixed ***supply*** $c_k \geq 1$ of identical, indivisible copies of item k in the auction.

Each bid j consists of a monetary bid amount b_j and an associated (unique) bidder i_j. An integer quantity a_{kj} of each item k must be received by bidder i_j at the conclusion of the auction for bid j to be considered ***accepted***.

Bidder i's ***valuation*** for a set of items S is denoted $v_i(S)$.

Bidder i's bid on a set of items S is denoted $b_i(S)$.

A ***forward auction*** is one with several buyers and one seller, in contrast to a ***reverse auction*** having several sellers and one buyer.

Except where explicitly noted, this section will focus on forward CAs.

Facts:

1. CAs are also sometimes referred to as *bundle auctions* or *package auctions*.

2. A market using combinatorial bids among several buyers and several sellers is called a *combinatorial exchange* (CE), or a *combinatorial double auction*. These two-way markets have different theoretical properties and are less frequently discussed in the literature or used in practice.

3. It is convenient to write the (row) vector of all bid amounts as b and the (column) vector of available supplies as c. Also the $|K| \times |J|$ matrix $A = (a_{kj})$, indexed by items and bids, indicates the quantity of item k specified in bid j.

4. For small numerical examples with unique items (i.e., $c_k = 1$ for all k), capital letters are often used as item names. For convenience, set braces and commas can be dropped in the expression for a bidder's valuation; e.g., bidder i's valuation for items A and B will be written $v_i(AB)$ rather than as $v_i(\{A, B\})$.

5. The valuation function is typically assumed to be *weakly monotonic*: i.e., $v(T) \geq v(S)$, for all $S \subseteq T$. This condition is usually called *free disposal*.

6. Bidders are often assumed to have an overall utility that is *quasi-linear* in money: i.e., receiving the set of items S and paying P_i dollars provides the net utility $u_i(S) = v_i(S) - P_i$ to bidder i.

Examples:

1. *Government procurement:* The Chilean government procures half a billion dollars in meal services annually using thousands of package bids [KiOlWe14]. Bus route services in London have been bought via a CA with a first-price rule (i.e., pay-as-bid) [CaPe06].

2. *Industrial procurement:* Using *expressive commerce* software platforms based on combinatorial procurement auctions, the firm CombineNet conducted \$35 billion in revenue in its first 447 business-to-business auctions over five years. Auction items included direct goods (e.g., food ingredients, steel, chemicals, fibers), indirect goods (e.g., office supplies, furnishing, computers), and services (e.g., transportation, consulting, advertising) [Sa13].

3. *Spectrum allocation:* Using a *combinatorial clock auction* (CCA) format, which combines iterative bidding with a final sealed-bid auction, governments have auctioned the rights to use telecommunications frequencies around the world, including those in the United Kingdom, the Netherlands, Denmark, Ireland, Switzerland, Australia, Austria, Slovenia, Canada, and Slovakia. Revenues were around \$19.5 billion for just ten auctions conducted in 2012 through 2014.

4. *Airport arrival and departure slots:* The FAA adopted a core-selecting combinatorial auction to allocate airport landing slots in 2008, but the auction was canceled for political reasons [CoCoOt09].

5. *Electricity auctions:* In the U.S. and Europe, regional wholesale markets for electrical power generation are governed by a complex sequence of contracts sold at auction, including long-term futures contracts for generation, "day-ahead" markets, and spot markets, some of which include CA concepts in their designs [Sh12].

6. *Off-shore wind energy tracts:* To facilitate the development of wind farms on the U.S. Outer Continental Shelf, CAs were developed that combine both price and non-price attributes into a multi-phase CA design [AuCr11].

7. *Real estate auctions:* A new multistory building in Amsterdam used a CA to sell a mixture of residential, office, dining (etc.) space, subject to municipal constraints, in order to maximize rent [GoEtAl14].

8. Suppose we have a set of $|K| = 3$ unique items $\{A, B, C\}$ for sale, with $|J| = 5$ bids from $|I| = 5$ bidders. (When a bidder bids on only one bundle, she is called *single-minded.*) Bidders submit bids $b_1(AB) = 15$, $b_2(C) = 7$, $b_3(AC) = 12$, $b_4(B) = 8$, and $b_5(ABC) = 16$. Since there are unique items, $c = (1, 1, 1)^T$. Bid amounts are collected as $b = (15, 7, 12, 8, 16)$ with the bundle structure yielding

$$A = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1 \end{pmatrix}.$$

16.7.2 WINNER DETERMINATION AND BID LANGUAGE

This subsection studies the winner determination problem (WDP), namely, that of finding a set of winning bids to maximize total monetary value. In order to formulate appropriate optimization problems, it is necessary to define the underlying bid language used to communicate bid information.

Definitions:

The ***OR bid language*** is a format for communicating bids in which a bidder submits a list of combinatorial bids, and the auctioneer is free to accept any subset of them (Bid_1 OR Bid_2 OR $\text{Bid}_3 \ldots$), subject to supply constraints over all accepted bids. By contrast, in the ***XOR bid language*** the auctioneer is constrained to accept at most one of the bids made by the same bidder (Bid_1 XOR Bid_2 XOR $\text{Bid}_3 \ldots$).

The $|I| \times |J|$ binary matrix $B = (b_{ij})$ consists of entries in which $b_{ij} = 1$ if and only if $i_j = i$. Thus, the unit entries of row i of B identify those bids made by bidder i.

Facts:

1. The winner determination problem for the OR bid language (WDP-OR) can be formulated as the following 0-1 integer programming problem (see §16.1.8) in the binary decision variables x: namely, $x_j = 1$ if and only if bid j is accepted by the auctioneer in the final allocation of auction items to bidders. Here it is assumed that all a_{kj} and c_k values are nonnegative.

$$\begin{aligned} \text{maximize:} \quad & bx \\ \text{subject to:} \quad & Ax \le c \\ & x \in \{0,1\}^{|J|}. \end{aligned} \tag{1}$$

2. The (feasibility) constraints in (1) state that no more than c_k copies of item k can be allocated; i.e., each row enforces $\sum_{j \in J} a_{kj} x_j \le c_k$ for each item k.

3. Under the OR bid language, a bidder cannot express preferences for substitute items. (See Example 1.)

4. WDP-OR is an NP-hard optimization problem for an arbitrary set of bids. This remains true if $b_j = 1$ for all submitted bids and if each bid is restricted to be on sets of three or fewer items [RoPeHa98].

5. Assume $c_k = 1$ for all k. Suppose the *permissible* subsets to be bid on form a tree structure: if S_1 and S_2 are both allowed to be bid on, then either one set contains the other or they are disjoint. Then WDP-OR is solvable in $O(n^2)$ time [RoPeHa98].

6. Assume $c_k = 1$ for all k, and that permissible packages include only contiguous intervals from the list of items K. The resulting matrix A will exhibit the consecutive ones property and WDP-OR is solvable in $O(n^2)$ time. This describes the auctioning of real estate along a coastline with bids only on contiguous land. The case of a closed loop of coastline around an island can be solved in $O(n^3)$ time [RoPeHa98].

7. Since the OR bid language cannot express preferences for substitute items (e.g., I wish to have exactly one of these items and would refuse/throw away any additional items), the more expressive XOR bid language may be preferred, which can communicate any value function over subsets.

8. The winner determination problem for the XOR bid language (WDP-XOR) can be formulated as the following 0-1 integer programming problem (see §16.1.8) in the binary decision variables x: namely, $x_j = 1$ if and only if bid j is accepted by the auctioneer in the final allocation of auction items to bidders.

$$\begin{aligned} \text{maximize:} \quad & bx \\ \text{subject to:} \quad & Ax \le c \\ & Bx \le 1 \\ & x \in \{0,1\}^{|J|}. \end{aligned} \tag{2}$$

9. Each of the second set of constraints from (2) is indexed by a unique bidder i and can be written as $\sum_{j \in J | i_j = i} x_j \le 1$.

10. A solution to WDP-XOR is referred to as *efficient*, based on its connection to the First Fundamental Welfare Theorem of Economics. When all bids are truthful, a solution to WDP-XOR corresponds exactly to the classical notion of *allocative efficiency*.

11. WDP-XOR is an NP-hard optimization problem for an arbitrary set of bids. This remains true if $b_j = 1$ for all submitted bids and each bid is restricted to be on sets of two or fewer items [vHMu01].

12. If each bidder submits a bid on every subset of K (communicating at least $2^{|K|} - 1$ nonempty subsets), then both WDP-OR and WDP-XOR can be solved in polynomial time by dynamic programming. However, even for relatively small $|K|$ the burden of communicating so many bids becomes prohibitive [RoPeHa98].

13. Both WDP-OR and WDP-XOR do not admit a polynomial-time approximation scheme (unless P = NP) [BeFu99].

14. Among the most-studied special cases is that of *unit demand*, in which each bidder wants to consume at most one item, and so is willing to bid only on single-item bundles. This setting is often called the *assignment game*. When bidders are restricted to bid for each item individually, formulation (2) becomes totally unimodular and WDP is hence polynomially solvable. (See also §16.7.3, Fact 3 and §16.7.4, Fact 3.)

15. Early work in CAs looked at forming larger bids through the combination of atomic bids on items or subsets using logical connectives like OR, XOR, AND, etc. Various combinations such as OR-of-XOR and XOR-of-OR have been studied.

16. The desire to pay $500 for any n of the items from a particular subset cannot be written efficiently (as the size of the subset grows) with simple logical connectives, unless an explicit "n-of-the-set$\{\}$" operator is introduced [BoHo01].

Examples:

1. To illustrate Fact 3, suppose that $v_i(A) = v_i(B) = v_i(AB) = 10$. In the OR bidding language, the bidder cannot express this preference to the auctioneer. If the bidder submits $b_i(A) = b_i(B) = 10$, WDP-OR always allows the auctioneer to award both bids at a total value of 20, ignoring any bid $b_i(AB)$ below 20.

2. Returning to Example 8 of §16.7.1, the solutions to both WDP-OR and WD-XOR are identical (because bidders are all single-minded) with winning bids $b_1(AB) = 15$ and $b_2(C) = 7$. Now suppose instead that the first two bids come from one bidder and the remaining from a second bidder (i.e., change the problem to bids $b_1(AB) = 15$, $b_1(C) = 7$, $b_2(AC) = 12$, $b_2(B) = 8$, and $b_2(ABC) = 16$). While WDP-OR remains essentially unchanged (except that the two winning bids are from the same bidder), for WDP-XOR we must employ the matrix

$$B = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 \end{pmatrix}$$

as in (2), to enforce a single winning bid per bidder. The WDP-XOR solution is to award $b_2(ABC) = 16$, as the auction can no longer accept the first and second bids together, or the third and fourth bids together, both of which are better solutions under WDP-OR.

3. The XOR-language has been used in practice in several spectrum license CCAs in Europe. Adjacent licenses with similar transmission properties were grouped into categories and sold in a first CA to allocate the number of licenses won in each of a few categories, with a second "assignment stage" CA used to determine a particular contiguous assignment of bandwidth won in the first auction. This two-stage design helped to set prices on similar items, and to reduce both the communication burden (number of bundles to bid on) and the computational burden of winner determination.

4. Combining the flexibility/communication benefits of OR and the richer expression as in XOR, an important bid language introduced in the early CA literature is OR*, which consists of OR bids in which a bidder could place fictitious items into her bids, or equivalently, allow bidders to insert XOR-type constraints [Ni06].

5. For many practical auction applications, devising a manageable domain-specific bid language (format to succinctly express relevant packages without an explosion of communication requirements) can be a nontrivial task. Several papers take this approach for a specific application area. For example, [GoEtAl15] look at packages of TV ad slots.

6. The 2014 Canadian spectrum license auction used an "XOR of base + OR" bidding language in a CCA format.

- http://www.ic.gc.ca/eic/site/smt-gst.nsf/eng/sf10726.html

For each base + OR collection of bids conveyed, if a bidder receives the base package, then the auctioneer may also accept any of the following OR package bids. At most one base + OR collection could be accepted from each bidder (an XOR structure). This allowed for many more packages to be covered by bids, important because the number of licenses in the auction (spanning several regions and frequency categories) made the number of packages to consider quite large.

16.7.3 PRICE DETERMINATION AND INCENTIVE COMPATIBILITY

For simplicity, this subsection focuses on the XOR language.

Definitions:

For any auction, P_i will denote the total final ***payment*** of bidder i.

Where convenient, p_k will represent the ***unit price*** of item k.

Bidder i's ***surplus*** is her observed or inferred profit, given by $s_i = b_i(S_i) - P_i$, where S_i is her winning package, emphasizing that this is not her true payoff or profit if she does not bid ***truthfully***, i.e., does not bid $b_i(S) = v_i(S)$. Typically, CAs satisfy ***individual rationality***, in which $s_i \geq 0$ for all i.

An allocation and bundle-pricing scheme are in ***competitive equilibrium*** if and only if (i) the allocation is efficient when bids are replaced by prices, and (ii) a bidder prefers the bundle and price assigned to her relative to any other bundle at its prescribed price. The bundle she receives, possibly empty, is said to be in her ***demand set*** at these prices. The classical concept of a Walrasian equilibrium, also applied to continuous rather than discrete commodities, demands that all items with a positive price are sold.

An auction is ***dominant-strategy incentive compatible*** (***DSIC***) if the strategy to set $b_i(S) = v_i(S)$ for all S provides at least as much utility to each bidder i as any other bidding strategy she could choose.

A subset of bidders is called a ***coalition***. The optimal objective value of WDP solved over coalition $C \subseteq I$ (by ignoring the bids of others) is written as $WDP(C)$. When bids are true values, this gives the value of the ***coalitional welfare function***, written $w(C)$.

The ***Vickrey-Clarke-Groves*** (***VCG***) ***mechanism*** is the efficient auction mechanism in which each bidder pays $P_i = b_i(S_i) - WDP(I) + WDP(I \backslash i)$. The quantity $WDP(I) - WDP(I \backslash i)$ is called the ***VCG discount***.

A welfare function exhibits the ***buyers-are-substitutes*** condition if and only if $w(I) - w(I \backslash C) \geq \sum_{i \in C} w(I) - w(I \backslash i)$ for all $C \subset I$.

If the buyers-are-substitutes property holds for every subset of I, the welfare function is said to exhibit ***buyer-submodularity*** on I.

The outcome of an auction is ***blocked*** if there is some coalition of bidders who would each agree to an alternative outcome that would also be preferred by the seller (because of greater total payments). As in cooperative game theory, an unblocked outcome is said to be in the ***core***.

An efficient auction that selects payments P_i in the core when bids are treated as truthful is called ***core-selecting*** [DaMi08].

Facts:

1. An allocation is supported by competitive equilibrium prices if and only if it is efficient, but the prices may be nonlinear in items and non-anonymous (i.e., different bidders may see different prices for the same bundle). See [MiPa07] for the computation of universal competitive equilibrium prices.

2. Whenever the LP relaxation of formulation (2) yields an integral solution, the LP dual provides Walrasian equilibrium prices. In particular, the dual variables associated with item capacities yield linear prices for each item that can be added to form anonymous bundle prices. When the LP relaxation solution value strictly exceeds the integer solution value, competitive equilibrium linear item prices do not exist. (Exercise: Prove these statements using LP duality theory and complementary slackness. Hint: first show that dual variables associated with matrix B equal the surplus amounts s_i.)

3. In the assignment game context (see §16.7.2, Fact 14), [Le83] showed that among all optimal solutions to the LP dual of (2), those that minimize payments are the VCG prices.

4. When item prices p_k exist that form a competitive equilibrium, the auction adding those prices to form bundle payments is core-selecting. (Exercise: Prove this fact. Use Fact 2 and Fact 11.)

5. The VCG mechanism is the unique efficient DSIC individually rational payment rule [GrLa77].

6. Bidders-are-substitutes is a necessary and sufficient condition for VCG to be supported in competitive equilibrium [BiOs02].

7. When the VCG outcome is in the core, it is the unique bidder-dominant point (strictly preferred by all winners) in the core [AuMi02].

8. When the VCG outcome is not in the core, there is no bidder-dominant outcome. Payments may be as low as zero despite large counter-bids, and VCG is vulnerable to collusive manipulation and false-name bidding [AuMi02]. (See Example 2.)

9. Buyer-submodularity of the welfare function guarantees that the VCG outcome is in the core [AuMi02].

10. If the *substitutes* (also called *goods-are-substitutes* or *gross substitutes*) condition holds for all bidders (a property discussed in the economics literature in which a price increase on one good cannot cause a necessary drop in demand of a different good), then buyer-submodularity holds [AuMi02]. (See Example 1.)

11. Core-selecting payments can be found via constraint generation. Given a candidate set of payments for a particular efficient solution, solving WDP with bids lowered by the current surplus will find the most violated core constraint [DaRa07]. With winning bid amounts b_i^* for winning bidders $i \in W$, the core constraint for any coalition C can be written as $\sum_{i \in W \setminus C} P_i \geq WDP(C) - \sum_{i \in C} b_i^*$.

12. When the VCG outcome is in the core, a bidder-optimal core-selecting algorithm arrives at the VCG outcome.

13. In a CA, pay-as-bid is always a core-selecting outcome (so the core is always nonempty.) The core in a CE may be empty.

14. In a CE, VCG may violate budget balance: VCG payments exceed revenue, requiring outside funds.

Examples:

1. Let $b_1(A) = 4$, $b_1(B) = 3$, and $b_1(AB) = 6$; $b_2(A) = 3$, $b_2(B) = 4$, and $b_2(AB) = 5$. Here the bidders treat the items as substitutes (Fact 10), and so the VCG outcome is in the core (Fact 9). (Exercise: Determine winning bids and compute VCG payments. Attempt a few non-truthful strategies by a single bidder to see that there is no benefit.)

2. Let $b_1(A) = b_2(B) = b_3(AB) = 20$. VCG yields zero payments and is not in the core. (See Fact 8.) If $v_1(A) < 20$ this illustrates successful collusive or false-name bidding for VCG [AuMi02]. Any individually rational outcome with $P_1 + P_2 = 20$ is a bidder-optimal core-selecting outcome.

3. Let $b_1(AB) = b_2(AC) = b_3(BC) = 10$ and $b_4(ABC) = 12$. Linear item prices that form a competitive equilibrium do not exist (assuming individual rationality). VCG and bidder-optimal core-selection both have $P_4 = 10$, but this cannot be decomposed into equilibrium item prices. (Exercise: Prove the non-existence of item prices for this numerical example.)

4. Let $b_1(A) = b_2(B) = b_3(C) = 20$, $b_4(AB) = 28$, $b_5(AC) = 26$, and $b_7(A) = b_8(B) = b_9(C) = 10$. Minimum-revenue core-selecting payments are given by $P_1 = 16$, $P_2 = 12$, and $P_3 = 10$, which if taken as item prices form a Walrasian equilibrium. However, VCG payments $P_1 = P_2 = P_3 = 10$ are not in the core [DaRa07]. (Exercise: Demonstrate that VCG is not in the core for this example.)

16.7.4 DEMAND REVELATION

Among the most important properties of traditional auctions is their ability to elicit information about the demand in a market through an iterative process (e.g., calling successively higher prices for a single good). With CAs, however, it is impossible in many cases to guarantee truthful demand revelation through an iterative process (i.e., to implement VCG by calling out market prices and asking for demand reports). Here we mention some facts and heuristic techniques concerning iterative auction procedures in the CA setting.

Definitions:

An iterative CA consisting of simultaneous single-item auctions, in which item prices are announced for each item in successive rounds, with price increases on items experiencing excess demand, is called a ***simultaneous ascending auction*** (***SAA***) or ***simultaneous multi-round auction*** (***SMRA***).

The ***exposure problem*** occurs in a SAA when a bidder feels the need to keep bidding on a set of complementary items, exposing her to the risk of getting an incomplete (less valuable) subset. It may also refer to the situation in which a bidder must actively bid on substitute items, not knowing which one she might get, exposing her to the risk of winning more than one when only one is desired.

Similar to the SAA process, ascending linear-item prices over several rounds have also been used as the ***clock phase*** of a multi-phase CCA auction. In this case the bids in each round are translated into XOR package bids to be used in a subsequent sealed-bid WDP called the ***supplementary bidding phase***. Bidders can place additional supplementary bids beyond those revealed in the clock phase.

Because a SAA or clock phase is intended to reveal demand information for the market as a whole, ***activity rules*** are often used to assure that bidders reveal their demand in early rounds, rather than withholding information about the packages of interest, or their value, until later rounds.

Among the simplest activity rules applied in practice is an ***eligibility points*** system. Each item is assigned a number of eligibility points prior to the auction, and bidding is restricted such that the total of eligibility points for the package bid on by a bidder is not allowed to go up from one round to the next successive auction rounds.

Under a ***revealed preference*** activity rule, each bidder is forced to bid self-consistently according to an assumed utility functional form.

Straightforward bidding occurs in an iterative auction when a bidder always truthfully reports her packages of highest surplus at the current prices. This may also be called ***myopic*** bidding, as a bidder bids without regard to any potential future rounds, as if the current round will be the last.

Iterative CAs with nonlinear prices have been proposed based on real-time computation of a ***winning level*** and ***deadness level*** for any package of interest. If a bidder submits a package bid just above the current winning level, then it is guaranteed to become a winning bid (at least until another later bid might knock it out). Any bid below the deadness level can never become winning (no matter what bids are submitted in the future). A bid between the winning level and deadness level of a bundle will not become winning immediately, but may become winning with the help of other bids in future rounds.

Facts:

1. There is no ascending-price auction using linear and anonymous item prices that is guaranteed to implement the VCG outcome, even when attention is restricted to bidder preferences satisfying the substitutes property [GuSt00].

2. If the substitutes condition holds (see §16.7.3, Fact 10), then the SAA with straightforward bidding closely approximates a competitive equilibrium (dependent on the bid increment). With at least three bidders and one bidder who violates the substitutes property, no competitive linear item prices exist [Mi00]. Efficiency can be quite low for an iterative linear-price auction in the worst case. For example, [BiShZi13] give a $\frac{2}{|K|+1}$ upper bound.

3. In the assignment game context (see §16.7.2, Fact 14), [DeGaSo86] among others provide a primal-dual algorithm related to the Hungarian algorithm that implements the VCG auction iteratively. The auctioneer announces prices and bidders report which items maximize their utility at the stated prices (myopic bidding). An assignment is attempted at each round with prices rising on over-demanded items until an assignment is found.

4. With $|K| = 1$ and diminishing marginal values for the single item, buyers-are-substitutes holds and VCG can be implemented with an ascending auction [Au04].

5. Assuming buyer-submodularity and straightforward bidding, the ascending proxy auction [AuMi02] and iBundle(3) [PaUn00] terminate with minimal competitive equilibrium payments corresponding to the VCG outcome. (This does not guarantee a linear item price decomposition of VCG, however.)

6. Assuming concave utility functions that are additively separable in money and items, [BiEtAl11] consider a seller selling bundles corresponding to bases of a matroid, with applications in scheduling and network formation markets. They provide an ascending auction that terminates at the VCG outcome in such a setting.

7. Eligibility point activity rules have been used in several spectrum license auctions, but are considered somewhat easy to manipulate. Consequently, there has been a move towards revealed-preference activity rules.

8. For the standard (most simple) revealed-preference activity rule, assume quasi-linear preferences and no budget constraints, and consider any two auction rounds t_1 and t_2, with respective item-price vectors p^{t_1} and p^{t_2}. If a given bidder bids on packages defined by vectors a^{t_1} and a^{t_2}, then regardless of her hidden values for these bundles, self-consistency demands that $(p^{t_2} - p^{t_1})(a^{t_2} - a^{t_1}) \leq 0$. Bids violating this inequality will be rejected according to the activity rule [AuCtMi06]. (Exercise: Prove that a truthful bidder who knows her valuation function will never violate this activity rule under these assumptions.)

9. The previously mentioned revealed-preference rule may be too restrictive in practice, as budget constraints may be important and/or learning about preferences (due to imperfect knowledge of one's own valuation function) may be desired. So relaxed versions of this concept have been explored [AuBa14].

10. [AdGu05] introduced the concepts of winning levels and deadness levels for the OR language, which were later extended by [PeZiBi13] to the XOR setting, where the computation of deadness levels is shown to be Π_2^P-complete.

Examples:

1. Let bidder 1's bids be given by [(8 for A) XOR (8 for B)] OR [(8 for C) XOR (8 for D)]; bidder 2's bids are [(6 for A) XOR (2 for C)] OR (6 for B); bidder 3's bids are [(2 for B) XOR (6 for D)] OR (6 for C). In one efficient allocation, bidder 1 gets $\{A, D\}$, bidder 2 gets $\{B\}$, and bidder 3 gets $\{C\}$, with VCG payments of 12, 2, and 2, respectively. However, the minimal Walrasian equilibrium prices are given by $(6, 6, 6, 6)$. This example demonstrates preferences that satisfy the substitutes property yet cannot achieve the VCG outcome in anonymous linear prices. (See Fact 1.)

2. Assume quasi-linear preferences and no budget constraints. Suppose at auction round 1 we have $p^1 = (1, 5)$ with submitted bid $a^1 = (1, 1)^T$. Then suppose that at some later auction round 2 we have $p^2 = (3, 5)$ with $a^2 = (2, 0)^T$. This violates the standard revealed-preference activity rule (Fact 8) since $(p^2 - p^1)(a^2 - a^1) > 0$. In other words, from round 1 to 2 the price of bundle $(1, 1)^T$ increased by 2, while the price of $(2, 0)^T$ increased by 4; if you prefer the former bundle in round 1, you will continue to prefer it after it experiences a smaller price increase.

3. Suppose that in the previous example, the bidder has $v((1, 1)^T) = 12$ and $v((2, 0)^T) = 7$, but now assume he has a budget of 7. He would prefer the first bundle under both p^1 and p^2, but cannot pay 8 for it under p^2, so instead demands the latter bundle. This shows a weakness of revealed-preference rules when budgets are taken into consideration.

4. Consider an iterative CA in which bidders submit package bids in turn, after querying the auctioneer for the current winning level and deadness level of any bundle(s) of interest (see Fact 10). Suppose the following bids have already been made by five different bidders: $b_1(B) = 5$, $b_2(C) = 5$, $b_3(AD) = 50$, $b_4(AB) = 30$, and $b_5(CD) = 40$. Bidders 4 and 5 are currently winning. If a sixth bidder now queries the auctioneer about her bundle of interest, $\{B, C\}$, a winning level of 20 is reported; bidding at least one bid increment above 20 will assure winning, because added to bidder 3's bid it will exceed the current winning bids of bidders 4 and 5, i.e., $b_3(AD) + b_6(BC) > b_4(AB) + b_5(CD)$. The reported deadness level for $\{B, C\}$ would be 10; any amount not exceeding 10 results in the bid being rejected in favor of $b_1(B) + b_2(C) = 10$.

16.8 VERY LARGE-SCALE NEIGHBORHOOD SEARCH

There are numerous optimization problems of interest that are too difficult to solve to optimality in a reasonable amount of time. A practical remedy is to employ heuristics that can quickly compute good quality solutions. Neighborhood search algorithms, also called local search algorithms, represent a wide class of heuristics where at each iteration the algorithm searches for a better quality solution in a "neighborhood" of the current solution. A critical issue in neighborhood search is defining the neighborhood itself. As a rule of thumb, the larger the neighborhood, the better the quality of a locally optimal solution. However, the larger the neighborhood, the longer will be the time required to search the neighborhood explicitly. A large neighborhood will not produce an effective heuristic unless one can search the large neighborhood efficiently. This section concentrates on neighborhood search algorithms where the size of the neighborhood is "very large" with respect to the size of the input data, yet the neighborhood can be implicitly searched in an efficient manner.

16.8.1 BASIC CONCEPTS

Definitions:

A ***combinatorial optimization problem*** (***COP***) is an optimization problem of the form: minimize $\{f(S) \mid S \in \mathcal{F}\}$ where $\mathcal{F} \subseteq 2^E$ is a finite set of ***feasible solutions***. In this context, $E = \{e_1, e_2, \ldots, e_n\}$ is a finite set of elements called the ***ground set***, $f : \mathcal{F} \to \mathcal{R}$ is the ***objective function***, and 2^E denotes the set of all subsets of E. For example, in the Traveling Salesman Problem (TSP) of §10.7.1, E corresponds to the edges in the graph, $\mathcal{F}$ corresponds to the set of feasible TSP tours, and $f(S)$ corresponds to the total length of the tour $S \in \mathcal{F}$.

A ***neighborhood function*** $\mathcal{N}$ is a point-to-set map $\mathcal{N} : \mathcal{F} \to 2^{\mathcal{F}}$. Given a feasible solution $S \in \mathcal{F}$, the set $\mathcal{N}(S)$ is called the ***neighborhood*** of the solution S. The ***size*** of a neighborhood is the cardinality of the set $\mathcal{N}(S)$.

An operation that modifies a solution S_i to obtain a solution $S_{i+1} \in \mathcal{N}(S_i)$ is called a ***move***. If $f(S_{i+1}) < f(S_i)$, then the move is ***improving***.

A solution $S^* \in \mathcal{F}$ is ***locally optimal*** with respect to a neighborhood function $\mathcal{N}$ if and only if $f(S^*) \leq f(S)$ for all $S \in \mathcal{N}(S^*)$.

A ***neighborhood search algorithm***, also called a ***local search algorithm***, is an iterative algorithm that begins with a solution S_{i-1} at the ith ***iteration***, and moves to an improving solution $S_i \in \mathcal{N}(S_{i-1})$ if one exists. Otherwise, the algorithm terminates with S_{i-1}.

A ***very large-scale neighborhood*** is a neighborhood that has "very large" size with respect to the problem input. Typically, these neighborhoods are exponentially large, but this term is often used informally to describe neighborhoods that are too large to explicitly search in practice.

A ***very large-scale neighborhood*** (***VLSN***) ***search algorithm*** is a neighborhood search algorithm that searches a very large-scale neighborhood at each iteration.

Facts:

1. Algorithm 1 describes a generic neighborhood search algorithm, in which the initial solution S_0 is input. The subroutine $\texttt{BestNeighbor}(S_{i-1}, \mathcal{N}, f)$ returns the best solution, according to the objective function f, from the neighborhood $\mathcal{N}(S_{i-1})$.

Algorithm 1: **Generic neighborhood search.**

```
input: $S_0$
output: best solution found by neighborhood search
$i \leftarrow 0$
repeat
    $i \leftarrow i + 1$
    $S_i \leftarrow \texttt{BestNeighbor}(S_{i-1}, \mathcal{N}, f)$
until $f(S_i) \geq f(S_{i-1})$
return $S_{i-1}$
```

2. The term VLSN search was originally coined in the survey paper by Ahuja et al. [AhEtal02].

3. Surveys of VLSN search techniques can be found in [AhEtal02], [AhEtal07], and [PiRo10]. A survey of VLSN search techniques, designed specifically for the Traveling Salesman Problem, can be found in Deǐneko and Woeginger [DeWo00].

4. VLSN search algorithms have been used to solve a wide range of well-structured and complex real-world problems: vehicle routing problems [ErOrSt06], facility location problems [AhEtal04b], generalized knapsack problems [CuAh05], and parallel machine scheduling problems [FrNeSc04].

5. VLSN search algorithms have also been developed for many industrial applications: airline fleet assignment [AhEtal07a], [AhEtal04a], railroad freight blocking [AhJhLi07], intermodal load planning [NeJhAh09], and steel manufacturing [DaEtal07].

Examples:

Although the focus is on VLSN search algorithms for NP-hard COPs, the next three illustrations of VLSN search are for polynomially solvable optimization problems.

1. *Column generation for linear programming:* The simplex method (see §16.1) can be viewed as a neighborhood search algorithm. A basic feasible solution is determined from the set of basic columns B. A move (or pivot) exchanges one column from B with a column from N, the set of nonbasic columns. The neighborhood of a basic feasible solution is the set of all basic feasible solutions that may be obtained by a single pivot. The simplex method can be interpreted as a VLSN search when the set of columns is too large to be represented explicitly and where column generation is used to determine the entering variable.

2. *Cycle canceling for the minimum cost flow problem:* Consider the minimum cost flow problem (see §10.5) for a network $G = (V, A)$, where each vertex $v \in V$ has a supply/demand $b(v)$ and where the unit cost of sending flow on edge (i, j) is c_{ij}. For a given feasible flow x, the neighborhood of x consists of all feasible flows that can be obtained from x by sending flow around a negative cost cycle in the residual network induced by x [AhMaOr93].

3. *Augmenting path algorithm for the maximum cardinality matching problem:* Consider the maximum cardinality matching problem (see §10.2) for an undirected graph

$G = (V, A)$. A matching is a collection of edges with no two edges incident with a common vertex. Relative to the path $P = [v_1, \ldots, v_{2k}]$ in G, let $A_1(P) = \{(v_{2j-1}, v_{2j}) \mid 1 \leq j \leq k\}$ and $A_2(P) = \{(v_{2j}, v_{2j+1}) \mid 1 \leq j \leq k-1\}$. The path P is augmenting with respect to the matching M if $M \cap A_1(P) = \emptyset$ and $A_2(P) \subseteq M$. To augment along the path P is to replace M by $(M \backslash A_2(P)) \cup A_1(P)$. The neighborhood of M consists of all matchings that can be obtained from M via augmenting paths. Berge [Be57] showed that if M is not a maximum matching, then there is an augmenting path with respect to M. Edmonds [Ed65] developed the blossom algorithm (see §10.2.3) for determining an augmenting path if one exists. The blossom algorithm is widely considered to be one of the most elegant algorithms in all of combinatorial optimization.

16.8.2 VARIABLE-DEPTH NEIGHBORHOOD SEARCH ALGORITHMS

Neighborhoods based on exchanging two or three elements can often be explicitly searched in a reasonable amount of time. Exchanging a larger number of elements may lead to neighborhoods containing better local optimal solutions, but they typically cannot be searched efficiently. Variable-depth search algorithms are local search algorithms that (in principle) consider neighborhoods where a variable number of elements can be exchanged; to make the search practical, heuristics are used. There are variable-depth search algorithms for a large number of applications that attain near optimal solutions efficiently. Such algorithms are the focus of this subsection.

Definitions:

Let S_i and S_{i+1} be solutions of a COP with ground set E. The move from solution S_i to solution S_{i+1} is a ***k*-exchange** if $|S_i \backslash S_{i+1}| = |S_{i+1} \backslash S_i| = k$ for a positive integer k. A neighborhood where $|S_i \backslash S_{i+1}| = |S_{i+1} \backslash S_i| \leq k$ for all $S_{i+1} \in \mathcal{N}(S_i)$ is a ***k*-exchange neighborhood** of S_i. A k-exchange neighborhood is said to have ***depth*** k.

A ***variable-depth neighborhood search algorithm*** begins with a solution S_{i-1} at the ith iteration, and moves to an improving solution S_i in the $|E|$-exchange neighborhood of S_{i-1} if an improvement can be determined. Otherwise, the algorithm terminates with S_{i-1}. Typically, at each iteration, a variable-depth neighborhood search algorithm only partially explores the k-exchange neighborhood for each $k \in \{1, 2, \ldots, |E|\}$, thus avoiding the $\Omega(|E|^k)$ lower bound from explicitly searching the entire neighborhood.

An ***ejection chain*** is a variable-depth neighborhood search algorithm that iteratively generates a structured alternating sequence of additions/deletions $S_1, S_2, \ldots, S_k$ where

- $|S_1| = |S_j|$ for all odd values of j, and
- $|S_2| = |S_j|$ for all even values of j.

Facts:

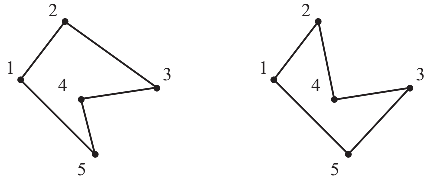
1. The first variable-depth neighborhood search algorithm was developed by Kernighan and Lin [KeLi70] for a set of graph partitioning problems.

2. Ejections chains were introduced by Glover [Gl96] for solving the TSP. Glover originally based ejection chains by extending and generalizing the ideas of Lin and Kernighan [LiKe73].

3. Many variable-depth search techniques, particularly those for vehicle routing problems, rely on ejection chains at each iteration in order to search the neighborhood.

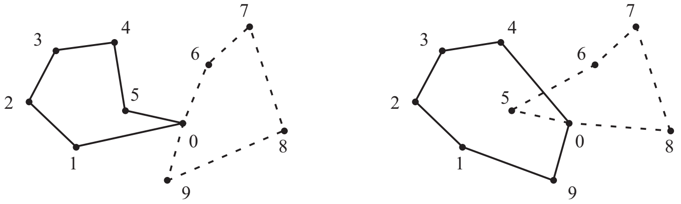
Examples:

1. A traveling salesman tour $[1,2,3,4,5,1]$ is shown in part (a) of the following figure. Part (b) shows a 2-exchange of this tour in which edges $(2,3)$ and $(4,5)$ are replaced by edges $(2,4)$ and $(3,5)$, forming the new tour $[1,2,4,3,5,1]$.



(a) (b)

2. In the context of the vehicle routing problem (see §10.7.2), the following figure shows in part (a) a feasible assignment of two vehicles that service nine customers from a central depot at location 0. Part (b) indicates the result of a 1-exchange in which customers 5 and 9 are interchanged, again resulting in a feasible solution.



(a) (b)

3. The maximum cut problem (MAX CUT) is defined as follows. Given an undirected graph $G=(V,A)$ where each edge $e \in A$ has weight w_e, partition the vertices V into two subsets X and Y to maximize the sum of the weights of the edges in the cut $(X,Y)=\{(i,j) \mid i \in X \text{ and } j \in Y\}$. Let $f(X,Y)$ denote the sum of the weights in the cut (X,Y).

Algorithm 2 describes a generic variable-depth search algorithm for MAX CUT, given the initial solution S_0 as input. The ith iteration of the algorithm starts with a solution S_{i-1} and either moves to a new solution S_i where $f(S_i) > f(S_{i-1})$ or maintains the solution S_{i-1} if no better solution is discovered within the ith iteration. Within each iteration of the variable-depth search, there are as many as $|V|$ *rounds*. Here M_j denotes the set of vertices that may not be moved during round $j+1$, and (X_j,Y_j) denotes the cut constructed during round j.

The subroutine `flip`(X_{j-1},Y_{j-1},v) returns a new cut (X_j,Y_j), where vertex v has been moved from the subset containing it to the other subset. For example, if $v \in X_{j-1}$, then $X_j = X_{j-1} \backslash v$ and $Y_j = Y_{j-1} \cup \{v\}$.

```
Algorithm 2: Generic variable-depth search for MAX CUT
  input: $S_0$
  output: best solution found by variable-depth search
  $i \leftarrow 0$
  repeat
    $i \leftarrow i+1$
    $M_0 \leftarrow \emptyset$
    $(X_0, Y_0) \leftarrow S_{i-1}$
    for $j = 1$ to $|V|$ do
      $v_j^* \leftarrow \operatorname{argmax}_{v \in V \setminus M_{j-1}} \{f(\texttt{flip}(X_{j-1}, Y_{j-1}, v))\}$
      $M_j \leftarrow M_{j-1} \cup \{v_j^*\}$
      $(X_j, Y_j) \leftarrow \texttt{flip}(X_{j-1}, Y_{j-1}, v_j^*)$
    end for
    $S_i \leftarrow \{(X_k, Y_k) \mid k = \operatorname{argmax}_{j \in \{1,\ldots,|V|\}} f(X_j, Y_j)\}$
  until $f(S_i) \le f(S_{i-1})$
  return $S_{i-1}$
```

16.8.3 CYCLIC EXCHANGE NEIGHBORHOOD SEARCH ALGORITHMS

The cyclic exchange neighborhood was developed for solving minimum cost partition problems. Suppose that $S = \{S_1, S_2, \ldots, S_K\}$ is a partition of E. Roughly speaking, a move in a cyclic exchange neighborhood permits one element to be transferred into S_j and permits another element to be transferred out of S_j, for several of the subsets S_j of the partition S. We discuss cyclic exchange neighborhoods and reference applications to a wide range of settings.

Definitions:

Let E be the ground set for a COP. The collection of subsets $\{S_1, S_2, \ldots, S_K\}$ is a ***K*-partition** of E if no subset is empty, the sets are pairwise disjoint, and the union of the sets is E.

Suppose that c is a function defined on the subsets of E; that is, $c(E')$ is the cost of subset E' of E.

A ***partitioning problem*** is a COP where the objective is to find a partition $T = \{T_1, T_2, \ldots, T_K\}$ of E that minimizes $\sum_{j=1}^{K} c(T_j)$.

Let $S = \{S_1, S_2, \ldots, S_K\}$ and $T = \{T_1, T_2, \ldots, T_K\}$ be two K-partitions of E. We say that T is a ***1-neighbor*** of S if $|T_j \setminus S_j| \le 1$ and if $|S_j \setminus T_j| \le 1$ for each $j = 1, \ldots, K$. If T is a 1-neighbor of S, then T is obtained from S via a ***1-transfer***.

Suppose that $S = \{S_1, S_2, \ldots, S_K\}$ is a K-partition and that $T = \{T_1, T_2, \ldots, T_K\}$ is obtained from S via a 1-transfer. From S and T, we can construct the ***(S, T)*-transfer graph**, having vertex set E. For each $k = 1, \ldots, K$, if T_k is obtained from S_k by inserting element i and deleting element j (that is, $T_k = (S_k \backslash i) \cup \{j\}$), then (i, j) is an edge of the (S, T)-transfer graph.

If the (S, T)-transfer graph consists of a single cycle, we say that T is obtained from S via a ***cyclic exchange***. Specifically, if the cycle is $[i_1, \ldots, i_k, i_1]$, then T is obtained from S as follows: for each $j = 1, \ldots, k$, one inserts i_j into the subset of S containing i_{j+1} and then deletes i_{j+1} from that subset. (Here, i_{k+1} is equivalent to i_1.) Similarly, if the (S, T)-transfer graph consists of a single path, we say that T is obtained from S via a ***path exchange***. The ***cyclic exchange neighborhood*** (resp., ***path exchange neighborhood***) of a K-partition S consists of all K-partitions that can be obtained from S by a single cyclic (resp., path) exchange.

To find an improving cyclic exchange starting with the K-partition $S = \{S_1, S_2, \ldots, S_K\}$ we create a new graph called the ***improvement graph***. The vertex set of the improvement graph is E. For every pair i, j of elements of E that are in different subsets of the partition S, there is an edge (i, j) in the improvement graph. Suppose S_k is the part of S that contains element j. Then the edge (i, j) is interpreted as a transfer of element i into S_k and a transfer of element j out of S_k. Let $S'_k = (S_k \backslash \{j\}) \cup \{i\}$ be the resulting subset. The cost of the edge (i, j) in the improvement graph is $c_{ij} = c(S'_k) - c(S_k)$, which is the net change in cost of transferring element i into S_k and transferring element j out.

A cycle $C = [i_1, \ldots, i_k, i_1]$ in the improvement graph is ***subset-disjoint*** with respect to a K-partition S if no two elements of C belong to the same subset of S.

Facts:

1. Cyclic exchange neighborhoods were introduced by Thompson and Orlin [ThOr89] and Thompson and Psaraftis [ThPs93].

2. Finding a minimum cost subset-disjoint cycle is NP-hard [ThOr89], but it is one of those NP-hard problems that is relatively easy to solve in practice. Thus, heuristics are used to search the improvement graph in practice. Effective heuristics for constructing negative cost subset-disjoint cycles are presented in Thompson and Psaraftis [ThPs93] and in Ahuja et al. [AhOrSh01].

3. The improvement graphs and the transfer graphs are closely related. Suppose that C is a subset-disjoint cycle in the improvement graph for partition S, and that T is the partition obtained by performing the cyclic exchange induced by C. Then the (S, T)-transfer graph consists of the cycle C.

4. *Symmetry*: if T is a 1-neighbor of S, then S is a 1-neighbor of T.

5. If T is a 1-neighbor of S, then the (S, T)-transfer graph is a disjoint union of cycles and paths because each vertex of the graph has at most one incoming edge and at most one outgoing edge.

6. Suppose S is a K-partition, and let G be the resulting improvement graph. There is a one-to-one correspondence between cyclic exchanges from S and subset-disjoint directed cycles in G.

7. Suppose S is a K-partition, and let G be the resulting improvement graph. The cost of a subset-disjoint cycle C is the net change in objective value obtained after performing the induced cyclic transfer.

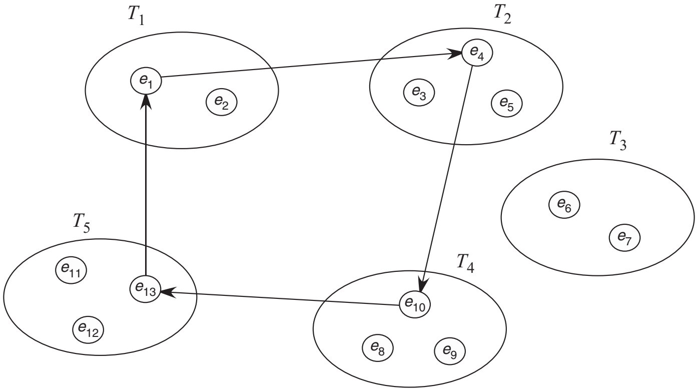
8. In practice, it is often much faster to obtain the current improvement graph by updating the improvement graph from the previous iteration rather than constructing a new improvement graph from scratch.

9. A path exchange may be transformed into a cyclic exchange by adding dummy vertices. This allows one to use a single unified search algorithm to identify improving cyclic exchanges and path exchanges.

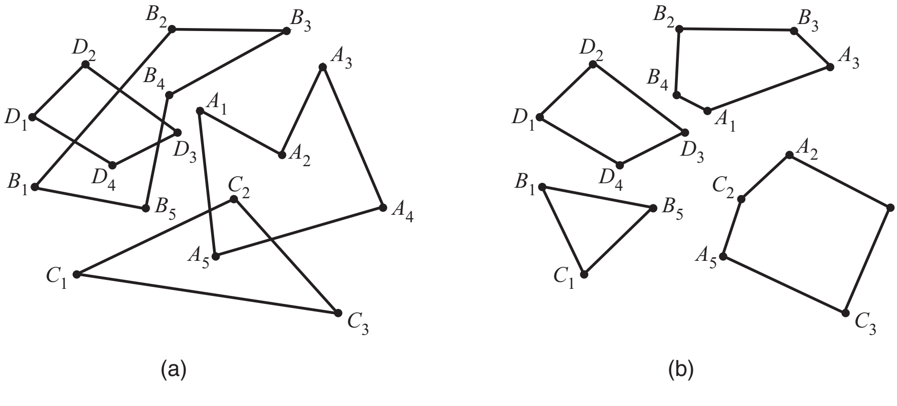
10. For K-partitions, the cyclic exchange neighborhood is of size $O(n^K)$, where $n = |E|$. When K is permitted to grow with n, the size of the neighborhood is typically exponential.

Examples:

1. The following figure illustrates a cyclic exchange. Here, vertex e_1 will be transferred from subset T_1 to subset T_2. Vertex e_4 will be transferred from subset T_2 to subset T_4. Vertex e_{10} will be transferred from subset T_4 to T_5. Finally, the cyclic exchange will be completed by transferring vertex e_{13} from subset T_5 to subset T_1.



2. The following figure illustrates a cyclic exchange for a VRP [AgEtal03]. In general, a cyclic exchange for VRP transfers customer demands in a circular manner among several routes. This example illustrates a "3-cyclic, 2-exchange" scheme where two customers from each of three routes are transferred to the next route in the cycle. Here there are four routes $I_1, \ldots, I_4$ and the customers being served by each route are $I_1 = \{A_1, \ldots, A_5\}$, $I_2 = \{B_1, \ldots, B_5\}$, $I_3 = \{C_1, \ldots, C_3\}$, and $I_4 = \{D_1, \ldots, D_4\}$. This 3-cyclic 2-exchange involves only routes I_1, I_2, and I_3. Two customers $\{A_1, A_3\}$ from route I_1 are transferred to route I_2; two customers $\{B_1, B_5\}$ from route I_2 are moved to route I_3; two customers $\{C_2, C_3\}$ from I_3 are transferred to I_1; route I_4 is left unchanged. Let $S = \{I_1, \ldots, I_4\}$ and $S' = \{I'_1, \ldots, I'_4\}$ represent the set of routes before and after a cyclic exchange occurs,



and let $f(I)$ represent the optimal cost of route I. The cost of this cyclic exchange is $\sum_{i=1}^{4}[f(I_i') - f(I_i)]$.

3. *Capacitated minimum spanning tree problem (CMST):* The CMST (see §10.6.1) is the problem of choosing a minimum weight spanning tree subject to the following constraint: if one deletes the root vertex and its incident edges, then each remaining connected component has at most K vertices, where K is part of the input. This problem models applications in which the goal is to develop a minimum cost computer network connecting n computers to a single hub (or server), where bandwidth is limited. Ahuja et al. [AhOrSh01], [AhOrSh03] used cyclic exchanges to obtain solutions to a set of benchmark instances for the CMST. In each benchmark instance, they either obtained or improved upon the best previously reported solution.

4. *Facility location problems:* In facility location problems (see §16.2), the goal is to determine the location of a collection of facilities, and also to assign customers to facilities, to minimize the sum of the distances from customers to facilities. Ahuja et al. [AhEtal04b] developed a cyclic exchange VLSN search algorithm for a capacitated facility location problem. Scaparra et al. [ScPaSc04] created an algorithm based on the cyclic exchange neighborhood for solving the closely related capacitated vertex p-center problem. In both cases, the algorithms based on cyclic exchanges produced nearly optimal solutions and were fast on benchmark instances.

16.8.4 OTHER VLSN SEARCH ALGORITHMS

In designing very large-scale neighborhood search algorithms, researchers have drawn inspiration and techniques from more than 50 years of research and algorithmic development in mathematical programming and computer science algorithms. In this subsection, we describe a diverse collection of approaches for developing very large-scale neighborhood search algorithms.

Examples:

1. *Neighborhoods based on combining independent moves:* Compounded independent move (CIM) neighborhoods are neighborhoods based on simultaneously executing two or more moves whose effects on the objective value are independent of one another; that is, the change in the objective value due to the compound move is guaranteed to be the sum of the changes due to the individual moves. CIM neighborhoods were introduced by Congram et al. [CoPoVe02] for a machine scheduling problem and by Potts and van de Velde [PoVe95] for the TSP. Their techniques searched a CIM neighborhood with dynamic programming, and they referred to their approach as *dynasearch*. Ergun et al. [ErOrSt06] and Gendreau et al. [GeEtal06a] searched CIM neighborhoods to solve vehicle routing problems. Taillard [Ta03] used CIM neighborhoods for solving clustering problems. Dror and Levy [DrLe86] used CIM neighborhoods for solving the inventory routing problem.

2. *Neighborhoods based on context-free grammars:* Bompadre and Orlin [BoOr05] showed how to use context-free grammars (CFGs) to generate exponentially large neighborhoods for sequencing problems. Moreover, for some sequencing problems such as the TSP and the linear ordering problem (see §16.9.1), they developed an algorithm that takes the grammar and the problem data as input and then finds the minimum cost neighbor in polynomial time. In addition to presenting an innovative use of CFGs, this paper demonstrates how a single algorithm can be used to search a wide range of different exponentially sized neighborhoods.

3. *Neighborhoods based on mathematical programming:* Suppose that x is a solution to a mathematical programming problem. For a given subset I of indices, we say that another feasible solution y is *I-adjacent* to x if $y_i = x_i$ for $i \in I$, and we say that y is in the *I-neighborhood* of x. I-neighborhoods are conveniently searched using mathematical programming software. This neighborhood can be used in constraint programming (e.g., Pesant and Gendreau [PeGe99] and Davenport et al. [DaEtal07]) as well as in integer programming (e.g., Danna et al. [DaRoLe05]). For example, the relaxation induced neighborhood search (RINS) algorithm of Danna et al. has been implemented in the CPLEX Mixed Integer Programming (MIP) solver.

4. *Neighborhoods based on polynomially solvable special cases:* Researchers have developed a substantial literature on polynomial-time algorithms for special cases of NP-hard COPs. Many of the special cases are neighborhood-inducing, and lead to very large-scale neighborhoods that can be searched in polynomial time. For example, Carlier and Villon [CaVi90] presented a polynomial-time algorithm for finding an optimal *pyramidal tour*, that is, a sequence $i_1, \ldots, i_n$ such that for some value k, the indices in the subsequence $i_1, \ldots, i_k$ are in increasing order, and the indices in the subsequence $i_k, \ldots, i_n$ are in decreasing order. For a given tour T, its pyramidal neighborhood is the set of pyramidal tours that would result if one first relabeled the vertices (or cities) so that $T = [1, \ldots, n]$. Therefore, any algorithm for finding a minimum cost pyramidal tour can be used for finding a minimum cost pyramidal neighbor.

As another example, for a given fixed value K, there is a polynomial-time dynamic program for finding an optimal tour $[i_1, \ldots, i_n]$ subject to the constraint that $i_j < j + K$ for each j. Simonetti and Balas [SiBa96] developed a very large-scale neighborhood that uses this dynamic program as the search engine.

5. *Neighborhoods that exploit local structure:* Ahuja et al. [AhJhLi07] created a neighborhood tailored to a railroad blocking problem. Blocking problems, which also arise in parcel delivery, trucking and air transportation, model how to consolidate a large number of shipments into *blocks* to reduce the total handling costs. The VLSN search algorithm devised by Ahuja et al. iteratively improves solutions by permitting changes to the blocking at one rail station at a time.

16.9 TABU SEARCH

Tabu search is a metaheuristic solution methodology applicable to general optimization problems. It is distinguished by its use of adaptive (flexible) memory and responsive exploration of the solution space. In this way the search can learn to exploit specific areas of the solution space as well as explore new terrain.

16.9.1 BASIC CONCEPTS

Tabu search starts from an initial solution and explores the solution space by making transformations to move from one solution to the next. The use of flexible memory promotes good move combinations and solution attributes by modifying the neighborhood searched at each step.

Definitions:

Tabu search (***TS***) is a search technique that proceeds iteratively from one (feasible) ***solution*** to another until a chosen termination criterion is satisfied. It can be applied to ***optimization problems*** of the form: minimize $\{f(x) \mid x \in X\}$, where the set X summarizes the constraints on the decision variables x.

Each solution $x \in X$ has an associated ***neighborhood*** $N(x) \subseteq X$. The solution $x' \in N(x)$ is reached from x by a ***move*** operation; in this case, x' is a ***neighbor*** of x.

The ***move value*** v is the change in the objective function value f from the current solution to the solution after the move: i.e., $v = f(x') - f(x)$. An ***improving move*** has $v < 0$ while a ***nonimproving move*** has $v \geq 0$. A ***best neighbor*** of x (according to the objective function value) is a neighbor $x' \in N(x)$ having the smallest value $f(x')$ over all neighbors of x.

Recency-based (***short-term***) ***memory*** is used in TS to obtain a modified neighborhood $N^*(x) \subseteq N(x)$ by eliminating (making tabu) recently visited solutions.

Facts:

1. Tabu search was first proposed by Fred Glover [Gl86]. The most cited reference is the book *Tabu Search* by Fred Glover and Manuel Laguna [GlLa97].

2. The word *tabu* (or *taboo*) comes from the Polynesian language Tongan, in which it indicates objects that cannot be touched because they are sacred.

3. Whereas the steepest descent procedure only makes improving moves, TS allows the choice of a best neighbor x' of x even when the move is nonimproving.

4. By using short-term strategies, it is possible that a solution x can be visited more than once, but it is likely that the corresponding reduced neighborhood $N^*(x)$ will be different each time.

5. TS memory structures are based on recording *attributes* as well as the most recent history of the search trajectory (recency-based memory).

6. Selected attributes that occur in solutions recently visited are *tabu-active*, and solutions that contain tabu-active elements, or particular combinations of these attributes, are classified as *tabu*. This prevents certain solutions from the recent past from belonging to $N^*(x)$ and hence from being revisited.

7. The number of iterations that an attribute remains tabu-active (the *tabu tenure*) can be static (fixed throughout the search) or dynamic (vary either systematically or probabilistically).

8. *Aspiration criteria* can be used to override tabu activation rules. The most common aspiration criterion consists of removing a tabu classification from a trial move when the move yields a solution better than the best obtained so far.

9. The overall structure of tabu search, employing short-term memory, is displayed in Algorithm 1. The solutions x^{next} chosen during the Intensification Phase are either not classified tabu (as shown in Algorithm 1) or their tabu status has been overridden by the aspiration criteria (not shown in Algorithm 1).

```
Algorithm 1: Short-term memory tabu search.
 input: initial solution $x^0 \in X$
 output: best solution $x^{\text{best}}$ found during the search
 $x^{\text{now}} = x^{\text{best}} = x^0$
 repeat Intensification Phase
    choose $x^{\text{next}} \in N^*(x^{\text{now}})$
    $x^{\text{now}} \leftarrow x^{\text{next}}$
    if $f(x^{\text{now}}) < f(x^{\text{best}})$ then $x^{\text{best}} \leftarrow x^{\text{now}}$
    update recency-based memory and tabu status
 until termination criteria satisfied
```

Examples:

1. *Linear ordering problem (LOP):* Given a matrix of weights, the LOP consists of finding a permutation x of the columns (and rows) of the matrix in order to maximize the sum of the weights in the upper triangle. Let $x = (1, 2, 3, 4)$ be a solution to a LOP of size 4, defined by the following table.

	1	2	3	4
1	0	12	−5	3
2	6	0	3	4
3	−8	7	0	−2
4	4	0	3	0

The objective function value $f(x) = 12 - 5 + 3 + 3 + 4 - 2 = 15$. If a move is defined as the swap of two elements in the permutation, where each element represents the index of the same row and column, then the swap $(1, 2)$ results in the following table.

	2	1	3	4
2	0	6	3	4
1	12	0	−5	3
3	7	−8	0	−2
4	0	4	3	0

The neighborhood of x consists of the following solutions x'.

move	x'	$f(x')$
$(1,2)$	$(2,1,3,4)$	9
$(1,3)$	$(3,2,1,4)$	10
$(1,4)$	$(4,2,3,1)$	8
$(2,3)$	$(1,3,2,4)$	19
$(2,4)$	$(1,4,3,2)$	20
$(3,4)$	$(1,2,4,3)$	20

2. *Knapsack problem:* Here we seek to maximize the overall profit obtained by placing a subset of items in a knapsack with total weight capacity 100. Each item has a known profit and weight. A formulation in terms of 0-1 variables x_j is

$$\begin{aligned} \max\ & 67x_1 + 500x_2 + 98x_3 + 200x_4 + 120x_5 + 312x_6 + 100x_7 + 200x_8 + 180x_9 + 100x_{10} \\ \text{s.t.}\ & 5x_1 + 45x_2 + 9x_3 + 19x_4 + 12x_5 + 32x_6 + 11x_7 + 23x_8 + 21x_9 + 14x_{10} \le 100 \\ & x_j \in \{0,1\} \end{aligned}$$

An initial solution x^0 can be found using a greedy heuristic: namely, successively select items in decreasing order of their bang-for-buck ratio (profit/weight), continuing until adding one more item exceeds the capacity of the knapsack. The following table shows these ratios; notice that the variables $x_1, \ldots, x_{10}$ are already indexed by decreasing ratios. This greedy heuristic successively chooses items $1, 2, 3, 4, 5$ for the initial solution, giving $x^0 = (1,1,1,1,1,0,0,0,0,0)$ with total profit 985 and total weight 90.

item	1	2	3	4	5	6	7	8	9	10
profit	67	500	98	200	120	312	100	200	180	100
weight	5	45	9	19	12	32	11	23	21	14
ratio	13.40	11.11	10.89	10.53	10.00	9.75	9.09	8.70	8.57	7.14

3. We continue with the previous example. Suppose that a move is defined as a "flip" move: i.e., the value of a single variable x_j is changed from either zero to one or from one to zero. The neighborhood $N(x^0)$ of the current solution x^0 is then shown in the following table. The *move* column indicates the new value of the flipped variable, while the *neighbor* column shows the indices of the variables set to 1 as a result of the move.

j	*move*	*neighbor*	*profit*	*weight*
1	$x_1 = 0$	$\{2,3,4,5\}$	918	85
2	$x_2 = 0$	$\{1,3,4,5\}$	485	45
3	$x_3 = 0$	$\{1,2,4,5\}$	887	81
4	$x_4 = 0$	$\{1,2,3,5\}$	785	71
5	$x_5 = 0$	$\{1,2,3,4\}$	865	78
6	$x_6 = 1$	$\{1,2,3,4,5,6\}$	1297	122
7	$x_7 = 1$	$\{1,2,3,4,5,7\}$	1085	101
8	$x_8 = 1$	$\{1,2,3,4,5,8\}$	1185	113
9	$x_9 = 1$	$\{1,2,3,4,5,9\}$	1165	111
10	$x_{10} = 1$	$\{1,2,3,4,5,10\}$	1085	104

Suppose the search is not allowed to visit infeasible solutions. Then there is no improving move in the neighborhood of the current solution (recall that we have a maximization problem, not a minimization problem). If we adopt the best-improving strategy, then the first move in the table, changing the value of x_1 to zero, is the best one in $N(x^0)$, giving $x^{\text{next}} = (0, 1, 1, 1, 1, 0, 0, 0, 0, 0)$ with a profit of 918.

4. We show how short-term memory can be incorporated into the previous 0-1 knapsack example. Let the attribute of interest be the index of the variable chosen to change values. Any move that includes such an index is classified as tabu, and we set the tabu tenure to be three iterations. Using this memory structure, we determine the next solution x^{next}. Subject to the constraint that $x_1 = 0$ and considering only a single "flip" move, a best neighbor of $x^{\text{now}} = (0, 1, 1, 1, 1, 0, 0, 0, 0, 0)$ turns out to be $x^{\text{next}} = (0, 1, 1, 1, 1, 0, 1, 0, 0, 0)$, achieved by changing the value of x_7. The corresponding profit is 1018 with a weight of 96. The following table shows shows ten iterations of the procedure using this short-term memory structure. The *tabu active* column lists the indices of the tabu active variables; each index remains tabu for three iterations. The *move* column indicates the flipped variable, while the *solution* column shows the solution after the move has been executed. The resulting profit and weight are shown in the last two columns. The best solution found after ten iterations occurs in the second iteration and has a profit of 1018.

iteration	*tabu active*	*move*	*solution*	*profit*	*weight*
0			$\{1, 2, 3, 4, 5\}$	985	90
1		1	$\{2, 3, 4, 5\}$	918	85
2	1	7	$\{2, 3, 4, 5, 7\}$	1018	96
3	7 1	3	$\{2, 4, 5, 7\}$	920	87
4	3 7 1	5	$\{2, 4, 7\}$	800	75
5	5 3 7	8	$\{2, 4, 7, 8\}$	1000	98
6	8 5 3	7	$\{2, 4, 8\}$	900	87
7	7 8 5	3	$\{2, 3, 4, 8\}$	998	96
8	3 7 8	4	$\{2, 3, 8\}$	798	77
9	4 3 7	9	$\{2, 3, 8, 9\}$	978	98
10	9 4 3	8	$\{2, 3, 9\}$	778	75

5. An alternative neighborhood definition for the 0-1 knapsack problem could be one in which the values of two variables are flipped. Instead of 10 neighbors, this move generates 45 neighbors, corresponding to all combinations of two variables. A potential short-term memory structure for this neighborhood could be as follows.

- attributes: indices of the variables chosen to change values
- tabu move: one that includes at least one tabu active variable
- tabu tenure: three iterations for a variable flipping from 1 to 0, and two iterations for a variable flipping from 0 to 1

The tabu tenure recognizes that in a typical knapsack problem there will be more variables outside the knapsack (i.e., with their values set to zero) than those inside the knapsack (i.e., with their values set to one). Therefore, if a variable leaves the knapsack, the tabu tenure keeps this item outside longer than when an item enters the knapsack.

6. The LOP in Example 1 provides a few choices for a short-term memory design in a tabu search that employs swap moves (i.e., exchanges of the positions of two rows/columns). One of those designs is as follows.

- attributes: indices of the elements (rows/columns) chosen to exchange positions
- tabu move: one that includes at least one tabu active variable
- tabu tenure: two iterations for the element exchanging to the lower position, and three iterations for the element moving to the higher position in the permutation

This tabu tenure structure identifies that elements moving to the earlier position in the permutation make a larger contribution to the objective function value. Arguably, these elements have moved to their "preferred" position and therefore there is no need to force them to stay there.

16.9.2 LONG-TERM MEMORY

Long-term memory plays an important role in creating the right balance between intensification and diversification of a tabu search. Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. Diversification, on the other hand, encourages the search process to examine unvisited regions and the generation of solutions that differ in significant ways from those previously seen.

Definitions:

Frequency-based (***long-term***) ***memory*** is used in TS to obtain a modified neighborhood $N^*(x) \supseteq N(x)$ in order to expand the neighborhood and examine unvisited regions.

Frequencies consist of ratios, whose numerators represent either transition counts or residence counts. A ***transition count*** is the number of iterations where an attribute changes (enters or leaves) the solutions visited. A ***residence count*** is the number of iterations where an attribute belongs to the solutions visited. The denominators generally represent one of three types of quantities: (1) the total number of occurrences of all events represented by the numerators (such as the total number of iterations), (2) the sum (or average) of the numerators, or (3) the maximum numerator value.

Facts:

1. The use of long-term memory does not require long solution runs before its benefits become visible.

2. The chance of finding still better solutions as time grows—in the case where an optimal solution has not already been found—is enhanced by using long-term TS memory in addition to short-term memory.

3. Residence frequencies and transition frequencies sometimes convey related information, but in general they carry different implications.

4. A high residence frequency may indicate that an attribute is highly attractive if the domain consists of high quality solutions, or may indicate the opposite if the domain consists of low quality solutions.

5. Frequency-based memory is used to define penalty and incentive values to modify the evaluation of moves and therefore determine which moves are selected. In a minimization problem, the modified move value function has the following mathematical form:

$$v' = v(1 + pq).$$

Here v is the original move value, p is the penalty factor, q is the frequency ratio, and v' is the modified move value. When $p = 0$ the original move value is not modified. A value $p > 0$ penalizes the move and v' makes it less attractive. A value $p < 0$ provides an incentive and v' makes the move more attractive.

6. Penalty/incentive functions based on frequency ratios are also used in restarting procedures that employ greedy choices. Penalty/incentive functions bias the selections and induce diversification.

7. Algorithm 2 shows how a restarting procedure based on long-term memory may be superimposed on the short-term memory tabu search in Algorithm 1.

```
Algorithm 2: Tabu search with long-term memory.
  input: initial solution $x^0 \in X$
  output: best solution $x^{\text{best}}$ found during the search
  $x^{\text{now}} = x^{\text{best}} = x^0$
  repeat Diversification Phase
    reset recency-based memory
    if $x^{\text{now}} = \emptyset$ then $x^{\text{now}} \leftarrow$ diversified starting solution
    repeat Intensification Phase
      choose $x^{\text{next}} \in N^*(x^{\text{now}})$
      $x^{\text{now}} \leftarrow x^{\text{next}}$
      if $f(x^{\text{now}}) < f(x^{\text{best}})$ then $x^{\text{best}} \leftarrow x^{\text{now}}$
      update recency-based memory and tabu status
      update frequency-based memory
    until termination criteria satisfied
  until termination criteria satisfied
```

Example:

1. Suppose that in the knapsack problem described in §16.9.1, Example 2 we define the residency ratio q as the number of times an item was in the knapsack divided by the current number of visited solutions. We then restart the search by erasing the short-term memory and generating a solution with the following function:

$$r' = r(1 - q),$$

where r is the original bang-for-buck ratio. This function reduces the attractiveness of elements with large q values. The new starting solution is built by giving priority to the elements with large r' and thus inducing diversification.

16.9.3 STRATEGIC OSCILLATION

Strategic oscillation provides a means to achieve an effective interplay between intensification and diversification over the intermediate to long term. Strategic oscillation operates by orienting moves in relation to the feasibility boundary, which represents a point where a search would normally stop. Instead of stopping when this boundary is reached, however, the rules for selecting moves are modified to permit the region defined by the feasibility boundary to be crossed. The approach then proceeds for a specified depth beyond the oscillation boundary, and turns around. The oscillation boundary again is approached and crossed, this time from the opposite direction, and the method proceeds to a new turning point.

Definitions:

The process of repeatedly approaching and crossing the feasibility boundary from different directions creates an oscillatory behavior, and so characterizes the ***strategic oscillation*** method.

The implementation of strategic oscillation entails the selection of a proximity measure and the oscillation amplitude. The ***proximity measure*** assigns a numerical value to moving toward or away from the feasibility boundary. Proximity measures are defined in reference to the problem constraints. The ***oscillation amplitude*** is controlled by a specified number of moves m. If a move is made that causes the search to cross the feasibility boundary, then the search is allowed to make $m - 1$ additional moves in the same direction (i.e., moving away from the feasibility boundary) before turning around.

Facts:

1. In combinatorial optimization problems that require the selection of k elements, the rule to delete elements from the solution will typically be different in character from the one used for adding elements. In other words, one rule is not simply the inverse of the other.

2. Rule differences are features of strategic oscillation that provide an enhanced heuristic vitality. The application of different rules may be accompanied by crossing a boundary to different depths on different sides. An option is to approach and retreat from the boundary while remaining on a single side, without crossing (i.e., electing a crossing of "zero depth").

3. In both one-sided and two-sided oscillation approaches it is frequently important to spend additional search time in regions close to the feasibility boundary, and especially to spend time at the boundary itself.

4. In problems for which feasibility is determined by a set of constraints, vector-valued functions can be used to control the oscillation. In this case, controlling the search by bounding this function can be viewed as manipulating a parameterization of the constraint set.

Examples:

1. In a combinatorial optimization problem consisting of selecting k out of a given number of elements, a proximity measure t may be the difference between the number of elements that have been selected and k. Feasible solutions are those for which $t = 0$. Solutions with $t > 0$ have too many elements and solutions with $t < 0$ have too few. Moves can be designed to keep the search at $t = 0$ or to create an oscillation pattern around $t = 0$.

2. The feasibility boundary in the knapsack problem is defined by the capacity of the knapsack, which is 100 in §16.9.1, Example 2. To create simple oscillation around the feasible boundary, the search is allowed to cross to the infeasible region and m is set to 1. The proximity measure t is defined as the difference between the total weight of the items in the knapsack and the knapsack capacity. Therefore, $t > 0$ indicates an infeasible solution while $t \leq 0$ corresponds to a feasible solution. The procedure operates with the following rules:

- When approaching the feasibility boundary from the feasible region, select the best non-tabu feasible move. If no feasible move is available, then select the non-tabu move that improves profit the most.
- When approaching the feasibility boundary from the infeasible region, select the non-tabu move that removes the variable with the smallest bang-for-buck ratio.

The short-term memory structure is the same as the one defined in §16.9.1. Therefore, the move selections have to be done by considering the tabu classifications. The following table shows 10 iterations of TS with strategic oscillation. The initial solution is given by the bang-for-buck heuristic.

iteration	*tabu active*	*move*	*solution*	*profit*	*weight*
0			$\{1, 2, 3, 4, 5\}$	985	90
1		6	$\{1, 2, 3, 4, 5, 6\}$	1297	122
2	6	5	$\{1, 2, 3, 4, 6\}$	1177	110
3	5 6	4	$\{1, 2, 3, 6\}$	977	91
4	4 5 6	8	$\{1, 2, 3, 6, 8\}$	1177	114
5	8 4 5	6	$\{1, 2, 3, 8\}$	865	82
6	6 8 4	9	$\{1, 2, 3, 8, 9\}$	1045	103
7	9 6 8	3	$\{1, 2, 8, 9\}$	947	94
8	3 9 6	4	$\{1, 2, 4, 8, 9\}$	1147	113
9	4 3 9	8	$\{1, 2, 4, 9\}$	947	90
10	8 4 3	3	$\{1, 2, 3, 4, 9\}$	1045	99

The oscillation can be observed in the *weight* column. It is noteworthy to discuss the move made in the last iteration. The move is selected even though the move is classified tabu (note that 3 appears in the *tabu active* list). The initial solution is the best-known feasible solution at that point and it has an objective function value of 985. Therefore, an aspiration criterion that overrides the tabu status of a move can be invoked (see §16.9.1, Fact 8). The criterion states that the tabu classification can be overridden if the move leads to a solution that is better than the best solution found so far.

16.9.4 PATH RELINKING

A useful integration of intensification and diversification strategies occurs in the approach called path relinking. This approach generates new solutions by exploring trajectories that connect reference solutions—by starting from one of these solutions, called an initiating solution, and generating a path in the neighborhood space that leads toward the other solutions, called guiding solutions. This is accomplished by selecting moves that introduce attributes contained in the guiding solutions.

Definition:

Path relinking is a strategy that seeks to incorporate attributes of high quality solutions, by creating inducements to favor these attributes in the moves selected. However, instead of using an inducement that merely encourages the inclusion of such attributes, the path relinking approach subordinates all other considerations to the goal of choosing moves that introduce the attributes of the guiding solution, in order to create a "good attribute composition" in the current solution.

Facts:

1. At each step, path relinking chooses the best move, according to the change in the objective function value, from the restricted set of moves that incorporate a maximum number of the attributes in the guiding solutions.

2. Path relinking can be used to generate intensification strategies by choosing reference solutions that lie in a common region or that share common features.

3. Diversification strategies based on path relinking characteristically select reference solutions that come from different regions or that exhibit contrasting features.

4. Membership in the reference set is determined by setting a threshold that is connected to the objective function value of the best solution found during the search.

5. The initiating solution can be used to give a beginning partial construction, by specifying particular attributes as a basis for the remaining constructive steps. Constructive neighborhoods can be viewed as a feasibility-restoring mechanism since a null or partially constructed solution does not satisfy all conditions to qualify as feasible.

6. Path relinking can make use of destructive neighborhoods, where an initial solution is "overloaded" with attributes donated by the guiding solutions, and such attributes are progressively stripped away or modified until reaching a set with an appropriate composition.

7. Path relinking consists of the following steps:

- Identify the neighborhood structure and associated solution attributes for path relinking (possibly different from those of other TS strategies applied to the problem).
- Select a collection of two or more reference solutions, and identify which members will serve as the initiating solution and the guiding solution(s). (Reference solutions can be infeasible, such as "incomplete" or "overloaded" solution components treated by constructive or destructive neighborhoods.)
- Move from the initiating solution toward the guiding solution(s), generating one or more intermediate solutions.

Example:

1. Consider the following two reference solutions for the knapsack problem in §16.9.1, Example 2.

solution	1	2	3	4	5	6	7	8	9	10	*profit*	*weight*
1	0	1	1	0	1	0	1	0	1	0	998	98
2	1	1	1	1	1	0	0	0	0	0	985	90

These solutions were found with a TS that used simple moves consisting of flipping one variable at a time. Both of these solutions are feasible. Suppose that solution 2 is chosen as the initiating solution and that solution 1 is the guiding solution. The relinking process starts by identifying the values that are common to both solutions. These correspond to variables 2, 3, and 5. Swap moves are used during the path relinking process in order to keep the intermediate solutions close to the feasibility boundary. A swap in this context corresponds to adding one item to the knapsack while taking another item out of the knapsack. This means that a variable that is set to 1 in the initiating solution and to 0 in the guiding solution must be paired with a variable that is set to 0 in the initiating solution and to 1 in the guiding solution. The pairs in our example are $(1, 7), (1, 9), (4, 7)$, and $(4, 9)$. The next table shows the intermediate solutions that result from these swaps.

swap	1	2	3	4	5	6	7	8	9	10	*profit*	*weight*
$(1, 7)$	0	1	1	1	1	0	1	0	0	0	1018	96
$(1, 9)$	0	1	1	1	1	0	0	0	1	0	1098	106
$(4, 7)$	1	1	1	0	1	0	1	0	0	0	885	82
$(4, 9)$	1	1	1	0	1	0	0	0	1	0	965	92

The best feasible swap is $(1, 7)$ and the search moves to the intermediate solution with profit 1018 and weight 96. After the move, there is only one swap left to reach the guiding solution, namely $(4, 9)$. In this case, the process produced only one intermediate solution; however, in general, path relinking visits more solutions during the transformation of the initiating solution into the guiding solution.

THEORETICAL COMPUTER SCIENCE

INTRODUCTION

Theoretical computer science is concerned with modeling computational problems and solving them algorithmically. It strives to distinguish what can be computed from what cannot. If a problem can be solved by an algorithm, it is important to know the amount of space and time needed.

GLOSSARY

abelian square: a word having the pattern xx^p, where x^p is a permutation of x.

acceptance probability (of input word by a probabilistic TM): the sum of the probabilities over all acceptance paths of computation.

Ackermann function: a very rapidly growing function that is recursive, but not primitive recursive.

algorithm: a finite list of instructions designed to accomplish a specified computation or other task.

alphabet: a finite set of *symbols*.

ambiguous context-free grammar: a grammar whose language has a string having two different leftmost derivations.

analysis of an algorithm: an estimation of its cost of execution, especially of its running time.

antecedent of a production $\alpha \to \beta$: the string α that precedes the arrow.

average-case running time: the expected running time of an algorithm, usually expressed asymptotically in terms of the input size.

Backus-Naur (or ***Backus normal***) ***form*** (***BNF***): a metalanguage used to specify computer language syntax.

busy beaver function: the function $BB(n)$ whose value is the maximum number of 1s that an n-state Turing machine can print and still halt.

busy beaver machine, n-state: an n-state Turing machine on the alphabet $\Sigma = \{\#, 1\}$ that accepts an input tape filled with blanks (#s) and halts after placing a maximum number of 1s on the tape.

cellular automaton (***n-dimensional***): an interconnection network in which there is a processor at each integer lattice point of n-dimensional Euclidean space, and each processor communicates with its immediate neighbors.

characteristic function (of a language): the function on strings that has value *yes* for elements in the language, and *no* otherwise.

characteristic function (of a set): the function whose value is 1 for elements of the set, and 0 otherwise.

Chomsky hierarchy: four classes of grammars, with increasing restrictions.

Chomsky normal form (for a production rule): the form $A \to BC$ where B and C are nonterminals or the form $A \to a$ where a is a terminal.

Church's thesis (or the ***Church-Turing thesis***): the premise that the intuitive notion of what is computable or partially computable should be formally defined as computable by a Turing machine.

code (for an alphabet): a language C of nonempty words, such that whenever a word w can be written as a concatenation of words in C, the write-up is always unique. That is, if $w = x_1 \ldots x_m = y_1 \ldots y_n$ where $x_i, y_j \in C$, then $m = n$ and $x_i = y_i$ for $i = 1, \ldots, m$.

code indicator (of a language): the sum of the code indicators of all words in the language.

code indicator (of a word $w \in V^*$): the number $ci(w) = |V|^{-|w|}$.

collapse (of the polynomial hierarchy to the ith rank): the circumstance that PH $=$ Σ_i^p, for some $i \geq 0$.

common PRAM (or ***CRCW***^{com}): a CRCW PRAM model in which concurrent writes to the same location are permitted if all processors write the same data.

comparison sort: a sorting algorithm that uses only comparisons between keys to determine the sorted order.

complement (of language L over alphabet V): the language $\overline{L}$, where complementation is taken with respect to V^*.

$\mathcal{C}$-complete language (where $\mathcal{C}$ is a class of languages): a language A such that A is $\mathcal{C}$-hard and $A \in \mathcal{C}$.

complexity (of an algorithm): an asymptotic measure of the number of operations or the running time needed for a complete execution; sometimes, a measure of the total amount of computational space needed.

complexity (of a function): usually, the minimum complexity of any algorithm representing the function; sometimes, the length or complicatedness of the list of instructions.

complexity (of a function), ***Kolmogorov-Chaitin type***: a measure of the minimum complicatedness of any algorithm representing the function, usually according to the number of instructions in the algorithm (and *not* related to its running time).

coNP: the complexity class Π_1^p, which contains every language A such that $\overline{A} \in \Sigma_1^p$.

concatenation (of two languages L_1 and L_2): the set $\{xy \mid x \in L_1,\ y \in L_2\}$, denoted L_1L_2.

concatenation (of two strings): the result of appending the second string to the right end of the first.

consequent (of a production $\alpha \to \beta$): the string β that follows the arrow.

context-free (or ***type 2***) ***grammar***: a grammar in which the antecedent of each production is a single nonterminal.

context-sensitive (or ***type 1***) ***grammar***: a grammar where every production $\alpha \to \beta$ (except possibly $S \to \lambda$) has the form $\alpha = uAv$ and $\beta = uxv$.

CRCW concurrent read concurrent write: a PRAM model in which both concurrent reads from and concurrent writes to the same location are allowed.

CREW concurrent read exclusive write: a PRAM model where concurrent reads are allowed, but not concurrent writes to the same location.

cube (over an alphabet): a word having the pattern xxx.

derivation (of the string y from the string x): a sequence of substitutions, according to the production rules, that transforms string y into string z. The notation $x \Longrightarrow^* y$ means that such a derivation exists.

deterministic finite automaton (***DFA***): a model of a computer for deciding membership in a set.

emptiness problem for grammars: deciding whether the language generated by a grammar is empty.

empty string: the string of length zero, that is, the string with no symbols; often written λ.

equivalence problem for grammars: deciding whether two grammars are equivalent.

equivalent automata: automata that accept the same language.

equivalent grammars: grammars that generate the same language.

EREW exclusive read exclusive write: a PRAM model in which neither concurrent reads from nor concurrent writes to the same location are allowed.

existential lower bound (for an algorithm): a lower bound for its number of execution steps that holds for at least one input.

existential lower bound (for a problem): a lower bound for every algorithm that can solve that problem.

finite automaton: a DFA or an NFA.

finite-state machine: a finite automaton or finite transducer.

finite-state machine with output: another name for a finite transducer.

finiteness problem (for a grammar): deciding whether the language generated by that grammar is finite.

finite transducer: a model of a computer for calculating a function, like a finite automaton, except that it also produces an output string each time it reads an input symbol.

free monoid (generated by an alphabet): the set of all strings composable from symbols in the alphabet, with the operation of string concatenation.

frequency (of a symbol in a string): the number of occurrences of the symbol in the string.

Game of Life: a 2-dimensional cellular automaton designed by John H. Conway.

Gödel numbering (of a set): a method for encoding Turing machines as products of prime powers; more generally, a similar one-to-one recursive function on an arbitrary set whose image in $\mathcal{N}$ is a recursive set.

grammar: a set of *production* rules of the form $\alpha \to \beta$ that allow one to derive strings by repeated substitution.

halting problem: the problem of designing an algorithm capable of deciding which computations $P(x)$ halt and which do not, where P is a computer program (or Turing machine) and x is a possible input to P.

$\mathcal{C}$-hard language ($\mathcal{C}$ a class of languages): a language A such that every language in class $\mathcal{C}$ is polynomial-time reducible to A.

Hilbert's tenth problem: the (undecidable) problem of determining for an arbitrary multivariate polynomial equation $p(x_1, \ldots, x_n) = 0$ whether there exists a solution consisting of integers.

inclusion problem for languages: deciding whether one language is included in another.

inherently ambiguous context-free language: a context-free language such that every context-free grammar for the language is ambiguous.

input size: the quantity of data supplied as input to a computation.

interconnection network model: a parallel computation model as a digraph in which each vertex represents a processor, and in each phase, each processor communicates with its neighbors and makes a computation.

inverse of a morphism: for morphism $h\colon V^* \to U^*$, the mapping $h^{-1}\colon U^* \to 2^{V^*}$ defined for $x \in U^*$ by $h^{-1}(x) = \{y \in V^* \mid h(y) = x\}$.

Kleene closure (or ***Kleene star***): of a language L, the set of all iterated concatenations of zero or more words in L, denoted L^*.

language (accepted by a machine, e.g., finite automaton, PDA, or Turing): the set of all accepted strings.

language (generated by the grammar G): the language $L(G)$ of words consisting of terminal symbols derivable from the start symbol.

language (over an alphabet V): a subset of the free monoid V^*; that is, a set of strings.

Las Vegas algorithm: an algorithm that always produces correct output, whose running time is a random variable.

Las Vegas to Monte Carlo transformation: the Monte Carlo algorithm obtained by running the Las Vegas scheme for $kE[T]$ steps and halting, where $E[T]$ is the expected Las Vegas running time.

leftmost derivation: a derivation in which at each step the leftmost nonterminal is replaced.

leftmost language (generated by the grammar G): the language of strings of terminals with leftmost derivations from the start symbol.

length set (of a language L): the set $\{|x| \mid x \in L\}$.

length-increasing (***or type 1***) ***grammar***: a grammar in which the consequent β of each production $\alpha \to \beta$ (except $S \to \lambda$, if present) is at least as long as its antecedent α.

linear grammar: a context-free grammar where each consequent contains at most one nonterminal.

Mealy machine: a finite transducer whose output function always produces a single symbol.

membership problem (for a grammar G): given an input string x, deciding whether $x \in L(G)$.

mirror image (of a language L): the language obtained by reversing every string in L.

Monte Carlo algorithm: an algorithm that has a bounded number of computational steps and produces incorrect output with some low probability.

Monte Carlo to Las Vegas transformation: the Las Vegas algorithm of repeatedly running that Monte Carlo algorithm until correct output occurs.

Moore machine: a Mealy machine such that for every state k and every pair of input symbols s_1 and s_2, the outputs $\tau(k, s_1)$ and $\tau(k, s_2)$ are the same.

morphism (from the alphabet V to the alphabet U): a function $s\colon V \to U$.

nondeterministic finite automaton (***NFA***): a model like a DFA, but there may be several different states to which a transition is possible, instead of only one.

nondeterministic polynomial-time computation on a TM: a computation such that there exists a polynomial function $p(n)$ such that for any input of size n there is a computational path on the TM whose length is at most $p(n)$ steps.

nondeterministic Turing machine: a model like a deterministic Turing machine, except that the transition function Δ maps each state-symbol pair to a set of state-symbol-direction triples.

nonterminal (in a grammar): a symbol that may be replaced when a production is applied.

nontrivial family of languages: a family that contains at least one language different from $\emptyset$ and $\{\lambda\}$.

NP: the complexity class of languages nondeterministically TM-decidable in polynomial time.

NP-complete language: a language A such that A is NP-hard and $A \in$ NP.

NP-complete problem: a decision problem equivalent to deciding membership in an NP-complete language.

NP-hard language: a language A such that every language in complexity class NP is polynomial-time reducible to A.

oracle (for a language): a machine state that decides whether or not a given string is in that language.

oracle Turing machine: like a Turing machine, except equipped with a special second tape on which it can write a string to query an oracle for a fixed language L.

P: the complexity class of languages deterministically TM-decidable in polynomial time.

palindrome: a string that is identical to its reverse.

parallel computation model: a computational model that permits more than one instruction to be executed simultaneously, instead of requiring that they be executed sequentially.

parsing a string: in theoretical computer science, a *derivation*.

partial function: an incomplete rule that assigns values to some elements in its domain but not necessarily to all of them.

partial function ϕ_M induced by a TM M: the rule that associates to each input v for which M's computation halts the output $\phi_M(v)$, and is otherwise undefined.

partial recursive function: a partial function derivable from the constant zero functions $\zeta_n(x_1, \ldots, x_n) = 0$, the successor function $\sigma(n) = n + 1$, and the projection functions $\pi_i^n(x_1, \ldots, x_n) = x_i$, using multivariate composition, multivariate primitive recursion, and unbounded minimalization.

pattern (over an alphabet V): a string of variables over that alphabet; regarded as present in a particular word $w \in V^*$ if there exists an assignment of strings from V^+ to the variables in that pattern such that the word formed thereby is a substring of w.

polynomial hierarchy (***PH***): the union of the complexity classes Σ_n^p, for $n \geq 0$.

polynomial-space computation (of a function by a TM M): a computation by M of that function such that there exists a polynomial function $p(n)$ such that for every input of size n, the calculation workspace takes at most $p(n)$ positions on the tape.

polynomial-time computation (of a function by a TM M): a computation by M of that function such that there exists a polynomial function $p(n)$ such that for every input of size n, the calculation takes at most $p(n)$ steps.

positive closure (***or Kleene plus***): Of a language L, the set of all iterated concatenations of words in L excluding the empty word, denoted L^+.

n*th *power of a language: the set of all iterated concatenations $w_1w_2\ldots w_n$ where each w_i is a word in the language.

PRAM memory conflict: the conflict that occurs when more than one processor attempts concurrently to write to or read from the same global memory register.

PRAM parallel random access machine: a model of parallel computation as a set of global memory registers and a set of processors, each with access to its own local registers.

primitive recursion: a restricted way of defining $f(n+1)$ in terms of $f(n)$.

primitive recursive function: any function derivable from the constant zero functions $\zeta_k(x_1, \ldots, x_k) = 0$, the successor function $\sigma(n) = n+1$, and the projection functions $\pi_i^n(x_1, \ldots, x_n) = x_i$, using multivariate composition and multivariate primitive recursion.

probabilistic Turing machine: a nondeterministic Turing machine M with exactly two choices of a next state at each step, both with probability $\frac{1}{2}$ and independent of all previous choices.

production rule (in a grammar): a rule for making a substitution in a string.

projection function, ***n-place***: a function $\pi_i^n(x_1, \ldots, x_n) = x_i$ that maps an n-tuple to its ith coordinate.

PSPACE: the complexity class of languages TM-decidable in polynomial space.

pumping lemma: any one of several results in formal language theory concerned with rewriting strings; used in impossibility proofs.

pushdown automaton (***PDA***): a (possibly nondeterministic) finite automaton equipped with a stack.

random access machine (***RAM***): a computation model with several arithmetic registers and an infinite number of memory registers.

randomized algorithm: an algorithm that makes random choices during its execution, guided by the output of a random (or pseudo-random) number generator.

recursive language: a language with a decidable membership question.

recursive set: a set whose characteristic function is recursive.

recursively enumerable set: a set that is either empty or the image of a recursive function.

reducibility in polynomial-time (of language A to language B): the existence of a polynomial-time computable function f such that $x \in A$ if and only if $f(x) \in B$, for each string x in the alphabet of language A; denoted by $A \leq_m^p B$.

reduction: a strategy for solving a problem by transforming its natural form of input into the input form for another problem, solving that other problem on the transformed input, and transforming the answer back into the original problem domain.

regular expression (over an alphabet V): a string w in the symbols of V and the special set $\{\epsilon,\ ),\ (,\ +,\ *\}$ such that $w \in V$ or $w = \epsilon$, or (continuing recursively) $w = (\alpha\beta), (\alpha + \beta),$ or α^*, where α and β are regular expressions.

regular (or ***type 3***) ***grammar***: a grammar such that every production $\alpha \rightarrow \beta$ has antecedent $\alpha \in N$ and consequent $\beta \in T \cup TN \cup \{\lambda\}$.

regular language: a language that can be obtained from elements of its alphabet using finitely many times the operations of union, concatenation, and Kleene star.

regularity problem (for grammars): deciding whether $L(G)$ is a regular language.

reverse (of the string x): the string x^R obtained by writing x backwards.

running time: the number of primitive operation steps executed by an algorithm, usually expressed in big-O asymptotic notation (or sometimes Θ-notation) as a formula based on the input size.

space complexity (of an algorithm): a measure of the amount of computational space needed in the execution, relative to the size of the input.

sparse language: a language A for which there is a polynomial function $p(n)$ such that for every $n \in \mathcal{N}$, there are at most $p(n)$ elements of length n in A.

square (over an alphabet): the pattern xx, or any word having that pattern.

square-free word: a word having no subwords with the pattern xx.

start symbol (in a grammar): a designated nonterminal from which every word of the language is generated.

state diagram (for a finite automaton): a labeled digraph whose vertices represent the states and whose arcs represent the transitions.

string (accepted by a finite automaton): a string that can cause the automaton to end up in an accepting state, immediately after the last transition.

string (accepted by a PDA): an input string that can lead to the stack being empty and the PDA being in an accepting state after the last transition.

string (accepted by a TM M): a string w such that M halts on input w.

string: a finite sequence of symbols from some alphabet.

substitution (for the alphabet V in the alphabet U): a mapping $s\colon V \longrightarrow 2^{U^*}$, which means that each symbol $b \in V$ may be replaced by any of the strings in the set $s(b)$; extends to strings of V^*.

terminal (in a grammar): a symbol that cannot be replaced by other symbols.

time complexity (of an algorithm): a function representing the number of operations or the running time needed, using the size of the input as its argument.

total function: a partial function defined on all of its domain, i.e., a function.

tractable problem: a problem that can be solved by an algorithm with polynomial-time complexity.

λ-transition (in an NFA): a transition that could occur without reading any symbols of the input string.

transition table (for a DFA): a table whose rows are indexed by the states and whose columns are indexed by the symbols, such that the entry in row r and column c is the state to which the DFA moves if it reads symbol c while in state r.

trapping state (of a finite automaton): a non-accepting state from which every outward arc is a self-loop.

trio: a nontrivial family of languages closed under λ-free morphisms, inverse morphisms, and intersection with regular languages.

Turing-acceptable language: a language that has a TM M that accepts it.

Turing-computable function: a function f such that there is a TM M with $f = \phi_M$.

Turing-decidable language: a language whose characteristic function is Turing- computable.

Turing machine (TM): an automaton whose head can move one character in either direction and that can replace the symbol it reads by a different symbol.

Turing-p-reducibility (of language A to language B): the existence of a deterministic oracle TM M^B that decides language A in polynomial time. Notation: $A \leq_T^p B$.

Turing's test (of whether a given computer can think): are its responses to a series of written questions indistinguishable from human responses (by a person who does not know who gave the responses)?

type 0 grammar: a grammar with no restrictions.

type 1 grammar: a length-increasing grammar, or equivalently, a context-sensitive grammar.

type 2 grammar: a context-free grammar.

type 3 grammar: a regular grammar.

unambiguous context-free language: a context-free language that has a context-free grammar that is not ambiguous.

unbounded minimalization: a way of using a function or partial function to define a new function or partial function.

uncomputable function: a function whose values cannot be calculated by a Turing machine (or by a computer program).

undecidable problem: a decision problem whose answers cannot be given by a Turing machine (or by a computer program).

universal Turing machine: a TM that can simulate every TM.

unsolvable problem: a problem that cannot be decided by a recursive function. Equivalently, an undecidable problem.

variable (over an alphabet V): a symbol not in V whose values range over V^*.

word: usually a finite sequence of symbols (same as *string*), sometimes a countably infinite sequence.

word equation (over an alphabet V): an expression $\alpha = \beta$, such that α and β are words containing letters from V and some variables over V.

word inequality: the negation of a word equation, commonly written as $\alpha \neq \beta$.

worst-case running time: the maximum number of execution steps of an algorithm, usually expressed in big-O asymptotic notation (or sometimes Θ-notation) as a formula based on the input size.

17.1 COMPUTATIONAL MODELS

The objective of a computer, no matter what input/output or memory devices are attached, is ultimately to make logical decisions and to calculate the values of functions. Any decision problem can be represented as recognizing whether an input string is in a specified subset; calculating a function amounts to accepting an input string and producing an output string. At this fundamental level, the fundamental models in Table 1 can serve as the theoretical basis for all sequential computers.

Table 1: Fundamental computational models.

model	*description*	*comment*
DFA $= (K, s, F, \Sigma, \delta)$ $K =$ set of states, start at $s \in K$, accepting states $F \subseteq K$, input alphabet Σ, transition fn $\delta\colon K \times \Sigma \to K$	deterministic finite automaton: scans a tape once; decides whether to accept	recognizes regular languages
NFA $= (K, s, F, \Sigma, \Delta)$ K, s, F, Σ like DFA, transition fn $\Delta\colon K \times \Sigma^* \to \mathcal{P}(K)$	nondeterministic finite automaton	equivalent power to DFA
$(K, s, \Sigma_I, \Sigma_O, \delta, \tau)$ $K =$ set of states, start at $s \in K$, in-alphabet Σ_I, out-alphabet Σ_O, transition fn $\delta\colon K \times \Sigma_I \to K$, output fn $\delta\colon K \times \Sigma_I \to \Sigma_O^*$	Finite transducer: also called "finite-state machine with output"	Special cases: Mealy machine writes one output symbol per input symbol; in Moore machine, output symbol depends only on state before transition
PDA $= (K, s, F, \Sigma, \Gamma, \Delta)$ K, s, F, Σ as DFA, stack alphabet Γ, transition fn $\Delta\colon K \times \Sigma^* \times \Gamma^* \to \mathcal{P}(K \times \Gamma^*)$	Pushdown automaton: uses stack for storage, nondeterministic	recognizes context-free languages
TM $= (K, s, h, \Sigma, \delta)$ $K =$ set of states, start at $s \in K$, halting state $h \notin K$, alphabet Σ, transition fn $\delta\colon K \times \Sigma \to K \times \Sigma \times \{L, R\} \cup \{h\}$	Turing machine: has two-way tape with rewritable symbols	decides membership in recursive sets; equivalent power to nondeterministic version

17.1.1 FINITE-STATE MACHINES

Definitions:

If Σ is a set of symbols, then Σ^* is the set of all (finite) strings made from symbols of Σ.

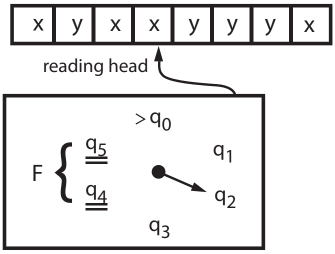
A ***deterministic finite automaton***, abbreviated ***DFA***, models a computer for decision-making as a 5-tuple $(K, s, F, \Sigma, \delta)$ such that

- K is a finite set of ***states***;
- $s \in K$ (***starting state***);
- $F \subseteq K$ (***accepting states***);

- Σ is a finite ***alphabet*** of ***symbols***;
- $\delta : K \times \Sigma \to K$ (***transition function***).

A DFA is also known as a ***(deterministic) finite-state recognizer***.

The ***computer model*** for a DFA consists of a logic box, programmed by the transition function δ. It has a read-only head that examines an input tape while moving in only one direction. Whenever it reads symbol c on the tape while in state q, the automaton switches into state $\delta(q, c)$ and moves to the next symbol. The string is considered to be accepted if the automaton is in an accepting state after the last transition.



A ***nondeterministic finite automaton***, or ***NFA***, is a 5-tuple $(K, s, F, \Sigma, \Delta)$ like a DFA, except that Δ is a function from $K \times \Sigma^*$ to $\mathcal{P}(K)$ (the set of all subsets of K).

The ***computer model*** for an NFA is like the computer model for a DFA. However, if it reads string u on the input string while in state q, the automaton may switch to any of the states in the set $\Delta(q, u)$ and move to the symbol after u. The string is considered to be accepted if *it is possible for* the automaton to be in an accepting state after the last transition.

A ***finite automaton*** is either a DFA or an NFA.

A ***state diagram*** for a DFA is a digraph with vertex set K such that for each state q and each symbol c there is an arc from vertex q to vertex $\delta(q, c)$, labeled with c. (Sometimes a single arc is labeled with multiple symbols, instead of drawing multiple arcs between the same pair of states.) The starting state is designated by an entering arrow and the accepting states by double circles. A state diagram for an NFA is similar, except that for each state p in $\Delta(q, u)$ there is an arc from vertex q to vertex p labeled with the string u, which may be the empty string λ.

A ***transition table*** for a DFA is a table with rows indexed by the states in K and columns indexed by the symbols in Σ, such that the entry in row q and column c is $\delta(q, c)$. The starting-state row label is marked with a ">" and the accepting-state row labels are underscored.

A ***configuration*** for a finite automaton is a pair (q, w) with $q \in K$ and $w \in \Sigma^*$. It signifies that the automaton is in state q with the head at the first symbol of string w. (Since the head moves in only one direction, a common assumption is that it consumes each symbol as it reads.)

The DFA configuration (q, w) ***yields the configuration*** (q', w') ***in one step*** if deleting the initial symbol, call it c, of the string w gives the string w', and $\delta(q, c) = q'$. *Notation:* $(q, w) \vdash_M (q', w')$.

The NFA configuration (q, w) ***yields the configuration*** (q', w') ***in one step*** if there is an initial prefix u on the string w whose deletion gives the string w', and $q' \in \Delta(q, u)$.

The configuration (q, w) ***yields*** the configuration (q', w') if there is a sequence of configurations $(q, w) = (q_0, w_0), (q_1, w_1), \ldots, (q_n, w_n) = (q', w')$ such that $(q_{i-1}, w_{i-1}) \vdash_M (q_i, w_i)$, for $i = 1, \ldots, n$. *Notation:* $(q, w) \vdash_M^* (q', w')$.

A string w is ***accepted by finite automaton*** M if there is an accepting state q such that $(s, w) \vdash_M^* (q, \lambda)$. That is, machine M accepts string w if, starting in state s at the first symbol, its transition sequence can ultimately lead to an accepting state, immediately after its last transition.

The ***language accepted by a finite automaton*** M is the set of all strings accepted by M. It is denoted $L(M)$.

Finite automata M_1 and M_2 are ***equivalent*** if $L(M_1) = L(M_2)$; that is, if they accept the same language.

A ***trapping state*** of a finite automaton is a non-accepting state where every outward arc is a self-loop. To simplify state diagrams, trapping states are often not explicitly drawn.

A (***deterministic***) ***finite transducer***, also known as a ***finite-state machine with output***, models a function-calculating computer as a 6-tuple $(K, s, \Sigma_I, \Sigma_O, \delta, \tau)$ such that

- K is a finite set of ***states***;
- $s \in K$ (***starting state***);
- Σ_I is a finite alphabet of ***input symbols***;
- Σ_O is a finite alphabet of ***output symbols***;
- $\delta \colon K \times \Sigma_I \to K$ (***transition function***);
- $\tau \colon K \times \Sigma_I \to \Sigma_O^*$ (***output function***).

A ***Mealy machine*** is a finite transducer whose output function always produces a single symbol.

A ***Moore machine*** is a Mealy machine such that for every state k and every pair of input symbols s_1 and s_2, the outputs $\tau(k, s_1)$ and $\tau(k, s_2)$ are the same.

A ***finite-state machine*** is a finite automaton or a finite transducer.

Facts:

1. Finite-state machines are the design plan of many practical electronic control devices, for instance in wristwatches or automobiles.

2. The phrase “finite-state machine” refers to a finite-state model that may or may not have output capacity and that may or may not be nondeterministic.

3. For every NFA, there is an equivalent DFA. (M. Rabin and D. Scott, 1959)

4. In software design, NFAs are commonly used in preference to DFAs because they often achieve the same task with fewer states.

5. The nondeterminism of an NFA is that possibly $u = \lambda$, or that possibly there are two states p and p' in $\Delta(q, u)$, so that in state q the NFA might read substring u and switch into either state p or state p'.

6. NFAs are often defined so that λ-transitions are the only possible instances of nondeterminism. In this seemingly more restrictive kind of NFA, the transition function is a map from $K \times (\Sigma \cup \{\lambda\})$ to K.

7. The class of languages accepted by finite automata is closed under all of the following operations:

- union;
- concatenation;
- Kleene star (see §17.3.2);
- complementation;
- intersection.

8. *Kleene's theorem*: A language is regular (§17.3.4) if and only if it is the language accepted by some finite automaton. (S. Kleene, 1956)

9. Some lexical scanning processes of compilers use finite automata.

10. The relation "yields" for finite automata is the reflexive, transitive closure of the relation $\vdash_M$.

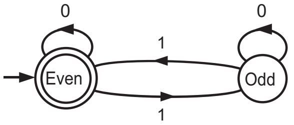
11. Both Moore machines and Mealy machines have the computational capability of an unrestricted finite transducer.

12. More comprehensive coverage of finite-state machines is provided by many textbooks, including [Si14] and [LePa97].

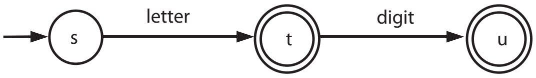
Examples:

1. The DFA specified by the following transition table and state diagram decides whether a binary string has an even number of 1s. Formally, $M = (K, s, F, \Sigma, \delta)$ with $K = \{\text{Even, Odd}\}$, $s = \text{Even}$, $F = \{\text{Even}\}$, and $\Sigma = \{0, 1\}$.

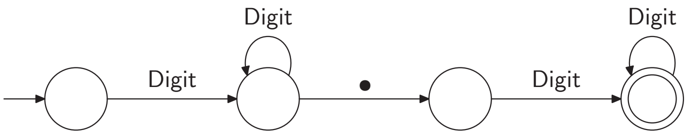
	0	1
> Even	Even	Odd
Odd	Odd	Even



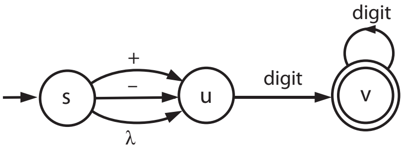
2. In one early form of the language BASIC, an identifier could be a letter or a letter followed by a digit. The following state diagram specifies a DFA that accepts this:



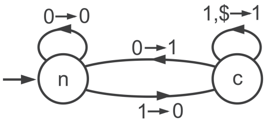
3. A "proper fixed-point numeral" is a nonempty string of decimal digits, followed by a decimal point, and then another nonempty string of digits. For instance, the number zero would be represented as "0.0". The following DFA decides whether the input string is such a numeral.



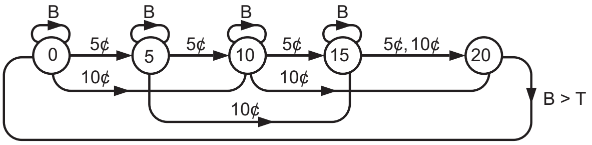
4. An "integer" in some programming languages is a nonempty string of decimal digits, possibly preceded by a sign + or −. The following NFA recognizes such an integer.



5. The following finite-state transducer has $\{0, 1, \$\}$ and $\{0, 1\}$ for its input and output alphabets, respectively, where "\$" serves as an end-of-string marker. It reads a binary numeral, starting at the units digit, and prints a binary numeral whose value is double the input numeral.



6. The following finite-state machine models a vending machine for a 20-cent toy. The possible inputs are nickels and dimes, and a push of a button releases the toy if enough change has been deposited. Each state indicates the amount that has been deposited. This machine may be regarded as a transducer that produces symbol T (toy) if it receives input B while in state 20.



7. NFAs can be used to model various solitaire games and puzzles, such as making a complete knight's tour of a chessboard.

17.1.2 PUSHDOWN AUTOMATA

Definitions:

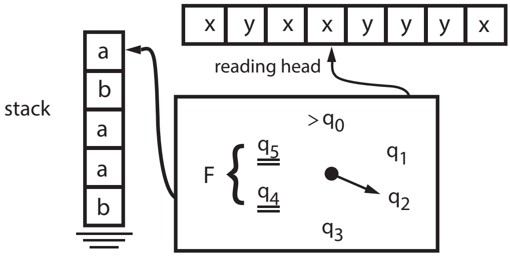
A ***pushdown automaton*** (***PDA***) is essentially a (possibly nondeterministic) finite automaton equipped with a stack. It is given by a 6-tuple $(K, s, F, \Sigma, \Gamma, \Delta)$ such that

- K is a finite set of ***states***;
- $s \in K$ (***starting state***);
- $F \subseteq K$ (***accepting states***);
- Σ is a finite ***alphabet of input symbols***;
- Γ is a finite ***alphabet of stack symbols***;
- $\Delta\colon K \times \Sigma^* \times \Gamma^* \to \mathcal{P}(K \times \Gamma^*)$ (***transition function***).

A ***transition*** of a PDA is an element (q, γ) in some $\Delta(p, u, \beta)$. The idea is that from state p, the PDA may read the substring u and the stack substring β, and transfer into state q while popping β and pushing γ, thereby replacing β by γ.

Note: A PDA is frequently defined so that the only strings that can be read or written or pushed or popped are single characters and the empty string. This has no effect on the computational generality.

The ***computer model*** for a PDA consists of a logic box, programmed by Δ, equipped with a read-only head that examines an input tape while moving in only one direction, and also equipped with a stack. When it reads substring u from input while in state p with substring β at the top of the stack, the automaton selects a corresponding entry from Δ and makes that transition.



A ***configuration*** for a PDA is a triple (p, u, β) such that $p \in K$, $u \in \Sigma^*$, and $\beta \in \Gamma^*$.

The PDA configuration $(p, ux, \beta\alpha)$ ***yields the configuration*** $(q, x, \gamma\alpha)$ ***in one step*** if there is a transition $((p, u, \beta), (q, \gamma))$. *Notation:* $(p, ux, \beta\alpha) \vdash_M (q, x, \gamma\alpha)$.

The PDA configuration C ***yields*** the configuration C', denoted $C \vdash_M^* C'$, if there is a sequence of configurations $C = C_0, C_1, \ldots, C_n = C$ such that $C_{i-1} \vdash_M C_i$, for $i = 1, \ldots, n$.

A string $w \in \Sigma^*$ is ***accepted*** by a PDA M if there is an accepting state q such that $(s, w) \vdash_M^* (q, \lambda, \lambda)$. That is, it accepts string w if, starting in state s at the first symbol, its transition sequence can ultimately lead to an accepting state and an empty stack after it has read the last symbol.

The ***language accepted*** by a PDA M is the set of all strings accepted by M. It is denoted $L(M)$.

A ***state diagram*** for a PDA is a digraph with vertex set K such that for each pair (q, γ) in $\Delta(p, u, \beta)$ there is an arc from vertex p to vertex q, labeled $u, \beta \to \gamma$. (Sometimes a single arc is labeled with multiple symbols, instead of drawing multiple arcs between the same pair of states.) The starting state is designated by an entering arrow, and the accepting states by a double circle.

Facts:

1. The PDA model was invented by A. G. Oettinger in 1961.

2. A language L is context-free (see §17.3.3) if and only if there is a pushdown automaton M such that L is the language accepted by M. (M. Schützenberger 1963, and independently by N. Chomsky and by J. Evey)

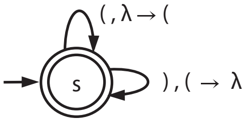
3. A PDA can test whether a string is a palindrome, or whether all the left and right parentheses are matched, but a DFA cannot.

4. The class of languages accepted by deterministic PDAs is smaller than the class accepted by nondeterministic PDAs.

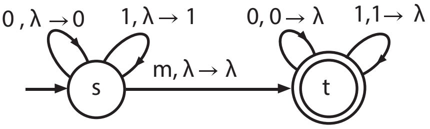
5. More comprehensive coverage of pushdown automata is provided by many textbooks, including [Si14] and [LePa97].

Examples:

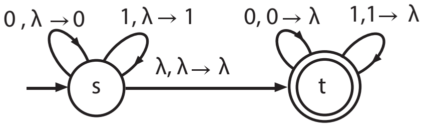
1. The following PDA decides whether a sequence of left and right parentheses is well-nested, in the sense that every left parenthesis is uniquely matched to a right parenthesis, and vice versa. It is necessary and sufficient that, in counting left and right parentheses while reading from left to right, the number of right parentheses never exceeds the number of left parentheses and that the total counts are the same.



2. The following PDA decides whether a string from the alphabet $\{0, 1, m\}$ has the form bmb^r where b is a bitstring and b^r its reverse. The middle m signals when to switch from pushing symbols onto the stack to popping them off.



3. The following nondeterministic PDA decides whether a binary string is of the form bb^r, that is, an even-length palindromic bitstring. In effect, it considers every character interspace as the possible middle.



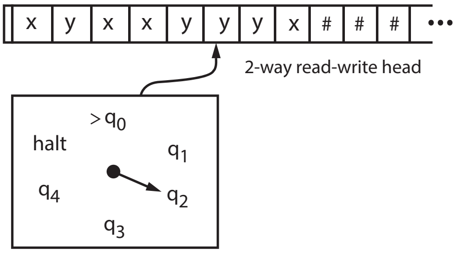
17.1.3 TURING MACHINES

Definitions:

A ***Turing machine*** (***TM***) models a computer as a 5-tuple $(K, s, h, \Sigma, \delta)$ such that

- K is a finite set of ***states***;
- $s \in K$ (***starting state***);
- $h \notin K$ (***halting state***);
- Σ is a finite set of symbols, including the ***blank*** #; (***alphabet***);
- $\delta\colon K \times \Sigma \to (K \times \Sigma \times \{L, R\}) \cup \{h\}$ (***transition function***).

The ***computer model*** for a Turing machine consists of a logic box, programmed by δ, equipped with a read-write head that examines an input tape with a left end but no right end. To start a computation, the input string is written at the left end of the tape, and the rest of the tape filled with blanks. The head starts at the leftmost symbol. Whenever the Turing machine reads symbol b on the tape while in state q, its internal logic produces the triple $\delta(q, b) = (p, c, D)$, and the machine switches into state p, replaces b by c, and moves one space in direction D, that is, either to the left (L) or to the right (R).



A ***transition table*** for a Turing machine is a table whose rows are labeled with the states and whose columns are labeled with the symbols, such that the entry in row q and column b is $\delta(q, b)$. Thus, a typical table entry is a triple indicating to which state to switch from q, the symbol to replace b, and whether to move one square to the right or to the left. However, another possibility is that a table entry is the halt state h.

A ***configuration*** for a Turing machine is a quadruple (q, u, b, v), such that $q \in K \cup \{h\}$, $u, v \in \Sigma^*$, and $b \in \Sigma$, commonly written as $(q, u\underline{b}v)$. This means that the Turing machine is in state q, that the present value of the tape is ubv, that the head is presently at the indicated b, and that the rest of the tape to the right is filled with blanks.

The Turing machine configuration $(p, u\underline{b}v)$ ***yields the configuration*** $(q, x\underline{c}y)$ ***in one step*** if the transition $\delta(p, b)$ changes configuration $(p, u\underline{b}v)$ to configuration $(q, x\underline{c}y)$. This is denoted by $(p, u\underline{b}v) \vdash_M (q, x\underline{c}y)$.

The Turing machine ***accepts*** string w if it enters the halting state h after starting with w on the tape.

An ***infinite loop*** for a Turing machine is an infinite sequence of configurations C_0, C_1, $C_2, \ldots$ such that $C_{i-1} \vdash_M C_i$, for $i = 1, 2, \ldots$.

A Turing machine ***hangs*** if it moves left off the left end of the tape.

The ***output*** of a Turing machine is the string from the left end of the tape up to the last non-blank character if the computation halts, and undefined otherwise.

The ***partial function*** ϕ_M ***induced by a Turing machine*** M maps each input v for which the computation halts to the output $\phi_M(v)$, and is otherwise undefined.

A function $f\colon \Sigma^* \to \Sigma^*$ is ***Turing-computable*** if there is a Turing machine M that halts for all inputs, and computes the function f, that is, $f(v) = \phi_M(v)$ for all $v \in \Sigma^*$.

A Turing machine $M = (K, s, h, \Sigma, \delta)$ ***simulates*** another Turing machine $M' = (K', s'$, $h, \Sigma', \delta')$ if there exists a Turing-computable function $\beta\colon \Sigma'^* \to \Sigma^*$ such that $\phi_M(\beta(w)) = \phi_{M'}(w)$ for all $w \in domain(\phi_{M'})$ and $\phi_M(\beta(w))$ is undefined for all $w \notin domain(\phi_{M'})$.

A ***universal Turing machine*** is a Turing machine $U = (K_U, s_U, h_U, \Sigma_U, \delta_U)$ that can simulate every Turing machine, in the following sense. There is a rule α_U for encoding any Turing machine M and a rule β_U for encoding any input w to M, such that $\phi_U(\alpha_U(M)\#\beta_U(w))$ is defined and equals $\phi_M(w)$ whenever $\phi_M(w)$ is defined, and is undefined otherwise.

A language $L \subseteq \Sigma^*$ is ***Turing-acceptable*** if there exists a Turing machine M that accepts it. That is, $L = \{w \in \Sigma^* \mid M \text{ accepts } w\}$.

The ***characteristic function*** $\chi_L\colon \Sigma^* \to \{yes, no\}$ of a language $L \subseteq \Sigma^*$ is given by the rule $\chi_L(w) = yes$ if $w \in L$, and no otherwise.

A language is ***Turing-decidable*** if its characteristic function is Turing-computable.

A (subset-membership) decision problem is ***undecidable*** if it does not correspond to a Turing-decidable language.

An ***n-state busy beaver machine*** is an n-state Turing machine on the alphabet $\Sigma = \{\#, 1\}$ that accepts a two-way infinite input tape filled with #s and halts after placing a maximum number of 1s on the tape. (The name *busy beaver* is from an analogy between the machine piling up 1s and a beaver piling up logs.)

The ***busy beaver function*** $BB(n)$ has as its value the number of 1s on the output tape of an n-state busy beaver machine.

A ***nondeterministic Turing machine*** is defined like a Turing machine, except that instead of a transition function that assigns a unique change of symbol and direction of motion for the head, there is a transition function that permits more than one possibility.

A ***linear bounded automaton*** (or ***LBA***) is representable as a (possibly nondeterministic) Turing machine that is fed only the finite stretch of tape containing the input word, rather than an infinite tape.

Facts:

1. A Turing machine is commonly regarded as a program to compute the partial function ϕ_M.

2. Every Turing-decidable language is Turing-acceptable.

3. If a language $L \subseteq \Sigma^*$ is Turing-decidable, then its complement $\overline{L}$ is also Turing-decidable.

4. Every Turing-acceptable language $L \subseteq \Sigma^*$ whose complement $\overline{L}$ is also Turing-acceptable is a Turing-decidable language.

5. The following problems about Turing machines are undecidable:

(a) Given a TM M and an input string w, does M halt on input w?

(b) Given a TM M, does M halt on the empty tape?

(c) Given a TM M, does there exist an input w for which M halts?

(d) Given a TM M, does M halt on every input string?

(e) Given two TMs M_1 and M_2, do they accept the same input?

(f) Given two numbers n and k, is $BB(n) > k$?

6. In view of part (d) of the preceding fact, there is no way to tell whether an arbitrary computer program in a general language always halts, much less whether it calculates what it is supposed to calculate.

7. It is possible to construct a universal Turing machine. A universal Turing machine with six states and four symbols was constructed in 1982 by Y. Rogozhin.

8. The busy beaver problem was invented by Tibor Radó in 1962.

9. Turing machines have been extended in several ways, including: infiniteness in two directions, more work tapes, and two-dimensional tapes.

10. Some of the extensions of a Turing machine can perform computations more quickly and are easier to program.

11. Any function that can be computed by a Turing machine with (a) a two-way infinite tape, (b) k tapes, and/or (c) two-dimensional tapes, can also be computed by some standard Turing machine.

12. Any language that can be decided by a nondeterministic Turing machine can also be decided by some standard Turing machine.

13. The following table gives known values and lower bounds for the busy beaver function:

n	1	2	3	4	5	6
$BB(n)$	1	4	6	13	≥ 4098	$> 10^{18267}$

14. A linear bounded automaton is less powerful than a Turing machine. However, it is more powerful than a pushdown automaton.

15. Alan M. Turing (1912–1954) was a British mathematician whose cryptanalytic work during World War II led to the decryption of ciphertext from the German cipher machine called the Enigma. This work was dramatized in the 2014 film "The Imitation Game".

16. Turing proposed that a machine be regarded as "thinking" if its responses to written questions cannot be distinguished from those of a person. This criterion is called *Turing's test*.

17. More comprehensive coverage of Turing machines is provided by many textbooks, including [Si14] and [LePa97].

Examples:

1. This is a 1-state Turing machine with alphabet $\Sigma = \{0, 1, \#\}$ that changes every character preceding the first blank into a blank. It accepts any string over its alphabet.

	0	1	#
$\rightarrow a$	$\#aR$	$\#aR$	h

2. This 3-state Turing machine with alphabet $\Sigma = \{0, 1, \#\}$ doesn't change its input tape at all. It halts whenever it encounters the third '1'. Thus, it accepts any tape with at least three 1s but accepts no other strings.

	0	1	#
$\rightarrow a$	$0aR$	$1bR$	$\#aR$
b	$0bR$	$1cR$	$\#bR$
c	$0cR$	h	$\#cR$

3. This 3-state Turing machine with alphabet $\Sigma = \{1, \#\}$ adds two positive integers, each represented as a string of 1s. For instance, the tape $111\#11\#\#\#\cdots$ becomes $11111\#\#\#\cdots$.

	1	#
$\rightarrow a$	$1aR$	$1bR$
b	$1bR$	$\#cL$
c	$\#cR$	h

4. This 2-state Turing machine shows that $BB(2)$ is at least 4.

	#	1
$\rightarrow a$	$1bL$	$1bR$
b	$1aR$	h

5. This 3-state Turing machine shows that $BB(3)$ is at least 6.

	#	1
$\rightarrow a$	$1bR$	$1cL$
b	$1cR$	h
c	$1aL$	$\#bL$

17.1.4 PARALLEL COMPUTATIONAL MODELS

Definitions:

A ***parallel computation model*** permits more than one instruction to be executed simultaneously, instead of requiring that they be executed sequentially.

An ***interconnection network*** models parallel computation as a digraph in which each vertex represents a processor. In each phase a processor communicates with its neighbors and makes a computation.

An n-dimensional ***cellular automaton*** is an interconnection network in which there is a processor at each integer lattice point of n-dimensional Euclidean space, and each processor communicates with its immediate neighbors.

A ***random access machine*** (***RAM***) has several arithmetic registers and an infinite number of memory registers (often modeled as an infinite array), each of which can be accessed immediately via its address (the index in the array).

A ***parallel random access machine*** (***PRAM***) models parallel computation as a set of *global memory registers* $\{M_j \mid j = 1, 2, \ldots\}$ and a set of *processors* $\{P_j \mid j = 1, 2, \ldots\}$. Each processor P_j also has sole access to an infinite sequence of *local registers*.

In a PRAM, a ***processor*** performs *read* and *write* instructions involving global memory, and other instructions involving only its local memory. All processors of a PRAM perform the same program in synchrony, so that all processors that are not idle are performing their task under the same instruction of the program.

In a PRAM, the concurrent construct $\mathbf{par}[a \le j \le b]P_j : S_j$ means that each processor P_j for $a \le j \le b$ is performing the operation S_j. The operation could be a calculation, a read from some global register, or a write to some global register.

In a PRAM, a ***computation*** starts when all the processors execute the first instruction. It stops when all processors halt. The contents of the global memory are regarded as the output.

In a PRAM, a ***memory conflict*** occurs when more than one processor attempts concurrently to write to or read from the same global memory register.

- In ***exclusive read exclusive write*** (***EREW***), neither concurrent reads from nor concurrent writes to the same location are allowed.
- In ***concurrent read exclusive write*** (***CREW***), concurrent reads are allowed, but not concurrent writes to the same location.
- In ***concurrent read concurrent write*** (***CRCW***), both concurrent reads from and concurrent writes to the same location are allowed.

In the ***common PRAM*** (***CRCW^{com} PRAM***) model, concurrent writes to the same location are permitted provided all processors are trying to write the same data.

Facts:

1. Some commercially available parallel computers have an array of elements in which a single broadcast instruction applying to every element is executed simultaneously for all the elements.

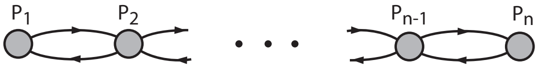
2. Random access machines are considered theoretical models of real sequential computers.

3. PRAM programs are often described using high-level programming language constructs for array processing that are similar to sequential array processing, except that the PRAM array locations are processed in parallel.

4. Whereas $O(n)$ is regarded as fast for sequential processing, a parallel algorithm tends to be regarded as fast if it runs in $O(\log n)$ time, where n is the size of the input.

Examples:

1. A parallel computer for *sorting* up to n items can be modeled as a row of processors $P_1, P_1, \ldots, P_n$ each joined to its immediate predecessor P_{j-1} and its immediate successor P_{j+1}. On the first phase and on all subsequent odd-numbered phases, each processor pair (P_{2j+1}, P_{2j+2}) compares items and swaps, if necessary, so that the smaller item ends up in the lower-indexed processor. On the second phase and on all subsequent even-numbered phases, each processor pair (P_{2j}, P_{2j+1}) compares items and swaps, if necessary, so that the smaller item ends up in the lower-indexed processor. After n phases, the items are sorted in ascending order.



2. *EREW PRAM: finding the maximum*: Given n numbers, with $n = 2^r$, store the numbers in global registers $M_n, \ldots, M_{2n-1}$. Then execute the following:

```
for $i = r - 1$ downto 0
    par$[2^i \le j \le 2^{i+1}]\, P_j : M_j := \max\{M_{2j}, M_{2j+1}\}$
```

The maximum ends up in global register M_1.

3. *CRCW^{com} PRAM: finding the maximum*: Given n numbers, store the numbers in global registers $M_1, \ldots, M_n$. Use n^2 processors $P_{i,j}, 1 \le i, j \le n$ as follows:

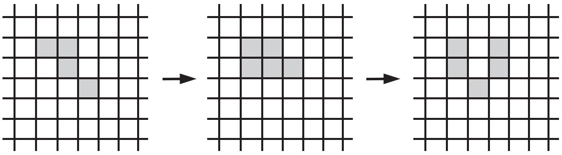
```
par$[1 \le i, j \le n]\, P_{i,j} : M_{i+n} := 0$
par$[1 \le i, j \le n]\, P_{i,j}$ : if $M_i < M_j$ then $M_{i+n} := 1$
    $\{M_{i+n} = 0$ if and only if $M_i = \max\{M_1, \ldots, M_n\}\}$
par$[1 \le i, j \le n]\, P_{i,j}$ : if $M_{n+i} = 0$ then $M_0 := M_i$
```

This program is much faster than the EREW program, because all pairs are compared simultaneously in a single parallel step.

4. *Game of Life*: The "Game of Life", invented by mathematician John H. Conway, is played on an infinite checkerboard. The *neighbors* of a square are the eight squares that touch it, including at its corners. In the initial configuration c_0 of the game, some squares are regarded as *alive* and all others *dead*. Each configuration c_k gives birth to a new configuration c_{k+1}, according to the following rules:

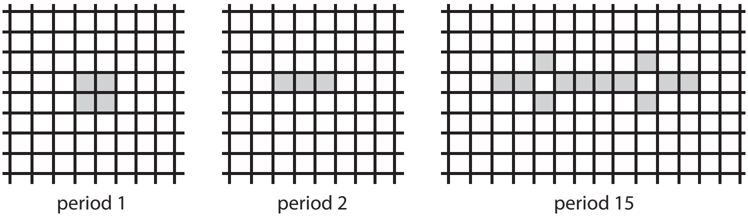
- a live cell remains alive if it has either exactly two or exactly three live neighbors;
- a dead cell comes alive if and only if it has exactly three live neighbors.

The following sequence of configurations illustrates these rules.



The “Game of Life” can be regarded as a cellular automaton in which the squares are the processors and each processor is joined to its eight neighbors.

5. A configuration in the “Game of Life” has *periodicity* n if every nth configuration is the same, and n is the smallest such number. Here are three periodic configurations.



17.2 COMPUTABILITY

The theory of computability is concerned with distinguishing what can be computed from what cannot. This is not a question of skill at performing calculations. The remarkable truth is that the impossibility of computing certain functions can be proved from the definition of what it means to compute a function.

17.2.1 RECURSIVE FUNCTIONS AND CHURCH’S THESIS

The implicit domain for the theory of computability is the set $\mathcal{N}$ of natural numbers. The encoding of problems concerned with arbitrary objects into terms of natural numbers permits general application of this theory.

Definitions:

The n-place ***constant zero function*** is the function $\zeta_n(x_1, \ldots, x_n) = 0$.

The ***successor function*** is the function $\sigma(n) = n + 1$.

The ith n-place ***projection function*** is the function $\pi_i^n(x_1, \ldots, x_n) = x_i$.

The (***multivariate***) ***composition*** of the n-place function $f(x_1, \ldots, x_n)$ and the n m-place functions $g_1(x_1, \ldots, x_m), \ldots, g_n(x_1, \ldots, x_m)$ is the m-place function

$$h(x_1, \ldots, x_m) = f(g_1(x_1, \ldots, x_m), \ldots, g_n(x_1, \ldots, x_m)).$$

(***Multivariate***) ***primitive recursion*** uses a previously defined $(n+2)$-place function $f(x_1, \ldots, x_{n+2})$ and a previously defined n-place function $g(x_1, \ldots, x_n)$ to define the following new $(n+1)$-place function:

$$h(x_1, \ldots, x_{n+1}) = \begin{cases} g(x_1, \ldots, x_n) & \text{if } x_{n+1} = 0; \\ f(x_1, \ldots, x_{n+1}, h(x_1, \ldots, x_n, x_{n+1} - 1)) & \text{otherwise.} \end{cases}$$

Unbounded minimalization uses an $(n+1)$-place function $f(x_1, \ldots, x_{n+1})$ to define the following new n-place function, which is denoted $\mu_m[f(x_1, \ldots, x_n, m) = 0]$:

$$g(x_1, \ldots, x_n) = \begin{cases} \text{the least } y \text{ such that } f(x_1, \ldots, x_n, y) = 0 & \text{if it exists;} \\ 0 & \text{otherwise.} \end{cases}$$

An $(n+1)$-place function $f(x_1, \ldots, x_{n+1})$ is ***regular*** if for every n-tuple $(x_1, \ldots, x_n)$ there is a $y \in \mathcal{N}$ such that $f(x_1, \ldots, x_n, y) = 0$.

The class $\mathcal{P}$ of ***primitive recursive functions*** is the smallest class of functions that contains

- the constant zero functions $\zeta_n(x_1, \ldots, x_n) = 0$, for all $n \in \mathcal{N}$;
- the successor function $\sigma(n) = n + 1$;
- the projection functions $\pi_i^n(x_1, \ldots, x_n) = x_i$, for all $n \in \mathcal{N}$ and $1 \le i \le n$;

and is closed under multivariate composition and multivariate primitive recursion.

The class $\mathcal{RF}$ of ***recursive functions*** is the smallest class of functions that contains

- the constant zero functions $\zeta_n(x_1, \ldots, x_n) = 0$, for all $n \in \mathcal{N}$;
- the successor function $\sigma(n) = n + 1$;
- the projection functions $\pi_i^n(x_1, \ldots, x_n) = x_i$, for all $n \in \mathcal{N}$ and $1 \le i \le n$;

and is closed under multivariate composition, multivariate primitive recursion, and the application of unbounded minimalization to regular functions.

A ***recursive function*** is a function in $\mathcal{RF}$.

Church's thesis, or the ***Church-Turing thesis***, is the premise that recursive functions and Turing machines are capable of representing every function that is computable or partially computable.

A ***partial function*** on $\mathcal{N}$ is a function whose values are possibly undefined for certain natural numbers.

A partial function on $\mathcal{N}$ is called ***total*** if it is defined on every natural number.

The class $\mathcal{PR}$ of ***partial recursive functions*** is the smallest class of partial functions that contains the constant zero functions ζ, the successor function σ, and the projection functions π_i^n, and is closed under multivariate composition, multivariate primitive recursion, and the arbitrary application of unbounded minimalization.

A ***partial recursive function*** is a function in $\mathcal{PR}$.

A partial recursive function f is ***represented by the Turing machine*** M if machine M calculates the value $f(n)$ for every number n on which f is defined and fails to halt for every number on which f is undefined.

The ***Ackermann function*** $A\colon \mathcal{N} \times \mathcal{N} \to \mathcal{N}$ is defined by

$$\begin{aligned}
&A(0, j) = j + 1;\\
&A(i + 1, 0) = A(i, 1);\\
&A(i + 1, j + 1) = A(i, A(i + 1, j)).
\end{aligned}$$

Facts:

1. The standard integer functions of arithmetic, including addition, subtraction, multiplication, division, and exponentiation, are all primitive recursive functions.

2. A function is a partial recursive function if and only if it can be represented by a Turing machine.

3. There are several other models of computation that are equivalent to partial recursive functions and to Turing machines, including labeled Markov algorithms and Post production systems.

4. Church's thesis identifies formal concepts (recursive functions and Turing machines) with the intuitive concept of what is computable; so it is not something that is subject to proof.

5. Church's thesis is often invoked in the proof of theorems about computable functions to avoid dealing with low-level details of the model of computation.

6. The Ackermann function is recursive but not primitive recursive.

7. The Ackermann function grows faster than any primitive recursive function, in the following sense. For every primitive recursive function $f(n)$, there is an integer n_0 such that $f(n) < A(n, n)$ for all $n > n_0$.

Examples:

1. Addition is primitive recursive. Define

$$\begin{aligned}
&a(x, 0) = \pi_1^1(x);\\
&a(x, y + 1) = \sigma(\pi_3^3(x, y + 1, a(x, y))).
\end{aligned}$$

Then $a(x, y) = x + y$.

2. Multiplication is primitive recursive. Define

$$\begin{aligned}
&m(x, 0) = 0;\\
&m(x, y + 1) = a(m(x, y), \pi_2^2(x, y)), \text{ where } a(x, y) \text{ is addition.}
\end{aligned}$$

Then $m(x, y) = x \cdot y$.

3. Predecessor is primitive recursive. Define

$$\begin{aligned}
&p(0) = 0;\\
&p(x + 1) = \pi_1^1(x).
\end{aligned}$$

Then $p(x)$ is the predecessor function (where the predecessor of 0 is 0).

4. Nonnegative subtraction, denoted $x \dot{-} y$, is defined as $x - y$ if $x \geq y$ and 0 otherwise. Define

$$\begin{aligned}
&s(x, 0) = \pi_1^1(x);\\
&s(x, y + 1) = p(s(x, y)), \text{ where } p(x) \text{ is predecessor.}
\end{aligned}$$

Then $s(x, y) = x \dot{-} y$.

5. The function $p(n) =$ the nth prime number is a primitive recursive function.

17.2.2 RECURSIVE SETS AND DECIDABLE PROBLEMS

Definitions:

The ***characteristic function*** of a set A is the function

$$f(x) = \begin{cases} 1 & \text{if } x \in A; \\ 0 & \text{if } x \notin A. \end{cases}$$

A set A is ***recursive*** if its characteristic function is recursive.

A problem is (***computationally***) ***decidable*** (or solvable) if it can be represented as a membership problem that can be decided by a recursive function.

A set $A \subseteq \mathcal{N}$ is ***recursively enumerable*** (***r.e.***) if $A = \emptyset$ or A is the image of a recursive function.

A ***Gödel numbering*** of a set S is a one-to-one recursive function $g\colon S \to \mathcal{N}$ whose image in $\mathcal{N}$ is a recursive set.

Facts:

1. If a set A and its complement $\overline{A}$ are both recursively enumerable, then A is recursive.

2. If a recursively enumerable set A is the image of a nondecreasing function, then A is recursive.

3. A set is recursively enumerable if and only if it is the image of a partial recursive function.

4. A set is recursively enumerable if and only if it is the domain of a partial recursive function.

5. The set of Turing machines has a Gödel numbering.

Examples:

1. Every finite set of numbers is recursive.

2. The prime numbers are a recursive set.

3. The problem of deciding which Turing machines halt on all inputs is undecidable. The set of Gödel numbers for these Turing machines is neither recursive nor recursively enumerable.

4. For any fixed $c \in \mathcal{N}$, the problem of deciding which Turing machines halt when the number c is supplied as input is undecidable. The set of Gödel numbers for these Turing machines is recursively enumerable, but not recursive.

5. The problem of deciding which Turing machines halt when their own Gödel number is supplied as input is undecidable. The set of Gödel numbers for these Turing machines is recursively enumerable, but not recursive.

6. *Hilbert's tenth problem*: Hilbert's tenth problem (posed in 1900) was the problem of devising an algorithm to determine, given a polynomial $p(x_1, \ldots, x_n)$ with integer coefficients, whether there exists an integer root. Y. Matiyasevich proved in 1970 that no such algorithm exists. That is, the set of polynomials with integer coefficients that have an integer solution is not recursive. Hilbert's tenth problem is called a "natural example" of an undecidable problem, since the concepts used to define it are not from within computability theory (i.e., unlike problems concerned with the behavior of Turing machines). [Ma93]

17.3 LANGUAGES AND GRAMMARS

Strings of symbols are a general way to represent information, both in written text and in a computer. A language is a set of strings that are used within some domain of discourse, and a grammar is a system for generating a language. A grammar is what enables a compiler to determine whether a body of code is syntactically correct in a given computer language. Formal language theory is concerned with languages, grammars, and rudiments of combinatorics on strings. Applications of formal language theory range from natural and programming languages, developmental biology, and computer graphics, to semiotics, artificial intelligence, and artificial life.

17.3.1 ALPHABETS

Definitions:

An ***alphabet*** is a finite nonempty set.

A ***symbol*** is an element of an alphabet.

A ***string*** in an alphabet is a finite sequence of symbols over that alphabet.

A ***word*** in an alphabet is a finite or countably infinite sequence of symbols over that alphabet.

The ***length of a string*** w is the number of symbols in w, denoted $|w|$.

The ***empty string*** λ (or sometimes ϵ) is the string of length zero, that is, the string with no symbols.

The ***frequency*** $|w|_a$ of a symbol a in a string w is the number of occurrences of a in string w.

A ***substring*** of a string w is a sequence of consecutive symbols that occurs in w.

A ***subword*** of a word w is a sequence of consecutive symbols that occurs in w.

A ***prefix*** of a string w is a substring that starts at the leftmost symbol.

A ***suffix*** of a string w is a substring that ends at the rightmost symbol.

The ***reverse*** or ***mirror image*** x^R of the string $x = a_1a_2 \ldots a_n$ is the string $a_n \ldots a_2a_1$.

A ***palindrome*** is a string that is identical to its reverse.

A ***pseudopalindrome*** in an alphabet (such as English) that includes punctuation symbols (such as comma, hyphen, or blank) is a word that becomes a palindrome when all of its punctuation symbols are deleted.

The ***concatenation*** xy of two strings $x = a_1a_2 \ldots a_m$ and $y = b_1b_2 \ldots b_n$ is the string $a_1a_2 \ldots a_mb_1b_2 \ldots b_n$ obtained by appending string y to the right of string x.

The ***nth power of a string*** w, denoted w^n, is the concatenation of n copies of w.

The ***shuffle*** $x \sqcup\!\sqcup y$ of two strings $x = x_1 \ldots x_n$ and $y = y_1 \ldots y_n$ is the string $x_1y_1 \ldots x_ny_n$.

Facts:

1. A symbol of an alphabet is usually conceptualized as something that can be represented by a single byte or by a written character.

2. A finite word is a string.

3. The sum of the frequencies $|w|_a$ taken over all the symbols a in the alphabet equals the length of the string w.

4. The length $|xy|$ of a concatenation equals the sum $|x|+|y|$ of the lengths of the strings x and y from which it is formed.

5. The length of the nth power of a string w is $n \cdot |w|$.

6. When a pseudopalindrome occurs in a natural language, it is commonly called a palindrome.

Examples:

1. The English alphabet includes lower and upper case English letters, the blank symbol, the digits $0, 1, \ldots, 9$, and various punctuation symbols.

2. ASCII (*American Standard Code for Information Interchange*) is an alphabet of size 128 for many common computer languages. See Table 1.

3. ABLE WAS I ERE I SAW ELBA is a palindrome.

4. The names EVE, HANNAH, and OTTO are palindromes.

5. MADAM I'M ADAM and SIX AT-NOON TAXIS are pseudopalindromes.

6. The third power of the string 011 is 011011011.

7. The concatenation of BOOK and KEEPER is BOOKKEEPER.

8. The shuffle of FLOOD and RIVER is FRLIOVOEDR.

17.3.2 LANGUAGES

Definitions:

The ***free monoid*** V^* generated by the alphabet V is the structure whose domain is the set of all strings composable from symbols over V, with the operation of string concatenation.

A (***formal***) ***language*** on the alphabet V is a subset of the free monoid V^*.

The λ-***free semigroup*** V^+ on an alphabet V is the set $V^* - \{\lambda\}$, with the concatenation operation.

A λ-***free language*** on the alphabet V is a subset of the λ-free semigroup V^+.

The ***length set*** of a language L is the set $length(L) = \{\, |x| \mid x \in L \,\}$.

The ***concatenation*** L_1L_2 of two languages is the set $\{\, xy \mid x \in L_1,\ y \in L_2 \,\}$.

The ***ith power*** of a language L is the language L^i defined recursively by the rule $L^0 = \{\lambda\}$ and $L^{i+1} = L^iL$, $i \geq 0$.

The ***Kleene closure*** (or ***Kleene star***) L^* of a language L is the union $\bigcup_{i \geq 0} L^i$ of all its powers.

The ***positive closure*** (or ***Kleene plus***) L^+ of a language L is the union $\bigcup_{i \geq 1} L^i$ of all its powers excluding the zeroth power.

Table 1: ASCII codes and binary.

Control codes: ACK: acknowledge, BEL: bell, BS: backspace, CAN: cancel, CR: carriage return, DC1–4: device controls, DEL: delete, DLE: data link escape, EM: end of medium, ENQ: enquiry, EOT: end of transmission, ESC: escape, ETB: end of transmission block, ETX: end of text, FF: form feed, FS: file separator, GS: group separator, HT: horizontal tab, LF: line feed, NAK: negative acknowledgment, NUL: null, RS: record separator, SI: shift in, SO: shift out, SOH: start of heading, SP: space, STX: start of text, SUB: substitute, SYN: synchronous/idle, US: united separator, VT: vertical tab.

The ***union*** of two languages L_1 and L_2 is $L_1 \cup L_2$, using the usual set operation.

The ***intersection*** of two languages L_1 and L_2 is $L_1 \cap L_2$, using the usual set operation.

The ***complement*** of a language L over an alphabet V is the language $\overline{L}$, where complementation is taken with V^* as the universe.

A language is ***regular*** if it is any of the languages $\emptyset$, $\{\lambda\}$, or $\{b\}$, where b is a symbol of its alphabet, or if it can be obtained by applying the operations of union, concatenation, and Kleene star finitely many times to one of those languages.

The ***shuffle*** $L_1 ⧢ L_2$ of two languages L_1, L_2 is the language $\{w \in V^* \mid w = x ⧢ y$, for some $x \in L_1$, $y \in L_2\}$.

The ***mirror image*** $mi(L)$ of the language L is the language $\{x^R \mid x \in L\}$. It is also called the ***reverse*** of the language L.

The ***left quotient*** of the language L_1 with respect to the language L_2 on the same alphabet V, is the language $L_2 \backslash L_1$ containing every string of V^* that can be obtained from a string in L_1 by erasing a prefix from L_2. That is, $L_2 \backslash L_1 = \{w \in V^* \mid$ there is $x \in L_2$ such that $xw \in L_1\}$.

The ***left derivative*** of language L with respect to the string x over the same alphabet V is the language $\partial_x(L) = \{x\} \backslash L$.

The ***right quotient*** is the notion symmetric to left quotient.

The ***right derivative*** is the notion symmetric to left derivative.

A ***substitution*** for the alphabet V in the alphabet U is a mapping $s \colon V \longrightarrow 2^{U^*}$. This means that each symbol $b \in V$ may be replaced by any of the strings in the set $s(b)$.

A ***finite substitution*** is a substitution such that the replacement set $s(a)$ for each symbol $a \in V$ is finite.

The ***extension of a substitution*** $s \colon V \longrightarrow 2^{U^*}$ from its domain alphabet V to the set V^* of strings over V is given by the rules $s(\lambda) = \{\lambda\}$ and $s(ax) = s(a)s(x)$, for $a \in V, x \in V^*$.

A ***morphism from the alphabet*** V to the alphabet U is a substitution $s \colon V \longrightarrow 2^{U^*}$ such that the replacement set $s(a)$ for every symbol $a \in V$ is a singleton set.

A λ***-free substitution*** is a substitution such that λ is never substituted for a symbol. That is, $\lambda \notin s(a)$, for every symbol $a \in V$.

A λ***-free morphism*** is a morphism such that $s(a) \neq \{\lambda\}$, for every symbol $a \in V$.

The ***extension of a substitution*** $s \colon V \longrightarrow 2^{U^*}$ to the language $L \subseteq V^*$ is the language $s(L) = \bigcup_{x \in L} s(x)$ that contains every string in U^* obtainable from a string in L by making replacements permissible under substitution s.

The ***inverse of a morphism*** $h \colon V^* \longrightarrow U^*$ is the mapping $h^{-1} \colon U^* \longrightarrow 2^{V^*}$ defined by $h^{-1}(x) = \{y \in V^* \mid h(y) = x\}$, $x \in U^*$.

A family of languages is ***nontrivial*** if it contains at least one language different from $\emptyset$ and $\{\lambda\}$.

Facts:

1. The set of all binary strings with at least as many 1s as 0s is a language.

2. The set of all binary strings in which no two occurrences of 1 are consecutive is a language.

3. Some strings of a natural language such as English are categorized as nouns, verbs, and adjectives. Other more complicated strings are categorized as sentences.

4. Some strings of common computer languages are categorized as identifiers and arithmetic expressions. Other more complicated strings are categorized as statements, with subcategories such as assignment statements, if-statements, and while-statements.

Examples:

1. Natural languages and computer languages are formal languages.

2. The Kleene closure of the language $\{00, 01, 10, 11\}$ is the language of all strings of even length.

3. The left derivative {bee}\English includes the following strings: f, n, p, r, s, t, tle, ts, keeper, swax, feater, ping.

4. The substitution $0 \mapsto \{00, 01\}, 1 \mapsto \{10, 11\}$ over the free monoid $\{0, 1\}^*$ is the language of all strings of even length.

5. Given the alphabet $\{a, b\}$, define the morphism $\phi\colon \{a, b\} \longrightarrow \{a, b\}^*$ by the replacements $\phi(a) = ab$ and $\phi(b) = ba$, and define the string w_n by the recursion $w_0 = a$ and $w_{n+1} = \phi(w_n)$. Then

$$w_1 = ab, \quad w_2 = abba, \quad w_3 = abbabaab, \quad w_4 = abbabaabbaababba, \ldots .$$

6. In Example 5 each word w_n is a prefix of the next word w_{n+1}. The *Thue ω-word* is the infinite word $\lim_{n\to\infty} w_n$.

7. Given the alphabet $\{a, b\}$, define the morphism $\rho\colon \{a, b\} \longrightarrow \{a, b\}^*$ by the replacements $\rho(a) = ab$ and $\rho(b) = a$, and define the string w_n by the recursion $w_0 = a$ and $w_{n+1} = \phi(w_n)$. Then

$$w_1 = ab, \quad w_2 = aba, \quad w_3 = abaab, \quad w_4 = abaababa, \ldots .$$

8. In Example 7 each word w_n is a prefix of the next word w_{n+1}. The *Fibonacci ω-word* is the infinite word $\lim_{n\to\infty} w_n$.

9. A language is regular if and only if it is the language of strings accepted by some finite-state recognizer.

17.3.3 GRAMMARS AND THE CHOMSKY HIERARCHY

Definitions:

A ***phrase-structure grammar*** (or ***unrestricted grammar*** or ***type 0 grammar***) is a quadruple $G = (N, T, S, P)$ such that

- N is a finite alphabet of symbols called ***nonterminals***;
- T is a finite nonempty alphabet, disjoint from N, of symbols called ***terminals***;
- S is a nonterminal called the ***start symbol***;

- P is a finite set of ***production rules*** of the form $\alpha \to \beta$, where α is a string in $N \cup T$ that contains at least one nonterminal and β is a string in $N \cup T$.

The ***antecedent*** of a production $\alpha \to \beta$ is α. The ***consequent*** of a production $\alpha \to \beta$ is β.

The string y is ***directly derivable*** from the string x with respect to the grammar G if there is a production rule $u \to v \in P$ and if there are strings $w_1, w_2 \in (N \cup T)^*$ such that $x = w_1uw_2$ and $y = w_1vw_2$.

The ***direct derivability relation*** $x \Longrightarrow_G y$ (or $x \Longrightarrow y$, when the grammar G is understood) means that y is directly derivable from string x.

A ***derivation*** of the string y from the string x is a sequence of direct derivations $x \Longrightarrow z_1$, $z_1 \Longrightarrow z_2, \ldots, z_n \Longrightarrow y$. This is sometimes called ***parsing***.

The string y is ***derivable*** from the string x with respect to the grammar G if there is a derivation of y from x. *Notation*: $x \Longrightarrow^* y$.

The ***Chomsky normal form for a production rule*** is $A \to BC$, where B and C are nonterminals or the form $A \to a$ where a is a terminal.

The ***language generated by the grammar*** G is the language $L(G) = \{x \in T^* \mid S \Longrightarrow^* x\}$.

Grammars G_1 and G_2 are ***equivalent*** if $L(G_1) = L(G_2)$.

A ***leftmost derivation*** $x \Longrightarrow_{left} y$ is a derivation $x \Longrightarrow y$ in which at each step the leftmost nonterminal is replaced.

The ***leftmost language generated by the grammar*** G is the language $L_{left}(G)$ of strings of terminals with leftmost derivations from the start symbol S.

A grammar (N, T, S, P) is ***length-increasing*** (or ***monotonic***) if $|u| \leq |v|$ for all productions $u \to v$. (However, the production $S \to \lambda$ is allowed, provided that S does not appear in any consequent.)

A grammar (N, T, S, P) is ***context-sensitive*** (or of ***type 1***) if for each production $u \to v$, the antecedent and consequent have the form $u = u_1Au_2$ and $v = u_1xu_2$, for $u_1, u_2 \in (N \cup T)^*$, $A \in N$, $x \in (N \cup T)^+$. (The production $S \to \lambda$ is allowed, provided that S does not appear in any consequent.)

A grammar (N, T, S, P) is ***context-free*** (or of ***type 2***) if the antecedent of each production $u \to v$ is a nonterminal.

An ***L-system*** is a production-based model for growth and life development.

A grammar (N, T, S, P) is ***linear*** if each production $u \to v$ has its antecedent $u \in N$ and its consequent $v \in T^* \cup T^*NT^*$.

A grammar (N, T, S, P) is ***right-linear*** if each production $u \to v$ has $u \in N$ and $v \in T^* \cup T^*N$.

A grammar (N, T, S, P) is ***left-linear*** if each production $u \to v$ has $u \in N$ and $v \in T^* \cup NT^*$.

A grammar (N, T, S, P) is ***regular*** (or of ***type 3***) if each production $u \to v$ has $u \in N$ and $v \in T \cup TN \cup \{\lambda\}$.

Given a class of grammars, there are some basic decision problems about arbitrary grammars G_1, G_2 in the class:

equivalence: are the grammars G_1 and G_2 equivalent?

inclusion: is the language $L(G_1)$ contained in the language $L(G_2)$?

membership: given an arbitrary string x, is x an element of $L(G_1)$?

emptiness: is the language $L(G_1)$ empty?

finiteness: is the language $L(G_1)$ finite?

regularity: is $L(G_1)$ a regular language? (see §17.3.2)

The ***recursive*** languages are the languages with a decidable membership question.

The various classes of languages are denoted as follows:

RE (type 0): the class of all unrestricted languages;

CS (type 1): the class of all context-sensitive languages;

CF (type 2): the class of all context-free languages;

LIN: the class of all linear languages;

REG (type 3): the class of all regular languages.

Facts:

1. *Chomsky hierarchy*: The following strict inclusions hold.

$$\mathbf{REG} \subset \mathbf{LIN} \subset \mathbf{CF} \subset \mathbf{CS} \subset \mathbf{RE}.$$

2. The language of an unrestricted grammar is recursively enumerable (RE).

3. **CS** (context sensitive) $\subset$ {recursive languages} $\subset$ **RE** (unrestricted).

4. The class of languages generated by monotonic grammars is identical to the class of languages generated by context-sensitive grammars.

5. L-systems were introduced in 1968 by Aristid Lindenmayer (1922–1990), a Dutch biologist, to model the development of some plant systems. (See [Li16].)

6. The classes of languages generated by right-linear or by left-linear grammars coincide. This class is identical to the family of languages generated by regular grammars, as well as to the class of regular languages (see §17.3.2).

7. $L_{left}(G) \in$ **CF** (context-free) for each type-0 grammar G.

8. If G is a context-free grammar, then $L_{left}(G) = L(G)$.

9. Let G be a context-free grammar. Then there is an equivalent grammar G', with every rule in Chomsky normal form. Moreover, there is constructive method for transforming grammar G into the grammar G'.

10. The following table gives closure properties for Chomsky hierarchy classes.

	RE	**CS**	**CF**	**LIN**	**REG**
union	yes	yes	yes	yes	yes
intersection	yes	yes	no	no	yes
complement	no	yes	no	no	yes
concatenation	yes	yes	yes	no	yes
Kleene star	yes	yes	yes	no	yes
intersection with regular languages	yes	yes	yes	yes	yes
substitution	yes	no	yes	no	yes
λ-free substitution	yes	yes	yes	no	yes
morphisms	yes	no	yes	yes	yes
λ-free morphisms	yes	yes	yes	yes	yes
inverse morphisms	yes	yes	yes	yes	yes
left/right quotient	yes	no	no	no	yes
left/right quotients with regular languages	yes	no	yes	yes	yes
left/right derivative	yes	yes	yes	yes	yes
shuffle	yes	yes	no	no	yes
mirror image	yes	yes	yes	yes	yes

11. *Rice's theorem*: Let P be a nontrivial property of recursively enumerable languages (i.e., at least one grammar has property P and at least one grammar does not have property P). Then property P is undecidable.

12. A language is context-free if and only if it is the language accepted by some (possibly nondeterministic) pushdown automaton.

13. The following table summarizes the decidability properties of the grammar classes in the Chomsky hierarchy. In this table U stands for *undecidable*, D for *decidable*, and T for *trivial*.

	RE	**CS**	**CF**	**LIN**	**REG**
equivalence	U	U	U	U	D
inclusion	U	U	U	U	D
membership	U	D	D	D	D
emptiness	U	U	D	D	D
finiteness	U	U	D	D	D
regularity	U	U	U	U	T

Examples:

1. In the grammar $G = (N, T, S, P)$, where $N = \{S\}$, $T = \{0, 1\}$, and $P = \{S \to 0S1, S \to \lambda\}$, a derivation of the string 0011 is $S \Longrightarrow 0S1 \Longrightarrow 00S11 \Longrightarrow 0011$.

2. The following are examples of languages generated by the grammar $G = (N, T, S, P)$ with $N = \{S, x, y, z\}$, $T = \{0, 1, 2\}$:

production set P	*language L(G)*	*class*
$S \to 0x$, $x \to 1y$, $y \to 0x$, $x \to 1$, $y \to \lambda$	$\{01, 0101, 010101, \ldots\}$	regular
$S \to \lambda, S \to 0x, S \to 01, x \to S1$	$\{0^n1^n \mid n \geq 0\}$	linear
$S \to \lambda$, $S \to 0Sx2$, $2x \to x2$, $0x \to 01$, $1x \to 11$	$\{0^n1^n2^n \mid n \geq 0\}$	unrestricted

17.3.4 REGULAR AND CONTEXT-FREE LANGUAGES

Definitions:

Given an alphabet V, a ***regular expression*** over V is a string w over the alphabet $V \cup \{\epsilon,), (, +, *\}$ that has one of the following forms:

- $w \in V$ or $w = \epsilon$;
- $w = (\alpha\beta)$, where α and β are regular expressions;
- $w = (\alpha + \beta)$, where α and β are regular expressions;
- $w = \alpha^*$, where α is a regular expression.

The set of all regular expressions over alphabet V is denoted $\mathbf{rex}_V$.

The function L maps $\mathbf{rex}_V$ to the set of all languages over the alphabet V, using the following rules:

- $L(\epsilon) = \emptyset$, and $L(a) = \{a\}$ for all $a \in V$;
- $L((\alpha\beta)) = L(\alpha)L(\beta), L((\alpha + \beta)) = L(\alpha) \cup L(\beta)$, and $L(\alpha^*) = (L(\alpha))^*$.

A context-free grammar G is ***ambiguous*** if there is a string $x \in L(G)$ having two different leftmost derivations in G.

A context-free language L is ***inherently ambiguous*** if every context-free grammar of L is ambiguous; otherwise, language L is called ***unambiguous***.

Facts:

1. *Kleene's theorem*: A language L is regular if and only if there is a regular expression e such that $L = L(e)$.

2. Every context-free language over a one-letter alphabet is regular.

3. Every regular language L can be represented in the form $L = h_4(h_3^{-1}(h_2(h_1^{-1}(a^*b))))$, where h_1, h_2, h_3, h_4 are morphisms.

4. Each regular language is unambiguous.

5. There are inherently ambiguous linear languages.

6. The ambiguity problem for context-free grammars is undecidable.

7. The length set of a context-free language is a finite union of arithmetical progressions.

8. Every language L can be represented in the form $L = h(L_1 \cap L_2)$, as well as in the form $L = L_3 \backslash L_4$, where h is a morphism and L_1, L_2, L_3, L_4 are linear languages.

9. *Pumping lemma for regular languages*: If L is a regular language over the alphabet V, then there are numbers p and q such that every string $z \in L$ with length $|z| > p$ can be written in the form $z = uvw$, with $u, v, w \in V^*$, where $|uv| \leq q, v \neq \lambda$, so that $uv^iw \in L$ for all $i \geq 0$.

10. *Pumping lemma for linear languages*: If L is a linear language on the alphabet V, then there are numbers p and q such that every string $z \in L$ with length $|z| > p$ can be written in the form $z = uvwxy$, with $u, v, w, x, y \in V^*$, where $|uvxy| \leq q$ and $vx \neq \lambda$, so that $uv^iwx^iy \in L$ for all $i \geq 0$.

11. *Bar-Hillel (uvwxy, pumping) lemma for context-free languages*: If L is a context-free language over the alphabet V, then there are numbers p and q such that every string $z \in L$ with length $|z| > p$ can be written in the form $z = uvwxy$, with $u, v, w, x, y \in V^*$, where $|vwx| \leq q$ and $vx \neq \lambda$, so that $uv^iwx^iy \in L$ for all $i \geq 0$.

12. *Ogden's pumping lemma (pumping with marked positions)*: If L is a context-free language on the alphabet V, then there is a number p such that for every string $z \in L$ and for every set of at least p marked occurrences of symbols in z, we can write $z = uvwxy$, where (a) either each of u, v, w or each of w, x, y contains at least one marked symbol; (b) vwx contains at most p marked symbols; and (c) $uv^iwx^iy \in L$ for all $i \geq 0$.

13. Let G be a context-free grammar G. Then there is a grammar $G' = (N, T, S, P)$, with every rule of the form $A \to a\alpha$, for $A \in N, a \in T, \alpha \in (N \cup T)^*$, such that $L(G') = L(G) - \{\lambda\}$. Moreover, there is a constructive method for transforming grammar G into the grammar G', which is said to be in the *Greibach normal form*.

14. Let G be a context-free grammar G and (k, l, m) a triple of nonnegative integers. Then an equivalent grammar $G' = (N, T, S, P)$ can be effectively constructed whose every rule is in one of the following two forms:

- $A \to xByCz$, with $A, B, C \in N, x, y, z \in T^*$, and $|x| = k, |y| = l, |z| = m$;
- $A \to x$, with $A \in N, x \in T^*, |x| \in length(L(G))$.

Such a grammar G' is said to be in *super normal form*.

Examples:

1. The following are some regular expressions over $\{0, 1\}$ and the languages they represent.

1^*	all strings with no 0s
1^*01^*	all strings with exactly one 0
$1^*(0+\epsilon)1^*$	all strings with one or no 0s
$(0+1)(0+1)$	all strings of length 2
$(0+1)(0+1+\epsilon)$	all strings of length 1 or 2.

2. *Backus-Naur form* (*BNF*) (or *Backus normal form*) for specifying computer language syntax uses context-free production rules. Nonterminals are enclosed in brackets; the symbol ::= is used in place of →; and all the consequents of the same antecedent are written in the same statement with the alternative consequents separated by vertical bars. For instance, in some programming languages, the following might be the BNF for the lexical token called an identifier.

⟨identifier⟩ ::= ⟨letter⟩|⟨letter⟩⟨alphameric string⟩
⟨letter⟩ ::= a|b|c|d|e|f|g|h|i|j|k|l|m|n|o|p|q|r|s|t|u|v|w|x|y|z
⟨alphameric string⟩ ::= ⟨alphameric⟩|⟨alphameric string⟩⟨alphameric⟩
⟨alphameric⟩ ::= ⟨letter⟩|⟨digit⟩
⟨digit⟩ ::= 0|1|2|3|4|5|6|7|8|9

17.3.5 COMBINATORICS ON WORDS

Note: In this subsection, a *word* is taken to be finite.

Definitions:

A (***word***) ***variable*** over an alphabet V is a symbol (such as x or y) not in V whose values range over V^*.

A ***pattern*** in a word is a string of word variables.

A pattern is ***present*** in a word $w \in V^*$ if there exists an assignment of strings from V^+ to the variables in that pattern such that the word formed thereby is a substring of w.

A ***square*** is a word of the pattern "xx".

A ***square-free*** word is a word with no subwords of the pattern "xx".

A ***cube*** is a word of the pattern "xxx".

An ***abelian square*** is a word of the form xx^p, where x^p is some permutation of the word x.

A ***word equation*** over an alphabet V is an expression of the form $\alpha = \beta$ such that α and β are words containing letters of an alphabet V and some variables over V.

A ***word inequality*** is the negation of a word equation, which is commonly written in the form $\alpha \neq \beta$.

A ***solution*** to a system S of (finitely many) word equations and word inequalities is a list of words whose substitutions for their respective variables converts every word equation and word inequality in the system into a true proposition.

A ***code*** is a nonempty language $C \subseteq V^+$ such that whenever a word w in V can be written as a concatenation of words in C, the write-up is always unique. That is, if $w = x_1 \ldots x_m = y_1 \ldots y_n$, where $m, n \geq 1$, and $x_i, y_j \in C$, then $m = n$ and $x_i = y_i$ for $i = 1, \ldots, m$. This property is called ***unique decodability***.

The ***code indicator of a word*** $w \in V^*$ is the number $ci(w) = |V|^{-|w|}$.

The ***code indicator of a language*** is the sum of the code indicators of all words in the language.

Facts:

1. Certain patterns are *unavoidable* in sufficiently long words.

2. Squares are avoidable in alphabets with three or more letters; that is, there are arbitrarily long square-free words.

3. Cubes are avoidable over two-letter alphabets.

4. Although squares are avoidable in three-letter alphabets, abelian squares are unavoidable. Every word of length ≥ 8 over $V = \{a, b, c\}$ contains a subword of the form $xx^p, x \in V^+$, where x^p is a permutation of x.

5. Abelian squares are avoidable in alphabets with four or more letters.

6. It is *decidable* (by *Makanin's algorithm*) whether or not a system of word equations and inequalities has a solution.

7. It is decidable whether or not a given finite language is a code.

8. Every code C satisfies the inequality $ci(C) \leq 1$.

9. If a language $C = \{w_1, \ldots, w_n\}$ over V is not a code then, by the so-called *defect theorem*, the algebraic structure of C^* can be simulated by an alphabet with at most $n-1$ letters: the smallest free submonoid of V^* containing C is generated by at most $n-1$ words.

10. The following three conditions are equivalent for any two words u and v:

- $\{u, v\}$ is not a code;
- u and v are powers of the same word;
- $uv = vu$.

(This is a corollary to Fact 9.)

11. For every word $w \in V^+$, there are a unique shortest word $\rho(w)$ and an integer $n \geq 1$ such that $w = (\rho(w))^n$. (The word $\rho(w)$ is called the *primitive root* of w.)

12. *Lyndon's theorem*: If $uv = vw$ with $u, v, w \in V^*$, then there exist words $x, y \in V^*$ and a number $n \geq 0$ such that $u = xy, w = yx$ and $v = (xy)^n x = x(yx)^n$.

13. If $uv = vu$ with $u, v \in V^+$, then $\rho(u) = \rho(v)$ and, consequently, u and v are powers of the same word. (This is a corollary to Lyndon's theorem.)

14. Assume that words u^m and v^n have a common prefix or suffix of length $|u| + |v| - d$, where $u, v \in V^+, m, n \geq 1$ and $d = \gcd(|u|, |v|)$. Then $\rho(u) = \rho(v)$ and $|\rho(u)| \leq d$. Thus, if $d = 1$ then u and v are powers of the same letter.

15. If $u^m = v^n$, where $m, n \geq 1$, then u and v are powers of the same word. (This is a corollary to Fact 14.)

16. If $u^m v^n = w^p$, where $m, n, p \geq 2$, then $\rho(u) = \rho(v) = \rho(w)$.

Examples:

1. In the alphabet $V = \{a, b\}$, the only square-free three-letter words are aba and bab. The two possible extensions of aba by one letter are $abaa$, which contains the square aa, and $abab$, which is a square. Similarly, both extensions of bab by one letter contain a square. Thus, squares are unavoidable in words of length ≥ 4 over two-letter alphabets.

2. All solutions for the system $xaba = abax, xx \neq x, x \neq aba$, over the alphabet $V = \{a, b\}$ are (by the corollary to Lyndon's theorem) of the form $x = (aba)^n, n \geq 2$.

17.4 ALGORITHMIC COMPLEXITY

The "complexity of an algorithm" usually means a measure of the computational effort or cost of execution, relative to the "size" of the problem. Other factors that may affect this kind of complexity are the characteristics of the particular input and the values returned by random number generators. The most common complexity measure is *running time*, but other measures, such as *space utilized* and *number of comparisons*, are sometimes used. Another view of complexity focuses on the complicatedness of the algorithm, rather than on the effort needed to execute it.

17.4.1 OVERVIEW OF COMPLEXITY

To simplify discussion, it is assumed that every function and algorithm under consideration here has one argument. (Everything is easily generalized to multivariate functions by regarding the list of arguments as an n-tuple.)

Definitions:

A function $f\colon \mathcal{N} \to \mathcal{N}$ is ***asymptotic*** to a function $g\colon \mathcal{N} \to \mathcal{N}$ if $\lim_{n\to\infty} f(n)/g(n) = 1$. *Notation:* $f(n) \sim g(n)$. (See §1.3.3.)

The ***input size*** of the argument of an algorithm is the number of bits required to specify a value of that argument (or sometimes the argument's numeric value).

A (***cost-based***) ***complexity measure*** for an algorithm is any of several different asymptotic measures of cost or difficulty in running that algorithm, relative to the input size. It is given in big-O notation (or sometimes in Θ-notation). (See §1.3.3.)

A ***time-complexity*** measure of an algorithm is a big-O expression for the number of operations or the running time needed for a complete execution of that algorithm, represented as a function of the size of the input.

A ***space-complexity*** measure of an algorithm is a big-O expression for the amount of computational space needed in the execution of that algorithm, represented as a function of the size of the input.

An algorithm runs in ***polynomial time*** if its time-complexity is dominated by a polynomial.

An algorithm runs in ***polynomial space*** if its space-complexity is dominated by a polynomial.

A ***Kolmogorov-Chaitin complexity measure*** of an algorithm is a measure based on the number of instructions of the algorithm, which is taken as an estimate of the logical complicatedness.

The ***time-complexity*** of a computable function is the minimum time-complexity taken over all algorithms that compute the function.

The ***parallel time-complexity*** of a computable function is the minimum time-complexity taken over all parallel algorithms that compute the function.

The ***space-complexity*** of a computable function is the minimum space-complexity taken over all algorithms that compute the function.

A ***decision function*** is a function on a countably infinite domain that decides whether an object is in some specified subset of that domain.

A computable decision function is in ***class*** **P** (*polynomial*) if its time-complexity is polynomial.

A computable decision function is in ***class*** **NP** (*nondeterministic polynomial*) if its parallel time-complexity is polynomial.

A function g ***reduces*** a decision function h to a decision function f if $h = f \circ g$.

A computable decision function f is **NP-*hard*** if every decision function in class NP can be reduced to f by a polynomial-time function.

A computable decision function is **NP-*complete*** if it is NP-hard and is in class NP.

A ***tractable problem*** is a set-membership problem with a decision function in class P.

Facts:

1. The previous definitions can be rephrased in terms of problems and algorithms.

- A problem is in *class P* (or *tractable*) if it can be solved by an algorithm that runs in polynomial time;
- A problem is in *class NP* if, given a tentative solution (obtained by any means), it is possible to check that the solution is correct in polynomial time;
- A problem is *NP-complete* if it is in class NP and is NP-hard.

2. When considering whether a given problem belongs to P or NP, and whether it might be NP-complete, it is helpful to rewrite the problem, or an associated problem, as a decision problem (which has a yes/no answer) because decision problems have been easier to characterize and classify than general problems. For example, see the description of the traveling salesman problem in Example 3 in this section.

3. Time-complexity of sorting algorithms is typically measured by the number of comparisons needed.

4. The words *good*, *efficient*, and *feasible* are commonly used interchangeably to mean polynomial-time.

5. Additive and multiplicative constants that are ignored in big-O analysis of an algorithm can sometimes be too large for practical application.

6. That a problem belongs to P does not necessarily imply that it can be solved in a practical amount of time, since the polynomial bound of its complexity can be of high degree. Fortunately, however, for most problems in P arising in practical applications, the polynomial bound is of relatively small degree.

7. Belonging to class NP means that a solution can be *checked* in polynomial time, but not necessarily *found* in polynomial time.

8. When a problem is in class NP, it may be possible to solve the problem for cases arising in practical applications in a reasonable amount of time, even though there are other cases for which this is not true. Also, such problems can often be attacked using *approximation algorithms* that do not produce the exact solution, but instead produce a solution guaranteed to be close in some precise sense to the actual solution.

9. Every problem in class P is in class NP.

10. It often requires only a small change to transform a problem in class P to one in class NP. For example, the first four problems in Example 2 (Euler graph, edge cover, linear Diophantine equation, 2-satisfiability) are in class P, but the similar first four problems in Example 3 (Hamilton graph, vertex cover, quadratic Diophantine equation, 3-satisfiability), each of which results from seemingly small changes in the respective problem from class P, are in class NP.

11. To show a problem is NP-complete, the problem can be transformed (in a specific way) to a problem already known to be NP-complete. This is often much easier than showing directly that the problem is NP-complete. See [GaJo79] for details.

12. If there is an NP-hard problem that belongs to P, then P = NP.

13. Not all NP problems are known to be NP-complete. (See Example 4 for such a problem.)

14. Deciding whether P = NP is the outstanding problem in the theory of computational complexity. It is the common belief that P $\neq$ NP, based on an extensive search for polynomial-time solutions to various NP problems.

15. The first problem to be shown to be NP-complete was the *satisfiability problem* (Example 3). That the satisfiability problem is NP-complete is called *Cook's theorem*, after Steven A. Cook, who discovered it in 1971. [Co71]

16. In 1972 Richard Karp proved that the traveling salesman problem (TSP) (and many others) were NP-complete. [Ka72]

17. Hundreds of thousands of problems (in many areas, including mathematics, computer science, operations research, physics, biology) are known to be NP-complete.

18. Extensive information on NP-completeness (methods of proof, examples, etc.) can be found in [AtBl09a], [GaJo79], [GoDíTu14], and [vL90].

19. A more formal approach to complexity, given in terms of Turing machines, appears in §17.5.

Examples:

1. The following table gives some different input size variables for different problem types.

problem type	*typical input size parameters*
database sorting	number of records
graph algorithms	number of vertices and/or number of edges
arithmetic computation	numbers of digits in the numerals
convex hull construction	number of points

2. The following problems are in class P.

- *Euler graph*: given a graph, determine whether the graph has an Euler circuit;
- *edge cover*: given a graph G and positive integer n, determine whether there is a subset E of edges of G with $|E| \leq n$ and every vertex of G an endpoint of an edge in E;
- *linear Diophantine equation*: given positive integers a, b, c, determine whether $ax + by = c$ has a solution in positive integers x and y;
- *2-satisfiability*: given a Boolean expression in conjunctive normal form in which each sum contains only two variables, determine whether the expression is "satisfiable" (i.e., there is an assignment of 0 and 1 to the variables such that the expression has value 1);
- *cycle rank*: given a graph G and positive integer n, determine whether there is a subset E of edges of G with $|E| \leq n$ such that each cycle in G contains an edge in E;
- *linear programming*: maximize cx subject to $Ax \leq b$ where A is a given $q \times n$ matrix, c is a given row vector of length n, and b is a given column vector of length q (see §16.1.1).

3. The following problems are NP-complete.

- *Hamilton graph*: given a graph, determine whether the graph has a Hamilton circuit;
- *vertex cover*: given a graph G and positive integer n, determine whether there is a subset V of vertices of G with $|V| \leq n$ with every edge of G having an endpoint in V;
- *quadratic Diophantine equation*: given positive integers a, b, c, determine whether the equation $ax^2 + by = c$ has a solution in positive integers x and y;
- *3-satisfiability*: given a Boolean expression in conjunctive normal form in which each sum contains only three variables, determine whether the expression is "satisfiable" (i.e., there is an assignment of 0 and 1 to the variables such that the expression has value 1);
- *satisfiability*: given a Boolean expression in conjunctive normal form, determine whether the expression is "satisfiable" (i.e., there is an assignment of 0 and 1 to the variables such that the expression has value 1) (see Fact 15);
- *traveling salesman problem*: given a weighted graph and positive number k, determine whether there is a Hamilton circuit of weight at most k (see §10.7.1);

- *independent vertex set*: given a graph G and a positive integer n, determine whether G contains an independent vertex set of size at least n;
- *knapsack problem*: given a set S, values a_i and b_i for each $i \in S$, and numbers a and b, determine whether there is a subset $T \subseteq S$ such that $\sum_{i\in T} a_i \le a$ and $\sum_{i\in T} b_i \ge b$ (see §16.3.1);
- *bin packing problem*: given k bins (each of capacity c) and a collection of weights, determine whether the weights can be placed in the bins so that no bin has its capacity exceeded (see §16.3.2);
- *3-coloring*: given a graph G, determine whether its vertices can be colored with 3 colors;
- *clique problem*: given a graph G and positive integer n, determine whether G has a clique of size at least n;
- *dominating set*: given a graph G and positive integer n, determine whether G has a dominating set of size at most n;

4. The following problem is an NP problem, but not known to be NP-complete nor known to be in P.

- *graph isomorphism*: given two graphs, determine whether they are isomorphic.

17.4.2 WORST-CASE AND AVERAGE-CASE ANALYSIS

Definitions:

A ***worst-case complexity measure*** of an algorithm is based on the maximum computational cost for any input of that size. It is usually expressed in big-O asymptotic notation (or sometimes Θ-notation) as a formula based on the input size variables.

An ***average-case complexity measure*** of an algorithm is based on the expected computational cost over a random distribution of its inputs of a given size.

Facts:

1. Algorithmic analysis of deterministic algorithms often assumes a uniform random distribution of the possible inputs, when the actual distribution is unknown.

2. For sorting algorithms, an average-case analysis may assume that all input permutations of the keys to be sorted are equally likely. In practice, however, some permutations may be far more likely than others, e.g., already sorted, almost sorted, or reverse sorted.

3. The input size measures for average-case analysis are usually the same as for worst-case analysis.

Examples:

1. The following table gives the worst-case running times of some sorting algorithms [CoEtal09], where the input size parameter n is the number of records.

sorting method	*worst-case complexity*
insertion sort	$\Theta(n^2)$
selection sort	$\Theta(n^2)$
bubble sort	$\Theta(n^2)$
heapsort	$\Theta(n \log n)$
quicksort	$\Theta(n^2)$
mergesort	$\Theta(n \log n)$

2. The following table gives the worst-case running times of some graph algorithms, based on input size parameters $|V|$ and $|E|$, which are the numbers of vertices and edges.

graph algorithm	*worst-case complexity*
Kruskal's MST algorithm	$\Theta(\lvert E\rvert \log \lvert V\rvert)$
Dijkstra's shortest-path algorithm with linked-list priority queue	$O(\lvert V\rvert^2)$
Dijkstra's shortest-path algorithm with heap-based priority queue	$O(\lvert E\rvert \log \lvert V\rvert)$ [CoEtal09]
Dijkstra's shortest-path algorithm with Fibonacci-heap priority queue	$O(\lvert E\rvert + \lvert V\rvert \log \lvert V\rvert)$ [CoEtal09]
Edmonds-Karp max-flow algorithm	$O(\lvert V\rvert \cdot \lvert E\rvert^2)$

3. The following table gives the worst-case running times of some plane convex hull algorithms (see §13.5.1), based on the number n of points supplied as input.

convex hull algorithm	*worst-case complexity*
Graham Scan	$\Theta(n \log n)$
Jarvis March ("gift-wrapping")	$\Theta(nh)$, $h = \#$ corners (convex hull)
QuickHull	$O(n^2)$
MergeHull	$O(n \log n)$

4. The following table gives the average-case running times of some sorting algorithms, where the input size parameter n is the number of records.

sorting method	*average-case complexity*
insertion sort	$O(n^2)$
selection sort	$O(n^2)$
bubble sort	$O(n^2)$
heapsort	$O(n \log n)$
quicksort	$O(n \log n)$
mergesort	$O(n \log n)$

5. *Randomized quicksort* (Algorithm 1) [CoEtal09]: A subarray from index p to index r of an array A is sorted, using an external subroutine $random(p, r)$ that generates a number in the set $\{p, \ldots, r\}$ in $O(1)$ time. Another external subroutine $partition(A, p, r)$ rearranges the subarray $A[p\,..\,r]$ and returns an index q, $p \le q < r$, such that for $i = p, \ldots, q$, $A[i] \le A[q]$ and such that for $i = q+1, \ldots, r$, $A[i] > A[q]$; this subroutine runs in $\Theta(r - p)$ worst-case time.

Algorithm 1: **Randomized quicksort.**

```
procedure randomized-quicksort($A, p, r$)
if $p < r$ then
    $i := random(p, r)$
    exchange $A[p]$ and $A[i]$
    $q := partition(A, p, r)$
    randomized-quicksort($A, p, q$)
    randomized-quicksort($A, q + 1, r$)
```

To sort n keys, randomized quicksort takes $\Theta(n^2)$ time in the worst case (when unlucky enough to have partition sizes always unbalanced), but only $\Theta(n \log n)$ time in the average case (partition sizes are usually at least a constant fraction of the total).

6. *Convex hull*: For some distributions of n points in the plane, the expected value $E[h]$ of the number of vertices on the convex hull is known. This bound implies that the average-case running time of Jarvis March is an additional factor of n greater:

distribution	$E[h]$	*average-case running time*
uniform in convex polygon	$O(\log n)$	$O(n \log n)$
uniform in circle	$O(n^{\frac{1}{3}})$	$O(n^{\frac{4}{3}})$
normal in plane	$O(\sqrt{\log n})$	$O(n\sqrt{\log n})$

17.4.3 LOWER BOUNDS

Lower bounds on running times of algorithms are typically given as functions of input size using Ω-notation (see §1.3.3).

Definitions:

An ***existential lower bound*** for an algorithm is a lower bound for its running time that holds for at least one input.

An ***existential lower bound*** for a problem is a lower bound for every algorithm that could solve that problem.

A ***comparison sort*** is a sorting method that rearranges records based only on comparisons between keys.

The ***Euclidean minimum spanning tree*** (or ***Euclidean MST***) ***problem*** has as input vertices a set of n points in the plane and as output a spanning tree of minimum total edge length.

A ***reduction of a problem*** A to another problem B is the following sequence of steps:

- the input to problem A is transformed into an input to problem B;
- problem B is solved on the transformed input;
- the output of problem B is transformed back into a solution to problem A for the original input.

An $f(n)$ ***time reduction*** of problem A to problem B is a reduction such that the time for the three steps together is $f(n)$.

Facts:

1. For a given model of computation, if problem A has a lower bound of $T(n)$ and it reduces in $f(n)$ time to problem B, then problem B has a lower bound of $T(n) - f(n)$.

2. Every comparison sort on n records requires $\Omega(n \log n)$ comparisons in the worst case. This follows since there are $n!$ possible solutions, and each comparison can reduce this by at most a factor of 2. (Note that $\log_2(n!)$ is $\Omega(n \log n)$.)

3. Computing the Euclidean minimum spanning tree on n points takes $\Omega(n \log n)$ time in the worst case.

4. Unlike the Euclidean MST problem, most graph *problems* have no known nontrivial lower bound. Some graph *algorithms*, however, have lower bounds on their implementation.

5. Running Dijkstra's algorithm (see §10.3.2) on a directed graph with n vertices takes $\Omega(n \log n)$ time in the worst case.

6. Finding the vertices for the convex hull of n points in the plane, in *any* order, takes $\Omega(n \log n)$ time in the worst case.

7. Constructing the Voronoi diagram (see §13.5.3) on n points in the plane takes in the worst case $\Omega(n \log n)$ time.

Examples:

1. *An $O(n)$-time reduction of sorting to a gift-wrap of a convex hull*: Given a set of n positive numbers $\{x_1, \ldots, x_n\}$, first produce in $\Theta(n)$ time their respective squares $\{x_1^2, \ldots, x_n^2\}$. Since each point (x_j, x_j^2) lies on the parabola given by $y = x^2$, the Jarvis march on the convex hull of the points (x_j, x_j^2) is a list of points, ordered by abscissa. Sequentially read off the first coordinate of every point of the convex hull in $\Theta(n)$ time, thereby producing the sorted list of numbers. This implies that finding the gift-wrapped convex hull of n points requires at least $\Omega(n \log n) - \Theta(n) = \Omega(n \log n)$ time.

2. *An $O(n)$-time reduction of sorting numbers to Euclidean MST*: To sort n numbers $\{x_1, \ldots, x_n\}$, create n points $\{\,(x_i, 0) \mid 1 \leq i \leq n\}$ in the Euclidean plane. The Euclidean MST of this set contains an edge between points $(x_i, 0)$ and $(x_j, 0)$ if and only if the numbers x_i and x_j are consecutive in the sorted list of numbers. The Euclidean MST is easily converted back to a sorted list of numbers in $O(n)$ time. This implies that Euclidean MST requires at least $\Omega(n \log n) - \Theta(n) = \Omega(n \log n)$ time.

17.5 COMPLEXITY CLASSES

From a formal viewpoint, complexity theory is concerned with classifying the difficulty of testing for membership in various languages. This means deciding whether any given string is in the language. The general application of complexity theory is achieved by encoding decision problems on natural topics such as graph coloring and finding integer solutions to equations as set membership problems. A more comprehensive coverage of complexity theory is provided by many textbooks, including [DuKo00] and [HeOg02].

17.5.1 ORACLES AND THE POLYNOMIAL HIERARCHY

Throughout this section, whenever the *alphabet* is unspecified, it may be assumed to be the binary set $\{0, 1\}$. Also, throughout this section a *Turing machine* (see §17.1.3) is assumed to have among its states a unique *acceptance state* q_A and a unique *rejection state* q_R. All other states continue the computation.

Definitions:

A ***language over an alphabet*** is a set of strings on that alphabet (see §17.3.2).

A ***nondeterministic Turing machine*** is a 5-tuple $(K, s, h, \Sigma, \Delta)$ otherwise like a deterministic Turing machine, except that the transition function Δ maps each state-symbol pair (q, b) to a set of state-symbol-direction triples.

An ***oracle for a language*** L is a special computational state to which a machine presents a string w, which switches to special state Y ("yes") if $w \in L$ and to special state N ("no") if $w \notin L$.

An ***oracle Turing machine*** is a 6-tuple $(K, s, h, \Sigma, \delta$ or $\Delta, L)$, equipped with an oracle for language L and with a special second tape on which it can write a string over the alphabet of language L (which might be different from Σ). Aside from oracle steps, it is a Turing machine.

A Turing machine M ***accepts*** string w if there exists a computational path from the starting configuration with input w to the acceptance state q_A.

A Turing machine M ***rejects*** string w if it does not accept w. (Either M halts in rejection state q_R or does not halt.)

The ***language accepted by a Turing machine*** M is the set of all the strings it accepts. It is denoted $\mathcal{L}(M)$.

The Turing machine M ***decides*** the language $\mathcal{L}(M)$ if it always halts, even for input strings not in $\mathcal{L}(M)$.

A (possibly nondeterministic) Turing machine M is said to be of ***time complexity*** $\boldsymbol{T(n)}$ if for each n, each word x of length n, and (if M is nondeterministic) each sequence of nondeterministic choices made by M on input x, M halts within $T(|x|)$ steps.

A (possibly nondeterministic) Turing machine M is said to be of ***space complexity*** $\boldsymbol{S(n)}$ if for each n, each word x of length n, and (if M is nondeterministic) each sequence of nondeterministic choices made by M on input x, M scans at most $S(|x|)$ cells of any storage tape.

A Turing machine M has ***polynomial time complexity*** if there exists a polynomial $p(n)$ such that M is of time complexity $T(n)$.

A Turing machine M has ***polynomial space complexity*** if there exists a polynomial $p(n)$ such that M is of space complexity $T(n)$.

The complexity class **P** contains every language that can be decided by a deterministic TM with polynomial time complexity.

The complexity class **PSPACE** contains every language that can be decided by a deterministic TM with polynomial space complexity.

The complexity class **NP** contains every language that can be decided by a nondeterministic TM with polynomial time complexity.

For any language L, the complexity class $\mathbf{P}^{\boldsymbol{L}}$ contains every language that is decided in polynomial time by a deterministic TM with oracle L.

For any language L, the complexity class $\mathbf{NP}^{\boldsymbol{L}}$ contains every language that is decided in polynomial time by a nondeterministic TM with oracle L.

For any class $\mathcal{C}$ of languages, the complexity class $\mathbf{P}^{\boldsymbol{\mathcal{C}}}$ contains every language that is decidable in polynomial time by a deterministic TM with oracle $L \in \mathcal{C}$. Equivalently, notated in terms of reductions (see §17.5.2), $\mathrm{P}^{\mathcal{C}} = \{L \mid (\exists B \in \mathcal{C})[L \leq_T^p B]\}$.

For any class $\mathcal{C}$ of languages, the complexity class $\mathbf{NP}^{\boldsymbol{\mathcal{C}}}$ contains every language that is decidable in polynomial time by a nondeterministic TM with oracle $L \in \mathcal{C}$.

The complexity classes $\boldsymbol{\Sigma_n^p}$ are defined inductively by

$$\Sigma_k^p = \begin{cases} \mathrm{P} & \text{if } k = 0 \\ \mathrm{NP}^{\Sigma_{k-1}^p} & \text{if } k \geq 1. \end{cases}$$

The ***polynomial hierarchy*** **PH** is the collection comprising every language A for which there exists an n such that $A \in \Sigma_n^p$.

For $n \geq 0$, the polynomial hierarchy is said to ***collapse to its nth level*** if $\mathrm{PH} = \Sigma_n^p$. The polynomial hierarchy is said to ***collapse*** if for some $n \geq 0$ it collapses to its nth level.

For $n \geq 0$, the complexity class $\boldsymbol{\Pi_n^p}$ contains every language A such that $\overline{A} \in \Sigma_n^p$.

The complexity class **coNP** is Π_1^p.

The complexity class $\boldsymbol{\Delta_0^p}$ is P. For $n \in \mathcal{Z}^+$, the complexity class $\boldsymbol{\Delta_n^p}$ is $\mathrm{P}^{\Sigma_{n-1}^p}$.

The complexity class **P/poly** contains each set A such that there exist a set $B \in \mathrm{P}$, a function h, and a polynomial $f(\cdot)$ such that $(\forall n)[|h(n)| \leq f(n)]$ and $(\forall x)\,[x \in A \iff \langle x, h(|x|)\rangle \in B]$.

A language B is ***sparse*** if there exists a polynomial $p(n)$ such that for every $n \in \mathcal{N}$, there are at most $p(n)$ elements of length n in B.

Facts:

1. The following equalities hold: $\Sigma_0^p = \Pi_0^p = \Delta_0^p = \Delta_1^p = \mathrm{P}$.

2. For $n \geq 0$, the following relationships hold:

$$\Delta_n^p \subseteq \Sigma_n^p \cap \Pi_n^p \begin{smallmatrix} \subseteq \Sigma_n^p \subseteq \\ \subseteq \Pi_n^p \subseteq \end{smallmatrix} \Sigma_n^p \cup \Pi_n^p \subseteq \Delta_{n+1}^p.$$

3. $\mathrm{PH} \subseteq \mathrm{PSPACE}$.

4. If PH = PSPACE, then the polynomial hierarchy collapses.

5. *Downward separation*: For each $n \geq 0$ it holds that: if $\Sigma_n^p = \Sigma_{n+1}^p$, then $\mathrm{PH} = \Sigma_n^p$. In particular, P = NP if and only if P = PH.

6. *Downward separation*: For each $n \geq 1$ it holds that: if $\Sigma_n^p = \Pi_n^p$, then $\mathrm{PH} = \Sigma_n^p$.

7. $\mathrm{NP} = \Sigma_1^p$.

8. The complexity class Σ_n^p is closed under union and intersection, for all $n \geq 0$.

9. $\mathrm{P}^{\mathrm{NP} \cap \mathrm{coNP}} = \mathrm{NP} \cap \mathrm{coNP}$. More generally, $\mathrm{P}^{\Sigma_n^p \cap \Pi_n^p} = \Sigma_n^p \cap \Pi_n^p$ and $\mathrm{P}^{\Delta_n^p} = \Delta_n^p$, for all $n \geq 0$.

10. *Upward separation*: Nondeterministic exponential time $\left(\bigcup_{c>0} \mathrm{NTIME}[2^{cn}]\right)$ is equal to deterministic exponential time $\left(\bigcup_{c>0} \mathrm{DTIME}[2^{cn}]\right)$ if and only if NP − P contains no sparse sets.

11. *Succinct certificates*: For every language in NP there is a proof scheme in which each member (and only members) has a polynomial-size "proof" of membership that can be checked in deterministic polynomial time. Such a short membership proof is sometimes called a *succinct certificate*.

12. Sets in P/poly are said to "have small circuits." Many circuit classes less inclusive than P/poly play an important role in complexity theory; see [Vo99].

13. $\mathrm{P/poly} = \mathrm{P}^{\{S \,|\, S \text{ is sparse}\}}$.

Examples:

1. *Logical proposition problems*: The problem of deciding whether a particular assignment of TRUE-FALSE values to the variables satisfies a logical proposition is in P. Deciding whether a proposition has an assignment that satisfies it is in NP. Deciding whether all assignments satisfy it (i.e., whether the proposition is a tautology) is in coNP.

2. *Graph isomorphism problems*: Deciding whether a given vertex bijection between two graphs realizes a graph isomorphism is in P. Deciding whether two graphs are isomorphic is in NP.

3. *Graph coloring problems*: Deciding whether an assignment of colors from a set of three colors to the vertices of a graph is a proper coloring is in P. Deciding whether a graph has a proper 3-coloring is in NP.

4. *Unique maximum clique problem*: Define UMC to be the set of graphs G with a clique $U \subseteq V_G$ such that every other clique is strictly smaller than U. Then UMC is in the class $\Delta_2^p = \mathrm{P}^{\mathrm{NP}}$.

5. To prove by succinct certificate that a given graph has some clique of size at least k, one can provide a list of k distinct vertices that are mutually adjacent. (The mutual adjacency condition for the k vertices can be verified in polynomial time.)

6. *P-selectivity*: A set L is said to be *semi-feasible* (or, equivalently, *P-selective*) if there is a polynomial-time computable function f such that for all x and y, (a) $f(x, y) = x$ or $f(x, y) = y$, and (b) $\{x, y\} \cap L \neq \emptyset \implies f(x, y) \in L$. All semi-feasible sets are in P/poly. (This can be seen by a divide and conquer argument.)

7. *The primality problem*: The language PRIMES, which consists of the bitstrings that represent prime numbers when interpreted as binary numerals, is in P.

17.5.2 REDUCIBILITY AND NP-COMPLETENESS

Definitions:

A language A over alphabet Σ is ***polynomial-time reducible*** (or ***m-p-reducible***) to a language B, denoted $A \leq_m^p B$, if there exists a polynomial-time computable function f such that, for each $x \in \Sigma^*$, it holds that $x \in A$ if and only if $f(x) \in B$.

A language A is **NP-*hard*** if every language in NP is polynomial-time reducible to A.

A language A is **NP-*complete*** if A is NP-hard and $A \in$ NP.

For a class of languages $\mathcal{C}$, a language A is ***$\mathcal{C}$-hard*** if every language in $\mathcal{C}$ is polynomial-time reducible to A.

A language A is ***$\mathcal{C}$-complete*** if A is $\mathcal{C}$-hard and $A \in \mathcal{C}$.

A language A is ***Turing-p-reducible*** to the language B, denoted $A \leq_T^p B$, if there is a deterministic oracle TM M such that M^B decides A in polynomial time.

A language A is ***$\mathcal{C}$-Turing-p-hard*** if every language in $\mathcal{C}$ is Turing-p-reducible to A.

A language A is ***$\mathcal{C}$-Turing-p-complete*** if A is $\mathcal{C}$-Turing-p-hard and $A \in \mathcal{C}$.

Facts:

1. For most NP-complete problems, showing membership in NP is easy.

2. For integer linear programming, however, it is easy to show NP-hardness, but showing membership in NP is nontrivial.

3. Polynomial-time reducibility is also called *Karp reducibility* after Richard Karp.

4. Turing-p-reducibility is also called *Cook reducibility* after Stephen Cook.

5. The complement of any NP-complete problem is coNP-complete.

6. If A is polynomial-time reducible to B, then A is Turing-p-reducible to B.

7. If $A \leq_m^p B$ and $B \leq_m^p C$, then $A \leq_m^p C$.

8. If $A \leq_T^p B$ and $B \leq_T^p C$, then $A \leq_T^p C$.

9. *Downward closure*: For $n \geq 0$, if $A \in \Sigma_n^p$ and $B \leq_m^p A$ then $B \in \Sigma_n^p$. In particular, if any NP-complete set is in P, then P = NP.

10. *Karp-Lipton theorem*: If there is a sparse NP-$\leq_T^p$-hard set, then PH = Σ_2^p.

11. If there is a sparse NP-$\leq_T^p$-complete set, then PH = Δ_2^p.

12. *Mahaney's theorem*: If there is a sparse NP-hard (or NP-complete) set, then P = NP.

13. *Ladner's theorem*: If P $\neq$ NP, then there exists a set in NP $-$ P that is not NP-complete.

14. A large catalog of NP-complete problems appears in [GaJo79]. A few of the most commonly cited appear in §17.4.1. A similar catalog for higher levels of the polynomial hierarchy appears in [ScUm02].

Examples:

1. For examples of NP-complete problems, see §17.4.1, Example 3.

2. *Quantified Boolean formulas*: Let QBF be the class of true statements of the form

$$(\exists x_1)\,(\forall x_2)\,(\exists x_3)\,(\forall x_4)\,\ldots\,(Q_z x_z)\,[F(x_1, x_2, \ldots, x_z)],$$

where F is a quantifier-free formula over the Boolean variables $x_1, \ldots, x_z$ and where Q_z is $\exists$ if z is odd and $\forall$ if z is even. QBF is PSPACE-complete.

3. *Tautologies problem*: The classic coNP-complete language is the set TAUTOLOGY of all logical propositions that are satisfied by every assignment of logical values to the variables.

4. *Graph isomorphism problem*: It is not known whether the set GI of isomorphic graph pairs is in coNP or whether GI is NP-complete, though it is known that GI is NP-complete only if the polynomial hierarchy collapses.

17.5.3 PROBABILISTIC TURING MACHINES

Definitions:

A ***probabilistic Turing machine*** is a nondeterministic Turing machine M with exactly two choices at each step. Each such choice occurs with probability $\frac{1}{2}$, and is independent of all previous choices.

The ***acceptance probability*** $p_M(w)$ that a probabilistic Turing machine M accepts input word w is the sum of the probabilities over all accepting computation paths on input w.

A probabilistic Turing machine M ***accepts language*** L ***with one-sided error*** if $p_M(w) > \frac{1}{2}$ if $w \in L$, and $p_M(w) = 0$ if $w \notin L$.

A probabilistic Turing machine M ***accepts language*** L ***with two-sided error*** if $p_M(w) > \frac{1}{2}$ if $w \in L$, and $p_M(w) \leq \frac{1}{2}$ if $w \notin L$.

A probabilistic Turing machine M ***accepts language*** L ***with bounded two-sided error*** if there exists some $\epsilon > 0$ such that for all w, $p_M(w) > \frac{1}{2} + \epsilon$ if $w \in L$ and $p_M(w) < \frac{1}{2} - \epsilon$ if $w \notin L$.

The complexity class **RP** (the random polynomial-time languages) is the class of languages that are decided by Turing machines with one-sided error in polynomial time.

The complexity class **coRP** contains the language A if $\overline{A} \in \mathrm{RP}$.

The complexity class **ZPP** (the zero-error probabilistic polynomial-time languages) is the intersection $\mathrm{RP} \cap \mathrm{coRP}$.

The complexity class **PP** (the probabilistic polynomial-time languages) is the class of languages that are decided by Turing machines with two-sided error in polynomial time.

The complexity class **BPP** (the bounded-error probabilistic polynomial-time languages) is decided by Turing machines with bounded two-sided error in polynomial time.

The complexity class **#P** is the class of all functions f such that there exists a nondeterministic polynomial-time Turing machine M such that, for each x, $f(x) = \#\mathrm{acc}_M(x)$, where $\#\mathrm{acc}_M(x)$ denotes the number of accepting computation paths of machine M on input x.

The major types of polynomial-time reductions defined for functions include Turing reductions, metric reductions, many-one reductions, and parsimonious reductions. The latter three of these are defined as follows. A function $e : \Sigma^* \rightarrow \mathcal{N}$ ***polynomial-time metric reduces*** to a function $h : \Sigma^* \rightarrow \mathcal{N}$ if there exist two polynomial-time computable functions φ and ψ such that $(\forall x \in \Sigma^*)[e(x) = \psi(x, h(\varphi(x)))]$. A function $e : \Sigma^* \rightarrow \mathcal{N}$ ***polynomial-time many-one reduces*** to a function $h : \Sigma^* \rightarrow \mathcal{N}$ if there exist two polynomial-time computable functions φ and ψ such that $(\forall x \in \Sigma^*)[e(x) = \psi(h(\varphi(x)))]$. A function $e : \Sigma^* \rightarrow \mathcal{N}$ ***parsimoniously reduces*** to a function $h : \Sigma^* \rightarrow \mathcal{N}$ if there is a polynomial-time computable function φ such that $(\forall x \in \Sigma^*)[e(x) = h(\varphi(x))]$.

Let $\leq_\alpha$ be a reduction that is defined for functions. A function f is said to be ***#P-complete with respect to*** $\leq_\alpha$ ***reductions*** if $f \in \#\mathrm{P}$ and for every $g \in \#\mathrm{P}$ it holds that $g \leq_\alpha f$.

Facts:

1. ZPP is exactly the class of languages accepted by error-free probabilistic Turing machines running in expected polynomial time.

2. $\mathrm{ZPP} = \mathrm{RP} \cap \mathrm{coRP} \begin{smallmatrix} \subseteq \mathrm{RP} \subseteq \\ \subseteq \mathrm{coRP} \subseteq \end{smallmatrix} \mathrm{RP} \cup \mathrm{coRP} \subseteq \mathrm{BPP} \subseteq \mathrm{PP} \subseteq \mathrm{PSPACE}$.

3. $\mathrm{RP} \subseteq \mathrm{NP} \subseteq \mathrm{PP}$.

4. $\mathrm{ZPP}^{\mathrm{ZPP}} = \mathrm{P}^{\mathrm{ZPP}} = \mathrm{ZPP}$; $\mathrm{BPP}^{\mathrm{BPP}} = \mathrm{P}^{\mathrm{BPP}} = \mathrm{BPP}$.

5. $\mathrm{BPP} \subseteq \mathrm{P/poly}$.

6. $\mathrm{BPP} \subseteq \mathrm{NP}^{\mathrm{BPP}} \subseteq \mathrm{ZPP}^{\mathrm{NP}} \subseteq \Sigma_2^p \cap \Pi_2^p$.

7. If there is a sparse NP-$\leq_T^p$-hard set, then $\mathrm{PH} = \mathrm{ZPP}^{\mathrm{NP}}$. (This extends the Karp-Lipton theorem of §17.5.2.)

8. $\mathrm{PH} \subseteq \mathrm{PP}^{\mathrm{PH}} \subseteq \mathrm{P}^{\mathrm{PP}} = \mathrm{P}^{\#\mathrm{P}}$.

9. PP is closed under all Boolean operations.

10. If $\mathrm{NP} \subseteq \mathrm{BPP}$ then $\mathrm{BPP} = \mathrm{PH}$ and $\mathrm{RP} = \mathrm{NP}$.

11. It remains an open question whether BPP, RP, coRP, or ZPP have complete languages.

Examples:

1. *$SAT \in PP$*: Consider a probabilistic polynomial-time Turing machine M that, given a proposition F, immediately flips its coin. If the result is "heads", then proposition F is accepted and machine M halts. If "tails", then the machine, by a series of coin flips, randomly assigns each variable to be either true or false, and (on that computation path) accepts F if the resulting assignment satisfies the proposition. Thus F is accepted with probability exactly $\frac{1}{2}$ if F is unsatisfiable, and is accepted with probability at least $\frac{1}{2} + \frac{1}{2^{k+1}}$ if F is satisfiable, where k is the number of logical variables in F. Thus SAT $\in$ PP. This implies that NP $\subseteq$ PP, since the language SAT is NP-complete.

2. *Equality of polynomial products*: Given two lists of rational-coefficient polynomials, where each polynomial in the lists has been specified by a list of (coefficient, degree) pairs, the problem of deciding whether the product of the polynomials in the first list yields the same polynomial as the product of the polynomials in the second list is in the class coRP. This is because if the products are equal, then they will evaluate to the same value on any argument, yet if the products are unequal then it can be argued that the products will differ with sufficient probability on a randomly chosen argument.

3. *MAJORITY-SAT is PP-complete*: The language *MAJORITY-SAT* is the set of (quantifier-free) Boolean formulas F such that F is satisfied by more than half of the possible variable assignments.

4. *#SAT*: #SAT, the function that maps from Boolean formulas F to the number of solutions of F, is #P-complete with respect to parsimonious reductions (and thus with respect to many-one, metric, and Turing reductions).

5. *#SAT Is as Hard to Enumeratively Approximate (aka List Approximate) as It Is to Compute Exactly*: If there exists a polynomial-time function f mapping from Boolean formulas to lists of integers such that for each Boolean formula F it holds that the number of solutions of F (i.e., $\#SAT(\mathrm{F})$) is one of the integers in the list $f(F)$, then #SAT can be computed in polynomial time.

6. *The Power Index*: Power indices are very important in cooperative game theory and political science. Given a list of states and for each a positive natural number indicating the number of votes that state has, the raw Shapley-Shubik power index of a state s is the number of permutations of the list in which the sum of the weights of all the states coming before s in the permutation is less than or equal to half the total weight but the sum of the weights of all the states up to and including s is strictly greater than half the total weight. Informally, the index is a measure of how often s is the player who puts a coalition over the finish line if players join the coalition in random order. The raw Shapley-Shubik power index is #P-complete with respect to many-one reductions (and thus with respect to metric and Turing reductions), but is not #P-complete with respect to parsimonious reductions.

17.6 RANDOMIZED ALGORITHMS

General randomization principles for algorithms have many specific applications. In particular, random algorithms from number theory have applications in cryptography and fingerprinting, Also, randomized algorithms for partitioning, for searching and sorting, and for graph problems such as mincut and matching, including some heuristics for NP-complete problems, have applications in testing and applications for parallel or distributed environments.

17.6.1 OVERVIEW AND GENERAL PARADIGMS

Most randomized algorithms follow a few general paradigms. For many further topics not covered here, see the excellent survey papers [Ka91,We83] and also the textbook [MoRa95].

Definition:

A ***randomized algorithm*** is an algorithm that makes random choices during its execution. Such random choices are guided by the output of a random (or, in practice, pseudo-random) number generator.

Facts:

1. Many problems have no known deterministic algorithms to match the efficiency of randomized algorithms. Even for problems for which efficient deterministic algorithms are known, randomized algorithms are often remarkably easier to understand and implement.

2. Worst-case instances of a randomized algorithm occur when the algorithm performs badly for the overwhelming majority of its probabilistic choices.

3. *Abundance of witnesses paradigm*: Deciding whether a given input has a certain property sometimes reduces to finding a combinatorial object “witnessing” the property. When the space of all potential witnesses is too large to be searched exhaustively, it sometimes suffices to inspect a small random sample, selected so that one of the elements of the sample will be a suitable witness with very high probability.

4. *Random sampling*: Sometimes a small random sample is indicative of the population as a whole.

5. Intuitively, the power of randomization is analogous to the standard game-theoretic fact that probabilistic game strategies are substantially more effective than deterministic ones. That is, an algorithm can be regarded as a player, and the problem to be solved can be regarded as an adversary trying to present the player with input instances on which the algorithm exhibits worst-case performance.

6. If an algorithm is deterministic, then the game-theoretic adversary knows in advance the entire strategy of the player. Thus, the worst-case instances are well defined and can be presented as input to the algorithm. If an algorithm is probabilistic, then the game-theoretic adversary does not know in advance the output of the random number generator. In particular, worst-case instances under deterministic strategies may be smoothed out by randomization.

Examples:

1. *Cryptography*: Some public key cryptography is based on the sharp dichotomy between the efficiency of deciding whether a number is prime or composite, and the apparent hardness of actually factoring composite numbers.

2. *Fingerprinting*: A large data object is represented by a much smaller "fingerprint" such that, with very high probability, distinct objects map to distinct fingerprints. A similar strategy is used for "hashing" (see §18.4) where large objects are mapped to much smaller keys with very low probabilities of collisions.

3. *Testing identities*: It is often possible to check if an algebraic expression is identically equal to zero by substituting random values for the variables and checking whether the expression evaluates to zero.

4. *Symmetry breaking*: It is often necessary for a set of processes to come collectively to an arbitrary but consistent decision among a set of indistinguishable possibilities. There is a method to break such symmetries using randomization: this yields an efficient parallel perfect matching algorithm, as well as protocols for distributed environments, computation in the presence of errors, and Byzantine agreements.

5. *Load balancing*: For problems involving choice among resources, such as processors or communication links, randomization can be useful in spreading out the load.

6. *The probabilistic method*: The probabilistic method is to demonstrate that a combinatorial object of interest occurs with nonzero probability in a suitably defined probability space. Sometimes the probabilistic method yields efficient algorithmic constructions rather than mere existential arguments. (See §7.11.)

17.6.2 LAS VEGAS AND MONTE CARLO ALGORITHMS

Randomized algorithms are classified into two types: Monte Carlo algorithms and Las Vegas algorithms.

Definitions:

A ***Monte Carlo algorithm*** has bounded running time and produces correct output with probability bounded away from zero.

The ***success amplification method for a Monte Carlo algorithm*** is to perform k independent runs of the algorithm.

A ***Las Vegas algorithm*** always produces correct output. However, its running time is a random variable, whose expectation and variance are quantified in the analysis of the algorithm.

The ***success amplification method for a Las Vegas algorithm*** is to perform $k/2$ independent Las Vegas runs of $2E[T]$ steps each, where $E[T]$ is the expected Las Vegas running time.

The ***Monte Carlo to Las Vegas transformation***, starting from a Monte Carlo algorithm, is the Las Vegas algorithm of repeatedly running the Monte Carlo algorithm until a success occurs.

The ***Las Vegas to Monte Carlo transformation***, starting from a Las Vegas algorithm, is the Monte Carlo algorithm obtained by running the Las Vegas scheme for $kE[T]$ steps and halting.

Facts:

1. If the probability of success of a single run is p, then the probability under the success amplification method that k independent runs fail is $(1-p)^k$. Thus, the probability of success becomes $1-(1-p)^k$.

2. If p is the probability of success of a Monte Carlo algorithm, then the expected number of Las Vegas trials before a success occurs is $1/p$.

3. *Markov's inequality*: The probability that a positive random variable exceeds k times its expectation is at most $\frac{1}{k}$.

4. Markov's inequality yields a general method to bound variances of Las Vegas algorithms: If T is the running time of a Las Vegas algorithm, then $Pr[T > kE[T]] < 1/k$.

5. The probability that a transformed Las Vegas to Monte Carlo algorithm is successful is at least $1-1/k$.

6. If the expected running time of a Las Vegas algorithm is $E(T)$, then the running time of the amplified algorithm is $kE[T]$. However, the probability of success becomes $1-(\frac{1}{2})^{\frac{k}{2}}$.

Examples:

1. *A database problem*: In a large database whose keys are stored in no particular order, find a key that is not contained in that database, within time $O(N)$, where N is the size of the database. This would match the natural lower bound of $\Omega(N)$, the time required just to read the entire database. The deterministic strategy of sorting and checking for the first missing key would take time $O(N \log N)$. Assume $N = 2^{25}$ and that the keys are 32 digits long.

- *a Monte Carlo randomized strategy*: Pick a random 32-digit key and then scan the database! There are 2^{32} potential keys and only N keys in the database. Thus, the probability that a randomly chosen key is not in the database is at least $1-2^{-7}$, which is greater than 99%. The running time is dominated by a single scan of the database to check whether the randomly chosen key is suitable. Thus, it completes in $O(N)$ time.
- *success amplification*: The probability that among k independently chosen random keys none is found suitable is less than $0.01^k = 10^{-2k}$; this quantity becomes negligible, even for very small values of k. The running time of this amplified algorithm is $O(kN)$.
- *from Monte Carlo to Las Vegas*: Repeatedly pick random keys until a suitable key is found. The expected number of trials before a suitable key is found is $\frac{1}{p} < \frac{100}{99}$. Thus, the expected running time is $O(\frac{100N}{99}) = O(N)$.

2. *Finding the median*: Among n keys find the mth in increasing order. The deterministic strategy of sorting would take time $O(n \log n)$. Algorithm 1 does this within time $O(n)$ as follows.

- *a Las Vegas randomized strategy*: Pick a random key s from the database and consider the sets X and Y of keys in the database that are smaller and larger, respectively, than s. If $|X| \geq m$, then the problem reduces to finding the mth key in X. If $n-|Y| \leq m$, then the problem reduces to finding the $(m-(n-|Y|))$th key in Y. Finally, if $|X| < m < n-|Y|$, then s is the mth key.

```
Algorithm 1:  In a set $A$ of $n$ distinct keys, find the $m$th smallest.
input: a set $A$ with $n = |A|$, and an integer $m$ with $1 \leq m \leq n$
FIND $(A, m)$
if $A = \{s\}$ then return $s$
else
  pick $s$ uniformly at random from $A$
  compute $X = \{a \in A \mid a < s\}$ and $Y = \{a \in A \mid a > s\}$
  if $|X| \geq m$ then call FIND$(X, m)$
  if $n - |Y| \leq m$ then call FIND$(Y, m - (n - |Y|))$
  if $|X| < m < n - |Y|$ then return $s$
```

- *expected running time*: The randomly chosen key s splits the database into pieces X and Y which are, on average, of size $\frac{n}{2}$, and in most cases substantially smaller than n. Thus, the problem of looking for a key in a set of size n reduces to a problem of looking for a key in a set of size "approximately" $\frac{n}{2}$ and a running time of the type $T(n) \approx T(\frac{n}{2}) + O(n) = O(n)$ can intuitively be expected. More precisely, let $T(n, m)$ denote the running time to find the mth key. Since any of the keys could equally likely be picked as the splitter s, one can formulate a recurrence for the expectation $E[T(n, m)]$, which solves to $E[T(n, m)] = O(n)$, for all m.
- *variance*: Markov's inequality bounds the variance of the running time by $Pr[\,T(n, m) > kE[T(n, m)]\,] < \frac{1}{k}$.

3. *Primality testing*: Algorithm 2 produces correct output with probability at least $1 - (\frac{1}{2})^k$. Thus, after $\log n$ trials of selecting a random integer less than n and testing, the likelihood is very high for reasonably large n, that a prime number will be obtained. This follows from the prime number theorem and Markov's inequality.

```
Algorithm 2:  Test primality of $n$ (with $k$ witnesses).
input: positive integers $n$ and $k$ with $n$ odd
pick $a_1, \ldots, a_k$, each independently and uniformly at random from $\{2, 3, \ldots, n-1\}$
compute $\gcd(n, a_i)$ for all $1 \leq i \leq k$
    {$\gcd(n, a_i)$ can be computed efficiently using the Euclidean algorithm}
if there exists an $a_i$ with $\gcd(n, a_i) \neq 1$ then output "composite" and halt
else: compute $z_i = a_i^{(n-1)/2} \pmod{n}$ for all $a_i$ with $1 \leq i \leq k$
    {$z_i$ can be computed efficiently by repeated squaring}
if for some $i$, $z_i \not\equiv \pm 1 \pmod{n}$ then output "composite"
else if for some $i$, $z_i \equiv -1 \pmod{n}$ then output "probably prime"
else output "probably composite"
```

INFORMATION STRUCTURES

INTRODUCTION

Information structures are groupings of related information into records and organization of the records into databases. The mathematical structure of a record is specified as an abstract datatype and represented concretely as a linkage of segments of computer memory. General chapter references are [AhHoUl83], [Kn97], and [Kn98].

GLOSSARY

abstract datatype (***ADT***): a mathematically specified datatype equipped with operations that can be performed on its data objects.

adaptive bubblesort: a bubblesort that stops the first time a scan produces no transpositions.

ADT-constructor: any of the three operations *string of*, *set of*, or *tuple of* used to build more complex ADTs from simpler ADTs.

alphabetic datatype: an elementary datatype whose domain is a finite set of symbols, and whose only primary operation is a total ordering query.

ambivalent data structure: a structure that keeps track of several alternatives at many of its vertices, even though a global examination of the structure would determine which of these alternatives is optimal.

array data structure: an indexed sequence of cells $\langle a_j \mid j = d, \ldots, u \rangle$ of fixed size, with consecutive indices.

AVL tree: a binary search tree with the property that the two subtrees of each node differ by at most one in height.

binary search: a recursive search method that proceeds by comparing the target key to the key in the middle of the list, in order to determine which half of the list could contain the target item, if it is present.

binary search tree: a binary tree in which the key at each node is larger than all the keys in its left subtree, but smaller than all the keys in its right subtree.

binary search tree structure: a binary-tree structure in which for every cell, all cells accessible through the left child have lower keys, and all cells accessible through the right child have higher keys.

binary tree structure: a tree structure such that each cell has two pointers.

bubblesort: a sort that repeatedly scans an array from the highest index to the lowest, on each iteration swapping every out-of-order pair of consecutive items that is encountered.

cell (in a concrete data structure): a storage unit within the data structure that may contain data and pointers to other cells.

certificate (for a property of a graph G): another graph that has the specified property if and only if the graph G has the property.

chaining method (for hash tables): a hashing method that resolves collisions by placing all the records whose keys map to the same location in the main array into a linked list (chain), which is rooted at that location, but stored in the secondary array.

circular linked list: a set of cells, each with two pointers, one designated as its *forward pointer* and the other as its *backward pointer*, plus a header with one or more pointers to *current cells*, such that these conditions hold: (1) the sequence of cells formed by following the forward pointers, starting from any cell, traverses the entire set and returns to the starting cell; and (2) the sequence of cells formed by following the backward pointers, starting from any cell, traverses the entire set and returns to the starting cell.

closed hash table: a hash table in which collisions are resolved without the use of secondary storage space, that is, by probing in the main array to find available locations.

cluster (in a spanning tree): a set of vertices whose induced subgraph is connected.

clustering property (of a probe function): the undesirable possibility that parts of the probe sequences generated for two different keys are identical.

collision instance (of a hash function): a pair of different keys for which the value of the hash function is the same.

collision resolution (of a hashing process): a procedure within the hashing process used to define a sequence of alternative locations for storage of a record whose key collides with the key of an existing record in the table.

comparison sort: a sorting method in which the final sorted order is based solely on comparisons between elements in the input sequence.

concrete data structure: a mathematical model for storing the current value of a structured variable in computer memory.

database: a set of *records*, stored in a computer.

datatype: a set of objects, called the domain, and a set of mappings, called primary operations, from the domain to itself or to the domain of some other datatype.

deheaping: removing the highest priority entry from a heap and patching the result so that the heap properties are restored.

dictionary: an abstract datatype whose domain is a set of keyed pairs, in which arbitrary pairs may be accessed directly.

domain (of a datatype): the set of objects within that datatype.

dyadic graph property: a property defined with respect to pairs of vertices.

dynamic structure (for a database): an information structure for the database whose configuration may be changed, for instance, by the insertion or deletion of elements.

dynamic update operation: (on a graph) an operation that changes the graph and keeps track of whether the graph has some designated property.

edge-incidence table (for a graph): a dictionary whose keys are the vertices of a graph or digraph. The data component for each key vertex is a list of all the edges that are incident on that vertex. Each self-loop occurs twice in the list.

elementary datatype: an alphabetic datatype or a numeric datatype, usually intended for direct representation in the hardware of a computer.

endpoint table (for a graph): a dictionary whose keys are the edges. The data component for each key edge is the set of endpoints for that edge. If an edge is directed, then its endpoints are marked as head and tail.

enheaping: placing a new entry into its correctly prioritized position in a heap.

entry (in a database): a 2-tuple, whose first component is a key, and whose second component is some data; also called a *record*.

external sorting method: a method that uses external storage, such as hard disk or tape, outside the main memory during the sorting process.

far end (of a one-way linked list): the cell that contains a null pointer.

Fibonacci heap: a modification of a heap, using the Fibonacci sequence, that permits more efficient implementation of a priority queue than a heap based on a left-complete binary tree.

FIFO property (of a database): the property that the item retrieved is always the item inserted the longest ago. FIFO means "first-in-first-out".

flat notation (in a postcondition of a primary operation specification): the value $X^\flat$ of the variable X before the specified operation is executed.

fullness (of a closed hash table): the ratio of the number of records presently in the table to the size of the table.

generic datatype: a specification in an ADT-template that means that there are no restrictions whatsoever on that datatype.

hash function (for storing records in a table): a function that maps each key to a location in the table.

hash table: an array of locations for records (entries) in which each record is identified by a unique key, and in which a hash function is used to perform the table-access operations (of insertion, deletion, and search), possibly involving the use of a secondary array to resolve competition for locations.

hashing: storage-retrieval in a large table in which the table location is computed from the key of each data entry.

header (of a concrete data structure): a special memory unit (but not a cell) that contains current information about the entire configuration and pointers to some critical cells in the structure.

heap: a concrete data structure that represents a priority tree as an array.

heapsort: sorting a set of entries by first enheaping all items and then successively deheaping them.

incidence matrix (for a graph): a 0-1 matrix that specifies the incidence relation, where rows are indexed by the vertices and columns by the edges. The entry in the row corresponding to vertex v and edge e is 1, if v is an endpoint of e, and 0 otherwise.

in-place realization (of a sorting method): a method that uses, beyond the space needed for one copy of each data entry, only a constant amount of additional space, regardless of the size of the list to be sorted.

insertion sort: a sort that transforms an unsorted list into a sorted list by iteratively transferring the next item from the remaining items in the unsorted input list and inserting it into correct position in the sorted output list.

internal sorting method: any method that keeps all the entries in the primary memory of the computer during the process of rearrangement.

key (in a database entry): a value from an ordered set, used to store and retrieve data.

key domain: the ordered set from which values of keys are drawn.

key entry (of a record in a table): a value from an ordered set (e.g., integer identification codes or alphabetic strings) used to store records in the table.

key randomization: a "preliminary" procedure within the hashing process for mapping non-numeric keys (or keys with poor distribution) into (more uniformly) random distributed integers in the domain of the hash function.

keyed pair: a 2-tuple whose first component, called a *key*, is used to locate the data in the second component.

left child (of a cell in a binary tree structure): the cell to which the first pointer points.

left-complete binary tree: either a binary tree that is complete, or a balanced binary tree (§9.1.2) such that at depth one less than the maximum, the following hold: (1) all nodes with two children are to the left of all nodes with one or no children; (2) all nodes with no children are to the right of all nodes with one or two children; and (3) there is at most one node with only one child, which must be a left child.

LIFO property (of a database): the property that the item retrieved is always the item most recently inserted. LIFO means "last-in-first-out".

linear search: the technique of scanning the entries of a list in sequence, until either some stopping condition occurs or the entire list has been scanned.

mergesort: a sort that partitions an unsorted list into lists of length one and then iteratively merges them until a single sorted list is obtained.

near end (of a one-way linked list): the cell that is pointed to by the header and by no other cell.

nearly complete (property of a binary tree): the possible property that the binary tree is complete at every level except possibly at the bottom level. At the bottom level, all the missing leaves are to the right of all the present leaves.

null pointer: a pointer that points to an artificial location, which serves as a signal to an algorithm to react somewhat differently than to a pointer to an actual location.

numeric datatype: an elementary datatype whose domain is a set of *numbers* and whose primary operations are a total ordering query and the arithmetic operators $+$ (addition), $\times$ (multiplication), and $-$ (change of sign).

one-way linked list: a set of cells, each with one pointer, such that: (1) exactly one of these cells is pointed to by the header but by no cell; (2) exactly one cell contains a null pointer; and (3) the sequence of cells formed by following the pointers, starting from the header, traverses the entire set, ending with the cell containing the null pointer.

open hash table: a hash table that uses a secondary array to resolve collisions.

ordered datatype: a datatype with an order relation such that any two elements can be compared.

pivot (in a quicksort): an entry at which the sequence is split.

plane graph: a planar graph, together with a particular imbedding in the plane.

pointer (to a cell): a representation of that cell's location in computer memory.

postcondition (of a primary operation): a list of conditions that must hold after the operation is executed, if the precondition is satisfied when the operation commences.

precondition (of a primary operation): a list of conditions that must hold immediately before the operation is executed, for the operation to execute as specified.

primary key: the key component of highest precedence, when the key has more than one component.

primary operation (for a datatype): a basic operation that retrieves information from an object in the domain or modifies the object.

priority queue: an abstract datatype whose domain is a set of records, in which only the entry with the largest key is immediately accessible.

priority tree: a nearly complete binary tree whose nodes are assigned data entries from an ordered set of "priorities", such that there is no node whose priority supersedes the priority of its parent node.

probe function: a function used iteratively to calculate an alternative location in a closed hash table when the initial location calculated from the key or the previous probe location is already occupied.

probe sequence (for a hash table location): the sequence of locations calculated by the probe function in its effort to find an unoccupied place in the table.

query (to a datatype): a primary or secondary operation that changes nothing and returns a logical value, i.e., *true* or *false*.

queue: an abstract datatype that organizes the records into a sequence, such that records are inserted at one end (called the *back* of the queue) and extractions are made from the other end (called the *front*).

quicksort: sorting by recursively partitioning a list around an entry (the pivot) so that all smaller items precede the pivot and all larger items follow it.

radix sort: a sort using iterative partitioning into queues and recombining by concatenation, in which the partitioning is based on a digit in a numeral.

random access list: an abstract datatype whose domain is a set of records such that the values of the key field range within an interval of integers $a \leq k \leq b$; this permits implementations that execute primary operations faster than a general table.

rank (of an element of a finite ordered set): the number of elements that it exceeds or equals.

rank-counting sort: sorting by calculating the rank for each element, and then assigning each element to its correct position according to its rank.

record: a 2-tuple, whose first component is a key, and whose second component is some data; also called an *entry*.

record in a table: a table entry containing a key and some data.

right child (of a cell in a binary-tree structure): the cell to which the second pointer points.

root cell (of a tree structure): the cell to which the header points.

scanning a database (or a portion of a database): examining every record in that database (or portion).

searching (a database): seeking either a target entry with a specific key or a target entry whose key has some specified property.

secondary key: the key component of next highest precedence, when the key has more than one component.

secondary operation (for a datatype): an operation constructed from primary operations and from previously defined secondary operations.

selection sort: a sort that transforms an unsorted list into a sorted list by iteratively finding the item with smallest key from the remaining items in the unsorted input list and appending it to the end of the sorted output list.

sequence of: an ADT-constructor that converts a datatype with domain D into a new datatype, whose domain is the set of all finite sequences of objects from domain D, and whose primary operations are some sequence operations.

set of: an ADT-constructor that converts a datatype with domain D into a new datatype, whose domain is the set of all subsets of objects from domain D, and whose primary operations are set operations.

shakersort: a bubblesort variation that alternates between bubbling upward and sinking downward on alternate scans.

Shellsort: a sorting method that involves partitioning a list into sublists and insertion sorting each of the sublists.

sinking sort: a "reverse bubblesort" that scans an array repeatedly from the lowest index to the highest, each time swapping every out-of-order pair of consecutive items that is encountered.

size (of a cell in a data structure): the number of bytes of computer memory that the cell occupies.

size (of a hash table): the number of locations in the main array in which the records are stored. (If chaining is used to resolve collision, the total number of records stored may exceed the size of the main array.)

sorting algorithm: a method for arranging the entries of a database into a sequence that conforms to the order of their keys.

sparse certificate: a strong certificate (for a property of a graph G) in which the number of edges is $O(|V_G|)$.

sparse sequence: a sequence in which nearly all the entries are zeros.

stable certificate: a certificate produced by a stable function.

stable (***certificate***) ***function***: a function A that maps graphs to strong certificates such that: (1) $A(G \cup H) = A(A(G) \cup H)$; and (2) $A(G - e)$ differs from $A(G)$ by $O(1)$ edges, where e is an edge in G.

stack: an abstract datatype that organizes the records into a sequence, in which insertion and extraction are made at the same end (called the *top* of the stack).

static structure (for a database): an information structure for the database whose configuration does not change during an algorithmic process.

strong certificate (for a property of a graph G): a certificate graph G' for G with the same vertex set as G such that, for every graph H, the graph $G \cup H$ has property $\mathcal{P}$ if and only if $G' \cup H$ has property $\mathcal{P}$.

table: a set of keyed pairs, in which arbitrary pairs may be accessed directly; used as the domain of a dictionary.

target (of a database search): an entry whose key has been designated as the objective of the search.

2-3 *tree*: a tree in which each non-leaf node has 2 or 3 children, and in which every path from the root to a leaf is of the same length.

tree structure: a concrete data structure such that the header points to a single cell, and such that from that cell to each other cell, there is a single chain of pointers.

k-tuple of: an ADT-constructor that converts a list of k datatypes into a new datatype, whose domain is the Cartesian product of the domains of the datatypes in that list, and whose primary operations are the projection functions from a k-tuple to each of its coordinates.

two-way incidence structure (for a graph): a pair consisting of an edge-incidence table and an endpoint table.

two-way linked list: a set of cells, each with two pointers, one designated as its *forward pointer* and the other as its *backward pointer*, plus a header with a forward pointer and a backward pointer, such that these conditions hold: (1) considering only the forward pointers, it is a one-way linked list; and (2) following the sequence of backward pointers yields the reverse of the sequence obtained by following the forward pointers.

two-way sequential list: an ADT-template whose domain is strings, in which an entry is reached by applying the access operations *forward* and *backward*. Insertions are made before or after the *current* location.

union-find datatype: an abstract datatype whose records are mutually disjoint sets, in which there is a primary operation to locate the set containing a specified target element and a primary operation of merging two sets.

18.1 ABSTRACT DATATYPES

Organizing numbers and symbols into various kinds of records is a principal activity of information engineering. The organizational structure of a record is called a datatype. Abstractly, a datatype is characterized by a formal description of its domain and of the intrinsic operations by which information is entered, modified, and retrieved. Providing the specification at this abstract level ensures that the datatype is independent of the underlying types of information elements stored within the structure, and independent also of the hardware and software used to implement this organization. See [AhHoUl83] and [Kn97].

18.1.1 ABSTRACT SPECIFICATION OF RECORDS AND DATABASES

Information engineering uses discrete mathematics as a source of models for various kinds of records and databases. The language of abstract mathematics is used to specify a complex structure in terms of its elements. Constructors and templates are used to create new kinds of data from old kinds.

Definitions:

A ***datatype*** consists of a set of objects, called the *domain*, and a set of mappings, called *primary operations*, from the domain to itself or to the domain of some other datatype.

The ***domain*** of a datatype is its set of objects.

A ***primary operation*** for a datatype is a basic operation that retrieves information from an object in the domain or modifies the object.

A ***secondary operation*** on the domain of a datatype is an operation constructed from primary operations and previously defined secondary operations.

A ***query*** is a primary or secondary operation on a datatype domain that preserves the values of all its arguments and returns a logical value, i.e., *true* or *false*.

An ***alphabetic datatype*** is a datatype whose domain is a finite set of *symbols*. Its only primary operation is a total ordering query.

A ***numeric datatype*** is a datatype whose domain is a set of *numbers* and whose primary operations are a total ordering query and the arithmetic operators + (addition), × (multiplication), and − (change of sign).

An ***elementary datatype*** is an alphabetic datatype or a numeric datatype, usually intended for direct representation in the hardware of a computer.

An ***abstract datatype*** (***ADT***) is a mathematically specified datatype equipped with operations that can be performed on its data objects.

An ***ADT-constructor*** is a template that converts a datatype into a new ADT.

The constructor ***sequence of*** transforms a datatype X-type with domain D into a new datatype "sequence of X-type" whose domain is the set Seq_D of all finite sequences of elements of D. The primary operations of the resulting datatype are

- ***header***(s), which yields a singleton sequence whose only element is the first object in the sequence s (or the empty sequence, if the sequence s is empty);
- ***trailer***(s), which deletes the first entry of sequence s (or yields the empty sequence, if the sequence s is empty);
- ***concat***(s, t), which concatenates the two sequences;
- ***first***(s), which gives the value of the first entry of a nonempty sequence s;
- ***append***(s, d), which appends to sequence $s \in Seq_D$ an entry $d \in D$;
- ***nullseq***( ), whose value is the null sequence λ.

The constructor ***set of*** converts a datatype X-type with domain D into a new datatype "set of X-type" whose domain is the set of all subsets of D. The primary operations are

- ***inclusion***(S, T), a query whose value is true if $S \subseteq T$;
- ***union***(S, T), whose value is $S \cup T$;
- ***intersection***(S, T), whose value is $S \cap T$;
- ***difference***(S, T), whose value is $S - T$;
- ***choose***(S), whose value is an arbitrary element of a nonempty subset S;
- ***singleton***(d), which transforms an element of D into the singleton set whose only entry is d;
- ***emptyset***( ), whose value is the empty set $\emptyset$;
- ***universe***( ), whose value is the underlying domain D.

The constructor ***k-tuple of*** converts a list of k datatypes

$$X_1\text{-type},\ X_2\text{-type},\ \ldots,\ X_k\text{-type}$$

into a new datatype "k-tuple $(X_1, \ldots, X_k)$" whose domain is the Cartesian product $D_1 \times D_2 \times \cdots \times D_k$ of the domains of the respective datatypes in that list. The primary operations are the projection functions

- ***coord***$_j(s)$, which gives the value of the jth coordinate of the k-tuple s;
- ***entuple*** $(d_1, \ldots, d_k)$, whose value is the k-tuple whose jth coordinate is the element d_j of domain D_j.

An ***elementary ADT-constructor*** is any of the three operations *sequence of*, *set of*, or *tuple of* used to build more complex ADTs from simpler ADTs.

The ***Iverson truth function*** assigns to a proposition p the integer value (p) such that

$$(p) = \begin{cases} 1 & \text{if } p \text{ is true;} \\ 0 & \text{otherwise.} \end{cases}$$

A ***datatype specification*** uses a combination of elementary datatypes and ADT-constructors to specify the domain and the primary operations. It may also use the following mathematical notation:

- $\emptyset$ denotes the empty set;
- λ denotes the empty sequence;
- $\cdot$ denotes the operation of appending one element to a sequence;
- $\circ$ denotes the sequence concatenation operation.

Moreover, every primary operation is either a query or a procedure.

Specifying a datatype as ***generic*** in an ADT-template means that any datatype can be used in that part of the template as a block in the construction of the new datatype.

Specifying a datatype as ***ordered*** in an ADT-template means that any ordered datatype can be used in that part of the template as a block in the construction of the new datatype.

The ***precondition*** of a primary operation is a list of conditions that must hold immediately before the operation is executed, for it to execute as described.

The ***postcondition*** of a primary operation is a specification of conditions that must hold after the operation is executed, if the precondition is satisfied when the operation commences.

The ***flat notation*** $X^\flat$ in a postcondition of a primary operation specification means the value of the variable X before that operation is executed. Unadorned X (without the $\flat$) means the value of X after the operation.

Facts:

1. The domain of an ADT is specified as a mathematical model, without saying how its elements are to be represented.

2. Sometimes the domain of a datatype is specified by roster. Other times it is specified with the use of set-theoretic operations.

3. A primary operation of an ADT is specified functionally. That is, its value on every element of the domain is declared, but the choice of an algorithm to be used in its implementation is omitted.

4. A primary operation may be implemented so that it has direct access to the data representing the value of the computational variable to which it is applied.

5. A primary operation can modify the information within a variable in its datatype or retrieve information from a variable.

6. A secondary function is implemented through calls to the primary operations from which it is ultimately composed.

7. There is no set of standard conventions for writing ADTs.

8. Software designers frequently specify a particular concrete information structure (see §18.2), instead of writing an ADT.

9. The advantage of writing an ADT, rather than a concrete datatype, is that it leaves the implementer room to find a new (and possibly improved) way to meet the requirements of the task.

10. In a datatype specification, a functional subprogram is represented by a procedure that produces a non-boolean value, and a variable to receive that value is specified as its last parameter.

Examples:

1. Elementary numeric datatypes include the integers and the reals.

2. Elementary alphabetic datatypes include the ASCII set and the decimal digits.

3. *Complex_number* is a datatype that represents complex numbers and their addition and multiplication.

```
ADT complex_number:
Domain
  2-tuple ($re$: real, $im$: real)
Primary Operations
  sum ($w$: complex_number, $z$: complex_number)
  Comment: add two complex numbers.
    {pre: none}
    {post: $sum(w,z) = entuple\big(re(w) + re(z),\ im(w) + im(z)\big)$}
  prod ($w$: complex_number, $z$: complex_number)
  Comment: multiply two complex numbers.
    {pre: none}
    {post: $prod(w,z) = entuple$
          $\big(re(w) \cdot re(z) - im(w) \cdot im(z),\ re(w) \cdot im(z) + im(w) \cdot re(z)\big)$}
```

4. *Baseten_digit* is a datatype that might be used in the construction of base-ten numerals representing arbitrarily large integers and their addition.

```
ADT baseten_digit:
Domain
  $\{0, 1, 2, 3, 4, 5, 6, 7, 8, 9\}$: integers
Primary Operations
  add_digits ($x$: baseten_digit, $y$: baseten_digit)
    {pre: none}
    {post: $add\_digits(x,y) = x + y \textbf{ mod } 10$}
  addcarry: ($x$: baseten_digit, $y$: baseten_digit)
    {pre: none}
    {post: $addcarry(x,y) = (x + y \geq 10)$}
```

5. The datatype *alphastring* represents sequences of lowercase English letters.

ADT ***alphastring***:
Domain
sequence of $\{a, b, c, d, e, f, g, h, i, j, k, l, m, n, o, p, q, r, s, t, u, v, w, x, y, z\}$
Primary Operations
none except from the *constructor* sequence of

6. The ***union-find*** constructor transforms a datatype on domain set S into a datatype whose objects are of three kinds: elements of S, subsets of S, and partitions of S. There is a primary operation to merge two cells of a partition, and a primary operation to locate the cell of a partition that contains a specified target element.

18.1.2 STACKS AND QUEUES

Access to entries in the interior of a list is unnecessary much of the time. Restricting access to the first and last entries is a precaution to prevent mistakes.

Definitions:

A ***stack*** is an ADT whose domain is a sequence, one end of which is called the *top*, and the other the *bottom*. One primary operation, called *pushing*, appends a new entry to the top; the other, called *popping*, removes the entry at the top and returns its value. No entry may be examined, added to the stack, or deleted from the stack except by an iterated composition of these operations.

The ***top of a stack*** is the end of that *stack* that can be accessed directly.

Pushing an entry onto a stack means appending it to the top of the stack.

Popping an entry from a stack means deleting it from the top of the stack and possibly examining the data it contains.

The ***LIFO property*** of a database is that the item retrieved is always the item most recently inserted. LIFO means "last-in-first-out".

A ***queue*** is an ADT whose domain is a sequence, one end of which is called the *front*, and the other the *back*. One primary operation, called *enqueueing*, appends a new entry to the back; the other, called *dequeueing*, removes the entry at the front and returns its value. No entry may be examined, added to the queue, or deleted from the queue except by an iterated composition of these operations.

The ***back of a queue*** is the end to which entries may be appended.

The ***front of a queue*** is the end from which entries may be deleted and possibly examined.

Enqueueing an entry into a queue means appending it to the back of the queue.

Dequeueing an entry from a queue means deleting it from the front of the queue, and possibly examining the data it contains.

The ***FIFO property*** of a database is that the item retrieved is always the item inserted the longest ago. FIFO means "first-in-first-out".

Facts:

1. Abstract specification of stacks and queues mentions only the behavior of those datatypes and totally avoids all details of implementation. This permits a skillful implementer to innovate with efficient concrete structures (see §18.2) that meet the behavioral specification.

2. Abstract specification of stacks and queues is consistent with the principles of object-oriented programming, in which details of implementation are hidden inside the data objects, so that the rest of the program perceives only the specified functional behavior.

3. All stacks have the LIFO property. For any stack S and for any element b, after executing the sequence of instructions

$$\text{push}(S, b),\ \text{pop}(S, x)$$

the resulting value of the stack S is whatever it was before the operations.

4. A stack is most commonly implemented as a linked list (see §18.2.2).

5. After changing the value of the variable y to that of the top entry on the stack S, the sequence of instructions

$$\text{pop}(S, x),\ y := x,\ \text{push}(x)$$

restores S to its previous state.

6. All queues have the FIFO property. Given an empty queue Q and two elements b_1 and b_2, the sequence of operations

$$\text{enqueue}(Q, b_1),\ \text{enqueue}(Q, b_2),\ \text{dequeue}(Q, x_1),\ \text{dequeue}(Q, x_2),$$

yields $x_1 = b_1$, $x_2 = b_2$, and $Q = \lambda$.

7. A queue is most commonly implemented as a linked list (see §18.2.2).

Examples:

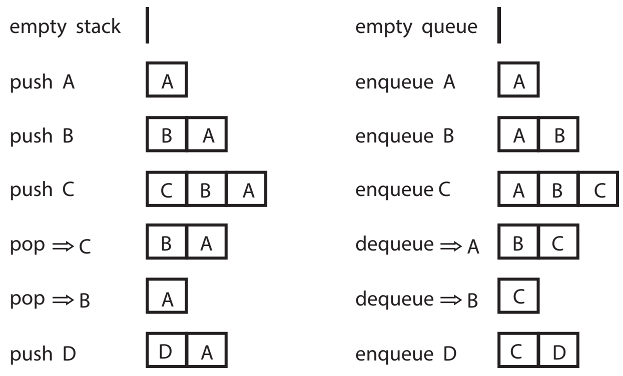
1. The following pseudocode specifies the ADT ***stack of D***, where D is an arbitrary datatype.

```
Domain
  sequence of $D$: generic
Primary Operations
  create_stack ($S$: stack)
  Comment: Initialize variable $S$ as an empty stack.
    {pre: none}
    {post: $S = \lambda$}
  push ($S$: stack, $x$: element of $D$)
  Comment: Put value of $x$ at top of stack $S$
    {pre: none}
    {post: $S = x \cdot S^\flat$}
  pop ($S$: stack, $x$: element of $D$)
  Comment: Remove top item of stack $S$; return it as value of variable $x$.
    {pre: $S \neq \lambda$}
    {post: $x \cdot S = S^\flat$}
  query_empty_stack ($S$: stack)
  Comment: Decide whether stack $S$ is empty.
    {pre: none}
    {post: query_empty_stack = $(S = \lambda)$}
```

2. The following pseudocode specifies the ADT ***queue of D***, where D is an arbitrary datatype.

```
Domain
  sequence of $D$: generic
Primary Operations
  create_queue ($Q$: queue)
  Comment: Initialize $Q$ as an empty queue.
    {pre: none}
    {post: $Q = \lambda$ }
  enqueue ($Q$: queue, $x$: element of $D$)
  Comment: Put $x$ at the back of queue $Q$.
    {pre: none}
    {post: $Q = Q^\flat \cdot x$}
  dequeue ($Q$: queue, $x$: element of $D$)
  Comment: Delete front of $Q$; return as $x$.
    {pre: $Q \neq \lambda$}
    {post: $Q^\flat = x \cdot Q$}
  query_empty_queue ( $Q$: queue)
  Comment: Decide whether queue $Q$ is empty.
    {pre: none}
    {post: query_empty_queue = $(Q = \lambda)$}
```

3. The following figure illustrates the difference between stacking (last-in-first-out) and queueing (first-in-first out).



18.1.3 TWO-WAY SEQUENTIAL LISTS

A two-way sequential list conceptualizes a linear list as having a current location, so that entries may be inserted or deleted only at the current location.

Definitions:

A ***two-way sequential list*** is a list with a designated location at which access is permitted.

The ***current location*** of a two-way sequential list is the location at which access is permitted.

The ***forepart*** of a two-way sequential list is the part preceding the current location, which is empty when the current location is at the start of the list.

The ***aftpart*** of a two-way sequential list is the part following the current location, which is empty when the current location is at the finish of the list.

Facts:

1. A two-way sequential list does not maintain place-in-list numbers for the entries. The result of such an additional requirement would force the insert operation to renumber the part of the list following a newly inserted entry. This would slow the performance.

2. A two-way sequential list is easily implemented as a pair of stacks.

Example:

1. The following pseudocode specifies the ADT ***seq_list of D***.

```
Domain
  2-tuple (fore: sequence of $D$, aft: sequence of $D$)
  type $D$: generic
Primary Operations
  create_list ($L$: seq_list)
  Comment: Initialize an empty list $L$.
    {pre: none}
    {post: $fore(L) = \lambda \ \wedge \ aft(L) = \lambda$}
  reset_to_start ($L$: seq_list)
  Comment: Reset to start of list.
    {pre: none}
    {post: $fore(L) = \lambda \ \wedge \ aft(L) \ = \ fore(L^\flat) \circ \ aft(L^\flat)$}
  advance ($L$: seq_list)
  Comment: Advance current position by one element.
    {pre: $aft(L) \neq \lambda$}
    {post: $(\exists x : D)[fore(L) = fore(L^\flat) \cdot x \wedge \ aft(L^\flat) = x \cdot aft(L)]$}
  query_atstart ($L$: seq_list)
    {pre: none}
    {post: $query\_atstart = (fore(L) = \lambda)$}
  query_atfinish ($L$: seq_list)
    {pre: none}
    {post: $query\_atfinish = (aft(L) = \lambda)$}
  insert ($L$: seq_list, $x$: element of $D$)
    {pre: none}
    {post: $aft(L) = x \cdot aft(L^\flat) \wedge fore(L) = fore(L^\flat)$}
  remove ($L$: seq_list, $x$: element of $D$)
    {pre: $aft(L) \neq \lambda$}
    {post: $aft(L^\flat) = x \cdot aft(L) \wedge fore(L) = fore(L^\flat)$}
  swap_right ($L$: seq_list, $M$: seq_list)
    {pre: none}
    {post: $fore(L) = fore(L^\flat) \wedge fore(M) = fore(M^\flat)$
        $\wedge aft(L) = aft(M^\flat) \wedge aft(M) = aft(L^\flat)$}
```

18.1.4 DICTIONARIES AND RANDOM ACCESS LISTS

Definitions:

A ***keyed pair*** is a 2-tuple whose first entry, which is called a *key*, is from an ordered datatype and is used to access data in the second entry.

A ***table*** is a set of keyed pairs such that no two keys are identical.

A ***random access list*** is a table whose keys are consecutive integers.

A ***dictionary*** is another name for a table.

Facts:

1. A static table (whose size n does not change) can be implemented as an array.

2. A dynamic table (which permits inserts and deletes) is often implemented as a binary search tree (see §18.2.3).

3. Specifying a datatype as a dictionary means that its primary retrieval operation can execute in $\Theta(n)$ time.

4. Specifying a datatype as a random access list means that its primary retrieval operation can execute in $\Theta(1)$ time.

Examples:

1. The following pseudocode specifies the ADT ***table***.

```
Domain
  set of table_entry
  type table_entry: 2-tuple ($key$: ordered, $data$: generic)
Primary Operations
  create_table ($T$: table)
    {pre: $none$}
    {post: $T = \lambda$}
  insert_entry ($T$: table, $e$: table_entry)
    {pre: $(\forall e' \in T)[\text{ key}(e') \neq \text{key}(e)]$}
    {post: $T = T^\flat \cup \{e\}$}
  remove_entry ($T$: table, $e$: table_entry)
    {pre: e $\in T$}
    {post: $T = T^\flat - \{e\}$}
  find_entry ($T$: table, $k$: key, found: boolean, $e$: table_entry)
    {pre: $none$}
    {post: $\big((\exists e' \in T)[e'.key = k]) \wedge (found = true) \wedge (e = e')\big)$
        $\vee\big(\neg(\exists e' \in T)[e'.key = k] \wedge found = false\big)$}
```

2. The following pseudocode specifies the ADT ***Random access list***.

```
Domain
  set of table_entry
  type table_entry: 2-tuple ($key$: subrange of integers, $data$: generic)
Primary Operations
  Exactly the same as for the ADT table.
```

18.1.5 PRIORITY QUEUES

A priority queue is an "unfair queue", in which entries are not dequeued on a first-enqueued basis. Instead, each entry has a priority, and is dequeued on a highest priority basis.

Definition:

A ***priority queue*** is a set of keyed pairs, such that the key of the entry returned by a dequeue operation is not exceeded by the key of any other entry currently in the queue.

Facts:

1. A priority queue is usually implemented as a heap (see §18.2.4).

2. Two different entries in a priority queue may have the same key.

3. The operating system for a multi-user programming environment places computational tasks into a priority queue.

Example:

1. The following pseudocode specifies the ADT ***P_queue***.

```
Domain
  set of Pq_entry
  type Pq_entry: 2-tuple ($key$: ordered, $data$: generic)
Primary Operations
  create_Pq ($PQ$: P_queue)
    { pre: $none$ }
    { post: $PQ = \lambda$ }
  enPqueue($PQ$: P_queue, $e$: Pq_entry)
    { pre: $none$ }
    { post: $PQ = PQ^\flat \cup \{e\}$ }
  dePqueue ($PQ$: P_queue, $e$: Pq_entry)
    { pre: $PQ \neq \emptyset$ }
    { post: $(e \in PQ^\flat) \wedge (\forall e' \in PQ)[key(e) \leq key(e')] \wedge PQ = PQ^\flat - \{e\}$ }
  query_empty_Pqueue($PQ$: P_queue)
    { pre: $none$ }
    { post: query_empty_Pqueue = (PQ = $\lambda$) }
```

18.2 CONCRETE DATA STRUCTURES

Concrete data structures configure computer memory into containers of related information. They are used to implement abstract datatypes. Contiguous stretches of memory are regarded as arrays, and noncontiguous portions are linked with pointers.

18.2.1 MODELING COMPUTER STORAGE AND RETRIEVAL

There are a few generic concepts common to nearly all concrete data structures.

Definitions:

A ***concrete data structure*** is a mathematical model for storing the current value of a structured variable in computer memory.

A ***cell*** in a concrete data structure S is a unit within the data structure that may contain data and pointers to other cells.

The ***header*** of a concrete data structure is a special unit that contains current information about the entire configuration and pointers to some critical cells in the structure. It is *not* a cell.

An ***insert operation*** insert(S: structure, c: cell, loc: location) inserts a new cell c into structure S at location loc.

A ***delete operation*** delete(S: structure, loc: location) deletes from a structure S the cell at location loc.

A ***target predicate*** for a concrete data structure is a predicate that applies to the cells.

A ***find operation*** find(S: structure, t: target, loc: location) searches a structure S for a cell that satisfies target predicate t. It returns $false$ if there is no such cell. In addition to returning the boolean value *true* if there is such a cell, it also assigns to its location parameter loc the location of such a cell.

A ***next operation*** next(S: structure, loc: location) returns the boolean value *true* if the structure S is nonempty, in which case it also assigns to its location parameter loc the location of whatever cell it regards as next; it returns $false$ if S is empty.

The ***size of a cell*** is the number of bytes of computer memory it occupies.

A ***pointer to a cell*** is a representation of its location in computer memory.

A ***null pointer*** is a pointer that points to an artificial location. Detecting a null pointer is a signal to an algorithm to react somewhat differently than to a pointer to an actual location.

Facts:

1. There may be several alternative suitable concrete data structures that can be used to implement a given abstract datatype.

2. If the records of a database are all of the same fixed size, then the records themselves may be in the cells of a concrete data structure.

3. If the size of records is variable, then the cells of the concrete data structure often contain pointers to the actual data, rather than the data itself. This permits faster execution of operations.

4. The most common form of target predicate for a concrete data structure is an assertion that a key component of the cell matches some designated value.

18.2.2 ARRAYS AND LINKED LISTS

Definitions:

An ***array*** is an indexed sequence of identically structured cells $\langle a_j \mid j = d, \ldots, u \rangle$, with consecutive indices.

An array is ***zero-based*** if its lowest index is zero.

A ***one-way linked list*** is a set of cells, each with one pointer, such that

- exactly one of these cells is pointed to by the header but by no cell;
- exactly one cell contains a null pointer;
- the sequence of cells formed by following the pointers, starting from the header, traverses the entire set, ending with the cell containing the null pointer.

The ***far end of a one-way linked list*** is the cell that contains a null pointer.

The ***near end of a one-way linked list*** is the cell that is pointed to by the header and by no other cell.

A ***two-way linked list*** is a set of cells, each with two pointers, one designated as its *forward pointer* and the other as its *backward pointer*, plus a header with a forward pointer and a backward pointer, such that

- considering only the forward pointers, it is a one-way linked list;
- following the sequence of backward pointers yields the reverse of the sequence obtained by following the forward pointers.

A ***sparse sequence*** is a sequence in which nearly all the entries are zeros.

A ***circular linked list*** is a set of cells, each with two pointers, one designated as its *forward pointer* and the other as its *backward pointer*, plus a header with one or more pointers to *current cells*, such that

- the sequence of cells formed by following the forward pointers, starting from any cell, traverses the entire set and returns to the starting cell;
- the sequence of cells formed by following the backward pointers, starting from any cell, traverses the entire set and returns to the starting cell.

Facts:

1. A random access list (see §18.1.4) can be implemented as an array so that a $find$ operation executes in $O(1)$ time.

2. A stack (see §18.1.2) can be implemented as a one-way linked list with its top at the near end, so that *push* and *pop* both execute in $O(1)$ time.

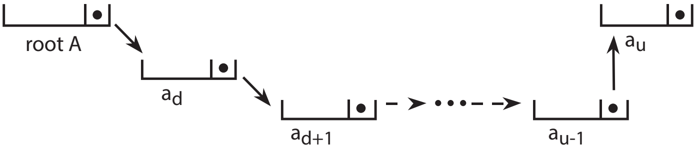
3. A queue (see §18.1.2) can be implemented as a two-way linked list with its back at the near end of the forward list and its front at the far end, so that *enqueue* and *dequeue* both execute in $O(1)$ time.

4. A two-way sequential list (see §18.1.3) can be implemented as a two-way linked list, or as a pair of one-way linked lists.

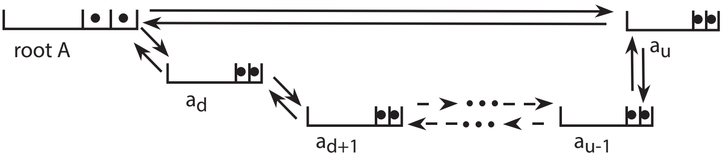
Examples:

1. The following figure illustrates an array with cells $a_d, \ldots, a_u$.

2. The following figure illustrates a one-way linked list, with cell a_d at the near end and cell a_u at the far end.



3. The following figure illustrates a two-way linked list.



4. Representing a sparse finite sequence by a linked list can save space. The cell given to each nonzero entry includes its position in the sequence and points to the cell with the next nonzero entry.

5. A queue whose maximum length is bounded can be represented by a circular linked list with two header pointers, one to the back and one to the front of the queue. The number of cells equals the maximum queue length. This eliminates the need for "garbage collection".

18.2.3 BINARY SEARCH TREES

Definitions:

A ***tree structure*** on n cells is a concrete data structure such that the header points to a single cell, and such that from that cell to each other cell, there is a single chain of pointers.

The ***root cell*** of a tree structure is the cell to which the header points.

A ***binary tree structure*** is a tree structure such that each cell has two pointers.

The ***left child*** of a cell in a binary tree structure is the cell to which the first pointer points.

The ***right child*** of a cell in a binary tree structure is the cell to which the second pointer points.

A ***binary search tree structure*** is a binary tree structure in which for every cell, all cells accessible through the left child have lower keys, and all cells accessible through the right child have higher keys.

Facts:

1. The *ADT table* is commonly implemented as a binary search tree structure.

2. The average running time for the *ADT table* operations of *insertion*, *deletion*, and *find* is $O(\log n)$. The time may be worse if relatively few cells have two children.

3. Using a *2-3 tree structure* instead of a binary search tree structure for the *ADT table* operations reduces the worst-case running time from $O(n)$ to $O(\log n)$.

4. Algorithm 1 can be used in the binary search tree operations of finding, inserting, and deleting.

Algorithm 1: **BSTsearch**(T, t).

```
input: a binary-search tree $T$ and a target key $t$
output: if $t \in T$, the address of the node with key $t$, else the address where $t$
        could be inserted
if $root(T)$ = NULL then return address of $root$
else if $t < key(root)$ then BSTsearch($leftsubtree(T), t$)
else if $t = key(root)$ then return address of $root$
else BSTsearch($rightsubtree(T), t$)
```

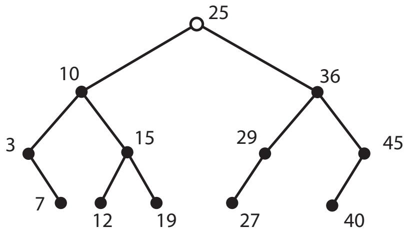
5. To find a target key t in the binary search tree T, first apply BSTsearch(T, t). If the address of a null pointer is returned, then there is no node with key t. Otherwise, the address returned is a node with key t.

6. To insert a node with target key t into the binary search tree T, first apply the algorithm BSTsearch(T, t). Then install the node at the location returned.

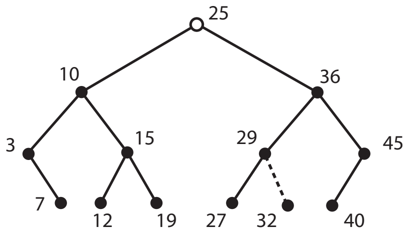
7. To delete node t from the binary search tree T, first apply BSTsearch(T, t). Then replace node t either by the node with the largest key in the left subtree or by the node with the smallest key in the right subtree.

Examples:

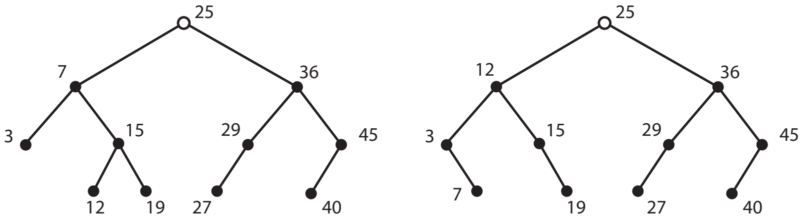
1. The following figure illustrates a binary search tree.



2. Inserting 32 into the BST of Example 1 yields the following BST.



3. Deleting node 10 from the BST of Example 1 would yield one of the following two BSTs.



18.2.4 PRIORITY TREES AND HEAPS

Definitions:

A binary tree is ***left-complete*** if it is complete or if it is a balanced binary tree (§9.1.2) such that at depth one less than the maximum, the following conditions hold:

- all nodes with two children are to the left of all nodes with one or no children;
- all nodes with no children are to the right of all nodes with one or two children;
- there is at most one node with only one child, which must be a left-child.

A ***priority tree*** is a left-complete binary tree, with the following additional structure:

- each node has an attribute called a *key*;
- the values of the keys are drawn from a partially ordered set;
- no node has a higher priority key than its parent.

A ***heap*** is a representation of a priority tree as a zero-based array, such that each node is represented at the location in the array whose index equals its location in the breadth-first-search order of the tree. Thus

- $index(root) = 0$;
- $index(leftchild(v)) = 2 \times index(v) + 1$;
- $index(rightchild(v)) = 2 \times index(v) + 2$;
- $index(parent(v)) = \lfloor \frac{index(v)-1}{2} \rfloor$.

Enheaping an entry into a heap means placing it into a correctly prioritized position.

Trickle-up means enheaping by Algorithm 2.

```
Algorithm 2: PriorityTreeEnqueue $(T, x)$.
  input: a priority tree $T$ and a new entry $x$
  output: tree $T$ with the new node $x$ inserted so that it remains a priority tree
  install entry $x$ into the first vacant spot in the left-complete tree $T$
  while $x \neq root(T)$ and $priority(x) > priority(parent(x))$
    swap $x$ with $parent(x)$
```

Deheaping an entry from a heap means taking the root as the deheaped entry and patching its left subtree and its right subtree back into a single tree.

Trickle-down means deheaping by Algorithm 3.

```
Algorithm 3: PriorityTreeDequeue $(T)$.
  input: a priority tree $T$
  output: tree $T - root(T)$ with priority-tree shape restored
  replace $root(T)$ by rightmost entry $y$ at bottom level of $T$
  while $y$ is not a leaf and [$priority(y) \leq priority(leftchild(y))$ or
        $priority(y) \leq priority(rightchild(y))$]
    if $priority(leftchild(y)) > priority(rightchild(y))$
      then swap $y$ with $leftchild(y)$
      else swap $y$ with $rightchild(y)$
```

A ***Fibonacci heap*** is a modification of a heap, using the Fibonacci sequence, that permits more efficient implementation of a priority queue than a heap based on a left-complete binary tree.

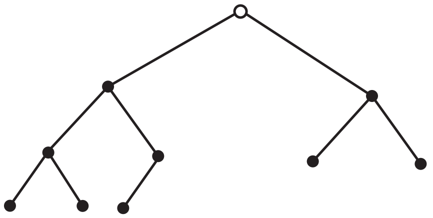
Facts:

1. For a tree with n nodes, the worst-case execution time of the priority tree enqueueing algorithm (Algorithm 2) is in the class $\Theta(\log n)$.

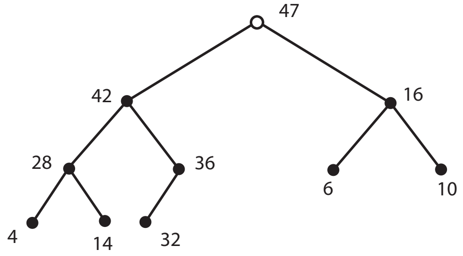
2. For a tree with n nodes, the worst-case execution time of the priority tree dequeueing algorithm (Algorithm 3) is in the class $\Theta(\log n)$.

Examples:

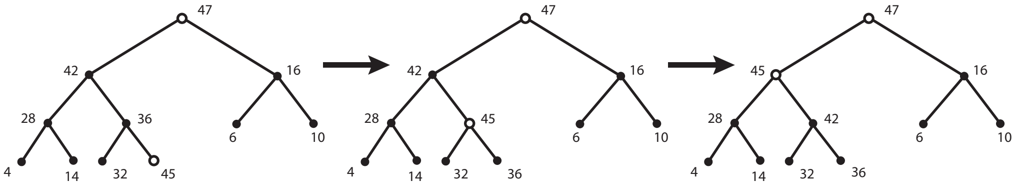
1. The following figure shows a left-complete binary tree.



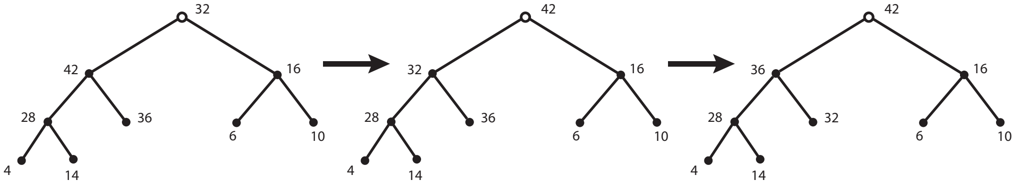
2. The following figure shows a priority tree of height 3.



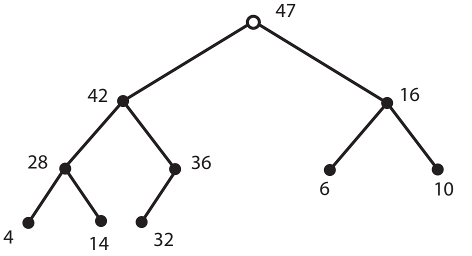
3. The following figure illustrates a priority tree insertion. It shows how 45 is inserted into the priority tree of Example 2 in the correct location to maintain the left-compete binary tree shape and then rises until the priority property is restored.



4. The following figure illustrates a priority tree deletion. It shows how the left-complete binary tree shape and priority property are restored after the root is removed from the priority tree of Example 2.



5. The following heap corresponds to the priority tree of Example 2. Observe that the keys occur in the array according to the breadth-first-search order of their vertices.



index	0	1	2	3	4	5	6	7	8	9
key	47	42	16	28	36	6	10	4	14	32

18.2.5 NETWORK INCIDENCE STRUCTURES

Definitions:

An ***incidence matrix*** for a graph is a 0-1 matrix that specifies the incidence relation. The rows are indexed by the vertices and the columns by the edges. The entry in the row corresponding to vertex v and edge e is 1 if v is an endpoint of e, and 0 otherwise.

An ***endpoint table*** for a graph (§8.1.1) is a *dictionary* whose keys are the edges. The data component for each key edge is the set of endpoints for that edge. If an edge is directed, then its endpoints are marked as *head* and *tail.*

An ***edge-incidence table*** is a *dictionary* whose keys are the vertices of a graph or digraph. The data component for each key vertex is a list of all the edges that are incident on that vertex. Each self-loop occurs twice in the list.

A ***two-way incidence structure*** for a graph is a pair consisting of an edge-incidence table and an endpoint table.

Facts:

1. The time required to insert a new vertex v into a two-way incidence structure for a graph with n vertices and m edges is in $\Theta(\log n)$. By way of contrast, the time for an incidence matrix is in $\Theta(n \cdot m)$.

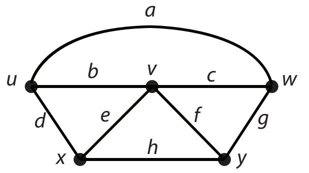
2. The time required to delete a vertex v from a two-way incidence structure for a graph with n vertices and m edges is in $\Theta(\log n + \deg(v))$. By way of contrast, the time for an incidence matrix is in $\Theta(n \cdot m)$.

3. The time required to insert a new edge e into a two-way incidence structure for a graph with n vertices and m edges is in $\Theta(\log m)$. By way of contrast, the time for an incidence matrix is in $\Theta(m \cdot n)$.

4. An edge-incidence table can represent an imbedding of a graph on a surface as a rotation system (§8.8.3).

Example:

1. The following graph corresponds to the network incidence structure given below.



EDGE-INCIDENCE TABLE

u.	a	b	d	
v.	b	c	e	f
w.	a	c	g	
x.	d	e	h	
y.	f	g	h	

ENDPOINT TABLE

a.	u	w
b.	u	v
c.	v	w
d.	u	x
e.	v	x
f.	v	y
g.	w	y
h.	x	y

18.3 SORTING AND SEARCHING

Since commercial data processing involves frequent sorting and searching of large quantities of data, efficient sorting and searching algorithms are of great practical importance. Sorting and searching strategies are also of fundamental theoretical importance, since sorting and searching steps occur in many algorithms. The following table compares the performance of some of the most common methods for sorting n items.

sorting method	*average time factors*	*comments*
expanding a sorted subsequence		
selection sort	$\approx \frac{n^2}{2}$ comparisons $\approx n$ exchanges	
insertion sort	$\approx \frac{n^2}{4}$ comparisons $\approx \frac{n^2}{8}$ exchanges	linear if input file is "almost sorted"
Shellsort	$< n^{3/2}$ comparisons	for "good" increments $1, 4, 13, 40, 131, \ldots$
exchanging out-of-order pairs		
bubblesort	$\approx \frac{n^2}{2}$ comparisons $\approx \frac{n^2}{4}$ exchanges	one pass if input file is already sorted
sinking sort	$\approx \frac{n^2}{2}$ comparisons $\approx \frac{n^2}{4}$ exchanges	one pass if input file is already sorted
shakersort	$\approx \frac{n^2}{2}$ comparisons $\approx \frac{n^2}{4}$ exchanges	
heapsort	$< 2n \log_2 n$ comparisons	always $\Theta(n \log n)$
divide-and-conquer		
mergesort	$\approx n \log_2 n$ comparisons	always $\Theta(n \log n)$
quicksort	$\approx 2n \log_2 n$ comparisons	worst-case $\frac{n^2}{2}$
sorting by distribution		
rank-counting	$\Theta(n)$	
radix sort on k-digit key	$\approx n \log_2 n$ comparisons	

18.3.1 GENERIC CONCEPTS FOR SORTING AND SEARCHING

Definitions:

A ***database*** is a set of *entries*, stored in a computer as an *information structure.*

An ***entry*** in a database is a 2-tuple whose first component is a *key* and whose second component is some data.

A ***key*** in a database entry is a value from an ordered set, used to store and retrieve data.

The ***key domain*** is the ordered set from which keys are drawn.

The ***primary key*** is the component of highest precedence, when the key for database records has more than one component.

The ***secondary key*** is the component of next highest precedence after the primary key.

A ***record*** is another name for a database entry.

Sorting is the process of arranging a collection of database entries into a sequence that conforms to the order of their keys.

Searching a database means using a systematic procedure to find an entry with a key designated as the objective of the search.

Scanning a database (or a portion of a database) means examining every record in that database (or portion).

The ***target*** of a database search is an entry whose key has been designated as the objective of the search.

A ***comparison sort*** is any sorting method that uses only comparisons of keys.

An ***internal sorting method*** keeps all the entries in the primary memory of the computer during the process of rearrangement.

An ***external sorting method*** uses external storage outside the main memory during the sorting process.

An ***in-place realization*** of a sorting method uses, beyond the space needed for one copy of each data entry, only a constant amount of additional space, regardless of the size of the list to be sorted.

A ***dynamic structure*** for a database is an information structure whose configuration may change during an algorithmic process, for instance, by the insertion or deletion of elements.

A ***static structure*** for a database is a data structure whose configuration does not change during an algorithmic process.

Facts:

1. Several different general strategies for sorting are given in the following subsections. Each leads to more than one method for sorting.

2. Some elementary sorting methods take $O(n^2)$ time. Most practical comparison sorting methods require $O(n \log n)$ time.

3. The worst-case running time of any comparison sort is at least $\Omega(n \log n)$.

Examples:

1. The following are all internal comparison sorts: selection sort (§18.3.2), insertion sort (§18.3.2), Shellsort (§18.3.2), bubblesort (§18.3.3), heapsort (§18.3.3), and quicksort (§18.3.4).

2. Mergesort (§18.3.4) is a comparison sort that may be either internal or external.

3. *Database model for a telephone directory*: Each entry has as key the name of a person and as data that person's telephone number. The target of a search is the entry for a person whose number one wishes to call. Names of persons form an ordered key domain under a modified lexicographic ("alphabetic") ordering, in which it is understood that a family name (a "last name" in European-based cultures) has higher precedence than a given name.

4. *Database model for a reverse telephone directory*: In a reverse telephone directory entry, the key is a telephone number and the data is the name of the person with that number. This permits the telephone company to retrieve the name of the person who has a particular phone number, for instance, if someone inquires why some particular telephone number occurs on a long-distance phone bill.

5. *Database model for credit card information*: In a credit card database, the key to each entry is a credit card number, and the data includes the name of the cardholder, the maximum credit limit, and the present balance.

18.3.2 SORTING BY EXPANDING A SORTED SUBSEQUENCE

One general strategy for sorting is to iteratively expand a sorted subsequence, most often implemented as an array or a linked list, until the expanded subsequence ultimately contains all the entries of the database.

Definitions:

A ***selection sort*** iteratively transforms an unsorted input sequence into a sorted output sequence. At each iteration, it *selects* the item with smallest key from the remaining items in the unsorted input sequence and appends that item at the end of the sorted output sequence.

An ***insertion sort*** iteratively transforms an unsorted input sequence into a sorted output sequence. At each iteration, it takes the first remaining item from the unsorted input subsequence and *inserts* it into its proper position in the sorted output sequence.

A ***Shellsort*** of an unsorted sequence $a_1, \ldots, a_n$ is based on a list of *increments* of decreasing size: $h_1 > h_2 > \cdots > h_t = 1$. On the kth iteration, the sequence is partitioned into h_k subsequences, such that for $j = 1, \ldots, h_k$, the jth subsequence is

$$\left\langle a_{j+rh_k} \mid 0 \leq r \leq \frac{n-j}{h_k} \right\rangle$$

and each of these j subsequences is sorted by an insertion sort.

Facts:

1. Selection sorts and insertion sorts both have time-complexity $O(n^2)$ in the worst case.

2. The time-complexity of a selection sort is independent of the order of the input sequence, since finding the smallest remaining item requires scanning all the remaining items.

3. The running time of an insertion sort can be significantly reduced for "almost sorted" sequences, with time $O(n)$ as the limiting case.

4. Optimizing the running time of a Shellsort involves some very difficult mathematical problems, many of which have not yet been solved. In particular, it is not known which choice of increments yields the best result.

5. It is known that Shellsort increments should not be multiples of each other, if the objective is to achieve fast execution.

6. Evidence supporting the efficiency of the Shellsort increment list $\ldots, 40, 13, 4, 1$ according to the rule $h_{i-1} = 3h_i + 1$ is given by Knuth [Kn98]. The increment list $\ldots, 15, 7, 3, 1$ satisfying the rule $h_{i-1} = 2h_i + 1$ is also recommended.

7. Shellsort is a refinement of a straight insertion sort. The motivation for its design in 1959 by D. L. Shell is based on the observation that an insertion sort works very fast for "almost sorted" sequences.

8. Shellsort is guaranteed to produce a sorted list, because on the last pass, it applies an insertion sort to the whole sequence.

9. An in-place realization of the strategy of expanding a sorted subsequence conceptually partitions the array into a sorted subsequence at the front of the array $A[1..n]$ and an unsorted subsequence of remaining items at the back. Initially, the sorted subsequence is the empty sequence and the unsorted subsequence is the whole list. At each step of the iteration, the sorted front part expands by one item and the unsorted back part contracts by one item.

Algorithms:

1. Algorithm 1 is an in-place realization of a selection sort.

```
Algorithm 1: SelectionSort of array $A[1..n]$.
for $i := 1$ to $n - 1$
   minindex := $i$;  minkey := $A[i]$
   for $j := i + 1$ to $n$
      if $A[j] <$ minkey then
         minindex := $j$;  minkey := $A[j]$
   swap $A[i]$ with $A$[minindex]
```

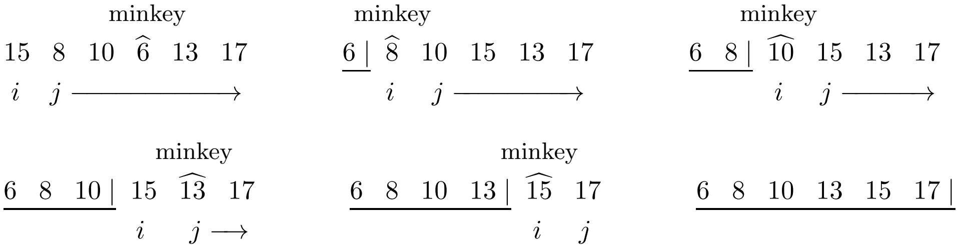
2. Algorithm 2 is an in-place realization of an insertion sort.

```
Algorithm 2: InsertionSort of array $A[1..n]$.
for $i := 2$ to $n$
   nextkey := $A[i]$;  $j := i - 1$
   while $j > 0$ and $A[j] >$ nextkey
      $A[j + 1] := A[j]$;  $j := j - 1$
   $A[j + 1]$ := nextkey
```

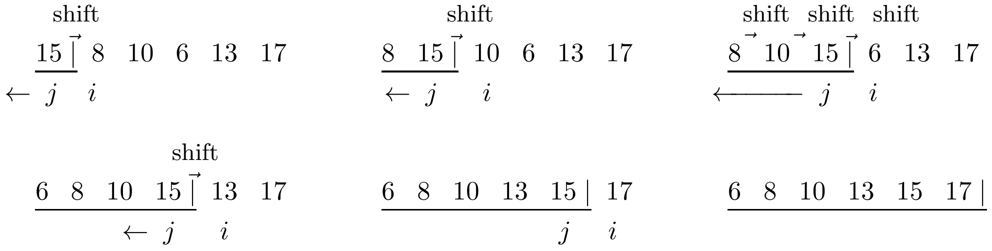
Examples:

In the following examples of single-list implementations of SelectionSort and InsertionSort, the symbol "$\underline{\quad|}$" separates the sorted subsequence at the front from the remaining unsorted subsequence at the back. The arrows "←" and "→" indicate how far the index j moves during an iteration.

1. On the sequence $15, 8, 10, 6, 13, 17$, SelectionSort would progress as follows:



2. On the sequence $15, 8, 10, 6, 13, 17$, InsertionSort would progress as follows:



3. If $n = 13$ and $h_3 = 4$, then on the third iteration, ShellSort would insertion sort the following subsequences:

$$a_1, a_5, a_9, a_{13}$$
$$a_2, a_6, a_{10}$$
$$a_3, a_7, a_{11}$$
$$a_4, a_8, a_{12}$$

18.3.3 SORTING BY EXCHANGING OUT-OF-ORDER PAIRS

A standard measure of the totality of disorder of a sequence of n items is the number of pairs (a_i, a_j) such that $i < j$ but $a_i > a_j$. Thus, the disorder ranges from 0 (i.e., totally ordered) to $\binom{n}{2}$ (i.e., in reverse order). The strategy of exchange sorts is to swap out-of-order pairs until all pairs are in order.

Definitions:

A ***bubblesort*** scans an array $A[1..n]$ repeatedly from the highest index to lower indices, each time swapping every out-of-order pair of consecutive items that is encountered.

A ***sinking sort*** scans an array $A[1..n]$ repeatedly from the lowest index to higher indices, each time swapping every out-of-order pair of consecutive items that is encountered.

A ***shakersort*** scans an array $A[1..n]$ repeatedly, and alternates between bubbling upward and sinking downward on alternate scans.

A bubblesort, sinking sort, or shakersort is ***adaptive*** if it stops the first time a scan produces no transpositions.

Heapsort sorts a sequence of entries by iteratively enheaping them all into a heap (§18.2.4) and then iteratively deheaping them all. The order in which they deheap is sorted.

Facts:

1. The name “bubblesort” suggests imagery in which lighter items (i.e., earlier in the prescribed order of the key domain) bubble to the top of the list.

2. The name “sinking sort” suggests that heavier items sink to the bottom.

3. The name “shakersort” suggests a salt shaker that is turned upside down.

4. Since each swap during an exchange sort reduces the total disorder, it follows that each scan brings the list closer to perfect order. By transitivity of the order relation, it follows that if every consecutive pair in a sequence is in the correct order, then the entire sequence is in order.

5. After the first pass of a bubblesort from bottom to top, the smallest element is certain to be in its correct final position at the beginning of the list. After the second pass, the second largest element must be in its correct position, and so on.

6. Bubblesort has worst-case time complexity $O(n^2)$.

7. For “almost sorted” sequences, an adaptive bubblesort can run much faster than $O(n^2)$ time.

8. The priority property implies that the root of a priority tree is assigned the data entry with first precedence.

9. Whereas a sequence of length n has $\binom{n}{2}$ pairs that might be out of order, a binary tree of n elements has at most $n \log n$ pairs that could be out of order, if one compares only those pairs such that one node is an ancestor of the other.

10. Heapsort improves upon the idea of bubblesort because it bubbles only along tree paths between a bottom node and the root, instead of along the much longer path in a linear sequence from a last item to the first.

11. Heapsort runs in $O(n \log n)$ time.

12. Heapsort was invented by J. W. J. Williams in 1964.

Algorithms:

1. Algorithm 3 is an adaptive version of bubblesort.

```
Algorithm 3: BubbleSort of array $A$[1..n].
  $first := 1$;  $last := n$;  $exchange :=$ true
  while $exchange$
     $first := first + 1$;  $exchange :=$ false
     for $i := last$ downto $first$
        if $A[i] < A[i-1]$ then
           swap $A[i]$ and $A[i-1]$; $exchange :=$ true
```

2. Algorithm 4 is a heapsort algorithm.

```
Algorithm 4: HeapSort of array $A$[0..n] into array $B$[0..n].
  procedure heapify($i$)
  if ($A[i]$ is not a leaf) and (a child of $A[i]$ is larger than $A[i]$) then
     let $A[k]$ be the larger child of $A[i]$
     swap $A[i]$ and $A[k]$
     heapify($k$)
  procedure buildheap
  for $i := \lfloor \frac{n}{2} \rfloor$ downto 0
     heapify($i$)
  main program heapsort
  buildheap for $i = 0$ to $n$
     deheap root of $A$ and transfer its value to $B[n-i]$
```

Examples:

1. When cancelled checks are returned to the payer by a bank, they may be in nearly sorted order, since the payees are likely to deposit checks quite soon after they arrive. Thus, they arrive for collection in an order rather close to the order in which they are written. A shakersort might work quite quickly on such a distribution.

2. Starting with the unsorted list $L = 15, 8, 10, 6, 17, 13$, bubblesort would produce the following sequence of lists.

initial list:	15	8	10	6	17	13
after one pass:	6	15	8	10	13	17
after two passes:	6	8	15	10	13	17
after three passes:	6	8	10	15	13	17
after four passes:	6	8	10	13	15	17

3. Starting with the unsorted list $L = 15, 8, 10, 6, 17, 13$, sinking sort would produce the following sequence of lists.

initial list:	15	8	10	6	17	13
after one pass:	8	10	6	15	13	17
after two passes:	8	6	10	13	15	17
after three passes:	6	8	10	13	15	17

4. Starting with the unsorted list $L = 15, 8, 10, 6, 17, 13$, shakersort would produce the following sequence of lists:

initial list:	15	8	10	6	17	13
after one pass:	6	15	8	10	13	17
after two passes:	6	8	10	13	15	17

18.3.4 SORTING BY DIVIDE-AND-CONQUER

The strategy of a divide-and-conquer sort is to partition the given sequence into smaller subsequences, to sort the subsequences recursively, and finally to merge the sorted subsequences into a single sorted sequence.

Definitions:

A ***top-down mergesort*** splits the input sequence into two equal (or nearly equal) sized subsequences, recursively mergesorts the two subsequences, and finally merges the two sorted subsequences into a single sorted sequence.

A ***bottom-up mergesort*** initially regards each entry in its input sequence as a list of length one. It merges two consecutive pairs at a time into lists of length two. Then it merges the lists of length two into lists of length four. Ultimately, all the initial items are merged into a single list.

A ***quicksort*** selects an element x (called the *pivot*) in the input list and splits the input list into two subsequences S_1 and S_2 such that every element in S_1 is no larger than x and every element in S_2 is no smaller than x. Next it recursively sorts S_1 and S_2. Then it concatenates the two sorted subsequences into a single sorted sequence.

The ***pivot*** in a quicksort iteration is the element x at which the sequence is split.

Facts:

1. A top-down mergesort is usually implemented as an internal sort.

2. A bottom-up mergesort is a common form of external sort.

3. An outstanding merit of quicksort is that it can be performed quickly within a single array.

4. Quicksort was first described by C. A. R. Hoare in 1962.

5. The running time of a mergesort is $O(n \log n)$.

6. In the worst case, a quicksort takes time $\Omega(n^2)$.

7. Choosing the quicksort pivot at random tends to avoid worst-case behavior.

8. The average running time for a quicksort is $O(n \log n)$.

9. External sorting is used to process very large files, much too large to fit into the primary memory of any computer.

10. The emphasis in devising good external sorting algorithms is on decreasing the number of times the data are accessed because the time required to transfer data back and forth between the the primary memory and the tape usually far outweighs the time required to perform comparisons on data in the primary memory.

11. Formal algorithms and more detailed discussions of external sorting can be found in [Kn98].

12. In an external sort, the number of times each element is read from or written to the external memory is $\log(\frac{n}{m}) + 1$, where m is the available internal memory size. Improvements on the construction of runs as well as on the merging process are possible (see [Kn98]).

Algorithms:

1. Algorithm 5 merges two sorted sequences into a single sorted sequence.

Algorithm 5: **Merge two sequences.**

```
procedure merge($A[1..m], B[1..h], C[\,]$)
{Merge two sorted sequences $A$ and $B$ into a single sorted sequence $C$}
$i_A := 1$;  $i_B := 1$;  $i_C := 1$
while $i_A \le m$ and $i_B \le h$
    if $A[i_A] \le B[i_B]$ then
        $C[i_C] := A[i_A]$;  $i_A := i_A + 1$
    else
        $C[i_C] := B[i_B]$;  $i_B := i_B + 1$
    $i_C := i_C + 1$
if $i_A > m$ then
    move the remaining elements in $B$ to $C$
else
    move the remaining elements in $A$ to $C$
```

2. Algorithm 6 mergesorts a sequence internally.

Algorithm 6: **MergeSort S.**

```
procedure mergesort($S$)
if $length(S) \leq 1$ then return else
  split $S$ into two (equal or nearly equal)-sized subsequences $S_1$ and $S_2$
  mergesort $S_1$
  mergesort $S_2$
  merge($S_1, S_2$)
```

3. In a typical external mergesort such as Algorithm 7, there are two input tapes and two output tapes. The entries are initially arranged onto the two input tapes, with half the entries on each tape, and regarded as sublists of length one. A sublist from the first input tape is merged with a sublist from the second input tape and written as a sublist of doubled length onto the first output tape. Then the next sublist from the first input tape is merged with the next sublist from the second input tape and written as a sublist of doubled length onto the second output tape. The alternating process is iterated until the sublists from the input tapes have all been merged into sublists of doubled length onto the two output tapes. Then the two output tapes become input tapes to another iteration of the merging process. This continues until all the original entries are in a single list.

Algorithm 7: **External MergeSort sequence S of length n.**

```
for $i := 1$ to $\lceil \log n \rceil$
  for $j := 1$ to $\lceil \frac{\log n}{4i} \rceil$
    merge next sublist from input $A$ with next sublist from input $B$,
        writing merged sublist onto output tape $C$
    merge next sublist from input $A$ with next sublist from input $B$,
        writing merged sublist onto output tape $D$
  reset output tape $C$ as input tape $A$ and vice versa
  reset output tape $D$ as input tape $B$ and vice versa
```

4. The generic quicksort algorithm QuickSort (Algorithm 8) does not specify how to select a pivot.

Algorithm 8: **QuickSort.**

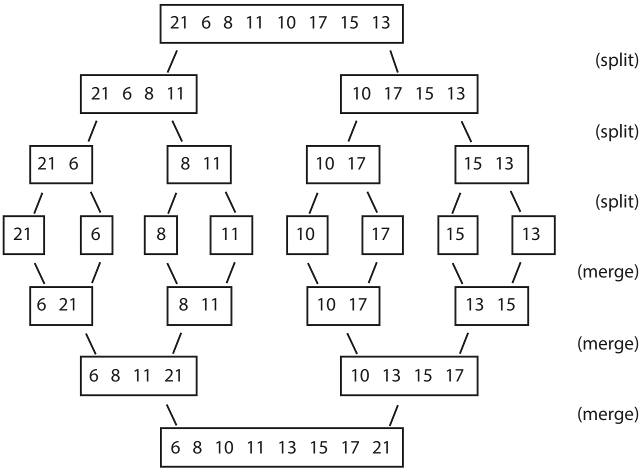
```
procedure split($x, S$)
for each element $y$ in $S$ do
  if $x \geq y$ then
    put $y$ in $S_1$
  else
    put $y$ in $S_2$

main program
if $length(S) \leq 1$ then return else
  choose an arbitrary element $x$ in sequence $S$
```

```
split($x, S$) into $S_1$ and $S_2$
recursively sort $S_1$ and $S_2$
concatenate the two sorted subsequences
```

Example:

1. The following illustrates MergeSort on the sequence $S = 21, 6, 8, 11, 10, 17, 15, 13$.



18.3.5 SORTING BY DISTRIBUTION

Prior knowledge of the distribution of the elements of the input sequence sometimes permits sorting algorithms to break the lower bound of $\Omega(n \log n)$ for running time of comparison sorts.

Definitions:

The ***rank*** of an element of a finite ordered set is the number of elements that it exceeds or equals.

A ***rank-counting sort*** calculates the "rank" for each element, and then assigns the elements directly to their correct position according to their rank.

In a ***base-ten radix sort***, the keys are base-ten integer numerals with at most k digits. Each entry is appended to one of ten queues $Q_0, \ldots, Q_9$, according to the value of its least significant digit, after which the list $Q_0 \circ \cdots \circ Q_9$ is formed by concatenation. The concatenated list is then similarly separated into ten queues, according to the values of the next least significant digit. This process is iterated up to the most significant digit.

A ***radix sort*** is a sort like the base-ten radix sort, using an arbitrary radix, not necessarily ten.

Facts:

1. A rank-counting sort gives favorable results when the input keys are n different positive integers, all bounded by cn for some constant c.

2. The running time of a rank-counting sort is $O(n)$. The RankCountingSort (Algorithm 9) can be modified so that it sorts in linear time even when the input elements are not all distinct [CoEtal09].

3. It can be proved that a radix sort correctly sorts the input (see [Kn98]).

4. The running time of RadixSort is bounded by $O(kn)$, where k is the maximum number of digits in a key. When k is a constant independent of n, RadixSort sorts in linear time. Note, however, that if the input consists of n distinct numbers and the base of the numbers is fixed, then k is of order $\Omega(\log n)$.

Algorithms:

1. In the rank-counting sort (Algorithm 9), the array A contains n input elements, the array B is the output array, and the array C is an auxiliary array of size cn used for counting. Step 3 causes count $C[A[j]\,]$ to be the rank of entry $A[j]$.

Algorithm 9: **RankCountingSort of array $A[1..]$ into array $B[1..n]$.**

```
{pre : $\max(A[i]) \leq cn$}
for $i := 1$ to $cn$
    $C[i] := 0$
for $j := 1$ to $n$
    $C[A[j]] := 1$
for $i := 2$ to $cn$
    $C[i] := C[i] + C[i-1]$
for $j := 1$ to $n$
    $B[C[A[j]]] := A[j]$
```

2. The base-ten radix sort (Algorithm 10) starts with an input list A whose keys have at most k digits.

Algorithm 10: **RadixSort of array $A[1..n]$.**

```
for $d := 1$ to $k$
    for $i := 0$ to $9$
        make $Q_i$ an empty queue
    for $j := 1$ to $n$
        let $h$ be the $j$th digit of $A[j]$
        append $A[j]$ to queue $Q_h$
    $A := Q_0 \circ \cdots \circ Q_9$   {Concatenation}
```

18.3.6 SEARCHING

Definitions:

Searching a database means seeking either a target entry with a specific key or a target entry whose key has some specified property.

Linear search is the technique of scanning the entries of a list in sequence, either until some stopping condition occurs or the entire list has been scanned.

Binary search is a recursive technique for seeking a specific target entry in a list. The target key is compared to the key in the middle of the list, in order to determine which half of the list could contain the target item, if it is present.

Hashing is storage-retrieval in a large table in which the table location is computed from the key of each data entry (see §18.4).

A ***binary search tree*** is a binary tree in which each node has an attribute called its *key*, and the keys are elements of an ordered datatype (e.g., the integers or alphabetic strings). Moreover, at each node v the key is larger than all the keys in its left subtree, but smaller than all the keys in its right subtree.

A ***2-3 tree*** is a tree in which each non-leaf node has 2 or 3 children, and in which every path from the root to a leaf is of the same length.

An ***AVL tree*** is a binary search tree with the property that the two subtrees of each node differ by at most 1 in height.

Facts:

1. Some common database search objectives are for a specified target entry, for the maximum entry, for the minimum entry, or for the kth smallest entry.

2. The performance of a dynamic database structure that permits insertions and deletions is measured by the time needed for insertions and deletions, as well as the time needed for searching.

3. A binary search runs in average time $O(\log n)$ to search for a specified element x in a sorted list of n elements.

4. In the worst case of searching by comparison-based algorithms for a specified target element in a sorted list of length n, $\Omega(\log n)$ comparisons are necessary.

5. A randomly constructed n-node binary search tree has expected height of at most $2\log n$.

6. An AVL tree of n nodes has depth $O(\log n)$.

7. Insertion and deletion on an AVL tree, with patching if needed so that the result is an AVL tree, can be performed in $O(\log n)$ worst-case running time [Kn98].

8. AVL trees are named for their inventors, G. M. Adelson-Velskii and Y. M. Landis.

9. A 2-3 tree for a set S of entries can be constructed by assigning the entries to the leaves of the tree in order of increasing key from left to right. Each non-leaf node v is labeled with two elements $L[v]$ and $M[v]$, which are the largest keys in the subtrees rooted at its left child and middle child, respectively.

10. The operations of searching, finding a maximum or minimum, inserting a new entry, and deleting an entry all execute within $O(\log n)$ time.

Algorithms:

1. To search for a specified target key x in a sorted list $A[1..n]$, a call to the recursive algorithm BinarySearch $(A, 1, n, x)$ in Algorithm 11 can be used. Its technique is to compare the target to the middle entry of the list and to decide thereby in which half the target might occur; then that half remains as the active portion of the list for the next iteration of the search step, while the other half becomes inactive.

```
Algorithm 11: BinarySearch $(A, L, U, x)$.
  {Look for $x$ in $A[L..U]$; report its position if found, else report 0}
  if $L = U$ then
    if $x = A[L]$ then return $L$ else return 0
  else
    $M := \lfloor \frac{L+U}{2} \rfloor$
    if $x > A[M]$ then
      return BinarySearch $(A, M + 1, U, x)$
    else return BinarySearch $(A, L, M, x)$
```

2. *Find the maximum [minimum] in an unsorted list*: Scan the list from start to finish and keep track of the largest [smallest] seen so far.

3. *Finding the maximum in a binary search tree*: Start at the root and follow the right-child pointers until some node has no right child. That node must contain the maximum.

4. *Finding the minimum in a binary search tree*: Start at the root and follow the left-child pointers until some node has no left child. That node must contain the minimum.

5. *Searching for a target entry x in a 2-3 tree*: Start at the root, and use the keys at non-leaf nodes to locate the correct leaf, as described by Algorithm 12.

```
Algorithm 12: 23TSearch$(x, r)$.
  {Case 1: $r$ is a leaf}
    if $r$ is labeled with $x$ then return "yes" else return "no"
  {Case 2: $r$ is not a leaf}
    if $x \le L[r]$ then return 23TSearch$(x, \text{leftchild}(r))$
    else if $x \le M[r]$ then return 23TSearch$(x, \text{midchild}(r))$
    else if $x$ has a right child then return 23TSearch$(x, \text{rightchild}(r))$
    else return "no"
```

6. *Finding the maximum in a 2-3 tree*: Starting from the root, follow the right-child pointers to the rightmost leaf, which contains the maximum entry.

7. *Finding the minimum in a 2-3 tree*: Starting from the root, follow the left-child pointers to the leftmost leaf, which contains the minimum entry.

8. *To insert a new entry x into a 2-3 tree*: First locate the non-leaf node v whose child x "should" be. If v is a 2-child node v, then simply install x as a third child of v. If v already has three children, then let v keep as children the two smallest of the set comprising its three children and x. A new non-leaf node u becomes the parent of the largest member of this set. Now recursively insert node u as a new child to the parent of node v. If the process eventually makes the root of the tree a 4-child node, then the last step is to create a new root with two new children, each of which has two of the four children of the former root. Note that the labels of some non-leaf nodes may be updated in this process.

9. *To delete an entry x from a 2-3 tree*: Essentially, reverse the manner by which an element is inserted. First find the leaf v containing x. If the parent p of v has three children, then the leaf v is simply deleted. If p has only two children v and v', then select an adjacent sibling p' of p. If p' has only two children, then make v' a child of p', and recursively delete the node p from the tree. If p' has three children, then make an appropriate child of p' into a new child of p and delete the node v (note that now both p and p' have two children). Again the process may progress recursively to the root of the tree, such that it is necessary to delete one of the only two children of the root. In this case, delete the root and make the remaining child of the root into a new root of the tree. Labels of some non-leaf nodes may need to be updated in this process.

10. *Searching in a random list*: Finding the kth smallest element, for an arbitrary k, in a random list of size n can also be done in linear time. The algorithm, Algorithm 13, is based on the method of "Prune and Search". That is, the process first prunes away in linear time a constant factor of the elements in the input, then recursively searches the rest. A careful analysis shows that each of the two sets S_1 and S_2 contains at most $\frac{7n}{10}$ elements. Therefore, if $T(n)$ is the running time of Algorithm 13 for n elements, it follows that $T(n) \le T(\frac{n}{5}) + T(\frac{7n}{10}) + O(n)$. This relation gives $T(n) = O(n)$.

```
Algorithm 13: Finding-the-kth-Smallest.
  divide the $n$ input elements into $\lceil \frac{n}{5} \rceil$ groups of five elements
  find the median for each of the $\lceil \frac{n}{5} \rceil$ groups
  recursively find the median $m^*$ of these group medians
  partition the input into two sets $S_1$ and $S_2$ such that each element in $S_1$ is no
      larger than $m^*$ and each element in $S_2$ is no smaller than $m^*$
  if $S_1$ has $\ge k$ elements then
    recursively find the $k$th smallest element in $S_1$
  else
    recursively find the $(k - |S_1|)$th smallest element in $S_2$
```

Example:

1. We apply Algorithm 11 to search for the target 64 in the following 16-element list:

$$5, 8, 9, 13, 16, 22, 25, 36, 47, 49, 64, 81, 100, 121, 144, 169.$$

First split it into these two 8-element sublists

$$5, 8, 9, 13, 16, 22, 25, 36 \qquad 47, 49, 64, 81, 100, 121, 144, 169$$

and then compare 64 to the largest item in the first list. Since $64 > 36$, it follows that 64, if present in the original list, would have to be in the second sublist. Next split the active sublist further into these two 4-element sublists

$$47, 49, 64, 81 \qquad 100, 121, 144, 169$$

and then compare 64 to the largest item in the first new sublist. Since $64 \le 81$, it follows that 64, if present, would have to be in the second sublist. Therefore, resplit the active sublist further into these two 2-element sublists

$$47, 49 \qquad 64, 81$$

and then compare the target 64 to the largest item in the first new sublist. Since $64 > 49$, it follows that 64, if present, would have to be in the second sublist. Therefore, resplit the active sublist further into these two 1-element sublists

$$64 \qquad 81$$

and then compare 64 to the largest item in the first new sublist. Since $64 \leq 64$, it follows that 64, if present, would have to be in the first sublist. Since that sublist has only one element, namely 64, the target 64 is compared to that one element. Since they are a match, the target has been located as the 11th item in the original list.

18.4 HASHING

Hashing, also known as "address calculation" and as "scatter storage", is a mathematical approach to organizing records within a table. The objective is to reduce the amount of time needed to find a record with a given key. Hashing is best suited for "dynamic" tables, that is, for databases whose use involves interspersed lookups and insertions. Dynamic dictionaries (such as spelling checkers) and compiler-generated symbol tables are examples of applications where hashing may be useful.

18.4.1 HASH FUNCTIONS

Hashing is an approach to placing records into a table and retrieving them when needed, in which the location for a record is calculated by an algorithm called a hash function.

Definitions:

A ***record*** is a pair of the form (k:*key*, d:*data*), in which the second component is data and the first component is a *key* used to store it in a table and to retrieve it subsequently from that table.

A ***key domain*** is an ordered set, usually the integers, whose members serve as keys for the *records* of a table. No two different records have the same key.

A ***hash table*** is an array, in which the location for storing and retrieving a record are calculated from the key of that record.

A ***hash function*** h is a function that maps a key domain to an interval of integers $[0..m-1]$. The intent is that a record with key k is to be stored in or retrieved from the location $h(k)$ in the table.

A ***collision*** occurs when a hash function h assigns the same table location to two different keys $k_1 \neq k_2$, i.e., when $h(k_1) = h(k_2)$.

Collision resolution is the process of finding an alternative location for a new record whose key collides with that of a record already in the table.

The ***fullness*** of a hash table T is the ratio $\alpha(T) = \frac{n}{m}$ of the number n of records in the table to the capacity m of the table.

Facts:

1. Hashing is often used when the set of keys (of the records in the database) is not a consecutive sequence of integers or easily convertible to a consecutive sequence of integers.

2. Keys that are non-numeric (or do not have a good random distribution) can be transformed into integers by using or modifying their binary representation. The resulting integers are called *virtual keys*.

3. It is desirable for a hash function to have the *simplicity property*, i.e., that it takes only a few simple operations to compute the hash function value.

4. It is desirable for a hash function to have the *uniformity property*, i.e., that each possible location in the range $0, \ldots, m-1$ of the hash function $h\colon K \to [0..m{-}1]$ is generated with equal likelihood, that is, with probability $\frac{1}{m}$.

Examples:

1. The *division method* $h(k) = k \textbf{ mod } m$ is a simple hash function that can be used when the keys of the records are integers that extend far beyond a feasible table size. The table size m must be chosen carefully to avoid high instance of collision, without wasting too much storage space. Selecting m to be a prime not close to a power of 2 is typically a good choice.

2. The *multiplication method* is another simple hashing rule. First the key (in base 2) is multiplied by a constant value A such that $0 < A < 1$, and then $p = \log m$ bits are selected for the hash function value from somewhere in the fractional part of the resulting base-2 numeral, often required to be away from its low end. (This is similar to some methods for generating random numbers.)

3. As a simplified example of a multiplicative hash function, consider table size $m = 16$, address size $p = \log 16 = 4$ bits, and key size $w = 6$ bits. With fractional constant $A = 0.101011_2$, use the first four bits of the fractional part. For instance, given key $k = 011011_2$, first calculate $R = A \cdot k = 010010.001001_2$. Then take $k = 0010_2$, the low-end four bits of the fractional part. Knuth [Kn98] suggests $A = 0.6180339887...$ as a good choice of a multiplier.

18.4.2 COLLISION RESOLUTION

Definitions:

Collision resolution is the process of computing an alternative location for a colliding record. The two basic methods are *chaining* and *rehashing*.

Chaining is a collision resolution method that involves auxiliary storage space for records outside the confines of the main array. Each slot in the main table can be used as the root of a linked list that contains all the records assigned to that location by the hash function. Each additional colliding record is inserted at the front of the linked list. When searching for a record, the list is traversed until the record is found, or until the end of the list is reached.

The ***size of a chained hash table*** is the number of linked list headers (i.e., the size of the main array). Thus, a chained hash table said to be of size m may be used to store a database with more than m records.

Rehashing is a collision resolution method in which there is no auxiliary storage outside the main table, so that a colliding record must be stored elsewhere in the main table, that is, at a location other than that assigned by the hash function to its key k. A collision resolution function finds the substitute location.

A ***collision resolution function*** under rehashing generates a *probe sequence* $\langle h_0(k) = h(k), h_1(k), h_2(k), \ldots, h_{m-1}(k)\rangle$. The new record is inserted into the first unoccupied probe location. When searching for a record, the successive probes are tried until the record is found or the probe finds an unoccupied location (i.e., unsuccessful search).

A ***probe sequence*** for key k is a sequence $\langle h_0(k), h_1(k), h_2(k), \ldots, h_{m-1}(k)\rangle$ of possible storage locations in the table T that runs without repetition through the entire set $\langle 0, 1, 2, \ldots, m-1\rangle$ of locations in the table, as possible places to store the record with key k.

Clustering is a hashing phenomenon in which after two keys collide, their probe sequences continue to collide.

Linear probing means trying to resolve a collision at location $h(k)$ with a probe sequence of the form $h_i(k) = (h_0(k) + ci)$ **mod** m.

Quadratic probing means trying to resolve a collision at location $h(k)$ by using a probe sequence of the form $h_i(k) = (h_0(k) + c_1 i + c_2 i^2)$ **mod** m.

A ***secondary hash function*** is a hash function used to generate a probe sequence, once a collision has occurred.

Double hashing means using a primary hash function h and a secondary hash function h' to resolve collisions, so that $h_i(k) = (h(k) + ih'(k))$ **mod** m.

Facts:

1. In designing a hash function, an objective is to keep the length of the probe sequences short, so that records are stored and retrieved quickly.

2. Under chain hashing, inserting a record always requires $O(1)$ time.

3. Under chain hashing, the time to find a record is proportional to the length of the chain from its key, and the average length of a chain in the table equals the fullness α of the table.

4. Under chain hashing, if the number of records in the table is proportional to the table capacity, then a *find* operation needs $O(1)$ time, on average.

5. Under chain hashing, a *delete* operation consists of a *find* with time proportional to table fullness, followed by removal from a linked list, which requires only $O(1)$ time.

6. Analysis of rehashing performance is based on the following assumptions:

- uniform distribution of keys: each possible key in the key domain is equally likely to occur as the key of some record;
- uniform distribution of initial hash locations (see §18.4.1);
- uniform distribution of probe sequences: each possible probe sequence

$$\langle h_0(k), h_1(k), h_2(k), \ldots, h_{m-1}(k)\rangle,$$

  regarded as a permutation on the set of all table locations, is equally likely.

7. Under rehashing, the expected time to perform an *insert* operation is the same as the expected time for unsuccessful search, and is at most $\frac{1}{1-\alpha}$.

8. Under rehashing, the expected time $E(\alpha)$ to perform a successful *find* operation is at most $\frac{1}{\alpha}\ln\frac{1}{1-\alpha} + \frac{1}{\alpha}$. For instance, $E(0.5) = 3.386$ and $E(0.9) = 3.670$. That means that if a table is 90% full, a record will be found, on average, with 3.67 probes.

9. Under rehashing, location of the deleted record needs to be marked as *deleted* so that subsequent probe sequences do not terminate prematurely. Moreover, the running time of a *delete* operation is the same as for a successful *find* operation. (It also causes the measure of fullness for searches to be different from that used for insertions, because a new record can be inserted into the location marked as *deleted*). However, in most applications that use hashing, records are never deleted.

Examples:

1. The following example of linear probing uses prime modulus $m = 1013$ and prime multiplier $c = 367$. The keys are taken to be social security numbers.

key k	$h_0(k)$	$h_1(k)$
113548956	773	
146834522	172	
207639313	651	
359487245	896	
378545523	592	
435112760	896	250
670149788	651	
721666437	172	539
762456748	12	

2. Linear probing suffers from clustering. That is, if $h_i(k_1) = h_j(k_2)$, then $h_{i+p}(k_1) = h_{j+p}(k_2)$ for all $p = 1, 2, \ldots$. All probe sequences follow the same (linear) pattern, from which it follows that long chains of filled locations will cause a large number of probes needed to insert a new record (and to locate it later).

3. Quadratic probing suffers from clustering. That is, if $h_0(k_1) = h_0(k_2)$, then $h_i(k_1) = h_i(k_2)$ for $i = 1, 2, \ldots$.

4. Pairing the primary hash function $h(k) = k \textbf{ mod } p$ with the secondary hash function $h'(k) = k \textbf{ div } p$, where p is a prime, yields the double hash function $h_i(k) = (h_0(k) + ih'(k)) \textbf{ mod } p$.

18.5 DYNAMIC GRAPH ALGORITHMS

Dynamic graph algorithms are algorithms that maintain information with regard to properties of a (possibly edge-weighted) graph while the graph is changing. These algorithms are useful in a number of application areas, including communication networks, VLSI design, distributed computing, and graphics, where the underlying graphs are subject to dynamic changes. Efficient dynamic graph algorithms are also used as subroutines in algorithms that build and modify graphs as part of larger tasks, e.g., the algorithm for constructing Voronoi diagrams by building planar subdivisions.

Notation: Throughout this section, n and m denote the number of vertices and the number of edges, respectively, of the graph G that is being maintained and queried dynamically.

18.5.1 DYNAMICALLY MAINTAINABLE PROPERTIES

Definitions:

A (***dynamic***) ***update operation*** is an operation on a graph that keeps track of whether the graph has a designated property.

A ***query*** is a request for information about the designated property.

Facts:

1. The primitive update operations for most dynamic graph algorithms are edge insertions and deletions and, in the case of edge-weighted graphs, changes in edge weights.

2. For most dynamic graph algorithms, insertion or deletion of an isolated vertex can be accomplished by an easy modification of a nondynamic algorithm.

3. The insertion or deletion of vertices together with their incident edges is usually harder and has to be done by iterating the associated edge update operation.

4. There is a trade-off between the time required for update operations and the time required to respond to queries about the property being maintained. Thus, running times of the update operations depend strongly on the property being maintained.

5. Nontrivial dynamic algorithms corresponding to several graph properties are known (see Examples).

Examples:

1. *Connectivity*: The permitted query is whether two vertices x and y are in the same component. Permitted updates are edge insertions, edge deletions, and isolated vertex insertions. Frederickson [Fr85] provides an algorithm for maintaining minimum spanning forests that can easily be adapted to this problem. Improvements in running times have been achieved by [EpEtal92b] and [EpGaIt93].

2. *Bipartiteness*: Update operations are the same as for connectivity (Example 1). A query simply asks whether a graph is bipartite. An algorithm is presented in [EpEtal92b], with an improvement in [EpGaIt93].

3. *Minimum spanning forests*: The query is whether an edge is in a minimum spanning forest. The graph is weighted, and the update operations are increments and decrements of weights. (Edge insertion is accomplished by lowering the edge weight from ∞ and edge deletion by incrementing the edge weight to ∞.) [Fr85] contains the early result, with improvements by [EpGaIt93]. The plane and planar graph cases have been considered by [EpEtal92b] and [EpEtal93].

4. *Biconnectivity and 2-edge connectivity*: Update operations are the same as for connectivity (Example 1). Queries ask whether two given vertices lie in the same biconnected (resp., 2-edge connected) component. Efficient algorithms for maintaining biconnectivity are found in [EpEtal92b], [EpGaIt93], [Ra93], and [HeRaSu94]. Efficient algorithms for maintaining 2-edge connectivity are found in [EpEtal92b], [Fr91], and [Fr85]. Any algorithm for dynamically maintaining biconnectivity translates to an algorithm with the same time bounds for 2-edge connectivity [GaIt91].

5. *Planarity*: Update operations include edge insertions and deletions. Queries ask whether the graph is currently planar. Variants include queries that would test whether the addition of a particular edge would destroy the current imbedding. Algorithms are described in [EpEtal93] and [Ra93].

18.5.2 TECHNIQUES

Definitions:

A ***partially dynamic algorithm*** is usually an algorithm that handles only edge insertions and, for edge-weighted graphs, decrements in edge weights. Less commonly, this term can refer to an algorithm that handles only edge deletions or weight increments.

A ***cluster*** in a spanning tree T for a graph G is a set of vertices such that the subgraph of T induced on these vertices is connected.

An ***ambivalent data structure*** is a structure that, at many of its vertices, keeps track of several alternatives, despite the fact that a global examination of the structure would determine which of these alternatives is optimal.

A ***certificate*** for property $\mathcal{P}$ and graph G is a graph G' such that G has property $\mathcal{P}$ if and only if G' has property $\mathcal{P}$.

A ***strong certificate*** for property $\mathcal{P}$ and graph G is a graph G', on the same vertex set as G, such that, for every graph H, $G \cup H$ has property $\mathcal{P}$ if and only if $G' \cup H$ has property $\mathcal{P}$.

A ***sparse certificate*** is a strong certificate in which the number of edges is $O(n)$.

A function A that maps graphs to strong certificates is ***stable*** if it satisfies

- $A(G \cup H) = A(A(G) \cup H)$;
- $A(G - e)$ differs from $A(G)$ by $O(1)$ edges, where e is an edge in G.

A ***stable certificate*** is one produced by a stable mapping.

A ***plane graph*** is a planar graph, together with a particular imbedding in the plane.

A ***compressed certificate*** for a property $\mathcal{P}$ of G, where $G = (V, E)$ is a subgraph of a larger graph F and $X \subset V$ separates G from $F - G$, is a small certificate $G' = (V', E')$ with $X \subset V'$ such that, for any graph H that is attached to G only at the vertices of X, $H \cup G$ has property $\mathcal{P}$ if and only if $H \cup G'$ does, and $|V'| = O(|X|)$.

A graph property $\mathcal{P}$ is ***dyadic*** if it is defined with respect to a pair of vertices (x, y).

A graph C is a ***certificate of a dyadic property*** $\mathcal{P}$ for X in G if and only if, for any H with $V(H) \cap V(G) \subset X$ and every x and y in $V(H)$, $\mathcal{P}$ is true for (x, y) in the graph $G \cup H$ if and only if it is true for (x, y) in the graph $C \cup H$.

Facts:

1. Using the union-find data structure [Ta75], it is possible to maintain connectivity information in $O(\alpha(m, n))$ amortized time per update or query. Here $\alpha(m, n)$ denotes the inverse Ackermann function, and it grows extremely slowly.

2. For other graph properties, such as 2-edge connectivity and biconnectivity, a data structure called the *link/condense tree* [WeTa92] maintains information in $O(\alpha(m, n))$ amortized time per update or query.

3. The link/condense tree supports the operation of condensing an entire path in the tree into a single vertex. This is important in the applications considered, because the insertion of an edge may cause several biconnected components or 2-edge connected components to be combined into one.

4. Link/condense trees are based on *dynamic trees*. [SlTa83]

5. The dynamic tree data structure maintains a set of rooted trees. It supports the operations of *linking* the root of one tree as the child of a vertex in another tree, *cutting* a tree at a specified edge, and *everting* a tree to make a specified vertex the root in worst-case $O(\log n)$ time per operation. It also supports other operations based on keys stored at vertices, such as finding the minimum key on the path from a given vertex to the root in $O(\log n)$ time.

6. To maintain minimum spanning trees in an edge-weighted, connected graph subject to changes in edge weights, Frederickson [Fr85] uses *clustering* and *topology trees* in Algorithm 1.

```
Algorithm 1: Maintaining a minimum spanning tree.
  Preprocessing:
    find a minimum spanning tree $T$ of the initial graph $G$
    maintain a dynamic tree of $T$, using [SlTa83]
    let $z := n^{2/3}$
    group the vertices of $T$ into clusters whose sizes are between $z$ and $3z - 2$
    {There will be $\Theta(n^{1/3})$ such clusters}
    for each pair of clusters $i, j$ maintain the set of edges $E_{ij}$ as a min-heap
  Updates:
    decreases in tree edge weights do not change anything
    increases in non-tree edge weights are handled by a suitable update of the
      appropriate min-heap
    decreases in non-tree edge weights are handled by using the dynamic tree
      appropriately
    if tree edge $e$ increases in weight, remove it, thus partitioning the clusters into
      two sets; then find an edge of minimum cost between clusters on opposite sides
      of the partition
```

7. Ambivalence may permit faster updates, possibly at the cost of slower queries.

8. Frederickson [Fr91] presents an ambivalent data structure for spanning forests that builds on the ideas of multilevel partitions and (2-dimensional) topology trees developed in [Fr85].

9. Let $\mathcal{P}$ be a property for which sparse certificates can be found in time $f(n,m)$. Suppose that there is a data structure that can be built in time $g(n,m)$ and permits static testing of property $\mathcal{P}$ in time $q(n,m)$. Then there is a fully dynamic data structure for testing whether a graph has property $\mathcal{P}$; update time for this structure is $f(n,O(n))O(\log(\frac{m}{n})) + g(n,O(n))$, and query time is $q(n,O(n))$. This "basic sparsification technique" is used to dynamize static algorithms. To use it, one need only be able to compute sparse certificates efficiently.

10. The *sparsification* method of [EpEtal92b] partitions the input graph into sparse subgraphs (with $O(n)$ edges) and summarizes the relevant information about each subgraph in an even sparser "certificate". Certificates are merged in pairs, producing larger subgraphs that are themselves sparsified using the certificate technique. The result is a balanced binary tree in which each vertex is a sparse certificate. Each insertion or deletion of an edge in the input graph causes changes in $\log(\frac{m}{n})$ tree vertices. Because these changes occur in graphs with $O(n)$ edges, instead of the m edges in the input graph, time bounds for updates are reduced in most natural problems.

11. Let $\mathcal{P}$ be a property for which stable sparse certificates can be maintained in time $f(n,m)$ per update. Suppose that there is a fully dynamic algorithm for $\mathcal{P}$ with update time $g(n,m)$ and query time $q(n,m)$. Then this algorithm can be sped up; specifically, $\mathcal{P}$ can be maintained fully dynamically in time $f(n,O(n))O(\log(\frac{m}{n})) + g(n,O(n))$ per update, with query time $q(n,O(n))$. Because this "stable sparsification technique" is used to speed up existing dynamic algorithms, it often yields better results than the basic sparsification technique described in Fact 10. However, to use it, one must be able to maintain stable sparse certificates efficiently; this is a more stringent requirement than what is needed to apply basic sparsification.

12. Eppstein, Galil, and Italiano [EpGaIt93] improve the sparsification technique to remove the $\log(\frac{m}{n})$ factor in these bounds. They achieve this improvement by partitioning the edge set of the original graph more carefully.

13. Dynamic algorithms restricted to plane graphs have been considered by several authors. Eppstein et al. [EpEtal93] introduce a variant of sparsification that permits the design of efficient dynamic algorithms for planar graphs in an imbedding-independent way, as long as the updates to the graph preserve planarity. Because these graphs are already sparse, Eppstein et al. design a separator-based sparsification technique.

14. The fact that separator sizes are sublinear ($O(\sqrt{n})$ for planar graphs) allows the possibility of maintaining sublinear certificates. Eppstein et al. [EpEtal93] use a separator-based decomposition tree as the sparsification tree and show how to compute it in linear time and maintain it dynamically. They use it to show the following: For a property $\mathcal{P}$ for which compressed certificates can be built in time $T(n)$, a data structure for testing $\mathcal{P}$ built in time $P(n)$, and queries answered in time $Q(n)$, a fully dynamic algorithm for maintaining $\mathcal{P}$ under planarity-preserving insertions and deletions takes amortized time $P(O(n^{1/2})) + T(O(n^{1/2}))$ per update and $Q(O(n^{1/2}))$ per query.

15. A dyadic property $\mathcal{P}$, for which compressed certificates can be built in time $T(n)$, a data structure for testing $\mathcal{P}$ built in time $P(n)$, and queries answered in time $Q(n)$, can be maintained with updates taking $T(O(n^{1/2}))$ amortized time and queries taking $P(O(n^{1/2})) + Q(O(n^{1/2})) + T(O(n^{1/2}))$ worst-case time.

16. In dealing with plane (as opposed to planar) graphs and allowing only updates that can be performed in a planarity-preserving manner on the existing imbedding, simpler techniques that rely on planar duality can be used [EpEtal92b].

17. When maintaining minimum spanning trees under updates that change only edge weights, the most difficult operation to handle is an increase in the weight of an MST edge. However, in the dual graph this can be viewed as a decrease in the weight of a non-MST edge. This idea and the handling of edge insertions and deletions are addressed by the data structures of [GuSt85] and the *edge-ordered tree* data structure of [EpEtal92b]. These data structures help maintain the subdivision and its dual in the face of general updates and also help perform required access operations efficiently. Edge-ordered trees are an adaptation of the dynamic trees of [SlTa83].

18. Knowledge of the imbedding allows one to use topology trees in more efficient ways. Specifically, Rauch [Ra94] partitions the non-tree edges into equivalence classes called *bundles*. In the cyclical ordering of edges emanating from a cluster, bundles are carefully chosen, consecutive subsets of edges.

18.5.3 APPLICATIONS

Examples:

1. *Bipartiteness* [EpEtal92a], [EpGaIt93]: A graph that is not bipartite contains an odd cycle. The graph formed by adding the shortest edge inducing an odd cycle (if any) to the minimum spanning forest is a stable certificate of (non-)bipartiteness. Using the clustering techniques of [Fr85] and the improved sparsification techniques of [EpGaIt93], this certificate can be maintained in $O(n^{1/2})$ time per update. The query time in this example is $O(1)$; one bit is used to indicate whether the operation is maintaining a certificate of bipartiteness or of non-bipartiteness.

2. *Minimum spanning forests* [EpEtal92a], [EpGaIt93], [Fr85]: In this example, the goal is not to maintain a data structure that supports efficient testing of a property, but rather to maintain the minimum spanning forest itself as edges are added to and deleted from the input graph. It is shown in [EpEtal92a] how to define a canonical minimum spanning forest that serves as the analogue of a stable sparse certificate. Frederickson [Fr85] uses the topological approach to obtain a fully dynamic algorithm that maintains minimum spanning forests in time $O(m^{1/2})$ per update. Applying the improved stable sparsification technique with $f(n,m) = g(n,m) = O(m^{1/2})$ yields a fully dynamic minimum spanning forest algorithm with update time $O(n^{1/2})$. For plane graphs, [EpEtal92b] show that both updates and queries can be performed in $O(\log n)$ time per operation; for planar graphs, [EpEtal93] show that $O(\log^2 n)$ time per deletion and $O(\log n)$ time per insertion are sufficient.

3. *Connectivity* [EpEtal92a], [EpGaIt93], [Fr85]: Simple enhancements to the minimum spanning forest algorithms in [Fr85] yield fully dynamic algorithms for the connectivity problem in which the update times are the same as they are for minimum spanning forests, and the query times are $O(1)$. Thus, as in Example 2, applying improved stable sparsification with $f(n,m) = g(n,m) = O(m^{1/2})$ yields a fully dynamic connectivity algorithm with update time $O(n^{1/2})$ and query time $O(1)$. Similarly, the planar and plane graph algorithms for minimum spanning trees can be generalized to work for minimum spanning forests and adapted to maintain connected components.

4. *Biconnectivity* [EpEtal92a], [EpGaIt93], [HeRaSu94], [Ra93]: Cheriyan, Kao, and Thurimella [ChKaTh93] show that $C_2 = C_1 \cup B_2$ is a sparse certificate for biconnectivity, where C_1 is a breadth-first spanning forest of the input graph G, and B_2 is a breadth-first spanning forest of $G - C_1$. Eppstein et al. [EpEtal92a] show that C_2 is in fact a strong certificate of biconnectivity. These strong certificates can be found in time $O(m)$, using classical breadth-first search algorithms. Applying improved sparsification with $f(n,m) = g(n,m) = O(m)$ yields a fully dynamic algorithm for maintaining the biconnected components of a graph that has update time $O(n)$.

5. The approach to biconnectivity in [Ra94] is to partition the graph G into clusters and decompose a query that asks whether vertices u and v lie in the same biconnected component into a query in the cluster of u, a query in the cluster of v, and a query between clusters. The 2-dimensional topology tree is adapted in a novel way, and the ambivalent data structures previously defined for connectivity and 2-edge connectivity are extended to test biconnectivity between clusters. To test biconnectivity within a cluster C, the entire subgraph induced by C and a compressed certificate of $G - C$ are maintained. Using all these ingredients, [Ra94] obtains amortized $O(m^{1/2})$ time per update and $O(1)$ worst-case time per query.

6. Using clever data structures based on topology trees, bundles, and the idea of *recipes*, first introduced in this context in [HeRaSu94], the problem of fully dynamic biconnectivity for plane graphs can be solved in $O(\log^2 n)$ time per update and $O(\log n)$ time per query.

7. *2-edge connectivity* [EpEtal92a], [Fr85], [Fr91]: Thurimella [Th89] and Nagamochi and Ibaraki [NaIb92] show that the following structure U_2 is a certificate for 2-edge connectivity: $U_2 = U_1 \cup F_2$, where U_1 is a spanning forest of G, and F_2 is a spanning forest of $G - U_1$. Eppstein et al. [EpEtal92a] show that U_2 is in fact a stable, sparse certificate. Frederickson's minimum spanning forest algorithm [Fr85] can be adapted to maintain

U_2 in time $f(n,m) = O(m^{1/2})$. Frederickson's ambivalent data structure technique [Fr91] can be used to test 2-edge connectivity with update time $g(n,m) = O(m^{1/2})$ and query time $q(n,m) = O(\log n)$. Here a "query" is a pair of vertices, and the answer is "yes" if they are in the same 2-edge connected component and "no" otherwise. Applying improved stable sparsification yields a fully dynamic algorithm with update time $O(n^{1/2})$ and query time $O(\log n)$.

8. *Planarity* [EpEtal93], [Ra93]: Eppstein et al. [EpEtal93] use the separator-based sparsification technique to obtain a fully dynamic planarity-testing algorithm for general graphs that answers queries of the form "is the graph currently planar?" and "would the insertion of this edge preserve planarity?". Their algorithm requires amortized running time $O(n^{1/2})$ per update or query. Italiano, La Poutré, and Rauch [ItLaRa93] use topology trees, bundles, and recipes to obtain a fully dynamic algorithm on plane graphs that tests whether the insertion of a particular edge would destroy the given imbedding. Their algorithm requires time $O(\log^2 n)$ for updates and queries.

18.5.4 RECENT RESULTS AND OPEN QUESTIONS

Examples:

1. Alberts and Henzinger [AlHe95] investigate dynamic algorithms on random graphs with n vertices and m_0 edges on which a sequence of k arbitrary update operations is performed. They obtain expected update times of $O(k \log n + \sum_{i=1}^{k} \frac{n}{\sqrt{m_i}})$ for minimum spanning forest, connectivity, and bipartiteness and $O(k \log n + \sqrt{\log n} \sum_{i=1}^{k} \frac{n}{\sqrt{m_i}})$ for 2-edge connectivity. The data structures required for these algorithms use linear space, and the preprocessing times match those of the best algorithms for finding a minimum spanning forest.

2. Fredman and Henzinger [FrHe98] investigate lower bounds in the cell probe model of computation and obtain good results for k-edge connectivity, k-vertex connectivity, and planarity-testing of imbedded planar graphs. Both average-case analysis and lower bounds are important topics for future research on dynamic graph algorithms.

3. Klein et al. [KlEtal94] give a fully dynamic algorithm for the all-pairs shortest path problem on planar graphs. If the sum of the absolute values of the edge-lengths is D, then the time per operation is $O(n^{9/7} \log D)$ (worst case for queries, edge deletion, and length changes, and amortized for edge insertion); the space requirement is $O(n)$. Several types of partially dynamic algorithms for shortest paths appear in [AuEtal91], [EvGa85], [FrMaNa94], and [Ro85].

4. King [Ki99] developed a fully dynamic algorithm for maintaining all pairs shortest paths in directed graphs where the weights of the edges are positive integers less than a bound b; this algorithm runs in $O(n^{2.5}\sqrt{b \log n})$ amortized time.

5. Henzinger and King [HeKi99] obtained fully dynamic, randomized algorithms for connectivity, 2-edge connectivity, bipartiteness, cycle equivalence, and constant-weight minimum spanning trees that have polylogarithmic expected time per operation.

DATA MINING

INTRODUCTION

The amount of data generated daily has exploded over the past few decades. This data is found in digital files, databases, and on the Internet. Much of the data is publicly available, but much is privately held by individuals and a wide variety of different types of organizations. With the continuing collection of so much data, attention has grown in using this data to discover new information. The subject of data mining has rapidly evolved to meet this need; it is the process of uncovering relationships between elements in large datasets. Data mining techniques take the input data and output a representation that expresses information contained in the data or knowledge about the data. Data mining plays an important role in many diverse disciplines, including retail business, climate science, bioinformatics, telecommunications, and computer security.

Although data mining is usually considered to be part of computer science, it employs a wide range of mathematical concepts and techniques. This chapter can be used to learn about many of the important tasks in data mining, the key mathematical ideas used, and some of the important algorithms used in data mining.

Data mining has an excellent chance of being useful wherever a large amount of information has been collected. For example, data mining is used in banking, marketing, retail sales, manufacturing, customer relationship management, fraud detection, intrusion detection, healthcare, bioinformatics, criminology, meteorology, and most other disciplines where large information stores are amassed.

Note. Different and sometimes conflicting terminology is used in the data mining literature. Consequently, when consulting data mining literature it is important to determine the terminology being used. Here, we present the most commonly used terms and mention some synonymous terminology.

GLOSSARY

agglomerative hierarchical clustering: a technique that starts from single-entity clusters and successively merges clusters until all objects belong to the same cluster.

anomaly: a data point that is significantly different from other data points and that is considered abnormal in some way.

anomaly detection: a method for finding data points that are anomalies (or outliers).

association rule: a rule stating that if some features in a specified set have particular values in an instance, then another feature has a high probability to have a specified value.

basket: a collection of data items (synonymous with *itemset* or *transaction*).

classification: the process of constructing a classifier from data (also known as *supervised learning*) and using this classifier to predict the class of new data points.

classifier: a function or model that takes an element of a test set and predicts the class of that element.

cluster: a set of instances that are similar in some way to each other, but distinct from points outside the cluster in this same manner.

clustering: the process of partitioning a collection of data points into sets, where the points in each set are similar to one another in some way and separated from other data points in the same way. (In machine learning, it is also known as *unsupervised learning*.)

count: the number of transactions in which an item or set of items occurs.

data mining: the process of analyzing data using mathematical techniques and algorithms to learn new information.

decision tree: a representation as a tree, where each non-leaf node denotes a test on an attribute, each branch represents an outcome of the test, and each leaf node has a class label.

dimension: a function on data points. See also *feature*.

distance measure: a numerical indication of how far apart two instances (points) are.

divisive hierarchical clustering: a technique that starts from a cluster containing all objects and successively refines clusters until all objects belong to different clusters.

entropy: a measure of the amount of disorder in a set of examples.

feature: a function on data points. See also *dimension*.

frequent itemset mining: the process of finding those itemsets that occur in a predefined fraction of the transactions in a specified set of transactions.

homogeneity (of a cluster): a measure of similarity of the objects in a cluster.

instance: a data point.

item: a data element.

itemset: a collection of data items.

knowledge discovery in databases: the complete process of obtaining useful knowledge from collections of data, of which data mining is a part.

linear model for classification: a model in which a line or hyperplane is drawn to divide the dataset into positive and negative (in the binary case) examples. New points are classified depending on which side of the line/hyperplane they fall.

metric space: a set of points together with a real-valued distance function $d(x, y)$ called a *metric* that maps pairs of points x, y to the real numbers, where distances cannot be negative, the distance between two points can only be 0 if the points are the same, the distance is symmetric, and the distance satisfies the triangle inequality.

naive Bayes classifier: a classifier, predicated on the assumption that features are independent of one another, which predicts that an item belongs to the class producing the largest probability that this item belongs to it.

nearest neighbor classifier: a classifier in which training instances are stored and a test example is put into the class of its closest point among the training instances.

outlier: a data point significantly different from the other data points and considered to be abnormal in some way.

outlier detection (or ***anomaly detection***): a method for finding data points that are outliers (or anomalies).

separation of a cluster: a measure of how different objects in a cluster are from those in different clusters.

similarity measure: a numerical indication of the closeness of two instances (points).

spectral clustering: a clustering technique that uses the eigenvalues and eigenvectors of certain graph-based matrices.

support (for a set of items): the fraction of the transactions that contain this set of items as a subset.

test set: a set of points with class labels, where each point is described by a vector of feature values.

training set: a set of points with class labels, used by a classification method to learn the classifier.

transaction: a collection of data items (synonymous with *itemset* and *basket*).

19.1 DATA MINING FUNDAMENTALS

Diverse techniques can be used in data mining to derive useful information from large sets of data. Nevertheless, a large percentage of data mining involves solving a few important types of problems. These problems are: finding relationships between variables in databases (solved by constructing association rules, covered in §19.2), assigning categories to data items (solved by classifying items, covered in §19.3), partitioning datasets into meaningful categories (solved by creating clusters of items, covered in §19.4), and finding data points that do not conform to an expected pattern (solved using outlier or anomaly detection, covered in §19.5). Comprehensive coverage of data mining, discussing the five areas listed here as well as many other problems, can be found in [Ag15], [HaKaPe12], [LeRaUl14], and [MaRo10].

19.1.1 BASIC CONCEPTS

Definitions:

An ***association rule*** is a rule stating that if some features have particular values in an instance, then another feature has a high probability to have a specified value.

Big data is the name used to describe datasets that are so large or so complex that conventional software tools for working with them are inadequate.

A ***classifier*** is a function that can be used to distinguish a particular class of data from other data.

Classification is the process of constructing a classifier from the data. (In machine learning, classification is also known as ***supervised learning***.)

Clustering is the process of partitioning the data points into groups of data points, where the points in each group are similar to one another in some way and separated from other data points in the same way. (In machine learning, it is also known as ***unsupervised learning***.)

A ***cluster*** is a group of instances that are similar in some way to each other, but distinct from points outside the cluster in the same way.

Data mining is the discipline that employs mathematical techniques and algorithms to build models and analyze large collections of data in order to obtain useful information.

A ***dimension*** or ***feature*** is a function on data points.

An ***instance*** is a data point.

The process of obtaining useful knowledge from collections of data is called ***Knowledge Discovery in Databases*** (***KDD***).

An ***outlier*** (or ***anomaly***) is a data point that so significantly differs from the other data points that it is considered to be abnormal in some way.

Outlier detection or ***anomaly detection*** is a method for determining that a data point is an outlier. It can be seen as complementary to clustering.

A ***relational database*** consists of a collection of tables, each consisting of a set of attributes (or fields) and containing a set of records, where each record is an n-tuple for some positive integer n.

Facts:

1. Data mining techniques are used within the larger process known as Knowledge Discovery in Databases (KDD) (see [FaPiSm96] and [MaRo10]), which involves other aspects of computing.

2. The goal of KDD is to obtain useful knowledge from stored data. The steps of KDD (as described in [FaPiSm96]) are

- Modeling the application domain, the relevant prior knowledge, and the goals.
- Creating a target dataset by focusing on specific data samples and features.
- Carrying out data cleaning and preprocessing by removing noise and outliers, collecting the necessary information to account for noise, and deciding how to handle missing data fields.
- Performing data reduction and projection by finding useful features to represent the data (depending on the goals of the process) and using dimensionality reduction methods to reduce the number of features.
- Choosing the particular data mining method, such as classification, clustering, constructing association methods, and so on.
- Choosing the particular data mining algorithm(s) and deciding on particular parameters.
- Performing the data mining task and deriving the representations that are output by the chosen method.
- Interpreting the mined patterns.
- Assimilating the discovered knowledge.

3. Data mining generally refers to the modeling and analysis steps of KDD, and not the other steps. In particular, data mining focuses on building mathematical models, selecting the appropriate data mining tasks, applying the appropriate algorithms, and generating and interpreting the output of these algorithms.

4. Special methods are often needed to handle *big data*, that is, large datasets that cannot be handled in the usual way on computers because of their massive size (ranging from terabytes to petabytes). Also, the number of dimensions or features may be so large that it is difficult to derive knowledge about the data. For discussions of these issues see [LeRaUl14].

5. Data mining can be used to analyze large collections of a wide range of data types. In this chapter the focus is on mining data that is stored in flat files (containing numbers or text) or in relational databases.

6. Techniques for mining data not stored in flat files or rational data bases, such as data from multimedia databases, spatial databases, time-series databases, and the Web, are not addressed in this chapter. (See [MaRo10] for information about data mining of these and other types of specialized data collections.)

7. Following [Ag15], we can abstractly view the data mining problem by considering the data being in the form of an $n \times d$ data matrix $\mathcal{D}$, where n is the number of records and d is the number of columns (or dimensions).

- *Relationships between columns.* Finding frequent relationships between columns is the association rule mining problem. If a particular column is identified as being more important (i.e., a class), then the problem of data classification is that of determining the relationships between the other columns and this column.
- *Relationships between rows.* Finding those subsets of rows in which the values of the columns are similar is clustering. Finding those rows in which the values of the columns are very different from the values of the columns in other rows is outlier analysis, and the row with the different values is an anomaly.

8. The Iris dataset, created by the statistician Sir Ronald Fisher in 1936, is commonly used to illustrate methods of data mining and machine learning. This dataset contains 150 instances, encompassing three classes of flowers: *Iris setosa*, *Iris versicolor*, and *Iris virginica*. The data includes four numerical attributes (sepal length, sepal width, petal length, and petal width), measured in centimeters.

9. Singular Value Decomposition is used in a wide variety of data mining tasks, including classification and clustering, two of the key tasks of data mining. It is also useful in developing recommender systems. (See §6.7.4 for this and other applications.)

10. There are many diverse data mining software packages available, including both public domain and commercial packages. Public domain packages include

- Weka, written in Java and developed at the University of Waikato in New Zealand (`http://www.cs.waikato.ac.nz/ml/weka/`)
- R, a free software platform for statistical computing that can be extended with many different packages (`https://www.r-project.org/`)
- Rapid Miner, an environment for machine learning and data mining processes (`https://rapidminer.com/`)
- ELKI, open-source data mining software in Java that specializes in classification and outlier detection (`https://elki-project.github.io/`)

Commercial software packages for data mining include

- SAS Enterprise Modeler (`http://support.sas.com/software/products/miner/`)
- IBM SPSS Modeler (`https://www.ibm.com/us-en/marketplace/spss-modeler`)
- MATLAB toolboxes with data mining capabilities (`https://www.mathworks.com/products.html`)

Consult the later sections of this chapter for more information about these and other more specialized software tools for data mining tasks.

Examples:

1. Financial accesses, such as using a credit or debit card, create data that can be mined to learn interesting information about spending and buying behavior.

2. Telephone and cell phone usage data records can be mined to obtain many types of useful information, such as finding groups of people who communicate with one another.

3. Many on-line retailers mine customer purchase records to recommend other products for customers to buy. For example, two customers can be considered similar if the purchase sets of the two customers have a large *similarity measure* (§19.1.2). Likewise, we can consider two products to be similar if the two sets of customers who have purchased these items have a large similarity measure.

4. The *Netflix Challenge* was a competition to develop an algorithm to predict a person's ratings for films based upon his/her ratings for other films. Other similar problems are product recommendations made by on-line retailers such as Amazon.com, as well as the recommendation of news articles to a reader based on articles they have read previously.

5. Classification may be used to develop a method of determining which loan applications are acceptable and which are too risky.

6. Association rules may be used by a retail establishment to determine which products to suggest to a customer who has just purchased a product. If the customer has just bought a PC and a digital camera, perhaps he/she might buy a memory card [HaKaPe12].

7. Outlier analysis can be used by a credit card company to determine if a transaction is likely to be due to fraud. For example, the purchase may be in a city or a type of store not usual for that particular customer.

8. Records of which items are commonly bought together can help a large retailer with product placement and advertising.

9. The database of adverse drug reactions has been mined to find new signals of adverse reactions to drugs.

10. When users access Web services, access logs are created at servers and various cluster profiles are maintained at commercial Web sites. These logs can be mined to understand patterns of user accesses, or unusual patterns indicating criminal behavior.

11. Records of meteorological data have been mined to learn predictors of conditions like temperature and rainfall.

19.1.2 Measures of Proximity

In data mining, models not only include collections of data, but also specific ways to determine how similar different data points are or how far apart they are. We describe here some of the most important of these measures of proximity. They are used in building models and in classification, clustering, and outlier detection.

Definitions:

A ***distance measure*** or (***dissimilarity measure***) is a numerical indication of how far apart two instances (points) are. High values indicate that the instances (points) are different, whereas low values indicate that they are similar.

A ***similarity measure*** is a numerical indication of the closeness of two instances (points). High values indicate that the two instances (points) are similar, whereas low values indicate that they are different.

A ***metric space*** consists of a set of points and a real-valued function $d(x, y)$, called a ***metric***, mapping pairs of points to the real numbers and satisfying for all points x, y, z

- $d(x, y) \geq 0$ (distances cannot be negative);
- $d(x, y) = 0$ if and only if $x = y$ (distance can only be 0 if the two points are the same);
- $d(x, y) = d(y, x)$ (***symmetry***);
- $d(x, y) \leq d(x, z) + d(z, y)$ (***triangle inequality***).

Euclidean n-space is the set of n-tuples of real numbers.

The ***Euclidean distance*** between $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ is given by $d_2(x, y) = \left(\sum_{i=1}^{n}(x_i - y_i)^2\right)^{1/2}$.

The ***Manhattan distance*** between $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ is given by $d_1(x, y) = \sum_{i=1}^{n} |x_i - y_i|$.

The ***Chebyshev distance*** (or ***supremum distance***) between $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ is given by $d_\infty(x, y) = \max_{i=1}^{n} |x_i - y_i|$.

More generally, whenever r is a real number with $r \geq 1$, the distance measure $d_r(x, y) = (\sum_{i=1}^{n} |x_i - y_i|^r)^{1/r}$ is a metric, known as the ***Minkowski distance***.

The ***Hamming distance*** between two vectors is the number of components in which the vectors differ.

The ***cosine similarity*** of the n-tuples $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ is

$$\frac{x \cdot y}{\parallel x \parallel \parallel y \parallel}.$$

The ***cosine distance*** of the n-tuples $x = (x_1, x_2, \ldots, x_n)$ and $y = (y_1, y_2, \ldots, y_n)$ is the arccosine of their cosine similarity.

The ***Jaccard similarity*** of the sets A and B equals $|A \cap B|/|A \cup B|$.

The ***Jaccard distance*** between two sets A and B is defined to be $d(A, B) = 1 - |A \cap B|/|A \cup B|$.

The ***edit distance*** between the strings x and y is the smallest number of insertions and/or deletions of single characters that can be used to convert string x into string y.

The ***term vector*** of a document containing n different words $w_1, w_2, \ldots, w_n$ is the n-tuple $(f_1, f_2, \ldots, f_n)$, where f_i is the number of occurrences of word w_i in the document.

Facts:

1. In data mining, a wide variety of different distance measures and metrics are used. These measure the distance between real numbers, sets, strings, and other objects.

2. A metric is a distance measure, but not all distance measures are metrics.

3. Among the proximity measures commonly used in data mining are Euclidean distance, cosine similarity and distance, Manhattan distance, and supremum distance.

4. The Euclidean distance and Manhattan distance are special cases of the Minkowski metric with $r = 2$ and $r = 1$, respectively.

5. Minkowski distance with parameter r is also called the ℓ_r distance (based on the ℓ_r norm). Euclidean distance, Chebyshev distance, and Manhattan distance correspond to ℓ_2, ℓ_∞, and ℓ_1, respectively.

6. From real analysis it follows that $\lim_{r\to\infty} d_r(x,y) = \max_{i=1}^{n} |x_i - y_i|$, which is the Chebyshev distance between x and y. This implies that Chebyshev distance is a metric, but it is easier to prove this directly from the definition.

7. Chebyshev distance is also known as *chessboard distance*, because in chess the minimum number of moves needed by a king to go from one square on a chessboard to another is the Chebyshev distance between the centers of the squares.

8. The cosine similarity of two vectors x and y is the cosine of the angle θ between them. Here, the vectors have real numbers as entries. In data mining, vectors may have some or all entries that only take only a finite number of values. For instance, some entries may only take on the values 0 and 1.

9. The cosine distance is used to measure the angle between vectors.

10. The Jaccard similarity of two sets is the ratio of the size of their intersection to the size of their union.

11. Jaccard distance is a metric on every space of sets [LeRaUl14].

12. On-line retailers can use customer purchase records to recommend other products for customers to buy. For example, two customers can be considered similar if their purchase sets have large Jaccard similarity. Likewise, two products can be considered similar if the two sets of customers who have purchased these items have large Jaccard similarity.

13. The similarity of two documents can be measured by finding the cosine similarity of their term vectors.

14. The Jaccard similarity and Jaccard distance between two documents depends on the particular sets we associate with these documents. The most common choices are the set of all words a document contains or the set of all strings of length k it contains (called *k-shingles* or *k-grams*), where k is a positive integer selected large enough so that the probability that any given shingle appearing in the document is low.

15. The edit distance $d(x,y)$, where x and y are two strings, equals $l(x) + l(y) - l(LCS(x,y))$, where $l(s)$ denotes the length of the string s and $LCS(x,y)$ is the longest common subsequence of x and y.

16. Hamming distance is a metric on every space of vectors.

17. The Manhattan distance gets its name because it measures the distance required to walk between two addresses in the part of Manhattan (in New York City) where all streets run either north-south or east-west. It is also called *taxicab distance*.

Examples:

1. Let $S = \{2,4,5,6,8\}$ and $T = \{1,3,4,5,7\}$. Because $S \cap T$ is $\{4,5\}$ and $S \cup T$ is {1, 2, 3, 4, 5, 6, 7, 8}, the Jaccard similarity of S and T is $|S\cap T|/|S \cup T| = 2/8 = 0.25$. The Jaccard distance is $1 - S \cap T|/|S\cup T| = 1 - 0.25 = 0.75$.

2. Jaccard distance can be used to measure the distance between documents. There are a variety of ways to associate sets with documents. For instance, documents can be viewed as sets of words. They can also be viewed as collections of k-shingles or k-grams, where k specifies the length of the character sequence.

3. Here we find the similarity of and the distance between the vectors $x = (2,4,-1)$ and $y = (4,2,1)$ using a variety of measures and metrics.

- The Hamming distance between x and y is 3, because x and y differ in all three components.

- The Manhattan distance between x and y is $|2-4|+|4-2|+|-1-1| = 2+2+2 = 6$ and the Chebyshev distance between them is 2.
- The cosine similarity of x and y is

$$\frac{8+8-1}{\sqrt{2^2+4^2+(-1)^2}\cdot\sqrt{4^2+2^2+1^2}} = \frac{17}{\sqrt{21}\cdot\sqrt{21}} = \frac{17}{21} \approx 0.8095.$$

- The cosine distance between x and y is $\arccos(\frac{17}{21}) \approx 35.95^o$.

4. The edit distance between the strings $x = dcba$ and $y = fcab$ is 4 because one can convert x to y by first deleting the d, then inserting an f before the c, then deleting the b, and finally inserting a b after the a. There is no way to change x into y using only three insertions and/or deletions.

19.2 FREQUENT ITEMSET MINING AND ASSOCIATION RULES

The mining of association rules is one of the classic areas of data mining. It is based on one of the more fundamental methods for characterizing data, the finding of frequent itemsets. There are many areas of application besides the original retail application.

Definitions:

In this area of data mining, an element of the dataset is called an ***item***.

A collection of items is known as an ***itemset*** (or ***basket*** or ***transaction***). The items are objects of some sort from a universe U. The term ***k-itemset*** is used to denote an itemset that contains exactly k items.

A ***transaction*** is an n-tuple of items for some positive integer n.

The data to be analyzed consists of a set T of ***transactions*** (or ***itemsets*** or ***market-baskets***).

The number of transactions in which an item I or set of items occurs is called the ***count*** of I, defined as

$$count(I) = |\{t_i \mid I \subseteq t_i,\ t_i \in T\}|,$$

where $T = \{t_1, t_2, \ldots, t_n\}$ is the set of transactions. [Sometimes the word "support" is used for this quantity, conflicting with the more common usage of this word given in the next definition.]

The ***support*** for an item or set of items I is the fraction of the transactions that contain I as a subset. That is,

$$support(I) = \frac{count(I)}{|T|}.$$

Note that the support of I is the probability of I occurring in a transaction.

If an item or set of items I occurs in more than s percent of the transactions, where s is called the ***support threshold***, I is said to be ***frequent***. [For those authors who treat "support" as an absolute number, s is an absolute number as well.]

Suppose S is a set of items. An ***association rule*** is an implication of the form $I \to J$, where I and J are disjoint subsets of S.

Given a set of transactions $T = \{t_1, t_2, \ldots, t_n\}$, ***frequent itemset mining*** is the process of finding those itemsets that occur in a predefined fraction m of the transactions in T.

The predefined fraction m is called the ***minimum support*** (or ***minimum support threshold***).

The ***confidence*** of an association rule $I \to J$ is the support for $I \cup J$ divided by the support for I. That is,

$$\mathit{confidence}(I \to J) = \frac{\mathit{support}(I \cup J)}{\mathit{support}(I)}.$$

The ***support*** of an association rule $I \to J$ is the support for $I \cup J$. That is,

$$\mathit{support}(I \to J) = \mathit{support}(I \cup J).$$

The ***interest*** [LeRaUl14] of an association rule $I \to J$ is the difference between the confidence of the rule and the support of J. That is,

$$\mathit{interest}(I \to J) = \mathit{confidence}(I \to J) - \mathit{support}(J).$$

The ***lift*** of an association rule $I \to J$ is the confidence of the rule divided by the support of J. That is,

$$\mathit{lift}(I \to J) = \frac{\mathit{confidence}(I \to J)}{\mathit{support}(J)}.$$

Facts:

1. The original application of mining the frequency of itemsets to find association rules analyzed grocery or department store data. This is the origin of the *market-basket* model of data, which is based on *baskets* of *items*. Typically the number of baskets is very large and they are stored in a file containing a sequence of baskets. The number of items in a basket is much smaller than the total number of possible items.

2. The folklore is that one of of the earliest discoveries made from market-basket data analysis is that people who buy diapers tend to be likely to buy beer. The discovered rule is then $\mathit{diapers} \to \mathit{beer}$.

3. The support of every subset J of an itemset I is at least that of the support of itemset I. This property is called the *support monotonicity property*.

4. If a set I of items is frequent, then so is every subset of I. This property is called *monotonicity* or the *downward closure property*.

5. Rules with high confidence are useful, but confidence does not require a connection between itemsets I and J. The confidence of the rule expresses the conditional probability $Pr(J \mid I)$.

6. Interest expresses the type of connection between I and J. If the percentage of the transactions with I and also J is the same as the percentage with J alone, then there is no connection and the interest value will be 0. A positive number indicates a positive connection and a negative one indicates that the occurrence of I makes it less likely that J occurs.

7. If the lift of the association rule $I \to J$ is greater than 1, then I and J are positively correlated. If the lift is 1, then I and J are independent and the rule is not interesting. If the lift is below 1, then there is a negative correlation.

8. The best-known algorithm for counting frequent subsets is the *apriori algorithm* introduced by C. Agrawal and R. Srikant in 1994. Given a set of transactions and a minimum support threshold *minsup*, this algorithm finds the itemsets that are subsets containing at least *minsup* transactions in the database using a bottom-up approach. Frequent subsets are extended, an item at a time (*candidate generation*), and groups of candidates are tested to determine those transactions with successively larger numbers of elements. The algorithm terminates when no additional extensions exist. Details of this algorithm can be found in [Ag15].

9. If there is a large number of items, the space needed to count the itemsets can become prohibitive. For 2-itemsets in a universe of 1000 objects, the number of 2-itemsets is $\binom{1000}{2} = 499{,}500$. If we want to consider 3-itemsets, then an additional $\binom{1000}{3} = 166{,}167{,}000$ possibilities must be included. There are several techniques to reduce the amount of space needed to store the counts of itemsets [LeRaUl14].

10. Generally, the size of the file containing the transactions is very large and does not fit in main memory. An important issue is reducing the number of times it is necessary to read the file containing the transactions.

11. Another well-known method for obtaining frequent itemsets is called *frequent pattern growth* or *FP-growth*. The first scan of the database counts the frequent pairs as in the apriori algorithm. The second pass builds the *FP-tree*. Further mining is done on the FP-tree and no further scans over the transaction database are needed. Discussion of this method as well as others can be found in [Ag15], [HaKaPe12], and [TaStKu06].

12. A transaction can be a document or a web page. The items are the words that occur in the document. Assuming that we ignore frequently occurring words (known as *stop words*), then frequent itemsets would represent words that often occur together in documents.

13. Transactions can be sentences and the items can represent the documents in which the sentence occurs. Frequent itemsets are then documents that share common sentences.

14. Many measures have been proposed to evaluate whether rules are interesting or useful. Discussion of these various options can be found in [Ag15], [HaKaPe12], and [TaStKu06]. Generally an association rule is considered to be *interesting* if it satisfies both a minimum support threshold and a minimum confidence threshold, where these threshold values are set by the user.

15. Following are some free software tools for finding association rules and mining frequent itemsets:

- arules, an R extension package (`https://cran.r-project.org/web/packages/arules/index.html`)
- ARtool, a collection of algorithms and tools for the mining of association rules in binary databases (`http://www.cs.umb.edu/~laur/ARtool/index.html`)
- FIMI (Frequent Item Mining Implementations) site (`http://fimi.ua.ac.be/`)
- opusminer, an R package providing an interface to OPUS Miner for finding key associations in transaction data (`https://cran.r-project.org/web/packages/opusminer/index.html`)

Examples:

1. Suppose the association rule iPhone 8 → iPad Pro for transactions made at an Apple Store has support 3% and confidence 15%. Then in 3% of all transactions at the store an iPhone 8 and an iPad Pro were purchased (perhaps with other items), and 15% of the customers who bought an iPhone 8 at the Apple Store also bought an iPad Pro at this store.

2. Consider the following supermarket transactions from one hour at the Healthy Eating Emporium:

Transaction ID	Items
1	{Kefir, Tortillas}
2	{Cone Filters, Kefir, Kombucha, Tortillas, Omega-3}
3	{Almonds, Apples, Cone Filters, Kefir, Soy Butter}
4	{Tortillas, Coconut Milk, Cone Filters, Kefir, Kombucha, Tortillas}
5	{Cone Filters, Tortillas, Kefir, Kombucha, Omega-3}

The count for {Tortillas} is 4, and therefore the support is 4/5. The count for {Kefir, Kombucha} is 3, and therefore the support is 3/5. The support for {Kombucha, Kefir} → {Omega-3} is 2/5 and the confidence is $\frac{2/5}{3/5} = 2/3$. Since the support for Omega-3 is 2/5, the rule is somewhat interesting as the interest is $2/3 - 2/5 = 4/15$.

3. Frequent itemset analysis can be used for applications that do not involve market-basket analysis. Some examples [LeRaUl14] are the following:

- The items consist of biomarkers (e.g., genes or blood proteins) and diseases. Each basket represents data about a patient, e.g., genome, blood-chemistry analysis, and medical history with regard to diseases. A frequent itemset that contains a disease and one or more biomarkers provides a possible test for the disease.
- The items are documents and the baskets are sentences. An item is in a basket if the sentence represented by the basket occurs in that document. Pairs of items that occur in several baskets provide an indication that those documents share several sentences and can be evidence of plagiarism.
- Documents are represented by baskets and the items are the words that occur in the document. If the most common words (stop words) are ignored, then frequent pairs may indicate a joint concept or related concepts.

19.3 CLASSIFICATION METHODS

Classification is the problem of identifying the class or category of a data item given a dataset of examples that are already identified as belonging to particular classes. A new example can be given to the classifier and the classifier will predict the category of the new example.

Definitions:

Items that are to be classified are m-tuples, where the different dimensions are called ***features***. Different features can belong to different sets, such as the set of real numbers, the set of positive integers, or some finite set. These items are also called ***instances*** or ***data points***.

The goal of classification is to create a model that will specify (or predict) the ***class label*** that identifies the class each new data item belongs to.

The ***training set*** given to a classification method is a set of items used by the classification method to ***learn*** (or create) the classifier. Each point or example in the training set is an m-tuple $(x_1, x_2, \ldots, x_m)$ of feature values, where each x_i is a value or measurement for the corresponding feature F_i, except for one value x_i, which is the class of that item.

The ***test set*** is a set of items, each described by a vector of feature values, given to a classifier that predicts the class of each of these items.

The ***classifier*** is a model that takes an item $\mathbf{X}_j$ of the test set and predicts the class of that point.

The ***instance space*** is the m-dimensional space containing the items to be classified.

A ***nearest neighbor classifier*** is a classifier that assigns the class of the nearest item to this item using a specified metric.

A ***k-nearest neighbor classifier*** finds the classes of the k nearest neighbors to an item (using a specified metric) and assigns to the item the class a majority of these items belong to. Here the parameter k is chosen so that the classifier selects the most appropriate classes to the items.

A ***perceptron*** is a threshold function applied to the n-tuple $(x_1, x_2, \ldots, x_n)$, where each x_i is a real number. A perceptron with weights $w_1, w_2, \ldots, w_n$ and threshold value Θ outputs 1 if $\sum_{i=1}^{n} w_i x_i \geq \Theta$ and gives -1 otherwise.

A dataset is ***linearly separable*** given a perceptron if there is a hyperplane that separates all the points for which a perceptron has value 1 from those where it has value -1.

A ***linear model*** for classification draws a line or hyperplane dividing the dataset into positive and negative examples (in the binary case). New points are classified depending on which side of the line/hyperplane they fall.

An ***decision tree*** represents a concept using a tree structure, where each non-leaf node denotes a test on an attribute, each branch represents an outcome of the test, and each leaf node has a class label.

A ***naive Bayes classifier*** provides the probability that an item is a member of a particular class, assuming that the features occur independently of one another.

Suppose that D is a partition of the classified training items, where there are v different classes $C_1, C_2, \ldots, C_v$. Let $C_{i,D}$ be the set of data items of C_i that belong to D. Then the ***entropy*** or ***expected information*** required to classify an item in D is

$$\mathit{Entropy}(D) = -\sum_{i=1}^{v} |C_{i,D}|/|D| \log_2\{|C_{i,D}|/|D|\}.$$

Suppose that D is a partition of the classified training items and D is partitioned using an attribute A with m distinct values $a_1, a_2, \ldots, a_m$ into subsets $D_1, D_2, \ldots D_m$, where D_i contains the items in D for which the value of A is a_i. Then the ***entropy*** or ***expected information*** of D with partition A is

$$\mathit{Entropy}_A(D) = \sum_{i=1}^{m} |D_i| \mathit{Entropy}(D_i)/|D|.$$

The ***information gain*** obtained by a partition using an attribute A of a set D of classified training items is $\mathit{Gain}(A) = \mathit{Entropy}(D) - \mathit{Entropy}_A(D)$.

Facts:

1. Classification is also called *supervised learning* (in the parlance of machine learning) because the training set includes the classes of the items in the training set and a new item is classified using a classifier built from this training set. This contrasts with clustering (discussed in §19.4), where the classes of the items in the training set are not known in advance.

2. Many different classification methods are used, including the nearest neighbor classifier, the k-nearest neighbor classifier, perceptrons, linear classifiers, support vector machines, decision tree learning classifiers, naive Bayesian classifiers, and neural network classifiers. However, many other classification methods have been invented and new ones are being developed with some regularity.

3. A perceptron can be used as a classifier only if the data is linearly separable.

4. Perceptrons can be used for binary classification, that is, when each feature takes on one of two values (such as TRUE and FALSE, 1 and -1, and so on). They can be used even when there is an extremely large number of features, such as for the classification of documents where there is a feature for each word in a dictionary that takes the value 1 if the word appears in the document and the value -1 if it does not.

5. In nearest neighbor and k-nearest neighbor classifiers, when all the values of items in all dimensions are numerical, Euclidean distance is usually used. However, for certain other applications alternative metrics might be preferable. When all values are discrete, the Hamming distance can be used.

6. The choice of k for a k-nearest neighbor classifier depends on the particular type of data. However, the general idea is to make k small enough so that only relatively nearby items are among the closest k items to new examples, but large enough to minimize the effects of data items that may have resulted from measurement error or noise. Some experts suggest that k should equal the square root of the number of items in the training set.

7. The nearest neighbor classifier produces a Voronoi tessellation (§13.5.3) of the instance space. The cell of a new example determines its class.

8. When a nearest neighbor or a k-nearest neighbor classifier is used, it is important to scale or normalize the units in each dimension. Otherwise, dimensions where the values fall in wider ranges will dominate and dimensions where values are closer together will have little effect on the results of the classifier.

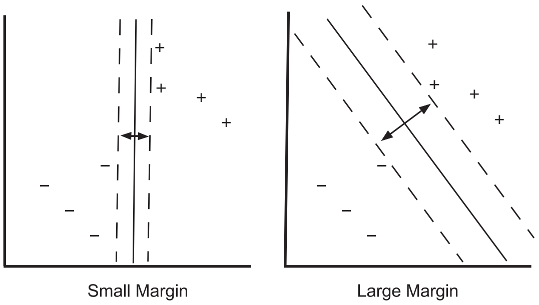
9. Consider the case of deciding whether or not a point $x = (x_1, x_2, \ldots, x_n)$ is a member of some category C. In a linear classifier, prediction is based on a weighted sum, where each feature has a weight w_i, giving

$$f(x) = \sum_{i=1}^{n} w_i x_i.$$

If $f(x)$ is positive then the point x is a positive example of C, otherwise its class is not C. Typically the vectors x are normalized so that $\| x \| = 1$. The vector w can be seen as defining a hyperplane separating the positive and negative examples of C.

10. A *support vector machine (SVM)* uses a nonlinear mapping (if necessary) to transform the training set into a higher dimension where the data is linearly separable. Here we can search for an optimal separating hyperplane, which operates as a decision boundary that separates the points of the two classes. The optimality of the separating hyperplane is in the sense that it is a *maximal margin hyperplane*, one that separates the points with the largest *margin* so that none of the data points lie within this margin of the hyperplane. The margin of a hyperplane is the distance from this hyperplane to the data points closest to it. We describe part of the process used by SVM in Fact 11. Full details can be found in [Ag15] and [HaKaPe12].

11. The goal of the SVM process is to find a hyperplane $w \cdot x + b = 0$ that not only separates the data points, but also has the maximum margin γ. The following figure illustrates the difference that choice of the decision line or hyperplane can make on the margin. The core of the SVM optimization process ensures that this margin γ is as large as possible.



12. A decision tree can be built in various ways using a greedy algorithm that uses a top-down recursive divide-and-conquer approach. The training set is recursively partitioned into successively smaller subsets during the construction of the tree. At the end of the process, the tree that has been constructed contains both *decision nodes* and *leaf nodes*. The decision nodes represent steps where sets are partitioned into smaller subsets, while leaf nodes represent classifications of items.

13. The ID3 algorithm, developed by J. R. Quinlan, uses the attribute with the highest information gain to drive a greedy algorithm used to build a decision tree. At a splitting step of the algorithm, the attribute with the highest information gain is selected as the splitting node.

14. To illustrate the process of creating a decision tree, we consider a simple scenario. The recursive decision tree learning algorithm (Algorithm 1) begins at the root and successively works downwards.

Algorithm 1: **Decision Tree Learning.**

```
Decision-Tree-Learning(Examples, Attributes)
    if Examples is empty, return the leaf node labeled with the most frequent
        categorization in the example set
    create a new node for the tree
    if all examples are positive, return the node as a leaf node labeled with yes
    if all examples are negative, return the node as a leaf node labeled with no
    if Attributes is empty, return the leaf node labeled with the most frequent
        categorization in the example set
    else select the attribute A from Attributes that best classifies the examples
        and make A the label for node
    for each value $v_i$ of A
        add a new branch below node with the branch label of $v_i$
```

```
      set $Examples_{v_i}$ to the portions of $Examples$ that have $v_i$ for attribute $A$
      add to this branch the subtree
        Decision-Tree-Learning($Examples_{v_i}$, $Attributes-A$)
```

15. Algorithm 1 at each call creates a node (the outermost call creating the root). Its arguments are a set of examples and the attributes by which the examples are categorized (the outermost call being given the complete set of examples and attributes). As the recursion proceeds, the sets *Examples* and *Attributes* become smaller.

At each call, a determination is made with regard to how to label the node created in that call. If all of the examples are of the same category, then the node is a leaf and is labeled with either `Yes` or `No`. If the set of examples is empty or if the attributes are empty, the algorithm with this training set has no basis upon which it can categorize instances corresponding to this path in the tree. The node therefore must be a leaf and by default it is given the most frequent label.

Otherwise, at each step the algorithm needs to determine which is the best attribute to use as the label for a node. Once the attribute for a node is chosen, there will then be as many branches below that node as there are values for the chosen attribute. The idea is to prefer smaller trees. Therefore at each step the best attribute is the one that classifies the most examples. This can be given a mathematically precise definition by using the notions of entropy and information gain.

16. Locality sensitive hashing can be used to find nearest neighbors in near constant time [LeRaUl14].

17. Classification can also be done using *neural networks*, which are loosely based on a biological model. In a neural network there are layers of nodes and weights between the nodes. A perceptron is the simplest type of neural network. More expressive learning methods use networks with hidden layers of nodes and weights between the input and output layers. Backpropagation is used to train the network [LeRaUl14], [HaKaPe12].

18. Many software packages, including those mentioned in §19.1.1, support a wide variety of classification algorithms. Some packages that can be used without charge are listed next:

- ELKI is open-source data mining software written in Java with an emphasis on unsupervised methods in cluster analysis (`https://elki-project.github.io/`)
- SGI MLC++ provides open-source code written in C++ at Stanford University for machine learning (classification), including implementations of the ID3 algorithm for decision trees and algorithms for nearest neighbor algorithms (`http://www.sgi.com/tech/mlc/`)
- The Scikit-learn open-source toolkit contains many classification methods including those discussed here. They are all implemented in Python. Scikit-learn is included with both the Anaconda Continuum and the Enthought Canopy distributions of Python packages (`http://scikit-learn.org/stable/`)

Examples:

1. Classification can be used to determine whether an e-mail is spam, using two classes for e-mails: spam and nonspam. Features that can be used are whether there are punctuation errors in e-mail headers, whether certain suspect keywords are present, whether nonsense strings are found, and so on.

2. Classification can help determine whether a patient has a particular disease using as features the symptoms and medical data of this patient.

3. Categorizing documents by primary topic using keyword counts as features can be done via classification.

4. People can be categorized into the type of vacation they may be interested in based on personal data including age, income, age of children, whether they have visited certain places, and so on.

5. Optical character recognition can classify each written character into the letter it represents by looking at various features.

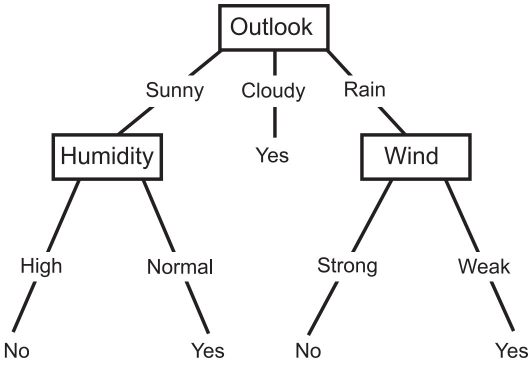
6. Classifying videos can be done to determine whether a new example depicts a particular activity.

7. We can use two dimensions of data from the Iris database, sepalwidth and petalwidth, to classify new instances using the nearest neighbor classifier. The training set we use includes three instances, with the following known values for (sepalwidth, petalwidth, class).

Sample 1:	(3.4, 0.4, *Iris setosa*)
Sample 2:	(2.7, 1.3, *Iris versicolor*)
Sample 3:	(3.0, 2.1, *Iris virginica*)

We classify a new instance (3.8, 2.0) by computing the Euclidean distance between this new instance and each of the three classified instances (using just the first two dimensions), obtaining 1.65 for Sample 1, 1.30 for Sample 2, and 0.81 for Sample 3. Because the third instance is the closest, the new sample is classified as *Iris virginica*.

8. The days when a particular person will play an outdoor sport (such as golf) based on the weather can be classified using a decision tree (as done in [Qu93],[Mi97], and [WiFrHa11]). A possible decision tree for this problem is displayed next. To explore the decision tree, one starts at the root and follows the values for each attribute of the day to be classified until arriving at a leaf. The classification is then the label of this leaf. For example, if the Outlook for today is *Sunny* and the Humidity is *High*, then golf will not be played. But if the Outlook for today is *Cloudy* then golf will be played.



9. To illustrate the method of constructing decision trees, consider the training examples shown in the following table. Because there are nine positive examples and five negative examples, it follows that $Entropy(S) = -(9/14)\cdot\log_2(9/14) - (5/14)\cdot\log_2(5/14) = 0.940$. Now, consider the options for choosing the first attribute for the decision tree of whether golf will be played based on the given data. The information gain values for the attributes are computed as follows:

$$
\begin{array}{ll}
Gain(S, \text{Outlook}) = 0.246 & Gain(S, \text{Humidity}) = 0.151 \\
Gain(S, \text{Wind}) = 0.048 & Gain(S, \text{Temperature}) = 0.246
\end{array}
$$

Day	Outlook	Temperature	Humidity	Wind	Play
Ex1	Sunny	Hot	High	Weak	No
Ex2	Sunny	Hot	High	Strong	No
Ex3	Cloudy	Hot	High	Weak	Yes
Ex4	Rain	Mild	High	Weak	Yes
Ex5	Rain	Cool	Normal	Weak	Yes
Ex6	Rain	Cool	Normal	Strong	No
Ex7	Cloudy	Cool	Normal	Strong	Yes
Ex8	Sunny	Mild	High	Weak	No
Ex9	Sunny	Cool	Normal	Weak	Yes
Ex10	Rain	Mild	Normal	Weak	Yes
Ex11	Sunny	Mild	Normal	Strong	Yes
Ex12	Cloudy	Mild	High	Strong	Yes
Ex13	Cloudy	Hot	Normal	Weak	Yes
Ex14	Rain	Mild	High	Strong	No

We see that Outlook gives us the highest information gain. Splitting on Outlook gives us three branches. The instances where the value equals *Cloudy* are all decided as positive. Of those with the value *Sunny*, 3 out of 5 are negative; of those with the value *Rain*, 2 out of 5 are negative. If we were to choose Wind, then there would be two branches. Those instances under the *Weak* branch give 6 out of 8 positive while those under the *Strong* branch give 3 out of 6 positive. The value of information gain does roughly correspond with our intuitions of how well the choice of attribute serves to categorize the instances.

10. Consider the problem of using the naive Bayes classifier to classify a new instance of the weather data above [Mi97], [WiFrHa11]. For this instance **X**, Outlook = *Sunny*, Temperature = *Cool*, Humidity = *High*, and Wind = *Strong*. We can estimate the needed probabilities as follows:

$$Pr(\text{Play} = \textit{Yes}) = 9/14 = 0.64$$

$$Pr(\text{Play} = \textit{No}) = 5/14 = 0.36$$

$$Pr(\text{Wind} = \textit{Strong} \mid \text{Play} = \textit{Yes}) = 3/9 = 0.33$$

$$Pr(\text{Wind} = \textit{Strong} \mid \text{Play} = \textit{No}) = 3/5 = 0.60$$

$$Pr(\text{Outlook} = \textit{Sunny} \mid \text{Play} = \textit{Yes}) = 2/9 = 0.22$$

$$Pr(\text{Outlook} = \textit{Sunny} \mid \text{Play} = \textit{No}) = 3/5 = 0.60$$

$$Pr(\text{Play} = \textit{Yes} \mid \mathbf{X}) = 0.64 \times 0.33 \times 0.22 \times 0.33 \times 0.33 = 0.0051$$

$$Pr(\text{Play} = \textit{No} \mid \mathbf{X}) = 0.36 \times 0.60 \times 0.60 \times 0.20 \times 0.60 = 0.016$$

So the naive Bayes classifier predicts that the specified day should be placed in the *No* category.

19.4 CLUSTERING

Clustering is a powerful tool for automated analysis of data. It addresses the following general problem: given a set of entities, find subsets (or clusters) that are homogeneous and/or well separated. Homogeneity means that entities in the same cluster should be similar, while separation means that entities in different clusters should differ from one another. Clustering is ubiquitous, with applications in the natural sciences, psychology, medicine, engineering, economics, marketing, and other fields.

19.4.1 BASIC CONCEPTS

Definitions:

A ***sample*** is a set $O = \{o_1, o_2, \ldots, o_n\}$ of n entities/objects among which clusters are to be found.

An $n \times s$ ***data matrix*** X is obtained by measuring or observing s features of the entities of O.

An $n \times n$ ***matrix of dissimilarities*** $D = (d_{ij})$ between entities of O is computed from the matrix X. Typically, these quantities satisfy $d_{ij} = d_{ji} \geq 0$ for $i, j = 1, 2, \ldots, n$ and $d_{ii} = 0$ for $i = 1, 2, \ldots, n$. These values do not need to satisfy the triangle inequalities, i.e., to be distances.

A ***criterion*** expresses ***homogeneity*** and/or ***separation*** of the clusters in the clustering to be found.

Homogeneity of a cluster C_ℓ is commonly measured by

- the ***diameter*** $d(C_\ell)$ of C_ℓ, or maximum dissimilarity between entities of C_ℓ:
$$d(C_\ell) = \max_{i,j:o_i,o_j \in C_\ell} d_{ij};$$
- the ***radius*** $r(C_\ell)$ of C_ℓ, or minimum among all entities o_i of C_ℓ of the maximum dissimilarity between o_i and another entity of C_ℓ:
$$r(C_\ell) = \min_{i:o_i \in C_\ell} \max_{j:o_j \in C_\ell} d_{ij};$$
- the ***star*** $st(C_\ell)$ of C_ℓ, or minimum among all entities o_i of C_ℓ of the sum of dissimilarities between o_i and the other entities of C_ℓ:
$$st(C_\ell) = \min_{i:o_i \in C_\ell} \sum_{j:o_j \in C_\ell} d_{ij};$$
- the ***clique*** $cl(C_\ell)$ of C_ℓ, or sum of dissimilarities between entities of C_ℓ:
$$cl(C_\ell) = \sum_{i<j:o_i,o_j \in C_\ell} d_{ij}.$$

Separation of the cluster C_ℓ can be expressed by

- the ***split*** $s(C_\ell)$ of C_ℓ, or minimum dissimilarity between an entity of C_ℓ and one outside C_ℓ:
$$s(C_\ell) = \min_{i:o_i \in C_\ell, j:o_j \notin C_\ell} d_{ij};$$
- the ***cut*** $c(C_\ell)$ of C_ℓ, or sum of dissimilarities between entities of C_ℓ and entities outside C_ℓ:
$$c(C_\ell) = \sum_{i:o_i \in C_\ell} \sum_{j:o_j \notin C_\ell} d_{ij}.$$

Also used are the ***normalized*** star, clique, or cut obtained by dividing $st(C_\ell)$ by $|C_\ell|-1$, $cl(C_\ell)$ by $|C_\ell|(|C_\ell|-1)$, and $c(C_\ell)$ by $|C_\ell|(n-|C_\ell|)$, respectively.

Facts:

1. Criteria for assessing the overall effectiveness of a given clustering can be based on the six measures defined earlier, which can be combined by summing or by calculating the threshold (maximum or minimum) of the component cluster measures. The overall objective is to *maximize* the combined separation measure or to *minimize* the combined homogeneity measure.

2. The clustering problem is old. It can be traced back to Aristotle and was already much studied by 18th century naturalists such as Buffon, Cuvier, and Linné.

3. The set of entities O may be associated with a mixture of distributions, the number and parameters of which are to be found [Mi96, Chapter 2].

4. Dissimilarities can be computed from sources other than the data matrix X, for instance when comparing biological sequences or partitions.

5. Specific distance and dissimilarity for entities represented by binary variables can be derived in an ad hoc manner [An73], [GrRa69].

6. Nominal (or categorical) variables with more than two states as well as numerical data can be transformed into binary variables [BoEtal97].

7. An axiomatic study of dissimilarities can be found in [Ba89].

8. Instead of computing dissimilarities, clustering can be performed directly on the matrix X (e.g., Algorithm 3 of §19.4.4).

9. The computational complexity of a clustering problem depends on the criterion used. For instance, split maximization is polynomially solvable [DeHa80] while diameter minimization is NP-hard [Br78].

10. Cluster analysis is not the only way to study dissimilarities or distances between entities in the field of data analysis. Another common technique is *principal component analysis* [Jo02].

11. A popular online source for benchmark datasets commonly used in cluster analysis is the UCI Machine Learning Repository located at

- `https://protect-us.mimecast.com/s/oXA1BRUZEdqZIQ?domain=archive.ics.uci.edu`

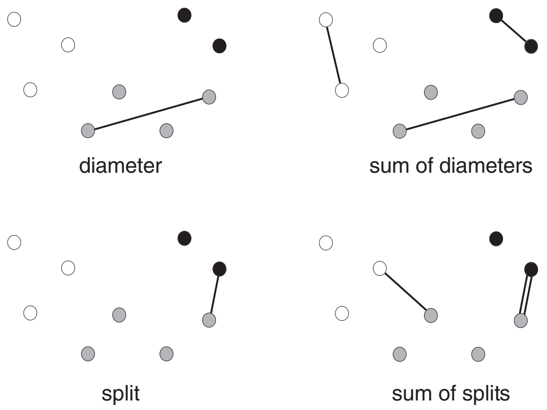
Examples:

1. Consider four entities o_1, o_2, o_3, o_4 comprising a cluster C_ℓ, for which the associated matrix of dissimilarities is given by

$$D = \begin{bmatrix} 0 & 3 & 4 & 5 \\ 3 & 0 & 6 & 8 \\ 4 & 6 & 0 & 1 \\ 5 & 8 & 1 & 0 \end{bmatrix}.$$

Then $d(C_\ell) = 8$ since $d_{24} = 8$, $r(C_\ell) = 5$ since $d_{14} = 5$, $st(C_\ell) = 11$, and $cl(C_\ell) = 27$.

2. The next figure illustrates three clusters, consisting of 2, 3, and 4 entities, respectively. The top portion of the figure uses the *diameter* of the clusters to obtain an overall measure: the left-hand side shows the maximum (threshold) cluster diameter, while the right-hand side shows that the sum of the three cluster diameters is considered. The bottom portion of the figure uses the *split* of the clusters to obtain an overall measure: the left-hand side shows the minimum (threshold) cluster split, while the right-hand side shows that the sum of the three splits is considered.



diameter

sum of diameters

split

sum of splits

3. The Iris dataset [Fi36] is one of the most popular datasets used in cluster analysis. It consists of $n = 150$ samples obtained from each of three species of Iris flowers (*Iris setosa*, *Iris virginica*, and *Iris versicolor*). Each sample has $s = 4$ measured characteristics (in mm): sepal length, sepal width, petal length, and petal width. Clustering is used in this context to determine species of plants or animals from a given set of observations.

4. To find out which of 15 well-known politicians are perceived as similar, a representative sample of people is given all 105 possible pairs of these politicians, and asked to rank the pairs in terms of their similarity. By suitable aggregation of the rankings, a symmetric distance matrix can be obtained whose values can be used to find groups of similar politicians, with as much difference as possible between the groups. This could, for example, be relevant in forming election campaign teams [Sp85].

5. Recommendation algorithms are best known for their use on e-commerce web sites, where they exploit input about a customer's interests to generate a list of recommended items. Many applications use only the items that customers purchase and explicitly rate to represent their interests, but they can also use other attributes, including items viewed, demographic data, subject interests, and favorite artists. Clustering techniques work by identifying groups of consumers who appear to have similar preferences. Once the clusters are created, predictions for an individual can be made by averaging the opinions of the other consumers in that cluster. Thus, the store radically changes based on customer interests, showing programming titles to a software engineer and baby toys to a new parent [LiSmYo03], [ScKoRi01].

19.4.2 TYPES OF CLUSTERING

Definitions:

Cluster analysis methods are based on generating certain collections of sets:

(i) ***Subset*** C of O;

(ii) ***Partition*** $P_k = \{C_1, C_2, \ldots, C_k\}$ of O into k clusters such that

(ii a) $C_j \neq \emptyset$, for $j = 1, 2, \ldots, k$;

(ii b) $C_i \cap C_j = \emptyset$, for $i, j = 1, 2, \ldots, k$ and $i \neq j$;

(ii c) $\bigcup_{j=1}^{k} C_j = O$;

(iii) ***Packing*** $Pa_k = \{C_1, C_2, \ldots, C_k\}$ of O with k clusters: same as (ii) but without (ii c);

(iv) ***Covering*** $Co_k = \{C_1, C_2, \ldots, C_k\}$ of O with k clusters: same as (ii) but without (ii b);

(v) ***Hierarchy*** $H = \{P_1, P_2, \ldots, P_q\}$ of $q \leq n$ partitions of O. The set of partitions $P_1, P_2, \ldots, P_q$ of O is such that $C_i \in P_c, C_j \in P_d$ and $c > d$ imply $C_i \subset C_j$ or $C_i \cap C_j = \emptyset$ for all i, j, with $i \neq j$, and $c, d = 1, 2, \ldots, q$.

Facts:

1. By far the most frequently used types of clustering are the partition and the *complete hierarchy of partitions*, i.e., the one containing n partitions.

2. Not all clustering criteria are independent. For instance, partitioning with the minimum sum of cliques criterion is equivalent to partitioning with the maximum sum of cuts criterion, since

$$\sum_{\ell=1}^{k} cl(C_\ell) + \frac{\sum_{\ell=1}^{k} c(C_\ell)}{2} = \Delta,$$

with Δ constant for all partitions P_k.

3. Relaxations of hierarchies are also studied. They include *hierarchies of packings* [MaBe83], *weak hierarchies* [BaDr89], and *pyramids* [BeDi85].

4. In *constrained clustering*, additional requirements are imposed on the clusters. The most frequent ones are bounds on their cardinality, bounds on their weight, assuming entities with weights (or connectedness), and assuming an adjacency matrix between entities is given.

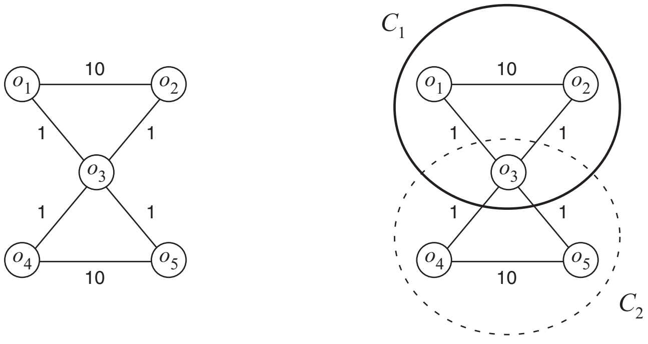
5. In *fuzzy clustering*, each entity has a degree of membership in one or several clusters. These values represent the likelihood that the entity is assigned to that cluster.

Examples:

1. For the graph shown in part (a) of the following figure, we wish to cluster the five entities into two clusters C_1 and C_2 to minimize the overall radius, i.e., $\max\{r(C_1), r(C_2)\}$. The associated matrix of dissimilarities is given by

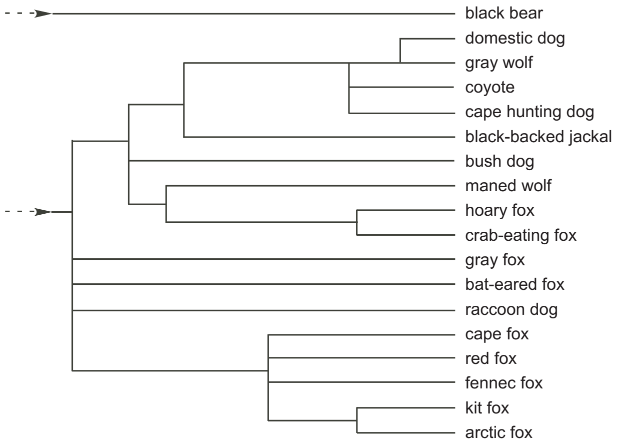
$$D = \begin{bmatrix} 0 & 10 & 1 & \infty & \infty \\ 10 & 0 & 1 & \infty & \infty \\ 1 & 1 & 0 & 1 & 1 \\ \infty & \infty & 1 & 0 & 10 \\ \infty & \infty & 1 & 10 & 0 \end{bmatrix}.$$

In an optimal *partition*, one of the clusters must have radius equal to 10 due to the presence of entities o_1 and o_2, or entities o_4 and o_5, in the same cluster. In a *covering*, entity o_3 is allowed to belong to two clusters at the same time, and so it is possible to construct two clusters with radius equal to 1, as shown in part (b) of the figure.



(a) (b)

2. A phylogenetic tree (§20.2) is a classical example of a hierarchy of partitions. Fusions of clusters are represented by the moment when two species (or two sets of species) have separated from each other in the course of history. The next figure illustrates the evolution of dogs—the Family Canidae.



19.4.3 HIERARCHICAL CLUSTERING

This subsection discusses algorithms that can be used to carry out hierarchical clustering. Both agglomerative methods as well as divisive methods are discussed.

Agglomerative Algorithms:

Agglomerative hierarchical clustering algorithms are among the oldest and still most frequently used methods for cluster analysis. They start from an initial partition into n single-entity clusters, and successively merge clusters according to some specified local criterion until all entities belong to the same cluster.

Definitions:

A ***local criterion*** is a criterion that uses only the information provided by the current partition.

Let $G_c = (V, E)$ denote a complete graph, having a vertex v_i associated with each entitiy

o_i, for $i = 1, 2, \dots, n$, and with edge (v_i, v_j) weighted by the dissimilarity d_{ij}, for $i < j$. Let MST denote a ***minimum spanning tree*** of G_c; see §10.1.1.

The ***single-linkage*** algorithm merges at each step two clusters achieving the smallest inter-cluster dissimilarity.

The ***complete-linkage*** algorithm merges at each step two clusters for which the resulting cluster has smallest diameter.

Facts:

1. Algorithm 1 uses a local criterion to successively merge partitions until all entities belong to a single cluster.

```
Algorithm 1: Agglomerative hierarchical algorithm.
  input: set $O = \{o_1, o_2, \dots, o_n\}$ of $n$ entities
  output: a hierarchy $H = \{P_1, P_2, \dots, P_n\}$ of partitions of $O$
  $C_i := \{o_i\}, i = 1, 2, \dots, n$
  $P_n := \{C_1, C_2, \dots, C_n\}$
  $k := 1$
    while $n - k > 1$ do
      select $C_i, C_j \in P_{n-k+1}$ following a local criterion
      $C_{n+k} := C_i \cup C_j$
      $P_{n-k} := (P_{n-k+1} \cup \{C_{n+k}\}) \backslash \{C_i, C_j\}$
      $k := k + 1$
```

2. The values of the split for all subsets of entities of O, and hence for all partitions of O, belong to the set of dissimilarity values associated with the set of edges of any MST of G_c [Ro67].

3. The single-linkage algorithm provides maximum split partitions at all levels of the hierarchy [DeHa80]. This is a corollary of Fact 2.

4. For other criteria, the partitions obtained after several steps of an agglomerative algorithm are not necessary optimal. For instance, the complete-linkage algorithm does not guarantee that after two or more steps the resulting partition is optimal regarding the minimum diameter.

5. Computer code, in Fortran and Javascript, that implements the single-linkage and complete-linkage algorithms can be found at the sites

- https://protect-us.mimecast.com/s/ANrmBzUvd34vSd?domain=pitt.edu
- https://protect-us.mimecast.com/s/3RmXBoh8AQ08uM?domain=code.google.com

6. A parametric formula gives new dissimilarity values between cluster C_k and C_i, C_j when these latter two are merged [LaWi67]:

$$d_{k,i \cup j} = \alpha_i d_{ik} + \alpha_j d_{jk} + \delta |d_{ik} - d_{jk}|$$

The parameters for single-linkage and complete-linkage algorithms are given next.

method	α_i	α_j	δ
single-linkage	$\frac{1}{2}$	$\frac{1}{2}$	$-\frac{1}{2}$
complete-linkage	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$

Clusters to be merged at each iteration are those corresponding to the smallest updated dissimilarity. Using a heap yields an $O(n^2 \log n)$ implementation of Algorithm 1.

7. Four other hierarchical clustering methods are based on an extension of the previous formula; further extensions are due to [Ja91].

8. Better algorithmic complexity can be derived in a few cases. For example, finding the MST of G_c, ranking its edges by nondecreasing values, and merging entities at endpoints of successive edges yields a $\theta(n^2)$ implementation of the single-linkage algorithm. At each iteration, clusters correspond to connected components of a graph with the same vertex set as G_c and having as edges those of the MST considered.

9. The *reducibility property*

$$d(C_i, C_j) \leq \min\{d(C_i, C_k), d(C_j, C_k)\}$$

implies

$$\min\{d(C_i, C_k), d(C_j, C_k)\} \leq d((C_i \cup C_j), C_k) \quad \forall i, j, k.$$

This means that by merging two clusters C_i and C_j, less dissimilar between themselves than with another cluster C_k, cannot make the resultant cluster $C_i \cup C_j$ less dissimilar to C_k than C_i and C_j alone.

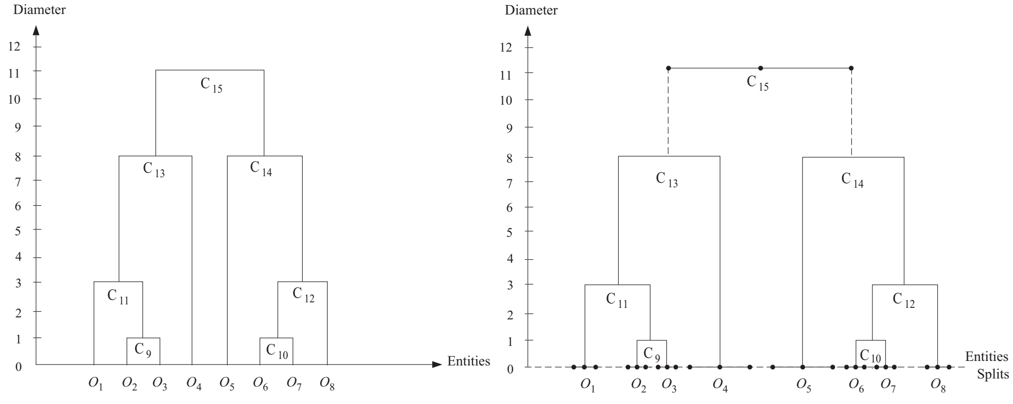
The dissimilarities $D = (d_{ij})$ induce a *nearest neighbor* relation, with one or more pairs of reciprocal near neighbors. When the reducibility property holds, each pair of reciprocal near neighbors will be merged before merging with other clusters.

10. Updating chains of nearest neighbors yields $\theta(n^2)$ agglomerative hierarchical clustering algorithms [Be82], [Mu83].

11. The results of hierarchical clustering can be represented graphically by a *dendrogram* [Co71] or an *espalier* [HaJaSi96]. Vertical lines correspond to entities or clusters, and horizontal lines joining endpoints of vertical lines correspond to mergings of clusters. The height of the horizontal lines corresponds to the value of the updated dissimilarity between the clusters merged, which can be a measure of separation or homogeneity of the clusters obtained. In an espalier the length of the horizontal lines is used to represent a second measure of homogeneity or separation of the clusters.

Examples:

1. The following figure illustrates a hierarchical clustering of eight entities. The left portion shows a dendrogram and the right portion shows an espalier.



2. We apply the single-linkage algorithm to the following matrix of dissimilarities associated with five entities:

	$C_1 = \{o_1\}$	$C_2 = \{o_2\}$	$C_3 = \{o_3\}$	$C_4 = \{o_4\}$	$C_5 = \{o_5\}$
$C_1 = \{o_1\}$	0	1^*	4	7	5
$C_2 = \{o_2\}$	1^*	0	7	6	2
$C_3 = \{o_3\}$	4	7	0	3	8
$C_4 = \{o_4\}$	7	6	3	0	5
$C_5 = \{o_5\}$	5	2	8	5	0

The smallest split is between clusters C_1 and C_2, which are therefore merged into a single cluster $C_6 = C_1 \cup C_2$. By using the updating formula presented in Fact 6, new dissimilarity values are obtained.

	C_6	C_3	C_4	C_5
C_6	0	4	6	2^*
C_3	4	0	3	8
C_4	6	3	0	5
C_5	2^*	8	5	0

Since the current smallest split is found now between clusters C_5 and C_6, they are merged into cluster $C_7 = C_5 \cup C_6$, and then the matrix of dissimilarities is updated likewise.

	C_7	C_3	C_4
C_7	0	4	5
C_3	4	0	3^*
C_4	5	3^*	0

Clusters C_3 and C_4 are next merged together to create cluster $C_8 = C_3 \cup C_4$. After that, we reach the last level of the hierarchy of partitions by merging clusters C_7 and C_8 to form a single cluster C_9.

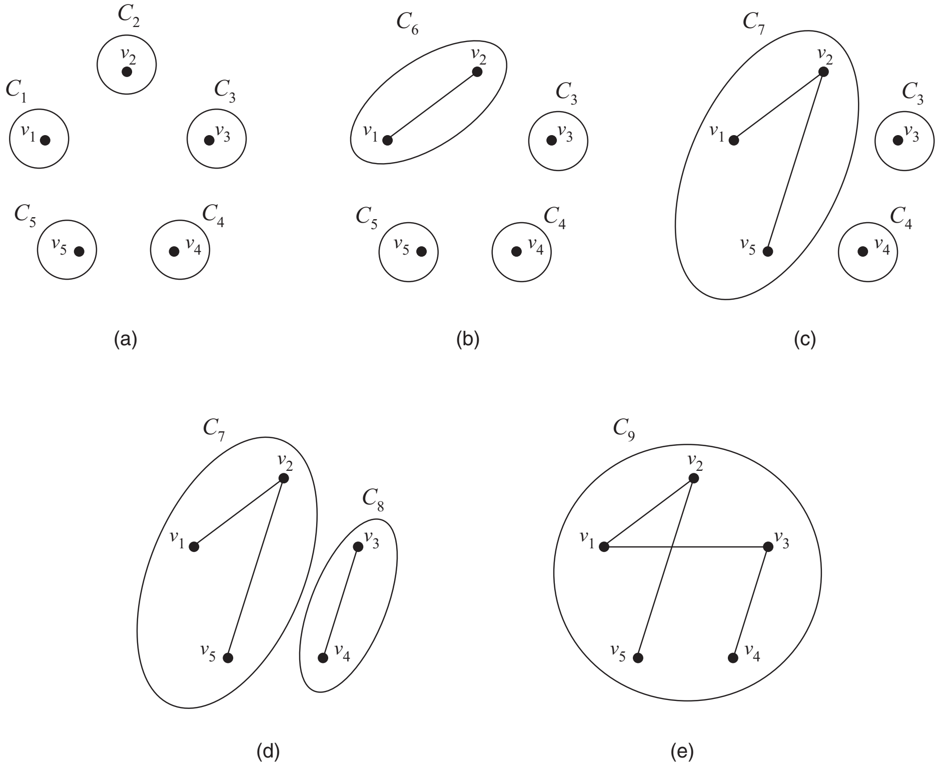
	C_7	C_8
C_7	0	4^*
C_8	4^*	0

The single-linkage algorithm obtains maximum split partitions at the five levels of the hierarchy. As next shown, this is not a coincidence.

3. Consider the complete graph $G_c = (V, E)$ with vertices v_i associated with the entities o_i of Example 2, and with edges (v_i, v_j) weighted by the dissimilarities d_{ij} presented in its first table. The MST of G_c contains the following edges, listed by nondecreasing weight: (v_1, v_2) (weight 1), (v_2, v_5) (weight 2), (v_3, v_4) (weight 3), and (v_1, v_3) (weight 4). Now consider a graph G' with the same vertex set as G_c and where clusters correspond to its different connected components. This is shown in part (a) of the following figure.

The single-linkage algorithm, based on finding the MST of G_c (Fact 8), considers the MST edges in nondecreasing order, and at each iteration connects components of G' using these edges. In this example, it starts by considering edge (v_1, v_2) and connecting these vertices in order to create the connected component $C_6 = \{v_1, v_2\}$; see part (b). The following steps of the clustering are shown in parts (c)–(e), Namely, the next edge (v_2, v_5) connects v_5 to C_6, creating $C_7 = \{v_1, v_2, v_5\}$. A new connected component C_8

is formed by connecting vertices v_3 and v_4. Finally, the two connected components are merged into a single connected component of G' by considering edge (v_1, v_3). The sequence of clusters obtained corresponds to that found in the previous example (Fact 2).

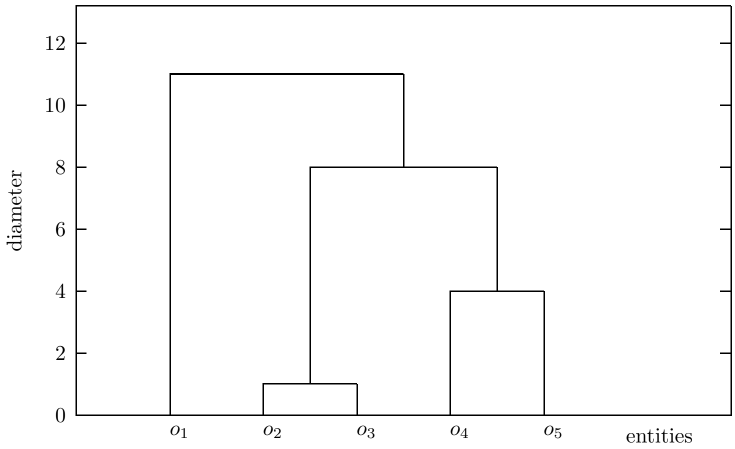


4. Consider the following set of five entities as well as its matrix of dissimilarities:

	o_1	o_2	o_3	o_4	o_5
o_1	0	4	9	7	11
o_2	4	0	1	6	3
o_3	9	1	0	8	6
o_4	7	6	8	0	4
o_5	11	3	6	4	0

The complete-linkage algorithm applied to this set of entities produces the dendrogram presented next, which represents the successive agglomerations performed by the algorithm with the purpose of minimizing the diameter of each of the partitions obtained in the hierarchy.

The complete-linkage algorithm is not assured of finding minimum diameter partitions at all levels of the hierarchy (Fact 4). For instance, a better bipartition could have been obtained by clustering entities o_1 and o_4 in one cluster and entities o_2, o_3, and o_5 in another one, yielding a bipartition of diameter 7.



Divisive Algorithms:

Divisive hierarchical clustering algorithms are less frequently used than agglomerative ones. They proceed from an initial cluster containing all entities and then perform successive bipartitions of one cluster at a time until all entities belong to different clusters.

Definitions:

Let MST′ denote a ***maximum spanning tree*** of G_c; see §10.1.1.

A ***coloring*** of a graph is an assignment of colors to its vertices such that no two adjacent vertices have the same color; see §8.6.1. A ***bicoloring*** of a graph is a coloring that uses only two colors.

An ***odd cycle*** in a graph is one containing an odd number of vertices.

Facts:

1. Algorithm 2 uses two local criteria to successively refine partitions until each entity belongs to a single cluster.

Algorithm 2: **Divisive hierarchical algorithm.**

```
input: set $O = \{o_1, o_2, \ldots, o_n\}$ of $n$ entities
output: a hierarchy $H = \{P_1, P_2, \ldots, P_n\}$ of partitions of $O$
$P_1 := \{C_1\} = \{\{o_1, o_2, \ldots, o_n\}\}$
$k := 1$
  while $k < n$ do
    select $C_i \in P_k$ following a first local criterion
    partition $C_i$ into $C_{2k}$ and $C_{2k+1}$ following a second local criterion
    $P_{k+1} := (P_k \cup \{C_{2k}\} \cup \{C_{2k+1}\}) \setminus \{C_i\}$
    $k := k + 1$
```

2. The role of the first local criterion in Algorithm 2 is not crucial, as it only determines the order in which clusters will be bipartitioned. The second criterion is more difficult to apply since optimal bipartitioning of the chosen cluster according to a given criterion is a problem which may be NP-hard.

3. The unique bicoloring of MST′ defines a minimum diameter bipartition of O [MoSu91]. The diameter of this bipartition is equal to the largest dissimilarity of an edge outside MST′ closing an odd cycle in MST′.

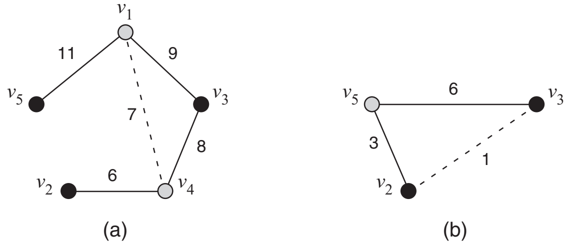
4. Fact 3 yields an $O(n^2 \log n)$ divisive hierarchical algorithm for the minimum diameter criterion by building simultaneously maximum spanning trees at all levels of the hierarchy [GuHaJa91].

Example:

5. Consider the matrix of dissimilarities between five entities from Example 4 in §19.4.3:

$$\begin{array}{c|ccccc|}
 & o_1 & o_2 & o_3 & o_4 & o_5 \\
\hline
o_1 & 0 & 4 & 9 & 7 & 11 \\
o_2 & 4 & 0 & 1 & 6 & 3 \\
o_3 & 9 & 1 & 0 & 8 & 6 \\
o_4 & 7 & 6 & 8 & 0 & 4 \\
o_5 & 11 & 3 & 6 & 4 & 0 \\
\hline
\end{array}$$

The MST′ of the associated complete graph G_c consists of the edges (v_1, v_5) (weight 11), (v_1, v_3) (weight 9), (v_3, v_4) (weight 8), and (v_2, v_4) (weight 6). The largest dissimilarity of an edge outside MST′ closing an odd cycle in MST′ is provided by edge (v_1, v_4) having weight 7; see part (a) of the following figure. This is the value of the diameter of the bipartition obtained from bicoloring the vertices in MST′ (Fact 3), i.e., the partition formed by clusters $C_2 = \{o_1, o_4\}$ and $C_3 = \{o_2, o_3, o_5\}$.



For the next step, since the diameter of the partition results from cluster $C_2 = \{o_1, o_4\}$, this cluster is chosen to be divided by the first local criterion, yielding a new partition $C_4 = \{o_1\}$, $C_5 = \{o_4\}$, and $C_3 = \{o_2, o_3, o_5\}$ of diameter equal to 6 due to the dissimilarity between entities o_3 and o_5 in C_3. Thus, cluster C_3 is chosen to be divided by the first local criterion. A new MST′ for the partial complete graph composed of vertices v_2, v_3, v_5 has edges (v_3, v_5) (weight 6) and (v_2, v_5) (weight 3); see part (b) of the figure. Then a bipartition of C_3 is performed in order to build clusters $C_6 = \{o_2, o_3\}$ and $C_7 = \{o_5\}$, yielding a partition of diameter equal to 1 due to the dissimilarity between entities o_2 and o_3 in cluster C_6. Finally, the last bipartition over C_6 is trivial, and the last level of the hierarchy is attained.

19.4.4 PARTITIONING

Definitions:

Let $h(\cdot)$ be a homogeneity (or heterogeneity) function on the subsets of O.

An ***optimal substructure*** indicates that optimal solutions of subproblems can be used to find optimal solutions of the overall problem.

A problem has ***overlapping subproblems*** if the problem can be broken down into subproblems which are reused several times.

Dynamic programming is a method of solving problems exhibiting the properties of overlapping subproblems and optimal substructure in a much faster way than complete enumeration of solutions.

Recursion is a method of defining functions in which the function being defined is applied within its own definition.

Branch-and-bound (§16.1.8) consists of an implicit enumeration of all solutions using a tree, where large subsets of solutions are pruned before being explored by using upper and lower bounds on the quantity being optimized.

Valid inequalities are inequalities in a mathematical programming formulation of a problem that are necessarily satisfied by its variables.

Facts:

1. Dynamic programming provides an exact algorithm for partitioning by exploiting the recursion

$$f_k^*(O') = \begin{cases} \underset{O_k \subset O'}{opt} \left(f_{k-1}^*(O' - O_k) + h(O_k)\right) \text{ for } k > 1 \\ h(O'), \text{ for } k = 1 \end{cases}$$

where $f_k^*(O')$ denotes the optimal value for partitioning the set $O' \subseteq O$ into k clusters, and additivity is assumed. This formula is easily modified if the value of the objective function is equal to the maximum or the minimum value for each of the clusters. Applying this equation takes time exponential in n, so only small sets of entities may be considered. Constraints can sometimes accelerate the computations, e.g., if all clusters must be small.

2. The single-linkage algorithm provides optimal partitions for the split criterion at all levels of the hierarchy. So it is also a $\theta(n^2)$ algorithm for maximizing the split of a partition of O into k clusters.

3. Let $\mathcal{C} = \{C_1, C_2, \ldots, C_{2n-1}\}$ denote the set of clusters obtained when applying the single-linkage algorithm to O. Then for all k there exists a partition P_k^* that maximizes the sum of splits and consists solely of clusters of $\mathcal{C}$ [HaJaFr89].

4. Let t be the smallest dissimilarity value such that the partial graph $G_t = (V, E_t)$ of G with $E_t = \{(v_i, v_j) \mid d_{ij} \geq t\}$ is k-colorable. Then the color classes in any optimal k-coloring of G_t define a minimum diameter partition of O into k clusters [Ch75], [HaDe78].

5. Partitions obtained with the single-linkage algorithm may suffer from the *chaining effect*: dissimilar entities at the ends of a long chain of pairwise similar entities are assigned to the same cluster. Partitions obtained by the coloring algorithm for minimum diameter may suffer from the *dissection effect*: similar entities may be assigned to different clusters.

6. Bicriterion cluster analysis algorithms seek compromise solutions in order to avoid chaining and dissection effects [DeHa80].

7. Branch-and-bound algorithms have been applied, with some success, to several partitioning problems in cluster analysis [Di85], [KlAr91], [KoNaFu75]. Their efficiency depends on sharpness of the bounds used, availability of a good heuristic solution, and efficient branching, i.e., rules that improve bounds for all subproblems obtained in a fairly balanced way.

8. Brusco and Stahl [BrSt05] proposed a *repetitive branch-and-bound algorithm* (RBBA) that solves subproblems in sequence by repeating a branch-and-bound procedure. In RBBA, the resolution of a given subproblem by branch-and-bound depends on the optimal solutions of smaller subproblems already solved by the algorithm, as a look-ahead component in the bound. For instance, using the minimum diameter criterion, RBBA can solve exactly instances with $n \leq 250$ entities and $k \leq 20$ clusters.

9. Good results can also be obtained when bounds result from the solution of a mathematical program combined with heuristic methods. For minimum sum-of-stars partitioning, primal-dual variable neighborhood search [HaEtal07] solved exactly for the first time instances with $n = 15{,}000$.

10. Several valid inequalities are given in [GrWa90] for the sum-of-cliques criterion. These results are used in a cutting plane algorithm [GrWa89] to solve instances with $n \leq 158$. It appears that triangle inequalities (i.e., valid inequalities which state that if the pairs of entities o_i, o_j and o_j, o_k belong to the same cluster then o_i, o_k also belong to the same cluster) suffice in almost all cases.

11. Partitioning problems in cluster analysis can be formulated by considering all possible clusters in the following mathematical program:

$$\begin{array}{rl} \text{minimize:} & \sum\limits_{t\in T} h(C_t) y_t \\ \text{subject to:} & \sum\limits_{t\in T} a_{it} y_t = 1, \quad i = 1, \ldots, n \\ & \sum\limits_{t\in T} y_t = k \\ & y_t \in \{0,1\}, \quad t \in T \end{array}$$

where $T = \{1, \ldots, 2^n - 1\}$ and a_{it} equals 1 if entity o_i belongs to cluster C_t and is 0 otherwise. Variable y_t equals 1 if cluster C_t is in the optimal partition and is 0 otherwise. This is a large linear partitioning problem with a size constraint, for which the number of variables is exponential in the number of entities n.

12. The standard way to tackle the mathematical program in Fact 11 is to solve the linear relaxation by means of *column generation* [DeDeSo05], and then apply branch-and-bound. The entering column is obtained by solving the following auxiliary problem, whose unknowns are the coefficients a_i of the column:

$$\begin{array}{rl} \text{minimize:} & h(C_t) - \sum_{i=1}^{n} a_i \lambda_i + \sigma \\ \text{subject to:} & a_i \in \{0,1\}, \quad i = 1, \ldots, n. \end{array}$$

Here λ_i for $i = 1, \ldots, n$ and σ are the dual variables at the current iteration. Difficulty varies depending on the form of $h(C_t)$ as a function of the a_i.

Once the entering column is found, the linear program solver proceeds. However, convergence may be slow, particularly if there are few clusters in the partition and hence massive degeneracy of the optimal solution. In fact, even when the optimal solution is found, many more iterations may be needed to prove its optimality. Once the linear relaxation of the problem is solved, one must check for integrality of the solution. If the solution is not integer, branch-and-bound is needed.

Examples:

1. Consider three entities with the associated matrix of dissimilarities given by

$$\begin{array}{c|ccc|} & o_1 & o_2 & o_3 \\ \hline o_1 & 0 & 4 & 9 \\ o_2 & 4 & 0 & 1 \\ o_3 & 9 & 1 & 0 \\ \hline \end{array}$$

They are easily clustered by simple inspection regardless of the criterion chosen. The goal here is to show how dynamic programming works in solving a partitioning problem (Fact 1). Suppose we want to minimize the diameter of a bipartition over these entities.

The algorithm starts with $f_1^*(o_1) = 0$, $f_1^*(o_2) = 0$, $f_1^*(o_3) = 0$ since $h(o_i) = 0$ for $i = 1, 2, 3$. It is useless to calculate $f_2^*(o_i)$ for $i = 1, 2, 3$ since k is larger than n. Then the algorithm proceeds by calculating

$$f_1^*(O_{12} = \{o_1, o_2\}) = h(O_{12}) = 4,\ f_1^*(O_{13} = \{o_1, o_3\}) = h(O_{13}) = 9,$$
$$f_1^*(O_{23} = \{o_2, o_3\}) = h(O_{23}) = 1,\ f_1^*(O_{123} = \{o_1, o_2, o_3\}) = h(O_{123}) = 9.$$

With all the $f_1^*(\cdot)$ now calculated we obtain

$$\begin{aligned} f_2^*(O_{123}) &= \min\{f_1^*(O_{123}) + h(\emptyset), f_1^*(O_{12}) + h(o_3), f_1^*(O_{13}) + h(o_2), f_1^*(O_{23}) + h(o_1), \\ &\qquad f_1^*(o_1) + h(O_{23}), f_1^*(o_2) + h(O_{13}), f_1^*(o_3) + h(O_{12})\} \\ &= f_1^*(O_{23}) + h(o_1) = 1, \end{aligned}$$

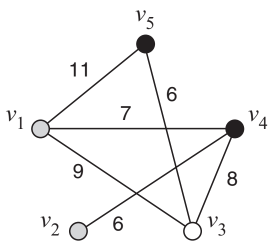
which results in $C_1 = \{o_1\}$ and $C_2 = \{o_2, o_3\}$.

2. In Example 2 of §19.4.3, the single-linkage algorithm for $n = 5$ entities obtained $(5 \times 4)/2 - 1 = 9$ different clusters: $C_1 = \{o_1\}, C_2 = \{o_2\}, C_3 = \{o_3\}, C_4 = \{o_4\}, C_5 = \{o_5\}, C_6 = \{o_1, o_2\}, C_7 = \{o_1, o_2, o_5\}, C_8 = \{o_3, o_4\}$, and $C_9 = \{o_1, o_2, o_3, o_4, o_5\}$. If a maximum sum-of-splits partition with four clusters is demanded, from $\binom{5}{2} = 10$ different possibilities, we can restrict ourselves to only two due to Fact 3:

$$P_4^1 = \{C_6, C_3, C_4, C_5\},\ P_4^2 = \{C_1, C_2, C_8, C_5\},$$

which results in $P_4^* = P_4^1$ with sum of splits equal to 10. Here, the maximum split partition of size 4 obtained by the single-linkage algorithm coincides with the one that maximizes the sum of splits, though this is not always true.

3. The minimum diameter partition with $k = 3$ for the five entities with matrix of dissimilarities presented in Example 4 of §19.4.3 is determined by the smallest dissimilarity value t such that the partial graph $G_t = (V, E_t)$ of G with $E_t = \{(v_i, v_j) \mid d_{ij} \geq t\}$ is 3-colorable (Fact 4). For the given example, the smallest t for which G_t is 3-colorable is equal to 5, since the partial graph G_t shown next is no longer 3-colorable if edges (v_1, v_2) and (v_4, v_5) of weight 4 are added to it. The diameter of the partition $P_3^* = \{\{o_1, o_2\}, \{o_3\}, \{o_4, o_5\}\}$ is equal to 4.



▷ Partitioning in Euclidean Space

Here we suppose that the entities o_i are points x_i of an s-dimensional Euclidean space.

Definitions:

The homogeneity of cluster C_j is measured by reference to a ***center*** of C_j, which is not in general a point belonging to the cluster.

A popular criterion for partitioning points in Euclidean space is the ***minimum sum-of-squares*** criterion $ss(C_j)$ given by

$$ss(C_j) = \sum_{i:o_i \in C_j} (\|x_i - \overline{x}\|_2)^2,$$

where $\| \cdot \|_2$ denotes Euclidean distance and $\overline{x}$ is given by the ***centroid*** of the points x_i in cluster C_j, i.e.,

$$\overline{x} = \frac{1}{|C_j|} \sum_{i:o_i \in C_j} x_i.$$

Other criteria can also be used:

- the ***variance*** $v(C_j)$ of C_j, defined as $ss(C_j)$ divided by $|C_j|$;
- the ***continuous radius*** $cr(C_j)$ of C_j, defined by

$$cr(C_j) = \min_{x \in \mathcal{R}^s} \max_{i:o_i \in C_j} \|x_i - x\|_2;$$

- the ***continuous star*** $cst(C_j)$ of C_j, defined by

$$cst(C_j) = \min_{x \in \mathcal{R}^s} \sum_{i:o_i \in C_j} \|x_i - x\|_2.$$

Facts:

1. The minimum sum-of-squares criterion addresses both homogeneity and separation [Sp80]. It is well known as the criterion tackled by the classical k-means clustering procedure [Ma67], described by Algorithm 3. From an initial partition, the k-means algorithm proceeds by reassigning the entities to their closest centroids and updating the cluster centroids until stability is reached. It produces not only the cluster centroids $\overline{x}_j$ but also the cluster membership function m.

Algorithm 3: ***k*-means.**

```
input: set $X = \{x_1, x_2, \ldots, x_n\}$ of $n$ points in $\mathcal{R}^s$, number of clusters $k$
output: cluster centroids $\overline{X} = \{\overline{x}_1, \ldots, \overline{x}_k\} \in \mathcal{R}^s$, $m : X \to \{1, \ldots, k\}$
choose initial values of $\overline{X}$
for $i := 1$ to $n$
  $m(x_i) := \text{argmin}_{j \in \{1,\ldots,k\}} (\|x_i - \overline{x}_j\|_2)^2$
repeat
  for $j := 1$ to $k$
    calculate the centroid $\overline{x}_j$
  for $i := 1$ to $n$
    $m(x_i) := \text{argmin}_{j \in \{1,\ldots,k\}} (\|x_i - \overline{x}_j\|_2)^2$
until $m$ does not change
```

2. The centroids used by criteria $ss(C_j)$ and $v(C_j)$ may be usefully considered as representative of clusters in some applications.

3. The sum of squares of cluster C_j is equal to the sum of all squared distances between pairs of entities of this cluster divided by its cardinality:

$$ss(C_j) = \frac{1}{|C_j|} \sum_{i:o_i \in C_j} \sum_{\ell \neq i : o_\ell \in C_j} (\|x_i - x_\ell\|_2)^2.$$

4. The entities of clusters C_1 and C_2 in a bipartition may be separated by a hyperplane of $\mathcal{R}^s$. Moreover, one may choose this hyperplane from among those going through 1 to s entities [Ha67]. This implies that the number of bipartitions is polynomially bounded for fixed dimensions. Using this fact, one can devise an exact polynomial $O(n^{s+1} \log n)$ algorithm for minimum sum-of-squares hierarchical divisive clustering of points in s-dimensional space [HaJaMl98].

5. Minimum sum-of-squares clustering is NP-hard for general dimensions even when $k = 2$ [AlEtal09]. For general values of k, the problem is NP-hard even in the plane [MaNiVa09]. If both k and the dimension s are fixed, the problem can be solved in $O(n^{sk+1})$ time [InKaIm94], which may be very time consuming even for instances in the plane. Exact methods with exponential computational complexity include dynamic programming [vOMe04], branch-and-bound [Br06], column generation [dMEtal00], concave minimization [XiPe05], and semidefinite programming [AlHa09], [PeXi05].

6. Implementations of the k-means algorithm can be found at the sites

- `https://protect-us.mimecast.com/s/dqYaBRipEOKpFJ?domain=bonsai.hgc.jp`
- `https://protect-us.mimecast.com/s/DzxkBmIOQ58OUg?domain=cs.umd.edu`
- `https://protect-us.mimecast.com/s/8JQwBdfQvNrQhK?domain=alglib.net`

7. Because reassignments are performed only if profitable and the number of partitions is finite, the k-means algorithm always converges to a local minimum. Better local minima are provided with the j-means heuristic [HaMl01a] combined with variable-depth neighborhood search [HaMl01b]; see §16.8.2. A detailed comparative study of heuristics for minimum sum-of-squares clustering with many references is provided in [BrSt07].

8. Problems in one-dimensional Euclidean space are best solved by dynamic programming. This method works well when optimal clusters possess the *string property*, i.e., consist of consecutive points on the line. Assume $o_1, o_2, \ldots, o_n$ are indexed in order of nondecreasing values of $x_1, x_2, \ldots, x_n$. Let $h(\cdot)$ be a homogeneity function on the subsets of O and let F_m^k be the optimal value of clustering $o_1, o_2, \ldots, o_m$ into k clusters. The dynamic programming recursion may be written

$$F_m^k = \min_{i \in \{k, k+1, \ldots, m\}} \{F_{i-1}^{k-1} + h(C_{i,m})\}$$

where $C_{i,m} = \{o_i, o_{i+1}, \ldots, o_m\}$. Using updating to compute $h(\cdot)$ for all potential clusters yields $O(n^2)$ algorithms for various criteria [Ra71], [Sp80].

9. The objective in the classical *Fermat-Weber problem* is to locate a facility in $\mathcal{R}^s$ in order to minimize the sum of its weighted Euclidean distances to the locations of a given set of users. It is a central problem in continuous location theory [We93]; see §16.2.5. Applying the continuous star criterion is equivalent to the Fermat-Weber problem with equally weighted Euclidean distances.

10. For $A \in \mathcal{R}^{s \times s}$ and $b \in \mathcal{R}^s$,

$$\|x_1 - x_2\| = \|Ax_1 + b - Ax_2 - b\|$$

if and only if A is orthogonal, i.e., criteria involving Euclidean distances are invariant with respect to orthogonal transformations and translations.

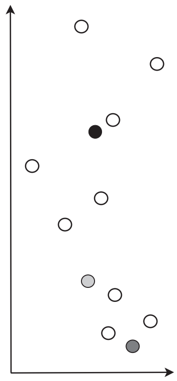
An interesting question is whether the optimal solution would change if scaling of measurements is performed over the data. In general, a scale transformation is defined as a nonsingular matrix $H \in \mathcal{R}^{s\times s}$ with $H = \text{diag}(h_1, \ldots, h_s)$ ($h_\ell \neq 0$ for $\ell = 1, \ldots, s$). From the previous equation, we observe that Euclidean distance criteria are invariant with respect to scale transformations if $h_\ell = \pm 1$ for $\ell = 1, \ldots, s$, i.e., the composition of optimal partitions is unaffected by scale transformations only if they amount to no more than a change of sign. This is very restrictive for practical applications.

Examples:

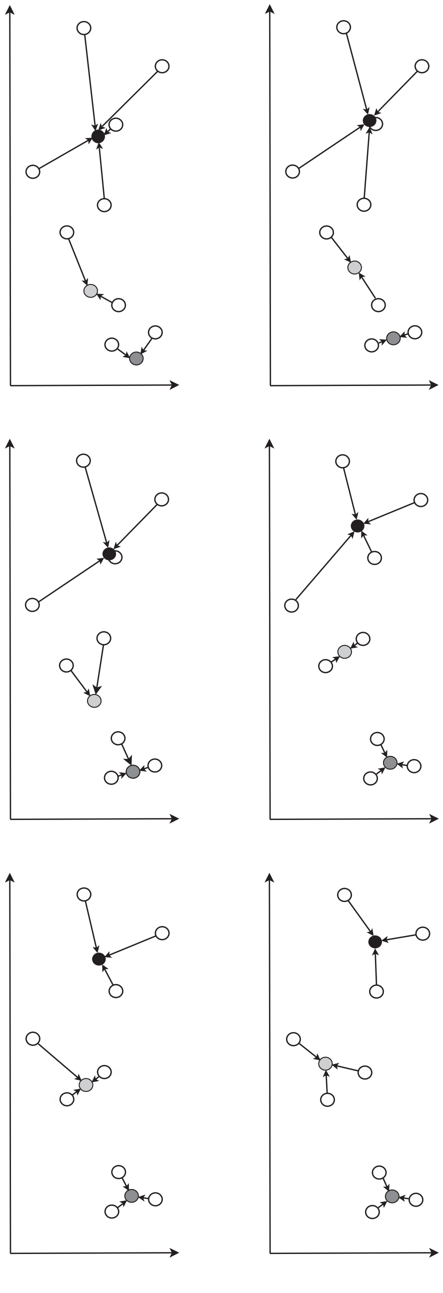
1. Color image quantization is a data compression technique that reduces the total set of colors in a digital image to a representative subset. In the RGB color model, a true color image is represented by a matrix of pixel colors, each consisting of 24 bits: one byte for red, one byte for green, and one byte for blue components. However, it is often the case that only $k \ll 2^{24} \approx 16.8$ million possible colors are stored.

The problem can be modeled by considering an image I as a function $I : \Omega \to \mathcal{R}^3$, $\Omega \subset \mathcal{Z} \times \mathcal{Z}$, with each dimension of $I(\Omega) = \{I(x) \mid x \in \Omega\}$ representing one of the red, green, and blue components of a pixel color, with values ranging between 0 and 255. Thus, color quantization of I for the RGB color model consists of solving a partitioning problem in the 3-dimensional Euclidean space $I(\Omega)$ with the number of clusters equal to k. After clusters $C_1, C_2, \ldots, C_k$ are obtained, the color $I(x)$ of each pixel $x \in \Omega$ is replaced by the centroid of its cluster.

2. We provide an example of the k-means algorithm applied in $\mathcal{R}^2$ to partitioning nine entities into three clusters. The first figure illustrates the initialization of the k-means algorithm, defined by first determining the initial positions for the centroids of each cluster (e.g., by random selection).



The next figure presents three iterations of the algorithm, performed until stabilization is reached. The left-hand side of each panel shows the assignment step of the algorithm where each point is assigned to its closest centroid, while the right-hand side indicates the updated positions of the cluster centroids.



3. Consider two data matrices X and X', each corresponding to the coordinates of six points in the plane:

$$X = \begin{pmatrix} 0 & 48 \\ 6 & 48 \\ 0 & 24 \\ 6 & 24 \\ 0 & 0 \\ 6 & 0 \end{pmatrix}, \quad X' = \begin{pmatrix} 0 & 12 \\ 24 & 12 \\ 0 & 6 \\ 24 & 6 \\ 0 & 0 \\ 24 & 0 \end{pmatrix}.$$

It is easy to verify that $X' = XH$ where $H = \begin{pmatrix} 4 & 0 \\ 0 & 1/4 \end{pmatrix}$.

Not surprisingly, since H is not orthogonal, the optimal partitions differ for the data matrices X and X' (Fact 10). For instance, if the minimum sum-of-squares criterion is used with $k = 2$, the optimal bipartition for points in X is given by $\{\{x_1, x_2, x_3, x_4\}, \{x_5, x_6\}\}$, while for points in X' it is given by $\{\{x'_1, x'_3, x'_5\}, \{x'_2, x'_4, x'_6\}\}$.

19.4.5 SPECTRAL CLUSTERING

There are several other clustering methods found in the literature (e.g., model-based clustering [FrRa02], additive clustering [Mi87], and subspace clustering [PaHaLi04]). Among these methods, spectral clustering algorithms have become very popular in recent years. Their main appeal relies on the fact that they are based on standard linear algebra and are simple to implement. Spectral clustering techniques use the eigenvalues and eigenvectors of certain graph-based matrices in order to cluster data.

Definitions:

The ***unnormalized graph Laplacian*** is defined as $L = S - D$, where $D = (d_{ij})$ and $S = \text{diag}(s_1, s_2, \ldots, s_n)$ with diagonal elements defined by $s_i = \sum_{j=1}^{n} d_{ij}$. It is customary to let D represent a matrix of *similarities*, i.e., if d_{ij} is very large (small), then objects o_i and o_j are very similar (different).

The ***normalized graph Laplacian*** is given by $L_{norm} = S^{-1}L = I - S^{-1}D$.

Facts:

1. A thorough coverage of Laplacian matrices and spectral clustering is found in [Ch97].

2. A different normalized graph Laplacian matrix $L_b = S^{-1/2}LS^{-1/2}$ can be used by spectral clustering algorithms [NgJoWe02].

3. The term *normalization* means that the largest eigenvalue is less than or equal to 2, with equality only when the graph is bipartite.

4. Since L_{norm} and L_b are positive semidefinite all their eigenvalues range between 0 and 2.

5. According to [vL07], L_b does not present any computational advantages over L_{norm}. In fact, spectral clustering with the eigenvectors of L_b might be problematic if they contain particularly small entries.

6. The matrix L satisfies the following properties [Mo91]:

- $f^T L f = \frac{1}{2} \sum_{i,j=1}^{n} d_{ij}(f_i - f_j)^2$ holds for every vector $f \in \mathcal{R}^n$;
- L is symmetric and positive semidefinite;

- The smallest eigenvalue of L is 0, and a corresponding eigenvector is the constant one vector $(1, 1, \ldots, 1)^T$;
- L has n nonnegative, real-valued eigenvalues $0 = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$.

7. The unnormalized spectral clustering algorithm (Algorithm 4) uses the unnormalized Laplacian matrix L to change the representation of the data matrix X to points $y_i \in \mathcal{R}^k$ for $i = 1, \ldots, n$. Then the k-means procedure is executed on these points in order to obtain the output clustering for the original data. Thus, if the k-means procedure classifies points y_i and y_j into the same cluster, then the output clustering likewise assigns entities o_i and o_j to the same cluster.

Algorithm 4: **Unnormalized spectral clustering.**

```
input: similarity matrix $D \in \mathcal{R}^{n \times n}$, number of clusters $k$
output: clusters $C_1, \ldots, C_k$
construct a graph $G = (V, E)$ from $D$
compute the unnormalized Laplacian $L$
compute the first $k$ eigenvectors $\overline{f}_1, \ldots, \overline{f}_k$ of $L$ associated with its $k$ smallest
    eigenvalues
let $\overline{V} \in \mathcal{R}^{n \times k}$ be the matrix containing the vectors $\overline{f}_1, \ldots, \overline{f}_k$ as columns
for $i := 1$ to $n$
    let $y_i \in \mathcal{R}^k$ be the vector corresponding to the $i$th row of $\overline{V}$
cluster the points $(y_i)_{i=1,\ldots,n} \in \mathcal{R}^k$ into $k$ clusters using the $k$-means algorithm
```

8. The normalized Laplacian L_{norm} satisfies the following properties [Ch97]:

- λ is an eigenvalue of L_{norm} with eigenvector $\overline{f}$ if and only if λ and $\overline{f}$ solve the generalized eigenproblem $L\overline{f} = \lambda S\overline{f}$;
- 0 is an eigenvalue of L_{norm}, and a corresponding eigenvector is the constant one vector $(1, 1, \ldots, 1)^T$;
- L_{norm} is positive semidefinite and has n real-valued eigenvalues $0 = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$.

9. The normalized spectral clustering algorithm (Algorithm 5) is similar to the unnormalized version presented in Fact 7, except that it uses the eigenvectors of the normalized Laplacian matrix L_{norm} instead of those of L.

Algorithm 5: **Normalized spectral clustering.**

```
input: similarity matrix $D \in \mathcal{R}^{n \times n}$, number of clusters $k$
output: clusters $C_1, \ldots, C_k$
construct a graph $G = (V, E)$ from $D$
compute the unnormalized Laplacian $L$
compute the first $k$ eigenvectors $\overline{f}_1, \ldots, \overline{f}_k$, associated with the $k$ smallest
    eigenvalues of $L_{norm}$ that solve the generalized eigenproblem $L\overline{f} = \lambda S\overline{f}$
let $\overline{V} \in \mathcal{R}^{n \times k}$ be the matrix containing the vectors $\overline{f}_1, \ldots, \overline{f}_k$ as columns
for $i := 1$ to $n$
    let $y_i \in \mathcal{R}^k$ be the vector corresponding to the $i$th row of $\overline{V}$
cluster the points $(y_i)_{i=1,\ldots,n} \in \mathcal{R}^k$ into $k$ clusters using the $k$-means algorithm
```

10. The similarity graphs G used by Algorithm 4 and Algorithm 5 may not be complete. In fact, there are several ways of constructing a graph from a similarity matrix D such that similarity relationships are well represented, e.g., fully connected graphs, ε-neighborhood graphs, or k-nearest neighbor graphs [vL07].

11. Let $G = (V, E)$ be an undirected graph with nonnegative weights on edges and with $|V| = n$. Then the multiplicity of 0 as an eigenvalue of L and L_{norm} is equal to the number of connected components of G [Mo97]. Moreover, the eigenspace of 0 is spanned by the indicator vectors associated with those components, where the indicator vector $\sigma_A = (t_1, \ldots, t_n)^T \in \mathcal{R}^n$ of a connected component with vertices $A \subseteq V$ is defined such that $t_i = 1$ if $v_i \in A$ and $t_i = 0$ otherwise.

12. Unnormalized spectral clustering provides a relaxation to minimizing the *ratio cut* criterion [HaKa92], which is expressed as

$$Rcut(P_k = \{C_1, C_2, \ldots, C_k\}) = \sum_{j=1}^{k} \frac{c(C_j)}{|C_j|}.$$

13. Normalized spectral clustering provides a relaxation to minimizing the *normalized cut* criterion [ShMa00], which is defined as

$$Ncut(P_k = \{C_1, C_2, \ldots, C_k\}) = \sum_{j=1}^{k} \frac{c(C_j)}{\sum_{i:o_i \in C_j} s_i}.$$

14. An argument in favor of normalized spectral clustering is that $Ncut$ expresses both homogeneity and separation. In fact,

$$\sum_{i,j:o_i,o_j \in C_\ell} d_{ij} = \sum_{i,j:o_i \in C_\ell} d_{ij} - \sum_{i,j:o_i \in C_\ell, o_j \in O \setminus C_\ell} d_{ij} = \sum_{i:o_i \in C_\ell} s_i - c(C_\ell).$$

Hence, homogeneity is maximized for a cluster C_ℓ if $c(C_\ell)$ is small and if $\sum_{i:o_i \in C_\ell} s_i$ is large. Both of these conditions are optimized for the $Ncut$ criterion. However, $Rcut$ aims to maximize $|C_\ell|$ of each cluster $\ell = 1, \ldots, k$, though the cardinality of a cluster is not necessarily related to homogeneity as it also depends on the similarities between the entities it contains.

15. Separation is maximized for both the $Ncut$ and $Rcut$ criteria since there is a term $c(C_\ell)$ for each cluster C_ℓ, $\ell = 1, \ldots, k$, which is minimized in the numerator of both formulas (recall that D is now a similarity matrix).

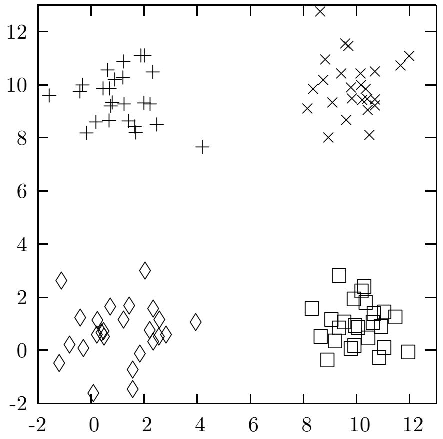
16. MATLAB code for spectral clustering is available at the sites

- `https://protect-us.mimecast.com/s/QQegB6F2AeL2C2?domain=cis.upenn.edu`
- `https://protect-us.mimecast.com/s/xN7GBqUevdgeU0?domain=mathworks.com/44879-spectral-clustering`

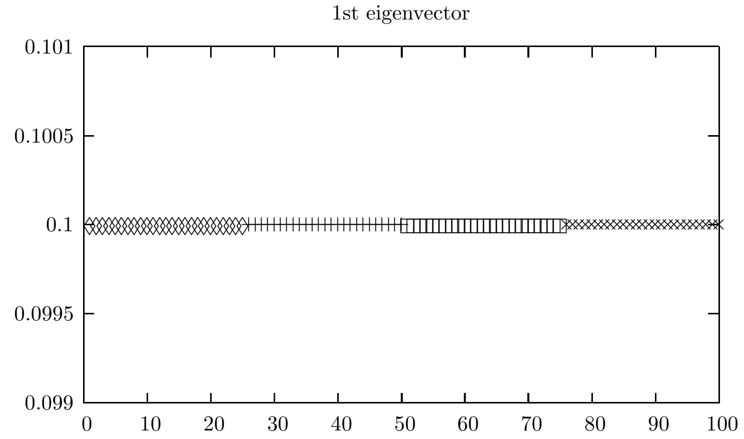
17. Besides its parallel with graph partitioning, spectral clustering is also related to random walks on the similarity graph [MeSh01] and perturbation theory [vL07].

Example:

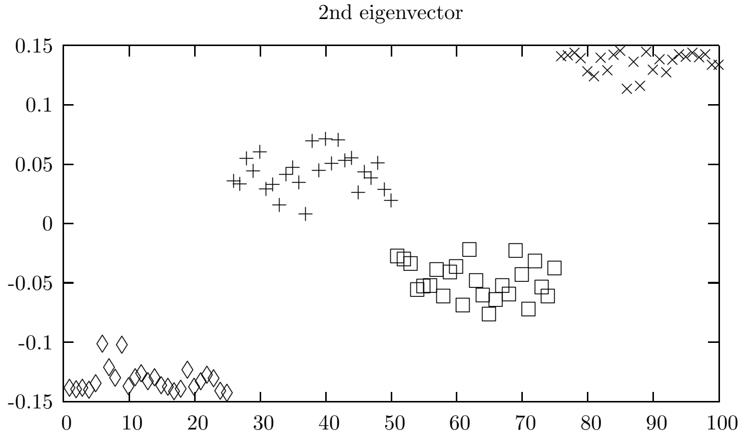
1. One hundred points are generated in the plane and plotted in following figure. The similarity matrix is constructed such that d_{ij} for two points x_i and x_j is given by the inverse of their Euclidean distance. Each group of 25 points is generated by adding normal(0,1) perturbations to the points $(1, 1), (1, 10), (10, 1), (10, 10)$. The different types of marker represent the natural clusters for the dataset. A complete graph G, weighted by the entries of matrix D, is used as the similarity graph. The first four eigenvectors of L_{norm} are displayed in the next figures. The coordinates of an eigenvector $\overline{f} \in \mathcal{R}^{100}$ are plotted consistent with the original 100 data points.



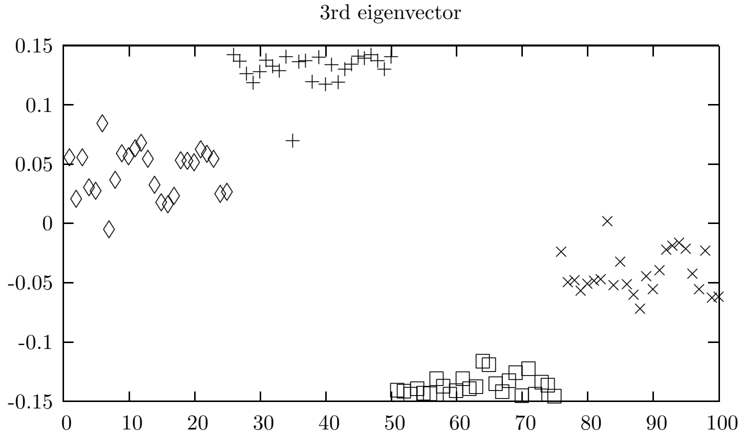
The first eigenvalue of L_{norm} is 0. Since G is fully connected its multiplicity is equal to 1, and the first eigenvector is the constant one vector multiplied by a scalar (note that G is a weighted graph).



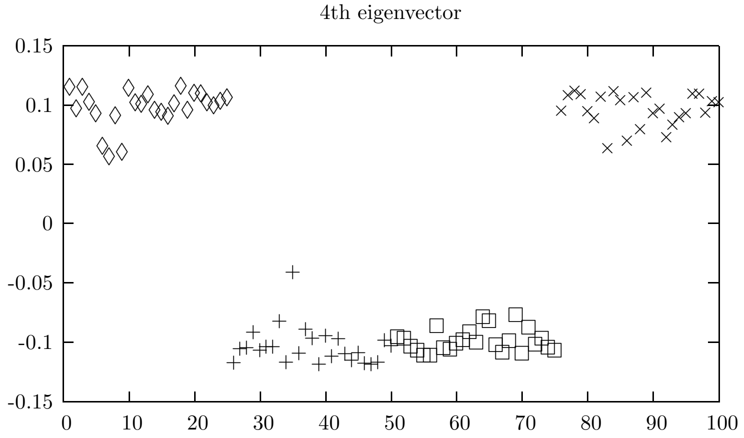
The following eigenvectors carry all the information about the clusters. If clusters in the upper parts of the graphics are distinguished from clusters in the lower parts, we notice that the second eigenvector separates clusters $\Diamond$ and $\Box$ from clusters $+$ and $\times$. Similarly, the third eigenvector separates clusters $\Diamond$ and $+$ from clusters $\Box$ and $\times$, while the fourth eigenvector separates clusters $\Diamond$ and $\times$ from $\Box$ and $+$. If the k-means procedure is then applied to the rows of these eigenvectors, it identifies the correct four clusters.



2nd eigenvector



3rd eigenvector



4th eigenvector

19.5 OUTLIER DETECTION

Outlier detection, also known as anomaly detection, involves finding data points that do not fit in with other data points in some important way. Outlier detection has many important applications in diverse areas, including finance, medicine, network security, and image processing. Outlier detection is complementary to that of clustering in that it determines individual data points that are so different from the bulk of the data that they can be classified as anomalies and not included in a cluster.

Definitions:

An ***outlier*** (or anomaly) is a data point that differs so significantly from other data points that it is unlikely to have been generated by the same mechanism.

Collective outliers collectively deviate from a dataset, even though individual data points do not.

Statistical methods (or ***model-based methods***) for outlier detection assume that normal data objects are generated by a statistical model. (However, outliers are data points that do not follow the model.)

Among statistical methods, ***parametric methods*** for outlier detection assume normal data are objects that are generated by a parametric distribution with parameter θ. The *probability density function* $f(y, \theta)$ gives the probability than an object y is generated by the distribution. If the probability is small, then it is likely that it is an outlier [HaKaPe12].

Among statistical methods, ***nonparametric methods*** for outlier detection do not assume a prior statistical model, but instead try to determine the model from the data.

Proximity-based methods classify as outliers those objects that are significantly farther away than are other objects to points nearby, using some measure of distance or similarity.

The ***distance-based outlier score*** of an object is its distance to its kth nearest neighbor, where the integer k is specified by the user.

Among proximity-based methods, ***distance-based outlier detection methods*** look at the *neighborhood of a point*. A point is an outlier if its neighborhood does not have a sufficient number of other points.

Among proximity-based methods, ***density-based outlier detection methods*** classify a point as an outlier if its density is much lower than that of its neighbors.

Clustering-based methods classify as outliers objects that either do not belong to a cluster or belong to small or sparse clusters.

Classification-based approaches are given a training set of examples of outliers and non-outliers. A classification method is then used to learn to predict whether a point is an outlier.

Mahalanobis distance is the distance between a point and the centroid of a cluster, normalized by the standard deviation in each dimension.

Facts:

1. Surveys of methods for outlier detection can be found in [Ag15] and [HoAu04].

2. Classification methods can be used to find outliers. One way this might be done successfully is to use an outlier class containing items that deviate significantly from the other data points.

3. Clustering methods can be adapted to find outliers by finding clusters and then looking for data points that are far from these. Normal points may belong to large dense clusters, while outliers do not. However, this approach does not work when normal data points do not share strong patterns, while outliers do.

4. If the assumption is made that univariate data has a normal distribution, then the *maximum likelihood method* [HaKaPe12] can be used to estimate the mean μ and the standard deviation σ by maximizing the *log-likelihood function*:

$$\ln \mathcal{L}(\mu, \sigma^2) = \sum_{i=1}^{n} \ln f(x_i \mid (\mu, \sigma^2)) =$$

$$-\frac{n}{2}\ln(2\pi) - \frac{n}{2}\ln(\sigma^2) - \frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i - \mu)^2.$$

Here n is the number of examples and $f(x \mid (\mu, \sigma^2))$ is the normal probability density function. Derivatives with respect to μ and σ^2 are taken and one obtains the following *maximum likelihood estimates*:

$$\hat{\mu} = \bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i, \quad \hat{\sigma}^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x}).$$

Any object more than three standard deviations from the mean of the estimated distribution is considered to be an outlier.

5. Another method is to compute the *interquartile range* (IQR). The first quartile $Q1$ is the point dividing the lower 25% of the data from the upper 75%, and the third quartile $Q3$ is the point dividing the lower 75% of the data from the upper 25%. The IQR is defined as $Q3 - Q1$. Any point that is more than $1.5 \times IQR$ below the lower quartile $Q1$ or $1.5 \times IQR$ above the upper quartile $Q3$ is considered to be an outlier [HaKaPe12].

6. Grubb's test is a straightforward statistical method for finding univariate outliers [HaKaPe12]. A z-score is computed for each point x in the dataset using

$$z = \frac{\mid x - \bar{x} \mid}{s},$$

where $\bar{x}$ is the sample mean and s is the sample standard deviation of the given data. A point x is considered an outlier if

$$z \geq \frac{N-1}{\sqrt{N}}\sqrt{\frac{t^2_{\alpha/(2N),N-2}}{N-2+t^2_{\alpha/(2N),N-2}}},$$

where $t^2_{\alpha/(2N),N-2}$ is the value taken by a t-distribution at a significance level of $\alpha/(2N)$, with N being the number of points in the dataset.

7. Multivariate outlier detection can be done using the Mahalanobis distance measure [HaKaPe12]. For a multivariate dataset, let $\bar{\mathbf{o}}$ be the mean vector. For a point $\mathbf{o}$ in the dataset, the Mahalanobis distance from $\mathbf{o}$ to $\bar{\mathbf{o}}$ is given by

$$\text{MDist}(\mathbf{o}, \bar{\mathbf{o}}) = (\mathbf{o} - \bar{\mathbf{o}})^T S^{-1}(\mathbf{o} - \bar{\mathbf{o}}),$$

where S is the covariance matrix. The following steps are needed for outlier detection:

- Calculate the mean vector from the multivariate dataset.
- For each point o, calculate $\mathrm{MDist}(o, \bar{o})$, the Mahalanobis distance from o to $\bar{o}$.
- Detect outliers using Grubb's test on the set $\{\mathrm{MDist}(o, \bar{o}) \mid o \in D\}$.
- If $\mathrm{MDist}(o, \bar{o})$ represents an outlier then o is an outlier.

8. Multivariate outlier detection can also be done using the χ^2 statistic [HaKaPe12].

9. A nonparametric method can be used to construct a histogram from the input data. The bins can be of equal width or equal depth. If a point falls within a bin, then it is considered normal. If it falls outside the bins, it is considered an outlier [HaKaPe12].

10. A proximity-based approach can be based on the concept of *distance-based outliers*. Given a set D of data items, the user specifies a distance threshold r to define a neighborhood of a point. For each point o, the number of points within the r-neighborhood is determined. If most of the points in the dataset are far away from o, then the point o is an outlier. Specifically, given a *distance threshold* $r \geq 0$, a *fraction threshold* $0 < \pi \leq 1$, and a distance measure $\mathrm{dist}(x, y)$, a point o is a *distance-based outlier* if

$$\frac{\| \{o' \mid \mathrm{dist}(o, o') \leq r\} \|}{|D|} \leq \pi.$$

An algorithm for finding distance-based outliers using this notion is given in [HaKaPe12].

11. Most data mining software packages support outlier detection. Some worthy of special mention are the following:

- Scikit-learn, bundled with many Python data science distributions, contains outlier detection methods (`http://scikit-learn.org/stable/modules/outlier_detection.html`)
- Weka, a Java-based data mining kit, has tools to detect and to remove outliers and extreme values (`http://www.cs.waikato.ac.nz/ml/weka/`)
- ELKI is a data mining software written in Java with an emphasis on unsupervised methods in outlier analysis (`https://elki-project.github.io/`)

12. The Outlier Detection DataSets (ODDS) collection includes a large collection of datasets from different domains (`http://odds.cs.stonybrook.edu`). For instance, it contains the YelpCHI database of reviews of hotels and restaurants in the Chicago area. Yelp has a filtering algorithm that identifies reviews as fake or suspicious and puts them in a filtered list. Of the 67,395 reviews in this database, 13.23% have been put in the filtered list.

Examples:

1. Outlier detection can be used to identify credit card fraud. For this application, outliers represent unusual purchases or patterns of purchases in credit card activity.

2. Network intrusions can be detected using outlier detection by determining whether TCP connection data is dissimilar from normal traffic.

3. Insider stock trading has been detected using techniques from outlier analysis.

4. Outlier detection has many applications in image processing, including mammography and video surveillance.

5. (Adapted from [HaKaPe12]) Suppose that a city's average July temperatures over ten years are $24.0°, 28.9°, 28.9°, 29.0°, 29.1°, 29.1°, 29.2°, 29.2°, 29.3°, 29.4°$. Assume that the average temperatures follow a normal distribution determined by the mean μ and the standard deviation σ. Then the maximum likelihood estimates for the mean and standard deviation are

$$\hat{\mu} = \frac{24.0 + 28.9 + 28.9 + 29.0 + 29.1 + 29.1 + 29.2 + 29.2 + 29.3 + 29.4}{10} = 28.61$$

and

$$\hat{\sigma}^2 = [(24.0-28.61)^2+(28.9-28.61)^2+(28.9-28.61)^2+(29.0-28.61)^2+(29.1-28.61)^2+$$

$$(29.1-28.61)^2+(29.2-28.61)^2+(29.2-28.61)^2+(29.3-28.61)^2+(29.4-28.61)^2]/10\approx 2.29,$$

giving $\hat{\sigma} = \sqrt{2.29} = 1.51$. Then, following Fact 4, the value 24.0° is identified as an outlier because it is 4.61° away from the sample mean and $\frac{4.61}{1.51} = 3.04 > 3$.

INTRODUCTION

Modern biology makes use of a variety of discrete and combinatorial methods in order to better understand biological phenomena at both the microscopic and macroscopic levels. This chapter explains how such methods are useful in understanding the structure and properties of the genome (both DNA and RNA structures), gene regulatory networks, the firings of neurons, the classification and evolution of species, as well as competition between species. A variety of modern algorithms for analyzing biological data are also presented in this chapter.

GLOSSARY

alignment (of two sequences): a matching in which individual letters/nulls from each sequence are placed into correspondence.

alignment score: the sum of scores for aligned pairs of letters/nulls in an alignment.

arc diagram: a representation of an RNA structure in which the bases are placed along a line and arcs (drawn in the upper-half plane) join base pairs.

basal species (in a food web): species located at the bottom of the food web.

Boolean network: a polynomial dynamical system over $\mathbf{F}_2$.

boxicity (of a graph G): the smallest dimension p such that two vertices are connected by an edge in G if and only if their corresponding p-dimensional boxes overlap.

Burrows-Wheeler Transform BWT (of a string): a reversible transformation of the string used to perform efficient query searches.

cellular automaton: a lattice of cells, which at each step take on a value based on the values present in its neighboring cells.

code (of a cover): the combinatorial neural code whose codewords correspond to regions defined by intersections of open sets in the cover.

combinatorial neural code: a collection of binary codewords in which each binary digit is interpreted as the state (on/off) of a neuron.

common enemy graph: a graph whose vertices represent the species in a food web and whose edges (a, b) signify that species a and species b have a common predator.

competition graph: a graph whose vertices represent the species in a food web and whose edges (a, b) signify that species a and species b have a common prey.

de Bruijn graph: a directed graph whose vertices consist of all length-k sequences over an alphabet and in which the edge (u, v) indicates that the suffix of u equals the prefix of v.

dependency graph (for a finite dynamical system): a directed graph whose vertices correspond to variables and whose directed edges indicate functional dependencies between variables.

discrete-time dynamical system: a system based on variables $x_1, x_2, \ldots, x_n$ and state transition functions for each variable x_i.

DNA segment: a sequence of bases on a DNA strand, represented as a string over the alphabet {A, C, G, T}.

DNA target sequence: a long unknown DNA sequence that is to be decoded.

Euler path (in a graph): a path that traverses every edge of the graph exactly once.

expanded sequence: a sequence into which null characters may be inserted.

food web: a directed graph whose vertices correspond to species and whose arcs correspond to direct predator/prey relationships.

genetic algorithm: a heuristic search algorithm that mimics natural biological evolution, whereby a population of candidate solutions evolves over time via mutation and recombination.

genome assembler: a computer program that carries out the gene assembly process from given input data.

global pairwise alignment (of sequences): an alignment in which all letters and nulls of the two (expanded) sequences must be aligned.

Hamilton path (in a graph): a path that visits every vertex of the graph exactly once.

hybridization (of a DNA strand): a technique to produce a list of all subsequences of the DNA strand having some fixed length k.

hyperplane code: a combinatorial code obtained from the output of a one-layer feed-forward neural network.

KMP algorithm: an efficient algorithm for finding an exact match between a query string and a database.

Knudsen-Hein grammar: a probabilistic context-free grammar used to represent RNA secondary structures.

local pairwise alignment (of sequences): an alignment of arbitrary-length segments of the two (expanded) sequences.

maximum agreement subtree: a subtree induced by the largest set of common taxa.

nearest neighbor interchange: an exchange of two subtrees appearing on opposite sides of an internal tree edge.

nerve (of a cover): the simplicial complex defined by the nonempty intersections of the given open sets.

neural ring: a quotient ring associated with a combinatorial code.

nucleotide: an organic molecule (having a distinguished nitrogenous base) that serves as a building block for DNA and RNA.

overlap graph: a graph whose vertices represent known DNA strands and whose edges represent overlaps between these DNA strands.

overlap-layout-consensus method: a technique for reassembling a DNA strand from known DNA fragments.

path graph: a representation of possible alignments of two sequences using a rectangular array of nodes joined by directed horizontal, vertical, and diagonal edges.

phylogenetic tree: a tree whose leaves are labeled with taxa (taxonomical units).

polytomy: a vertex in a phylogenetic tree with degree exceeding three.

predator projection graph: a weighted graph based on the competition graph.

prey projection graph: a weighted graph based on the common enemy graph.

RNA sequence: a sequence over the four letter alphabet {A, C, G, U}.

Robinson-Foulds distance: a measure of proximity between two trees, given by the number of edge-induced partitions occurring in one tree but not the other.

secondary structure: an RNA structure whose arc diagram has no crossings.

seed: a relatively short matching subsequence that serves as an anchor point for larger matches between two sequences.

shortest common superstring: a shortest string that contains each of a given set of strings as a consecutive sequence.

shotgun sequencing: a method in which many copies of a DNA target sequence are broken up into pieces, which are then individually sequenced and recombined.

state-space graph (for an n-dimensional dynamical system): a directed graph whose vertices represent n-tuple states and whose edges represent transitions between such states.

substitution matrix: a prescription of the score produced when two specified letters are aligned.

suffix array (for a string): a lexicographically sorted array of all suffixes of the string.

suffix tree (for a string): a compact representation of all suffixes of the string.

trophic level (of a species x): a positioning measure based on the length of paths to x from basal species that x consumes, either directly or indirectly, in a food web.

Yule-Harding distribution: a model for generating all rooted binary trees based on certain rules for speciation.

20.1 SEQUENCE ALIGNMENT

Alignments are a powerful way to compare related DNA or protein sequences. They can be used to capture various facts about the sequences aligned, such as common evolutionary descent or common structural function. We take the general view that the alignment of letters from two or multiple sequences represents the hypothesis that they are descended from a common ancestral sequence.

DNA molecules are composed of chains of nucleotides, and protein molecules are composed of chains of amino acids. The specific order of nucleotides or amino acids within these chains are respectively called DNA and protein sequences. Perhaps chief among the various biological functions of DNA sequences is to encode protein sequences, because proteins are involved in most of the biological functions of living cells.

DNA sequences, and the protein sequences they encode, evolve by mutation followed by natural selection. There are a variety of mechanisms for DNA mutation, but the most common result is the substitution of a single nucleotide for another, or the deletion or insertion of one or several adjacent nucleotides. At the protein level, the most common resulting mutations are the substitution of one amino acid for another, or the insertion or deletion of one or multiple adjacent amino acids. There is no simple biological mechanism for exchanging the order of two letters in a DNA or protein sequence, so an alignment representing the common descent of two DNA or protein sequences is co-linear, with no "crossovers" between corresponding letters.

20.1.1 GLOBAL AND LOCAL PAIRWISE ALIGNMENTS

Definitions:

An ***alphabet*** is a finite set of letters and a ***sequence*** S is a finite string of letters, each chosen from the alphabet.

A ***null character***, generally represented by the symbol "–", is a character not in the alphabet that signifies an absent letter.

Given a sequence S, an ***expanded sequence*** S' is the sequence S with an arbitrary number of null characters placed at its start, its end, or between any two of its characters.

A ***global pairwise alignment*** of sequences S and T is a one-to-one co-linear correspondence of expanded sequences S' and T', such that no nulls from S' and T' correspond.

A ***local pairwise alignment*** of sequences S and T is a one-to-one co-linear correspondence of equal-length segments of the expanded sequences S' and T', such that no nulls from the segments correspond.

Facts:

1. DNA molecules are composed of two strands, each a string of nucleotides, represented by the four letters A, C, G, T.

2. The strands of a DNA molecule are directional and run in opposite directions. Each nucleotide in one strand of a DNA molecule is paired, through chemical interaction, with a complementary nucleotide in the other strand: A always pairs with T, and C with G. Because of this complementarity, the nucleotide sequence of one strand determines the nucleotide sequence of the other, and thus a DNA molecule is generally represented by the nucleotide sequence of one of its strands, with that of the other implied.

3. Proteins are composed of one, or multiple, chemically interacting amino acid chains, but here we confine our attention to single chains. An amino acid chain is a directional string of amino acids. There are twenty commonly occurring amino acids abbreviated by the letters A, C, D, E, F, G, H, I, K, L, M, N, P, Q, R, S, T, V, W, Y.

4. A particular amino acid is encoded by three adjacent DNA nucleotides, called a *codon*; for example, the codon ATG represents the amino acid methionine, or M. Some amino acids are encoded by only one codon, whereas others by as many as six. The table describing the correspondence between all $4^3 = 64$ possible codons and the 20 amino acids they represent is called the *genetic code*; except for minor variations, it is universal to all life on earth. The genetic code contains three *stop codons* that represent no amino acid.

Examples:

1. One possible global alignment of the protein sequences VHLTPEEKSAVTALWG and VAFTEKQEALVSSSLEAF is

```
VHLT--PEEKSAV-TALWG-
VAFTEKQEA--LVSSSLEAF
```

2. One possible local alignment of the DNA sequences GTTACTTTGGACCCTCAA and AAATTGATCTTTTAAC is

```
TTTGGACC
T-T-GATC
```

20.1.2 PAIRWISE ALIGNMENT SCORES

In order to select among the many possible global or local alignments of two sequences, it is useful to assign an objective function, or score, to each possible alignment. We then seek an alignment with an optimal score, using the convention that higher scores are better. The simplest way to score an alignment is to specify scores for aligning particular letters to one another, or for aligning letters to nulls, and then to define the score of an alignment as the sum of the scores of all its aligned letters and nulls.

Definitions:

A ***column*** of a pairwise alignment is the one-to-one correspondence of a single letter (or null) in one sequence with a single letter (or null) in the other.

A ***substitution*** is a column that aligns two letters. A ***substitution score*** is a score defined for a substitution involving a particular pair of letters.

An ***indel*** is a column that aligns a letter with a null. An ***indel score*** is the score defined for aligning a letter with a null.

A ***gap of length k*** is composed of k adjacent indels, each of which contains a letter from one expanded sequence and a null from the other.

The ***alignment score*** is the sum of the substitution and the indel scores of an alignment's columns.

An ***optimal alignment*** is an alignment with maximum score.

Facts:

1. An alignment of two identical letters is still termed a substitution.

2. The term *indel* represents an abbreviation for “insertion or deletion”.

3. Indel scores are usually chosen to be independent of the particular letter aligned with a null, but this restriction is not necessary.

4. The definition of an alignment score will be generalized later (see §20.1.6).

Example:

1. Consider the following alignment of two DNA sequences:

```
TGA-CG
-GTACC
```

Suppose the substitution scores for all columns aligning identical letters are +5 and for all columns aligning mismatching letters are -1. Also, suppose all indel scores are -2. Then the alignment score for this DNA alignment is $-2+5-1-2+5-1=4$.

20.1.3 PATH GRAPHS AND OPTIMAL GLOBAL PAIRWISE ALIGNMENT

The most fruitful algorithms for pairwise sequence alignment are based on the concept of a path graph.

Definitions:

Suppose we have two sequences of lengths m and n, respectively. The ***path graph*** consists of a rectangular $(m+1)\times(n+1)$ array of ***nodes***, with directed horizontal, vertical, and diagonal ***edges*** between adjacent nodes. The m letters of the first sequence are placed between successive rows of this array and the n letters of the second sequence are placed between successive columns of this array. Diagonal edges of the path graph correspond to substitutions, while horizontal and vertical edges correspond to indels. Scores for the directed edges derive from the corresponding substitution and indel scores.

Facts:

1. The rectangular array underlying the path graph is composed of $m \times n$ *cells*. Each cell is associated with a letter of the first sequence and a letter of the second sequence. The diagonal edge ($\searrow$) in this cell has weight corresponding to the substitution score for these two letters. The lower horizontal edge ($\rightarrow$) in a cell corresponds to a null in the first expanded sequence, and the rightmost vertical edge ($\downarrow$) in a cell corresponds to a null in the second expanded sequence; in each case, the null follows the letter that the diagonal edge signifies aligning.

2. There is a one-to-one correspondence between alignments and directed paths beginning at the upper left node $(0,0)$ of the path graph and ending at the lower right node (m,n). The score of an alignment equals the sum of the edge scores along its corresponding path.

3. The problem of finding an optimal global alignment is then transformed into finding an optimal path through the path graph.

4. Although the number of possible paths through the path graph grows exponentially with m and n, optimal alignments can be found without examining all paths.

5. Algorithm 1 uses a dynamic programming approach to find optimal paths in an efficient way. In brief, there are at most three nodes at locations $(i-1,j),(i,j-1),(i-1,j-1)$ with edges leading into a particular node at location (i,j). Therefore, if one knows the score of an optimal path from the origin to each of these three nodes, one can easily calculate the score of an optimal path through each of these nodes into (i,j). The highest score among these paths is then the score of an optimal path to (i,j). Optimal alignment scores for each node in a path graph may thus be calculated by simply filling in scores for the nodes sequentially, beginning at the origin, and proceeding from left to right along each row in turn [NeWu70], [Sa72], [Se74].

Algorithm 1: **Global pairwise alignment algorithm.**

```
input: two sequences of lengths $m$ and $n$, respectively
output: the optimal global alignment score as well as optimal alignments
```

```
create the corresponding path graph $G$ with $(m+1)\times(n+1)$ nodes, indexed from
  0 to $m$ and from 0 to $n$
label the upper left node of $G$ with 0
label the rest of the first row and the first column of $G$, based on the indel scores
for each remaining node in location $(i,j)$ of the array compute
  Vscore := label$(i-1,j)$ + score of edge from $(i-1,j)$ to $(i,j)$
  Hscore := label$(i,j-1)$ + score of edge from $(i,j-1)$ to $(i,j)$
  Dscore := label$(i-1,j-1)$ + score of edge from $(i-1,j-1)$ to $(i,j)$
  label$(i,j)$ := max{Vscore, Hscore, Dscore}; mark any edge achieving this
    maximum value
label$(m,n)$ represents the optimal global alignment score and the marked edges
  can be used to retrieve alignments achieving this optimal score
```

6. In Algorithm 1, the values Vscore, Hscore, and Dscore represent the scores of paths using (respectively) the vertical, horizontal, and diagonal edges entering the node located at (i,j). By tracing back along the marked edges, starting from the lower right corner of G, one can obtain optimal alignments for the given pair of sequences.

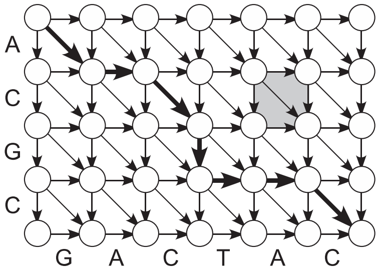
7. To align sequences of lengths m and n, the time and space complexity of Algorithm 1 are each $O(mn)$. The space complexity can be reduced to $O(\min\{m,n\})$ [MyMi88].

8. There are various methods for speeding up the algorithm by avoiding the consideration of nodes through which an optimal alignment cannot possibly pass [Fi84], [Sp89].

9. Optimal alignments are unaltered by multiplying all substitution and indel scores by a positive constant. Optimal alignments are unaltered by adding a constant a to all substitution scores, and $a/2$ to all indel scores.

Examples:

1. We wish to align the sequences S_1 = ACGC and S_2 = GACTAC. The corresponding path graph G has nodes arranged in an $(m+1)\times(n+1) = 5\times 7$ rectangular array. The four letters of the first sequence are placed between successive rows of G and the six letters of the second sequence are placed between successive columns of G. The shaded cell corresponds to aligning the first letter C of the first sequence and the second letter A of the second sequence.



The highlighted path (from the upper left node to the lower right node in G) corresponds to the alignment

```
A-CG--C
GAC-TAC
```

2. Suppose that substitution scores are +1 for matches and 0 for mismatches, and that indel scores are −1. Then the alignment in Example 1 has score $0-1+1-1-1-1+1=-2$. This is not, however, an optimal global alignment of S_1 and S_2.

3. Optimal alignments, based on the substitution and indel scores specified in Example 2, can be found using Algorithm 1. After labeling the upper left node with 0, we label nodes in the first row and first column using $-1,-2,-3,\ldots$ since the indel scores are −1. Each remaining node is labeled with the maximum sum of node label plus edge score, taken over the three nodes adjacent to and leading into the given node.

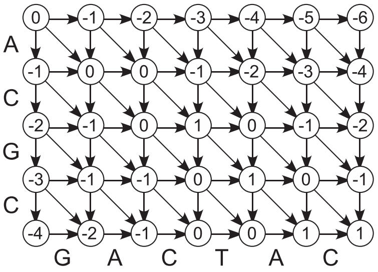
For example, to label the node at location $(2,1)$ we consider its three incident edges:

$(1,1)\rightarrow(2,1)$: label of $(1,1)$ + edge score (indel) $=0-1=-1$

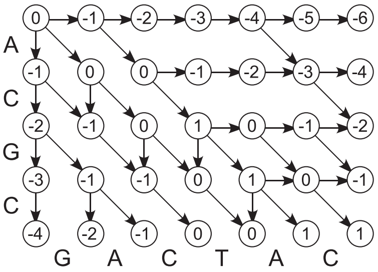
$(2,0)\rightarrow(2,1)$: label of $(2,0)$ + edge score (indel) $=-2-1=-3$

$(1,0)\rightarrow(2,1)$: label of $(1,0)$ + edge score (mismatch C, G) $=-1+0=-1$

Node $(2,1)$ thus receives as its label the maximum sum −1. The following figure shows all node labels obtained by following Algorithm 1. Since the label of the lower right node $(4,6)$ is 1, this represents the optimal global alignment score.

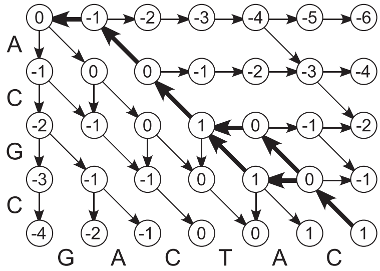


4. In order to reconstruct the alignment or alignments corresponding to this optimal score, the edge or edges corresponding to the best path into each node have been marked. In Example 3, the edges $(1,1)$ and $(1,0)$ both give the maximum label −1 and so are marked. All edges marked during the execution of Algorithm 1 are shown in the following path graph.



5. We can then trace back along marked edges from the terminal node $(5,7)$ to the origin node $(1,1)$, giving the highlighted edges shown in the following figure. From these two paths, we obtain the two optimal alignments of S_1 and S_2, each with (maximum) score = +1:

```
-ACG-C      -AC-GC
GACTAC      GACTAC
```



20.1.4 OPTIMAL LOCAL PAIRWISE ALIGNMENT

Many protein or DNA sequences are related only across subsequences, but not over their entire lengths. To recognize these relationships, it is useful to introduce the concept of a local alignment (§20.1.1) and to describe algorithms capable of finding optimal local alignments.

Facts:

1. Algorithm 1 from the previous section can be modified [SmWa81] to find optimal local alignment(s) of two sequences by making a few minor modifications.

- Allow a path to start, with score 0, at any node within the path graph, not just at the origin (top left) node. Thus, if all paths into a given a node have negative score, none of them is chosen as optimal.
- Record which node within the path graph receives the highest score, and start tracing back from there, rather than from the terminal node.
- Terminate the traceback when a node with score 0 is reached.

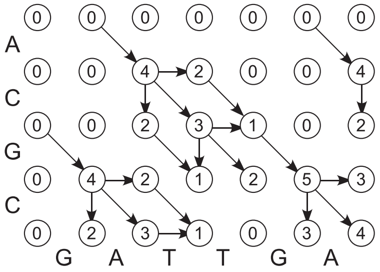
2. To align sequences of lengths m and n, the time and space complexity for this local alignment algorithm are each $O(mn)$. The space complexity can be reduced to $O(\min\{m, n\})$ [MyMi88].

3. Optimal local alignments are unaltered by multiplying all substitution and indel scores by a positive constant.

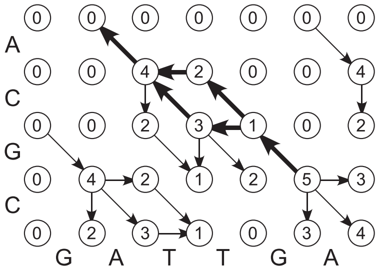
4. In addition to optimal local alignment(s), one may wish to find other local alignments that align regions of the sequences in question that are not implicated in the optimal local alignment. One may define "locally optimal" local alignments as those whose path within the path graph has a score greater than or equal to the score for the path of any local alignment that shares a common edge or node [Se84]. All such locally optimal local alignments can also be found in $O(mn)$ time [AlEr86b].

Examples:

1. We wish to align the sequences S_1 = ACGC and S_2 = GATTGA. We construct a path graph with $(m+1) \times (n+1) = 5 \times 7$ nodes. Suppose that substitution scores are $+4$ for matches and -1 for mismatches, and that indel scores are -2. The following figure shows the resulting labels for locally aligning these sequences, with only marked edges shown.



2. The largest score obtained is 5 so this is the optimal local alignment score. Tracing back from this location $(4, 6)$ yields the highlighted edges shown next.



As a result, we find two optimal local alignments, each with score 5:

```
AC-G          A-CG
ATTG          ATTG
```

20.1.5 SUBSTITUTION MATRICES

Although the algorithms described in §20.1.3 and §20.1.4 are unaffected by the choice of substitution scores, the quality of the alignments they return depends strongly on which scores are used. In particular, this subsection discusses the use of certain substitution matrices to specify scoring values.

Definitions:

A ***substitution matrix*** $S = (s_{ij})$ prescribes the score value when letters i and j are aligned.

A ***log-odds matrix*** S is defined by $s_{ij} = \log \frac{q_{ij}}{p_i p_j}$. Here q_{ij} is the ***target frequency*** with which the letters i and j are estimated to appear in columns from accurate alignments of related sequences; p_i and p_j are the ***background probabilities*** with which the letters i and j would appear by chance.

Facts:

1. Many different substitution matrices have been proposed, but theory and practice suggest that the best substitution matrices are log-odds matrices [Al91], [DaScOr78], [KaAl90].

2. The target frequencies should depend upon the degree of evolutionary divergence separating the sequences compared, and various methods of estimating these frequencies for proteins have been described, giving rise to the commonly used PAM [ScDa78] and BLOSUM [HeHe92] series of substitution matrices.

20.1.6 AFFINE GAP SCORES

A single mutational event can insert or delete multiple nucleotides into or from a DNA sequence, and this can result in multiple contiguous amino acids being inserted into or deleted from the encoded protein sequence. Thus, an alignment in which the several insertions or deletions are adjacent to one another makes more biological sense than one in which these insertions and deletions are separated. The scoring systems considered earlier, however, do not reflect this biological fact. One remedy is to modify the alignment scoring system by defining appropriate scores for gaps of various lengths in place of scores for individual indels.

Definition:

Affine gap scores are given by $g(k) = -(a + bk)$, where k is the gap length and a, b are (generally nonnegative) constants.

Facts:

1. It is evident that when $a = 0$, the affine gap score $g(k)$ is equivalent to indel scores of $-b$. However, when $a > 0$, the score for k adjacent indels is better than that for k indels separated by substitution columns.

2. For either global or local alignments, the basic algorithms described in §20.1.3 and in §20.1.4 must be modified to accommodate affine gap costs. Fortunately, it is possible to do this while retaining $O(mn)$ time complexity by remembering not just the score of the best path into each node, but also the best score for a path that arrives through a horizontal, vertical, or diagonal edge [AlEr86a], [Go82]. For example, the incremental score for a path leading out of a node along a horizontal edge is $-b$ for a path that arrived along a horizontal edge, but is $-(a + b)$ for a path that arrived along any other type of edge.

3. It is possible to construct $O(mn)$ algorithms based on $g(k)$ that are more involved than affine gap scores [MiMy88], but these algorithms are fairly complex and in practice almost never used.

4. The elements of sequence alignment considered here been generalized in a great variety of ways. These include rapid heuristic database search algorithms [AlEtal90], [PeLi88]; protein profile construction and comparison [AlEtal97], [GrMcEi87]; and multiple sequence alignment, for which there is a vast and growing literature.

Example:

1. The practical difference in using affine gap costs in place of simple indel costs can be illustrated in the optimal local alignments resulting from the comparison of two protein sequences. Both alignments shown next employ BLOSUM-62 substitution scores [HeHe92], but the first alignment uses indel scores of -6, while the second uses gap scores of $g(k) = -(11 + k)$. Identical letters are echoed on the central lines of these alignments, and the sequence positions of the letters at the start and end of each line are provided. The second alignment contains many fewer gaps, but also a smaller number of identical aligned letters.

20.1.7 SEQUENCE ALIGNMENT HEURISTICS

Sequence alignment, as described so far, is computationally intensive, with the algorithms requiring an execution time quadratic in the size of the sequences being aligned. In the general case this run time is unavoidable. However, faster execution times can be obtained when the sequences being aligned have high levels of similarity. Here we discuss banded methods, exclusion methods, and the use of seeds to initiate searches.

Definitions:

Suppose that G is the path graph for the alignment of two sequences. The ***diagonal*** of G consists of all nodes at locations $(0,0), (1,1), \ldots, (m,n)$. A ***band of width d*** consists of all nodes within (Manhattan) distance d of the diagonal of G.

A ***k-mer*** is a subsequence of length k found within a given sequence (see §20.4.1).

A ***seed*** is a relatively short matching subsequence that serves as an anchor point for larger matches between sequences. A ***spaced seed*** is a k-mer within which a number t of fixed positions (denoted by $*$) are allowed to match any letter; the spaced seed then has ***width*** k and ***weight*** $k - t$.

Facts:

1. Suppose that two given sequences differ by at most d edits (at most d letters are changed, inserted, or deleted between the two sequences). Then an optimal path in the path graph G cannot pass through nodes that are further than distance d from the diagonal of G as each "move" away from the diagonal implies an additional difference being incorporated in the alignment.

2. By Fact 1 it is sufficient to compute the alignment scores for just a subset of the nodes in G, specifically for nodes in the band of width d. Using this banded alignment algorithm, an optimal alignment can then be determined in $O(\min\{m,n\}d)$ time [ChPeMi92].

3. The value d does not need to be known a priori. Rather, an algorithm that adapts dynamically to the actual similarity between the sequences can be devised by performing a binary search for the band that encompasses the optimal path through the path graph. Specifically, one starts with an initial guess for d, e.g., by setting $d = 1$. The banded alignment algorithm is then executed to find an alignment that occurs within the band of width d. If the resulting alignment contains fewer than d edits, then this is also the optimal alignment. If the alignment contains more than d edits, then d is doubled, and the process is repeated until an optimal alignment is found.

4. The dynamic algorithm presented in Fact 3 also takes $O(\min\{m,n\}d)$ time, though it can be up to four times slower than an algorithm that starts with an initial correct guess for the value of d.

5. A special case of alignment occurs when one sequence is much longer than the other one, e.g., when aligning one short sequence against an entire genome, or when aligning a sequence against a database. In such situations, a run time proportional to the product of the lengths of the two sequences can be prohibitive. Heuristics have been developed that can focus on the regions of the alignment table that contain high-quality alignments.

6. Suppose we are searching for an alignment of a (query) sequence of length m within a longer sequence (database) of length n, where $m \ll n$. Specifically, we are looking for alignments with up to d differences (indels or substitutions). Then any inexact alignment with d or fewer differences must contain an exact match between the query sequence and the database that is of length at least $\lfloor m/(d+1) \rfloor$. Indeed, the worst-case scenario has the d differences equally separated along the sequence, breaking it up into $d+1$ segments.

7. *Exclusion methods*: These approaches, based on Fact 6, use exact matching to speed up inexact alignment [WuMa92]. First we identify all exact matches of length $\lfloor m/(d+1) \rfloor$ between the two strings, corresponding to diagonal segments within the path graph. Then we perform the banded alignment procedure to find the highest scoring alignment within the neighborhood of the exact match. This procedure is guaranteed to find an optimal alignment with fewer than d edits, if one exists, and is faster than the full alignment algorithm as only a small fraction of the entire path graph needs to be explored. Regions of the path graph that cannot contain good alignments are excluded from consideration.

8. A key factor determining the speed-up we can expect is the length of the exact match being sought: $k = \lfloor m/(d+1) \rfloor$. For small values of k (i.e., when the error being tolerated is high with respect to the size of the query sequence), the expected number of k-mers that yield a match between the sequence and the database can be very high, making this approach inefficient.

9. The size of k specified in Fact 8 is unnecessarily conservative as it derives from a worst-case scenario where errors are equally distributed throughout the sequence. A random distribution of errors within the sequence is unlikely to be uniform and so contains exact segments that can be much longer than $\lfloor m/(d+1) \rfloor$.

10. The value of k could be determined from theoretical principles, e.g., by setting k to be the expected length of the longest edit-free segment within an alignment of length m that contains d randomly distributed edits. In practice, the exact value of d is usually not known, and k is set empirically to a value that minimizes the number of alignments that need to be performed without missing too many alignments.

11. To increase sensitivity without sacrificing speed, Ma et al. [MaTrLi02] suggested the use of spaced seeds. The intuition behind the use of spaced seeds is that the "don't care" symbols allow the seed to match even if a difference occurs in the middle of the seed.

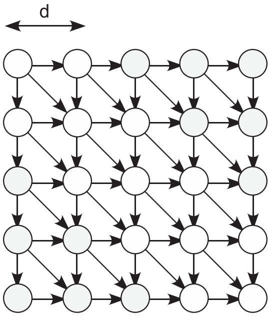
12. Spaced seeds have a higher sensitivity than the exact k-mer seeds of the same weight without a corresponding increase in the number of matches that need to be explored. In practice, algorithms relying on spaced seeds use a combination of multiple seeds in order to maximize sensitivity. Finding the optimal combination of seeds is NP-hard [MaLi07]; however simple heuristic algorithms are highly effective in practice [IlIl07].

13. Spaced seeds can be generalized by extending the original observation underlying all exclusion methods—that any alignment of high enough fidelity must contain a long enough exact match between the query and the database. It can be shown [GhPo09], [KaNa07] that any alignment of high enough fidelity must contain a long enough inexact alignment of higher fidelity than the original one. Specifically, if strings L_1 and L_2 of length ℓ match with an edit distance k, there exist substrings E_1 in L_1 and E_2 in L_2 of length e such that the two substrings match with an edit distance no greater than $k/(\ell - e)$ [GhPo09].

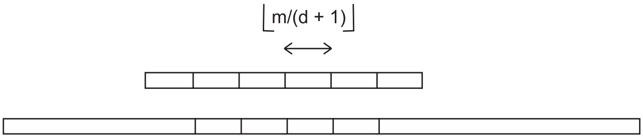
14. Using Fact 13, one could search for inexact seeds that match between a query and a database using a fast inexact alignment algorithm that can tolerate a limited number of edits, and then use the resulting anchors to search for the full alignment. This generalization provides a higher sensitivity than approaches based on spaced seeds.

Examples:

1. The following figure illustrates a path graph with a band of width $d = 1$ indicated. An optimal alignment with at most d edits must occur within a band of width d on either side of the diagonal. Paths traversing the grayed nodes involve more than d edits.



2. In the worst-case scenario, the d edits are equally spaced along the sequence, implying that exact matches between the two strings are at least $\lfloor m/(d+1) \rfloor$ characters long:



3. The spaced seed 111∗111 denotes the set of k-mers of width 7 and weight 6. This seed allows the middle nucleotide to differ between the query sequence and the database sequence. In the following two strings, a spaced seed of width 7 is shared by two strings. Only the characters aligned to 1s in the spaced seed need to match between the two strings.

```
TATT | CGTCTGA | TCAT
     | 111*111 |
GTCT | CGTATGA | TGCT
```

20.1.8 EXACT STRING MATCHING

Underlying the exclusion methods described in §20.1.7 is the assumption that finding exact matches between two strings is computationally more efficient than finding inexact alignments. Exact string matching is of independent interest as well in many applications (e.g., web search engines largely rely on exact matching of query strings). As such, the problem has been extensively researched and many variants and algorithms have been described in the literature. Here we highlight several key results.

Definitions:

Given a string S, a ***suffix tree*** is a compact representation of all suffixes in S. It is a tree that contains a leaf for each suffix in S, and where each edge is labeled with a string of characters so that the path from the root to each leaf spells the corresponding suffix. The string spelled by the path from the root of a suffix tree to an internal node is termed the ***string label*** of the node.

The suffix tree also contains a collection of ***suffix links***, special edges connecting the node in the tree with string label $c\alpha$ (where c is a single character and α is a string) to the node with string label α.

The ***suffix array*** is a lexicographically sorted array of all suffixes of the string, together with information necessary for speeding up the search process.

Facts:

1. A naive search for exact matches between a query string of length m and a database of length n requires $O(mn)$ run time, by checking whether all m letters in the query match, starting at each of the $n - m + 1$ positions within the database.

2. *KMP algorithm*: Knuth, Morris, and Pratt [KnMoPr77] reduced the run time for exact matching to $O(m + n)$ by simple preprocessing of the query string. Specifically, at each position i in the query, the KMP algorithm defines sp_i to be the length of the longest nontrivial prefix of the query that matches a suffix of the string that ends at position i.

3. This information can be computed in $O(m)$ time and can be used to speed up alignment as follows. The query is compared to the database, one letter at a time, until a mismatch is detected at position $i + 1$ in the query. If sp_i is defined, the query is shifted to the right so that the prefix of the query aligns to the corresponding suffix of the string ending at position i prior to the shift. The comparison to the database continues from position $sp_i + 1$, as the properties of the sp_i values guarantee that all prior positions match the database sequence (these were already matched prior to the shift). If $sp_i = 0$, the query is shifted such that its first letter is aligned to the character mismatched prior to the shift, and the comparison between the query and the database starts from the first letter of the pattern.

4. Two observations establish an $O(n)$ run time for the search procedure, giving an $O(m + n)$ run time once the cost of preprocessing is taken into account.

- Once a character in the database is successfully matched to the query it is never again compared to the query, thereby bounding the total number of exact matches performed during the execution of the algorithm to n, the size of the database.
- Every mismatch triggers a shift of the query by at least one position; thus the number of mismatches is also bounded by n, yielding an overall $O(n)$ run time.

5. The KMP algorithm can be used to find full-length matches of a query against a database, as well as matches that involve just a prefix of the query (e.g., finding the longest prefix match in case a full-length match cannot be found). To address more complex exact matching problems, Weiner [We73] and McCreight [Mc76] independently developed suffix trees.

6. The strings represented by the path from the root to any node in the suffix tree are unique. In other words, the shared prefixes of strings represented in the tree are represented by the same path from the root to some internal node in the tree.

7. To ensure that the suffixes of S reach the leaves of the tree (i.e., no suffix is a prefix of some other suffix in the tree), a special character \$ not found in the alphabet is appended to the end of each string stored in the suffix tree.

8. Suffix links are useful in the efficient construction of suffix trees as well as for solving certain exact matching problems, such as identifying the longest substring that matches between the query and the database.

9. When appropriately structured, suffix trees require $O(m)$ space to store all the suffixes of a given string of length m. To achieve such space efficiency, each edge is labeled not with its string label, but with the coordinates within the string where the string label occurs (see Example 2). Each edge in the tree thus requires constant storage space, and the total size of the tree is determined by the number of leaves, equal to the number of suffixes m.

10. If a query is represented within a suffix tree, it can be aligned against a database as follows. Starting with the root of the tree, the matching process follows the edges of the tree that match the database sequence until either reaching a leaf (in which case the corresponding suffix represents a partial match between the query and the database) or a mismatch occurs. The algorithm then follows the suffix link starting from the node immediately above the location of the mismatch and the matching process continues from the same position in the database, starting from the new location in the tree. Following the suffix link implicitly discards the first character in the database and is equivalent to the shift procedure described in the KMP algorithm.

11. The search procedure requires $O(m + n)$ time, matching the time complexity of the KMP algorithm.

12. Despite its asymptotically linear space complexity, the suffix tree data structure requires a substantial amount of memory, estimated at over 20 bytes per letter. Manber and Myers [MaMy93] described an alternative approach for storing all the suffixes of a string in a compact way that uses substantially less space at the cost of a small additional increase in run time.

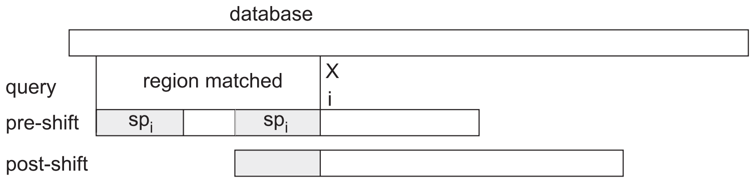
13. In a suffix array, the suffixes themselves are stored as simply an index within the original string, ensuring that the space usage is proportional to the size of the string even though the total length of all suffixes combined is proportional to the length of the string.

14. In addition to the suffixes, the data structure for a suffix array comprises an array that stores the *longest common prefix* (LCP) between adjacent suffixes. This information is necessary to efficiently search within the suffix array using binary search with just an additive overhead of $O(\log m)$. A trivial implementation of binary search within an array of m strings of length $O(m)$ requires $O(m \log m)$ time. Since the LCP values are only used for the binary search process, it is sufficient to record just the longest common prefixes of the pairs of strings that will be compared during the binary search, or $O(m)$ values. Suffix arrays thus occupy $O(m)$ space, and a sequence of length n can be searched against a suffix array in $O(n + \log m)$ time.

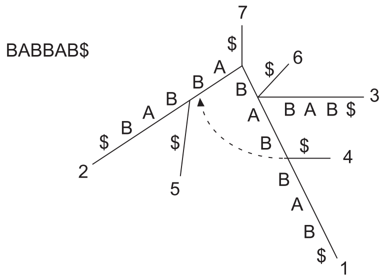
15. Constructing a suffix array involves sorting the set of suffixes of a string, a process that can be performed in $O(m \log m)$ time using an algorithm that takes advantage of the relationship between the suffixes of a same string [MaMy93].

Examples:

1. The following diagram illustrates the sp_i values used by the KMP algorithm and a shift after a mismatch occurs at position i in the query. The shaded regions correspond to identical sequences. After the shift, matching continues from the position marked X.



2. The following figure shows a suffix tree for the string BABBAB. The dashed line is a suffix link connecting the node labeled BAB to the node labeled AB. Edge labels are provided for clarity, but an efficient implementation would compress them to two integers. For example, the edge BAB\$ can be represented as $(4, 7)$, the range within the original string that spells this string.



20.1.9 INDEXING METHODS FOR STRING MATCHING

When searching for multiple query sequences against the same database, search efficiency can be increased by preprocessing or indexing the database. For the following, assume we are searching for exact matches between multiple sequences of length m and a database of length n.

Facts:

1. Storing the database in a suffix tree (§20.1.8) enables exact matching queries to be executed in time independent of the database size. For each query sequence, the matching process traverses the suffix tree from the root, following the path that matches the query until either a match is found, or a mismatch indicates the query does not match within the database, yielding a run time of $O(m)$ per query.

2. As discussed in §20.1.8, the main drawback of this strategy is the large memory necessary to store the suffix tree.

3. *Inverted index*: Finding short exact matches of length k between one or more query sequences and a database, a component of the exclusion methods described in §20.1.7, can be performed with a simple (inverted) index linking all strings of length k within the database to their location in the database. Lookups within the index can be performed efficiently if the entire index is stored in memory; however, the memory space necessary to store all k-mers within a database can be very large. Furthermore, k-mers that occur frequently within the database impact both memory usage and the time needed to search the index, and are usually excluded from the index in practical implementations.

4. *Burrows-Wheeler transform (BWT)*: A reversible permutation of the indexed string can be used to construct a memory-efficient indexing structure called the *FM index* [FeMa00]. The Burrows-Wheeler transform [BuWh94] of a string S can be constructed using Algorithm 2. It is assumed here that the added character \$ is lexicographically smallest.

```
Algorithm 2: Burrows-Wheeler transform.
  input: string $S$
  output: Burrows-Wheeler transform of $S$
  augment string $S$ by appending to its end a character $ not found in the alphabet
  construct a table $T$ comprising all circular rotations of $S$ as rows
  sort the rows of $T$ into lexicographic order
  return the last column in $T$ as the Burrows-Wheeler transform of $S$
```

5. The BWT and the suffix array of S are conceptually linked. The BWT represents the characters that precede the lexicographically ordered suffixes of S, and the BWT can be trivially constructed from the suffix array of S. See Example 2.

6. The BWT can be reversed, obtaining the original string, with the help of a simple observation: the order in which multiple instances of the same character occur in the first column of the sorted BWT table is the same as the order in which these characters occur in the last column of the table. Specifically, the first A in the last column corresponds to the same character in the original string as the first A in the first column, the third C in the last column corresponds to the same character in the original string as the third C in the first column, etc. This *last-to-first* (LF) mapping guides the reversal of the BWT; see Algorithm 3.

```
Algorithm 3: BWT reversal.
  input: BWT table $T$ for $S$
  output: original string $S$
  start with the first row of the BWT table and output the character $c$ in the last
    column; this is the last character in the original string
  repeat until the entire string is reconstructed
    use the LF property to identify the corresponding instance of $c$ in the first column
    prepend the character at the end of the respective row to the string reconstructed
      so far
```

7. In Algorithm 3 only the first and the last columns of the BWT matrix are necessary to reverse the transformation. The last column is the BWT itself, while the first column is simply the lexicographically sorted list of characters in the original string.

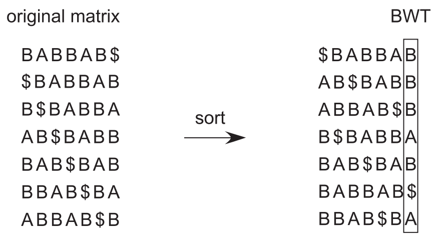
8. To efficiently perform the LF mapping it is necessary to know the index of each character within the last column. That is, for a character c within the ith row of the matrix we need to know the number of characters equal to c that occur within the rows above. Storing this information for each row of the matrix allows the LF lookup to occur in constant time; however, it requires a large amount of memory $O(n \log n)$ for a string of length n. A trade-off between run time and memory usage can be obtained by storing the index information at every bth row, yielding a memory usage of $O((n \log n)/b)$. Each LF mapping, however, requires $O(b)$ time as the index values need to be computed on the fly within the block between the selected rows. See Example 5.

9. The same procedure used for reversing the BWT can be used to match a query Q against a database stored in the BWT. This process is similar to a binary search in that the transitions between the first and last columns of the BWT matrix repeatedly shrink the range within which the query string may be found. See Algorithm 4.

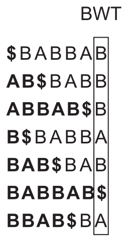
```
Algorithm 4: BWT query match.
  input: query $Q$, BWT matrix $T$
  output: matching string in the database
  identify the block of rows in $T$ starting with the last character in $Q$
  repeat until the query is fully matched
    within the last column of these rows, find those rows containing the rightmost
      unmatched character in $Q$; if no rows end in this character, no match has been
      found
    within the first columns of the BWT matrix, identify the rows starting with the
      characters found above
```

Examples:

1. We illustrate the Burrows-Wheeler transform of the string BABBAB. The character \$ is added to this string, giving the first row of the table shown on the left; the rows of this table represent successive circular rotations. After lexicographically sorting the rows, we obtain the BWT matrix on the right, whose last column is the Burrows-Wheeler transform of the original string.



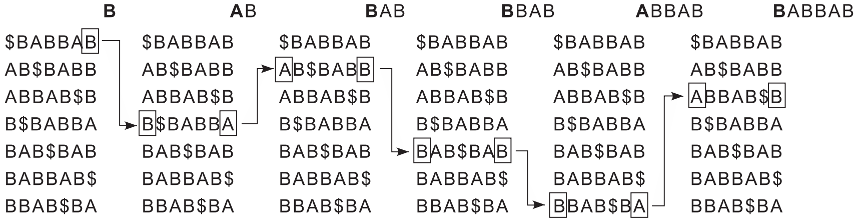
2. In the following figure, the suffix array of the string in Example 1 is shown highlighted in bold within the Burrows-Wheeler matrix.



```
        BWT
$BABBAB
AB$BABB
ABBAB$B
B$BABBA
BAB$BAB
BABBAB$
BBAB$BA
```

3. We illustrate the LF mapping for the BWT matrix shown in Example 1. The first B in the last column is the fourth B occurring in the original string BABBAB; the first B in the first column also corresponds to the fourth B in the original string. The second B in the last column is the third B occurring in the original string BABBAB; the second B in the first column also corresponds to the third B in the original string.

4. Here we show how to reverse the BWT in Example 1 to generate the original string BABBAB, starting from the rightmost character. The arrows indicate the LF mapping. The string being reconstructed is shown above the table with the latest character added shown in bold. Note that only the first and last columns of the table are needed for this operation.

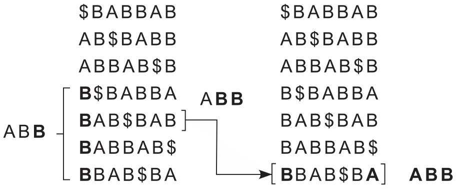


```
      B            AB           BAB          BBAB        ABBAB       BABBAB
$BABBAB     $BABBAB     $BABBAB     $BABBAB     $BABBAB     $BABBAB
AB$BABB     AB$BABB     AB$BABB     AB$BABB     AB$BABB     AB$BABB
ABBAB$B     ABBAB$B     ABBAB$B     ABBAB$B     ABBAB$B     ABBAB$B
B$BABBA     B$BABBA     B$BABBA     B$BABBA     B$BABBA     B$BABBA
BAB$BAB     BAB$BAB     BAB$BAB     BAB$BAB     BAB$BAB     BAB$BAB
BABBAB$     BABBAB$     BABBAB$     BABBAB$     BABBAB$     BABBAB$
BBAB$BA     BBAB$BA     BBAB$BA     BBAB$BA     BBAB$BA     BBAB$BA
```

5. A character index is needed for performing the LF mapping. The full index is shown on the left. On the right is a sparse index that stores the information every *b* rows.

```
          A  B                 A  B
$BABBAB   0  1       $BABBAB   0  1 ┐
AB$BABB   0  2       AB$BABB        │
ABBAB$B   0  3       ABBAB$B        ├ b
B$BABBA   1  3       B$BABBA   1  3 ┘
BAB$BAB   1  4       BAB$BAB
BABBAB$   1  4       BABBAB$
BBAB$BA   2  4       BBAB$BA   2  4
```

6. We illustrate the search process using a BWT/FM-index. The search range is iteratively refined as more characters in the query string ABB are being matched, starting with the rightmost character. The matched characters are shown in bold.



```
          $BABBAB         $BABBAB
          AB$BABB         AB$BABB
          ABBAB$B         ABBAB$B
        ┌ B$BABBA  ABB    B$BABBA
ABB  ─┤ BAB$BAB]─┐      BAB$BAB
        │ BABBAB$  │      BABBAB$
        └ BBAB$BA  └──►[BBAB$BA]  ABB
```

20.2 PHYLOGENETICS

Phylogenetics is the study of the evolutionary relationships among a collection of organisms. These relationships are displayed in the form of a tree whose leaves are labeled by the organisms. Internal vertices of the tree represent common ancestors. Biologists apply statistical and combinatorial techniques to construct trees from data such as DNA sequences. Phylogenetic trees are used in epidemiology, systematics, ecology, and linguistics. We review the basic combinatorial principles of the discipline. Most of the results can be found in [SeSt03] and [DrEtal11]. We refer the reader to [Fe04] for a biological perspective on phylogenetics which is grounded in sound mathematics. Discrete mathematicians may enjoy the recent textbook [HuRuSc10] on phylogenetic networks, while [PaSt05] provides a viewpoint on the subject from the perspective of algebraic geometry.

20.2.1 Phylogenetic Trees

Definitions:

The ***leaves*** of a tree are the vertices incident with a single edge.

The leaves of a ***phylogenetic tree*** are labeled with a set of operational taxonomical units or ***taxa***. A phylogenetic tree may be rooted or unrooted.

An ***internal edge*** is not incident with any of the taxa.

A vertex of a phylogenetic tree with degree greater than three is called a ***polytomy***. A ***binary tree*** has no polytomies.

Two leaves form a ***cherry*** if they are the only leaves adjacent to a common vertex.

Phylogenetic reconstruction is the process of transforming data about the relationships among a particular set of taxa into a phylogenetic tree which represents the underlying relationships.

Facts:

1. Evolution is thought of as a binary process. Therefore most phylogenetic reconstructions aim to return binary trees.

2. Operational taxonomical units typically refer to a set of organisms or a set of genes. However, they may also refer to non-living objects such as languages.

3. The input to a phylogenetic reconstruction algorithm is typically an aligned collection of nucleotide sequences, amino acid sequences, or discrete morphological data.

4. An unrooted binary tree with $n \geq 3$ taxa has $n-3$ internal edges. A rooted binary tree has a single additional internal edge.

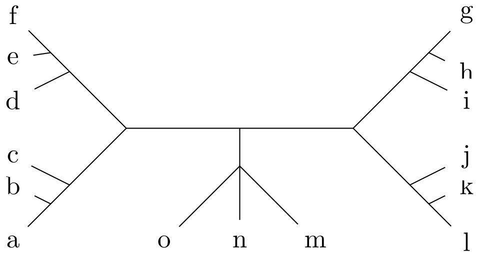
5. For n taxa the number of rooted binary phylogenetic trees is

$$(2n-3)!! = 1 \cdot 3 \cdot 5 \cdot 7 \ldots (2n-3).$$

This is also the number of unrooted binary trees with $n+1$ taxa. As there are more 57-taxa trees than there are atoms in the visible universe, phylogenetic reconstruction algorithms are often restricted from considering all possible trees as models.

Example:

1. The following figure displays a phylogenetic tree with 11 internal edges and 15 taxa $\{a, b, \ldots, o\}$. This tree has four cherries (ab, ef, gh and kl) and a single polytomy adjacent to taxa m, n and o.



20.2.2 Tree Comparisons

When testing phylogenetic reconstruction algorithms, one generates data assuming a fixed tree and model of evolution. Then one reconstructs trees using this simulated data. To test the performance of the reconstruction algorithm, the reconstructed trees are then compared to the fixed tree using a tree metric.

Definitions:

Every edge in a phylogenetic tree induces a ***split*** or partition of the set of taxa into two disjoint subsets.

The ***Robinson-Foulds distance*** between two trees is the number of splits which occur in one tree but not the other.

Each internal edge divides a binary tree into four subtrees. A ***nearest neighbor interchange*** exchanges two of the subtrees on opposite sides of the internal edge.

The ***nearest neighbor interchange distance*** between two binary trees is the minimum number of nearest neighbor interchanges required to transform one tree into the other.

Facts:

1. Both the Robinson-Foulds distance and the nearest neighbor interchange distance define metrics on the set of n-taxa trees.

2. The Robinson-Foulds distance can be computed in linear time [Da85], while computing the nearest neighbor interchange distance is an NP-complete problem [LiTrZh96].

3. Asymptotically, the proportion of trees that share s splits with a tree T follows a Poisson distribution with mean $\lambda = \frac{c}{2n}$, where n is the number of taxa and c is the number of cherries of T [BrSt09].

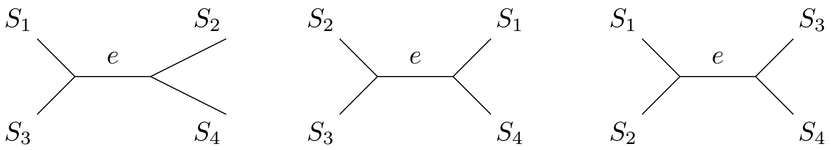
4. There exists a Hamilton walk connecting all binary n-taxa trees through a sequence of nearest neighbor interchanges [GoFoStJ13].

5. For an n-taxa tree, the nearest neighbor distance between any two trees is at most $n \log n + O(n)$ [LiTrZh96].

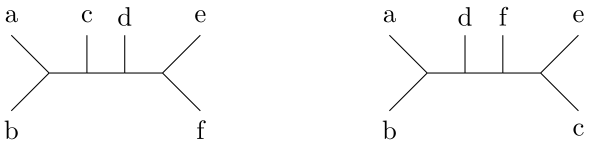
6. Maximum likelihood reconstruction assigns a likelihood score to each tree. Biologists select the tree which maximizes the likelihood of observing the data given the particular tree. In practice it is not feasible to compute a likelihood score for all possible trees. To address this issue a *guide tree* is computed using a fast algorithm. Likelihood scores for trees near the guide tree under the nearest neighbor interchange distance are compared to estimate the maximum likelihood tree [TaEtal11].

Examples:

1. Three trees differing by a single nearest neighbor interchange are shown in the following figure. Here S_1, S_2, S_3, S_4 represent subtrees connected by an internal edge e.

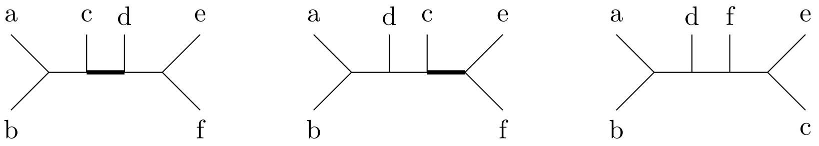


2. The tree shown on the left of the next figure has splits $\mathcal{S} = \{ab|cdef, abc|def, abcd|ef\}$ The tree pictured on the right has splits $\mathcal{S}' = \{ab|cdef, abd|cef, abdf|ce\}$.



Since there are four splits which appear in one tree but not the other (all but $abcd|ef$) the Robinson-Foulds distance between these trees is four.

3. The nearest neighbor interchange distance between the trees above is two as is demonstrated by the sequence of nearest neighbor interchanges shown in the following figure.



The nearest neighbor interchange distance cannot be smaller than two, since the trees differ by a Robinson-Foulds distance of four, and each interchange can only change a single split, so the difference in the number of splits can change by a maximum of two.

20.2.3 Tree Agreement

There are a variety of algorithms for combining trees on a shared set of taxa. These methods may seek to reconcile the tree differences or highlight their similarities.

Definitions:

Let T be a phylogenetic tree on a set of taxa $\mathcal{X}$. For every subset $\mathcal{S} \subseteq \mathcal{X}$, the ***induced subtree*** $T|\mathcal{S}$ is the tree constructed by taking the unique minimal connected subgraph of T containing the leaves in $\mathcal{S}$, and then removing all non-root vertices of degree two.

Given trees $T_1, T_2, \ldots, T_k$, a ***maximum agreement subtree*** is the induced subtree on the largest set $\mathcal{S} \subseteq \mathcal{X}$ such that $T_1|\mathcal{S} = T_2|\mathcal{S} = \cdots = T_k|\mathcal{S}$. The maximum agreement subtree need not be unique.

Given trees $T_1, T_2, \ldots, T_k$ on a set of taxa $\mathcal{X}$, the ***majority rules consensus tree*** is the tree T containing exactly the splits which occur in the majority of the trees $T_1, T_2, \ldots, T_k$.

Facts:

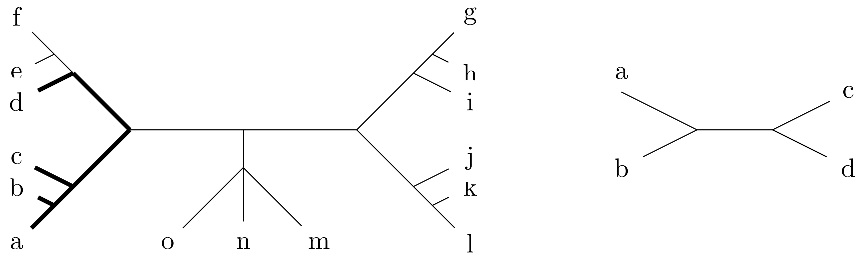
1. For any collection of trees on a set of taxa, both the majority rules consensus tree and the maximum agreement subtree exist. The majority rules consensus tree contains all of the taxa, while the maximum agreement subtree typically contains a proper subset of the taxa.

2. The majority rules consensus tree can be computed in linear time [AmClStJ03], while the maximum agreement subtree can be computed in $O(n \log n)$ time [CoEtal00].

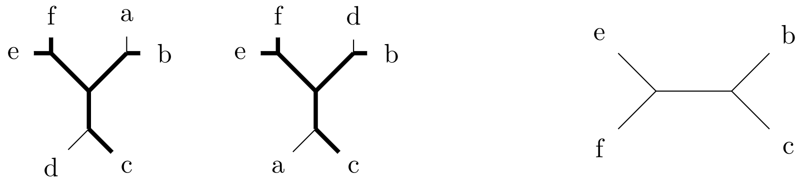
3. Two random binary phylogenetic trees on n taxa share a maximum agreement subtree on $\Omega(\log n)$ leaves [BrMcKSt03].

Examples:

1. The induced subtree on the set $\{a, b, c, d\}$ for the 15-taxa figure shown next is the 4-taxa tree on the right.



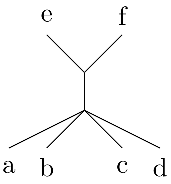
2. In the next figure, a maximum agreement subtree of the two 6-taxa trees pictured on the left is the 4-taxa tree pictured on the right.



3. The majority rules consensus tree will contain all of the taxa. The two trees from the preceding figure share only the split $(abcd|ef)$ so their majority rules consensus tree is forced to contain a polytomy, as pictured on the following page.

20.2.4 Tree Reconstruction

Distance methods of phylogenetic reconstruction algorithms were among the first applied to DNA sequence data and remain in use due to their speed and simplicity.



Definitions:

One may assign a positive ***branch length*** to each edge of a phylogenetic tree.

Given a collection of n taxa, a ***dissimilarity matrix*** is a nonnegative, symmetric $n \times n$ matrix where entry $a_{i,j}$ indicates the difference between taxa i and taxa j. We assume $a_{i,i} = 0$ for all $1 \leq i \leq n$.

A dissimilarity matrix is a ***metric*** if $a_{i,k} \leq a_{i,j} + a_{j,k}$ for all i, j, k.

A dissimilarity matrix is a ***tree metric*** if there exists a phylogenetic tree T such that for each pair i,j the matrix entry $a_{i,j}$ is the sum of the branch lengths along the unique path from leaf i to leaf j.

A dissimilarity matrix is ***ultra-metric*** if it is a tree metric for a rooted tree T in which every leaf is equidistant from the root.

Facts:

1. A dissimilarity matrix is frequently computed using a modified Hamming distance on a pair of DNA sequences. The number of evolutionary changes is under-counted by the Hamming distance. Various distance functions such as the Jukes-Cantor distance [JuCa69] have been developed to account for these missing changes.

2. Every metric on three or fewer taxa is a tree metric.

3. When there are at least four taxa, a dissimilarity matrix is a tree metric if and only if for all i, j, k, l we have $a_{i,j} + a_{k,l} \leq \max\{a_{i,k} + a_{j,l}, a_{i,l} + a_{j,k}\}$. This condition is known as the *four point condition*.

4. The set of tree metrics can be described by a *tropical variety* [SpSt04], while the set of ultra-metric trees can be described as a *polyhedral fan* [ArKl06].

5. With over 40,000 citations, neighbor joining [SaNe87], described in Algorithm 1, is the most popular distance-based algorithm.

Algorithm 1: **Neighbor joining.**

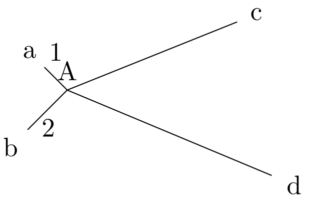
```
input: dissimilarity matrix $M = (m_{i,j})$
output: phylogenetic tree $T$
1. construct the matrix $S = (s_{i,j})$ with
        $s_{i,j} = (n-2)m_{i,j} - \sum_{k=1}^{n}(m_{i,k} + m_{j,k})$.
2. find a pair of taxa $i$ and $j$ which minimize $s_{i,j}$; construct a vertex $A$ on the
     tree which joins $i$ and $j$.
3. calculate the distance from the taxa $i$ and $j$ to the new vertex $A$ using the
     formula $d_{i,A} = \frac{1}{2}m_{i,j} + \frac{1}{2(n-2)}\sum_{k=1}^{n}(m_{i,k} - m_{j,k})$.
4. calculate the distance from all other taxa $x$ to the new vertex $A$ using the
     formula $d_{x,A} = \frac{1}{2}(m_{x,i} + m_{x,j} - m_{i,j})$.
5. repeat Step 1 using the dissimilarity matrix constructed by replacing the taxa
     $i$ and $j$ with the single newly constructed vertex $A$.
```

Examples:

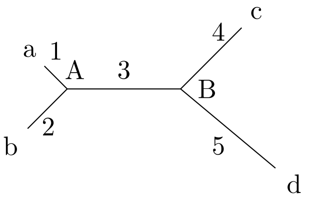
1. Given the dissimilarity matrix $M = \begin{bmatrix} 0 & 3 & 8 & 9 \\ 3 & 0 & 9 & 10 \\ 8 & 9 & 0 & 9 \\ 9 & 10 & 9 & 0 \end{bmatrix}$ for the set $\mathcal{X} = \{a, b, c, d\}$, we note that $m_{a,b} + m_{c,d} = 12, m_{a,c} + m_{b,d} = 18,$ and $m_{a,d} + m_{b,c} = 18$. The four point condition is satisfied, as each individual sum is less than or equal to the maximum of the other two. The four point condition can be reformulated to state that the maximum value of the three sums is obtained by more than one of the three pairs of taxa (here $m_{a,c} + m_{b,d}$ and $m_{a,d} + m_{b,c}$). This viewpoint leads to the interpretation of the space of trees as a *Tropical Grassmanian* (see [PaSt05] for details).

2. Since M satisfies the four point condition, we can use the neighbor joining algorithm to compute a tree whose pairwise distances match the dissimilarity matrix. First we compute the associated matrix $S = \begin{bmatrix} 0 & -36 & -30 & -30 \\ -36 & 0 & -30 & -30 \\ -30 & -30 & 0 & -36 \\ -30 & -30 & -36 & 0 \end{bmatrix}$.

We choose $s_{a,b}$ as the minimum entry and construct a new vertex A connecting the first two taxa. Using Steps 3 and 4 from Algorithm 1 we compute $d_{a,A} = 1, d_{b,A} = 2, d_{c,A} = 7, d_{d,A} = 8$. This gives the following tree.



We repeat the process on the new matrix where the first row and column now represent the newly constructed vertex A. First we compute $M = \begin{bmatrix} 0 & 7 & 8 \\ 7 & 0 & 9 \\ 8 & 9 & 0 \end{bmatrix}$. Then calculating the S matrix yields $S = \begin{bmatrix} 0 & -24 & -24 \\ -24 & 0 & -24 \\ -24 & -24 & 0 \end{bmatrix}$. Since there is a tie between all scores it doesn't matter which pair we join. For convenience we select $m_{A,c}$ to construct a new vertex B which connects A and the taxa c. Then we compute $d_{A,B} = 3, d_{c,B} = 4$ and $d_{d,B} = 5$. Neighbor joining returns the phylogenetic tree shown in the following figure. Notice that the pairwise distances among the taxa on this tree exactly match those in the dissimilarity matrix.



20.2.5 Tree Distributions

We would like to compare trees reconstructed from biological data to random trees. To make this notion precise requires an underlying distribution on the space of trees.

Definitions:

The ***uniform distribution*** on the space of rooted or unrooted trees assumes that each tree occurs with equal likelihood.

A ***ranked*** phylogenetic tree is a rooted binary tree where each internal vertex is assigned a number from $1, 2, \ldots, n-2$ such that if v_i is contained in the path from the root to a vertex v_j, then the number assigned to v_i must be less than the number assigned to v_j.

The ***Yule-Harding distribution*** on rooted binary phylogenetic trees is constructed by taking the uniform distribution on ranked phylogenetic trees and ignoring the rank.

Facts:

1. There are $\dfrac{n!(n-1)!}{2^{n-1}}$ ranked binary trees on a set of n taxa.

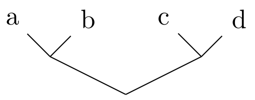
2. The probability of selecting a rooted binary tree T under the uniform model is $\dfrac{1}{(2n-3)!!}$. Under the Yule-Harding model this probability is $\dfrac{2^{n-1}}{n!\prod\limits_{v \in T}(Des(v)-1)}$, where $Des(v)$ denotes the number of leaves which are descendants of an internal vertex v.

3. In general, trees generated under Yule-Harding are more balanced about the root than trees generated under the uniform distribution.

4. Trees generated under a broad class of evolutionary assumptions follow the Yule-Harding distribution [LaSt13].

Examples:

1. The probability of observing the tree in the following figure is $\frac{1}{15}$ under the uniform distribution as it is one of the fifteen rooted 4-taxa trees.



2. The root of the tree above has four leaf descendants, and each of the other two internal vertices have two descendants. This allows us to compute the probability of this tree under the Yule-Harding model as

$$\frac{2^{n-1}}{n!\prod\limits_{v \in T}(Des(v)-1)} = \frac{8}{24(4-1)(2-1)(2-1)} = \frac{1}{9}.$$

3. The probability of a tree under the Yule-Harding model is completely determined by the tree topology. The three 4-taxa trees with the balanced topology all occur with probability $\frac{1}{9}$. The twelve 4-taxa trees which have unbalanced topology around the root occur with probability $\frac{1}{18}$. Under the uniform distribution $\frac{1}{5}$ of the rooted 4-taxa trees sampled are balanced, while under the Yule-Harding model $\frac{1}{3}$ are balanced.

20.2.6 Subtrees and Supertrees

Biologists seek to reconstruct trees of ever increasing size with the ultimate goal of building a tree containing every living organism. To reconstruct large trees, it is important to determine which collection of subtrees best reflects the structure of the tree itself. These subtrees can then be used as inputs into a supertree algorithm designed to reconstruct large trees from a collection of smaller input trees.

Definitions:

A ***quartet tree*** is a binary tree with four leaves. An unrooted quartet tree T is denoted $ab|cd$ if a and b form a cherry of T.

The ***support of a tree***, denoted $supp(T)$, is the collection of taxa at the leaves of T.

A tree T_1 ***displays*** a tree T_2 if $T_1|supp(T_2) = T_2$.

A collection of trees $T_1, T_2, \ldots, T_n$ is called ***definitive*** if there exists a unique tree which displays all of the trees in the collection.

A collection of subsets of taxa $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_k \subseteq \mathcal{X}$ is called ***decisive*** if for any tree T with taxa $\mathcal{X}$ the subtrees $T|\mathcal{S}_1, T|\mathcal{S}_2, \ldots, T|\mathcal{S}_k$ are definitive.

A collection of subsets $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_k \subseteq \mathcal{X}$ satisfies the ***four-way partition property*** if for all partitions of $\mathcal{X}$ into four nonempty sets $\mathcal{X}_1, \mathcal{X}_2, \mathcal{X}_3$ and $\mathcal{X}_4$ there exists a subset $\mathcal{S}_i$ which has a nonempty intersection with each of $\mathcal{X}_1$, $\mathcal{X}_2$, $\mathcal{X}_3, \mathcal{X}_4$.

Facts:

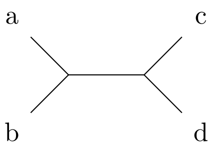
1. The collection of all 4-element subsets of a set of taxa is decisive.

2. For any unrooted binary n-taxa tree, there exists a collection of $n-3$ quartet trees which are definitive.

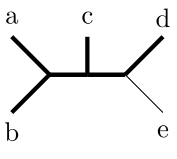
3. A collection of subsets of taxa $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_k \subseteq \mathcal{X}$ is decisive if and only if it satisfies the four-way partition property.

Examples:

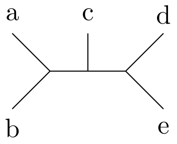
1. A quartet tree $q = ab|cd$ is shown in the following figure. The support of q is $\{a, b, c, d\}$.



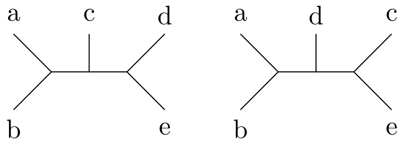
2. The quartet tree $q = ab|cd$ is displayed by the following 5-taxa tree since the induced subtree on the support of q is isomorphic to q.



3. For the taxon set $\mathcal{X} = \{a, b, c, d, e\}$ the quartet trees $ab|cd$ and $ac|de$ are definitive as they are only displayed by the tree in the next figure.



4. The quartets $ab|cd$ and $ab|ce$ are not definitive as they are displayed by both trees in the following figure.



5. The previous example also shows that the collection $\mathcal{T} = \{\{a, b, c, d\}, \{a, b, c, e\}\}$ is not decisive. However, the collection of subsets

$$\mathcal{S} = \{\{a, b, c, d\}, \{a, b, c, e\}, \{a, b, d, e\}, \{a, c, d, e\}\}$$

satisfies the four-way partition property and is thus decisive.

20.2.7 Applications

Facts:

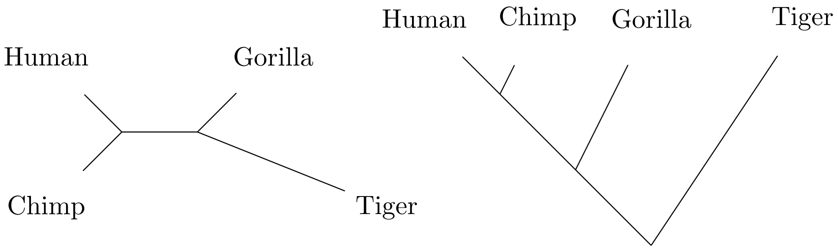
1. Most phylogenetic reconstruction algorithms return an unrooted tree. For that reason, biologists include a distantly related organism or *outgroup* in their sample to help place the root of the tree.

2. Phylogenetic trees provide a tool for understanding biodiversity. The simplest *measure of the biodiversity* of a set of taxa is the sum of the branch lengths in the subtree they induce. This metric is used in conservation biology when making decisions about which organisms to protect.

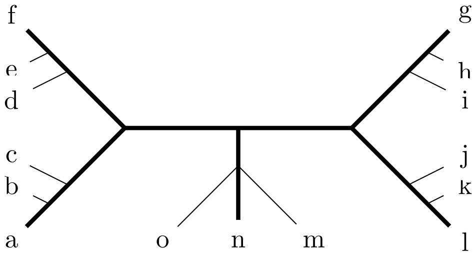
3. It is possible that trees reconstructed from different genes from the same collection of species do not agree. A *coalescent theory* describes how different gene trees can result from a single species tree. In fact the species tree may not even match the most prevalent gene tree [DeRo06].

Examples:

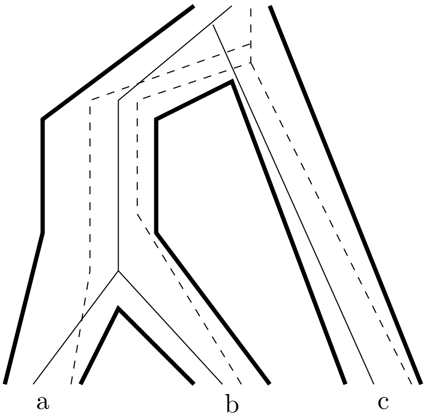
1. The following figure shows how a tiger could be used as an outgroup when reconstructing the evolutionary history of primates.



2. In the following figure, the taxa $\{a, f, g, l, n\}$ have the maximum biodiversity of any 5-taxa set for this tree.



3. In the next figure two gene trees evolve under the coalescent model within a species tree which is represented as a band-like tree enclosed in the thick lines. In this figure a, b and c represent distinct species. The dotted gene tree exhibits discordance with the species tree topology. The solid gene tree matches the species tree topology.



20.3 DISCRETE-TIME DYNAMICAL SYSTEMS

Discrete-time dynamical systems are used in mathematical biology to model and simulate interaction-based networks, such as gene regulatory networks. While the behavior of a biological system may be seen as continuous, in that it moves continuously from one state to another, the technology to record observations of the system, such as microarray chips, is not continuous and the available experimental data consist of collections of discrete instances of continuous processes.

20.3.1 BASIC CONCEPTS

Definitions:

A ***discrete-time dynamical system*** on n vertices is a triple $(N, \mathbf{X}, F)$ with the following properties:

1. N is a set of n variables $x_1, x_2, \ldots, x_n$;

2. $\mathbf{X} = X_1 \times \cdots \times X_n$ is the Cartesian product of ***state sets***, in which each X_i is the set of values, called ***states***, that variable i can take; and

3. $F = (f_1, \ldots, f_n) : \mathbf{X} \to \mathbf{X}$ is a function of the variables in N, called the ***global function***, and each $f_i : \mathbf{X} \to X_i$ is a ***transition function***, associated with vertex x_i.

The first ***iterate*** of point $\mathbf{x} = (x_1, \ldots, x_n) \in \mathbf{X}$ is $F(\mathbf{x})$, the second iterate is $F \circ F(\mathbf{x})$, and so on.

A sequence of iterates $\mathbf{x} \mapsto F(\mathbf{x}) \mapsto F \circ F(\mathbf{x}) \mapsto \cdots \mapsto F \circ \cdots \circ F(\mathbf{x})$ is called a ***trajectory***. The set of all iterates is called the ***orbit*** of $\mathbf{x} \in X$. A trajectory that starts and ends at the same point is called a (limit) ***cycle***. A point $\mathbf{x} \in \mathbf{X}$ is a ***fixed point*** (cycle of length one) when $F(\mathbf{x}) = \mathbf{x}$.

A dynamical system is a ***finite dynamical system*** if each state set X_i is a finite set.

A finite dynamical system is a ***polynomial dynamical system*** if $\mathbf{X} = k^n$ where k is a finite field.

Let R be a commutative ring. A ***polynomial ring*** $R[x_1, \ldots, x_n]$ in n variables is the set of all linear combinations of monomials of the form $\mathbf{x}^\alpha = x_1^{\alpha_1} \ldots x_n^{\alpha_n}$ over R, where α is the n-tuple exponent $\alpha = (\alpha_1, \ldots, \alpha_n) \in \mathcal{Z}^n_{\geq 0}$.

The ***support*** of $f \in R[x_1, \ldots, x_n]$, denoted *supp*$(f)$, is a subset $\{x_{i_1}, \ldots, x_{i_m}\}$ of $\{x_1, \ldots, x_n\}$ such that m is the smallest integer with $f \in R[x_{i_1}, \ldots, x_{i_m}]$.

Let F be an n-dimensional finite dynamical system. The ***dependency graph*** of F, denoted $\mathcal{D}(F)$, is a directed graph (V, E) where $V = \{x_1, \ldots, x_n\}$ and $E = \{(x_i, x_j) \mid x_i \in supp(f_j)\}$.

The ***state-space graph*** of an n-dimensional polynomial dynamical system $F : k^n \to k^n$, denoted $\mathcal{S}(F)$, is a directed graph (V, E) where $V = k^n$ and $E = \{(a, b) \mid a, b \in V \text{ and } F(a) = b\}$.

Facts:

1. For simplicity, it is often assumed that all vertices have the same state set, that is, $X_i = X$ for all $i = 1, \ldots, n$ and $\mathbf{X} = X^n$.

2. Let k be a finite field. Then every function $f : k^n \to k$ is a polynomial of degree at most n.

3. The structure of a finite field can be imposed on X by requiring that : X : is a power of a prime number.

4. Each transition function $f_i : X^n \to X$ is local in the sense it only depends on those variables that correspond to vertices to which i is connected by an edge in $\mathcal{D}(F)$.

5. Any polynomial dynamical system gives rise to a directed graph on n vertices through the construction of a dependency graph; the converse is also true: any directed graph on n vertices can be the dependency graph for a polynomial dynamical system (not unique).

6. The dynamics of a polynomial dynamical system $F : k^n \to k^n$ are uniquely represented by its state-space graph $\mathcal{S}(F)$ which has k^n vertices.

7. For visualization of state-space and dependency graphs of polynomial dynamical systems, the web-based software package ADAM is available at

- `http://adam.plantsimlab.org`

8. Boolean networks (see §20.3.2) can be viewed as polynomial dynamical systems over $k = \mathbf{F}_2$, the field of two elements.

Examples:

1. Let $D_1 = (N, \mathbf{X}, F)$ be a discrete-time dynamical system with $N = \{x_1, x_2, x_3\}$, $\mathbf{X} = \mathcal{Q}^3$, and $F = \{f_1, f_2, f_3\}$ where

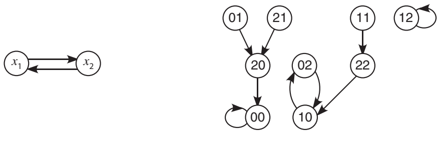
$$\begin{aligned} f_1 = f_1(x_1, x_2, x_3) &= 2x_1 + x_3 \\ f_2 = f_2(x_1, x_2, x_3) &= \frac{5.1x_3}{x_2 + 1} \\ f_3 = f_3(x_1, x_2, x_3) &= 3^{x_2}. \end{aligned}$$

We notice that $supp(f_1) = \{x_1, x_3\}$, $supp(f_2) = \{x_2, x_3\}$, and $supp(f_3) = \{x_2\}$. We find the first iterate of point $(0, 0, 1)$ by $F(0, 0, 1) = (f_1(0, 0, 1), f_2(0, 0, 1), f_3(0, 0, 1)) = (1, 5.1, 1)$. In this example the system iterations are determined through a synchronous update of the vertices; when the vertices operate on different time scales, a *sequential* updating scheme is needed. See [MoRe07] for an introduction to sequential dynamical systems.

2. Let $D_2 = (N, \mathbf{X}, F)$ be a finite (polynomial) dynamical system such that $N = \{x_1, x_2\}$, $\mathbf{X} = \mathbf{F}_3^2$, and $F : \mathbf{F}_3^2 \to \mathbf{F}_3^2$ with transition functions

$$\begin{aligned} f_1 = f_1(x_1, x_2) &= 2x_2 \\ f_2 = f_2(x_1, x_2) &= x_1 + x_1^2. \end{aligned}$$

The dependency graph of D_2 is shown in part (a) of the following figure. The state-space graph in part (b) consists of $3^2 = 9$ vertices arranged into three connected components. The system has two fixed points, (00) and (12), and a cycle of length 2.



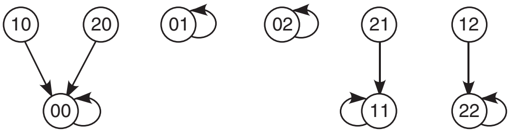
(a) (b)

3. Let $D_3 = (N, \mathbf{X}, F)$ be a polynomial dynamical system with $N = \{x_1, x_2\}$, $\mathbf{X} = \mathbf{F}_3^2$, and $F = \{f_1, f_2\}$ where

$$\begin{aligned} f_1 &= x_1^2 x_2 \\ f_2 &= x_2. \end{aligned}$$

D_3 is an example of a *monomial* dynamical system: each transition polynomial consists of a single monomial, i.e., $f_i = \mathbf{x}^\alpha$ for $i = 1, \ldots, n$. While little can be said about the length and shape of the cycles of a general finite dynamical system without explicitly calculating its state-space graph, for the case of monomial dynamical systems more is known [CoJaLa06].

4. Let D_3 be as in the previous example. It is also a representative of another important class of dynamical systems—*fixed point systems*. Such systems have only fixed points as cycles. As seen in the following figure, the system D_3 has the five fixed points $(00), (01), (02), (11), (22)$ and no other, longer cycles. Fixed point systems are important in biochemical modeling since biochemical networks often exhibit such steady-state dynamics [Lu12].



5. Laubenbacher and Stigler [LaSt04] address the reverse engineering problem of gene regulatory networks in the context of polynomial dynamical systems. They propose an algorithm that takes a discrete time series dataset $D = \{s_1, \ldots, s_m \mid s_i \in k^n, 1 \leq i \leq m\}$, where k is a finite field, and generates a *minimal* polynomial dynamical system $F = (f_1, \ldots, f_n)$ such that $F(s_i) = s_{i+1}$ for each $i < m$. By minimal it is meant that each f_j is reduced with respect to the ideal $\mathbf{I}(\{s_1, \ldots, s_m\}) = \cap_i \mathbf{I}(s_i)$ of polynomials vanishing on all input data points, i.e., all polynomial dynamical systems that fit the data differ by elements of $\mathbf{I}(\{s_1, \ldots, s_m\})$. Their algorithm is based on the Buchberger-Möller algorithm for Gröbner basis computation. It has been applied to the reverse engineering of a gene regulatory network responsible for the segment polarity development in *D. melanogaster*.

6. Simão et al. [SiEtal05] develop a qualitative model of tryptophan biosynthesis in *E. coli*. While the other vertices in the network model can be represented by binary variables, a ternary variable (taking the values 0, 1, 2) is needed for the vertex representing tryptophan.

20.3.2 BOOLEAN NETWORKS

Boolean networks were first used in the life sciences in the 1960s, when Stuart Kauffman introduced them to model gene regulatory networks as switching networks [Ka69]. They have the advantage of being computationally simple and intuitive, and they have been successfully used to model regulatory networks, preserving the qualitative, generic properties of global network dynamics.

Definitions:

A ***Boolean function*** is a function of the form $f : \mathcal{B}^n \to \mathcal{B}$ where $\mathcal{B} = \{0, 1\}$.

A ***Boolean network*** $G(V, F)$ is a set $V = \{x_1, \ldots, x_n\}$ of vertices representing network nodes, together with a global function $F = (f_1, \ldots, f_n)$, where $f_i : \mathcal{B}^n \to \mathcal{B}$ is the transition function associated with vertex x_i.

The ***maximum degree*** (sometimes called ***maximum connectivity***) $\Delta(G)$ of a Boolean network $G(V, F)$ refers to the maximum number of vertices in V that are adjacent to a single vertex.

A ***probabilistic Boolean network*** [ShEtal02] is a Boolean network in which to every vertex x_i, there corresponds a set $F_i = \{f_j^{(i)}\}_{j=1,\ldots,l(i)}$ where each $f_j^{(i)}$ (called a ***predictor***) is a possible transition function determining the value of x_i and $l(i)$ is the number of possible transition functions for x_i. If $l(i) = 1$ for all $i = 1, \ldots, n$, then $\prod_{i=1}^{n} l(i) = 1$ and the probabilistic Boolean network reduces to a standard Boolean network.

Let $\mathbf{f} = (f^{(1)}, \ldots, f^{(n)})$ be a random vector taking values in $F_1 \times \cdots \times F_n$. If $f^{(1)}, \ldots, f^{(n)}$ are independent, i.e., if the selection of the Boolean functions comprising a specific network is independent, the probabilistic Boolean network is said to be ***independent*** (see Fact 10).

A ***random Boolean network*** [Ka93] is another variation of a Boolean network in which the state of each vertex is determined by the connections coming from other (or the same) vertices. The connections are wired randomly, but remain fixed during the dynamics of the network. The way in which the vertices affect each other is not only determined by their connections, but also by logic functions, which are generated randomly using lookup tables for each vertex, taking the states of the connecting vertices as inputs and producing the state of the vertex as output. These also remain fixed during the dynamics of the network.

Facts:

1. A Boolean network on n vertices can be seen as a polynomial dynamical system over $\mathbf{F}_2$, the field of two elements, i.e., $F = (f_1, \ldots, f_n) : \mathbf{F}_2^n \to \mathbf{F}_2^n$ with $f_i : \mathbf{F}_2^n \to \mathbf{F}_2$. Its state-space graph $\mathcal{S}(F)$ consists of 2^n vertices and its dependency graph is $\mathcal{D}(F) = (V, E)$ where $E = \{(x_i, x_j) \mid x_i \in supp(f_j)\}$.

2. There are 2^{n2^n} different Boolean networks on n vertices.

3. The dynamics over a Boolean network flow according to the updating functions and scheme. Since the state space is finite (size 2^n, where n is the number of vertices), eventually a state will be repeated and it is said to have reached an *attractor*. If the attractor consists of one state, it is called a *steady state* or *fixed point*, whereas if it consists of two or more states, it is called a *cycle*. The set of states that flow towards an attractor is called the *attractor basin*.

4. Boolean functions are traditionally represented in terms of logical operations (AND ($\wedge$), OR ($\vee$), NOT ($\neg$)). They can also be expressed as polynomials over $\mathbf{F}_2$. Namely, any two logical variables a and b can be considered as values in $\mathbf{F}_2$ so $a \wedge b$ can be expressed as ab, $a \vee b$ as $a + b + ab$, and $\neg a$ as $a + 1$.

5. When Boolean networks are used to model gene regulatory networks (see Examples 1 and 2), typically $x_i = 1$ represents the fact that gene i is expressed and $x_i = 0$ means it is not expressed. The list of Boolean functions $F = (f_1, \ldots, f_n)$ represents the rules of regulatory interactions between genes. All network genes are assumed to update synchronously in accordance with the functions assigned to them and this process is then repeated. The artificial synchrony simplifies computation while preserving the qualitative, generic properties of global network dynamics [Hu99].

6. The maximum connectivity Δ in a Boolean network that models a gene regulatory network is interpreted as the maximum number of genes that regulate some single gene.

7. A low connectivity Δ is more realistic for a real gene regulatory network [ThEtal98].

8. A Boolean network model is often a suitable representation of genetic networks because genetic manipulation often involves either overexpression or deletion of a gene [Hu99].

9. A Boolean network model is often able to retain sufficient biological information to realistically model genetic regulatory networks. For example, a Boolean network model is able to provide a clear distinction between different classes of sarcomas and different subclasses of gliomas [ShZh02].

10. A realization of a probabilistic Boolean network at a given instant of time is determined by a vector of Boolean functions. If there are N possible realizations, then there are N vector functions $\mathbf{f}_1, \ldots, \mathbf{f}_N$ of the form $\mathbf{f}_k = (f^{(1)}_{k_1}, \ldots, f^{(n)}_{k_n})$, for $k = 1, \ldots, N$, $1 \leq k_i \leq l(i)$ and where $f^{(i)}_{k_i} \in F_i$, $i = 1, \ldots, n$.

11. Let $\mathbf{f} = (f^{(1)}, \ldots, f^{(n)})$ be a random vector taking values in $F_1 \times \cdots \times F_n$; the $f^{(i)}$ are not necessarily independent. Then the probability that a predictor $f^{(i)}_j$ is used to predict gene i is $c^{(i)}_j = \Pr\{f^{(i)} = f^{(i)}_j\} = \sum_{k: f^{(i)}_{k_i} = f^{(i)}_j} \Pr\{\mathbf{f} = \mathbf{f}_k\}$ and since the $c^{(i)}_j$ are probabilities, they must satisfy $\sum_{j=1}^{l(i)} c^{(i)}_j = 1$.

12. Kauffman was the first to propose random Boolean networks, supporting the hypothesis that living organisms could be constructed from random elements, without the need of precisely programmed elements [Ka93]. Random Boolean networks are generalizations of Boolean cellular automata (see §20.3.3).

13. The updating of the vertices in classic random Boolean networks is synchronous: the states of vertices at time $t + 1$ depend on the states of vertices at time t. There can be drastic differences if the updating scheme is changed [HaBo97].

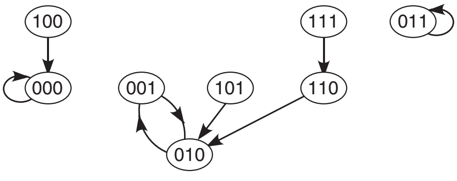
14. There are three phases that can be distinguished in a random Boolean network: *ordered*, *chaotic*, and *critical*. For definitions and methods for identifying the phases, see [Ka00].

Examples:

1. Let $G(V, F)$ be a Boolean network with $V = \{x_1, x_2, x_3\}$ and $F = (f_1, f_2, f_3)$ where

$$\begin{aligned} f_1 &= x_1 \wedge x_2 \wedge x_3 \\ f_2 &= (x_1 \vee x_2) \wedge x_3 \\ f_3 &= \neg x_1 \wedge x_2. \end{aligned}$$

As seen in the following figure, the state space contains two types of attractors: two fixed points, (000) and (011), with basins of attraction of sizes 2 and 1, respectively, and one cycle of length 2, with basin of attraction of size 5.



2. A simple model of the lactose metabolism in *E. coli* [StVe11], constructed under the assumptions that molecular synthesis and degradation require one time unit and extracellular lactose is always available, can be represented as

$$\begin{array}{ll} H_M = \neg R \wedge C & \\ H_P = M & H_B = M \\ H_C = \neg G_e & H_R = \neg A \wedge \neg A_l \\ H_A = L \wedge B & H_{A_l} = A \wedge L \wedge L_l \\ H_L = \neg G_e \wedge P \wedge L_e & H_{L_l} = \neg G_e \wedge (L \vee L_e) \end{array}$$

where

$M =$ *lac* mRNA

$P, B =$ lac permease and β-galactosidase, respectively

$C =$ catabolite activator protein CAP

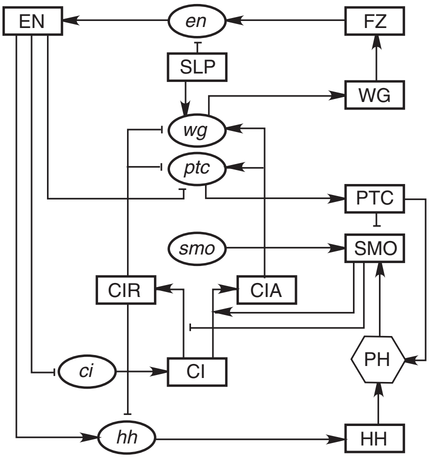
$R =$ repressor protein LacI

$L, A =$ lactose and allolactose (inducer), respectively

$L_l, A_l =$ (at least) low concentration of lactose and allolactose, respectively.

Here L_e and G_e represent extracellular lactose and glucose, respectively, and are considered as parameters in the model.

3. Albert and Othmer [AlOt03] constructed a Boolean model of the network of segment polarity genes in the fruitfly *D. melanogaster.* The model was built from inferences given gene and protein expression data. The following figure depicts the graph of connections in the Boolean model. The shape of the nodes indicates whether the corresponding substances are mRNAs (ellipses), proteins (rectangles), or protein complexes (hexagons). The edges of the network signify either biochemical reactions or regulatory interactions. Terminating arrows generally indicate activation, while terminating segments indicate inhibition.



4. Elementary cellular automata, discussed in §20.3.3, can also be viewed as Boolean networks whose dependency graph is circular and in which all vertices have the same local Boolean function.

20.3.3 CELLULAR AUTOMATA

Cellular automata are simple mathematical idealizations of natural systems. They were introduced by John von Neumann and Stanislaw Ulam as simple models in which to study biological processes such as self-reproduction [vN66, Ch. 5]. A cellular automaton is a discrete model that consists of a finite or infinite regular grid of cells, each in one of a finite number of states. Among other applications in systems biology, cellular automata are used to model reaction-diffusion systems [We97] and biological cells [MaDe06].

Largely inspired by cellular automata, scientists of various backgrounds, such as Arthur Burks (philosopher) [Bu71] and Christopher Langton (computer scientist) [La89], started seeking to mimic life mathematically and generate known features of life from basic principles under the premise that life can be manifested outside of biochemistry.

Definitions:

A ***cellular automaton*** is a lattice of identical sites (***cells***), each taking on a finite set of values. The lattice can be in any finite number of dimensions. The state of a cell at time t (time is discrete) is a function of the states of a finite number of cells (called its ***neighborhood***) at time $t-1$. These ***neighbors*** are a selection of cells relative to the specified cell, and do not change. Every cell has the same ***rule*** for updating, based on the values in this neighborhood. Each time the rules are applied to the whole lattice, a new ***generation*** is produced.

A ***one-dimensional cellular automaton*** of length n can be defined as a network on n vertices, where its dependency graph is a circle.

An ***elementary cellular automaton*** is a one-dimensional cellular automaton whose cells can only assume two values, e.g., 0 or 1.

Facts:

1. In the 1970s, John Conway's "Game of Life" [Ga70] (also see §17.1.4), a two-state, two-dimensional cellular automaton, became widely known. It is one of the simplest examples demonstrating that elaborate patterns and behaviors can emerge from very simple rules. A Java implementation can be found at

- `http://www.ibiblio.org/lifepatterns/`

2. An elementary cellular automaton is a ring consisting of a finite number of squares (cells). Each square has two neighbors: a square to its left and a square to its right. Each square can assume one of two colors. The color of each square in the next step depends on its current color and the colors of its two neighbors. All squares use the same rule to update their colors. Squares can be initialized to different colors.

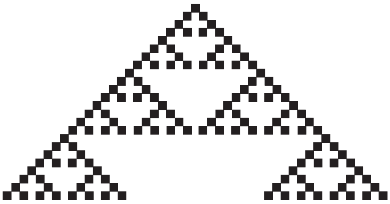
3. In 1982 Stephen Wolfram published the first of a series of papers [Wo82] systematically investigating elementary cellular automata. The unexpected complexity of the behavior of these simple rules led Wolfram to suspect that complexity in nature may be due to similar mechanisms.

Examples:

1. The following figure presents two generations of an elementary cellular automaton of length 8, with initial state given in part (a). Update rule: at time t each cell assumes whichever color had the majority among itself and its neighborhood at time $t-1$. An end cell's neighbors are its adjacent cell and the cell at the other end (the array "wraps around"). Part (b) shows the automaton's state after one update.

(a) (b)

2. The next figure shows a pattern obtained with a simple one-dimensional cellular automaton. Starting from a "seed" containing a single nonzero cell, subsequent lines are obtained by successive applications of the following update rule: $a_i^{(t+1)} = a_{i-1}^{(t)} + a_{i+1}^{(t)}$ (mod 2), where $a_i^{(t)}$ is the value of the cell at position i on time step t. The pattern obtained is Pascal's triangle of binomial coefficients, reduced modulo 2 [Wo82].



3. Some organisms, such as *Conus textile*, grow complicated forms by repeated application of simple local rules, closely resembling cellular automata [DeDo05].

4. Some researchers adopt a broader notion of artificial life and include synthetic biochemistry and robotics [Ke09], [ItSa14]. Other interesting examples of attempts at creating artificial life include the Digital Organism Simulation Environment (DOSE) [CaLi14], an executable DNA driven digital organism simulator, and OpenWorm [PaEtal12], an international open science project to simulate the roundworm *Caenorhabditis elegans* at the cellular level.

20.3.4 GENETIC ALGORITHMS

A genetic algorithm (GA) is a heuristic search algorithm that mimics the metaphor of natural biological evolution. GAs were originally developed as a means of studying the natural evolution process, and have been adapted for use in optimization since the 1960s [Go89], [Ho75], [Ko91]. They operate on a population of potential solutions, applying the principle of survival of the fittest to produce better and better approximations to a solution. GAs often outperform classical methods of optimization when applied to problems in fields as diverse as biology, genetics, engineering, art, economics, marketing, operations research, robotics, social sciences, physics, politics, and chemistry. Currently three are three main avenues of research in simulated evolution: genetic algorithms, evolution strategies, and evolutionary programming, each method emphasizing a different facet of natural evolution. A good introductory survey can be found in [Fo94].

Definitions:

Since GAs are inspired by natural evolution, terminology from genetics is often used. The definitions below are valid only within the context of GAs and may even sometimes disagree with their counterpart concepts from evolutionary biology [EiSm03].

A ***chromosome*** is a set of parameters that define a proposed solution to the given optimization problem. The chromosome is often represented as a vector, with elements being described as ***genes*** and varying values at specific positions called ***alleles***. Chromosomes are points in the ***genotype space*** where the search takes place.

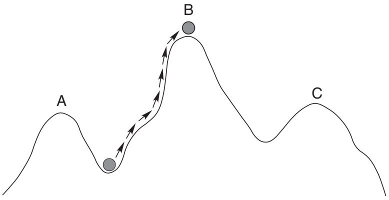
The objects forming possible solutions within the original problem context are referred to as ***phenotypes*** and their encoding, the ***individuals*** within the GA, are called ***genotypes***.

A ***population*** is a collection of genotypes (***individuals***), representing a possible solution.

Crossover, also called ***recombination***, is an operator applied to two or more selected individuals (***parents***) and results in one or more individuals (***children***). ***Mutation*** is applied to one individual and results in one new individual. Recombination and mutation, collectively called ***variation operators***, produce a set of new individuals that compete (based on their fitness) with the old ones for a place in the next generation.

A ***fitness function*** is a particular type of objective function that quantifies the optimality of a chromosome so that a particular chromosome may be ranked against all the other chromosomes. The chosen chromosomes are allowed to "breed" and mix their datasets, thus producing a new generation that will hopefully be even closer to the optimal.

Fitness landscapes are used to visualize the relationship between genotypes and reproductive success. Genotype ***fitness*** corresponds to the height of the landscape. The set of all possible genotypes, their degree of similarity, and their fitness values constitute the fitness landscape. In the following figure, points A and C are local optima, while point B is the global optimum. The trajectory of the filled circle traces a population that moves from a very low fitness value to the top of a peak.



Facts:

1. GAs consistently perform well in approximating solutions to all types of problems because they do not make any assumption about the underlying fitness landscape.

2. While there are variations in different GAs, the common idea behind all of them is that given a population of individuals, the environmental pressure causes natural selection that results in a rise in the fitness of the population. The environmental pressure is mimicked through the application of a fitness function that is to be maximized. The process starts by randomly creating a set of candidate solutions and applying the fitness function to identify the best candidates for creating the next generation by means of recombination and mutation. The process is repeated until an individual of sufficiently high fitness is found.

3. There is no guarantee that the best solution found by a GA is actually the optimal solution. In the context of GAs, "optimal solution" means the best solution we are able to find. The advantage of using a GA is that there is inherently some level of stochasticity; that is, there is always the possibility of mutating to a better solution, as long as the mutation rate is nonzero [LaHiOr15].

4. *Uniform crossover* is a typical method of crossover in which there is an equally likely chance that the child will take each particular gene from either parent (see Example 1). *One-point crossover* is another popular option (see Example 7).

5. During selection, fitter individuals have a higher chance to be selected but even weaker ones have a chance to survive and become parents. Combining recombination and mutation with selection generally leads to improved fitness.

6. Binary representation is commonly used for candidate solutions, encoding them as binary strings (see Example 5). Other representations, such as floating-point, can be found in the GA literature as well.

Examples:

1. In the "Rabbits and Grass" example discussed in [LaHiOr15], two randomly chosen solutions are selected, $p_1 = (0101010101)$ and $p_2 = (1110110010)$. A child solution is created using uniform crossover by going through each gene, i.e., each entry in the parent solutions, and randomly selecting one of the values. An example of a child solution might be $p_{new} = (0111110111)$. The child solution is then subjected to mutation, e.g., the second and the last entry of p_{new} are "mutated" through *bit-flipping* to obtain $p_{new}^{mut} = (0011110110)$. The algorithm continues for a predetermined number of steps, or until a certain condition is met. For example, one might run the algorithm for 50 generations. Another method is to repeat the process until no better solution has been found for some specified number of consecutive generations. When the algorithm terminates, the best current solution is selected as the candidate for an optimal solution [LaHiOr15].

2. GAs are population-based stochastic algorithms that repeatedly test individuals in a population against a fitness criterion. Algorithm 1 outlines the general principles of GAs [EiSm03].

```
Algorithm 1: General scheme of a GA.
  input: population with random candidate solutions
  output: suitable solution (candidate with sufficient quality)
  EVALUATE each candidate in the population
  while TERMINATION CONDITION not satisfied do
      SELECT parents
      CROSSOVER pairs of parents
      MUTATE resulting offspring
      EVALUATE new candidates
      SELECT individuals for next generation
  return an individual (that meets TERMINATION CONDITION)
```

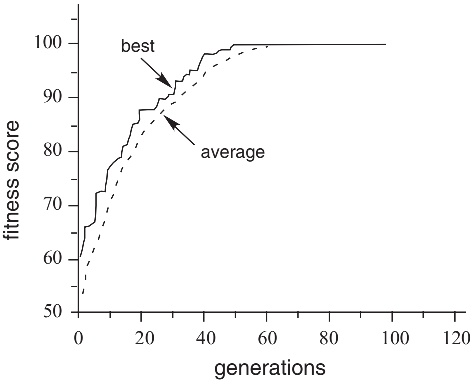
3. If the problem has a known optimal solution value, then reaching the optimal fitness level within a given precision can be used as a TERMINATION CONDITION in Algorithm 1. However, because of the stochastic nature of the GA, there is no guarantee of convergence. To ensure algorithm termination, other criteria are often applied, such as restricting the CPU time allowed, fixing the number of fitness evaluations permitted, terminating when the population diversity drops below a certain level, and setting a minimum fitness improvement for a number of generations or fitness evaluations.

4. There are many GA variations. Algorithm 1 can be modified, for example, so that the initial chromosomes are selected in a certain way, e.g., at random or so that they are very different from one another (i.e., solutions that come from different regions of the solution space). The crossover process can also be modified so that one parent is favored over another, or one can forego the mutation step altogether. The likelihood of mutation is another area where user input is important: a high level of mutation will result in more variation of child chromosomes, and thus will not incorporate the relative fitness of the parent chromosomes as much. On the other hand, if the mutation step is not included then there is a greater risk of the solutions converging to some solution that is only locally minimal [LaHiOr15].

5. Suppose we want to find an integer value x that maximizes $F(x) = -x^2$. Then the set of integers $\mathcal{Z}$ will be the set of phenotypes. Thus the integer 9 is a phenotype and, if binary coding is used, its genotype representation is 1001. The fitness function of this genotype could be defined as (the negative of) the square of its phenotype, $9^2 = 81$.

6. Suppose the goal is to find a vector of 100 bits, $\mathbf{x} \in \{0,1\}^{100}$, such that the sum of all of the bits in the vector is maximized. The fitness function could be written as

$F(\mathbf{x}) = \sum_{i=1}^{100} x_i$, where $\mathbf{x} = (x_1, x_2, \ldots, x_{100})$. A candidate solution is evaluated using F and its fitness is identified in the range between 0 and 100. Let an initial population of 100 parents be selected at random and subjected to selection using $F(\mathbf{x})$ with the probabilities of recombination and bit mutation being 0.8 and 0.01, respectively. The following figure shows the rate of improvement of the best vector in the population, and the average of all parents, at each generation. The process rapidly converges to the vector of all 1s, with optimum fitness value 100 [Fo94].



7. The *0-1 knapsack problem* (§16.3.1), an optimization problem that arises in many industrial problems, can be briefly described as follows. Given a set of n items, each of which has some value v_i attached to it and some cost c_i, how do we select a subset of those items with cost at most C_{max} that maximizes the overall value. A candidate solution for this problem can be represented as a binary string of length n, where a 1 in a given position indicates that an item is included and a 0 indicates that it is omitted. The corresponding genotype space G is the set of all such strings, whose size 2^n increases exponentially with the number of items considered.

While it might seem natural to define the phenotype space P to be identical to G, a one-to-one correspondence between the genotype and phenotype spaces leads to problems [EiSm03]. Instead, let the fitness of a given solution p, represented by a binary genotype g, be determined by summing the values of the included items: $Q_p = \sum_{i=1}^{n} v_i g_i$. In order to break the one-to-one correspondence between G and P, when creating a solution proceed as follows. Read from left to right along the binary string, and keep a running tally of the cost of included items. When a value 1 is encountered, first check to see if including the item would violate the capacity constraint $Q_p = \sum_{i=1}^{n} v_i g_i \leq C_{max}$; i.e., rather than interpreting a value 1 as meaning to include this item, interpret it as meaning to include this item *if* it does not violate the cost constraint.

For this problem, [EiSm03] chose as a recombination operator the one-point crossover, which aligns two parents and picks a random point along their length. The two offspring are created by exchanging the tails of the parents at that point. This operator is applied with 0.7 probability. That is, for each pair of parents select a random value uniformly between 0 and 1; if it is below 0.7 then create two offspring by crossover, otherwise make copies of the parents. Bit-flipping is used as a mutation operator: in each position invert the value with a small probability $p_m \in [0, 1)$, for example $p_m = 1/n$. A termination condition might be, for example, when no improvement in the fitness of the best member of the population has been observed for twenty five generations. Such a termination criterion is appropriate since the maximum value that can be achieved is not known.

20.4 GENOME ASSEMBLY

Every living organism has a genome that contains its complete hereditary information, encoded by long DNA sequences. Abstractly, the genome can be viewed as a set of strings over the alphabet $\{A, T, C, G\}$. The task of decoding, or sequencing a genome, is of considerable interest. However, it is a computationally daunting task because these sequences can be hundreds of billions of base pairs in length, and even the most advanced technology can only read sequences of a few thousand base pairs. As a result, sequencing a genome is done by breaking up numerous copies into small pieces which can be individually read. These fragments can then be reassembled into the original sequence by analyzing the overlaps, or by recording the length-k subsequences that they contain. This section provides an overview of approaches and algorithms developed to solve this massive biological jigsaw puzzle.

20.4.1 BASIC CONCEPTS

Definitions:

A strand of DNA consists of a sequence of four types of ***nucleotides*** distinguished by a nitrogenous ***base***: adenine (A), thymine (T), cytosine (C), or guanine (G).

A ***DNA segment*** is a consecutive subsequence of bases on a DNA strand, which one can represent as a string or sequence over the alphabet $\{A, T, C, G\}$.

A ***DNA target sequence*** is a long unknown DNA sequence that one wishes to decode, but is typically much too long to do so all at once, even using the state-of-the-art tools.

Long DNA strands need to be broken up into smaller strands called ***clones***, which are short enough to be individually sequenced using modern technology.

DNA clones that are sequenced are called ***reads***, or ***fragments***.

A ***k-mer*** of a string is a (consecutive) length-k substring. The ***prefix*** (respectively, ***suffix***) of a k-mer is its initial (respectively, terminal) $(k-1)$-mer.

The technique of ***sequencing by hybridization*** (SBH) uses a DNA microarray, or biochip, to determine all k-mers in the reads. This information is then used to reconstruct the target sequence.

Shotgun sequencing is a method where many copies of a long DNA strand are broken up randomly into clones, which are sequenced into reads. The original target sequence is reconstructed by analyzing the overlaps of the reads, or by the set of k-mers in the reads.

A ***genome assembler*** is a computer program that performs the algorithmic gene assembly process from given input data.

Facts:

1. Each base can chemically bond with a particular *complement* base, forming a *base pair* (bp). Specifically, A bonds with T, and C bonds with G.

2. The bases in a DNA strand are strung along a sugar-phosphate backbone. The carbon atoms in the sugar (ribose) are numbered $1'$ through $5'$. The $3'$ carbon in each sugar molecule is connected through a phosphate group to a 5′ carbon on the next one, giving each DNA strand a directionality.

3. A DNA molecule consists of two DNA strands that bond to each other and twist into a double-helix structure. These two strands bond in an anti-parallel fashion: namely, if the sequence of a DNA strand is $\mathbf{s} = (s_1, \ldots, s_n)$, then the complementary sequence is $\mathbf{t} = (t_1, \ldots, t_n)$, where $t_i = \overline{s}_{n-i+1}$, $i = 1, \ldots, n$, with the bar denoting the complement base.

4. DNA sequencing was invented in the late 1970s, using an in vitro chain termination method known as *Sanger sequencing* [SaNiCo77]. This led to the "first generation" of sequencers, which were the most widely used methods for about 25 years and which produced reads of 300–900 bp in length.

5. First-generation sequencers have been supplanted (but not replaced) by the development of high-throughput parallelized *next-generation* (Next-Gen) sequencing technologies.

6. Sequencing by hybridization using k-mers was developed in 1988 [DrEtal89]. The range $8 \le k \le 25$ was common.

7. DNA hybridization for genome assembly proved to be very limited due to both its accuracy and low values of k, but microarray technology that it utilized has since been widely used to measure gene expression.

8. The bacterium *Carsonella ruddii* has the smallest known genome—about 160,000 bp [NaEtal06]. The largest known genome belongs to the ameboid *Polychaos dubium*, containing approximately 670 billion bp. In contrast, the human genome has about 3 billion bp. The Animal Genome Size Database [Gr16] contains genomic data for over 5,600 animal species and is available online at

- `http://www.genomesize.com`

9. The first successful genome sequence was completed in 1995 by a team at The Institute for Genomic Research (TIGR) and Johns Hopkins University. They sequenced the entire 1.83 million base pair genome of the bacterium *Haemophilus influenzae* [FlEtal95].

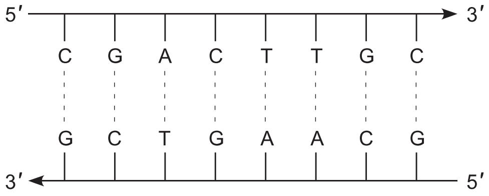
10. A breakthrough whole-genome sequence assembly project was completed in 2000 by Eugene Myers et al., using the Celera assembler [MyEtal00]. They sequenced the 135 million base pair genome of the fruit fly *Drosophila melanogaster*, which was over 25 times larger than any other genome assembled.

11. As of 2016, the single molecule real-time (SMRT) sequencer [RoCaSc13] from Pacific Biosciences can generate reads with an average length of 10,000–15,000 bp and a maximum of about 60,000 bp.

12. Other popular Next-Gen sequencers produce shorter but more accurate reads, such as those developed by the companies Illumina [BeEtal08] (up to 300 bp/read) and 454 Life Sciences [MaEtal05] (up to 600 bp/read).

Examples:

1. The following diagram shows the bases appearing in a short DNA strand CGACTTGC, oriented in the 5′ to 3′ direction. The complementary DNA strand is GCAAGTCG, also oriented in the 5′ to 3′ direction.



2. The following diagram illustrates a microarray that can be used to identify k-mers for $k = 3$. In particular, the DNA fragment ACTAGC contains the 3-mers ACT, CTA, TAG, and AGC, which are detected by the microarray shown.

AAA	AAC	AAG	AAT	ACA	ACC	ACG	ACT
AGA	AGC	AGG	AGT	ATA	ATC	ATG	ATT
CAA	CAC	CAG	CAT	CCA	CCC	CCG	CCT
CGA	CGC	CGG	CGT	CTA	CTC	CTG	CTT
GAA	GAC	GAG	GAT	GCA	GCC	GCG	GCT
GGA	GGC	GGG	GGT	GTA	GTC	GTG	GTT
TAA	TAC	TAG	TAT	TCA	TCC	TCG	TCT
TGA	TGC	TGG	TGT	TTA	TTC	TTG	TTT

20.4.2 OVERLAP GRAPH APPROACHES

The fragment assembly problem takes in a set of reads (strings) and asks for a larger string **s** that "best explains" the reads. Originally, this was approached as a modified shortest common superstring (SCS) problem with added constraints. The SCS problem can be solved by constructing a graph whose vertices are the reads and whose edges represent overlaps. Due to repeated substrings, it is well known that the fragment assembly problem is more complicated than SCS. Despite this, many assemblers still construct some type of "overlap graph" from the reads and then seek a Hamilton path. Such assemblers often break this into three distinct phases: overlap, layout, and consensus. This approach was introduced in 1984 [PeSöUk84]. It was the first widespread method for sequence assembly and was widely used for over 20 years, in popular assemblers such as PHRAP, PCAP [HuWa03], TIGR, and Celera [MyEtal00].

Definitions:

Given a collection of strings (reads) $S = \{\mathbf{s}_1, \ldots, \mathbf{s}_n\}$, a solution to the ***shortest common superstring*** (***SCS***) ***problem*** is a string **s** of minimum length that contains each $\mathbf{s}_i$ as a (consecutive) substring.

The ***overlap*** of $\mathbf{s}_i$ with $\mathbf{s}_j$ is the length of the longest suffix of $\mathbf{s}_i$ that is a prefix of $\mathbf{s}_j$.

Given S and a threshold $\ell > 0$, the ***overlap graph*** is a weighted directed graph constructed as follows:

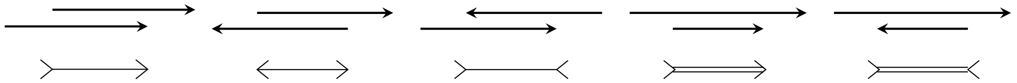
- the vertices are the strings $\mathbf{s}_i \in S$;
- there is a directed edge $\mathbf{s}_i \to \mathbf{s}_j$ if the overlap of $\mathbf{s}_i$ with $\mathbf{s}_j$ is at least ℓ;
- the cost (or weight) of an edge is negative of the overlap between $\mathbf{s}_i$ and $\mathbf{s}_j$.

A ***Hamilton path*** in a graph is a path that visits every vertex exactly once.

The three phases in the overlap-layout-consensus approach are

- ***overlap***: find significant overlaps between reads, taking into account difficulties such as unknown orientations and possible errors;
- ***layout***: construct an appropriate graph and find a Hamilton path corresponding to the optimal layout of overlapping reads;
- ***consensus***: fix errors and resolve discrepancies in the layout.

If the orientation of overlapping reads is known, then this information can be tracked by using annotated directed edges called ***dovetail edges***, as shown next:



(a) Regular dovetail (b) Prefix dovetail (c) Suffix dovetail (d) Containment I (e) Containment II

A ***dovetail path*** is a path in the overlap graph with the added requirement that it respects the orientation of the tails; i.e., two consecutive edges common to a vertex correspond to different ends of that fragment.

Facts:

1. An SCS corresponds to a minimum cost Hamilton path in the overlap graph.

2. Finding a minimum cost Hamilton path is an NP-hard problem, even if all edge weights are identical.

3. Some genomes are circular and others are linear. If the genome is circular, then an SCS corresponds to a minimum cost *Hamilton tour* (or cycle) instead of a minimum cost Hamilton path.

4. Non-optimal superstrings for the SCS problem can be found with a simple greedy heuristic [TaUk88]: at each step, merge two strings with maximum overlap. This is known to be a c-approximation algorithm for small c, with $c = 2$ conjectured. This heuristic is used by popular genome assemblers such as TIGR (see [SuEtal95], [PoKo04]), PHRAP, and CAP.

5. Due to the nature of DNA sequencing, the fragment assembly problem is harder than the standard SCS, due to the following difficulties:

- the orientation of the strings may not be known;
- there could be sequencing errors;
- there are usually long repeated substrings in the actual genome;
- there could be differences between inherited copies of a genome (for example, in humans, one copy is from the mother and the other is from the father).

6. Due to high computational costs, look-up tables are often used in the overlap phase. Dynamic programming is also used to find optimal alignments.

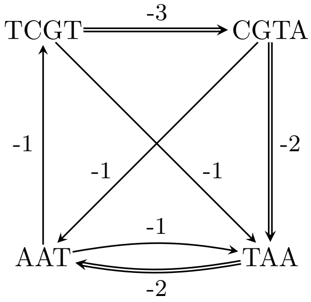
7. The biggest challenge with the fragment assembly problem is dealing with the abundance of (frequently long) repeated subsequences. This is usually part of the layout phase. As a result, the real genome is usually not the actual solution to the SCS problem, but much longer.

8. One way to handle repeats using an SCS approach is to assume that the sampling coverage is uniform, so that maximum likelihood methods can give evidence for repeated substrings.

9. Majority voting, Bayesian models, and dynamic programming have all been used within the consensus phase to determine an optimal multiple alignment.

Examples:

1. Given reads $S = \{$AAT, CGTA, TAA, TCGT$\}$, the overlap graph with threshold $\ell = 1$ is shown next.

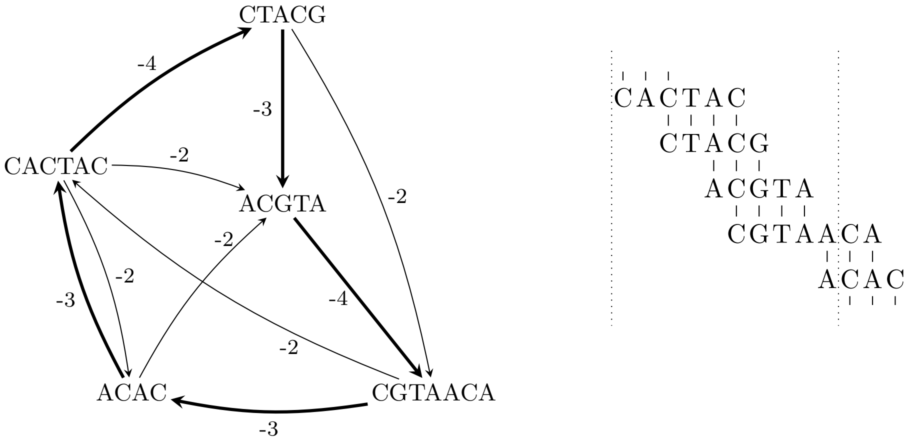


A minimum cost Hamilton path in this graph is given by TCGT → CGTA → TAA → AAT with cost -7. This sequence yields the shortest common superstring TCGTAAT, of length 7.

2. Suppose that the greedy heuristic is applied to the reads in Example 1. The strings TCGT and CGTA have maximum overlap (3) and are merged, giving the string TCGTA. Next, strings TAA and AAT have maximum overlap (2) and so are merged, giving the string TAAT. Finally, the strings TCGTA and TAAT are merged, producing the string TCGTAAT with length 7, which is optimal (see Example 1).

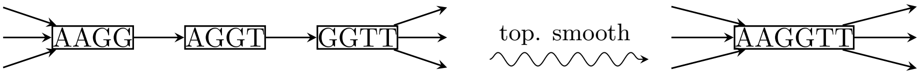
3. To see that the greedy heuristic need not produce a minimum length superstring, consider reads $S = \{$ATATATATC, GATATATAT, TATATATA$\}$. The strings GATATATAT and ATATATATC have maximum overlap (8); these two strings are merged, giving the new string GATATATATC. Since TATATATA and GATATATATC have no overlap, they can be concatenated in either order, say giving the string TATATATAGATATATATC of length 18. However, the SCS has length 12, obtained by overlapping GATATATAT, TATATATA, and ATATATATC, producing the optimal superstring GATATATATATC. This example can be generalized to show that the ratio between the heuristic length and the optimal length approaches 2 in these circumstances.

4. Consider a short circular genome CACTACGTAA, and suppose that shotgun sequencing produces the reads $\{$ACAC, ACGTA, CACTAC, CGTAACA, CTACG$\}$. The overlap graph is shown in the following figure, using an overlap threshold of $\ell = 2$ for the edges. The target sequence is represented in the overlap graph by a Hamilton tour, denoted by the thick edges.

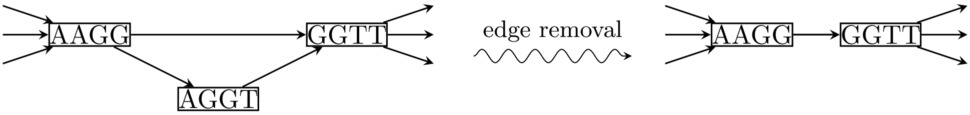


5. Simplifications of the overlap graph, such as the following [My95], are frequently implemented in the layout phase:

- require minimum overlap for edges;
- contained read removal: if $\mathbf{s}$ contains $\mathbf{s}'$, then remove $\mathbf{s}'$ and all incident edges;
- topologically smooth vertices: replace edges $a \to b$ and $b \to c$ with a single edge $a \to c$ if b has no other incident edges.



- transitive edge removal: given edges $a \to b$, $b \to c$, and $a \to c$, remove $a \to c$.



6. The consensus phase uses a multiple alignment to correct errors, as shown in the following example with four overlapping reads.

```
                 GACGGATTAAAATAAGC
Alignment:  TTAATGACGGATTAATA
                      ATTAAAATAAGCAGT
               ATGTCGGACTAAAATAA

Consensus:  TTAATGACGGATTAAAATAAGCAGT
```

20.4.3 DE BRUIJN GRAPH METHODS

The standard de Bruijn graph on m symbols (for genome assembly, $m = 4$) is a directed graph whose vertices consist of all length-k sequences and in which the edge (u, v) indicates that the suffix of u equals the prefix of v (see §3.1.7). A number of genome assemblers record all of the k-mers present in the reads, and then use a "modified de Bruijn graph" to reconstruct the target sequence. There are two main approaches: (i) represent the vertices as k-mers and edges as (prefix, suffix) pairs of $(k-1)$-mers, or (ii) represent each k-mer as an edge, whose vertices are its (prefix, suffix) $(k-1)$-mers. In the first approach, the solution is encoded as a Hamilton path (visiting every vertex exactly once), and in the second approach, as an Euler path (visiting every edge exactly once). There is no consensus name for these graphs in the literature, so we will call them Hamilton and Euler de Bruijn graphs, respectively.

Definitions:

Given a set of reads, construct the ***Hamilton de Bruijn graph*** as follows:

- the vertices are the k-mers that appear in some read;
- there is a directed edge $u \to v$ if the suffix of u is the prefix of v.

An ***Euler path*** in a graph is a path that traverses every edge exactly once.

Given a set of reads, construct the ***Euler de Bruijn graph*** as follows:

- the vertices are the $(k-1)$-mers that appear in some read;
- there is a directed edge $u \to v$ if some k-mer contains u as a prefix and v as a suffix.

Facts:

1. The early uses of sequencing by hybridization (SBH) used an overlap-layout-consensus approach. An Euler de Bruijn graph approach was proposed in 1989 [Pe89]. Another early SBH approach is described in [DrEtal93], with $k = 8$.

2. A Hamilton path in the Hamilton de Bruijn graph represents a feasible solution to the fragment assembly problem.

3. An Euler path in the Euler de Bruijn graph represents a feasible solution to the fragment assembly problem [IdWa95], [PeTaWa01].

4. If the genome is circular, then solutions to the fragment assembly problem correspond to Hamilton (or Euler) cycles instead of paths.

5. A directed graph has an Euler cycle (or tour) if and only if the in-degree of each vertex equals its out-degree. This property holds for both the standard and the Euler de Bruijn graphs.

6. Algorithm 1 (Hierholzer's algorithm) describes a simple approach for finding an Euler cycle in a directed graph satisfying the property given in Fact 5. It can be implemented to run in linear time. Also see §8.4.3.

Algorithm 1: **Euler cycle algorithm.**

```
pick a vertex $v$, and travel along unused edges until returning to $v$
while the cycle is not Eulerian
    pick a vertex $w$ on the cycle that has unused outgoing edges
    travel along unused edges until returning back at $w$
    merge cycles
```

7. Algorithm 1 can be easily adapted to find an Euler path in a directed graph that possesses such a path (but not an Euler cycle).

8. Further modifications or generalizations of de Bruijn graphs, such as weighted edges (counting how many times the k-mers occur), paired de Bruijn graphs [MeEtal11], and pathset graphs [PhEtal13], attempt to improve the process of resolving repeats.

9. Other modified de Bruijn graphs are used in different problems in bioinformatics, such as RNA assembly [GrEtal11], protein sequencing [BaEtal08], and synteny block reconstructions [PhPe10].

10. Unlike the overlap graphs, these modified de Bruijn graphs are not *read coherent*, meaning that some paths through the graph are not consistent with the reads [My05].

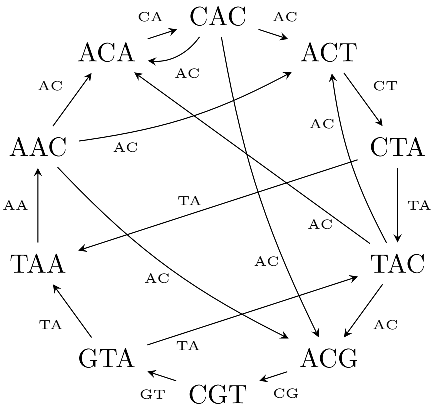
11. de Bruijn graph assemblers perform well when the read length is short. For longer reads (e.g., over 100 bp), overlap graph assemblers perform well [ScDeSa10].

12. When constructing a modified de Bruijn graph, the value of k should be small enough so that nearly all of the k-mers in the genome will be found in the reads. The range $30 \leq k \leq 60$ is common, and these k-mers are found directly from the reads (rather than from hybridization).

13. Overlap graph approaches were used in most first-generation sequencing projects which assembled the the first microbial genome in 1995 [FlEtal95] and the human genome in 2001. However, most Next-Gen assemblers favor de Bruijn graph methods.

Examples:

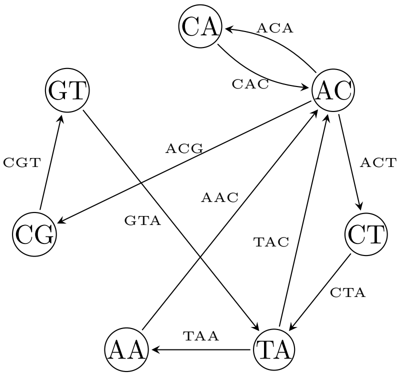
1. Recall Example 4 from §20.4.2, in which shotgun sequencing produced the reads {ACAC, ACGTA, CACTAC, CGTAACA, CTACG} from the (unknown) circular genome CACTACGTAA. The Hamilton de Bruijn graph for $k = 3$ is shown in the following figure.



The target sequence CACTACGTAA is represented in this directed graph by the Hamilton cycle that traverses the vertices in a clockwise order. Note that this directed graph contains other Hamilton cycles such as CAC → ACG → CGT → GTA → TAC → ACT → CTA → TAA → AAC → ACA → CAC, which encodes the alternative target sequence CACGTACTAA. Further sequencing data would then be needed to identify the correct target sequence.

In this example, the coverage of the reads is enough to recover all 3-mers in the original genome. However, removing any read destroys this property, which would change the de Bruijn graph. This highlights the importance of having a sufficiently high coverage so that all (or almost all) of the k-mers appear in at least one of the reads.

2. The next figure displays the Euler de Bruijn graph for the 3-mers present in the reads given in Example 1. The target sequence is represented in this graph by the Euler cycle CA → AC → CT → TA → AC → CG → GT → TA → AA → AC → CA.



Note that this graph supports several Euler cycles representing different target sequences. For example, the Euler cycle CA → AC → CG → GT → TA → AA → AC → CT → TA → AC → CA represents the different circular target sequence CACGTAACTA. Another difficulty arises from repeats: this same Euler de Bruijn graph would also be generated from the circular genome CACACTACGTAA in which CAC and ACA are repeated.

20.5 RNA FOLDING

Deoxyribonucleic acid (DNA) is a double-stranded macromolecule built from four types of nucleotides linked together along a sugar-phosphate backbone that twists into the familiar double-helix shape. Its cousin ribonucleic acid (RNA) is chemically similar but with several important differences: it is single-stranded, and the nucleobase uracil (U) takes the place of thymine (T). Since RNA has only one strand, it can fold and bond to itself. The specific structure into which RNA folds often plays an important role in its function. A central problem in computational biology is to predict how an RNA strand will fold given only its raw sequence of nucleotides. There are two main approaches to the folding prediction problem that both employ dynamic programming: the first attempts to minimize the structure's free energy, and the second generates structures using a context-free grammar and then selects the most likely structure.

20.5.1 BASIC CONCEPTS

Definitions:

A strand of RNA consists of a sequence of four types of ***nucleotides*** distinguished by a nitrogenous ***base*** (adenine (A), cytosine (C), guanine (G), uracil (U)) and connected along a sugar-phosphate backbone.

The carbon atoms in the sugar (ribose) are numbered $1'$ through $5'$ and the $3'$ carbon in each sugar molecule is connected through a phosphate group to a $5'$ carbon of the next sugar molecule. This gives directionality to the RNA chain: a "front" end called the ***5′-end*** and a "back" end called the ***3′-end***.

Adenine and guanine are ***purines***, and cytosine and uracil are ***pyrimidines***.

The RNA strand folds onto itself by a formation of hydrogen bonds between the bases from different nucleotides. Two bases that share a chemical bond are called a ***base pair***.

Facts:

1. The large majority of observed base pairs are either one of the two *Watson-Crick* pairs, AU (two hydrogen bonds) and CG (three hydrogen bonds), or the weaker *wobble pair*, GU (two hydrogen bonds). Other base pairs (e.g., purine-purine and pyrimidine-pyrimidine pairs) are thermodynamically unstable and thus rare.

2. The length of an RNA strand can vary from a few tens to a few thousand nucleotides.

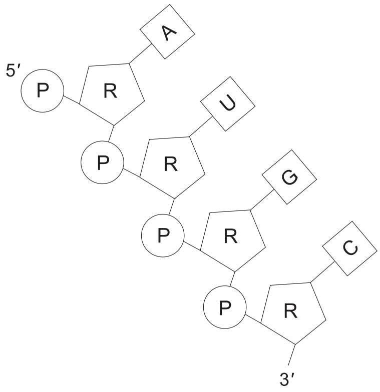
3. The structure of functional RNA has been evolutionary preserved. Therefore, when given a set of homologous RNA sequences (the ones with shared ancestry), a common structure can be found using covariation analysis. Even though highly accurate, this is a manual process that cannot be applied to a single sequence and an important problem in computational biology is the design of an equally accurate prediction method of low computational complexity.

4. There exist viruses whose genetic material consists of RNA instead of DNA (e.g., SARS, polio, ebola, measles, and HIV).

Example:

1. The following figure illustrates the structure of RNA. The four chemical bases (A, U, G, C) are attached to sugar groups (ribose R) on the sugar-phosphate (P) backbone.

The 5′ end is at the upper left and the 3′ end is at the lower right.



20.5.2 COMBINATORIAL MODELS

An RNA structure can be represented by a sequence over a four-letter alphabet with additional information encoding which bases form pairs. These are typically represented by graphs called arc diagrams.

Definitions:

An ***RNA sequence*** is a sequence $\mathbf{b} = b_1b_2 \dots b_n$, where $b_i \in \{\mathrm{A, C, G, U}\}$.

A ***partial matching*** of $V = \{1, \dots, n\}$ is a collection $\{(i_1, j_1), \dots, (i_k, j_k)\}$ of disjoint size-2 subsets of V called ***arcs***.

An ***RNA structure*** is an RNA sequence $\mathbf{b} = b_1b_2 \dots b_n$ along with a partial matching of $V = \{1, \dots, n\}$ which describes the base pairs. Elements in V are called ***nodes*** or ***vertices***.

A canonical way to view an RNA structure is by its ***arc diagram***: draw either $1, \dots, n$ or the sequence of bases horizontally, and then draw each arc (i, j) in the partial matching in the upper-half plane.

The ***length*** of the arc (i, j) is $j - i$. Two arcs (i_1, j_1) and (i_2, j_2) with $i_1 < i_2$ are ***crossing*** if $i_1 < i_2 < j_1 < j_2$. Otherwise, they are ***noncrossing***. These correspond to geometric crossings and noncrossings of arcs in the arc diagram representation of RNA.

If the RNA structure has no crossings then it is called a ***secondary structure***. Otherwise, it is called a ***pseudoknot structure*** [Re10].

A pseudoknot structure is ***k-noncrossing*** if it has no k arcs that are mutually crossing.

A ***stack*** or ***helix*** of size σ is a maximal sequence of ***nested arcs***

$$(i, j), (i + 1, j - 1), \dots, (i + (\sigma - 1), j - (\sigma - 1)) .$$

A node v is ***accessible*** from a base pair (i, j) if $i < v < j$ and there is no base pair (i', j') such that $i < i' < v < j' < j$. A base pair (v, w) is ***accessible*** from (i, j) if both v and w are accessible from it [SaEtal83].

The ***null loop***, or ***0-loop***, of an RNA structure is the set of nodes not accessible from any base pair.

The ***k-loop*** $\mathbf{L}_{i,j}$ closed by (i,j) is the subset of V formed from the $k-1$ base pairs and the isolated bases that are accessible from (i,j). The ***size*** of a loop is the number of isolated bases in it.

1-loops are also called ***hairpin loops*** and k-loops for $k \geq 3$ are termed ***multibranch loops***. There are three types of 2-loops. If (i',j') is the (unique) base pair accessible from (i,j), then the 2-loop closed by (i,j) is a

- ***stacked pair*** if $i'-i=j-j'=1$ (i.e., it has size 0),
- ***bulge loop*** if exactly one of $i'-i$ and $j-j'$ is >1,
- ***internal loop*** if both $i'-i$ and $j-j'$ are >1.

Facts:

1. Base pairs of length 1 are biophysically infeasible. Base pairs of length 2 are thermodynamically unstable and thus very rare. Most combinatorial models require a minimum arc length $\lambda \geq 2$, usually $\lambda = 3$ or $\lambda = 4$.

2. Let $T^{\lambda}(n)$ denote the number of length-n RNA secondary structures with minimum arc length at least λ. There is no known closed formula for $T^{\lambda}(n)$, but it satisfies the following recurrence [Wa78]:

$$T^{\lambda}(n) = T^{\lambda}(n-1) + \textstyle\sum_{k=0}^{n-(\lambda+1)} T^{\lambda}(n-2-k)T^{\lambda}(k).$$

3. The numbers $T^{\lambda}(n)$ grow exponentially in n [StWa79]. For example,

$$T^2(n) \sim \sqrt{\tfrac{15+7\sqrt{5}}{8\pi}}\, n^{-3/2} \left(\tfrac{3+\sqrt{5}}{2}\right)^n .$$

4. There is a bijection between secondary structures (noncrossing partial matchings) of length n and *Motzkin paths* of length n: namely, lattice paths in the plane from $(0,0)$ to $(n,0)$ consisting of three types of steps: $\nearrow$, $\searrow$, and $\longrightarrow$, where each has width 1.

5. The *point-bracket notation* of a size-n RNA secondary structure is a length-n string over the 3-element alphabet $\{\,(,\ \bullet,\ )\,\}$, where the three characters designate left arc endpoint, isolated vertex, and right arc endpoint, respectively. Such a string corresponds to a secondary structure if and only if any initial segment contains at least as many open parentheses as closed ones.

6. RNA secondary structures can also be represented as plane trees in different ways, capturing various degrees of detail of the structure.

7. There is a bijection between k-noncrossing pseudoknot structures and the following combinatorial structures (not defined here, see [ChEtal07]):

- integer lattice walks in $\mathcal{Z}^{k-1}$ that start and end at $(k-1,\ldots,2,1)$ in the fundamental Weyl chamber of type B_{k-1};
- vacillating standard Young tableaux of length n and height less than k.

8. Every RNA secondary structure has a well-defined *loop decomposition* [SaEtal83] of the vertex set into loops:

$$\mathbf{b} = \mathbf{L}_0 \bigcup \left(\textstyle\bigcup_{(i,j)} \mathbf{L}_{i,j} \right),$$

where $\mathbf{L}_0$ is the null loop and the $\mathbf{L}_{i,j}$ are distinct.

9. RNA pseudoknots were not discovered until 1982, when they were observed in the RNA of the turnip yellow mosaic virus [RiEtal82].

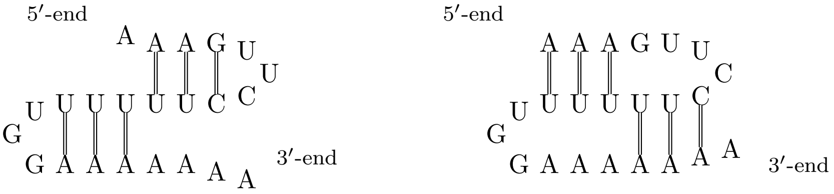
10. A database of hundreds of pseudoknots can be found at [TaEtal09]. Most observed pseudoknots are 3-noncrossing [TaEtal09].

11. The 3-noncrossing pseudoknots are precisely those that can be drawn as noncrossing diagrams, if base pairs are additionally allowed to be drawn as arcs in the lower half-plane.

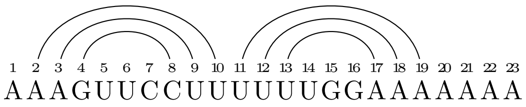
12. An RNA pseudoknot can be naturally associated a topological surface via a *ribbon graph* or *fatgraph* [BoEtal08], [PeEtal10]. This allows pseudoknots to be classified by their genus [AnEtal13].

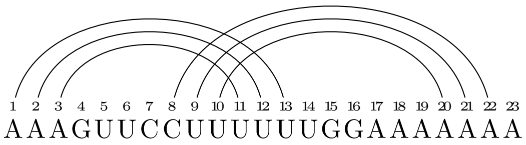
Examples:

1. Two folds of the RNA strand **b** = AAAGUUCCUUUUUUGGAAAAAAA are shown in the following diagram. The RNA structure on the left is a secondary structure because its arc diagram is noncrossing. The RNA structure on the right is a 3-noncrossing pseudoknot.

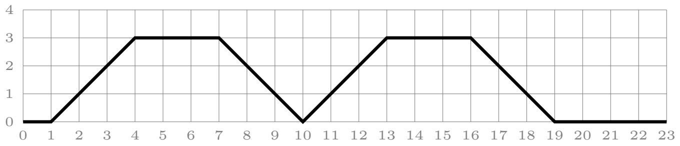


2. The arc diagrams corresponding to the RNA structures in Example 1 are shown next.



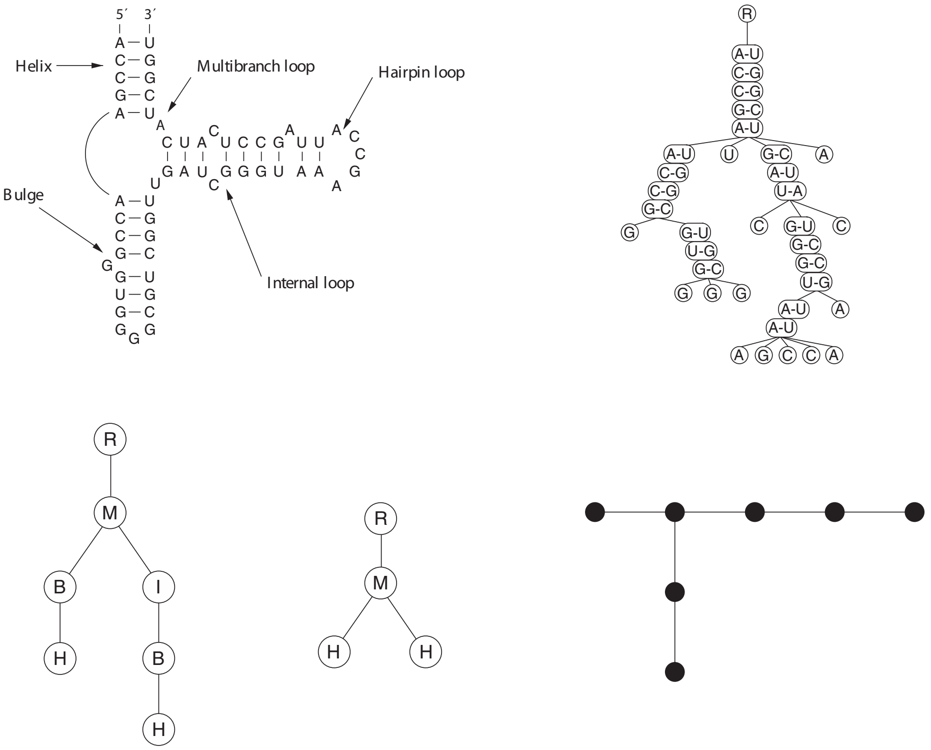


3. The Motzkin path and point-bracket notation of the secondary structure in Example 1 are displayed next.



• (((• • •))) (((• • •))) • • • •

4. The following figure shows an RNA structure with different types of loops together with several of its tree representations, capturing different levels of structural detail.



20.5.3 MINIMAL FREE ENERGY FOLDING ALGORITHMS

In thermodynamics, the *free energy* of a chemical structure is the amount of energy needed to maintain its structural integrity. The lower the free energy the more stable the structure is, whereas a positive free energy means that it would require energy to maintain it. In most thermodynamics models for RNA folding, energy parameters or “scores” are assigned to *substructures* (base pairs, loops, etc.), and the free energy is determined by summing over all of its substructures. Computing the minimum free energy structure of an RNA sequence is a discrete optimization problem.

Definitions:

The ***dynamic programming*** approach to finding the minimal free energy of a secondary structure of $\mathbf{b} = b_1 b_2 \dots b_n$ has two steps:

- ***recursive solution*** of the problem on substrings to find the overall minimal free energy;
- ***traceback***, which recovers a structure that achieves this minimum.

Let $e(i, j)$ be the free energy contribution if i and j were to form a base pair, and let $E(i, j)$ be the minimal energy of the subsequence $\mathbf{b}_{i,j} = b_i b_{i+1} \dots b_j$.

Facts:

1. A simple energy-based RNA folding model that maximizes the number of base pairs was proposed by Nussinov et al. [NuEtal78].

2. A weighted variant of the Nussinov model specifies the free energies $e(i,j)$ using

$$e(i,j) = \begin{cases} -3 & \{b_i, b_j\} = \{\mathrm{C}, \mathrm{G}\}, \qquad i \le j-4 \\ -2 & \{b_i, b_j\} = \{\mathrm{A}, \mathrm{U}\}, \qquad i \le j-4 \\ -1 & \{b_i, b_j\} = \{\mathrm{G}, \mathrm{U}\}, \qquad i \le j-4 \\ 0 & \text{otherwise.} \end{cases}$$

3. In the model specified by Fact 2, the energy scores of -3 and -2 represent the number of hydrogen bonds in the respective base pairs. The energy score -1 represents the two hydrogen bonds appearing in the (less stable) wobble pairs.

4. The $E(i,j)$ can be computed recursively via dynamic programming using

$$E(i,j) = \min \begin{cases} E(i, j-1) \\ \min\limits_{i \le k \le j-4} E(i, k-1) + E(k+1, j-1) + e(k,j). \end{cases}$$

5. The recursion in Fact 4 can be justified as follows. If $i > j-4$ then $E(i,j) = 0$. Otherwise, there are two possibilities for the structure that minimizes the energy: either j is unpaired, in which case there is a secondary structure on $\mathbf{b}_{i,j-1}$, or j is paired with some k, where $i \le k \le j-4$, in which case the noncrossing condition implies that the secondary structure splits into substructures on $\mathbf{b}_{i,k-1}$ and $\mathbf{b}_{k+1,j-1}$. The optimal energy score $E(i,j)$ is the minimum value resulting from these two cases.

6. The value $E(1,n)$ is the minimal free energy of $\mathbf{b} = \mathbf{b}_{1,n}$.

7. The main assumption in the energy-based structure prediction methods is that the RNA sequence folds to a structure that minimizes the free energy.

8. Nussinov's model is overly simplistic. A more complex model for the free energy of secondary structures is proposed in [TiEtal73]. In this model the free energy of a secondary structure is the sum of independent energies for each loop in the structure. The model has evolved substantially over the years and since it assumes that the thermodynamic stability of a base pair is dependent on the identity of the adjacent base pairs, it's known as the *nearest-neighbor thermodynamic model* (NNTM).

9. The free energy of an RNA structure depends primarily on three factors: (i) the helices, or stacks, which are generally stabilizing and contribute negative free energy; (ii) other loops, which are generally destabilizing and contribute positive free energy; and (iii) the surrounding temperature.

10. State-of-the-art models have thousands of experimentally and computationally determined parameters [TuMa10] and require computational resources to run, such as the publicly available UNAFold web server [MaZu08]. Another popular RNA folding program is the Vienna RNA Package [HoEtal94]. These programs, which exclude pseudoknots, can be accessed at

- `http://unafold.rna.albany.edu`
- `http://www.tbi.univie.ac.at/RNA`

11. The theromodynamics of multi-branch loops and pseudoknots is still poorly understood [DiTuMa01], [LyPe00].

12. The accuracy of the NNTM predictions varies widely [RoHe14].

13. Recent work in loop energy estimation ranks substructures more accurately but in ways that are not handled well by dynamic programming [AaNa10], [ZhEtal08].

14. Predicting RNA secondary structures containing pseudoknots of arbitrary types is NP complete for a large class of reasonable free-energy functions [LyPe00]. Energy-based, polynomial time algorithms for prediction of RNA secondary structures have been developed in [Ak00], [RiEd99], [UeEtal99] but each of them allows a restricted class of pseudoknots.

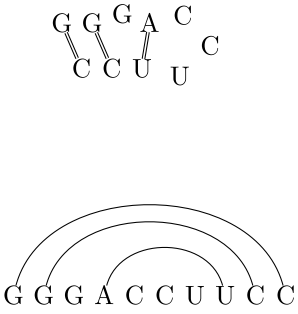
Examples:

1. Consider the sequence $\mathbf{b}$ = GGGACCUUCC. The $e(i,j)$ can be calculated using Fact 2. Namely, $e(1,5) = -3$, $e(1,6) = -3$, $e(2,6) = -3$, $e(1,7) = -1$, $e(2,7) = -1$, $\ldots$, $e(1,10) = -3$, $e(2,10) = -3$, $e(3,10) = -3$, $e(4,10) = 0$, $e(5,10) = 0$, $e(6,10) = 0$.

2. Using the sequence in Example 1, we can recursively calculate the $E(i,j)$ values. For example, $E(1,5) = \min\{E(1,4), E(1,0) + E(2,4) + e(1,5)\} = \min\{0, -3\} = -3$. In a similar way, we determine $E(1,6) = -3$ and $E(2,6) = -3$. Consequently, $E(1,7) = \min\{E(1,6), E(1,0) + E(2,6) + e(1,7), E(1,1) + E(3,6) + e(2,7), E(1,2) + E(4,6) + e(3,7)\} = \min\{-3, -4, -1, -1\} = -4$.

3. The values $E(i,j)$ can be conveniently stored in a table. The following table shows the values of $E(i,j)$ for the sequence $\mathbf{b}$ = GGGACCUUCC.

	G	G	G	A	C	C	U	U	C	C
G	0	0	0	0	−3	−3	−4	−4	−6	−8
G		0	0	0	0	−3	−3	−3	−5	−8
G			0	0	0	0	−1	−2	−5	−5
A				0	0	0	0	−2	−2	−2
C					0	0	0	0	0	0
C						0	0	0	0	0
U							0	0	0	0
U								0	0	0
C									0	0
C										0



$E(\mathbf{b}) = -8$

The minimal free energy is $E(1,10)$, which is the upper-right entry in the table. It is calculated as

$$\begin{aligned} E(1,10) &= \min\{E(1,9),\, E(1,0) + E(2,9) + e(1,10),\, E(1,1) + E(3,9) + e(2,10), \\ &\qquad E(1,2) + E(4,9) + e(3,10),\, E(1,3) + E(5,9) + e(4,10), \\ &\qquad E(1,4) + E(6,9) + e(5,10),\, E(1,5) + E(7,9) + e(6,10)\} \\ &= \min\{-6, -8, -8, -5, 0, 0, -3\} = -8. \end{aligned}$$

The actual RNA structure can be recovered by the dynamic programming traceback step: start by circling the $E(1,10)$ entry, then circle a value that could have preceded it in the recursive step, and repeat until a value of 0 is reached. The base pairs can be recovered from the "jumps" in the circled values. One RNA structure achieving this minimum energy is shown in the preceding figure.

20.5.4 LANGUAGE-THEORETIC METHODS

Formal language theory arose in the field of linguistics, in an attempt to understand the syntactic structure and evolution of natural languages. Since the 1950s, it has been applied to genetics, because DNA and RNA sequences can be viewed as languages over a four-letter alphabet.

Definitions:

A ***language*** is a set of (finite) strings over an alphabet Σ of ***terminal symbols***.

A ***grammar*** is a collection of production rules for strings in a given language that dictates how temporary ***nonterminal symbols*** can be rewritten into strings of terminal symbols, along with a distinguished ***start symbol*** S.

A ***derivation*** of a string α is a sequence of production rules transforming S into α.

A ***context-free grammar*** (***CFG***) is a grammar in which every production rule is of the form $V \to \alpha$, where V is a nonterminal symbol and α is a string of terminal and/or nonterminal symbols.

A ***stochastic context-free grammar*** (***SCFG***) assigns probabilities to the production rules, so that for each nonterminal symbol V, the probabilities $Pr(V \to \alpha_i)$ taken over all α_i sum to 1.

The ***Knudsen-Hein grammar*** [KnHe99] is an SCFG for RNA folding defined as follows, where $p_i + q_i = 1$ for each $i = 1, 2, 3$.

production	probability	production	probability
$S \to LS$	p_1	$S \to L$	q_1
$L \to dFd'$	p_2	$L \to s$	q_2
$F \to dFd'$	p_3	$F \to LS$	q_3

Each string in the resulting language corresponds to a secondary structure with minimal arc length 3. The terminals s, d, d' represent an isolated nucleotide, a left base pair end, and a right base pair end, respectively. The nonterminals L and F create loops and helices, respectively.

The ***probability of a derivation*** is the product of the probabilities of each individual rule used and the ***probability of a structure*** is the sum of all left-to-right derivations that yield that structure.

Facts:

1. The most restrictive class of grammars in the Chomsky hierarchy is the class of *regular grammars*. These can be used to generate RNA sequences but not RNA structures.

2. The location of terminal symbols in regular languages is uncorrelated. Long distance pairwise correlations between nucleotides in a sequence can be modeled by CFGs but not by regular grammars. Therefore, CFGs are generally used for RNA structure prediction algorithms.

3. Probabilistic modeling approaches for RNA secondary structure prediction using SCFGs were first introduced in the 1990s [SaEtal94].

4. The unknown probability parameters in an SCFG can be estimated using “training algorithms” such as the *inside-outside algorithm* [Ba79], [LaYo90].

5. The Cocke-Younger-Kasami algorithm finds the probability of the most likely secondary structure for a given RNA sequence. A traceback procedure can be used to recover a structure that achieves this maximum probability [DuEtal98].

6. The Knudsen-Hein grammar is used in the secondary structure prediction software Pfold [KnHe03]. This method predicts a structure for a set of aligned sequences. Predictions can be done on a web server at

- `http://www.daimi.au.dk/~compbio/pfold`

7. The Knudsen-Hein grammar was compared to eight other grammars in [DoEd04], and was shown to perform at least as well as more complicated grammars.

8. It has been shown that the number of different motifs (base pairs, helices, hairpin loops, internal loops, etc.) is normally distributed among structures generated by the Knudsen-Hein grammar [HePo14].

9. A topological approach to fold RNA pseudoknots with an SCFG has been proposed [ReEtal11]; citations within this work refer to other language-theoretic approaches that include pseudoknots.

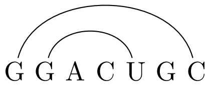
Example:

1. The unique left-to-right derivation of the structure $\mathcal{S}$ for $\mathbf{b}$ = GGACUGC is

$$S \overset{q_1}{\Longrightarrow} L \overset{p_2}{\Longrightarrow} dFd' \overset{q_3}{\Longrightarrow} dLSd' \overset{p_2}{\Longrightarrow} ddFd'Sd' \overset{q_3}{\Longrightarrow} ddLSd'Sd' \overset{q_2}{\Longrightarrow} ddsSd'Sd'$$
$$\overset{q_1}{\Longrightarrow} ddsLd'Sd' \overset{q_2}{\Longrightarrow} ddssd'Sd' \overset{q_1}{\Longrightarrow} ddssd'Ld' \overset{q_2}{\Longrightarrow} ddssd'sd'$$

and therefore $Pr(\mathcal{S}) = p_2^2 q_1^3 q_2^3 q_3^2$.

From the string $\alpha = ddssd'sd'$ we infer the following RNA structure



20.6 COMBINATORIAL NEURAL CODES

Neural codes are the brain's way of representing, transmitting, and storing information about the world. Combinatorial neural codes are based on binary patterns of neural activity, as opposed to the precise timing or rate of neural activity. The structure of a combinatorial code may reflect important aspects of the represented stimuli or network architecture. Combinatorial codes can be analyzed using an algebraic object called the neural ring.

20.6.1 BASIC CONCEPTS

From simultaneous recordings of neurons in the brain we can infer which subsets of neurons tend to fire together. This information is captured by a combinatorial code.

Definitions:

The set of neurons is denoted by $[n] = \{1, \ldots, n\}$.

An ***action potential***, or ***spike***, is an electrical event in a single neuron. This is the fundamental unit of neural activity. We say that a neuron "fires" action potentials, or spikes.

A ***spike train*** is a sequence of spike times for a single neuron. This captures the electrical activity of the neuron over time.

A ***codeword*** is a string of 0s and 1s, with a 1 for each active neuron and a 0 denoting silence; equivalently, it is a subset $\sigma \subseteq [n]$ of (active) neurons firing together. For example, if $n = 6$ the subset $\sigma = \{145\} \subseteq [6]$ is also denoted 100110.

A ***combinatorial neural code*** is a collection of codewords $\mathcal{C} \subseteq 2^{[n]}$. In other words, it is a binary code of length n, where each binary digit is interpreted as the "on" or "off" state of a neuron.

A ***maximal codeword*** is a codeword that is maximal in the code under inclusion. If $\sigma \in \mathcal{C}$ is maximal, then there is no $\tau \in \mathcal{C}$ such that $\tau \supsetneq \sigma$.

An ***abstract simplicial complex*** $\Delta \subseteq 2^{[n]}$ is a collection of subsets of $[n]$ that is closed under inclusion (see §16.6.1). That is, if $\sigma \in \Delta$ and $\tau \subset \sigma$, then $\tau \in \Delta$. A ***facet*** of Δ is an element of Δ that is maximal under inclusion.

The ***simplicial complex of a code***, $\Delta(\mathcal{C})$, is the smallest abstract simplicial complex on $[n]$ that contains all elements of $\mathcal{C}$:

$$\Delta(\mathcal{C}) = \{\sigma \subseteq [n] \mid \sigma \subseteq \tau \text{ for some } \tau \in \mathcal{C}\}.$$

Facts:

1. Spikes (action potentials) are all-or-none electrical events. It thus suffices to keep track only of the spike times, as in a spike train.

2. Most combinatorial neural codes appear ill-suited for error correction [CuEtal13a].

3. Simplicial complexes are heavily-studied objects in topology and algebraic combinatorics.

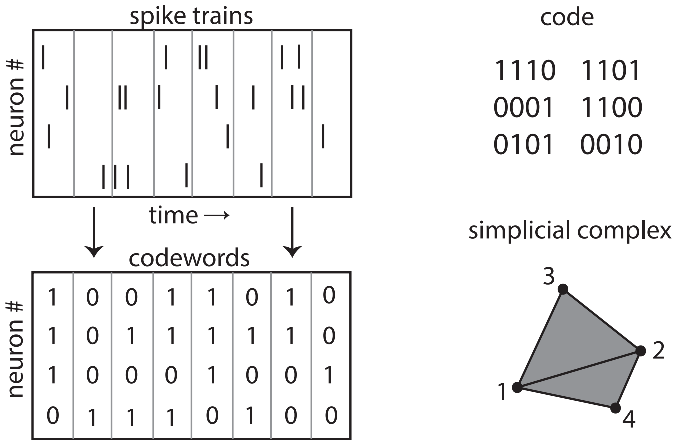
4. Each facet of $\Delta(\mathcal{C})$ corresponds to a maximal codeword of $\mathcal{C}$.

5. The simplicial complex $\Delta(\mathcal{C})$ is useful for analyzing a code, but discards important information. All codes with the same maximal codewords have the same simplicial complex.

6. Manin [Ma15] provides an historical overview contrasting neural codes with error-correcting codes and cryptography.

Example:

1. Combinatorial codes can be obtained from neural data by temporally binning the spikes into patterns of 0s and 1s. The following figure depicts a set of binned spike trains and the resulting codewords. The set of unique codewords is the code $\mathcal{C}$. The simplicial complex $\Delta(\mathcal{C})$ has facets corresponding to the two maximal codewords, 1110 and 1101.



1	0	0	1	1	0	1	0
1	0	1	1	1	1	1	0
1	0	0	0	1	0	0	1
0	1	1	1	0	1	0	0

1110 1101
0001 1100
0101 0010

20.6.2 THE CODE OF A COVER

An important type of combinatorial neural code is one defined by an arrangement of open sets in Euclidean space. The open sets correspond to receptive fields.

Definitions:

A ***stimulus space*** X is a parametric space of stimuli. The stimuli could be sensory, such as visual, auditory, or olfactory signals, or higher-level, such as an animal's position in space. Typically, a stimulus space is modeled as a subset of Euclidean space, $X \subseteq \mathcal{R}^d$.

A ***receptive field*** is a subset $U_i \subseteq X$ of the stimulus space corresponding to a single neuron i. The stimuli in U_i induce neuron i to fire.

A subset $V \subseteq \mathcal{R}^n$ is ***convex*** if, given any pair of points $x, y \in V$, the point $z = tx+(1-t)y$ is contained in V for any $t \in [0,1]$.

Convex receptive fields are convex subsets $U_i \subseteq X$.

A collection of open sets $\mathcal{U} = \{U_1, \ldots, U_n\}$ is an ***open cover*** of their union $\bigcup_{i=1}^n U_i$.

$\mathcal{U}$ is a ***good cover*** if every nonempty intersection $\bigcap_{i\in\sigma} U_i$ is contractible (that is, if it can be continuously shrunk to a point).

The ***nerve*** of an open cover $\mathcal{U}$ is the simplicial complex

$$\mathcal{N}(\mathcal{U}) = \{\sigma \subseteq [n] \mid \bigcap_{i\in\sigma} U_i \neq \emptyset\}.$$

Given an open cover $\mathcal{U}$, the ***code of the cover*** is the combinatorial neural code

$$\mathcal{C}(\mathcal{U}) = \{\sigma \subseteq [n] \mid \bigcap_{i\in\sigma} U_i \setminus \bigcup_{j\in[n]\setminus\sigma} U_j \neq \emptyset\}.$$

Facts:

1. Neurons in many brain areas, such as sensory cortices and the hippocampus, have activity patterns that can be characterized by receptive fields.

2. Receptive fields are computed experimentally by correlating neural responses to independently measured external stimuli.

3. Intersections of convex sets are always convex, and all convex sets are contractible. Thus, any open cover consisting of convex sets is a good cover.

4. Each codeword in $\mathcal{C}(\mathcal{U})$ corresponds to a region that is defined by the intersections of the open sets in $\mathcal{U}$ [CuEtal13b].

5. If $\mathcal{U}$ is an open cover, then $\mathcal{C}(\mathcal{U}) \subseteq \mathcal{N}(\mathcal{U})$ and $\Delta(\mathcal{C}(\mathcal{U})) = \mathcal{N}(U)$. The nerve of the cover can thus be recovered from the code by completing it to a simplicial complex, but the code contains additional information about $\mathcal{U}$ that is not captured by the nerve alone.

6. *Nerve lemma*: If $\mathcal{U}$ is a good cover, then the covered space $Y = \bigcup_{i=1}^{n} U_i$ is homotopy-equivalent to $\mathcal{N}(\mathcal{U})$. In particular, Y and $\mathcal{N}(\mathcal{U})$ have exactly the same homology groups.

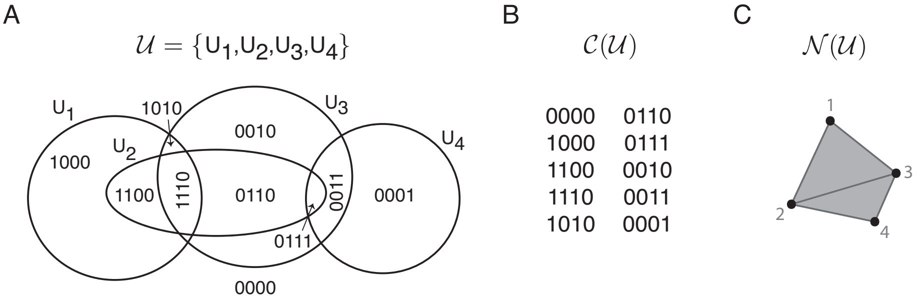
7. *Helly's theorem*: Consider k convex subsets $U_1, \ldots, U_k \subseteq \mathcal{R}^d$, for $d < k$. If the intersection of every $d+1$ of these sets is nonempty, then the full intersection $\bigcap_{i=1}^{k} U_i$ is also nonempty.

8. In addition to Helly's theorem and the Nerve lemma, there is a great deal known about $\mathcal{N}(\mathcal{U})$ for collections of convex sets in $\mathcal{R}^d$. In particular, the f-vectors of such simplicial complexes have been completely characterized by G. Kalai [Ka84], [Ka86].

9. The Nerve lemma has been exploited in the context of two-dimensional place field codes to show that topological features of an animal's environment could be inferred from neural codes representing position in the hippocampus [CuIt08].

Example:

1. The following figure, adapted from [CuEtal15], depicts an open cover consisting of four convex sets (A) as well as the corresponding code (B). The nerve of the cover (C) is identical to the simplicial complex $\Delta(\mathcal{C})$.



20.6.3 THE NEURAL RING AND IDEAL

The structure of a combinatorial code can be analyzed using the neural ring and ideal. These are algebraic objects that keep track of the combinatorics of the code, much as the Stanley-Reisner ring and ideal encode a simplicial complex [MiSt05]. For more details, see [CuEtal13b].

Definitions:

$\mathcal{F}_2$ is the field with two elements $\{0,1\}$. We can regard a codeword on n neurons as an element of $\mathcal{F}_2^n$ and a combinatorial neural code as a subset $\mathcal{C} \subseteq \mathcal{F}_2^n$.

$\mathcal{F}_2[x_1, \ldots, x_n]$ is a polynomial ring with coefficients in $\mathcal{F}_2$.

The ***ideal*** $\boldsymbol{I_{\mathcal{C}}}$ is the set of polynomials that vanish on all codewords in $\mathcal{C}$:

$$I_{\mathcal{C}} = I(\mathcal{C}) = \{f \in \mathcal{F}_2[x_1, \ldots, x_n] \mid f(c) = 0 \text{ for all } c \in \mathcal{C}\}.$$

The ***neural ring*** $\boldsymbol{R_{\mathcal{C}}}$ is the quotient ring

$$R_{\mathcal{C}} = \mathcal{F}_2[x_1, \ldots, x_n]/I_{\mathcal{C}}.$$

A ***pseudo-monomial*** is a polynomial $f \in \mathcal{F}_2[x_1, \ldots, x_n]$ that can be written as

$$f = \prod_{i\in\sigma} x_i \prod_{j\in\tau}(1 - x_j),$$

where $\sigma, \tau \subseteq [n]$ satisfy $\sigma \cap \tau = \emptyset$.

For any binary string $v \in \mathcal{F}_2^n$, the ***indicator function***

$$\chi_v = \prod_{\{i|v_i=1\}} x_i \prod_{\{j|v_j=0\}} (1 - x_j)$$

is a pseudo-monomial with the property that $\chi_v(v) = 1$ and $\chi_v(c) = 0$ for any $c \neq v$.

The ***neural ideal*** $\boldsymbol{J_{\mathcal{C}}}$ is generated by the indicator functions of all non-codewords:

$$J_{\mathcal{C}} = \langle \chi_\nu \mid \nu \in \mathcal{F}_2^n \setminus \mathcal{C}\rangle.$$

A pseudo-monomial $f \in J_{\mathcal{C}}$ is called ***minimal*** if there does not exist another pseudo-monomial $g \in J_{\mathcal{C}}$ with $\deg(g) < \deg(f)$ such that $f = hg$ for some $h \in \mathcal{F}_2[x_1, \ldots, x_n]$.

The ***canonical form*** of $J_{\mathcal{C}}$ is the set of all minimal pseudo-monomials:

$$\mathrm{CF}(J_{\mathcal{C}}) = \{f \in J_{\mathcal{C}} \mid f \text{ is a minimal pseudo-monomial}\}.$$

Facts:

1. A polynomial $f \in \mathcal{F}_2[x_1, \ldots, x_n]$ can be evaluated on a binary string of length n (such as a codeword) by simply replacing each indeterminate x_i with the 0/1 value of the i^{th} position in the string. For example, if $f = x_1x_3(1 - x_2) \in \mathcal{F}_2[x_1, \ldots, x_4]$, then $f(1011) = 1$ and $f(1100) = 0$.

2. Irrespective of $\mathcal{C}$, the ideal $I_{\mathcal{C}}$ always contains the relations $\mathcal{B} = \langle x_1^2 - x_1, \ldots, x_n^2 - x_n\rangle$, due to the binary nature of codewords.

3. The ideals $I_{\mathcal{C}}$ and $J_{\mathcal{C}}$ carry all the combinatorial information about the code $\mathcal{C}$. They are closely related: $I_{\mathcal{C}} = J_{\mathcal{C}} + \mathcal{B}$.

4. *Fundamental lemma*: Let $\mathcal{C} \subseteq \{0,1\}^n$ be a neural code, and let $\mathcal{U} = \{U_1, \ldots, U_n\}$ be any collection of open sets (not necessarily convex) such that $\mathcal{C} = \mathcal{C}(\mathcal{U})$. Then, for any pair of subsets $\sigma, \tau \subseteq [n]$,

$$\prod_{i\in\sigma} x_i \prod_{j\in\tau}(1 - x_j) \in I_{\mathcal{C}} \;\Leftrightarrow\; \bigcap_{i\in\sigma} U_i \subseteq \bigcup_{j\in\tau} U_j.$$

5. The canonical form is a special basis, similar to a Grobner basis but tailored to a different purpose. From the canonical form one can read off minimal relationships between receptive fields.

6. The canonical form $\mathrm{CF}(J_{\mathcal{C}})$ can be computed algorithmically, starting from the code $\mathcal{C}$. In [CuEtal13b, Section 4.5], one such algorithm is described that uses the primary decomposition of pseudo-monomial ideals. This algorithm has since been improved [CuYo15], and software for computing $\mathrm{CF}(J_{\mathcal{C}})$ is publicly available at

- `https://github.com/nebneuron/neural-ideal`

Examples:

1. The code $\mathcal{C}(\mathcal{U})$ shown in panel (B) of §20.6.2, Example 1 has ten codewords and six non-codewords: $0100, 1001, 0101, 1101, 1011$, and 1111. The neural ideal is

$$\begin{aligned} J_{\mathcal{C}} &= \langle x_2(1-x_1)(1-x_3)(1-x_4),\ x_1x_4(1-x_2)(1-x_3),\ x_2x_4(1-x_1)(1-x_3), \\ &\quad x_1x_2x_4(1-x_3),\ x_1x_3x_4(1-x_2),\ x_1x_2x_3x_4\rangle. \end{aligned}$$

The canonical form is

$$\mathrm{CF}(J_{\mathcal{C}}) = \{x_1x_4, x_2(1-x_1)(1-x_3),\ x_2x_4(1-x_3)\}.$$

Using the fundamental lemma, we can read off the following receptive field relationships: $U_1 \cap U_4 = \emptyset$, $U_2 \subseteq U_1 \cup U_3$, and $U_2 \cap U_4 \subseteq U_3$. This is consistent with the original arrangement of open sets shown in panel (A) of §20.6.2, Example 1.

2. The code $\mathcal{C} = \{111, 011, 001, 000\}$ on three neurons has the canonical form $\mathrm{CF}(J_{\mathcal{C}}) = \{x_1(1-x_2), x_1(1-x_3), x_2(1-x_3)\}$. This indicates that $U_1 \subseteq U_2$, $U_1 \subseteq U_3$, and $U_2 \subseteq U_3$.

20.6.4 CONVEX CODES

Definitions:

Let $\mathcal{C}$ be a combinatorial neural code on n neurons.

If there exists an open cover $\mathcal{U} = \{U_1, \ldots, U_n\}$ such that $\mathcal{C} = \mathcal{C}(\mathcal{U})$ and each U_i is a convex open subset of $\mathcal{R}^d$, then $\mathcal{C}$ is a ***convex code***.

The ***minimum embedding dimension*** $d(\mathcal{C})$ of a convex code is the minimum dimension such that $\mathcal{C}$ admits a convex representation.

A code $\mathcal{C} = \mathcal{C}(\mathcal{U})$ has a ***local obstruction*** if there exists a nonempty intersection $U_\sigma = \bigcap_{i\in\sigma} U_i$ such that $U_\sigma \subseteq \bigcup_{i\in\tau} U_i$, but the nerve of the cover $\{U_i \cap U_\sigma\}_{i\in\tau}$ is *not* contractible.

Facts:

1. Convex codes have been observed in several brain areas. Orientation-selective neurons in the visual cortex [BeBaSo95] have convex receptive fields that reflect a neuron's preference for a particular angle. Hippocampal place cells [McNEtal06], [OKDo71] are neurons that have spatial receptive fields, called *place fields*, that are typically convex.

2. If $\mathcal{C}$ has a local obstruction, then $\mathcal{C}$ is not a convex code.

3. All codes on $n \leq 2$ neurons are convex.

4. For $n \leq 3$ there are six non-convex codes (up to permutation-equivalence, including the all-zeros word): namely, $\{000, 010, 001, 110, 101\}$, $\{000, 010, 110, 101\}$, $\{000, 110, 101\}$, $\{000, 100, 010, 110, 101, 011\}$, $\{000, 100, 110, 101, 011\}$, $\{000, 110, 101, 011\}$.

Examples:

1. The code $\mathcal{C} = \mathcal{C}(\mathcal{U})$ shown in panel (B) of §20.6.2, Example 1 is convex by construction. Panel (A) shows a two-dimensional convex realization. The minimum embedding dimension for this code is $d(\mathcal{C}) = 2$.

2. Consider the code $\hat{\mathcal{C}} = \mathcal{C} \setminus \{0110\}$, where $\mathcal{C}$ is the code in Example 1. Code $\hat{\mathcal{C}}$ differs from $\mathcal{C}$ by only one codeword and has the same simplicial complex $\Delta(\hat{\mathcal{C}}) = \Delta(\mathcal{C})$. However, $\hat{\mathcal{C}}$ is not a convex code. It has a local obstruction because $U_2 \cap U_3 \subseteq U_1 \cup U_4$, yet the nerve of the cover of $U_\sigma = U_2 \cap U_3$ by $U_1 \cap U_\sigma$ and $U_4 \cap U_\sigma$ is disconnected, and thus not contractible.

3. The codes $\mathcal{C}_1 = \{111, 011, 001\}$ and $\mathcal{C}_2 = \{111, 101, 011, 110, 100, 010\}$ are both convex and have the same simplicial complex, but possess different embedding dimensions: $d(\mathcal{C}_1) = 1$, while $d(\mathcal{C}_2) = 2$.

Open Questions:

1. How do we determine, in general, whether or not a code is convex?

2. Are there other obstructions to convexity beyond local obstructions?

3. If a code is convex, what is the minimum embedding dimension?

20.6.5 FEEDFORWARD AND HYPERPLANE CODES

Hyperplane codes are an important class of combinatorial codes. These are codes that arise as an output of a one-layer feedforward neural network, and they are sometimes referred to as *feedforward codes*.

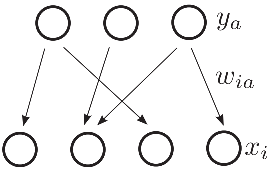
Definitions:

A ***hyperplane code*** is a convex code, where the underlying open convex cover $\mathcal{U} = \{U_i\}_{i=1}^n$ can be obtained as $U_i = X \cap H_i^+$, where $X \subseteq \mathcal{R}^m$ is an open convex set and the

$$H_i^+ = \{y \in \mathcal{R}^m \mid \sum_{a=1}^{m} w_{ia} y_a - \theta_i > 0\} \tag{3}$$

are open half-spaces.

A ***one-layer feedforward neural network*** is a network with input and output layers connected as shown in the following figure.



The network inputs nonnegative numbers $y_a \geq 0$ and outputs nonnegative numbers $x_i \geq 0$ according to the rule

$$x_i(y) = \phi\left(\sum_{a=1}^{m} w_{ia} y_a - \theta_i\right), \qquad i \in [n]. \tag{4}$$

Here $\theta_i \in \mathcal{R}$ are the neuronal thresholds, $w_{ia} \in \mathcal{R}$ are the effective strengths of the feedforward connections, and the ***transfer function*** $\phi\colon \mathcal{R} \to \mathcal{R}_{>0}$ satisfies the condition $\phi(t) = 0$ if $t \leq 0$ and $\phi(t) > 0$ if $t > 0$.

A ***feedforward code*** is a hyperplane code, where the underlying convex set X can be chosen to be the positive orthant $\mathcal{R}_+^m$. This class of codes arises as the output of a one-layer feedforward neural network (4), where positivity of each row of (4) corresponds to the halfspace H_i^+ in (3). Specifically the code of the network (4) is

$$\mathcal{C}(w, \theta) = \left\{\sigma \subseteq [n] \mid \exists y \in \mathcal{R}_+^m \text{ such that } x_i(y) > 0 \Leftrightarrow i \in \sigma\right\}.$$

Facts:

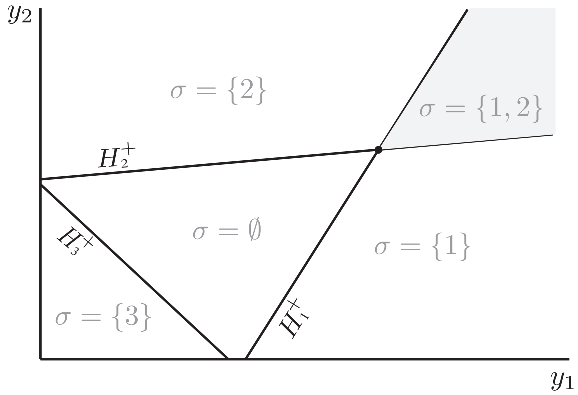
1. Hyperplane codes (and thus feedforward codes) are convex.

2. Not every convex code is a hyperplane code. Perhaps the smallest example is the code $\mathcal{C} = \{\varnothing, 2, 3, 4, 12, 13, 14, 123, 124\}$, which can be easily seen to possess a 2-dimensional convex realization. However, it can be proved to be not realizable as a hyperplane code.

3. *Theorem* [GiIt14]: For every simplicial complex K with n vertices, there exists a feedforward network (w, θ) described by (4) so that K is the simplicial complex of the appropriate feedforward code $K = \Delta(\mathcal{C}(w, \theta))$.

Example:

1. The following figure, adapted from [GiIt14], displays a feedforward code for a network with two neurons in the input layer, corresponding to the axes y_1 and y_2, and three neurons in the output layer, corresponding to the (oriented) hyperplanes H_1, H_2, and H_3. For each output neuron x_i, the inputs $y = (y_1, y_2)$ that yield $x_i(y) > 0$ lie in the positive halfspace H_i^+. The resulting code $\mathcal{C}$ consists of combinations of output neurons that can be simultaneously activated by at least one choice of nonnegative inputs.



$$\begin{aligned}\mathcal{C} &= \{\varnothing, \{1\}, \{2\}, \{3\}, \{1, 2\}\}\\ &= \{000, 100, 010, 001, 110\}\end{aligned}$$

20.7 FOOD WEBS AND GRAPHS

The study of food webs has occurred over the last fifty years, primarily undertaken by ecologists working in natural habitats. Mathematicians subsequently became interested in the graph-theoretical properties of food webs and their corresponding competition graphs. This section introduces food webs, together with associated graphs and parameters that play an important role in linking mathematics and ecology.

20.7.1 MODELING PREDATOR-PREY RELATIONSHIPS WITH FOOD WEBS

Food webs, through both direct and indirect interactions, describe the flow of energy through an ecosystem, moving from one organism to another. Understanding food webs can help to predict how important any given species is, and how ecosystems change with the addition of a new species or removal of an existing species.

Definitions:

A ***food web*** is represented by a directed graph (digraph) $D = (V, A)$ with vertex set V and arc set A. Each vertex represents a species in the ecosystem and the arc (x, y) is directed from a prey species x to a predator y of that prey.

A ***basal species*** is one that does not depend for food on any other organism in the ecosystem. That is, these are species located at the bottom of the food web.

Facts:

1. In the early 1960s, when food webs were first used to model predator-prey relationships, arcs were directed from predator to prey. The current usage, which tracks the flow of energy from prey to predator, reverses this earlier convention.

2. The interactions of species as they attempt to acquire food determine much of the structure of a community. Food webs represent these feeding relationships within a community.

3. Basal species correspond to vertices with no incoming arcs: vertices with *indegree* 0. Species at the top of the food web correspond to vertices with *outdegree* 0.

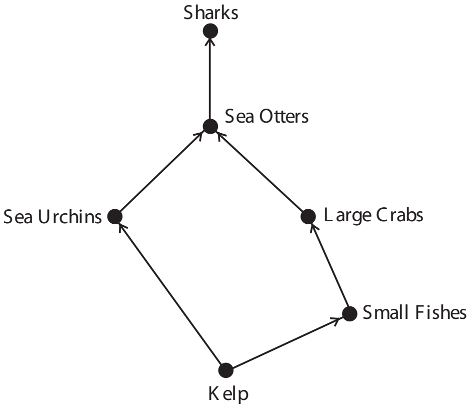
4. The digraph of a food web contains no directed cycles (since a species does not prey upon itself, either directly or indirectly).

5. Various online tools can be used to construct food webs from ecological data, such as

- `http://bioquest.org/esteem`

Examples:

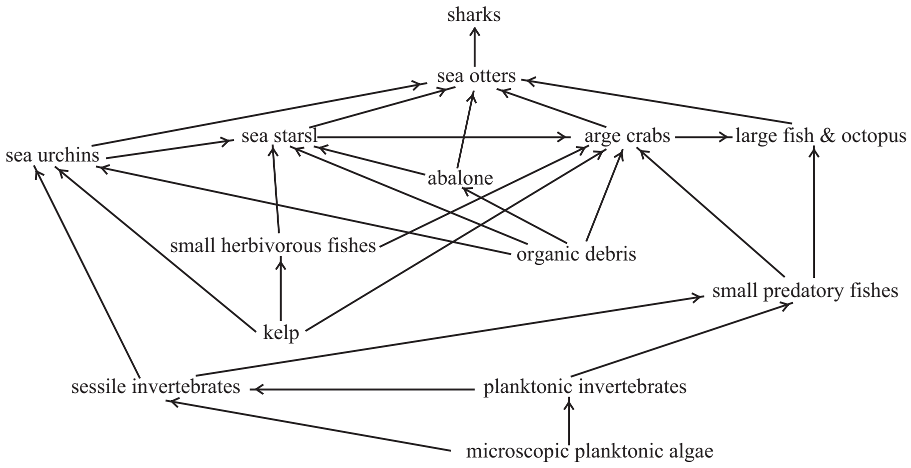
1. The following figure depicts a food web in which sharks eat sea otters, sea otters eat sea urchins and large crabs, large crabs eat small fishes, and sea urchins and small fishes eat kelp. Equivalently, sea urchins and large crabs are eaten by sea otters (both are prey for sea otters) and sea otters are prey for sharks. Kelp is the only basal species, whereas sharks are at the top of this food web.



2. A larger food web is defined by the following predator-prey relationships.

species	*species they feed on*
sharks	sea otters
sea otters	sea stars, sea urchins, large fish & octopus, large crabs, abalone
sea stars	abalone, small herbivorous fishes, sea urchins, organic debris
sea urchins	kelp, sessile invertebrates, organic debris
abalone	organic debris
large crabs	sea stars, small predatory fishes, organic debris, small herbivorous fishes, kelp
small predatory fishes	sessile invertebrates, planktonic invertebrates
small herbivorous fishes	kelp
large fish & octopus	large crabs, small predatory fishes
sessile invertebrates	microscopic planktonic algae, planktonic invertebrates
planktonic invertebrates	microscopic planktonic algae

From these relationships, the following food web can be constructed. The basal species are seen to be kelp, organic debris, and microscopic planktonic algae. Sharks are the only species at the top of this food web.



20.7.2 TROPHIC LEVEL AND TROPHIC STATUS

Trophic levels in food webs provide a way of organizing species in a community food web into feeding groups. Scientists have used various measures to classify species in a food web into these various feeding groups, typically based on the positioning of species in the food web.

Definitions:

The ***length*** of a path in a directed graph (digraph) D is the number of arcs in the path.

A ***shortest path*** between vertices x and y in D has the smallest length of any path from x to y; this shortest path length is denoted $d(x, y)$.

A ***longest path*** between vertices x and y in D has the largest length of any path from x to y; this longest path length is denoted $D(x,y)$.

Notation: We write $u \prec v$ if species v consumes species u, either directly or indirectly.

The ***trophic level*** (option 1) $TL_1(x)$ of species x is defined to be 0 if x is a basal species. Otherwise, it is the smallest length of a path to x from any basal species that x consumes, either directly or indirectly: $TL_1(x) = \min\{d(y,x) : y \prec x, \text{and } y \text{ is basal}\}$.

The ***trophic level*** (option 2) $TL_2(x)$ of species x is defined to be 0 if x is a basal species. Otherwise, it is the largest length of a path to x from any basal species that x consumes, either directly or indirectly: $TL_2(x) = \max\{D(y,x) : y \prec x, \text{and } y \text{ is basal}\}$.

The ***trophic status*** $TS(x)$ of species x is defined to be 0 if x is a basal species. Otherwise, it is given by $TS(x) = \sum\{D(y,x) : y \prec x\}$.

Species v is called ***dominant*** if there exists an arc (u,v), whose removal from the food web allows u to have uncontrolled growth, and thus become a new "dominant" species.

A species is ***trophic status dominant*** if its trophic status is greater than the number of non-basal species in the food web.

Facts:

1. Since the digraph D corresponding to a food web is acyclic, the longest path length $D(x,y)$ between any two vertices is well defined and finite.

2. The trophic level $TL_1(x)$ can be calculated recursively as follows:

$$TL_1(x) = 1 + \min\{TL_1(y) : (y,x) \in A\}, \text{ where } TL_1(x) = 0 \text{ if } x \text{ is a basal species.}$$

3. The trophic level $TL_2(x)$ can be calculated recursively as follows:

$$TL_2(x) = 1 + \max\{TL_2(y) : (y,x) \in A\}, \text{ where } TL_2(x) = 0 \text{ if } x \text{ is a basal species.}$$

4. $TL_2(x) \geq TL_1(x)$ holds for any species x in a food web.

5. Neither of the trophic level definitions TL_1 or TL_2 is entirely satisfactory in determining the hierarchical structure of a food web. For instance, neither definition reflects the number of species that are direct or indirect prey of a species.

6. A reasonable property is that if species x is a predator of species y, then the trophic level of species x is greater than the trophic level of species y. This property is satisfied by TL_2 and TS, but not by TL_1.

7. High trophic status of a species means that there are many paths of various lengths that reach that species in the food web, so the loss of any one path is inconsequential.

8. If vertex u has only one outgoing arc (u,v), then v is dominant. Such a vertex u therefore has outdegree 1.

9. The concept of trophic status dominance incorporates both the number of species that are direct or indirect prey and the extent of energy transfer, based on the trophic status of the species. This definition resembles the definition of status for people in a community or social network. In a social network, the status of person A is determined by the number of people who can reach A and the (worst-case) lengths of paths to A.

Examples:

1. The trophic level (option 1) values for Example 1 of §20.7.1 are computed as follows: $TL_1(\text{kelp}) = 0$; $TL_1(\text{sea urchins}) = TL_1(\text{small fishes}) = 1$; $TL_1(\text{large crabs}) = TL_1(\text{sea otters}) = 2$; $TL_1(\text{sharks}) = 3$. Notice that from Fact 2, we have $TL_1(\text{sea otters}) = 1 + \min\{TL_1(\text{sea urchins}), TL_1(\text{large crabs})\} = 1 + \min\{1, 2\} = 2$.

2. The trophic level (option 1) values for Example 2 of §20.7.1 are as follows: $TL_1(\text{kelp}) = TL_1(\text{organic debris}) = TL_1(\text{microscopic planktonic algae}) = 0$; $TL_1(\text{abalone}) = TL_1(\text{sea stars}) = TL_1(\text{sea urchins}) = TL_1(\text{large crabs}) = TL_1(\text{small herbivorous fishes}) = TL_1(\text{ sessile invertebrates}) = TL_1(\text{planktonic invertebrates}) = 1; TL_1(\text{sea otters}) = TL_1(\text{small predatory fishes}) = TL_1(\text{large fish \& octopus}) = 2$; $TL_1(\text{sharks}) = 3$. Fact 2 verifies that $TL_1(\text{sea otters}) = 1 + \min\{TL_1(\text{sea urchins}), TL_1(\text{sea stars}), TL_1(\text{large crabs}), TL_1(\text{large fish \& octopus})\} = 1 + \min\{1, 1, 1, 2\} = 2$.

3. The trophic level (option 2) values for Example 1 of §20.7.1 are computed as follows: $TL_2(\text{kelp}) = 0$; $TL_2(\text{sea urchins}) = TL_2(\text{small fishes}) = 1$; $TL_2(\text{large crabs}) = 2$; $TL_2(\text{sea otters}) = 3$; $TL_2(\text{sharks}) = 4$. Notice that from Fact 3, we have $TL_2(\text{sea otters}) = 1 + \max\{TL_2(\text{sea urchins}), TL_1(\text{large crabs})\} = 1 + \max\{1, 2\} = 3$.

4. The trophic level (option 2) values for Example 2 of §20.7.1 are computed as follows: $TL_2(\text{kelp}) = TL_2(\text{organic debris}) = TL_2(\text{microscopic planktonic algae}) = 0$; $TL_2(\text{small herbivorous fishes}) = TL_2(\text{abalone}) = TL_2(\text{planktonic invertebrates}) = 1; TL_2(\text{sessile invertebrates}) = 2$; $TL_2(\text{sea urchins}) = TL_2(\text{small predatory fishes}) = 3$; $TL_2(\text{sea stars}) = 4; TL_2(\text{large crabs}) = 5; TL_2(\text{large fish \& octopus}) = 6; TL_2(\text{sea otters}) = 7; TL_2(\text{ sharks}) = 8$. Notice that $TL_2(x) \geq TL_1(x)$ holds for each species x, as guaranteed by Fact 4.

5. The trophic status of sea otters in Example 1 of §20.7.1 can be calculated by first determining longest path lengths to sea otters from all species that sea otters feed upon (directly or indirectly): namely, $D(\text{sea urchins, sea otters}) = D(\text{large crabs, sea otters}) = 1$, $D(\text{small fishes, sea otters}) = 2$, $D(\text{kelp, sea otters}) = 3$. This gives $TS(\text{sea otters} = 1 + 1 + 2 + 3 = 7$. Similar calculations produce $TS(\text{kelp}) = 0$, $TS(\text{sea urchins}) = TS(\text{small fishes}) = 1$, $TS(\text{large crabs}) = 3$, and $TS(\text{sharks}) = 12$.

6. Trophic status for the species in Example 2 of §20.7.1 are found as $TS(\text{kelp}) = TS(\text{ organic debris}) = TS(\text{microscopic planktonic algae}) = 0$; $TS(\text{planktonic invertebrates}) = TS(\text{abalone}) = TS(\text{small herbivorous fishes}) = 1; TS(\text{sessile invertebrates}) = 3; TS(\text{small predatory fishes}) = 6; TS(\text{sea urchins}) = 8; TS(\text{sea stars}) = 16$; $TS(\text{large crabs}) = 26$; $TS(\text{large fish \& octopus}) = 37$; $TS(\text{sea otters}) = 49$; $TS(\text{sharks}) = 62$.

7. If the arc (sea urchins, sea otters) is removed from the food web in Example 1 of §20.7.1, then sea urchins will have uncontrolled growth and become a new "dominant" species in the food web. Therefore sea otters are considered a dominant species. Using Fact 8, since (small fishes, large crabs) is the only arc leaving small fishes, large crabs are a dominant species. Similarly, (sea otters, sharks) is the only arc leaving sea otters, so sharks are dominant.

8. In the food web for Example 2 of §20.7.1, both sharks and sea otters are dominant.

9. In the food web for Example 2 of §20.7.1, sharks, sea otters, sea stars, large crabs, and large fish & octopus are trophic status dominant since each has trophic status exceeding $14 - 3 = 11$. By contrast, only sharks and sea otters are dominant using the arc removal definition (see Example 8).

20.7.3 WEIGHTED FOOD WEBS

Not all ecological relationships have the same strength. Species may consume much more of one prey species than another. To model this, we can assign weights to the arcs of a food web to indicate food preferences.

Definitions:

The ***weight*** of arc (x, y) in a food web, denoted w_{xy}, is the proportional food contribution of species x to species y in the food web.

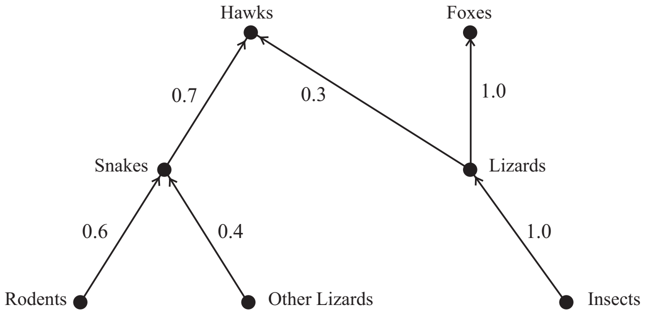
The ***flow-based trophic level*** $TL_F(x)$ of species x is defined to be 1 if x is a basal species. Otherwise, it is based on the weighted sum of flow-based trophic levels of the species y that it directly consumes: $TL_F(x) = 1 + \sum\{w_{yx}TL_F(y) \mid (y, x) \in A\}$.

Fact:

1. The sum of the weights of the incoming arcs to a species is 1, since the set of incoming arcs represents the full diet of the species.

Examples:

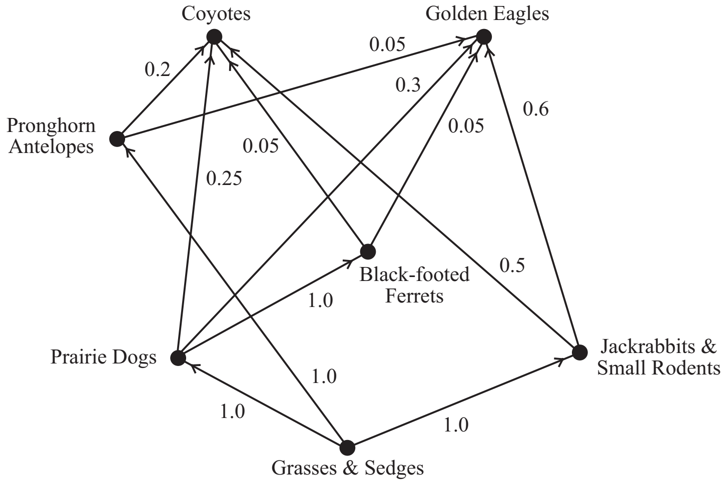
1. The following figure depicts a weighted food web. For example, the weight 0.6 on the arc from rodents to snakes indicates that snakes eat rodents more frequently than other lizards in the ratio of 6 to 4. Specifically, 60% of a snake's diet comes from rodents, while 40% of its diet comes from other lizards.



Here $TL_F(\text{snakes}) = 1 + 0.6(1) + 0.4(1) = 2$ and $TL_F(\text{lizards}) = 1 + 1(1) = 2$, so that $TL_F(\text{hawks}) = 1 + 0.7(2) + 0.3(2) = 3$.

2. If prairie dogs are removed from the following weighted food web, then black-footed ferrets have no food source and so will die off. If jackrabbits & small rodents are removed, and species can survive on 50% of their normal diet, then coyotes will survive, but golden eagles will have to increase their consumption of antelopes, prairie dogs, and black-footed ferrets, a challenge given their limited numbers.

Flow-based trophic levels for species in this weighted food web are given by TL_F(grasses & sedges) $= 1, TL_F$(prairie dogs) $= TL_F$(jackrabbits & small rodents) $= TL_F$(pronghorn antelopes)$= 2, TL_F$(black-footed ferrets) $= 3, TL_F$(golden eagles) $= TL_F$(coyotes) $= 3.05$.



20.7.4 COMPETITION GRAPHS

There has been considerable attention paid lately to creating graphical models for better understanding predator-prey relationships, especially to inform conservation policy makers. This subsection introduces several undirected graphs and parameters that are useful in understanding the competition of species.

Definitions:

Suppose a food web is represented by the directed acyclic graph D with n vertices and m arcs.

The ***directed connectance*** (***density***) of the digraph D is defined to be $C = \frac{m}{n^2}$.

The ***competition graph*** associated with D is an undirected graph G whose vertices are the species in D. There is an edge in G between species a and species b if and only if a and b have a common prey: i.e., there is some vertex x such that there exist arcs (x, a) and (x, b) in D.

The ***competition number*** $k(G)$ for a graph G is the fewest number of isolated vertices that need to be added to G so that G is the competition graph for some directed acyclic graph.

The ***common enemy graph*** associated with D is an undirected graph G whose vertices are the species in D. There is an edge in G between species a and species b if and only if a and b have a common predator: i.e., there is some vertex x such that there exist arcs (a, x) and (b, x) in D.

A ***clique*** of the graph G is a subgraph of G in which every pair of distinct vertices is connected by an edge in the subgraph. A ***maximal clique*** is a clique that cannot be extended by including additional vertices.

Facts:

1. If all possible arcs exist in the digraph D, there would be $n(n-1)$ arcs, so the maximum connectance is $1 - \frac{1}{n} < 1$; the minimum connectance is 0 if there are no arcs. Since species at the top of the food web have no outgoing arcs and the food web has no cycles, the maximum is much less than $1 - \frac{1}{n}$.

2. It was long believed that the higher the connectance the more stable the food web. In fact, using real or simulated models and population dynamics on the food web and competition graph, the steady state (stability) is achieved only for small n and C, particularly when the product $nC = \frac{m}{n} < 2$. These results are robust under the change of initial conditions and ecological parameters [DuWiMa02].

3. Competition graphs are also known as *niche overlap graphs* and *predator graphs*.

4. Common enemy graphs are also known as *prey graphs*.

5. If D is a directed acyclic graph, then there must exist an isolated vertex in its corresponding competition graph G. One such vertex would be a vertex having no incoming arcs in D. (Every directed acyclic graph contains at least one vertex of indegree 0.)

6. Any graph G can be the competition graph for some directed acyclic graph D by adding a sufficient number of isolated vertices to G.

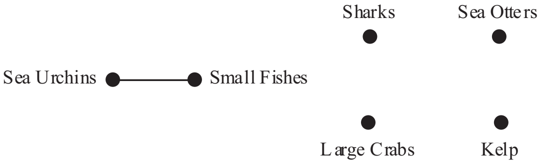
7. If G has exactly one hole (induced cycle of length at least 4), then $k(G) \leq 2$ [ChKi05].

8. $k(G) \leq$ number of holes $+ 1$ [MaScSc14].

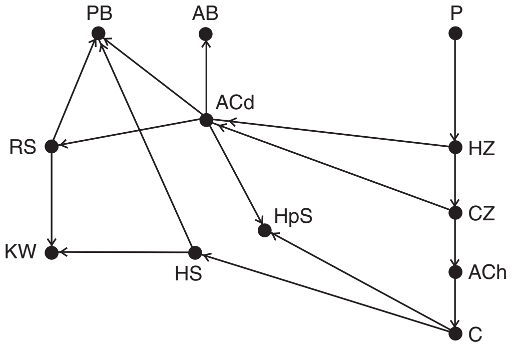
9. Determining the competition number is an NP-hard problem [Op82].

Examples:

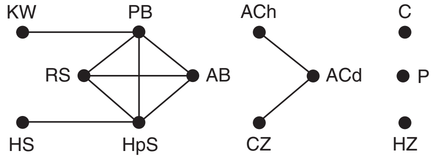
1. In the food web of §20.7.1, Example 1 sea urchins and small fishes both have kelp as a common prey, so (sea urchins, small fishes) is an edge of the competition graph. This simple competition graph, shown next, has one edge and four independent vertices.



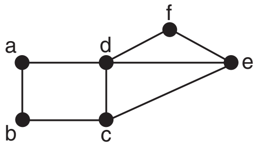
2. The following figure shows a food web D for the polar bear. Here we use the abbreviations PB (Polar Bear), AB (Arctic Birds), P (Phytoplankton), RS (Ringed Seal), ACd (Arctic Cod), HZ (Herbivorous Zooplankton), KW (Killer Whale), HS (Harbour Seal), ACh (Arctic Char), HpS (Harp Seal), CZ (Carnivorous Zooplankton), and C (Capelin). Note that Phytoplankton (P) is the only basal species of this food web.



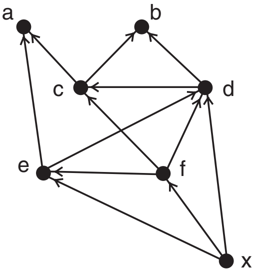
The corresponding competition graph G is shown next. The competition graph G contains the isolated vertices P, C, and HZ. Since there are arcs in D from ACd to PB, AB, RS, and HpS, those four vertices form a clique, in fact a maximal clique, in G.



3. The following graph G contains a single hole, the induced 4-cycle $abcd$. Therefore by Fact 7 it is possible to add at most two isolated vertices to G so that the result is a competition graph for some digraph D.



The digraph D shown next generates a competition graph that consists of G plus a single isolated vertex x. Thus $k(G) = 1$.



20.7.5 INTERVAL GRAPHS AND BOXICITY

This subsection discusses interval graphs and related concepts that are useful in assessing the dimension of community habitats.

Definitions:

A graph is an ***interval graph*** if we can find a set of intervals on the real line so that each vertex is assigned an interval and two vertices are joined by an edge if and only if their corresponding intervals overlap.

The ***boxicity*** $box(G)$ of graph G is the smallest positive integer p having the property that we can assign a box in Euclidean p-space to each vertex of G so that two vertices are connected by an edge of G if and only if their corresponding boxes overlap.

The ***clique matrix*** for a graph G is the binary matrix $M = (m_{ij})$, whose rows correspond to the maximal cliques of G and whose columns correspond to the vertices of G; m_{ij} is 1 if and only if vertex j is in maximal clique i, and is 0 otherwise.

A binary matrix has the ***consecutive ones property for columns*** if its rows can be permuted so that the 1s in each column occur consecutively.

The ***sink food web*** for a subset of species X in a food web is the induced subgraph defined by all species that are prey of species in X.

The ***source food web*** for a subset of species W in a food web is the induced subgraph defined by all species that are predators of species in W.

Facts:

1. If G is the competition graph corresponding to a real community food web and G is an interval graph, then the species in the food web have one-dimensional habitats or niches. That is, each species can be mapped to the real line with overlapping intervals if they have common prey, and this single dimension applies to each species in the web. This single dimension might be determined by temperature, moisture, pH, or a number of other factors.

2. The maximal cliques of an interval graph can be ordered in a sequence such that for any vertex v, the maximal cliques containing v occur consecutively in the sequence [FuGr65]. This is one way of determining if a graph is an interval graph—does such an ordering of maximal cliques exist?

3. A graph is an interval graph if and only if its clique matrix M has the consecutive ones property for columns [FuGr65].

4. A graph is an interval graph if and only if it does not contain one of the following "forbidden" structures as a subgraph: the cycle C_4, the complete bipartite graph $K_{3,3}$, or the graph H having a pendant edge attached to each vertex of the complete graph K_3 [GiHo64].

5. A graph is an interval graph if and only if it is a *chordal graph* (contains no holes) and its complement is a *comparability graph* (has a transitive orientation) [LeBo62].

6. Interval graphs have boxicity 1.

7. If the boxicity of the competition graph is 2, then the species in the associated food web have 2-dimensional habitats or niches.

8. Every graph can be represented as the intersection graph of boxes in some dimension, so boxicity is well defined in general. However, it is hard to compute [Co81].

9. There are fast algorithms to test if a graph is an interval graph. However, there are no fast ways known for computing the boxicity of a general graph [Co81], [CoRo83].

10. The parameter $box(G)$ is bounded above by the minimum size of a maximal matching (§10.2.1) in the complement of G. When G is dense and its complement is sparse, the boxicity tends to be small [Ro69].

11. In the 1960s, Joel Cohen found that food webs arising from "single habitat ecosystems" (homogeneous ecosystems) generally have competition graphs that are interval graphs. This remarkable empirical observation of Cohen, that real-world competition graphs are usually interval graphs, has led to a great deal of research on the structure of competition graphs and on the relation between the structure of digraphs and their corresponding competition graphs. It has also led to a great deal of research in ecology to determine just why this might be the case [Co78].

12. Using randomly generated food webs (digraphs), Cohen et al. showed that the probability that a competition graph is an interval graph goes to 0 as the number of species increases. In other words, it should be highly unlikely that competition graphs corresponding to food webs are interval graphs [CoKoMu79].

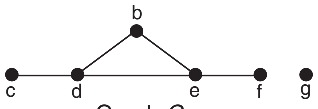
13. Cohen showed that a food web has a competition graph that is an interval graph if and only if each sink food web contained in it is an interval graph. However, the same is not true for source food webs [Co78].

14. A food web can have a competition graph that is an interval graph while some source food web contained in it has a competition graph that is not an interval graph. The following site provides an example of a food web whose competition graph is an interval graph, together with a subset W of vertices whose source food web has a competition graph of boxicity 2.

- `http://dimacs.rutgers.edu/IMB/TalksEtc/Foodwebs-and-Biodiversity-7-29-13.pdf`

Examples:

1. The competition graph G shown next is an interval graph, since we can associate intervals on the real line with its vertices so that the intervals corresponding to two vertices overlap if and only if there is an edge between the two vertices in G. One such representation is shown. Notice that the maximal cliques of G are cd, bde, ef. In this ordering, the maximal cliques containing each vertex occur consecutively (Fact 2).

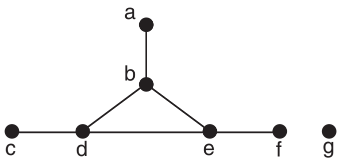


Graph G

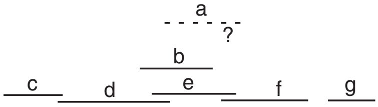
Using the above ordering of cliques and the alphabetical ordering of the vertices produces the following clique matrix, which has the consecutive ones property for columns (Fact 3):

$$M = \begin{pmatrix} 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 \end{pmatrix}.$$

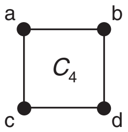
2. The competition graph G shown next is not an interval graph. An attempt to add an interval for vertex a to the interval representation given in Example 1 is not successful. There is no place for such an interval that intersects only the interval for b and no others. Since G contains the forbidden subgraph H from Fact 4, we are assured that G is not an interval graph. In fact, G has boxicity 2.

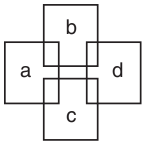


Graph G



3. Fact 4 guarantees that the cycle C_4 is not an interval graph. A representation using 2-dimensional boxes is shown below, so $box(C_4) = 2$.





20.7.6 PROJECTION GRAPHS

Projection graphs are weighted graphs based on competition graphs and common enemy graphs.

Definitions:

Suppose D is a food web with n vertices. Let T denote the set of top species (no outgoing arcs), B the set of basal species (no incoming arcs), and I the remaining (intermediate) species. Let x_{ij} be a 0-1 variable, with $x_{ij} = 1$ if arc (i, j) is in D and $x_{ij} = 0$ otherwise.

The ***predator projection graph*** (***PP***) associated with D has a vertex for each species in D and contains the edge (i, j) if i and j have a common prey. The weight $A(i, j)$ of edge (i, j) reflects the number of common prey:

$$A(i,j) = \frac{1}{n(|B| + |I|)} \sum \{x_{ki}x_{kj} \mid k \in B \cup I\}.$$

The ***prey projection graph*** (***EP***) associated with D has a vertex for each species in D and contains the edge (i, j) if i and j have a common predator. The weight $B(i, j)$ of edge (i, j) reflects the number of common predators:

$$B(i,j) = \frac{1}{n(|T| + |I|)} \sum \{x_{ik}x_{jk} \mid k \in T \cup I\}.$$

Facts:

1. The PP graph is a weighted competition graph minus the basal species, since they have no prey. We can use the competition graph to construct the PP graph, by removing the basal species and then labelling edge (i, j) with weight $A(i, j)$.

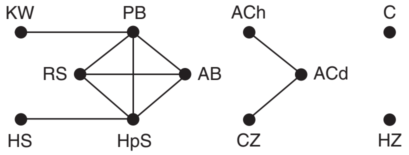
2. The EP graph is a weighted common enemy graph minus the top species, since they have no predators. We can use the common enemy graph to construct the EP graph, by removing the top species and then labelling edge (i, j) with weight $B(i, j)$.

3. The matrix of edge weights in the PP graph is given by $A = \alpha X^T X$, where $X = (x_{ij})$ and $\alpha = (n(n - |T|))^{-1}$.

4. The matrix of edge weights in the EP graph is given by $B = \beta X X^T$, where $X = (x_{ij})$ and $\beta = (n(n - |B|))^{-1}$.

Examples:

1. For the polar bear food web (§20.7.4, Example 2), Phytoplankton (P) is the only basal species so P does not appear in the corresponding PP graph, shown next.



The matrix of edge weights in the PP graph, normalized by the divisor $96 = 12 \times 8$, is given by

	PB	AB	RS	ACd	KW	HS	HpS	HZ	CZ	ACh	C
PB	0	.0104	.0104	0	.0208	0	.0104	0	0	0	0
AB	.0104	0	.0104	0	0	0	.0104	0	0	0	0
RS	.0104	.0104	0	0	0	0	.0104	0	0	0	0
ACd	0	0	0	0	0	0	0	0	.0104	.0104	0

20.7.7 OPEN QUESTIONS

There remain a number of open questions that suggest further study of graphs and that may inform conservationists and policy makers. Several are mentioned here.

1. Can we characterize the directed graphs whose corresponding competition graphs are interval graphs? This is a fundamental open question in applied graph theory. Indeed there is no forbidden list of digraphs (finite or infinite) such that when these digraphs are excluded, one automatically has a competition graph that is an interval graph.

2. What are the ecological characteristics of food webs that seem to lead to their competition graphs being interval graphs? Most directed graphs do not have interval graph competition graphs, yet statistically most actual food webs do have interval competition graphs. (This is an important unsolved problem described by Cohen, with no answers to date.)

3. What is the relationship between the boxicity of the competition graph of a food web and the boxicities of the competition graphs of its source food webs (note for every subset W there is a source food web)? These can indeed be different; see §20.7.5, Fact 14.

4. It has been shown recently that it is possible to determine if a graph has boxicity 2, yet it is difficult to determine if a graph has boxicity k for $k > 2$ (this is an NP-complete problem). There are no nice characterizations known for graphs with boxicity 2, in contrast to the case for interval graphs. Find a forbidden subgraph characterization for graphs of boxicity 2.

5. Is there any relationship between the indegrees and outdegrees of vertices in a food web, or the maximum indegree or outdegree over all vertices, and the competition number of the graph? If you limit the indegree or outdegree (or both) of all vertices in a digraph, is it more likely to have a competition graph that is an interval graph?

6. Is there any relationship between the connectance of a food web and the corresponding competition graph?

7. Are there mathematical results obtainable from using the PP and EP graphs that are not achievable from simply considering the competition graph, or its counterpart the common enemy graph? Do these have ecological consequences?

BIOGRAPHIES

Victor J. Katz

Niels Henrik Abel (1802–1829), born in Norway, was self-taught and studied the works of many mathematicians. When he was nineteen years old, he proved that there is no closed formula for solving the general fifth degree equation. He also worked in the areas of infinite series and elliptic functions and integrals. The term *abelian* group was coined in Abel's honor in 1870 by Camille Jordan.

Leonard Adleman (born 1945) is credited with coining the term "computer virus". He was one of the inventors (with Adi Shamir and Ronald Rivest) of the RSA encryption algorithm, currently used in secure data transmission. He received his Ph.D. from the University of California, Berkeley in 1976. Adleman is also the creator of the field of DNA computing, beginning with a 1994 paper in which he used DNA to solve an instance of the Hamiltonian Graph problem. He is currently a Professor of Computer Science and Molecular Biology at the University of Southern California

Kenneth Appel (1932–2013) is best known for his solution of the four-color problem (along with Wolfgang Haken). He received his Ph.D. from the University of Michigan in 1959 and spent most of his career at the University of Illinois. The proof of the four-color theorem broke new ground, since it rests on hundreds of hours of computer calculation. Although the proof was initially disdained by many in the mathematical community, it actually provided a start to a change in the attitudes of mathematicians to computers, and has led to much further use of computers, even in theoretical mathematics.

Aristotle (384–322 B.C.E.) was the most famous student at Plato's academy in Athens. After Plato's death in 347 B.C.E., he was invited to the court of Philip II of Macedon to educate Philip's son Alexander, who soon thereafter began his successful conquest of the Mediterranean world. Aristotle himself returned to Athens, where he founded his own school, the Lyceum, and spent the remainder of his life writing and lecturing. He wrote on numerous subjects, but is perhaps best known for his works on logic, including the *Prior Analytics* and the *Posterior Analytics*. In these works, Aristotle developed the notion of logical argument, based on several explicit principles. In particular, he built his arguments out of syllogisms and concluded that demonstrations using his procedures were the only certain way of attaining scientific knowledge.

Emil Artin (1898–1962) was born in Vienna and in 1921 received a Ph.D. from the University of Leipzig. He held a professorship at the University of Hamburg until 1937, when he came to the United States. In the U.S. he taught at the University of Notre Dame, Indiana University, and Princeton. In 1958 he returned to the University of Hamburg. Artin's mathematical contributions were in number theory, algebraic topology, linear algebra, and especially in many areas of abstract algebra.

Charles Babbage (1792–1871) was an English mathematician best known for his invention of two of the earliest computing machines, the *Difference Engine*, designed to calculate polynomial functions, and the *Analytical Engine*, a general purpose calculating machine. The Difference Engine was designed to use the idea that the nth order differences in nth degree polynomials were always constant and then to work backwards from those differences to the original polynomial values. Although Babbage received a grant from the British government to help in building the Engine, he never was able to complete one because of various difficulties in developing machine parts of sufficient accuracy. In addition, Babbage became interested in his more advanced Analytical Engine. This latter device was to consist of a *store*, in which the numerical variables were kept, and a *mill*, in which the operations were performed. The entire machine was to be controlled by instructions on punched cards. Unfortunately, although Babbage made numerous engineering drawings of sections of the Analytical Engine and gave a series of seminars in 1840 on its workings, he was never able to build a working model.

Paul Gustav Heinrich Bachmann (1837–1920) studied mathematics at the University of Berlin and at Göttingen. In 1862 he received a doctorate in group theory and held positions at the universities at Breslau and Münster. He wrote several volumes on number theory, introducing the big-O notation in his 1892 book.

John Backus (1924–2007) received bachelor's and master's degrees in mathematics from Columbia University. He led the group at IBM that developed FORTRAN in 1954. Later in the 1950s, he was an influential member of the international team that developed ALGOL, using the Backus-Naur form for the syntax of the language. He received the National Medal of Science in 1974 and the Turing Award in 1977 "for profound, influential, and lasting contributions to the design of practical high-level programming systems."

Abu-l-'Abbas Ahmad ibn Muhammad ibn al-Banna al-Marrakushi (1256–1321) was an Islamic mathematician who lived in Marrakech in what is now Morocco. Ibn al-Banna developed the first known proof of the basic combinatorial formulas, beginning by showing that the number of permutations of a set of n elements was $n!$ and then developing in a careful manner the multiplicative formula to compute the values for the number of combinations of k objects in a set of n. Using these two results, he also showed how to calculate the number of permutations of k objects from a set of n. The formulas themselves had been known in the Islamic world for many years, in connection with specific problems like calculating the number of words of a given length which could be formed from the letters of the Arabic alphabet. Ibn al-Banna's main contribution, then, was to abstract the general idea of permutations and combinations out of the various specific problem situations considered earlier.

Thomas Bayes (1702–1761) an English Nonconformist, wrote an *Introduction to the Doctrine of Fluxions* in 1736 as a response to Berkeley's *Analyst* with its severe criticism of the foundations of the calculus. He is best known, however, for attempting to answer the basic question of statistical inference in his *An Essay Towards Solving a Problem in the Doctrine of Chances*, published three years after his death. That basic question is to determine the probability of an event, given empirical evidence that it has occurred a certain number of times in a certain number of trials. To do this, Bayes gave a straightforward definition of probability and then proved that for two events E and F, the probability of E given that F has happened is the quotient of the probability of both E and F happening divided by the probability of F alone. By using areas to model probability, he was then able to show that, if x is the probability of an event happening in a single trial, if the event has happened p times in n trials, and if $0 < r < s < 1$, then the probability that x is between r and s is given by the quotient of two integrals. Although in principle these integrals can be calculated, there has been a great debate since Bayes' time about the circumstances under which his formula gives an appropriate answer.

James Bernoulli (***Jakob I***) (1654–1705) was one of eight mathematicians in three generations of his family. He was born in Basel, Switzerland, studied theology in addition to mathematics and astronomy, and entered the ministry. In 1682 be began to lecture at the University of Basel in natural philosophy and mechanics. He became professor at the University of Basel in 1687, and remained there until his death. His research included the areas of the calculus of variations, probability, and analytic geometry. His most well-known work is *Ars Conjectandi*, in which he described results in combinatorics and probability, including applications to gambling and the law of large numbers; this work also contained a reprint of the first formal treatise in probability, written in 1657 by Christiaan Huygens.

Bhaskara (1114–1185), the most famous of medieval Indian mathematicians, gave a complete algorithmic solution to the *Pell equation* $Dx^2 \pm 1 = y^2$. That equation had been studied by several earlier Indian mathematicians as well. Bhaskara served much of his adult life as the head of the astronomical observatory at Ujjain, some 300 miles northeast of Bombay, and became widely respected for his skills in astronomy and the mechanical arts, as well as mathematics. Bhaskara's mathematical contributions are chiefly found in two chapters, the *Lilavati* and the *Bijaganita*, of a major astronomical work, the *Siddhāntasiromani*. These include techniques of solving systems of linear equations with more unknowns than equations as well as the basic combinatorial formulas, although without any proofs.

Belá Bollobás (born 1943) was on the Hungarian team in the first three International Mathematical Olympiads, beginning in 1959, and won two gold medals, thereby coming to the attention of Paul Erdős, who encouraged him in his studies. Although he received his Ph.D. from the University of Budapest in 1967, he soon was able to leave Hungary and vowed not to return while it was still under communist control. He received a fellowship to Trinity College, Cambridge, where he remained until 1996, then accepted a professorship at the University of Memphis. He has made major contributions to fields of extremal graph theory and the theory of random graphs and has published several research monographs in his field as well as introductory textbooks in combinatorics and graph theory.

George Boole (1815–1864) was an English mathematician most famous for his work in logic. Born the son of a cobbler, he had to struggle to educate himself while supporting his family. But he was so successful in his self-education that he was able to set up his own school before he was 20 and was asked to give lectures on the work of Isaac Newton. In 1849 he applied for and was appointed to the professorship in mathematics at Queen's College, Cork, despite having no university degree. In 1847, Boole published a small book, *The Mathematical Analysis of Logic*, and seven years later expanded it into *An Investigation of the Laws of Thought*. In these books, Boole introduced what is now called Boolean algebra as part of his aim to "investigate the fundamental laws of those operations of the mind by which reasoning is performed; to give expression to them in the symbolical language of a Calculus, and upon this foundation to establish the science of Logic and construct its method." In addition to his work on logic, Boole wrote texts on differential equations and on difference equations that were used in Great Britain until the end of the nineteenth century.

William Burnside (1852–1927), was born in London, graduated from Cambridge in 1875, and remained there as lecturer until 1885. He then went to the Royal Naval College at Greenwich, where he stayed until he retired. Although he published much in applied mathematics, probability, and elliptic functions, he is best known for his extensive work in group theory (including the classic book *Theory of Groups*). His conjecture that groups of odd order are solvable was proved by Walter Feit and John Thompson and published in 1963.

Georg Ferdinand Ludwig Philip Cantor (1845–1918) was born in Russia to Danish parents, received a Ph.D. in number theory in 1867 at the University of Berlin, and in 1869 took a position at Halle University, where he remained until his retirement. He is regarded as a founder of set theory. He was interested in theology and the nature of the infinite. His work on the convergence of Fourier series led to his study of certain types of infinite sets of real numbers, and ultimately to an investigation of transfinite numbers.

Augustin-Louis Cauchy (1789–1857), the most prolific mathematician of the nineteenth century, is most famous for his textbooks in analysis written in the 1820s for use at the École Polytechnique, textbooks which became the model for calculus texts for the next hundred years. Although born in the year the French Revolution began, Cauchy was a staunch conservative. When the July Revolution of 1830 led to the overthrow of the last Bourbon king, Cauchy refused to take the oath of allegiance to the new king and went into a self-imposed exile in Italy and then in Prague. He did not return to his teaching posts until the Revolution of 1848 led to the removal of the requirement of an oath of allegiance. Among the many mathematical subjects to which he contributed besides calculus were the theory of matrices, in which he demonstrated that every symmetric matrix can be diagonalized by use of an orthogonal substitution, and the theory of permutations, in which he was the earliest to consider these from a functional point of view. In fact, he used a single letter, say S, to denote a permutation and S^{-1} to denote its inverse and then noted that the powers S, S^2, S^3, ... of a given permutation on a finite set must ultimately result in the identity. He also introduced the current notation $(a_1a_2 \ldots a_n)$ to denote the cyclic permutation on the letters $a_1, a_2, \ldots, a_n$.

Arthur Cayley (1821–1895), although graduating from Trinity College, Cambridge as Senior Wrangler, became a lawyer because there were no suitable mathematics positions available at that time in England. He produced nearly 300 mathematical papers during his fourteen years as a lawyer, and in 1863 was named Sadlerian professor of mathematics at Cambridge. Among his numerous mathematical achievements are the earliest abstract definition of a group in 1854, out of which he was able to calculate all possible groups of order up to eight, and the basic rules for operating with matrices, including a statement (without proof) of the Cayley-Hamilton theorem that every matrix satisfies its characteristic equation. Cayley also developed the mathematical theory of *trees* in an article in 1857. In particular, he dealt with the notion of a *rooted tree*, a tree with a designated vertex called a root, and developed a recursive formula for determining the number of different rooted trees in terms of its *branches* (edges). In 1874, Cayley applied his results on trees to the study of chemical isomers.

Pafnuty Lvovich Chebyshev (1821–1894) was a Russian mathematician who received his master's degree in 1846 from Moscow University. From 1860 until 1882 he was a professor at the University of St. Petersburg. His mathematical research in number theory dealt with congruences and the distribution of primes; he also studied the approximation of functions by polynomials.

Avram Noam Chomsky (born 1928) received a Ph.D. in linguistics at the University of Pennsylvania. For many years he was a professor of foreign languages and linguistics at M.I.T. He has made many significant contributions to the study of linguistics and the study of grammars, but is probably better known for his left-wing political activism.

Chrysippus (280–206 B.C.E.) was a Stoic philosopher who developed some of the basic principles of the propositional logic, which ultimately replaced Aristotle's logic of syllogisms. He was born in Cilicia, in what is now Turkey, but spent most of his life in Athens, and is said to have authored more than 700 treatises. Among his other achievements, Chrysippus analyzed the rules of inference in the propositional calculus, including the rules of *modus ponens*, *modus tollens*, the hypothetical syllogism, and the alternative syllogism.

Fan Chung (born 1949) was born in Taiwan and received her Ph.D. from the University of Pennsylvania in 1974. She became an expert in Ramsey theory and has also made numerous contributions to graph theory, in particular to the applications of graph theory in Internet computing, communication networks, and software reliability. She spent many years at Bell Labs, where she collaborated with Ron Graham and eventually married him. She is currently a Distinguished Professor of Mathematics at the University of California, San Diego.

Alonzo Church (1903–1995) studied under Hilbert at Göttingen, was on the faculty at Princeton from 1927 until 1967, and then held a faculty position at UCLA. He is a founding member of the Association for Symbolic Logic. He made many contributions in various areas of logic and the theory of algorithms, and stated the Church-Turing thesis (if a problem can be solved with an effective algorithm, then the problem can be solved by a Turing machine).

Clifford Cocks (born 1950) is a British mathematician and cryptographer who invented the public key algorithm in 1973 now known as the RSA algorithm (after its independent invention four years later by Ronald Rivest, Adi Shamir, and Len Adleman). Cocks had invented the algorithm, using prime factorization, while he was working for the Communications-Electronics Security Group in Britain, an arm of the United Kingdom Government Communications Headquarters (GCHQ). But although GCHQ did not use the algorithm, they treated it as classified information and did not release the research until 1997. In 2001, Cocks developed one of the first secure identity based encryption schemes.

George Dantzig (1914–2005) is an American mathematician who formulated the general linear programming problem of maximizing a linear objective function subject to several linear constraints and developed the simplex method of solution in 1947. His study of linear programming grew out of his World War II service as a member of Air Force Project SCOOP (Scientific Computation of Optimum Programs), a project chiefly concerned with resource allocation problems. After the war, linear programming was applied to numerous problems, especially military and economic ones, but it was not until such problems could be solved on a computer that the real impact of their solution could be felt. The first successful solution of a major linear programming problem on a computer took place in 1952 at the National Bureau of Standards. After he left the Air Force, Dantzig worked for the RAND Corporation and then served as a professor of operations research at Stanford University.

Richard Dedekind (1831–1916) was born in Brunswick, in northern Germany, and received a doctorate in mathematics at Göttingen under Gauss. He held positions at Göttingen and in Zurich before returning to the Polytechnikum in Brunswick. Although at various times he could have received an appointment to a major German university, he chose to remain in his home town where he felt he had sufficient freedom to pursue his mathematical research. Among his many contributions was his invention of the concept of ideals to resolve the problem of the lack of unique factorization in rings of algebraic integers. Even though the rings of integers themselves did not possess unique factorization, Dedekind showed that every ideal is either prime or uniquely expressible as the product of prime ideals. Dedekind published this theory as a supplement to the second edition (1871) of Dirichlet's *Vorlesungen über Zahlentheorie*, of which he was the editor. In the supplement, he also gave one of the first definitions of a field, confining this concept to subsets of the complex numbers.

Abraham de Moivre (1667–1754) was born into a Protestant family in Vitry, France, a town about 100 miles east of Paris, and studied in Protestant schools up to the age of 14. Soon after the revocation of the Edict of Nantes in 1685 made life very difficult for Protestants in France, however, he was imprisoned for two years. He then left France for England, never to return. Although he was elected to the Royal Society in 1697, in recognition of a paper on "A method of raising an infinite Multinomial to any given Power or extracting any given Root of the same", he never achieved a university position. He made his living by tutoring and by solving problems arising from games of chance and annuities for gamblers and speculators. De Moivre's major mathematical work was *The Doctrine of Chances* (1718, 1736, 1756), in which he devised methods for calculating probabilities by use of binomial coefficients. In particular, he derived the normal approximation to the binomial distribution and, in essence, invented the notion of the standard deviation.

Augustus De Morgan (1806–1871) graduated from Trinity College, Cambridge in 1827. He was the first mathematics professor at University College in London, where he remained on the faculty for 30 years. He founded the London Mathematical Society. He wrote over 1000 articles and textbooks in probability, calculus, algebra, set theory, and logic (including DeMorgan's laws, an abstraction of the duality principle for sets). He gave a precise definition of limit, developed tests for convergence of infinite series, and gave a clear explanation of the Principle of Mathematical Induction.

René Descartes (1596–1650) left school at 16 and went to Paris, where he studied mathematics for two years. In 1616 he earned a law degree at the University of Poitiers. In 1617 he enlisted in the army and traveled through Europe until 1629, when he settled in Holland for the next 20 years. During this productive period of his life he wrote on mathematics and philosophy, attempting to reduce the sciences to mathematics. In 1637 his *Discours* was published; this book contained the development of analytic geometry. In 1649 he has invited to tutor the Queen Christina of Sweden in philosophy. There he soon died of pneumonia.

Leonard Eugene Dickson (1874–1954) was born in Iowa and in 1896 received the first Ph.D. in mathematics given by the University of Chicago, where he spent much of his faculty career. His research interests included abstract algebra (including the study of matrix groups and finite fields) and number theory.

Edsger W. Dijkstra (1930–2002) was a Dutch computer scientist who helped shape the emerging field of computer science from both an engineering and theoretical perspective. In particular, he turned computer programming into a scientific discipline. He made contributions in many areas of the emerging domain of computer science. For example, he originated the phrase "structured programming", and his ideas in this area helped lay the foundation for the new discipline of software engineering. He is known for Dijkstra's algorithm, which found the shortest path in a graph between any two given nodes. He was also on the team that implemented the first compiler for the language ALGOL 60. After twenty years of work in the Netherlands, he joined the Burroughs Corporation in 1973 as a research fellow, moving eleven years later to the University of Texas at Austin, where he remained until his retirement.

Diophantus (c. 250) was an Alexandrian mathematician about whose life little is known except what is reported in an epigram of the *Greek Anthology* (c. 500), from which it can be calculated that he lived to the age of 84. His major work, however, the *Arithmetica*, has been extremely influential. Despite its title, this is a book on algebra, consisting mostly of an organized collection of problems translatable into what are today called indeterminate equations, all to be solved in rational numbers. Diophantus introduced the use of symbolism into algebra and outlined the basic rules for operating with algebraic expressions, including those involving subtraction. It was in a note appended to Problem II-8 of the 1621 Latin edition of the *Arithmetica* — to divide a given square number into two squares — that Pierre de Fermat first asserted the impossibility of dividing an nth power ($n > 2$) into the sum of two nth powers. This result, now known as Fermat's Last Theorem, was finally proved in 1994 by Andrew Wiles.

Charles Lutwidge Dodgson (1832–1898) is more familiarly known as Lewis Carroll, the pseudonym he used in writing his famous children's works *Alice in Wonderland* and *Through the Looking Glass*. Dodgson graduated from Oxford University in 1854 and the next year was appointed a lecturer in mathematics at Christ Church College, Oxford. Although he was not successful as a lecturer, he did contribute to four areas of mathematics: determinants, geometry, the mathematics of tournaments and elections, and recreational logic. In geometry, he wrote a five-act comedy, "Euclid and His Modern Rivals", about a mathematics lecturer Minos in whose dreams Euclid debates his *Elements* with various modernizers but always manages to demolish the opposition. He is better known, however, for his two books on logic, *Symbolic Logic* and *The Game of Logic*. In the first, he developed a symbolical calculus for analyzing logical arguments and wrote many humorous exercises designed to teach his methods, while in the second, he demonstrated a game which featured various forms of the syllogism.

Eratosthenes (276–194 B.C.E) was born in Cyrene (North Africa) and studied at Plato's Academy in Athens. He was tutor of the son of King Ptolemy III Euergetes in Alexandria and became chief librarian at Alexandria. He is recognized as the foremost scholar of his time and wrote in many areas, including number theory (his sieve for obtaining primes) and geometry. He introduced the concepts of meridians of longitude and parallels of latitude and used these to measure distances, including an estimation of the circumference of the earth.

Paul Erdős (1913–1996) was born in Budapest. At 21 he received a Ph.D. in mathematics from Eőtvős University. After leaving Hungary in 1934, he traveled extensively throughout the world, with very few possessions and no permanent home, working with other mathematicians in combinatorics, graph theory, number theory, and many other areas. He was author or coauthor of approximately 1500 papers with 500 coauthors.

Euclid (c. 300 B.C.E.) is responsible for the most famous mathematics text of all time, the *Elements*. Not only does this work deal with the standard results of plane geometry, but it also contains three chapters on number theory, one long chapter on irrational quantities, and three chapters on solid geometry, culminating with the construction of the five regular solids. The axiom-definition-theorem-proof style of Euclid's work has become the standard for formal mathematical writing up to the present day. But about Euclid's life virtually nothing is known. It is, however, generally assumed that he was among the first mathematicians at the Museum and Library of Alexandria, which was founded around 300 B.C.E by Ptolemy I Soter, the Macedonian general of Alexander the Great who became ruler of Egypt after Alexander's death in 323 B.C.E.

Leonhard Euler (1707–1783) was born in Basel, Switzerland and became one of the earliest members of the St. Petersburg Academy of Sciences. He was the most prolific mathematician of all time, making contributions to virtually every area of the subject. His series of analysis texts established many of the notations and methods still in use today. He created the calculus of variations and established the theory of surfaces in differential geometry. His study of the Königsberg bridge problem led to the formulation and solution of one of the first problems in graph theory. He made numerous discoveries in number theory, including a detailed study of the properties of residues of powers and the first statement of the quadratic reciprocity theorem. He developed an algebraic formula for determining the number of partitions of an integer n into m distinct parts, each of which is in a given set A of distinct positive integers. And in a paper of 1782, he even posed the problem of the existence of a pair of orthogonal Latin squares: If there are 36 officers, one of each of six ranks from each of six different regiments, can they be arranged in a square in such a way that each row and column contains exactly one officer of each rank and one from each regiment?

Abraham ibn Ezra (1089–1164) was a Spanish poet, philosopher, astrologer, and biblical commentator who was born in Tudela, but spent the latter part of his life as a wandering scholar in Italy, France, England, and Palestine. It was in an astrological text that ibn Ezra developed a method for calculating numbers of combinations, in connection with determining the number of possible conjunctions of the seven "planets" (including the sun and the moon). He gave a detailed argument for the cases $n = 7$, $k = 2$ to 7, of a rule which can easily be generalized to the modern formula $C(n,k) = \sum_{i=k-1}^{n-1} C(i,k-1)$. Ibn Ezra also wrote a work on arithmetic in which he introduced the Hebrew-speaking community to the decimal place-value system. He used the first nine letters of the Hebrew alphabet to represent the first nine numbers, used a circle to represent zero, and demonstrated various algorithms for calculation in this system.

Kamāl al-Dīn al-Fārisī (died 1320) was a Persian mathematician most famous for his work in optics. In fact, he wrote a detailed commentary on the great optical work of Ibn al-Haytham. But al-Fārisī also made major contributions to number theory. He produced a detailed study of the properties of *amicable numbers* (pairs of numbers in which the sum of the proper divisors of each is equal to the other). As part of this study, al-Fārisī developed and applied various combinatorial principles. He showed that the classical figurate numbers (triangular, pyramidal, etc.) could be interpreted as numbers of combinations and thus helped to found the theory of combinatorics on a more abstract basis.

Pierre de Fermat (1607–1665) was a lawyer and magistrate for whom mathematics was a pastime that led to contributions in many areas: calculus, number theory, analytic geometry, and probability theory. He received a bachelor's degree in civil law in 1631, and from 1648 until 1665 was King's Counsellor. He suffered an attack of the plague in 1652, and from then on he began to devote time to the study of mathematics. He helped give a mathematical basis to probability theory when, together with Blaise Pascal, he solved Méré's paradox: why is it less likely to roll a 6 at least once in four tosses of one die than to roll a double 6 in 24 tosses of two dice? He was a discoverer of analytic geometry and used infinitesimals to find tangent lines and determine maximum and minimum values of curves. In 1657 he published a series of mathematical challenges, including the conjecture that $x^n + y^n = z^n$ has no solution in positive integers if n is an integer greater than 2. He wrote in the margin of a book that he had a proof, but the proof would not fit in the margin. His conjecture was finally proved by Andrew Wiles in 1994.

Fibonacci (***Leonardo of Pisa***) (c. 1175–c. 1250) was the son of a Mediterranean merchant and government worker named Bonaccio (hence his name *filius Bonaccio*, "son of Bonaccio"). Fibonacci, born in Pisa and educated in Bougie (on the north coast of

Africa where his father was administrator of Pisa's trading post), traveled extensively around the Mediterranean. He is regarded as the greatest mathematician of the Middle Ages. In 1202 he wrote the book *Liber Abaci*, an extensive treatment of topics in arithmetic and algebra, and emphasized the benefits of Arabic numerals (which he knew about as a result of his travels). In this book he also discussed the rabbit problem that led to the sequence that bears his name: $1, 1, 2, 3, 5, 8, 13, \ldots$. In 1225 he wrote *Liber Quadratorum* (*Book of Squares*) as a response to a challenge from Master John of Palermo to "find a square number from which when five is added or subtracted, always arises a square number."

Lester R. Ford, Jr. (born 1927) is a pioneer in the field of network flows. He received his doctorate from the University of Illinois in 1953. Ford worked as a researcher for the Council for Economic and Industry Research and the RAND Corporation. While working at RAND, he collaborated with D. R. Fulkerson on seminal work on network flows. Their Ford-Fulkerson algorithm, first published in a technical report in 1954, finds the maximum flow in a capacitated network. His work on graph algorithms includes the widely used Bellman-Ford algorithm. This algorithm, invented with Richard Bellman, finds the shortest path in a weighted digraph in which edge weights can be negative. His father, Lester R. Ford, Sr., was a well-known mathematician who worked in number theory and was esteemed for his mathematical exposition.

Joseph Fourier (1768–1830), orphaned at the age of 9, was educated in the military school of his home town of Auxerre, 90 miles southeast of Paris. Although he hoped to become an army engineer, such a career was not available to him at the time because he was not of noble birth. He therefore took up a teaching position. During the Revolution, he was outspoken in defense of victims of the Terror of 1794. Although he was arrested, he was released after the death of Robespierre and was appointed in 1795 to a position at the École Polytechnique. After serving in various administrative posts under Napoleon, he was elected to the Académie des Sciences and from 1822 until his death served as its perpetual secretary. It was in connection with his work on heat diffusion, detailed in his *Analytic Theory of Heat* of 1822, and, in particular, with his solution of the *heat equation* $\frac{\partial v}{\partial t} = \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}$, that he developed the concept of a Fourier series. Fourier also analyzed the relationship between the series solution of a partial differential equation and an appropriate integral representation and thereby initiated the study of Fourier integrals and Fourier transforms.

Georg Frobenius (1849–1917) organized and analyzed the central ideas of the theory of matrices in his 1878 memoir "On linear substitutions and bilinear forms". Frobenius there defined the general notion of *equivalent* matrices. He also dealt with the special cases of *congruent* and *similar* matrices. Frobenius showed that when two symmetric matrices were similar, the transforming matrix could be taken to be *orthogonal*, one whose inverse equaled its transpose. He then made a detailed study of orthogonal matrices and showed that their eigenvalues were complex numbers of absolute value 1. He also gave the first complete proof of the Cayley-Hamilton theorem that a matrix satisfies its characteristic equation. Frobenius, a full professor in Zurich and later in Berlin, made his major mathematical contribution in the area of group theory. He was instrumental in developing the concept of an abstract group, as well as in investigating the theory of finite matrix groups and group characters.

Delbert Ray Fulkerson (1924–1976) received his Ph.D. at the University of Wisconsin, Madison in 1951. His most important work was the development (with Lester Ford, Jr.) of the Ford-Fulkerson algorithm, used to solve the maximum flow problem in capacitated networks. Such problems occur in many real-world situations such as airline crew scheduling and railway traffic flow. Fulkerson began his career at the

RAND Corporation and later served as Professor of Engineering at Cornell University. In his honor, the Fulkerson Prize for outstanding papers in discrete mathematics is awarded every three years jointly by the Mathematical Optimization Society and the American Mathematical Society.

David Gale (1921–2008) was a game theorist who received his Ph.D. in 1949 from Princeton University. He made major contributions to mathematical economics, including solving the n-dimensional Ramsey Problem and his theory of optimal economic growth. In fact, for the last half of his career, he held a joint appointment in mathematics, operations research, and economics at the University of California, Berkeley. He was always fascinated with various kinds of puzzles and math games and wrote the Mathematical Entertainments column of *The Mathematical Intelligencer* from 1991 to 1997.

Évariste Galois (1811–1832) led a brief, tragic life which ended in a duel fought under mysterious circumstances. He was born in Bourg-la-Reine, a town near Paris. He developed his mathematical talents early and submitted a memoir on the solvability of equations of prime degree to the French Academy in 1829. Unfortunately, the referees were never able to understand this memoir nor his revised version submitted in 1831. Meanwhile, Galois became involved in the revolutionary activities surrounding the July revolution of 1830 and was arrested for threatening the life of King Louis-Phillipe and then for wearing the uniform of a National Guard division which had been dissolved because of its perceived threat to the throne. His mathematics was not fully understood until fifteen years after his death when his manuscripts were finally published by Liouville in the *Journal des mathématique*. But Galois had in fact shown the relationship between subgroups of the group of permutations of the roots of a polynomial equation and the various extension fields generated by these roots, the relationship at the basis of what is now known as *Galois theory*. Galois also developed the notion of a finite field in connection with solving the problem of finding solutions to congruences $F(x) \equiv 0 \pmod{p}$, where $F(x)$ is a polynomial of degree n and no residue modulo the prime p is itself a solution.

Carl Friedrich Gauss (1777–1855), often referred to as the greatest mathematician who ever lived, was born in Brunswick, Germany. He received a Ph.D. from the University of Helmstedt in 1799, proving the Fundamental Theorem of Algebra as part of his dissertation. At age 24 Gauss published his important work on number theory, the *Disquisitiones Arithmeticae*, a work containing not only an extensive discussion of the theory of congruences, culminating in the quadratic reciprocity theorem, but also a detailed treatment of cyclotomic equations in which he showed how to construct regular n-gons by Euclidean techniques whenever n is prime and $n-1$ is a power of 2. Gauss also made fundamental contributions to the differential geometry of surfaces as well as to complex analysis, astronomy, geodesy, and statistics during his long tenure as a professor at the University of Göttingen. It was in connection with using the method of least squares to solve an astronomical problem that Gauss devised the systematic procedure for solving a system of linear equations today known as Gaussian elimination. (Unknown to Gauss, the method had appeared in Chinese mathematics texts 1800 years earlier.) Gauss' notebooks, discovered after his death, contained investigations in numerous areas of mathematics in which he did not publish, including the basics of non-Euclidean geometry.

Sophie Germain (1776–1831) was forced to study in private due to the turmoil of the French Revolution and the opposition of her parents. She nevertheless mastered mathematics through calculus and wanted to continue her study in the École Polytechnique when it opened in 1794. But because women were not admitted as students, she diligently collected and studied the lecture notes from various mathematics classes and, a few years later, began a correspondence with Gauss (under the pseudonym Monsieur LeBlanc, fearing that Gauss would not be willing to recognize the work of a woman) on ideas in number theory. She was, in fact, responsible for suggesting to the French general leading the army occupying Brunswick in 1807 that he insure Gauss' safety. Germain's chief mathematical contribution was in connection with Fermat's Last Theorem. She showed that $x^n + y^n = z^n$ has no positive integer solution where xyz is not divisible by n for any odd prime n less than 100. She also made contributions in the theory of elasticity and won a prize from the French Academy in 1815 for an essay in this field.

Kurt Gödel (1906–1978) was an Austrian mathematician who spent most of his life at the Institute for Advanced Study in Princeton. He made several surprising contributions to set theory, demonstrating that Hilbert's goal of showing that a reasonable axiomatic system for set theory could be proven to be complete and consistent was in fact impossible. In several seminal papers published in the 1930s, Gödel proved that it was impossible to prove internally the consistency of the axioms of any reasonable system of set theory containing the axioms for the natural numbers. Furthermore, he showed that any such system was inherently incomplete, that is, that there are propositions expressible in the system for which neither they nor their negations are provable. Gödel's investigations were stimulated by the problems surrounding the axiom of choice, the axiom that for any set S of nonempty disjoint sets, there is a subset T of the union of S that has exactly one element in common with each member of S. Since that axiom led to many counterintuitive results, it was important to show that the axiom could not lead to contradictions. But given his initial results, the best Gödel could do was to show that the axiom of choice was relatively consistent, that its addition to the Zermelo-Fraenkel axiom set did not lead to any contradictions that would not already have been implied without it.

Ronald Graham (born 1935) is a central figure in the development of discrete mathematics. He received his Ph.D. in 1962 from the University of California, Berkeley and spent most of his professional life at Bell Labs, although he was appointed to an endowed chair at the University of California, San Diego in 1999. His work has been seminal in the origin of three new branches of mathematics: Ramsey theory, computational geometry, and worst-case analysis of multiprocessing algorithms. He was a long-time collaborator with Paul Erdős, frequently housing that wandering mathematician during the last decades of his life. Graham served as president of the American Mathematical Society in 1993-1994 and the Mathematical Association of America in 2003-2004 and received the Steele Award for Lifetime Achievement from the former in 2003. He is also a skilled juggler and has served as president of the International Jugglers' Association.

Wolfgang Haken (born 1928), along with Kenneth Appel, produced the first proof of the four-color problem with the help of a computer, announcing it to the world on July 22, 1976. He then presented a paper describing the proof at the August, 1976 Summer Meeting of the American Mathematical Society in Toronto, to a very mixed reaction. Haken received his education in Germany, but spent most of his academic career at the University of Illinois. In addition to his work on the four-color problem, he has contributed numerous ideas to the subject of algorithmic topology.

Marshall Hall (1910–1990) was a group theorist whose 1959 textbook on the subject is still being used today. Hall received his Ph.D. from Yale in 1936 and later taught at Ohio State, the California Institute of Technology, and Emory University. During World War II, he spent time at Bletchley Park, working on breaking the German

Enigma codes. Among his important results in group theory was his solution of the Burnside problem of exponent 6, in which he showed that a finitely generated group in which the order of every element divides 6 must be finite. Later, he worked out (with James Senior) detailed descriptions of every group of order 32 and 64, publishing the results in an organized fashion in *The Groups of Order* 2^n $n \leq 6$. Hall is also famous for some fundamental work in the theory of projective planes as well as other areas of combinatorics.

William Rowan Hamilton (1805–1865), born in Dublin, was a child prodigy who became the Astronomer Royal of Ireland in 1827 in recognition of original work in optics accomplished during his undergraduate years at Trinity College, Dublin. In 1837, he showed how to introduce complex numbers into algebra axiomatically by considering $a + ib$ as a pair (a, b) of real numbers with appropriate computational rules. After many years of seeking an appropriate definition for multiplication rules for triples of numbers which could be applied to vector analysis in 3-dimensional space, he discovered that it was in fact necessary to consider quadruplets of numbers, which Hamilton named quaternions. Although quaternions never had the influence Hamilton forecast for them in physics, their noncommutative multiplication provided the first significant example of a mathematical system which did not obey one of the standard arithmetical laws of operation and thus opened the way for more “freedom” in the creation of mathematical systems. Among Hamilton’s other contributions was the development of the *Icosian* game, a graph with 20 vertices on which pieces were to be placed in accordance with various conditions, the overriding one being that a piece was always placed at the second vertex of an edge on which the previous piece had been placed. One of the problems Hamilton set for the game was, in essence, to discover a cyclic path on his game board which passed through each vertex exactly once. Such a path in a more general setting is today called a Hamilton circuit.

Richard W. Hamming (1915–1998) was born in Chicago and received a Ph.D. in mathematics from the University of Illinois in 1942. He was the author of the first major paper on error-correcting and detecting codes (1950). His work on this problem had been stimulated in 1947 when he was using an early Bell System relay computer on weekends only. During the weekends the machine was unattended and would dump any work in which it discovered an error and proceed to the next problem. Hamming realized that it would be worthwhile for the machine to be able not only to detect an error but also to correct it, so that his jobs would in fact be completed. In his paper, Hamming used a geometric model by considering an n-digit code word to be a vertex in the unit cube in the n-dimensional vector space over the field of two elements. He was then able to show that the relationship between the word length n and the number m of digits which carry the information was $2^m \leq \frac{2^n}{n+1}$. (The remaining $k = n - m$ digits are check digits which enable errors to be detected and corrected.) In particular, Hamming presented a particular type of code, today known as a Hamming code, with $n = 7$ and $m = 4$. In this code, the set of actual code words of 4 digits was a 4-dimensional vector subspace of the 7-dimensional space of all 7-digit binary strings.

Godfrey Harold Hardy (1877–1947) graduated from Trinity College, Cambridge in 1899. From 1906 until 1919 he was lecturer at Trinity College, and, recognizing the genius of Ramanujan, invited Ramanujan to Cambridge in 1914. Hardy held the Sullivan chair of geometry at Oxford from 1919 until 1931, when he returned to Cambridge, where he was Sadlerian professor of pure mathematics until 1942. He developed the Hardy-Weinberg law which predicts patterns of inheritance. His main areas of mathematical research were analysis and number theory, and he published over 100 joint papers with Cambridge colleague John Littlewood. Hardy's book *A Course in Pure Mathematics* revolutionized mathematics teaching, and his book *A Mathematician's Apology* gives his view of what mathematics is and the value of its study.

Abū 'Alī al-Hasan ibn al-Haytham (***Alhazen***) (965–1039) was one of the most influential Islamic scientists. He was born in Basra (now in Iraq) but spent most of his life in Egypt, after he was invited to work on a Nile control project. Although the project, an early version of the Aswan dam project, never came to fruition, ibn al-Haytham did produce in Egypt his most important scientific work, the *Optics*. This work was translated into Latin in the early thirteenth century and was studied and commented on in Europe for several centuries thereafter. Although there was much mathematics in the *Optics*, ibn al-Haytham's most interesting mathematical work was the development of a recursive procedure for producing formulas for the sum of any integral powers of the integers. Formulas for the sums of the integers, squares, and cubes had long been known, but ibn al-Haytham gave a consistent method for deriving these and used this to develop the formula for the sum of fourth powers. Although his method was easily generalizable to the discovery of formulas for fifth and higher powers, he gave none, probably because he only needed the fourth power rule in his computation of the volume of a paraboloid of revolution.

David Hilbert (1862–1943) was one of the last of the universal mathematicians, who contributed greatly to many areas of mathematics. Hilbert spent the first 33 years of his life in and around Königsberg, then capital of East Prussia, now in Russia. He attended the university there and, after receiving his doctorate, joined the faculty in 1885. He only rose to prominence, however, after he was called by Felix Klein to Göttingen, where he soon became one of the major reasons for that university's taking over from Berlin as the preeminent university for mathematics in Germany, and probably the world, through the first third of the twentieth century. Hilbert began his career with the study of algebraic forms, then turned to algebraic number theory, the foundations of geometry, integral equations, theoretical physics, and finally the foundations of mathematics. He is probably most famous for his lecture at the International Congress of Mathematicians in Paris in 1900, where he presented a list of 23 problems which he felt would be of central importance for mathematics in the twentieth century. Hilbert firmly believed that it was problems that drove mathematical progress and was always confident that, "*wir mussen wissen, wir werden wissen* (we must know, we will know)." After the Nazi seizure of power, Hilbert was forced to witness the demise of the Göttingen he knew and loved and died a lonely man during the Second World War.

Hypatia (c. 370–415), the first woman mathematician on record, lived in Alexandria. She was given a very thorough education in mathematics and philosophy by her father Theon and became a popular and respected teacher. She was responsible for detailed commentaries on several important Greek works, including Ptolemy's *Almagest*, Apollonius' *Conics*, and Diophantus' *Arithmetica*. Unfortunately, Hypatia was caught up in the pagan-Christian turmoil of her times and was murdered by an enraged mob.

Leonid Kantorovich (1912–1986) was a Soviet economist responsible for the development of linear optimization techniques in relation to planning in the Soviet economy. The starting point of this development was a set of problems posed by the Leningrad timber trust at the beginning of 1938 to the Mathematics Faculty at the University of Leningrad. Kantorovich explored these problems in his 1939 book *Mathematical Methods in the Organization and Planning of Production*. He believed that one way to increase productivity in a factory or an entire industrial organization was to improve the distribution of the work among individual machines, the orders to various suppliers, the different kinds of raw materials, the different types of fuels, and so on. He was the first to recognize that these problems could all be put into the same mathematical language and that the resulting mathematical problems could be solved numerically, but for various reasons his work was not pursued by Soviet economists or mathematicians.

Abū Bakr al-Karajī (died 1019) was an Islamic mathematician who worked in Baghdad. In the first decade of the eleventh century he composed a major work on algebra entitled *al-Fakhrī* (*The Marvelous*), in which he developed many algebraic techniques, including the laws of exponents and the algebra of polynomials, with the aim of systematizing methods for solving equations. He was also one of the early originators of a form of mathematical induction, which was best expressed in his proof of the formula for the sum of integral cubes.

Muhammad ibn Muhammad al-Fullāni al-Kishnāwī (died 1741) was a native of northern Nigeria and one of the few African black scholars known to have made contributions to “pure” mathematics before the modern era. Muhammad’s most important work, available in an incomplete manuscript in the library of the School of Oriental and African Studies in London, deals with the theory of magic squares. He gave a clear treatment of the “standard” construction of magic squares and also studied several other constructions — using knight’s moves, borders added to a magic square of lower order, and the formation of a square from a square number of smaller magic squares.

Stephen Cole Kleene (1909–1994) studied under Alonzo Church and received his Ph.D. from Princeton in 1934. His research has included the study of recursive functions, computability, decidability, and automata theory. In 1956 he proved Kleene’s Theorem, in which he characterized the sets that can be recognized by finite-state automata.

Felix Klein (1849–1925) received his doctorate at the University of Bonn in 1868. In 1872 he was appointed to a position at the University of Erlangen, and in his opening address laid out the *Erlanger Programm* for the study of geometry based on the structure of groups. He described different geometries in terms of the properties of a set that are invariant under a group of transformations on the set and gave a program of study using this definition. From 1875 until 1880 he taught at the Technische Hochschule in Munich, and from 1880 until 1886 in Leipzig. In 1886 Klein became head of the mathematics department at Göttingen and during his tenure raised the prestige of the institution greatly.

Donald E. Knuth (born 1938) received a Ph.D. in 1963 from the California Institute of Technology and held faculty positions at the California Institute of Technology (1963–1968) and Stanford (1968–1992). He made contributions in many areas, including the study of compilers and computational complexity. He is the designer of the mathematical typesetting system $\TeX$, and is the author of *The Art of Computer Programming*, the first comprehensive manual in the subject, published in many installments beginning in 1968. He received the Turing Award in 1974 and the National Medal of Technology in 1979.

Kazimierz Kuratowski (1896–1980) was the son of a famous Warsaw lawyer who became an active member of the Warsaw School of Mathematics after World War I. He taught both at Lwów Polytechnical University and at Warsaw University until the outbreak of World War II. During that war, because of the persecution of educated Poles, he went into hiding under an assumed name and taught at the clandestine

Warsaw University. After the war, he helped to revive Polish mathematics, serving as director of the Polish National Mathematics Institute. His major mathematical contributions were in topology. In particular, he formulated a version of a maximal principle equivalent to the axiom of choice. This principle is today known as Zorn's lemma. Kuratowski also contributed to the theory of graphs by proving in 1930 that any non-planar graph must contain a copy of one of two particularly simple non-planar graphs.

Joseph-Louis Lagrange (1736–1813) was born in Turin into a family of French descent. He was attracted to mathematics in school and at the age of 19 became a mathematics professor at the Royal Artillery School in Turin. At about the same time, having read a paper of Euler's on the calculus of variations, he wrote to Euler explaining a better method he had recently discovered. Euler praised Lagrange and arranged to present his paper to the Berlin Academy, to which he was later appointed when Euler returned to Russia. Although most famous for his *Analytical Mechanics*, a work which demonstrated how problems in mechanics can generally be reduced to solutions of ordinary or partial differential equations, and for his *Theory of Analytic Functions*, which attempted to reduce the ideas of calculus to those of algebraic analysis, he also made contributions in other areas. For example, he undertook a detailed review of solutions to quadratic, cubic, and quartic polynomials to see how these methods might generalize to higher degree polynomials. He was led to consider permutations on the roots of the equations and functions on the roots left unchanged by such permutations. As part of this work, he discovered a version of Lagrange's Theorem to the effect that the order of any subgroup of a group divides the order of the group. Although he did not complete his program and produce a method of solving higher degree polynomial equations, his methods were applied by others early in the nineteenth century to show that such solutions were impossible.

Gabriel Lamé (1795–1870) was educated at the École Polytechnique and the École des Mines before going to Russia to direct the School of Highways and Transportation in St. Petersburg. After his return to France in 1832, he taught at the École Polytechnique while also working as an engineering consultant. Lamé contributed original work to number theory, applied mathematics, and thermodynamics. His best-known work is his proof of the case $n = 5$ of Fermat's Last Theorem in 1839. Eight years later, he announced that he had found a general proof of the theorem, which began with the factorization of the expression $x^n + y^n$ over the complex numbers as $(x + y)(x + \alpha y)(x + \alpha^2 y) \ldots (x + \alpha^{n-1} y)$, where α is a primitive root of $x^n - 1 = 0$. He planned to show that the factors in this expression are all relatively prime and therefore that if $x^n + y^n = z^n$, then each of the factors would itself be an nth power. He would then use the technique of infinite descent to find a solution in smaller numbers. Unfortunately Lamé's idea required that the ring of integers in the cyclotomic field of the nth roots of unity be a unique factorization domain. And, as Kummer had already proved three years earlier, unique factorization in fact fails in many such domains.

Edmund Landau (1877–1938) received a doctorate under Frobenius and taught at the University of Berlin and at Göttingen. His research areas were analysis and analytic number theory, including the distribution of primes. He used the big-O notation (also called a Landau symbol) in his work to estimate the growth of various functions.

Pierre-Simon de Laplace (1749–1827) entered the University of Caen in 1766 to begin preparation for a career in the church. He soon discovered his mathematical talents, however, and in 1768 left for Paris to continue his studies. He later taught mathematics at the École Militaire to aspiring cadets. Legend has it that he examined, and passed, Napoleon there in 1785. He was later honored by both Napoleon and King Louis XVIII. Laplace is best known for his contributions to celestial mechanics, but he was also one of the founders of probability theory and made many contributions to mathematical statistics. In fact, he was one of the first to apply his theoretical results in statistics to a genuine problem in statistical inference, when he showed from the surplus of male to female births in Paris over a 25-year period that it was "morally certain" that the probability of a male birth was in fact greater than $\frac{1}{2}$.

Gottfried Wilhelm Leibniz (1646–1716), born in Leipzig, developed his version of the calculus some ten years after Isaac Newton, but published it much earlier. He based his calculus on the inverse relationship of sums and differences, generalized to infinitesimal quantities called differentials. Leibniz hoped that his most original contribution to philosophy would be the development of an alphabet of human thought, a way of representing all fundamental concepts symbolically and a method of combining these symbols to represent more complex thoughts. Although he never completed this project, his interest in finding appropriate symbols ultimately led him to the d and $\int$ symbols for the calculus that are used today. Leibniz spent much of his life in the diplomatic service of the Elector of Mainz and later was a Counsellor to the Duke of Hanover. But he always found time to pursue his mathematical ideas and to carry on a lively correspondence on the subject with colleagues all over Europe.

Levi ben Gerson (1288–1344) was a rabbi as well as an astronomer, philosopher, biblical commentator, and mathematician. He lived in Orange, in southern France, but little is known of his life. His most famous mathematical work is the *Maasei Hoshev* (The Art of the Calculator) (1321), which contains detailed proofs of the standard combinatorial formulas, some of which use the principle of mathematical induction. About a dozen copies of this medieval manuscript are extant, but it is not known whether the work had any direct influence elsewhere in Europe. Also, at the request of a French music theorist, Levi produced an elegant proof of the theorem that a power of two and a power of three cannot be consecutive numbers, except for the obvious cases of 2 and 3, 3 and 4, and 8 and 9.

László Lovász (born 1948) was so inspired as a high school student by Paul Erdős that he competed in the International Mathematical Olympiad in 1964, 1965, and 1966, winning a gold medal each time. He published his first paper, on graph theory, when he was only seventeen, and has since gone on to a remarkable career in which he has split time between Hungary and the United States. He has numerous results in discrete mathematics to his credit, results that have applications in other areas of mathematics as well as in computer science. He has developed new methods for solving combinatorial problems, including those relying on geometric polyhedral and topological techniques, thus showing that combinatorics deserves to be considered as one of the major branches of mathematics. Besides authoring several important research monographs, he has also written an elementary textbook introducing students to the basic ideas of discrete mathematics. His work has won him numerous prizes, and he served as president of the International Mathematical Union from 2007 to 2010.

Augusta Ada Byron King Lovelace (1815–1852) was the child of the famous poet George Gordon, the sixth Lord Byron, who left England five weeks after his daughter's birth and never saw her again. She was raised by her mother, Anna Isabella Millbanke, a student of mathematics herself, so she received considerably more mathematics education than was usual for girls of her time. She was tutored privately by well-known mathematicians, including William Frend and Augustus DeMorgan. Her husband, the Earl of Lovelace, was made a Fellow of the Royal Society in 1840, and through this connection, Ada was able to gain access to the books and papers she needed to continue her mathematical studies and, in particular, to understand the workings of Babbage's Analytical Engine. Her major mathematical work is a heavily annotated translation of a paper by the Italian mathematician L. F. Menabrea dealing with the Engine, in which she gave explicit descriptions of how it would solve specific problems and described, for the first time in print, what would today be called a computer program, in this case a program for computing the Bernoulli numbers. Interestingly, only her initials, A.A.L., were used in the published version of the paper. It was evidently not considered proper in mid-nineteenth century England for a woman of her class to publish a mathematical work.

Jan Łukasiewicz (1878–1956) studied at the University of Lwów and taught at the University of Lwów, the University of Warsaw, and the Royal Irish Academy. A logician, he worked in the area of many-valued logic, writing papers on three-valued and m-valued logics, He is best known for the parenthesis-free notation he developed for propositions, called Polish notation.

Percy Alexander MacMahon (1854–1929) was born into a British army family and joined the army himself in 1871, reaching the rank of major in 1889. Much of his army service was spent as an instructor at the Royal Military Academy. His early mathematical work dealt with invariants, following on the work of Cayley and Sylvester, but a study of symmetric functions eventually led to his interest in partitions and to his extension of the idea of a partition to higher dimensions. MacMahon's two volume treatise *Combinatorial Analysis* (1915–16) is a classic in the field. It identified and clarified the basic results of combinatorics and showed the way toward numerous applications.

Mahāvīra (ninth century) was an Indian mathematician of the medieval period whose major work, the *Ganitasārasañgraha*, was a compilation of problems solvable by various algebraic techniques. For example, the work included a version of the hundred fowls problem: "Doves are sold at the rate of 5 for 3 coins, cranes at the rate of 7 for 5, swans at the rate of 9 for 7, and peacocks at the rate of 3 for 9. A certain man was told to bring at these rates 100 birds for 100 coins for the amusement of the king's son and was sent to do so. What amount does he give for each?" Mahāvīra also presented, without proof and in words, the rule for calculating the number of combinations of r objects out of a set of n. His algorithm can be easily translated into the standard formula. Mahāvīra then applied the rule to two problems, one about combinations of tastes and another about combinations of jewels on a necklace.

Andrei Markov (1856–1922) was a Russian mathematician who first defined what are now called Markov chains in a paper of 1906 dealing with the Law of Large Numbers and subsequently proved many of the standard results about them. His interest in these chains stemmed from the needs of probability theory. Markov never dealt with their application to the sciences, only considering examples from literary texts, where the two possible states in the chain were vowels and consonants. Markov taught at St. Petersburg University from 1880 to 1905 and contributed to such fields as number theory, continued fractions, and approximation theory. He was an active participant in the liberal movement in pre-World War I Russia and often criticized publicly the actions of state authorities. In 1913, when as a member of the Academy of Sciences he was asked to participate in the pompous ceremonies celebrating the 300th anniversary of the Romanov dynasty, he instead organized a celebration of the 200th anniversary of Jacob Bernoulli's publication of the Law of Large Numbers.

Marin Mersenne (1588–1648) was educated in Jesuit schools and in 1611 joined the Order of Minims. From 1619 he lived in the Minim Convent de l'Annonciade near the

Place Royale in Paris and there held regular meetings of a group of mathematicians and scientists to discuss the latest ideas. Mersenne also served as the unofficial "secretary" of the republic of scientific letters in Europe. As such, he received material from various sources, copied it, and distributed it widely, thus serving as a "walking scientific journal". His own contributions were primarily in the area of music theory as detailed in his two great works on the subject, the *Harmonie universelle* and the *Harmonicorum libri*, both of which appeared in 1636. As part of his study of music, he developed the basic combinatorial formulas by considering the possible tunes one could create out of a given number of notes. Mersenne was also greatly interested in the relationship of theology to science. He was quite concerned when he learned that Galileo could not publish one of his works because of the Inquisition and, in fact, offered his assistance in this matter.

Hermann Minkowski (1864–1909) was a German mathematician who received his doctorate at the University of Königsberg. He became a lifelong friend of David Hilbert and, on Hilbert's suggestion, was called to Göttingen in 1902. In 1883, he shared the prize of the Paris Academy of Sciences for his essay on the topic of the representations of an integer as a sum of squares. In his essay, he reconstructed the entire theory of quadratic forms in n variables with integral coefficients. In further work on number theory, he brought to bear geometric ideas beginning with the realization that a symmetric convex body in n-space defines a notion of distance and hence a geometry in that space. The connection with number theory depends on the representation of forms by lattice points in space.

Aḥmad ibn Mun'im al-'Abdari (died 1228) was born in Andalusia, but then lived and taught in Marrakesh, probably at the Almohade court during the reign of Muḥammad al-Nāṣir. He is best known for his work *On the Science of Calculation*, which contains a long section titled "On denumerating the Words Such That a Person Cannot Express Himself without One of Them." That is, he attempted to count all possible words that can be formed out of the letters, including vowels, of the Arabic alphabet. He used various counting techniques, including what is now called the Pascal triangle, to show how this problem can be attacked. Although the question as posed cannot be answered in full, ibn Mun'im did give methods for finding partial answers. For example, he showed that the number of possible words of nine letters of which two are not repeated, two are repeated twice, and one is repeated three times is 5,968,924,232,544,000. In another section of his work, he discussed figured numbers, showing how they can be generated recursively and giving a rule for calculating the sum of consecutive figured numbers of a given type.

John F. Nash, Jr. (1928–2015) shared the 1994 Nobel Prize in Economics (together with Reinhard Selten and John Harsanyi) for fundamental contributions to game theory and its applications to economics. Nash earned his Ph.D. at Princeton University with a dissertation defining and explaining what became known as the Nash equilibrium in non-cooperative games. A group of players are in the Nash equilibrium if each one has chosen a strategy and no one can benefit by changing strategies, provided that all the other players keep their strategies unchanged. Nash proved that such an equilibrium exists under many game-theoretic conditions. As detailed in Sylvia Nasar's biography of Nash, "A Beautiful Mind", he suffered from paranoid schizophrenia for much of his adult life. He still managed to make major contributions, not only to game theory but to differential geometry and partial differential equations. In fact, in 2015 he shared the Abel Prize with Louis Nirenberg for his work on nonlinear partial differential equations. He was killed in an automobile accident on his way home from Norway, where he had received the award.

Peter Naur (1928–2016), born in Denmark, was originally an astronomer, using computers to calculate planetary motion, but in 1959 he became a full-time computer scientist. He was a developer of the programming language ALGOL and worked on compilers for ALGOL and COBOL. In 1969 he took a computer science faculty position at the University of Copenhagen, from which he retired in 1998. He won the Turing award in 2005 "for fundamental contributions to programming language design and the definition of ALGOL 60, to compiler design, and to the art and practice of computer programming."

Amalie Emmy Noether (1882–1935) received her doctorate from the University of Erlangen in 1908 and a few years later moved to Göttingen to assist Hilbert in the study of general relativity. During her eighteen years there, she was extremely influential in stimulating a new style of thinking in algebra by always emphasizing its structural rather than computational aspects. She was forced to leave Germany in the 1930s by the Nazis, but in 1934, she became a professor at Bryn Mawr College and a member of the Institute for Advanced Study. She is most famous for her work on Noetherian rings, and her influence is still evident in today's textbooks in abstract algebra.

Blaise Pascal (1623–1662) showed his mathematical precocity with his *Essay on Conics* of 1640, in which he stated his theorem that the opposite sides of a hexagon inscribed in a conic section always intersect in three collinear points. Pascal is better known, however, for his detailed study of what is now called Pascal's triangle of binomial coefficients. In that study Pascal gave an explicit description of mathematical induction and used that method, although not quite in the modern sense, to prove various properties of the numbers in the triangle, including a method of determining the appropriate division of stakes in a game interrupted before its conclusion. Pascal had earlier discussed this matter, along with various other ideas in the theory of probability, in correspondence with Fermat in the 1650s. These letters, in fact, can be considered the beginning of the mathematization of probability.

Giuseppe Peano (1858–1932) studied at the University of Turin and then spent the remainder of his life there as a professor of mathematics. He was originally known as an inspiring teacher, but as his studies turned to symbolic logic and the foundations of mathematics and he attempted to introduce some of these notions in his elementary classes, his teaching reputation changed for the worse. Peano is best known for his axioms for the natural numbers, first proposed in the *Arithmetices principia, nova methodo exposita* of 1889. One of these axioms describes the principle of mathematical induction. Peano was also among the first to present an axiomatic description of a (finite-dimensional) vector space. In his *Calcolo geometrico* of 1888, Peano described what he called a *linear system*, a set of quantities provided with the operations of addition and scalar multiplication which satisfy the standard properties. He was then able to give a coherent definition of the *dimension* of a linear system as the maximum number of linearly independent quantities in the system.

Charles Sanders Peirce (1839–1914) was born in Massachusetts, the son of a Harvard mathematics professor. He received a master's degree from Harvard in 1862 and an advanced degree in chemistry from the Lawrence Scientific School in 1863. He made contributions to many areas of the foundations and philosophy of mathematics. He was a prolific writer, leaving over 100,000 pages of unpublished manuscript at his death.

George Pólya (1887–1985) was a Hungarian mathematician who received his doctorate at Budapest in 1912. From 1914 to 1940 he taught in Zurich, then emigrated to the United States where he spent most of the rest of his professional life at Stanford

University. Pólya developed some influential enumeration ideas in several papers in the 1930s, in particular dealing with the counting of certain configurations that are not equivalent under the action of a particular permutation group. For example, there are 16 ways in which one can color the vertices of a square using two colors, but only six are non-equivalent under the various symmetries of the square. In 1937, Pólya published a major article in the field, "Combinatorial Enumeration of Groups, Graphs and Chemical Compounds", in which he discussed many mathematical aspects of the theory of enumeration and applied it to various problems. Pólya's work on problem solving and heuristics, summarized in his two volume work *Mathematics and Plausible Reasoning*, insured his fame as a mathematics educator; his ideas are at the forefront of recent reforms in mathematics education at all levels.

Qin Jiushao (1202–1261), born in Sichuan, published a general procedure for solving systems of linear congruences — the Chinese remainder theorem — in his *Shushu jiuzhang* (*Mathematical Treatise in Nine Sections*) in 1247, a procedure which makes essential use of the Euclidean algorithm. He also gave a complete description of a method for numerically solving polynomial equations of any degree. Qin's method had been developed in China over a period of more than a thousand years; it is similar to a method used in the Islamic world and is closely related to what is now called the Horner method of solution, published by William Horner in 1819. Qin studied mathematics at the Board of Astronomy, the Chinese agency responsible for calendrical computations. He later served the government in several offices, but because he was "extravagant and boastful", he was several times relieved of his duties because of corruption. These firings notwithstanding, Qin became a wealthy man and developed an impressive reputation in love affairs.

Willard Van Orman Quine (1908–2000) was a logician and philosopher who received his Ph.D. from Harvard in 1932 and remained with the university in various positions for the remainder of his life. He was a chief proponent of the view that philosophy is not conceptual analysis but is an abstract branch of the empirical sciences. While he wrote many expository works in logic, his most innovative work was in set theory, where at different times in his life he proposed three variants of axiomatic set theory. He also made many contributions to symbolic logic, where some of his results found applications in computer science.

Richard Rado (1906–1989) left Germany for Great Britain in 1933, once the racial laws were promulgated by the Nazis. He had already received a Ph.D. from the University of Berlin, but then received a second from Cambridge University two years later. Rado's most important contributions were in combinatorics, and he wrote many joint papers in the field with Paul Erdős. In particular, the two of them developed the partition calculus, which generalizes the following example: If six people meet by chance, then either at least three all know each other or there are at least three with no two knowing each other. Rado spent his academic career at three universities in England: the University of Sheffield, King's College, London, and the University of Reading, from which he retired.

Srinivasa Ramanujan (1887–1920) was born near Madras into the family of a bookkeeper. He studied mathematics on his own and soon began producing results in combinatorial analysis, some already known and others previously unknown. At the urging of friends, he sent some of his results to G. H. Hardy in England, who quickly recognized Ramanujan's genius and invited him to England to develop his untrained mathematical talent. During the war years from 1914 to 1917, Hardy and Ramanujan collaborated on a number of papers, including several dealing with the theory of partitions. Unfortunately, Ramanujan fell ill during his years in the unfamiliar climate of England and died at age 32 soon after returning to India. Ramanujan left behind several notebooks containing statements of thousands of results, enough work to keep many mathematicians occupied for years in understanding and proving them. The 2015 film "The Man Who Knew Infinity" depicts his time at Trinity College, Cambridge, and his mathematical collaborations with Hardy.

Frank Ramsey (1903–1930), son of the president of Magdalene College, Cambridge, was educated at Winchester and Trinity Colleges. He was then elected a fellow of King's College, where he spent the remainder of his life. Ramsey made important contributions to mathematical logic. What is now called Ramsey theory began with his clever combinatorial arguments to prove a generalization of the pigeonhole principle, published in the paper "On a Problem of Formal Logic". The problem of that paper was the *Entscheidungsproblem* (the decision problem), the problem of searching for a general method of determining the consistency of a logical formula. Ramsey also made contributions to the mathematical theory of economics and introduced the subjective interpretation to probability. In that interpretation, Ramsey argues that different people when presented with the same evidence, will have different degrees of belief. And the way to measure a person's belief is to propose a bet and see what are the lowest odds the person will accept. Ramsey's death at the age of 26 deprived the mathematical community of a brilliant young scholar.

Ronald Rivest (born 1947) is a cryptographer and professor at MIT. He received his Ph.D. in computer science from Stanford University in 1974 and three years later, along with Adi Shamir and Len Adleman, invented the RSA public key algorithm, now commonly used for secure data transmission. The algorithm is based on the difficulty of factoring the product of two large prime numbers. (The algorithm had been earlier invented by Clifford Cocks, but had not been published because it was classified.) According to legend, the algorithm was invented after the three had consumed much wine during a Passover seder at the home of a student. Rivest has invented other symmetric key encryption algorithms as well.

Alvin Roth (born 1951) won the Nobel Prize in Economics in 2012 (together with Lloyd Shapley) for his work in market design. One of his major achievements was demonstrating, in 1984, that the National Resident Matching Program, which matches new medical doctors with hospital residency programs, was stable and strategy-proof. His work was based on the theoretical foundations introduced by David Gale and Lloyd Shapley in 1962. He later worked with the New York public school system to redesign its matching programs for students entering high school, as well as with the Boston public school system for its matching of primary school students. More recently, he applied the ideas of stable matchings to the problem of paired kidney exchanges. Roth received his Ph.D. from Stanford University and is currently a faculty member at the same institution.

Bertrand Arthur William Russell (1872–1970) was born in Wales and studied at Trinity College, Cambridge. A philosopher/mathematician, he is one of the founders of modern logic and wrote over 40 books in different areas. In his most famous work, *Principia Mathematica*, published in 1910–13 with Alfred North Whitehead, he attempted to deduce the entire body of mathematics from a single set of primitive axioms. A pacifist, he fought for progressive causes, including women's suffrage in Great Britain and nuclear disarmament. In 1950 he won a Nobel Prize for literature.

al-Samaw'al ibn Yahyā ibn Yahūda al-Maghribī (1125–1180) was born in Baghdad to well-educated Jewish parents. Besides giving him a religious education, they encouraged him to study medicine and mathematics. He wrote his major mathematical work, *Al-Bāhir* (*The Shining*), an algebra text that dealt extensively with the algebra of polynomials, at the age of 19. In it, al-Samaw'al worked out the laws of exponents, both positive and negative, and showed how to divide polynomials even when the division was not exact. He also used a form of mathematical induction to prove the binomial theorem, that $(a+b)^n = \sum_{k=0}^{n} C(n,k)a^{n-k}b^k$, where the $C(n,k)$ are the entries in the Pascal triangle, for $n \leq 12$. In fact, he showed why each entry in the triangle can be formed by adding two numbers in the previous row. When al-Samaw'al was about 40, he decided to convert to Islam. To justify his conversion to the world, he wrote an autobiography in 1167 stating his arguments against Judaism, a work which became famous as a source of Islamic polemics against the Jews.

Issai Schur (1875–1941) was born in the Russian Empire but spent most of his academic life in Germany. He received his doctorate from the University of Berlin in 1901 and was a professor there from 1919 until he was forced to retire by the Nazis in 1935. In fact, he led a well-known school of mathematicians at Berlin working in group representations as well as some related ones. He is best known for his work in that field, but he also contributed significantly to combinatorics and number theory. In particular, when he realized in the 1920s that group representations were important for theoretical physics, he returned to their study with renewed energy and eventually gave a complete description of the rational representations of the general linear group. Unfortunately, after he was dismissed from his professorship, he declined some invitations to go abroad. Eventually, all avenues of work were closed to him in Germany. He was forced to relinquish membership in the Prussian Academy of Science. Finally, in 1939, he left Germany for Palestine where he died two years later.

Adi Shamir (born 1952) is an Israeli cryptographer who received his Ph.D. in computer science from the Weizmann Institute in 1977. He is the inventor (along with Ronald Rivest and Len Adleman) of the RSA public key algorithm, now used in secure data transmission. He has made numerous other contributions to cryptography and computer science, including the independent discovery of differential cryptanalysis (previously known to the U.S. National Security Agency). He is currently on the faculty both of the Weizmann Institute and the École Normale Supérieure in Paris.

Claude Elwood Shannon (1916–2001) applied Boolean algebra to switching circuits in his master's thesis at M.I.T in 1938. Shannon realized that a circuit can be represented by a set of equations and that the calculus necessary for manipulating these equations is precisely the Boolean algebra of logic. Simplifying these equations for a circuit would yield a simpler, equivalent circuit. Switches in Shannon's calculus were either open (represented by 1) or closed (represented by 0); placing switches in parallel was represented by the Boolean operation "+", while placing them in parallel was represented by "$\cdot$". Using the basic rules of Boolean algebra, Shannon was, for example, able to construct a circuit which would add two numbers given in binary representation. He received his Ph.D. in mathematics from M.I.T. in 1940 and spent much of his professional life at Bell Laboratories, where he worked on methods of transmitting data efficiently and made many fundamental contributions to information theory.

Lloyd Shapley (1923–2016) received the Nobel Prize in Economics (together with Alvin Roth) in 2012 after a long career in game theory and mathematical economics. He served in the U.S. Army Air Corps in World War II, after which he finished his education with a Ph.D. from Princeton in 1953. He was a professor at the University of California, Los Angeles from 1981, where he had a joint appointment in mathematics and economics. His Nobel Prize was awarded "for the theory of stable allocations and the practice of market design." In particular, he used Cooperative Game Theory to study methods to pair different players in a game in a stable matching, one in which no two players would prefer one another over their current counterparts.

Emanuel Sperner (1905–1980) was a German mathematician who received his doctorate in 1928 from the University of Hamburg. He is famous for several results in set theory discovered when he was a young man. Sperner's Theorem, published in 1928, describes the largest possible collection of subsets of a given set with the property that no subset in the collection contains any other subset in the collection. The result known as "Sperner's Lemma," proved about the same time, deals with the labelings of vertices in a special type of graph. Surprisingly, the lemma is crucial to an elegant proof of the Brouwer Fixed Point Theorem and has numerous other applications in topology. Sperner is also famous for his 1951 textbook *Introduction to Modern Algebra and Matrix Theory* (with Otto Schreier), in which fundamental concepts in algebra and in affine and projective geometry are treated simultaneously. Sperner became secretary of the German Mathematical Society in 1935, then resigned that position to become editor of the *Jahresbericht* of the Society until its closure at the end of 1943. He was a member of the board of the Society which, in 1938, wrote to all remaining Jewish members asking them to resign.

James Stirling (1692–1770) studied at Glasgow University and at Balliol College, Oxford and spent much of his life as a successful administrator of a mining company in Scotland. His mathematical work included an exposition of Newton's theory of cubic curves and a 1730 book entitled *Methodus Differentialis* which dealt with summation and interpolation formulas. In dealing with the convergence of series, Stirling found it useful to convert factorials into powers. By considering tables of factorials, he was able to derive the formula for $\log n!$, which leads to what is now known as Stirling's approximation: $n! \approx (\frac{n}{e})^n\sqrt{2\pi n}$. Stirling also developed the Stirling numbers of the first and second kinds, sequences of numbers important in enumeration.

Sun Zi (4th century) is the author of *Sunzi suanjing* (*Master Sun's Mathematical Manual*), a manual on arithmetical operations which eventually became part of the required course of study for Chinese civil servants. The most famous problem in the work is one of the first examples of what is today called the Chinese remainder problem: "We have things of which we do not know the number; if we count them by threes, the remainder is 2; if we count them by fives, the remainder is 3; if we count them by sevens, the remainder is 2. How many things are there?" Sun Zi gives the answer, 23, along with some explanation of how the problem should be solved. But since this is the only problem of its type in the book, it is not known whether Sun Zi had developed a general method of solving simultaneous linear congruences.

James Joseph Sylvester (1814–1897), who was born into a Jewish family in London and studied for several years at Cambridge, was not permitted to take his degree there for religious reasons. Therefore, he received his degree from Trinity College, Dublin and soon thereafter accepted a professorship at the University of Virginia. His horror of slavery, however, and an altercation with a student who did not show him the respect he felt he deserved led to his resignation after only a brief tenure. After his return to England, he spent 10 years as an attorney and 15 years as professor of mathematics at the Royal Military Academy at Woolwich. Sylvester returned to the United States in 1871 to accept the chair of mathematics at the newly opened Johns Hopkins University in Baltimore, where he founded the *American Journal of Mathematics* and helped initiate a tradition of graduate education in mathematics in the United States. Sylvester's primary mathematical contributions are in the fields of invariant theory and the theory of partitions.

Terence Tao (born 1975) is the youngest participant to date in the International Mathematical Olympiad, where he first competed on the Australian team at the age of ten and where he won a gold medal at thirteen. He received his Ph.D. from Princeton University at the age of 20 and then joined the faculty at UCLA, where he was promoted to full professor at the age of 24. In 2006, he won the Fields Medal "for his contributions to partial differential equations, combinatorics, harmonic analysis and additive number theory." Among his many accomplishments are his proof (with Ben Green) that it is always possible to find a progression of prime numbers of equal spacing and any length, and his new method of attack, in 2014, on the Navier-Stokes Millennium Problem.

Thābit ibn Qurra (836–901) was born in the south of what is now Turkey. His mathematical abilities were discovered by scholars from Baghdad, and so he was invited to the capital of the caliphate where he eventually became court astronomer. He translated many Greek mathematical works into Arabic and also produced an algebra text in which justifications of the algorithms for solving quadratic equations were based on theorems of Euclid's Book II. His major mathematical work, however, was the statement and proof of a result producing amicable numbers, a result that was transmitted to Europe via several Hebrew mathematical texts.

John Wilder Tukey (1915–2000) received a Ph.D. in topology from Princeton in 1939. After World War II he returned to Princeton as professor of statistics, where he founded the Department of Statistics in 1966. His work in statistics included the areas of spectra of time series and analysis of variance. He invented (with J. W. Cooley) the fast Fourier transform. He was awarded the National Medal of Science and served on the President's Science Advisory Committee. He also coined the word "bit" for a binary digit.

Alan Turing (1912–1954) studied mathematics at King's College, Cambridge and in 1936 invented the concept of a Turing machine to answer the questions of what a computation is and whether a given computation can in fact be carried out. This notion today lies at the basis of the modern all-purpose computer, a machine which can be programmed to do any desired computation. At the outbreak of World War II, Turing was called to serve at the Government Code and Cypher School in Bletchley Park in Buckinghamshire. It was there, during the next few years, that he led the successful effort to crack the German "Enigma" code, an effort which turned out to be central to the defeat of Nazi Germany. After the war, Turing continued his interest in automatic computing machines and so joined the National Physical Laboratory to work on the design of a computer, continuing this work after 1948 at the University of Manchester. Turing's promising career came to a grinding halt, however, when he was arrested in 1952 for homosexual acts. The penalty for this "crime" was submission to psychoanalysis and hormone treatments to "cure" the disease. Unfortunately, the cure proved worse than the disease, and, in a fit of depression, Turing committed suicide in June, 1954.

Alexandre-Théophile Vandermonde (1735–1796) was directed by his physician father to a career in music. However, he later developed a brief but intense interest in mathematics and wrote four important papers published in 1771 and 1772. These papers include fundamental contributions to the theory of the roots of equations, the theory of determinants, and the knight's tour problem. In the first paper, he showed that any symmetric function of the roots of a polynomial equation can be expressed in terms of the coefficients of the equation. His paper on determinants was the first logical, connected exposition of the subject, so he can be thought of as the founder of the theory. Toward the end of his life, he joined the cause of the French Revolution and held several different positions in government.

François Viète (1540–1603), a lawyer and advisor to two kings of France, was one of the earliest cryptanalysts and successfully decoded intercepted messages for his patrons. In fact, he was so successful in this endeavor that he was denounced by some who thought that the decipherment could only have been made by sorcery. Although a mathematician only by avocation, he made important contributions to the development of algebra. In particular, he introduced letters to stand for numerical constants, thus enabling him to break away from the style of verbal algorithms of his predecessors and treat general examples by formulas rather than by giving rules for specific problems.

Edward Waring (1734–1798) graduated from Magdalen College, Cambridge in 1757 with highest honors and shortly thereafter was named a Fellow of the University. In 1760, despite opposition because of his youth, he was named Lucasian Professor of Mathematics at Cambridge, a position he held until his death. To help solidify his position, then, he published the first chapter of his major work, *Miscellanea analytica*, which in later editions was renamed *Meditationes algebraicae*. Waring is best remembered for his conjecture that every integer is the sum of at most four squares, at most nine cubes, at most 19 fourth powers, and, in general, at most r kth powers, where r depends on k. The general theorem that there is a finite r for each k was proved by Hilbert in 1909. Although the result for squares was proved by Lagrange, the specific results for cubes and fourth powers were not proved until the twentieth century.

Andrew Viterbi (born 1935) is an electrical engineer who invented the Viterbi algorithm. This is a dynamic programming algorithm for finding the most likely sequence of hidden states that results in a sequence of observed events. The algorithm is used in cell phones, speech recognition, DNA analysis and other applications. Viterbi immigrated to the United States with his parents in 1939 because of the Italian racial laws restricting the civil rights of Jews. He received his Ph.D. from the University of Southern California. Besides serving as a professor of electrical engineering at both the University of California, Los Angeles and the University of California, San Diego, he was the co-founder of Qualcomm Inc., a semiconductor and telecommunications equipment company.

Hassler Whitney (1907–1989) received bachelor's degrees in both physics and music from Yale; in 1932 he received a doctorate in mathematics from Harvard. After a brief stay in Princeton, he returned to Harvard, where he taught until 1952, when he moved to the Institute for Advanced Study. Whitney produced more than a dozen papers on graph theory in the 1930s, after his interest was aroused by the four color problem. In particular, he defined the notion of the *dual graph* of a map. It was then possible to apply many of the results of the theory of graphs to gain insight into the four color problem. During the last twenty years of his life, Whitney devoted his energy to improving mathematical education, particularly at the elementary school level. He emphasized that young children should be encouraged to solve problems using their intuition, rather than only be taught techniques and results which have no connection to their experience.

Andrew Wiles (born 1953) is best known for his proof of Fermat's Last Theorem. Born in England, he first learned of the theorem when he was ten and vowed to be the first person to prove it. After receiving his Ph.D. from Cambridge, he spent time at the Institute for Advanced Study in Princeton and then joined the Princeton mathematics faculty, where he remained until he took a research professorship at Oxford in 2011. After he announced his proof in 1993 at a series of lectures at Cambridge University, the review process found a flaw in the proof. Fortunately, with the help of Richard Taylor, Wiles corrected the flaw the following year. The 1995 issue of the *Annals* *of Mathematics* contained the complete proof. The many new ideas in Wiles's work has led to many other new results in number theory. Wiles himself received the Abel prize in 2016 in recognition of his achievement.
