The mode of transmission of *H. pylori* is unclear, although both the fecal-oral and oral-oral routes are likely. There is evidence suggesting that transmission occurs between members of the same family. A definitive natural reservoir of *H. pylori* external to the human body has not been identified. Species closely related to *H. pylori* in the *Helicobacter* genus are known to colonize several mammalian species.

There are a variety of clinical circumstances in which testing for the presence of *H. pylori* infection should be considered. Guidelines published in 2007 by the American College of Gastroenterology (3) include the following. (i) Testing for *H. pylori* should be done only if the clinician plans to offer treatment for positive results. (ii) Testing is indicated for patients with gastric MALT lymphoma, active peptic ulcer disease, or a past history of documented peptic ulcer. (iii) Testing and treating (if results are positive) are a proven management strategy for patients under the age of 55 with uninvestigated dyspepsia and no concerning features for cancer, such as bleeding, anemia, early satiety, unexplained weight loss, progressive dysphagia, odynophagia, recurrent vomiting, family history of gastrointestinal cancer, or previous esophagogastric malignancy. The test-and-treat strategy avoids the cost and inconvenience of endoscopy for patients for whom the risk of gastric cancer is low. (iv) Deciding which test to use in which clinical situation depends in large part on whether the patient requires evaluation with upper endoscopy. The sensitivity, specificity, and costs of the individual tests to be used must also be considered (3). The American College of Gastroenterology guidelines also recommend confirmation of eradication in the following settings: (i) individuals with an *H. pylori*-associated ulcer, (ii) those with persistent dyspeptic symptoms despite the test-and-treat strategy, (iii) individuals with *H. pylori*-associated MALT lymphoma, and (iv) those having undergone resection of the stomach for early gastric cancer (3).

It should be noted that *H. pylori* is linked in the literature with a variety of extragastric diseases, with little or no causative effect, including neurological disorders, cardiovascular diseases, dermatologic diseases, and allergic disorders (4). However, there is some evidence to support eradication of *H. pylori* in patients with unexplained idiopathic thrombotic purpura, iron deficiency anemia, and vitamin B_{12} deficiency (4).

GENETIC HETEROGENEITY OF *H. PYLORI* STRAINS

Advances in molecular genetic methods have allowed the elucidation of the complete genome sequences of several *H. pylori* strains. In addition, DNA sequencing of a number of defined regions, along with other genetic techniques, has shown a high degree of heterogeneity among *H. pylori* strains, perhaps due to frequent genetic exchange between strains. With the notable exception of the CagA and VacA

doi:10.1128/9781555818722.ch45

status of the infecting strain, little is known about the impact of strain heterogeneity on serologic detection methods.

The CagA protein, which is highly immunogenic, is one of the most widely studied virulence factors of *H. pylori*. The *cag*A gene is one of the genes in the *cag* pathogenicity island (5). The severity of *H. pylori*-related disease is correlated with the presence of the *cag* pathogenicity island. The CagA protein is injected into gastric epithelial cells by a type IV secretion mechanism; once in these cells, it becomes tyrosine phosphorylated and mediates changes in the host cell signal transduction pathways and actin skeleton reorganization (5). Another important virulence factor, vacuolating cytotoxin (VacA), is so named because it causes vacuolization of cultured eukaryotic cells. The *vac*A gene encodes a 140-kDa toxin precursor and is present in all strains. However, its expression is transcriptionally regulated; therefore, only about 50% of all strains express the toxin. Epidemiological studies have shown an increased risk of developing gastric or peptic ulcers and/or gastric carcinoma in patients infected with *cag*A- and *vac*A-positive strains (6). More recently, researchers have focused on a variety of additional virulence factors, including the *ice*A, *bab*A, *oip*A, and *sab*A genes. In addition, an array of pro- and anti-inflammatory cytokine polymorphisms in the host are known to affect the infectious outcome (7). Despite marked progress in defining host and bacterial genotypes and their associations with gastroduodenal pathology, a definitive model describing pathogenesis is only beginning to emerge.

METHODS FOR DETECTION OF *H. PYLORI*

Multiple techniques have been developed for the diagnosis of *H. pylori* infection (8, 9). Due to the significant potential and actual clinical impact of *H. pylori* infection, the number of commercial tests available to diagnose infection has proliferated significantly over the past decade. In this chapter, the tests are discussed generically rather than listed specifically. These methods can be categorized into two broad categories. The first category includes invasive assays (which generally require the availability of gastric tissue obtained by endoscopic biopsy for histological examination), culture, molecular assays (such as PCR), and urease tests. Within the past several years, a minimally invasive string test has also become available. The second category involves noninvasive assays, which detect either an immunologic response (e.g., specific antibodies directed against *H. pylori*) in blood, urine, or saliva, metabolic products of *H. pylori* urease activity (urea breath test), or bacterial antigens or nucleic acid present in stool. The most common diagnostic tests for the detection of *H. pylori* infection are summarized in Table 1. Molecular methods not only permit highly sensitive detection of *H. pylori* but also allow detailed characterization of the infecting strain by detecting virulence-associated genes and/or antimicrobial-resistance genes. However, molecular techniques are generally available only in research laboratories. Local validation of diagnostic tests is important since factors such as the local prevalence of *H. pylori* infection, in addition to characteristics of the tests themselves, influence the predictive value of the tests.

Invasive Tests

Histologic examination of gastric tissue permits evaluation of the type and degree of inflammation and direct observation of bacteria, if present. The bacteria can be identified based on their characteristic spiral morphology and supramucosal location. *H. pylori* can sometimes be difficult to detect on hematoxylin-and-eosin-stained slides. Thus, special stains, such as the Warthin-Starry stain, in which darkly stained spiral bacteria appear prominent on a lightly colored background, are frequently employed, despite the technical demands and higher cost involved. Other staining methods, such as Giemsa staining, fluorescence *in situ* hybridization, and immunohistochemical staining, provide additional information, such as the direct detection of clarithromycin resistance (10). Histologic examination is required whenever conditions such as gastric cancer or MALT lymphoma are suspected.

Microbiological culture of *H. pylori* is the most specific diagnostic method, but the sensitivity of culture is usually significantly lower than that of other methods. There are several reasons for this low sensitivity. The patchy distribution of *H. pylori* organisms in gastric mucosa can lead to endoscopic sampling error, resulting in false-negative cultures. In addition, the isolation of *H. pylori* is technically demanding and requires proper specimen handling and transport, use of specialized media, and microaerophilic growth conditions. Isolation of the organism is highly recommended, however, whenever antimicrobial susceptibility testing of *H. pylori* is desired, such as when patients fail to respond to bacterial-eradication therapy.

An important characteristic of *H. pylori* that forms the basis of several diagnostic tests (the biopsy urease test and urea breath test) is the ability of the bacterium to produce large amounts of the enzyme urease. Urease catalyzes the hydrolysis of urea to ammonia and carbon dioxide. This reaction causes an increase in the pH of the surrounding medium, which can be detected by a pH indicator dye. Thus, the presence of urease activity, and hence of *H. pylori*, is heralded by a color change in the indicator. Commercial biopsy urease tests which provide a gel medium in which to incubate gastric biopsy specimens in the presence of urea and a pH indicator to detect the presence of preformed urease and hence of *H. pylori* are available; an example is the CLOtest. Results are available within 2 to 24 h, depending on the test and conditions used. Compared with histologic and culture methods, biopsy urease tests are the endoscopic method of choice for rapid diagnosis of *H. pylori* infection on the basis of low cost and excellent sensitivity and specificity. Because of the desire to know the patient's *H. pylori* status prior to discharge from the endoscopy suite, rapid urease tests in which biopsies are sandwiched between a reagent strip with a pH indicator and a pad containing urea have been developed. These tests' sensitivities and specificities at 1 h are slightly lower than those observed for agar gel tests at 24 h (11).

Once the biopsy specimen is obtained, the bacteria present can be detected or analyzed by molecular assays without the need for bacterial culture. PCR-based molecular assays have been developed to detect *H. pylori*-specific DNA from gastric biopsy specimens and from paraffin-embedded tissues. Additionally, genotyping of *H. pylori* strains for virulence factors such as *cag*A and *vac*A is possible using such specimens. However, PCR-based assays remain relatively labor-intensive and expensive and are generally not available in routine clinical laboratories.

As an alternative to endoscopic detection of *H. pylori*, a minimally invasive string test has become available (12). In this test, the patient swallows a capsule attached to a string. Subsequently, the string is removed and the upper 30 cm of the string is cut and discarded to reduce contamination with oral microbial microbiota. The material collected is then used to culture *H. pylori* on selective plates or to perform PCR testing to allow identification and characterization of *H. pylori* strains. Culture of *H. pylori* or detection of its presence

TABLE 1 Overview of diagnostic tests for detection of *H. pylori*

Test(s)	Requirement for endoscopy	Advantage(s)	Disadvantage(s)	Approximate sensitivity, specificity (%)
Histology	Yes	Allows evaluation of the type and degree of inflammation; required to determine whether malignancy is present	Results may vary, depending on pathologist experience; multiple biopsies are recommended	>75, >95
Culture	Yes	Allows strain characterization, including identification of antibiotic-resistant isolates and virulence factors	Results vary depending on gastric sampling and laboratory experience; considerable risk of false-negative results	>75, 100
Biopsy urease test (agar gel)	Yes	Rapid and inexpensive; endoscopic method of choice	May be falsely negative immediately after antibiotic treatment or during treatment with omeprazole	>90, >95
Rapid urease test	Yes	Results available within 1 h	As above; sensitivity and specificity are reduced compared to those of a biopsy urease test	~90, ~90
String test	No	Minimally invasive; alternative to endoscopy	Less sensitive than endoscopy	~80, 100
Urea breath tests using ^{14}C- or ^{13}C-labeled urea	No	Noninvasive; sealed breath samples can be sent to reference laboratories; the [^{13}C]urea breath test is preferred for children and when multiple tests are required; useful to assess eradication of *H. pylori*	[^{14}C]urea breath test involves low-level radiation exposure; [^{13}C]urea breath test requires specialized equipment (mass spectrometer)	>95, >95
Stool antigen	No	Noninvasive; monoclonal antibody-based tests give best results; useful to assess eradication of *H. pylori*	May be less sensitive in detecting eradication than urea breath test	>90, >95
Serology	No	Noninvasive; inexpensive and available commercially; suitable for population prevalence studies	Prolonged delays (mos) before antibody levels decrease after eradication	>95, >90
Urine antibody	No	Noninvasive; easy to obtain especially in children	Not available universally	>85, >90
Salivary antibody	No	Noninvasive; results are easy to obtain, especially for children	Not available universally	>80, >80
Molecular tests	Depends on specimen	Allow sensitive detection of *H. pylori* and specific virulence and antibiotic resistance markers	Not well standardized or available in routine clinical laboratories	Variable

by PCR using the string test has a sensitivity of about 80% or 91% compared to that of culture or PCR, respectively, of gastric biopsy specimens. The method is suitable for use in remote areas in which endoscopy is not available.

Noninvasive Tests

Urea breath testing involves oral administration of urea that has been labeled with either the ^{13}C or ^{14}C carbon isotope. In infected individuals, urea is metabolized to ammonia and carbon dioxide; the latter is excreted in the breath as labeled carbon dioxide. The amount of labeled carbon dioxide which is excreted can then be quantified. The [^{14}C]urea breath test involves low levels of radiation exposure but has the advantage that it can be performed in a relatively large number of laboratories equipped to detect such radioactivity. In contrast, the [^{13}C]urea breath test uses a nonradioactive isotope of urea, which requires a mass spectrometer to detect $^{13}CO_2$ in the breath sample (13). The [^{13}C]urea breath test is preferred when repeated testing of an individual is required. The [^{13}C]urea breath test has been validated for children as well. Urea breath testing is an excellent noninvasive method by which to evaluate successful eradication of *H. pylori*, since it reflects active bacterial metabolism and responds rapidly to changes in *H. pylori* infection status. Many referral centers now accept urea breath samples for analysis of $^{13}CO_2$ at moderate expense. The urea breath test has been considered to be the gold standard among noninvasive tests for the detection of active infection by *H. pylori* (8).

H. pylori colonizing the gastroduodenal regions tend to slough specific antigens into the stool, thus forming the basis of another method of detection: the stool antigen test. Rapid advances in the commercial development of *H. pylori* stool antigen test kits using polyclonal or monoclonal antibodies directed against specific antigens have made these tests affordable, with a sensitivity and specificity comparable to those of urea breath testing (9). As the next-most-common test after urea breath testing, stool antigen tests are recommended for noninvasive diagnosis of *H. pylori* before and after eradication therapy. In general, stool antigen tests using monoclonal antibody directed against *H. pylori* antigens are more sensitive than are tests using polyclonal antibodies. The high sensitivity (~95%) of monoclonal stool antigen tests is comparable to that observed using invasive testing procedures (14, 15). While polyclonal antibody-based stool testing is slightly less sensitive, a commercial polyclonal antibody-based stool antigen test showed a sensitivity of 84 to 94% and a specificity of 90 to 100% in a comparison with urea breath testing (14). In general, these stool antigen tests are performed within a clinical laboratory; hence, results may be delayed somewhat. Rapid stool antigen tests which can be performed at the point of care are now available. The reported sensitivities and specificities for initial diagnosis were 93 to 95% and 87 to 89%, respectively (14, 15).

Serologic Assays

Infection with *H. pylori* results in a systemic immune response characterized by circulating specific immunoglobulins (immunoglobulin G [IgG], IgA, and, acutely, IgM) (16). Spontaneous eradication of *H. pylori* infection rarely occurs. Thus, the presence of *H. pylori*-specific antibodies is indirect evidence of active infection. Serology was the first noninvasive test that became available after the successful cultivation of *H. pylori*. Since that time, serologic assays have proven particularly useful in studies of *H. pylori* prevalence in diverse populations around the world.

Enzyme-linked immunosorbent assay (ELISA) methodology is considered the optimal approach to serologic testing for *H. pylori* antibodies because such tests are noninvasive, simple to perform, rapid, and cost-effective compared to endoscopic biopsy. Further, serologic testing allows "global" sampling of gastric mucosal infection, whereas biopsy-based assays allow only localized sampling of the gastric mucosa. The choice of antigen is critical for the success of the ELISA. In general, four types of antigen have been used for detection of *H. pylori*-specific antibodies (17). These preparations include crude antigens, such as whole cells and whole-cell sonicates, cell fractions, such as glycine extracts and heat-stable antigens, component-enriched antigenic fractions, such as urease and the 120-kDa protein associated with vacuolating cytotoxic activity, and specific recombinant antigens, such as CagA. The sensitivities and specificities of several of the enriched antigen preparations typically exceed 95%. While analysis of whole-cell preparations of *H. pylori* by sodium dodecyl sulfate-polyacrylamide gel electrophoresis reveals a large number of polypeptides, generally no more than about 25 protein antigens are recognized by immunoblotting using sera from infected individuals. There is significant heterogeneity in the specificities of these antibodies. As shown by a variety of techniques, very few, if any, antigens are recognized by all positive sera. Among the most commonly recognized antigens are the 62- and 30-kDa subunits of urease and the 58-kDa homolog of the Cpn60 family of heat shock proteins (HspB). Considering the genetic heterogeneity of *H. pylori* strains, it is generally thought that use of pooled extracts from multiple and genetically diverse strains as antigen preparations for detection of antibody will improve diagnostic performance. A significant fraction of individuals infected with *H. pylori* also produce serum and local antibodies directed against the 120-kDa CagA protein and the 89-kDa VacA protein. Antibodies directed against CagA and/or VacA protein antigen have a strong association with the severity of gastritis and with gastric cancer (18).

Use of Specific Antigens in ELISA

H. pylori is a diverse bacterial species, with different clusters found in different parts of the world. Some authors have emphasized the need to use local strains as the source of antigen rather than foreign strains to obtain the best test results. This may be especially true in Asia (17).

Some serologic assays against specific virulence factors of *H. pylori* have been developed. The most important factor in using immunological methods for identifying VacA-specific antibodies by ELISA is the antigen preparation used to detect circulating antibodies. VacA proteins are quite diverse among *H. pylori* strains and are broadly classified as of the s1/m1 or s2/m2 type. While commercial kits are available for the detection of VacA antibodies by using immunoblot assays, most ELISAs have been developed with purified or enriched VacA protein fractions; this is a time-consuming and expensive approach (19). The availability of recombinant VacA protein will help to make the VacA ELISA more widely available.

Commercial assays which use recombinant CagA protein to detect CagA-specific IgG are now available (see http://www.antibodyresource.com for cytokine-associated gene A antibodies). These assays also use anti-human IgG monoclonal antibody enzyme conjugate to detect the presence of specific IgG. At least one assay has been automated to operate in a high-speed walk-away analyzer for 96-well ELISAs. Generally speaking, the use of ELISAs for the detection of antibodies to specific antigens is limited to research laboratories.

The possibility of false-negative serologic test results for *H. pylori* has to be considered for any individual with

an impaired immune response, e.g., the elderly, dialysis patients, immunosuppressed individuals, and organ recipients. In addition, chronic nonsteroidal anti-inflammatory drug treatment may suppress infection and decrease the sensitivity of serologic tests. False-negative results may also occur during the first few weeks of infection if methods which detect only IgG or IgA are used.

Value of Analysis of Specific Immunoglobulin Classes

In general, measurement of *H. pylori*-specific IgM levels has not proven useful in clinical laboratories because the time of infection is rarely known and patients' symptoms at the time of infection, if any, are nonspecific. A number of studies have evaluated the relative value of detecting *H. pylori*-specific IgG and IgA. Detection of *H. pylori*-specific IgA alone is generally less sensitive than detection of specific IgG antibodies alone. Testing for the presence of *H. pylori*-specific IgA in addition to IgG may increase test sensitivity slightly. However, the specificity of *H. pylori*-specific IgA appears to be at least equal to that of *H. pylori*-specific IgG (8, 9). Individuals who have IgA but not IgG antibodies against *H. pylori* are uncommon. As a result, most commercial serologic tests are based on the detection of *H. pylori*-specific IgG only.

H. pylori-Specific Antibodies in Body Fluids Other Than Serum

In an attempt to eliminate the need for venipuncture, diagnostic tests for the detection of IgG antibodies in the saliva and urine of adults and children have been developed (reviewed in reference 20). The sensitivity of detection of *H. pylori* antibodies in saliva generally ranges from 80 to 85%, while specificity generally ranges from 70 to 80%. The sensitivities of detection of *H. pylori* antibodies in urine generally range from 90 to 95%, with specificities of 90 to 95%. The ease of obtaining specimens is an obvious advantage of using urine as a source of IgG antibodies against *H. pylori* infection, especially with children (21, 22).

Immunoblot Analysis

Immunoblot analysis of whole-cell lysates of *H. pylori* permits a detailed analysis of antibody profiles and is useful for identifying immunologic responses to specific antigens. However, beyond research studies, immunoblot technology is of limited utility for several reasons. First, antibodies in some patients infected by specific strains of *H. pylori* may not recognize antigens if a single strain of *H. pylori* is used in the immunoblot assay. Second, the resolution of the immunoblot is limited, permitting only about 25 distinctive bands to be detected. It may be difficult to distinguish between antigens with similar molecular sizes. Finally, since immunoblot assays are labor-intensive and semiquantitative, this type of assay is not suitable for automation or for screening large collections of sera. One new commercial immunoblot method showed high sensitivity (99%) and specificity (98%) compared with those of three other methods (23). However, when CagA antibodies were determined by this assay, false-positive reactions were detected in patients infected with CagA-negative strains and in individuals not infected with *H. pylori* (23, 24). In general, immunoblot analysis is a research technique not available in routine clinical laboratories.

Rapid Serologic Tests

Over the past several years, a number of rapid near-patient tests have been marketed to detect antibodies to *H. pylori* in untreated individuals. These rapid tests are generally based on latex agglutination or flowthrough membrane-based enzyme immunoassays. Serum, plasma, or whole blood can be tested. Most of these tests detect IgG antibodies. While some studies have shown acceptable sensitivity and specificity, many qualitative rapid antibody tests have been clearly inferior to quantitative ELISAs. The use of rapid tests has not been recommended in Europe (2). The present authors recommend that if near-patient testing for *H. pylori* is to be instituted, the results of such tests must be correlated with results of serologic tests from the local reference laboratory on a select group of well-characterized patients before the test is accepted for widespread clinical use. These near-patient tests are generally more expensive than laboratory-based tests and have not been used widely.

Molecular Methods

Over the past decade and a half, a variety of DNA-based molecular techniques to detect *H. pylori*, determine susceptibility to clarithromycin, and serve as tools for strain typing have been developed. A major limitation of PCR-based detection methods for *H. pylori* is the inability to distinguish between living and dead organisms. Thus, PCR-based detection of *H. pylori* results in higher sensitivity than with other methods of detection. While molecular methods have been applied to the detection of *H. pylori*, such methods are not generally suitable for use in ordinary clinical settings.

PCR is as sensitive as culture in detecting *H. pylori* in gastric biopsy specimens. PCR has the advantage of allowing the detection of virulence factors such as *cagA*, *vacA* alleles, and other genetic factors. Real-time PCR has been used to estimate the gastric mucosal density of *H. pylori* (25). Chisholm et al. developed a multiplex PCR technique to detect *vacA* alleles in a single step (26). The latter authors reported perfect correlation with the genotypes determined directly in gastric biopsy specimens and in the *H. pylori* isolates cultured from the specimens. "Fingerprinting" of *H. pylori* strains can be performed on gastric biopsy specimens directly using PCR-restriction fragment length polymorphism analysis without having to culture bacteria. Real-time PCR using TaqMan technology has been applied to determine the bacterial load of *H. pylori* in the gastric mucosa. A good correlation was obtained with results obtained using the urea breath test (25). PCR has also been used to detect the presence of *H. pylori* in gastric samples collected using the string test.

Molecular methods to detect the resistance of *H. pylori* to clarithromycin by using cultured isolates or gastric biopsy specimens directly have been developed. Clarithromycin resistance is due to single point mutations in the peptidyltransferase region of the 23S rRNA gene (27); hence, detection of such mutations is well suited to PCR analysis. More recently, real-time PCR protocols which allow the detection of clarithromycin resistance-associated point mutations on the 23S rRNA have been developed (28).

PCR tests have been developed to detect *H. pylori* in human stool specimens (29). There are a number of potential limitations to the PCR method for detection of *H. pylori* in stool specimens. First, false-negative results may occur due to the presence of PCR inhibitors or to genetic variability. Second, false-positive results may occur as a result of contamination or nonspecific amplification of human genomic DNA. Finally, PCR detection of *H. pylori* has not yet been standardized and is not generally available in routine clinical laboratories. However, when appropriate steps are taken to purify DNA in fecal specimens by using various biochemical,

immunological, and physical steps prior to PCR amplification, the sensitivity and specificity of stool-based PCR for detection of *H. pylori* can approach 100% in the appropriate research setting (29). One-step PCR protocols using radiolabeled primers, an efficient extraction protocol, and 80 cycles of amplification to genotype *vacA* and detect *cagA* in stool specimens of *H. pylori*-infected individuals have been developed. PCR tests to detect *H. pylori* in stool specimens are used almost exclusively in research settings.

GENERAL APPROACH TO SEROLOGIC TESTING

Clinical Indications

As noted above, an accurate diagnosis of the presence of *H. pylori* infection should precede antimicrobial therapy. Routine serologic follow-up of patients after treatment for *H. pylori* infection is not recommended, since no clear guidelines to quantify the reduction of antibody level or the time period required to observe such a reduction or to correlate it with bacterial eradication have been established outside research settings.

Specimens

Generally, serum can be collected using standard phlebotomy techniques. There are no dietary restrictions prior to collection of the serum sample. Typically, no more than 10 μl of serum is needed to perform a single test.

Procedure

A variety of ELISA kits are available from manufacturers in North America and Europe. A general outline of methods involved in detecting *H. pylori*-specific IgG antibodies by ELISA is provided below. All procedures described in the package insert must be followed exactly as described for the particular test kit being used. In typical commercial ELISA kits, antigen is attached to the surfaces of microtiter plate wells, diluted serum is added to individual wells, and the *H. pylori*-specific IgG antibody, if present, binds to the antigen. All unbound antibody is washed away, and enzyme-conjugated anti-human IgG is added. The enzyme conjugate binds to the antibody complex. Excess enzyme conjugate is then washed away, and substrate is added. Bound enzyme conjugate begins a hydrolytic reaction. After a specified period, the enzyme reaction is stopped. The results are read by a spectrophotometer, which gives an indirect measurement of the amount of *H. pylori*-specific IgG antibody present in the serum.

Results and Interpretation

Typically, ELISA kits have a predetermined cutoff for absorbance values considered to be positive or negative. There is usually a range of absorbance values between which the reading is considered equivocal. It is recommended by many manufacturers that specimens giving equivocal results be retested. If the retest result is also equivocal, the report should be reported as "equivocal" and the sample should be retested by an alternate method or with a new serum specimen drawn after an interval of at least four weeks.

Commercial ELISAs are designed for use in the qualitative detection of *H. pylori*-specific IgG antibodies in human serum. Such tests typically assess the serologic status by using a single serum specimen per individual and are intended to be used as an aid in the diagnosis of *H. pylori* infection in individuals with gastrointestinal symptoms. Virtually all individuals infected with *H. pylori* possess IgG antibodies. Because infection with *H. pylori* is so prevalent and because it may be asymptomatic, many individuals apparently free of gastrointestinal symptoms exhibit *H. pylori*-specific antibodies. The prevalence of *H. pylori* antibodies increases with age. *H. pylori* antibodies are found in men and women at approximately equal rates. Blacks, Hispanics, and persons born outside the United States tend to show higher rates of infection with *H. pylori*.

Technical Limitations

Typically, icteric, lipemic, hemolyzed, or heat-inactivated serum may cause erroneous results; such samples should be avoided if possible. A positive test result indicates that the individual has antibodies to *H. pylori*. Such a result does not indicate that any existing symptoms are necessarily due to *H. pylori* infection. In the absence of prior therapy to eradicate *H. pylori* infection, the positive test result very probably indicates active infection with *H. pylori*. However, in the absence of an adequate patient history, a single positive serologic test result does not differentiate between active and past infection. A negative serologic test result indicates that the individual does not have detectable levels of antibody to *H. pylori*. If a sample is drawn too early during *H. pylori* infection, IgG antibodies may not be present.

Limitations of Serologic Assays in Monitoring Eradication

There are two basic limitations to the clinical utility of serology in monitoring the eradication of *H. pylori* infection. First, baseline and follow-up sera must be analyzed at the same time to minimize assay variability. Significant variability may result from assaying sera at different times or using different lots of reagent. Therefore, pretreatment sera must be saved to be analyzed along with posttherapy samples. This limitation requires that pretreatment specimens be saved for up to 12 months. The second limitation is that serology must be monitored for at least 3 months (and for 6 to 9 months in many cases) before a significant decrease in antibody concentration is observed. Depending on the clinical circumstances, this may represent an unacceptable delay. The percent decrease in the concentration of *H. pylori*-specific IgG which indicates eradication of infection in an individual patient has not been clearly established.

When serologic analysis is used in the evaluation of treatment success under controlled conditions, the absolute concentrations of *H. pylori*-specific IgG antibodies in the serum are less important than are the changes in concentrations from the pretreatment level. For example, over 60% of individuals from whom *H. pylori* was eradicated continued to have seropositive IgG levels (index value, >1.0) at 6, 9, and 12 months despite demonstrating a 20% reduction in antibody concentration (8). Thus, a single serum specimen from such an individual appears to reflect active infection with *H. pylori* in the absence of an adequate clinical history. In addition, specific antibodies may persist for years even after eradication of *H. pylori*. Some antigens, in particular the 120-kDa CagA protein, induce very persistent antibodies.

In summary, ELISAs for the detection of *H. pylori*-specific antibodies are sensitive, specific, and cost-effective for untreated individuals. The major limitation of such tests is the lack of a rapid, clear serologic response to the eradication of bacterial infection.

Assessment of Eradication of *H. pylori*

Because of the patchy nature of *H. pylori* infection, invasive methods are not optimal to assess bacterial eradication, since therapy may reduce the burden of *H. pylori* infection

but not completely eradicate the organism; biopsies may therefore provide false-negative results. PCR methods may give false-positive results by detecting residual nucleic acid from dead or dying bacteria. Serologic methods are not suitable for assessment of eradication since antibody levels can remain elevated for months to years even after successful eradication. The best methods for assessment of eradication of *H. pylori* are those which are capable of detecting active infection, such as the urea breath test and stool antigen test (30).

Pediatric iron deficiency has been recognized as an extragastric manifestation of *H. pylori* infection in otherwise asymptomatic *H. pylori* gastritis (4). In 2012, the FDA approved [^{13}C]urea breath testing in children under the age of 18 (http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm293278.htm). In the pediatric population, the stool antigen test and the [^{13}C]urea breath test are the methods of choice for diagnosis and "tests for cure" of *H. pylori*. These tests, in addition to endoscopy and histology, are now accepted standards of care in the United States (31). Diagnosis of *H. pylori* infection in children has been reviewed recently (19, 32).

The two noninvasive methods generally recommended for assessment of eradication of *H. pylori* are the urea breath test and the stool antigen test. Urea breath testing performed at least 4 weeks after treatment has been promoted as the test of choice to confirm bacterial eradication (2, 30). Both the [^{13}C]urea and [^{14}C]urea breath tests have been approved by the FDA for use in adults, while the [^{13}C]urea breath test was recently approved for children below 18 years of age. Stool antigen testing is a more widely available alternative, but it should not be performed sooner than 4 to 6 weeks after completion of treatment because of both false-positive and false-negative results in this time period (14, 15). However, the unpleasantness of the stool collection procedure may limit acceptance of this assay by patients. Posteradication, it has been reported that in populations with low *H. pylori* prevalence, the performance of the urea breath test is superior to that of the stool antigen test (2, 14).

It should be kept in mind that in individuals who fail eradication therapy, a gastric biopsy with culture may be necessary to determine the susceptibility of the infecting *H. pylori* strain(s).

As noted above, serologic tests are generally not useful to confirm eradication due to the significant time required for anti-*H. pylori* antibodies to decrease after therapy and due to the fact that the percent reduction in antibody titer signifying bacterial eradication has not been established.

Finally, it should be noted that while a low rate of reinfection with *H. pylori* has been noted in developed countries, a much higher rate of reinfection is observed in the developing world. Thus, caution is required to distinguish between failed eradication and reinfection by *H. pylori* in individual patients in developing countries (33).

Laboratory Diagnosis of Syphilis

JOHN L. SCHMITZ

46

BACKGROUND

The laboratory diagnosis of syphilis has relied, in large part, upon serologic methods for over 100 years (1). The causative organism, *Treponema pallidum*, is not amenable to *in vitro* culture, and antigen detection and nucleic acid amplification techniques have not become routinely used. While many of the serologic methods in use now have been in use for decades, their application, specifically the standard testing algorithm, is changing. In order to understand the interpretation of alternative testing algorithms, a thorough understanding of test characteristics is necessary. This chapter will review serologic tests for syphilis and their interpretation when they are applied to adults with and without HIV infection and to children.

EPIDEMIOLOGY

From 2005 through 2013, the rates of primary and secondary syphilis increased to 5.3 cases per 100,000 population (2). The largest increases were noted in men who have sex with men in the 25- to 29-year-old age group. The rate of primary and secondary syphilis in women was 0.9 per 100,000 in both 2005 and 2013. A slight increase in rates was noted between 2005 and 2009, followed by a decline to the 2013 level. In the United States, the rate of congenital syphilis was 7.8 cases per 100,000 live births in 2012. The rate reflects a decline in incidence over several years corresponding to the decline in incidence of primary and secondary syphilis in women. Globally, the WHO estimates 10.6 million new cases of syphilis annually in adults (48), while congenital syphilis is estimated to occur in 1 million pregnancies per year globally (3). The burden of infection is particularly heavy in resource-limited areas. This fact has stimulated the development of rapid, point-of-care diagnostics that can be used for large-scale testing with a limited traditional laboratory infrastructure.

MICROBIOLOGY

Four related spirochetes are agents of human treponemal disease. They are long (10 to 15 μm), slender (0.1 to 0.2 μm) corkscrew-shaped organisms that have not been cultivated *in vitro*. Because of their size, they cannot be visualized by standard bright-field microscopy. Dark-field microscopy is necessary for visualization from infected lesions. *T. pallidum* subsp. *pallidum*, the cause of venereal syphilis, is a human bacterial pathogen with no natural reservoir. The other pathogenic treponemes (4) that cause human infection include *T. pallidum* subsp. *endemicum* (bejel), *T. pallidum* subsp. *pertenue* (yaws), and *T. carateum* (pinta). These organisms are closely related genetically and exhibit serologic cross-reactivity.

NATURAL HISTORY OF ACQUIRED AND CONGENITAL SYPHILIS

In the natural history of acquired and congenital syphilis (5), the transmission of *T. pallidum* has occurred via contact with infectious primary or secondary lesions, blood transfusion (6), or transplantation (7). Vertical transmission can lead to the development of congenital syphilis. The incubation period of venereal syphilis is 10 to 90 days, after which the signs and symptoms of syphilis appear. Primary syphilis includes development of a chancre at the site of inoculation that may be associated with regional lymphadenopathy. Lesions contain viable treponemes that can be detected with dark-field microscopy. Spirochetes disseminate during this stage, leading to manifestations of secondary syphilis in approximately 25% of untreated patients weeks to months after primary disease.

The manifestations of secondary syphilis include skin lesions that may involve the palms and soles, fever, malaise, headache, lymphadenopathy, alopecia, hepatitis, gastrointestinal symptoms, and renal, musculoskeletal, neurologic, and ocular findings. Upon resolution of these symptoms, patients enter the latent phase of syphilis. Latent infection of less than 1 year in duration is classified as early latent, while duration of greater than 1 year is termed late latent syphilis. Eventually, up to 40% of individuals develop late (tertiary) syphilis. The manifestations of late syphilis include neurosyphilis and cardiovascular and gummatous syphilis.

Genital ulcer diseases have been suggested to increase the rate of acquisition of HIV infection (8). Some evidence that syphilis may influence HIV load exists as well (9). Clinical manifestations of syphilis appear typical for the most part in HIV-infected individuals, although some cases of more rapid progression and disease severity have been reported. The diagnosis of syphilis in HIV-infected patients is likewise usually typical, with occasional exceptions (10).

doi:10.1128/9781555818722.ch46

Manifestations of congenital syphilis are varied and can occur in fetuses, newborns, and children without treatment (11). Spontaneous abortion (stillbirth) may occur. Infants born with congenital infection may be asymptomatic at birth or present with various manifestations resulting from widespread dissemination of *T. pallidum* organisms. Early congenital syphilis (affecting those <2 years old) most commonly presents with hepatomegaly, nasal drainage, rash, lymphadenopathy, skeletal abnormalities, cerebrospinal fluid (CSF) abnormalities, or hematologic findings. Late latent congenital syphilis (>2 years of age) develops in 40% of untreated children and may manifest with facial abnormalities or with ocular, otic, oral, skin, neurologic, skeletal, or renal disease.

INDICATIONS FOR SYPHILIS TESTING

Individuals presenting with signs/symptoms of primary, secondary, or tertiary syphilis as well as persons with sexual exposure to an individual with any stage of syphilis infection should have serologic testing for syphilis (12). Sexually active men who have sex with men should be tested at least annually. Testing is also recommended for pregnant women at their first prenatal visit, in the third trimester, and at delivery if the patient is at high risk for syphilis. Infants born to mothers with reactive serologic tests for syphilis should also receive testing. The effectiveness of therapy should be assessed with nontreponemal testing 6 and 12 months after treatment.

LABORATORY DIAGNOSTIC METHODS

Direct Detection

Direct detection of *T. pallidum* in clinical samples relies upon microscopic examination. Dark-field microscopy is used to detect motile spirochetes in serous fluid from primary or secondary lesions, mucous patches, or lymph node aspirates that contain sufficient numbers of viable spirochetes (13). This technique is useful for diagnosis in primary, secondary, and early congenital infection.

Dark-field examination requires a properly calibrated microscope and skilled personnel. In addition, these resources must be physically close to the patient because slides must be examined immediately after preparation to ensure that viable organisms with characteristic morphology and motility are retained for proper interpretation. Serous fluid or aspirates are collected and placed on a glass slide that is coverslipped and immediately examined for appropriate morphology and motility. Results are reported as dark-field microscopy positive, dark-field microscopy negative, or dark-field microscopy unsatisfactory. The sensitivity of dark-field microscopy is approximately 80% (14). Examination of lesions from the oral cavity is not recommended due to the presence of *Treponema denticola*, a component of the oral flora. Additionally, antibiotic therapy or application of topical antibiotics may result in false-negative results. Likewise, the examination of healing lesions may also yield negative results.

The direct fluorescent antibody test for *Treponema pallidum* (15) is an alternative method for detection of *T. pallidum* in lesions. It utilizes the same sample types as used for dark-field examination. In addition, this approach can be used for oral and rectal samples due to its ability to specifically identify pathogenic species of *T. pallidum* in the presence of endogenous spirochetes. There is also a version of the direct fluorescent antibody test for *T. pallidum* that has been adapted for use in tissue sections (16).

PCR-based methods for the detection of *T. pallidum* DNA have been developed. They are of potential usefulness during early primary infection when seroconversion has not occurred and/or dark-field microscopy is unavailable. They may also be of use in the diagnosis of neurosyphilis due to the limitations of CSF antibody testing and in congenital syphilis due to the confounding of serologic testing by maternal antibody and limited experience with *T. pallidum*-specific IgM testing. The most commonly reported application of PCR-based detection of *T. pallidum* has been observed in samples derived from skin lesions and CSF. A recent meta-analysis (17) indicated that the highest likelihood ratios were found in studies using swabs from primary- or secondary-syphilis cases. For congenital syphilis, the highest likelihood ratios were found in CSF and blood from neonates. While of potential utility, PCR is not routinely available for the diagnosis of syphilis. It is available in some commercial reference laboratories (Focus Diagnostics).

SEROLOGY

Nontreponemal Tests

Because of the inability to culture *T. pallidum* and the limitations of available direct detection methods, serologic testing is the mainstay of syphilis diagnostics. Serologic testing employs two categories of assays differentiated by the antigen preparation used. The nontreponemal antibody tests employ a combination of cardiolipin, cholesterol, and lecithin as the antigen preparation, as opposed to antigens derived from *T. pallidum* itself. All of the nontreponemal methods are based on a flocculation reaction that develops upon reaction of IgG and/or IgM antibodies in serum with the nontreponemal antigen. These antibodies are produced to lipoidal materials released from damaged host cells or from treponemes (18). There are four standard nontreponemal antibody tests (Table 1). These tests differ in the ways in which flocculation is detected, the levels of stability of prepared antigens, and the sample types used. Procedural details are available for all four methods (19). The RPR card test (ASI [Arlington Scientific, Inc.]) is summarized here as an example.

A. Pipet 50 μl of serum into one circle of the testing card and spread it with a plastic stirrer.
B. Add 1 drop of well-shaken antigen suspension onto each circle.
C. Rotate cards for 8 min at 100 rpm under a humidifying cover.
D. Immediately visualize the test results under a high-intensity lamp.
E. Interpret as follows.
   1. A slight but definite clumping ranging to marked and intense clumping indicates reactivity.

TABLE 1 Nontreponemal serologic tests for syphilis

Test[a]	Antigen storage temp (°C)	Sample type(s)	Readout
VDRL	2–8	Serum[b], CSF	Microscopic
USR	2–8	Serum	Microscopic
RPR	2–8	Serum, plasma	Macroscopic
TRUST	2–30	Serum, plasma	Macroscopic

[a]VDRL, Veneral Disease Research Laboratory; USR, unheated serum reagin test; RPR, rapid plasma reagin; TRUST, toluidine red unheated serum test.
[b]Serum must be heated to 56°C for 30 min prior to testing.

2. A slight roughness or no clumping indicates nonreactivity.
3. All tests with a reactive or nonreactive rough RPR card test result should be tested by the quantitative procedure.

F. For the quantitative test, prepare a serial dilution of sample (undiluted and diluted 1:2, 1:4, 1:8, and 1:16 with 0.9% saline) directly on the RPR card. Dilutions of >1:16 should be made with a 1:50 dilution of nonreactive serum in place of 0.9% saline.
G. Add 1 drop of antigen suspension to each circle.
H. Rotate the card for 8 min at 100 rpm under a humidifying cover.
I. Read the results as instructed above. The endpoint titer is reported as the highest dilution giving a reactive result.

Interpretation of Nontreponemal Tests

The nontreponemal tests offer the advantages of simplicity and low cost. In addition, they provide a semiquantitative result (titer) that can be used to monitor the response to therapy. Positive results in these tests usually reflect active infection. Resolution of infection is associated with a decline in titer. The four nontreponemal tests have similar sensitivities that vary by disease stage, ranging from 78 to 86% in primary infections, 100% in secondary infections, 95 to 98% in latent infections, and 71 to 73% in late latent syphilis infections (20). Falsely negative results are more likely encountered during early primary infection and late latent syphilis. Especially during secondary-stage infections, these tests can be susceptible to the prozone effect (21–23). High levels of nontreponemal antibodies (antibody excess) can cause apparently nonreactive results. Dilution of samples suspected of exhibiting a prozone is necessary to detect reactivity. As discussed in the following paragraphs, a treponemal test may be better suited to assess infection status during late latent syphilis because of the decrease in sensitivity of nontreponemal tests. Nontreponemal tests can be used and interpreted in a similar fashion in HIV-infected individuals. However, unusually low and high results have been encountered (12).

The CSF Venereal Disease Research Laboratory (VDRL) assay is the only test considered standard for CSF analysis. Its performance should be limited to patients with reactive serologic tests for syphilis (24), and it should be accompanied by a CSF cell count and protein determination. It is considered specific for neurosyphilis; however, its sensitivity is not optimal. A CSF cell count of >5 cells/μl and a protein level of >40 mg/dl in a seropositive individual are consistent with neurosyphilis in the absence of a reactive CSF VDRL assay.

The diagnosis of congenital syphilis requires clinical and serologic evaluation of the mother and child (25). Serologic testing of neonates should be performed on serum (not cord blood). The use of the serologic tests in infants at risk of or suspected of having congenital syphilis is confounded by maternal antibody. While some infants have been found to have nontreponemal titers 4-fold greater than the maternal titer (considered highly probable for congenital infection), this finding is not common (26). Follow-up testing with nontreponemal tests should demonstrate a decline in titer to nonreactivity by 6 months in untreated infants without infection.

Success of treatment can and should be monitored with quantitative nontreponemal titers collected 6 and 12 months after therapy (12). Effective therapy is associated in most cases with a 4-fold decline in titer and eventual seroreversion. However, the time to seroreversion may be influenced by the stage of infection during which therapy is started. Twenty percent, or more, of treated individuals may not serorevert and remain serofast (27, 28). Treponemal antibodies typically do not serorevert with therapy. Successful treatment of neurosyphilis results in a decline in nontreponemal titers in the CSF, in addition to in blood.

Nontreponemal tests have limitations. False-positive tests can be encountered in a variety of infections and autoimmune and malignant diseases, as well as during pregnancy and with advancing age (20). Although the four tests use the same basic antigen preparation, slight variations in the antigen can lead to differing degrees of reactivity. As such, these tests should not be used interchangeably when an individual is monitored longitudinally for therapeutic response. The same test should be used in these instances. Due to the potential for false-positive reactions with these nonspecific tests, reactive results should be confirmed by performing a test using *T. pallidum*-specific antigens, i.e., a treponemal antibody test.

Treponemal Antibody Tests

In contrast to the nontreponemal tests, treponemal antibody tests use *T. pallidum* organisms or antigens to detect the presence of antibodies (20). These tests have typically been used as confirmatory assays for samples with reactive nontreponemal test results. Because of their increased sensitivities compared to those of nontreponemal tests in late latent syphilis, they may be used as the first-line test in suspect patients. A variety of test methods have been used for the detection of treponemal antibodies (20). The most common assays currently employed (Table 2) include the fluorescent treponemal antibody absorption (FTA-ABS) test, the *T. pallidum* passive particle agglutination (TP-PA) test, enzyme immunoassay (EIA), and chemiluminescent immunoassay (CLIA).

The FTA-ABS (29, 30) test is an indirect fluorescent antibody test that employs glass slides with whole *T. pallidum* organisms fixed to the surface. Sera are first diluted in sorbent, an extract from *Treponema phagedenis*, to reduce false-positive reactions. Absorbed patient serum is applied to the wells and incubated. After the wells are washed, fluorescein isothiocyanate-conjugated anti-human immunoglobulin is added. If IgM and/or IgG antibodies are bound to the organisms on the slides, the fluorescein isothiocyanate conjugate will bind. Unbound anti-immunoglobulin is washed away, and the slides are then coverslipped and viewed with a fluorescence microscope. The presence of apple green treponemes is a positive test indicating the presence of *T. pallidum*-specific antibody. Results are reported as reactive, minimally reactive, or nonreactive or with atypical fluorescence observed. A version of this test that detects *T. pallidum*-specific IgM antibodies has been reported (31); however, it is not in common use.

EIAs (32, 33) are also available for the detection of *T. pallidum*-specific antibody. A number of assays using various antigens and enzyme-labeled anti-IgG or anti-immunoglobulin are available (33, 34). In addition, IgM-specific EIA is available in some laboratories and may be of use in the diagnosis of congenital or early infectious syphilis (26, 35). EIAs are amenable to automation and have replaced nontreponemal tests as screening assays (reverse syphilis testing algorithm) in many large laboratories with high testing volumes. Their sensitivities and specificities are comparable to those of standard treponemal assays (33). CLIAs, like EIAs are also increasingly used in reverse testing algorithms. These assays are available on random-access instruments which perform a variety of immunoassays simultaneously in a high-throughput fashion (36).

TABLE 2 Common treponemal antibody tests[a]

Test[b]	Sample type(s)	Equipment	Readout
MHA-TP	Serum	Minimal	Agglutination
TP-PA test	Serum, plasma	Minimal	Agglutination
FTA-ABS test	Serum, CSF	Fluorescence microscope	IFA
EIA	Serum	EIA reader, EIA washer	Indirect EIA[c]
CLIA	Serum	Automated analyzer	Chemiluminescence

[a]All reagents were stored at 2 to 8°C.
[b]MHA-TP, microhemagglutination test for *T. pallidum*; TP-PA, *T. pallidum* particle agglutination; FTA-ABS, fluorescent treponemal antibody absorption; EIA, enzyme immunoassay; CLIA, chemiluminescent immunoassay; IFA, indirect fluorescent antibody test.
[c]For *T. pallidum*-specific IgM detection, IgM-capture assays are preferred.

The TP-PA test (37, 38) is a modification of the microhemagglutination test for *T. pallidum* (39) that substitutes gelatin particles for red cells as the carrier of *T. pallidum* antigen. A gelatin particle suspension coated with *T. pallidum* antigen is incubated with patient serum. If *T. pallidum* antibody is present, the particles agglutinate and form a mat in the bottom of the well of the microtiter tray. If no antibody is present, the gelatin particles form a button in the bottom of the well. The test requires no expensive equipment and is simple to perform. This test has sensitivity and specificity similar to those of the other treponemal antibody tests. A procedural outline for the Serodia TP-PA (Fujirebio Diagnostics, Inc.) test is provided as an example.

A. Reconstitute lyophilized sensitized (*T. pallidum* antigen) or nonsensitized (control) gelatin particles.
B. Place 4 drops (100 μl) of sample diluent in well 1 and 1 drop (25 μl) in wells 2 through 4 of a U-bottom microtiter plate.
C. Add 25 μl of patient specimen (serum or plasma) or reactive or nonreactive control sera into the first wells of four rows.
D. Mix the contents of well 1 and transfer 25 μl into well 2. Mix the contents of well 2 and transfer 25 μl into well 3. Mix the contents of well 3 and transfer 25 μl into well 4. Mix the contents of well 4 and discard 25 μl of solution from that well.
E. Add 25 μl of unsensitized particles to well 3 and 25 μl of sensitized particles to well 4.
F. Mix the contents of the wells, cover the plate, and incubate it at room temperature for 2 h. The incubation can be extended to overnight.
G. Place the plate onto a flat surface, preferably with a white background, and observe the pattern of agglutination in each well. A plate viewer may be used to enhance the visual interpretation.
    1. A nonreactive result occurs when gelatin particles form a button or a ring with a small hole in the center at the center of the well.
    2. An inconclusive result occurs when gelatin particles from a ring with a hole in the center.
    3. A reactive result occurs when a large ring with a rough outer margin is visible and peripheral agglutination is surrounded by a small red circle (1+), the bottom of the well is covered with agglutinated particles surrounded by a red circle (2+), or a smooth mat of cells covers the entire bottom of the well with or without a faint ring (3+).

A specimen that is nonreactive with unsensitized particles and reactive with sensitized particles is interpreted as reactive in this test. If a serum specimen demonstrates a positive reaction with both the sensitized and unsensitized particles, it can be retested by an absorption procedure. Specimens that are nonreactive with unsensitized particles but have an inconclusive reaction with sensitized particles are classified as having inconclusive results. The assay should be rerun or a new sample obtained for testing. Samples that are nonreactive with sensitized particles are classified as nonreactive.

Interpretation of Treponemal Tests

A reactive treponemal test is consistent with current or past infection. The sensitivities of the tests are similar to those of nontreponemal tests in primary infection (76 to 84%), secondary infection (100%), and latent infection (97 to 100%). They perform better in patients with late latent syphilis, however, as most people maintain treponemal antibodies for many years. Whether infections are cleared naturally or with antibiotics, people usually remain reactive (20). The use of the FTA-ABS test on CSF has been found to be more sensitive but less specific than the CSF VDRL test. As such, it has been considered to rule out neurosyphilis if it is negative. One must be particularly cognizant of the potential for false-positive reactivity if the CSF sample is contaminated with blood (40).

Although these tests use *T. pallidum* antigen, false-positive results can be encountered in healthy individuals (41) and in those with a variety of diseases (20). Recognized causes of false-positive results include infections with related spirochetes, systemic lupus erythematosus and other autoimmune diseases, and aging.

Rapid Point-of-Care Tests

A number of rapid tests for syphilis have been developed (42) in response to the need to provide testing in resource-limited settings where traditional serologic tests for syphilis may not be feasible or optimal for routine use. Point-of-care tests provide a fast, simple means to diagnose syphilis in both clinical and nonclinical settings, addressing the need to increase testing in these areas (43). These tests are commonly formatted as an immunochromatographic assay using treponemal antigens. One test has received CLIA-waived status, the Syphilis Health Check (Diagnostics Direct). A recent survey of 15 published studies calculated a median sensitivity of 86% and a specificity of 99% for rapid tests, which is comparable to those of nontreponemal screening (44).

QUALITY CONTROL AND ASSURANCE

Specific, detailed quality control practices are provided in the manual of tests for syphilis (19). Positive and negative

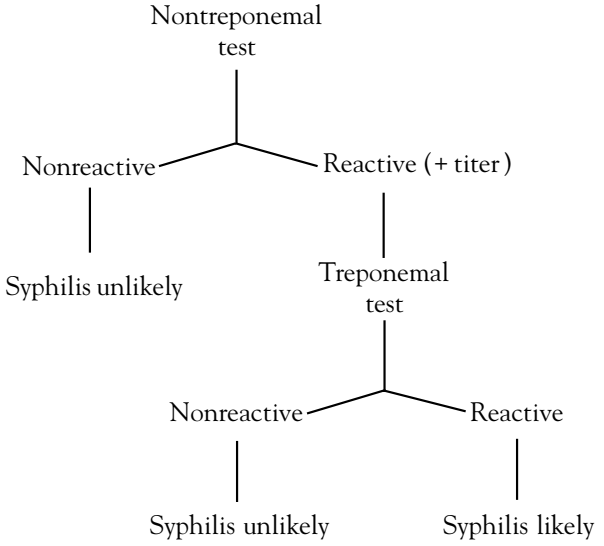

FIGURE 1 Traditional algorithm.

controls are available and run each day that the tests are performed. Detailed daily monitoring of equipment (e.g., needles and rotators for nontreponemal tests) is required to ensure consistency of results. External proficiency testing for syphilis serologic testing is available from several vendors, including the College of American Pathologists. Samples are provided for nontreponemal and treponemal testing of serum and VDRL testing of CSF. Proficiency testing for direct detection methods is not available, and laboratories must implement systems to assess proficiency for accreditation purposes.

TESTING ALGORITHMS

The classic approach for serologic diagnosis of infectious syphilis in adults is the standard algorithm (Fig. 1). In this approach, sera are first tested for the presence of nontreponemal antibody. If reactive in undiluted sera, the samples are serially diluted to determine the endpoint titer. Reactive results may indicate active infection. However, due to the potential for false-positive reactions with nontreponemal tests, reactive samples are confirmed with a treponemal antibody test. Treponemal tests are performed in a qualitative fashion, and titrations are not performed. A reactive treponemal result confirms syphilis infection. The limitations of this approach are its insufficient sensitivity in very early and late latent syphilis. In cases in which late latent syphilis is suspected after a nonreactive nontreponemal test, initial testing by treponemal methods is warranted.

Recently, an alternative to the standard algorithm has been employed. The reverse sequence testing algorithm (Fig. 2) is an alternative approach that employs a treponemal test, usually an EIA or CLIA, as the screening assay. If positive, a nontreponemal antibody test, such as RPR, is performed, and if the sample is reactive**,** a titer is obtained. In the case of a nonreactive nontreponemal test result, an alternative treponemal test (e.g., FTA-ABS or TP-PA test) is recommended to determine if the screening EIA or CLIA was falsely positive. It should be kept in mind that highly sensitive CLIA assays may detect lower levels of antibody than standard treponemal tests (FTA-ABS and TP-PA tests), which might lead to discordant results not due to a false-positive result.

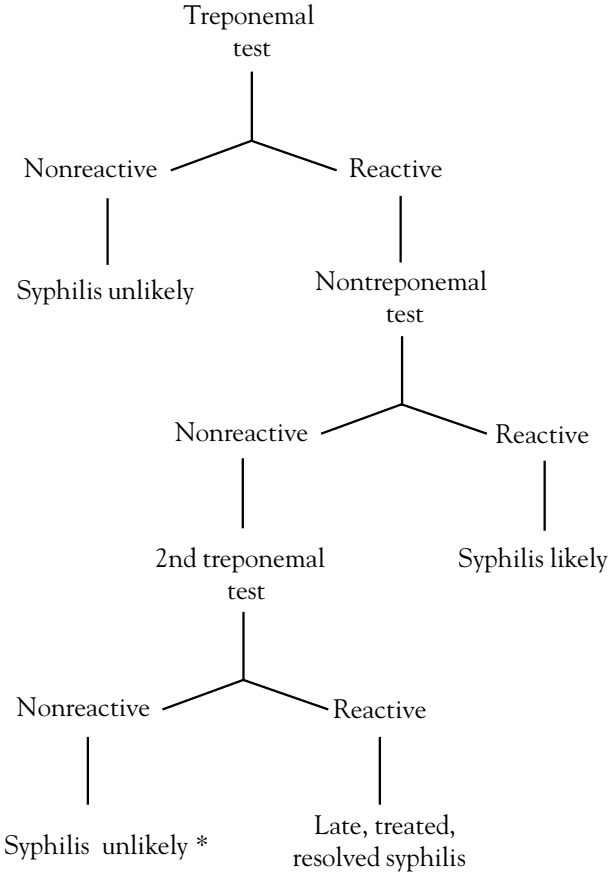

FIGURE 2 Reverse algorithm. *, may indicate a false-positive screening test result; however, a very sensitive screening test, such as CLIA, might be positive when the standard treponemal test is nonreactive.

The false-positivity rates of the screening EIAs or CLIAs vary based on the prevalence of syphilis in the population being tested (45). This approach has been developed in part to accommodate large test runs, rapid turnaround times, and objective analyses, as favored by commercial reference laboratories. In addition, it can effectively detect very early or late latent syphilis that may be missed with the standard algorithm (46, 47). However, sera that are confirmed treponemal-test reactive but nontreponemal-test nonreactive may present a more challenging interpretation. They may arise from cases of untreated late latent syphilis or syphilis treated in the past.

Lyme Disease, Relapsing Fever, and Leptospirosis

GUIQING WANG AND MARIA E. AGUERO-ROSENFELD

47

Lyme disease, relapsing fever, and leptospirosis are infections caused by spirochetes, a phylogenetically ancient and distinct group of microorganisms among the prokaryotes.

The taxonomy of the spirochetes has undergone significant revisions during the past decade. While all spirochetes remain in a single order, *Spirochaetales*, in the class *Spirochaetia* of the phylum *Spirochaetes* phy. nov., the order *Spirochaetales* has been reclassified into four families in the second edition of *Bergey's Manual of Systematic Bacteriology: Spirochaetaceae* (family I), *Brachyspiraceae* (family II), *Brevinemataceae* (family III), and *Leptospiraceae* (family IV) (1). The family *Spirochaetaceae* consists of four genera: *Spirochaeta* (genus I), *Borrelia* (genus II), *Cristispira* (genus III), and *Treponema* (genus IV). Family *Brachyspiraceae* contains a single genus, *Brachyspira*. Family *Brevinemataceae* fam. nov. has recently been validated with one genus, *Brevinema*. Family *Leptospiraceae* encompasses three genera: *Leptospira*, *Leptonema*, and *Turneriella* (1).

Three genera of spirochetes, *Borrelia*, *Leptospira*, and *Treponema*, are pathogenic to humans and are associated with Lyme disease and relapsing fever, leptospirosis, and syphilis, respectively. This chapter focuses on the laboratory diagnosis of Lyme disease, relapsing fever, and leptospirosis. The diagnosis of syphilis is presented in chapter 46 of this *Manual*.

LYME DISEASE

Taxonomy of Lyme *Borrelia*

The genus *Borrelia* comprises more than 40 species of arthropod vector-borne spirochetes that can be classified into two major groups. The first group of spirochetes contains 19 *Borrelia* species that have been validated or proposed since 1984 (2–4). The term "*Borrelia burgdorferi sensu lato*" has been collectively used to refer to all *Borrelia* species and isolates in this group. *Borrelia* species in the first group are transmitted by the hard *Ixodes* ticks and are associated with Lyme disease, or Lyme borreliosis (3). The second group of spirochetes includes 25 validated or proposed *Borrelia* species transmitted by soft ticks *Argasidae* with a few exceptions (i.e., louse-borne *B. recurrentis* and hard-tick-borne *Borrelia miyamotoi* and *Borrelia lonestari*). *Borrelia* species in the second major group are associated with human relapsing fever (RF). The term "relapsing fever *Borrelia*" has been used to refer to all *Borrelia* species and isolates in this group (5). In this chapter, we use the terms "Lyme *Borrelia*" to refer to *B. burgdorferi sensu lato* and "RF *Borrelia*" to refer to relapsing-fever-related *Borrelia* species.

Table 1 summarizes the characteristics of selected *Borrelia* species associated with human Lyme disease and relapsing fever. A complete list of current *Borrelia* species and their differential characteristics can be found in the recently published *Bergey's Manual of Systematic Bacteriology* (5).

Fourteen validated *Borrelia* species belong to the Lyme *Borrelia* group. They are *B. burgdorferi sensu stricto*, *Borrelia garinii*, *Borrelia afzelii*, *Borrelia japonica*, *Borrelia valaisiana*, *Borrelia lusitaniae*, *Borrelia tanukii*, *Borrelia turdi*, *Borrelia sinica*, *Borrelia spielmanii*, *Borrelia americana*, *Borrelia carolinensis*, *Borrelia bivariensis*, and *Borrelia kurtenbachii*. Among these, only *B. burgdorferi sensu stricto*, *B. garinii*, *Borrelia bivariensis*, and *B. afzelii* are well known to cause human diseases. Rare cases associated with infections of *B. valaisiana*, *B. lusitaniae*, and *B. spielmanii* have been reported; the pathogenicity of these species in humans remains to be elucidated.

Five additional *Borrelia* species in the Lyme *Borrelia* group have been proposed, but their taxonomic status has not been validly published due to the lack of sufficient data. These are *Borrelia andersonii*, *Borrelia bissettii*, *Borrelia californiensis*, *Borrelia yangtze*, and *Borrelia finlandensis*.

Epidemiology and Disease Spectrum

Lyme disease is widely distributed in the northern hemisphere among patients residing in North America, Europe, and Asia. It is the most common vector-borne disease in North America and Europe. Between 1992 and 2011, a total of 439,738 cases of Lyme disease, with an average of approximately 20,000 cases each year, were reported to the Centers for Disease Control and Prevention (CDC) in the U.S. Over 30,000 confirmed and probable cases are reported annually in recent years, while it is estimated that the number of annual cases may be more than 300,000, if including those unreported patients (6). Most reported Lyme disease cases in the U.S. are from the northeastern and midwestern states. In 2012, 95% of Lyme disease cases were reported from 13 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Virginia, and Wisconsin (7).

Areas of endemic Lyme disease in Europe include the British Isles, Scandinavia, western Europe and states of

doi:10.1128/9781555818722.ch47

TABLE 1 Characteristics of selected *Borrelia* species associated with Lyme disease and relapsing fever[a]

Taxon	Vector	Host	Distribution	Disease
Borrelia burgdorferi sensu lato				
B. afzelii	*Ixodes ricinus*, *Ixodes persulcatus*	Rodents	Europe, Asia	Lyme borreliosis
B. bavariensis	*Ixodes ricinus*, *Ixodes persulcatus*	Birds, rodents	Europe, Asia	Lyme borreliosis
B. bissettii	*Ixodes pacificus*, *Ixodes spinipalpis*, *Ixodes scapularis*	Rodents, birds	U.S., Europe?	Probably Lyme borreliosis
B. burgdorferi sensu stricto	*Ixodes scapularis*, *Ixodes pacificus*, *Ixodes ricinus*	Rodents, birds	U.S., Europe	Lyme borreliosis
B. garinii	*Ixodes ricinus*, *Ixodes persulcatus*	Birds, rodents	Europe, Asia	Lyme borreliosis
B. lusitaniae	*Ixodes ricinus*	Rodents, lizards	Central Europe	Probably Lyme borreliosis
B. spielmanii	*Ixodes ricinus*	Rodents	Europe	Probably Lyme borreliosis
B. valaisiana	*Ixodes ricinus*, *Ixodes nipponensis*, *Ixodes columnae*	Rodents, birds	Europe, Asia	Probably Lyme borreliosis
Relapsing fever borreliae				
B. baltazardii	Unknown	Unknown	Iran	Tick-borne relapsing fever
B. caucasica	*Ornithodoros verrucosus*	Rodents, humans	Caucasus	Tick-borne relapsing fever
B. coriaceae	*Ornithodoros coriaceus*	Probably deer	Western U.S.	Probably epizootic bovine abortion
B. crocidurae	*Ornithodoros sonrai*	Rodents, humans	Africa, Near East, Central Asia	Tick-borne relapsing fever
B. duttonii	*Ornithodoros moubata*	Man	Africa	Tick-borne relapsing fever
B. graingeri	*Ornithodoros graingeri*	Rodents, humans	East Africa	Tick-borne relapsing fever
B. hermsii	*Ornithodoros hermsi*	Rodents, humans	Western U.S. and Canada	Tick-borne relapsing fever
B. hispanica	*Ornithodoros erraticus*	Rodents, humans	Spain, Portugal, Morocco, Algeria, Tunisia	Tick-borne relapsing fever
B. lonestari	*Amblyomma americanum*	Rodents, birds?	Southeastern U.S.	Lyme-like illness? (Southern tick-associated rash illness)
B. latyschewii	*Ornithodoros tartakov-*	Rodents, reptiles, humans	Iran, Central Asia	Tick-borne relapsing fever
B. mazzottii	*Ornithodoros talaje*	Rodents, armadillos, monkeys, humans	Mexico and Guatemala	Tick-borne relapsing fever
B. miyamotoi	*Ixodes persulcatus*, *Ixodes scapularis*, *Ixodes ricinus*	Rodents	Japan, U.S., Sweden	Tick-borne borreliosis
B. parkeri	*Ornithodoros parkeri*	Rodents, humans	Western U.S.	Tick-borne relapsing fever
B. persica	*Ornithodoros tholozani*	Rodents, bats, humans	Middle East, Central Asia	Tick-borne relapsing fever
B. recurrentis	*Pediculus humanus*, subsp. *humanus*	Man	South America, Europe, Africa, Asia	Louse-borne relapsing fever
B. turicatae	*Ornithodoros turicatae*	Rodents, humans	U.S. and Mexico	Tick-borne relapsing fever
B. venezuelensis	*Ornithodoros rudis*	Rodents, humans	Central and South America	Tick-borne relapsing fever

[a]Adapted from reference 5.

the former USSR, from the Baltic States east through Russia to the Pacific Coast. It is estimated that more than 50,000 Lyme disease cases occur annually in the European countries (8). Lyme disease is also well documented in far-eastern Russia, Japan, and China.

B. burgdorferi is transmitted among reservoirs and hosts by ticks of the family *Ixodidae*, mainly ticks in the *Ixodes ricinus* complex. *Ixodes scapularis* and *I. pacificus* in the U.S. and *I. ricinus* and *I. persulcatus* in Eurasia are the principal vectors of the spirochaetes. The prevalence rate of *B. burgdorferi* in *I. scapularis* collected from endemic areas of the U.S. varies from 12% to almost 100% (9), and in *I. ricinus* in Europe from 0 to 58% (10). Coinfection with *B. burgdorferi* and other tick-borne pathogens such as *Babesia* sp. and *Anaplasma* sp. has been reported.

Clinical manifestations of human Lyme disease depend upon the stage of the infection and may affect dermatological, neurological, cardiac, and musculoskeletal systems (Table 2). Stage 1 consists of early infection (localized erythema migrans, EM), followed by stage 2 (disseminated infection) within days or weeks. Stage 3 (late infection) may develop months or years after the disease onset.

The clinical manifestations of Lyme disease also vary depending on the *Borrelia* species causing the disease. Although all species cause EM as the early manifestation, *B. burgdorferi sensu stricto* more frequently causes arthritis, and *B. afzelii* causes acrodermatitis chronica atrophicans (ACA) as late manifestations. By contrast, *B. garinii* is more frequently associated with early neurological manifestations (radiculoneuritis) (3).

EM is the clinical hallmark of early Lyme disease. It is recognized in about 60 to 80% of the patients with objective clinical evidence of *B. burgdorferi* infection (11). The rash typically begins at the site of the tick bite as an expanding red macule (erythema), sometimes with central clearing. At this stage, patients may be either asymptomatic or present with flu-like symptoms, such as headache, myalgia, arthralgias, and fever.

TABLE 2 Clinical manifestations of Lyme disease and specimen types for laboratory diagnosis

Clinical manifestation	Specimen for culture or PCR	Specimen for serologic testing
Stage I (early or localized infection): EM	Skin biopsy	Serum
	Plasma (10 to 20 ml for culture)	
Stage II (early or disseminated infection)		
Multiple EM	Skin biopsy	Serum
	Plasma (10 to 20 ml for culture)	
Lyme carditis		Serum
Neuroborreliosis	CSF	Serum and CSF
Stage III (late infection)		
Lyme arthritis	Synovial fluid or tissue	Serum
ACA	Skin biopsy	Serum
Neuroborreliosis	CSF	Serum and CSF

Dissemination of *B. burgdorferi* to the nervous system, joints, heart or other skin areas, and occasionally to other organs may give rise to a wide spectrum of manifestations in the involved systems. Usually, patients at this stage experience one or more of the following syndromes: multiple EM lesions, Lyme carditis, arthritis, and early neuroborreliosis including meningoradiculoneuritis (Bannwarth's syndrome), meningitis, meningoencephalitis, and/or facial palsy.

Late Lyme disease may develop among some untreated patients months to years after the onset of the disease. The major manifestations of late Lyme disease include Lyme arthritis, chronic neuroborreliosis and ACA. Post-Lyme disease syndrome, characterized by persistent arthralgia or neurocognitive or fatigue syndrome, has been reported in a small percentage of patients. There is currently no evidence that such persistent subjective symptoms are caused by active *B. burgdorferi* infection.

The diagnosis of Lyme disease can easily be made in an endemic area when the characteristic skin lesions, i.e., EM, borrelial lymphocytoma at typical sites (nipple or ear lobe) or ACA, are present. These last two clinical manifestations are most frequently seen in Europe. A history of a recent tick bite may be supportive, but only 30 to 54% of the culture-confirmed EM patients could recall a tick bite (12). In patients with EM, laboratory testing is neither necessary nor recommended (13). Diagnosis of Lyme disease on the basis of the presence of manifestations other than EM is challenging. Thus, laboratory confirmation is necessary for the diagnosis of Lyme disease in these patients.

Laboratory Diagnosis

Laboratory approaches for diagnosis of Lyme disease include direct detection of the spirochete or nucleic acid by culture and PCR, and indirect measurement of Lyme *Borrelia*-specific antibodies in suspected patients by various immunologic test methods. Because of limited utility of direct detection of *B. burgdorferi* in clinical specimens by culture and PCR assay, serology is currently the mainstay of laboratory testing to support the clinical diagnosis of Lyme disease, especially in patients with atypical EM and late Lyme disease. Elevated specific antibody to *B. burgdorferi* titers can usually be demonstrated.

Immunologic Test Methods

The U.S. FDA has approved over 70 commercial assays for serodiagnosis of Lyme disease since the late 1980s. It is estimated that 2.8 million to 3.4 million serologic tests for Lyme disease, with a cost of more than $100 million, are performed annually in the U.S. (13). Similarly, the overall expected cost for Lyme disease serologic testing and treatment is approximately 51 million Euros in Germany alone (14).

Lyme *Borrelia* Antigens of Importance in Immunodiagnosis

Protein profile analysis shows that the whole-cell lysates of the Lyme *Borrelia* comprise more than 50 visible protein bands in silver- or Coomassie blue-stained polyacrylamide gels. The *Borrelia* antigens of importance in serodiagnosis of early Lyme disease include flagellin (41 kDa), outer surface lipoprotein C (OspC, 21 to 25 kDa), Borrelia membrane protein A (P39 or BmpA, ~39 kDa), and Vmp-like protein (VlsE, 25 kDa). Patients with early Lyme disease usually develop antibodies against these antigens. Thus, IgM antibodies to these antigens are of most diagnostic importance in early Lyme disease.

Flagellin is an important structural and functional protein of *Borrelia* spp. It is a highly immunogenic and cross-reactive antigen. Strong IgG and IgM responses to this protein are developed within a few days after infection with the Lyme *Borrelia*. Many currently available immunoassays consist of purified flagella alone or have it as an antigenic mixture. Although highly immunogenic, this antigen is highly cross-reactive with antigens in other bacteria, particularly when denatured, as in immunoblots. Certain flagellin epitopes are also cross-reactive with antigens found in mammalian tissues such as neural tissues, synovium, and myocardial muscle. P39 is another conserved outer-surface lipoprotein among Lyme *Borrelia* that is highly immunogenic. IgG antibody against P39 is detectable in 15 to 64% of Lyme disease patients, depending on the clinical stage at which the sample is taken (15).

The Lyme *Borrelia* has a large number of surface-exposed lipoproteins, encoded by genes located on plasmids (16). Two of these lipoproteins, OspC and VlsE, are differentially expressed in different environmental conditions that the organism encounters. By contrast to OspA, which is expressed while *B. burgdorferi* is located in the midgut of the unfed tick, the expression of OspC is upregulated in the presence of blood components and at higher temperatures (35 to 37°C versus 25°C), i.e., after the tick obtains a blood meal from the susceptible mammal. The VlsE is a surface-exposed lipoprotein in Lyme *Borrelia* with functional similarity to the variable membrane proteins (Vmps) in RF borreliae. Although VlsE undergoes extensive antigenic variation *in vivo*, antibodies against an invariable region of the VlsE (IR6) are detectable in patients with acute EM and late stages of clinical disease and have been used for serodiagnosis of Lyme disease.

As disease progresses, antibodies to a larger number of borrelial antigens will develop, as will occur in any infectious disease. Therefore, patients with late manifestations of Lyme disease have antibodies to a larger number of antigens, such as to the 93-, 66-, 58-, 30-, 28-, and 18-kDa antigens. Untreated patients presenting with later manifestations of the disease are expected to present with a higher amount of antibodies reacting to a larger number of *B. burgdorferi* antigens. Lack of antibodies in a patient presenting with late manifestations of Lyme disease will make the diagnosis unlikely.

IFA for Antibody Detection

IFA uses cultured organisms fixed onto glass slides. Serum specimens are diluted in preparations that may include an absorbent such as material derived from Reiter treponema or egg yolk sac to remove nonspecific antibodies. After addition of fluorescein isothiocyanate-labeled anti-human IgG or IgM, the presence of antibodies is detected by fluorescence microscopy. Specimens testing reactive at screening dilutions are serially diluted. In general, antibody titers of $\geq$64 and $\geq$256 are considered as positive on the IFA with and without prior absorption, respectively (17). Limitations of this assay include the need for fluorescence microscopy and for well-trained personnel and the subjectivity in reading and interpreting fluorescence microscopy. Although IFAs are still commercially available, they have been largely replaced by enzyme immunoassays such as enzyme-linked immunosorbent technology (ELISA or EIA), and Western immunoblot.

Enzyme Immunoassays for Antibody Detection

The most common methods for detection of antibodies to *B. burgdorferi* are ELISA (13). Most of these assays use the whole-cell lysate of *B. burgdorferi* strain B31 as the source of antigen. Other strains of *B. burgdorferi* have been used in assays developed in the United States, and various Lyme *Borrelia* (*B. burgdorferi*, *B. garinii* and *B. afzelii*) species have been employed in in-house or commercial assays available in Europe. The antigen for whole-cell lysate-based assays is typically a complex mixture containing multiple immunogenic proteins, lipoproteins and carbohydrates. ELISA assays that detect IgM and IgG antibodies to *B. burgdorferi* routinely include a low-positive control used to assess the reactivity of patient samples. Patient reactivity (optical density, OD) is divided by the low-positive control and an index is calculated. Frequently, sera with an index of $<$0.8 are considered negative (nonreactive); those with an index of $>$0.8 to $<$1.09 are considered equivocal, and those with an index of $>$1.09 are considered positive.

Using sonicated whole-cell preparations of low-passage *B. burgdorferi sensu lato*, the sensitivity of ELISA is in general less than 50% in acute-phase sera of patients with EM of a duration of $<$1 week. Sensitivity increases over time after the first week in untreated patients with EM. Sensitivity is also high in patients with EM presenting with constitutional signs and symptoms or in those who have multiple EMs. Sensitivity is very high in patients with objective evidence of extracutaneous involvement (e.g., carditis or neuroborreliosis). ELISA is almost invariably positive in sera of patients with late disease such as arthritis.

The Lyme ELISA has advantages over other immunoassays, including ease of testing, objective generation of numerical values that correlate in relative terms with the quantity of antibodies present, and the capability of automation. One of the limitations of ELISA for detection of *B. burgdorferi sensu lato* antibodies is lack of standardization. Variations exist between assays in terms of antigenic composition and in the detection of specific immunoglobulin classes, particularly in the detection of IgM antibodies. Such variations may occur among different commercial kits as well as between lots of the same kit. Another limitation of the Lyme ELISA is the lack of specificity due to the use of whole-cell antigen preparations. The specificity of ELISA for detection of *B. burgdorferi* antibodies varies from 72 to 97% (13, 18).

Western Immunoblot for Antibody Detection

Whether *B. burgdorferi sensu lato* antigens elicit IgM versus IgG antibodies depends on the duration of infection and the manifestation of Lyme disease. The use of immunoblot assay allows the determination of which Lyme *Borrelia* antigens are immunoreactive at different stages of Lyme disease. In early Lyme disease, the most common IgM and IgG antibodies are directed to OspC and the flagellar antigens (41 kDa), while variable rates of IgM and IgG response to P39, VlsE, and other antigens (i.e., P93, P66, P45, P35, P30, and P18) may also be detected by immunoblot.

The number of antigens recognized in the IgM immunoblot and the intensity of the immune response as determined by band intensity are greater in sera of patients with EM and constitutional signs and symptoms, those with multiple EMs, or those with EM of a duration of more than 2 weeks at presentation, compared to asymptomatic patients with a solitary EM of a duration of less than 2 weeks. Interpretive criteria have been suggested for a standardized immunoblot for the three species of *B. burgdorferi sensu lato* that cause human disease in Europe (19).

In general, immunoblot has comparable or slightly higher sensitivity than ELISA for detection of early Lyme disease. The specificity of immunoblot is greater than that of ELISA, as interpretation of immunoblot relies on the

presence of specific immunoreactive bands. The major limitations of the immunoblot assay include the visual scoring and subjective interpretation of band intensity that may lead to false-positive readings, the higher cost, and the variability of antibody responses in patients with the same clinical manifestations of Lyme disease. Of particular concern is the scoring of weak bands on the IgM immunoblots, which leads to an erroneous positive interpretation. For these reasons, immunoblots perform better as supplemental tests of a sensitive EIA and should not be used as single-step testing.

Two-Tier Serologic Testing Algorithm

The use of earlier assays lacking the significant *B. burgdorferi* antigens, plus the indiscriminate use of serologic assays in populations with low prevalence for Lyme disease, has contributed to the belief that serology is not helpful in this disease. In 1994, the U.S. Association of State and Territorial Public Health Laboratory Directors and the CDC recommended a two-step approach in which samples are examined first by a sensitive test, such as ELISA or IFA. Samples testing reactive (equivocal and positive) by first-step assays are tested by separate IgG and IgM immunoblots. Samples showing reactivity to 2 of 3 significant bands, 41-, 39-, or 23-kDa (OspC) are considered positive by the IgM criteria. Samples showing 5 of 10 significant bands: 93, 66, 58, 45, 41, 39, 30, 28, 23 (OspC), and 18 kDa in IgG blots are considered positive by the IgG criteria (20). This two-step approach is also widely used by laboratories in Europe. Furthermore, the recommendations stated that the IgM immunoblot criteria should be used in patients with disease of <1 month duration, and IgG criteria could be used at any stage of the disease.

Evaluation of the two-tier testing in well-characterized populations of patients with different stages of Lyme disease has found that this approach offers a sensitivity of about 40% during the acute phase of EM and increases to over 60% during convalescence. Antibody development occurs regardless of antimicrobial treatment in a majority of patients. The sensitivity of the two-step approach is about 90% in patients presenting with early dissemination with neurological symptoms, particularly when the IgM immunoblot criteria is used and is close to 100% in those with late manifestations such as arthritis (21–23) (Table 3).

Limitations of the two-step test are that the first- and second-step assays are not independent, since both include antigenic mixtures of *B. burgdorferi*, in addition to the difficulty in interpreting immunoblot results and their high cost. Recently, several studies have addressed whether a one-step test, such as ELISAs using the VlsE C6 peptide as antigen, or an alternative two-tiered test that consists of a whole-cell sonicate EIA followed by a VlsE C6 EIA (22, 24), are of sufficient sensitivity and specificity to replace the widely used two-step approach. Given the variability of immunodominant antigens observed among different pathogenic Lyme *Borrelia* species and subtypes, particularly in Europe, and its slightly lower specificity, the one-step EIA strategy is not recommended for serodiagnosis of Lyme disease (18, 22). Compared to the standard two-step approach using EIA and immunoblot, recent studies demonstrated comparable sensitivity and specificity but lower cost by a new two-EIA test strategy (18, 22). These data are based on studies from a few laboratories in a limited number of patients. More studies are needed to determine the applicability of this two-EIA approach to replace the current standard two-step tests for serodiagnosis of patients with various manifestations of Lyme disease in both the U.S. and Europe.

Use of Recombinant or Peptide Antigens in Serology of Lyme Disease

Several antigens have been purified and recombinants have been developed and evaluated as a source of antigens in immunoassays. Among those are recombinant OspC, internal fragments of 41 kDa (41-i), P39 (BmpA), P66, P93, DbpA (decorin-binding protein A), BBK32, and others. The performance of these recombinant and peptide antigens for detection of IgM, IgG, or polyvalent antibodies in patients with various stages of Lyme disease has been reviewed elsewhere (21).

Peptide antigens that have been found to hold great promise include the pepC10 that contains the conserved C-terminal 10 amino acids of OspC. Although less variable than the parent OspC, this peptide also binds IgM antibodies present in sera of patients with early disease. Evaluations of the performance of this peptide antigen have shown it to be sensitive and specific. An ELISA test based on another peptide, OspC1, a highly conserved 20-amino-acid peptide epitope, showed comparable sensitivity but higher specificity than a pepC10-based method (25).

Another peptide antigen that has attracted great attention is the VlsE C6. This is a synthetic peptide reproducing the highly conserved invariable region 6 of the VlsE antigen. The C6 peptide-based ELISA and Western immunoblot assays with the addition of a VlsE band (26) have been reported to be comparable or more sensitive for laboratory diagnosis of patients with early and late Lyme disease. ELISA assays that use recombinant antigen or peptides or a combination have been approved by the FDA as first-step assays. Recent FDA-cleared first-step assays include the use of recombinant VlsE and synthetic pepC10 in a bead format (AtheNA Multi-Lyte system, Zeus Scientific, Inc.) and VlsE in a chemiluminescence assay (LIASON, DiaSorin S.p.A.).

TABLE 3 Comparative sensitivity of different immunologic methods to detect antibodies to *B. burgdorferi* in Lyme disease patients from the United States[a]

Test	% Reactivity in patients with:			
	EM, acute phase	EM, convalescent phase	Neurological involvement	Arthritis
Whole-cell EIA[b]	33–52	76–94	79–100	Nearly 100
VlsE C6 EIA[b]	34–43	59–92	67–100	67–100
Two-EIA[b]	37	89	100	100
Standard two-tier testing[c]	27–40	29–78	87–100	97–100

[b]EIA, enzyme immunoassay; two-EIA, whole-cell EIA followed by VlsE C6 EIA (22).
[c]Two-tier algorithm including a screening EIA and a confirmatory immunoblot as recommended by the CDC (20).

Other Immunologic Methods

Other immunologic methods for serodiagnosis of Lyme diseases include the measurement of functional borreliacidal antibodies, antibodies bound to circulating immune complexes, and host cellular immune response by T-lymphocyte and mononuclear cell proliferation assays. These assays have seldom been used as diagnostic tests due to their cumbersome nature and concerns about specificity and standardization.

Clinical Applications and Limitations of Serologic Tests

Current serological tests may be limited by the delay in development of an antibody response, cross-reactivity with other organisms, high background seroprevalence in asymptomatic persons residing in endemic areas, difficulty in distinguishing past from present infections, and lack of standardization. In addition, antigenic heterogeneity of *B. burgdorferi sensu lato* may influence the sensitivity and specificity of serological tests for Lyme disease, especially in Europe where three pathogenic species of *B. burgdorferi sensu lato* and at least eight OspA serotypes are well documented.

European investigators have long used assays including recombinant antigens derived from *B. garinii* and *B. afzelii*, the predominant *Borrelia* species causing disease in Europe. The antigenic variability is of greater magnitude in Lyme disease-causing organisms in different geographic regions of Europe than in the United States. Attempts have been made to standardize serologic testing in Europe.

It is noteworthy that serological tests for *B. burgdorferi* antibodies should be used only to support a clinical diagnosis of Lyme disease and not as the primary basis for making a diagnosis or for treatment decisions. The positive predictive value (the ability to diagnose disease) of a test depends on both the sensitivity and specificity of the assay and the prevalence of the disease in the population in which the test is being applied.

In addition, some technical issues need to be addressed in the laboratory performing the Lyme serologic tests. For example, evaluation of newly introduced first-tier assays and lots with well-characterized samples before their use in the laboratory is strongly recommended. Variations in reactivity using different lots from the same manufacturer as well as from different assays are not uncommon. Inclusion of well-characterized specimens testing weakly reactive or with borderline reactivities are also recommended.

For immunoblot tests, the most important limitation of these assays is the subjective interpretation. The most frequent error is the over-reading of the IgM immunoblots. These antibodies may remain detectable for long periods after successful treatment of early disease and may be present in low concentration in immunoblots. Scoring of faint bands leads to misinterpretation of IgM immunoblots. Inclusion of weak controls against which a band is read as well as scoring of bands using densitometry may be of help in solving this problem. IgM blots during acute disease characteristically show strong reactivity to the OspC and very frequently to the 41- and/or the 39-kDa antigens (Fig. 1).

IgG blots fulfilling the CDC criteria are found in sera of patients with disease of more than 1-month duration. Problems in fulfilling blot criteria may be found in sera of patients with early disseminated neurological disease who usually fulfill IgM criteria but may not yet have a positive IgG blot.

Direct Detection of *B. burgdorferi*

Microbiological confirmation of the presence of *B. burgdorferi* in clinical specimens provides definitive evidence of *B. burgdorferi* infections in patients with suspected Lyme disease. *B. burgdorferi* in clinical samples can be detected by microscopic examination of intact spirochetes, antigen test, *in vitro* cultivation of *B. burgdorferi*, and polymerase chain reaction analysis of *B. burgdorferi* nucleic acids. Of these, direct microscopic examination and antigen test are rarely used in clinical laboratories due to their low sensitivity and specificity. Direct detection of spirochetes in tissue specimens by histochemical staining is not reliable, because spirochetes cannot be distinguished easily from elastic tissue or procollagen fibers.

B. burgdorferi can be cultured *in vitro* in liquid Barbour Stoenner Kelly medium under microaerophilic conditions. The optimum growth temperature for *B. burgdorferi* is 30 to 34°C. *B. burgdorferi* has been cultured in up to 80% of skin biopsy samples of patients with EM. The organism has also been cultured on whole blood, serum, or plasma in up to 40% of samples collected from patients with early Lyme disease (27). Better yield of blood culture in early disease has been achieved by culturing blood volumes similar to those used in routine bacterial blood cultures. Recently, a new method of culturing spirochetes from the serum of U.S. patients with Lyme disease was reported to have exceptionally high clinical sensitivity (94%) and specificity (100%). Assessment of the culture results revealed potential false positivity due to laboratory contamination of patient samples (28). *B. burgdorferi* has been infrequently isolated from other samples, such as cerebrospinal fluid (CSF).

Molecular Diagnosis of *B. burgdorferi* Infection

Polymerase chain reaction detection of *B. burgdorferi* DNA represents an alternative approach for diagnosis of Lyme disease (reviewed in references 21 and 29). The diagnostic value of PCR may vary depending on the clinical diseases and PCR method being used. Currently, PCR-based molecular tests are employed in research settings. Such uses have involved (i) detection of nucleic acids of tick-borne pathogens in *Ixodes* ticks, (ii) culture confirmation of *B. burgdorferi*, and (iii) direct detection on skin or synovial tissues.

PCR has been used to detect the DNA of *B. burgdorferi* in skin biopsy, blood, urine, CSF, and synovial fluid specimens with variable diagnostic value. The sensitivity of PCR for detection of *B. burgdorferi* DNA in skin lesions is usually high with a median percent positivity of 69% for patients with EM and 76% for patients with ACA (21). In general, the sensitivity of PCR for detection of *B. burgdorferi* DNA in blood, plasma, or serum samples from patients with Lyme disease is low (<20%) due to the lack of spirochetemia or to transient or low-level spirochetemia. In a U.S. retrospective study, only 6 of 5,703 (0.1%) blood and 14 of 15,939 (0.09%) CSF specimens examined by a real-time PCR assay in the Mayo Clinic Laboratory were positive (30). PCR has also been successful on joint fluid or tissues from patients with untreated Lyme arthritis. PCR has a median sensitivity of 78% and is more sensitive than culture for detection of *B. burgdorferi* in synovial fluid specimens (21).

Limitations of Direct-Detection Methods

Due to the lack of commercially available and adequately validated assays, a reliable and standardized PCR protocol is needed to address the current challenges of persistent misconceptions, misunderstanding, and misdiagnosis of Lyme disease (31). Due to the above reasons, use of PCR in clinical settings—particularly on blood, CSF, or other body fluids, with the exception of synovial—should be discouraged.

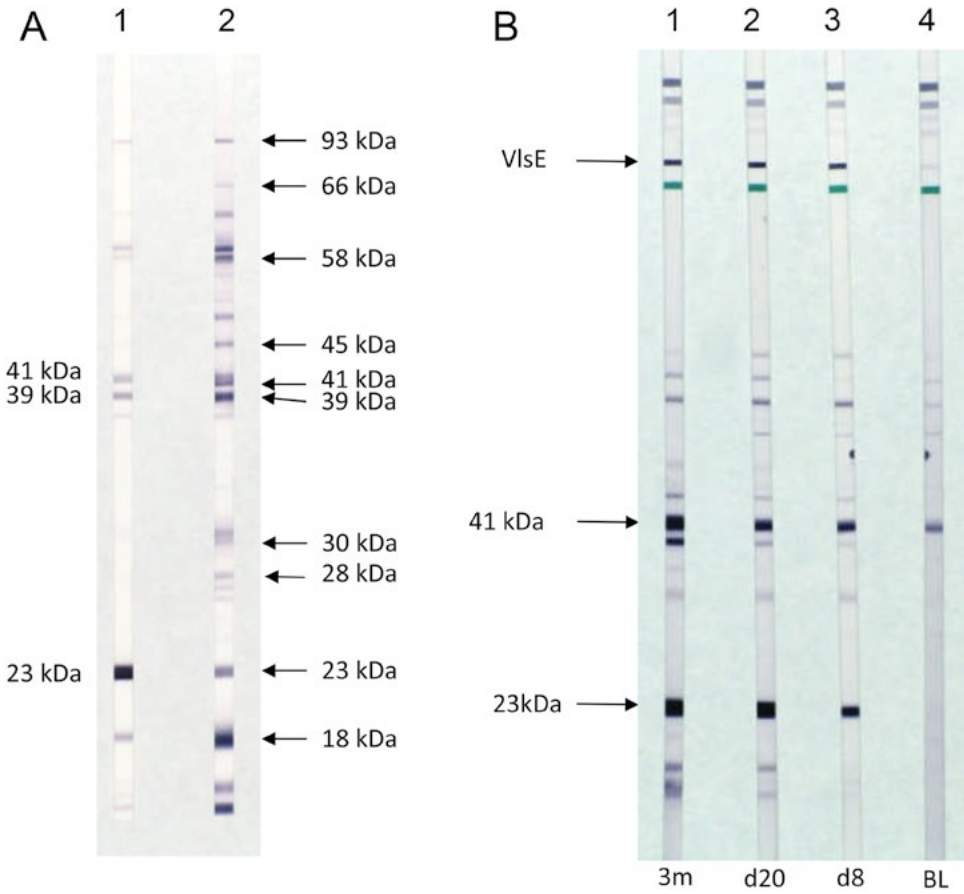

FIGURE 1 (A) Examples of positive Lyme IgM (lane 1) and IgG (lane 2) Western blots (MarDx Inc). The IgM and IgG bands in the CDC interpretive criteria are indicated. (B) VlsE–IgG Western blots (Viralab Inc, not currently FDA-approved in the U.S.) (26). Sequential sera from a culture-confirmed EM patient are shown in lanes 1 to 4. Serum samples were collected at Baseline (BL, lane 4), 8 days (d8, lane 3), 20 days (d20, lane 2) and 3 months (3m, lane 1) post onset of illness.

Test Interpretation and Practical Considerations

Diagnosis of EM is clinical and is based on the presence of an erythematous skin lesion at the site of the tick bite. Such lesion should be of a minimum of 5-cm diameter. For patients with atypical EM and noncutaneous manifestations or late Lyme disease, laboratory evidence of *B. burgdorferi* infection is required for confirmation of a diagnosis. Table 4 shows a comparison of the different diagnostic modalities used to confirm the diagnosis of Lyme disease.

The use of diagnostic methods aiming at the direct detection of *B. burgdorferi* in clinical samples such as culture or PCR is currently restricted to research laboratories in academic centers. PCR is also available through commercial laboratories, and its use should be restricted to joint fluids or joint tissues. A positive PCR result in a synovial-fluid specimen of a patient with exposure to an area where Lyme disease is endemic and who also has a positive *B. burgdorferi sensu lato* ELISA and IgG immunoblot is strongly supportive of a diagnosis of Lyme arthritis. Untreated patients with Lyme arthritis, as well as patients during the first days to weeks of therapy, may exhibit a positive PCR result in synovial fluid.

Positive PCR results for *B. burgdorferi sensu lato* nucleic acids obtained in samples from patients with possible extracutaneous manifestations of Lyme disease in the absence of serological evidence of *B. burgdorferi sensu lato* infection, however, should be interpreted with caution. In those situations, PCRs are often false positive. One of the limitations of nucleic acid-amplification methods is the generation of false-positive results due to contamination. Adherence to rigorous quality control steps is of utmost importance.

Serology is the most useful laboratory test that is widely available to support a clinical diagnosis of Lyme disease. The current recommended approach includes the use of two-tier testing. Interpretation of serology in Lyme disease requires an understanding of the use and limitations of the currently available tests for *B. burgdorferi sensu lato* antibodies, as follows.

(i) These tests detect antibodies reacting with *B. burgdorferi sensu lato* and can support the clinical suspicion of Lyme disease, but in and of themselves they do not diagnose Lyme disease.

(ii) Antibodies may not be detectable at the time the patient presents with signs and symptoms of early Lyme disease with EM, and their presence correlates directly with the duration of disease prior to seeking medical attention as well as with the presence of symptoms or objective signs of dissemination (for example, multiple EMs or cranial nerve palsies). For patients with early Lyme disease who have EM, the diagnosis is established on clinical grounds if the skin

TABLE 4 Comparison of different modalities for laboratory diagnosis of Lyme disease

Test method	Sensitivity (%)[a]
Culture	
Skin biopsy (EM, ACA)	60–80
Blood	10–40
PCR	
Skin biopsy (EM, ACA)	60–80
Blood and CSF	10–30
Synovial fluid	50–70
Two-tier serology	
EM, acute phase	30–40
EM, convalescent phase	80
Neuroborreliosis	80–90
Lyme arthritis	90–100

[a]Adapted from reference 21.

lesion is characteristic. In situations where the skin lesion is atypical or absent, tests to detect *B. burgdorferi sensu lato* antibodies may be necessary, as follows.

(a) When antibodies are not detectable or not diagnostic in the acute-phase serum specimen, a convalescent-phase specimen should be collected 2 to 4 weeks later and tested for *B. burgdorferi sensu lato* antibodies.

(b) In patients treated with antimicrobials, testing of the convalescent-phase sample within 1 month of onset of symptoms will maximize sensitivity, since the criteria for test positivity at this time point include IgM immunoblot seroconversion, whereas after 1 month IgG seroconversion is required for seropositivity.

(iii) Testing for *B. burgdorferi sensu lato* antibodies should include the two-tier approach as currently recommended. In those specimens testing positive or equivocal by first-tier assays, second-tier immunoblot is used to improve specificity. Immunoblot assay should not be used with sera testing negative by the first tier, as this would reduce specificity compared to the two-tier testing strategy.

(iv) *B. burgdorferi sensu lato* antibodies, both IgG and IgM, may persist for many years after successful treatment of Lyme disease. Thus, persistent seropositivity is not, *per se*, an indication of treatment failure. Persistence of antibodies to *B. burgdorferi sensu lato* in sera of individuals residing in areas where Lyme disease is endemic and who have been treated for Lyme disease, or who have resolved an asymptomatic infection, may limit the utility of future serologic testing as a diagnostic tool when such persons present with a new clinical event. In these circumstances, a change in reactivity between acute- and convalescent-phase specimens may be of assistance, although this has never been systematically evaluated. An increase in antibody concentration as determined by optical density in EIA, or by IFA titers, in first-tier assays, or by an increase in intensity or appearance of new immunoreactive bands by immunoblot might suggest a new or recent *B. burgdorferi sensu lato* infection. Physicians caring for these patients should store an aliquot of an acute-phase serum specimen to be submitted along with the convalescent-phase sample for testing in parallel for *B. burgdorferi sensu lato* antibodies.

(v) Patients with late manifestations of Lyme disease usually have a high concentration of antibodies by first-step tests and have numerous immunoreactive bands in IgG blots, often far surpassing the number of bands required in the IgG immunoblot interpretation criteria. A lack of seropositivity in patients suspected of having late Lyme disease practically excludes this diagnosis.

(vi) Laboratories performing *B. burgdorferi sensu lato* serology should use assays of proven performance as determined by the summary of surveys run by the College of American Pathologists or local or state proficiency programs.

(vii) Laboratorians should make an attempt to avoid scoring weak bands leading to false-positive readings in immunoblot, particularly IgM immunoblot. This can be avoided by strict adherence to comparison of band intensity to those of cutoff-intensity-control materials.

(viii) The use of laboratory tests or interpretation strategies that have not been appropriately validated is of great concern and is strongly discouraged. Currently there are commercial laboratories offering *B. burgdorferi sensu lato* urine antigen tests, immunofluorescent staining for cell wall-deficient forms of *B. burgdorferi sensu lato*, and lymphocyte transformation tests. In addition, some laboratories are performing PCR for *B. burgdorferi sensu lato* DNA on inappropriate samples, such as blood and urine, or are interpreting immunoblot by using criteria that have not been validated.

(ix) The use of *B. burgdorferi sensu lato* antibody testing should be restricted to patients with a 0.2 to 0.8 pretest probability of having Lyme disease, as recommended by the American College of Physicians (13). The use of these tests in unselected populations with a low pretest probability of the disease is more likely to yield false-positive than true-positive results. Testing is not recommended for patients presenting with classic EM, since treatment without testing is more cost effective, and *B. burgdorferi sensu lato* antibody assays have low sensitivity at this stage. Since the specificity of *B. burgdorferi sensu lato* antibody testing is not 100% and since 2.8 to 3.4 million tests are estimated to be done annually in the U.S., for every 1% reduction in test specificity there will be approximately 28,000 to 34,000 false-positive results per year, dwarfing the true-positive incidence of about 33,000 cases/year.

RELAPSING FEVER

Taxonomy

Currently there are 23 validated species in the RF *Borrelia* group (5). All but two of the 23 RF *Borrelia* species, *Borrelia coriaceae* and *Borrelia miyamotoi*, were described before the delineation of *B. burgdorferi* in 1984. The "new" RF *Borrelia* species isolated from patient blood samples and *Ornithodoros erraticus* ticks in Spain in the mid-1990s was recently confirmed to be *Borrelia hispanica* based on multilocus sequence data analysis (32). Recent genomic sequence analysis raises the possibility that *B. recurrentis*, *B. duttonii*, and *B. microti* may belong to a single species (33).

A few novel RF *Borrelia*-related species have been described, including *Borrelia lonestari* from hard tick *Amblyomma americanum* in North America, *Borrelia mvumii* from *Ornithodoros* ticks and patients in Tanzania, and *Borrelia microti* from *O. erraticus* in Iran.

Epidemiology and Disease Spectrum

Relapsing fever has been reported in continents of both the northern and southern hemispheres. It was once the cause of worldwide epidemic disease, especially for louse-borne relapsing fever (LBRF). Although the incidence of LBRF has decreased significantly during the last century, largely

due to improved living standards, there have been recent reports of LBRF in homeless people from France and there still exist areas of endemicity in Ethiopia and Sudan (34). Some authors have cautioned that relapsing fever is underreported and not considered in the differential diagnosis of febrile illnesses, particularly that tick-borne relapsing fever (TBRF) *Borrelia* can infect a variety of hosts, establishing a vast reservoir (34). Relapsing fever is now mostly a sporadic disease in most regions of the Old and New World, including the western U.S., southern British Columbia in Canada, the plateau regions of Mexico, Central and South America, the Mediterranean, Central Asia, and throughout much of Africa (35). In the U.S., human TBRF is typically distributed in a few states no further east than Montana, Colorado, New Mexico, and Texas.

Human relapsing fever is caused by at least 15 *Borrelia* species and is transmitted by the soft tick *Ornithodoros*, with the exception of LBRF, which has only humans as reservoirs and is transmitted only by the human-specific body louse *Pediculus humanus*. TBRF cases associated with infection of *B. miyamotoi*-like spirochete and transmitted by *Ixodes* ticks have recently been reported in Russia and the northeastern U.S.

In the U.S., human TBRF is mainly caused by infections of *B. hermsii* and *B. turicatae*, which are transmitted by soft ticks *O. hermsi* and *O. turicata*, respectively. TBRF in Eurasia is attributed mainly to *B. persica*, although other *Borrelia* species have also been described. *O. tholozani* is the most important tick vector for TBRF in Eurasia and can be found in India and Kashmir, the southern countries of the former USSR, Iran, Iraq, Syria, Jordan, Turkey, Israel, Egypt, and Cyprus. *B. hispanica* is responsible for the majority of cases in the Mediterranean regions where *O. erraticus* is predominant.

The overall clinical manifestations of louse LBRF and TBRF are similar, although not identical. Characteristically, both types of relapsing fever have recurring episodes of fever and nonspecific symptoms, i.e., severe headache, myalgias, arthralgias, and lethargy. The primary febrile episode normally has an acute onset with high fever that subsides in 3 to 6 days. After 7 to 9 days, fever and symptoms recur, although the duration and the intensity of the symptoms progressively decrease with each relapse. LBRF is usually associated with a single relapse, whereas multiple relapses can been seen in TBRF. The most common clinical signs of relapsing fever may include altered sensorium, conjunctival suffusion, petechiae, and diffuse abdominal tenderness with hepatomegaly and splenomegaly (35, 36).

Direct Microscopic Examination of Spirochete in Blood

Relapsing fever has traditionally been diagnosed by the demonstration of spirochetes in the blood of patients during febrile episodes. During the febrile illness, RF borreliae multiply in the bloodstream and are often present at levels in excess of 10^5 organisms/μL of blood. Among febrile patients, spirochetes can be found in approximately 70% of cases when blood smears are examined in Giemsa- or Wright's-stained thin and thick films by light microscopy, or by use of dark-field or phase-contrast microscopy of wet preparations (36). The sensitivity of microscopic methods can be improved by the use of acridine orange-stained blood smears with a fluorescence microscope or by examination of buffy coat smears.

The use of a centrifugation-based enrichment method, followed by Giemsa staining, allows detection of less than 10 spirochetes/ml in blood (37). If validated, this simple method can be an interesting alternative in a rural relapsing fever-endemic area.

Molecular Detection and Genotyping of Relapsing Fever Borreliae

PCR-based molecular techniques have shown promise for improved clinical diagnosis and epidemiologic assessment of relapsing fever (38). Elbir et al. reported that a multiplex real-time PCR assay targeting the 16S rRNA, *glpQ*, *recN*, and *recC* not only detected but also speciated the four closely related RF borreliae: *B. crocidurae*, *B. duttonii*, *B. recurrentis*, and *B. hispanica*, found in Africa (38).

Serologic Test Methods

Serological methods are not widely in use for laboratory diagnosis and management of patients with RF. Serologic tests include IFA, ELISA, and Western immunoblot. The currently available serological approaches that use whole-cell spirochete lysates as antigen sources may fail to discriminate between different *Borrelia* species, resulting in probable misidentification of patients as cases of Lyme disease. Also, seroconversion is rarely demonstrated during the first febrile episode, and prompt antibiotic therapy may abrogate the antibody response. Therefore, while positive results in any of these assays may strongly support the clinical diagnosis of relapsing fever, negative results are inconclusive.

Recent data suggest that relapsing fever may be distinguished from Lyme disease based on the presence of antibodies against an immunoreactive 39-kDa surface protein, glycerophosphodiester phosphodiesterase (GlpQ) (39) or a 57-kDa *Borrelia* immunogenic protein A (BipA) (40). Further evaluation and standardization of assays utilizing this antigen may justify its greater use. Despite the utility of laboratory diagnostic tests, the importance of a detailed case history and clinical presentation in the diagnosis of relapsing-fever borreliosis cannot be overemphasized.

Culture of Relapsing Fever Borreliae

Like *B. burgdorferi*, a variety of RF borreliae, including *B. hermsii*, *B. parkeri*, *B. turicatae*, *B. duttonii*, and *B. recurrentis*, can be cultivated *in vitro* in Barbour-Stoenner-Kelly medium. The sensitivity of culture is not yet sufficient for diagnosis and now is infrequently used compared to that in Lyme disease.

Alternatively, intraperitoneal injection of patient blood into mice or rats usually produces large numbers of spirochetes in the animals' blood within 3 to 5 days for TBRF borreliae. This provides another means for the isolation and presumptive identification of RF *Borrelia*.

Clinical Indications and Test Interpretation

Relapsing fever has usually an acute onset of high fever with systemic symptoms. During the course of illness, fever is remittent and often accompanied by tachycardia and tachypnea. Laboratory confirmation is recommended for patients with suspected LBRF or TBRF, based on the patient's clinical syndrome, tick bite history, and local epidemiological data.

The definitive diagnosis of relapsing fever is established by demonstrating the presence of borreliae in the peripheral blood of infected patients. The most direct and simple method is by microscopy. During acute febrile phases, spirochetemia often reaches 10^6 to 10^8 spirochetes/ml, and motile spirochetes can be visualized by dark-field microscopy

from wet preparations. In patients with low spirochetemia, concentration of the spirochetes by buffy coat or other approaches will increase the yield of positivity.

Like Lyme disease, culture is not a practical approach for laboratory diagnosis of relapsing fever. Real-time PCR assays are promising tools in detecting and genotyping the infecting spirochetes in patients in early stages of relapsing fever if available. Serologic tests are not routinely employed in the laboratory for the confirmation of relapsing fever. Immunoassay using recombinant GlpQ antigen is worthy of further exploration.

LEPTOSPIROSIS

Taxonomy

The genus *Leptospira* belongs to the family *Leptospiraceae* within the order *Spirochaetales* and class *Spirochaetes*. Historically, *Leptospira* was the only genus in the family *Leptospiraceae*. It was divided into two species: *L. interrogans*, comprising all pathogenic strains, and *L. biflexa*, containing the free-living, saprophytic strains from the environment. Within each species, strains are further differentiated by serovars on the basis of their reactivity with representative agglutination antibodies. Since a large number of serovars (>250) were described for pathogenic leptospires, antigenically related serovars were grouped into serogroups for convenience in serologic testing.

During the past 2 decades, the classification of spirochetes in the family *Leptospiraceae* has undergone significant changes. Many new species have been defined based on their genetic characteristics and relatedness. The family *Leptospiraceae* has now three genera. The genus *Leptospira* consists of at least 15 species with variable pathogenicity to humans, while single, nonpathogenic species belonging to the genera *Leptonema* and *Turneriella* have been defined (1).

Currently, there are 15 validated species and four additional genospecies with tentative species names in the genus *Leptospira* (Table 5). Based on 16S rRNA gene sequences, these *Leptospira* species are grouped into pathogenic, saprophytic species and intermediate species with uncertain pathogenicity. However, some species may contain both pathogenic and nonpathogenic serovars and strains, and one serovar may be found in more than one species. Therefore, it has been suggested that *Leptospira* strains should be characterized by both serologic and DNA-based techniques, and accurate differentiation of *Leptospira* species must rely on molecular characterization comparing 16S rRNA sequences or DNA-DNA reassociation analysis (41).

TABLE 5 *Leptospira* species and selected pathogenic serovars

Species	Selected pathogenic serovars
Pathogenic species	
L. interrogans	Icterohaemorrhagiae, Copenhageni, Canicola, Pomona, Australis, Autumnalis, Pyrogenes, Bratislava, Lai
L. alexanderi	Manhao 3
L. borgpetersenii	Ballum, Hardjo, Javanica
L. kirschneri	Bim, Bulgarica, Grippotyphosa, Cynopteri
L. meyeri	Sofia
L. noguchii	Panama, Pomona
L. santarosai	Bataviae
L. weilii	Celledoni, Sarmin
Leptospira genomospecies 1	Sichuan
B. Saprophytic species	
L. biflexa	
L. wolbachii	
Leptospira genomospecies 3	
Leptospira genomospecies 4	
Leptospira genomospecies 5	
C. Indeterminate	
L. broomii	
L. fainei	Hurtsbridge
L. inadai	
L. licerasiae	
L. wolffii	

Epidemiology and Disease Spectrum

Leptospirosis is a globally important zoonotic disease and an important public health problem in developing countries. Human infections are endemic in most regions, with the peak incidence occurring during the rainy season in tropical regions and during late summer to early fall in temperate regions.

The World Health Organization estimates the incidence of leptospirosis is 0.1 to 1.0 per 100,000 population per year in regions with a temperate climate, and >10 cases per 100,000 population in humid tropical regions. As a neglected infectious disease, the incidence of leptospirosis is probably largely underestimated, because of its asymptomatic nature in most cases and the limited diagnostic capacity in the regions where it has the highest prevalence. The most recent epidemics in Nicaragua (2007), Sri Lanka (2008), and the Philippines (2009) each affected thousands of patients and caused hundreds of deaths (42). In the United States, the highest incidence is found in Hawaii, with an annual incidence of approximately 128 cases/100,000 based on active surveillance in 1992.

Leptospirosis is maintained in nature by chronic renal infection of carrier animals. The most important reservoirs are rodents and other small mammals. Infected animals may excrete leptospires in their urine intermittently or continuously throughout life. Human infection often occurs through direct or indirect contact with urine or tissues of infected animals due to occupational exposure (i.e., veterinarians, workers in milking sheds on dairy farms, abattoir works, butchers, hunters, and animal handlers) or recreational or accidental contact.

Human leptospirosis is associated with a very broad spectrum of severity, ranging from subclinical, self-limited mild systemic illness to severe, potentially fatal illness accompanied by renal failure and liver failure. Approximately 90% of infected individuals have a subclinical presentation of mild severity. The clinical presentation in symptomatic patients usually has two distinct stages: an initial septicemic phase

followed by an immune phase in which the severe symptoms occur.

The acute septicemic phase of illness lasts 5 to 7 days in the majority of cases and presents with a febrile illness of sudden onset, fever (38 to 40°C), headache, chills, myalgias, abdominal pain, and conjunctivitis without purulent discharge. The immune phase of illness generally lasts 4 to 30 days with clinical symptoms such as jaundice, renal failure, cardiac arrhythmias, pulmonary symptoms, aseptic meningitis, conjunctivitis with or without hemorrhage, photophobia, eye pain, muscle tenderness, lymphadenopathy, and hepatosplenomegaly. Weil's disease, characterized by impaired hepatic and renal function, is the most distinctive form of severe leptospirosis.

Due to its nonspecific clinical presentations and potentially severe disease outcome, an early diagnosis of leptospirosis is essential for patient management because antibiotic treatment is most effective when initiated early in the course of the disease.

Serologic Diagnosis

Microscopic Agglutination Test

The microscopic agglutination test (MAT) detects both IgM and IgG classes of agglutinating antibodies against the surface antigens of *Leptospira*. MAT is considered the standard reference assay for laboratory diagnosis of leptospirosis.

Serum sample is the preferred specimen for serologic testing. The antibodies can be detected approximately 1 week after onset of symptoms and reach peak titers usually within 4 weeks. The titers following acute infection may be extremely high and may take months, or even years, to fall to low levels. Therefore, a pair of sera should be drawn at least 1 week apart and tested to confirm a diagnosis of leptospirosis if available.

Test Method

The MAT is an agglutination test, in which patients' sera are reacted with live or killed antigen suspension representing different serogroups or serovars of *Leptospira*. After incubation, the serum-antigen mixtures are examined by darkfield microscopy for agglutination and the titers are determined.

The MAT uses a panel of serovars (antigen) relevant to a testing region. The most commonly used serovars in the panel include Alexi, Australis, Autumnalis, Ballum, Bataviae, Borincana, Bratislava, Canicola, Celledoni, Copenhageni or Icterohaemorrhagiae, Cynopteri, Djasiman, Georgia, Grippotyphosa, Javanica, Mankarso, Pomona, Pyrogenes, Tarassovi, and Wolffi. The MAT is generally done using live spirochetes, but formalin-killed *Leptospira* may also be used. If the latter are used, titers are lower and the reactivity is somewhat less specific.

Also, a collection of antisera, corresponding to each serovar with a titer of ≥3,200, is needed as homologous controls for each antigen used in the assay. Antisera are available commercially or from the National Veterinary Services Laboratories, Ames, Iowa. A detailed protocol for performing the MAT can be found in the 7th edition of this *Manual* (43).

Interpretation and Limitations

The MAT results are reported as the reciprocal of the serum dilution that tested reactive for each antigen; a titer of ≥100 is considered positive.

The MAT can be used for confirmation and presumptive diagnosis of human leptospirosis cases, especially for febrile patients with nonspecific symptoms in endemic areas. It can also be used with human and animal sera in epidemiologic studies or outbreaks to determine the potential source of infection.

A 4-fold or greater increase in MAT titer to one or more serovars between paired serum specimens run in parallel, regardless of the interval between samples, confirms a diagnosis of leptospirosis. If only a single serum sample is available for testing, a titer of at least 800 in the presence of compatible symptoms is generally considered diagnostic in areas of endemic infection. In regions where leptospirosis is not endemic, the threshold titer for a presumptive diagnosis may be correspondingly lower. Currently, the U.S. Centers for Disease Control and Prevention uses a titer of ≥200 in a patient with clinically compatible illness as evidence for recent or current infection to indicate a probable case for epidemiological surveillance.

The diagnostic and epidemiological applications of the MAT are limited by its relatively low sensitivity when acute serum samples are tested. Up to 10% of patients may have delayed seroconversion or fail to seroconvert within 30 days of the clinical onset. Also, cross-reactive antibodies may be associated with syphilis, relapsing fever, Lyme disease, viral hepatitis, human immunodeficiency virus (HIV) infection, legionellosis, and autoimmune diseases.

In addition, antibodies in serum may cross-react between different serovars, especially in acute-phase samples; this is attributed to IgM antibodies. Most MAT assays use only 12 to 19 of the more than 250 known serovars. Thus, the MAT should not be used to infer the identity of the infecting serovar.

Rapid IgM Antibody Screening Tests

Due to the complexity of performance and interpretation, the use of MAT is now limited to regional and national reference laboratories. A rapid screening test for serum samples from suspected leptospirosis plays an important role in immediate case detection and clinical management. Several rapid screening tests are currently available. They are primarily IgM detection assays. Use of these assays as screening tests offers the potential to enhance the diagnostic capacity of many laboratories, particularly in developing countries, where most cases of leptospirosis occur.

Test Methods

Rapid IgM detection assays are available in several formats, including conventional IgM antibody-capture microplate ELISA (IgM ELISA) assay and some rapid diagnostic tests (RDTs).

The IgM ELISA assay is a useful screening tool for testing few or large numbers of specimens. It is commercially available or it can be prepared in house. Most IgM ELISA assays use whole-cell-derived antigens. It has been reported that the selection of antigens representing local serovars and the use of antigen prepared from intermediate species, such as *L. fainei*, may increase the assay sensitivity (44). The commercially available *Leptospira* IgM ELISA kit (PANBIO Inc, Columbia, MD) contains antigen-coated plates (12 8-well strips), wash buffer concentrate, serum diluent, horseradish peroxidase-conjugated anti-human IgM, tetramethyl benzidine substrate, stop solution, positive control serum, cutoff calibrator serum, and negative control serum. It is a solid-phase assay in which IgM present in serum binds to leptospiral antigen attached to the polystyrene surface of the microwell. Peroxidase-conjugated anti-human IgM reacts with the antigen-bound antibody. The detection system is a colorless substrate, tetramethyl benzidine substrate plus

hydrogen peroxide, which is hydrolyzed by the enzyme, and the chromogen changes to a blue color. The color intensity is directly related to the concentration of anti-*Leptospira* IgM antibodies in the test sample.

A variety of RDTs have been described and evaluated for screening of suspected cases of leptospirosis. These RDTs are based either on the immunochromatographic lateral flow technology (i.e., LeptoTek Lateral Flow, Organon Teknika BV, Boxtel, The Netherlands; Leptocheck-WB, Zephyr Biomedicals, Verna Goa, India) or on latex agglutination (i.e., LeptoTek Dri Dot, bioMérieux BV, Boxtel, The Netherlands). The dot ELISA dipstick (INDX Dip-S-Ticks; PANBIO Inc, Columbia, MD) uses a genus-specific antigen (*L. biflexa* serovar Patoc) dispensed as discrete dots on a solid membrane. Diluted patient serum reacts with the antigens on the assay strip, and alkaline phosphatase-conjugated anti-human immunoglobulin reacts with the bound antibodies from the patient's serum.

Interpretation and Limitations

The rapid IgM ELISA and RDTs can be quantitative or qualitative. The cutoff for positive may be test-kit and assay-specific and may need to be adjusted, verified, or established by the testing laboratory based on the prevalence of testing population.

A recent meta-analysis of IgM ELISAs reported an overall sensitivity and specificity of 80% and 94%, respectively (45). These IgM detection assays are intended for use in the diagnosis of acute infection. The presence of IgM antibody is considered suggestive of a recent or acute *Leptospira* infection. However, IgM may persist for months or years following recovery in some cases. Most rapid IgM assays should be used for screening tests, and confirmation of results with MAT and alternative tests is strongly recommended. The assay detects antibodies earlier than do the agglutination assays (indirect hemagglutination assay and MAT) and is ideal for use when only a few specimens are tested at a time.

Because IgM antibodies are not detectable until days 5 to 7 days after symptom onset, the sensitivity of these assays is low for patients in the early acute phase of illness. Cross-reactions in this assay have been observed with sera positive for autoimmune diseases, cytomegalovirus, HIV, group C *Neisseria meningitidis*, and viral hepatitis.

Culture of *Leptospira* in Body Fluids and Tissues

Leptospira can be detected by culture from blood, CSF, and peritoneal dialysate fluids during the first 10 days of illness, and from urine samples from the beginning of the second week of symptomatic illness. In some severe cases, the organisms can be detected in almost all tissues and organs and in urine for several weeks. For culture, the specimens should be collected as soon as possible while the patient is febrile and before the initiation of antibiotic treatment. Whole blood and deposit from spun plasma specimens are the preferred types of blood for culture.

The medium for cultivation of *Leptospira* is the semisolid Ellinghausen-McCullough-Johnson-Harris (EMJH) medium or Fletcher medium (Difco EMJH or Difco Fletcher medium; BD Diagnostic Systems, Sparks, MD). A modified solid medium (LVW agar) has also been described for rapid isolation and susceptibility testing of *Leptospira* spp. (46). Cultures in EMJH medium are incubated in sealed bottles at 28 to 30°C and examined weekly by dark-field microscopy. In one prospective cohort study in Thailand, the median time to culture positivity for the primary culture was 21 days, ranging from 7 to 84 days, indicating that the cultures should be maintained for at least 3 months before a negative result can be reported (47).

A positive culture provides the definitive diagnosis for leptospirosis in patients with compatible clinical syndromes. The overall yield of culture is only approximately 10% for patients with suspected leptospirosis (48).

Molecular Methods for Diagnosis and Subtyping

Because of the difficulty in culture and serologic identification of *Leptospira*, the development of accurate molecular tests for direct detection of leptospiral nucleic acid in clinical specimens has been a major advance in enabling early diagnosis of leptospirosis.

The most widely applicable molecular method is real-time PCR. 16S rRNA (*rrs*) is the most commonly used target for PCR assays (48). In a recent study, Agampodi et al. reported that the diagnostic sensitivity of a quantitative real-time PCR assay was 18.4% and 51.0% for whole blood and serum specimens, respectively (49). The bacterial load in serum and blood ranged from 10^2 to 10^6 organisms/ml, with a median leptospiral load of 8,616, 11,007, 36,100, and 15,882 organisms/ml for uncomplicated, renal failure, myocarditis, and multi-organ failure patients, respectively (49).

Two recent studies demonstrated that real-time PCR assays, using primers and probes targeting a gene encoding surface lipoprotein LipL32, have comparable sensitivity but higher specificity to *rrs*-based assays (50, 51). These LipL32-based PCR assays can potentially be a reliable, sensitive, and rapid test for the detection of *Leptospira* in acute patients.

Of the numerous molecular methods evaluated for subtyping, pulsed-field gel electrophoresis is the recommended method for strain typing and subtyping.

Clinical Indications and Test Interpretation

Culture and the microscopic agglutination test are gold-standard methods for leptospirosis diagnosis; however, they are not useful for early diagnosis. Current whole-cell-based rapid serological tests have low sensitivity for early phase leptospirosis and may have low specificity in highly endemic areas. PCR is demonstrably useful for early diagnosis, but it is unavailable in most developing countries. Thus, diagnostic methods that not only have higher sensitivity and accuracy for early phase leptospirosis but that are also widely applicable in developing countries remain to be developed. The availability of genome sequences and genetic tools of *Leptospira* spp. will accelerate our understanding of *Leptospira* pathogenesis and provide insights into the development of more efficient and accurate diagnostic tests for acute-phase leptospirosis.

Immunological Tests in Tuberculosis

CHRISTINE M. LITWIN

48

EPIDEMIOLOGY

Tuberculosis (TB) is one of the most common serious bacterial infections and remains a major challenge to global health. One-third of the human population has been infected with *Mycobacterium tuberculosis*. Globally, drug-resistant tuberculosis is emerging as a new epidemic, with approximately 0.5 million new multidrug-resistant cases annually. TB is second only to HIV as a worldwide cause of death from an infectious disease, and HIV infection, in turn, is a major risk factor for TB.

In 2011, there were an estimated 8.7 million new cases of TB (13% coinfected with HIV) and 1.4 million people died from the disease. These figures include almost 1 million deaths among HIV-negative individuals and 430,000 among people who were HIV positive. Unfortunately, the impairment of immunity caused by HIV infection implies that traditional immunological tests may be of limited value in the diagnosis of coexistent TB. The value of TB immunological testing in HIV-positive individuals is discussed for each of the available assays.

MODE OF SPREAD, RISK OF INFECTION, AND RISK OF PROGRESSION TO ACTIVE DISEASE

Most infections with *M. tuberculosis* are due to inhalation of bacteria-laden droplet nuclei transmitted by close contact with heavily infected individuals. After exposure to *M. tuberculosis*, approximately 30% of persons develop active infection (1). The remainder of infected persons harbor tubercle bacilli, which are either slowly replicating or killed in granulomas, and are without clinical symptoms. However, if cell-mediated immunity becomes impaired, residual living organisms may no longer be held in check and lead to the development of active TB. Latent TB infection (LTBI) is therefore defined as a clinical condition in which an individual has been infected with *M. tuberculosis*, but has no clinical manifestation of disease and negative cultures for the organism. In general, about 3 to 4% of infected individuals progress to active TB after the first year of exposure, and an additional 5% carry a lifetime risk of progressing to active disease (2).

DIAGNOSIS

Culture of the tubercle bacillus remains the gold standard for the diagnosis of active TB. Yet, at least one-third of patients with TB do not have a positive culture because of the inherent difficulty to grow *Mycobacterium* spp. Nucleic-amplification assays offer another technique for the direct detection of *M. tuberculosis* in clinical specimens. Significant progress has been made in the area of molecular diagnostics of TB infections. In July 2013, the FDA approved the Xpert MTB/RIF assay, which, in addition to having the ability to detect *M. tuberculosis* in clinical specimens, can also simultaneously determine if the *M. tuberculosis* strains contain genetic markers that makes them resistant to rifampin. For the diagnosis of LTBI, a delayed-hypersensitivity reaction to tuberculin or a blood test based on gamma interferon (IFN-γ) production by effectors and memory immune responses directed against *M. tuberculosis* antigens can be used. Currently, there are two commercially available FDA-approved IFN-γ release assays.

IMMUNOLOGY

TB requires a cellular immune response for control of infection. Antibodies are produced during active disease, but play no role in host defense. During infection, the different immune cells (e.g., macrophages, T cells) involved in the immune response directed against *M. tuberculosis* act to contain the infection (3). *M. tuberculosis* infection triggers a complex immune response that usually leads to the establishment of long-lasting memory T cells specifically directed against *M. tuberculosis* antigens. CD4 T cells that specifically recognize *M. tuberculosis* antigens produce IFN-γ essential for the activation of *M tuberculosis*-infected macrophages which, upon activation, can inhibit growth of the bacillus (4). IFN-γ release assays have been shown to predominantly measure the presence of *M. tuberculosis*-specific effector-memory T cells, the presence of which are considered indicative of previous *in vivo* exposure to the bacilli.

SCREENING TESTS FOR LATENT TB INFECTION

Tuberculin Testing

The tuberculin skin test (TST) has been used as a screening test for latent *M. tuberculosis* infection for more than a century. The test relies on the principles of delayed hypersensitivity to recruit memory T cells to the TST site. The

doi:10.1128/9781555818722.ch48

TST was first described by Koch in 1890 and developed by Mantoux in 1907. The first reagent used in skin testing, old tuberculin, was prepared by autoclaving and filtering autolyzed 8-week-old liquid cultures of *M. tuberculosis*. This protein extract was termed purified protein derivative (PPD). A large single lot of PPD produced by Seibert in 1939 (PPD-S) has become the international standard. Subsequent preparations have equivalent biological reactivity. The concentration has been determined such that 0.1 ml will be biologically equivalent to 0.1 μg of PPD-S (5 tuberculin units).

Tuberculin testing is performed by intradermal injection of PPD (0.1 ml) on the volar surface of the forearm with a beveled 26- or 27-gauge needle with the bevel facing upward (Mantoux test). The skin becomes raised and blanched with a 6 to 10 mm wheal if the injection has been properly placed intradermally. Deeper injections may result in false negatives due to wash out by vascular flow. The skin reaction is read at 48 to 72 h. The appropriate measurement is the diameter of induration, not the area of erythema. The diameter of induration should be read transversely across the forearm. The edge of induration can be established using a ballpoint pen.

Interpretation of the Tuberculin Test

Based on the sensitivity and specificity of the TST, three cutoff levels have been recommended for positive reactions: 5 mm, 10 mm, and 15 mm, depending on the clinical situation (Table 1). The 5-mm cutoff is used for high-risk patients such as those exposed to TB-infected persons or immunocompromised patients. The 10-mm cutoff is used for other types of high-risk patients. The 15-mm cutoff is used for patients with no risk factors.

The sensitivity of the TST ranges from 75 to 90% with 10 mm of induration, and nearly all patients with greater than 15 mm of induration are infected with *M. tuberculosis*. False-positive reactions may be caused by prior Bacilli-Calmette Guérin (BCG) vaccination or by cross-reactions caused by nontuberculous mycobacteria (NTM) (5). Technical failure due to improper injection of the PPD in the subcutaneous tissue rather than intradermally may cause a false-negative reaction. False-negative reactions occur in at least 20% of patients with active TB. Most of these false-negatives are due to the general illness and malnutrition that can reduce delayed hypersensitivity. These patients will become PPD positive 2 to 3 weeks after effective treatment of TB is initiated. Vaccination with live virus (measles, smallpox), viral infections (HIV), reticuloendothelial disease, and corticosteroid therapy may also cause false-negative reactions. During HIV infection, delayed hypersensitivity and tuberculin reactivity decreases as the CD4 cell count decreases. Testing for cutaneous anergy with antigens such as *Candida* or tetanus toxoid to control for this decrease in delayed hypersensitivity is not recommended because of the lack of reproducibility and standardization. Responsiveness to control antigens but not PPD will not necessarily exclude tuberculous infection. Immunosuppression due to stress, age, and various infectious diseases are other common causes of anergy.

Booster Effect

Tuberculin can restimulate remote hypersensitivity that has deteriorated over many years. The booster effect (a positive TST after a negative one) develops over several days after a first injection and may be persistent. This may cause interpretation problems, especially if a negative result is followed by a positive test approximately 10 weeks after a negative TST. For this reason, the "two-step method" is recommended at the time of initial testing for persons who may be tested periodically on a routine basis (e.g., health care workers). Nonreactors are retested 1 to 3 weeks after the initial test. If the second test result is positive, this indicates boosting rather than a recent tuberculin conversion due to a recent exposure. The individual should be considered infected and evaluated accordingly. However, booster reactions cannot always be distinguished from false-positive reactions due to past exposure to atypical mycobacteria.

TABLE 1 Definition of a positive tuberculin test

Diam of induration (mm)	Clinical situation
>5	Recent contacts of TB-case patients
	Human immunodeficiency virus (HIV)-infected persons
	Persons with fibrotic changes on chest radiograph consistent with prior TB
	Patients with organ transplants or otherwise immunosuppressed (e.g., receiving the equivalent of ≥15 mg/day of prednisone for 1 month or more)
>10	Recent immigrants (i.e., within the last 5 years) from countries with a high prevalence of TB
	Residents and employees of high-risk congregate settings: prisons and jails, nursing homes and long-term care facilities, hospitals, residential facilities for patients with AIDS, homeless shelters
	Injection-drug users
	Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head, neck, or lung) weight loss of ≥10% of ideal body weight, gastrectomy, jejunoileal bypass
	Children <5 years of age
	Infants, children, and adolescents exposed to adults at high risk for developing active TB
>15	Patients with no known risk factor for tuberculosis

IFN-γ Release Assays

In the past 10 years, IFN-γ release assays have been developed for the identification of an immune response to *M. tuberculosis*-specific antigens and are approved by the U.S. FDA and recommended by the U.S. Centers for Disease Control and Prevention (CDC) as an aid for the detection of LTBI. A major scientific advance has been the identification of the region of difference 1 (RD1) of *M. tuberculosis*, which is absent from all strains of BCG, thus reducing the potential for cross-reactivity with BCG. Sequence data show that RD1 was deleted upon attenuation of *Mycobacterium bovis* for development of BCG. Several antigenic proteins of *M. tuberculosis* encoded by genes located in RD1 have potential for specific diagnosis of TB. The best-studied RD1 proteins are culture-filtered protein 10 (CFP-10) and early-secreted antigenic-target 6-kDa protein (ESAT-6). These two proteins have been utilized as specific antigens in the IFN-γ release assays.

Currently, there are two commercially available FDA-approved IFN-γ release assays: the QuantiFERON-TB Gold In-Tube assay (QFT-GIT) (Cellestis Ltd, Australia) and T-SPOT.*TB* assay (T-SPOT.*TB*) (Oxford Immunotec, UK). The characteristics of the two different assays are summarized in Table 2.

QuantiFERON-TB Gold In-Tube Assay

The QFT-GIT is performed by drawing 1.0 ml of blood into each of three specialized blood collection tubes: the nil control tube, the mitogen control tube (containing phytohemagglutinin, a T-cell-activating mitogen), and a TB antigen tube. The TB antigen tube contains three highly specific *M. tuberculosis* antigens: ESAT-6, CFP-10, and TB7.7. In contrast to the PPD, the antigens in the QFT-GIT are absent in most NTM and BCG strains except for *M. marinum*, *M. kansasii*, and *M. szulgai*. *M. flavescens*, *M. gastrii*, *M. xenopi*, and *M. gordonae* may also be associated with false-positive reactions with either the QFT-GIT or the T-SPOT.*TB*.

Within 16 h of collection, the tubes are incubated for 16 to 24 h at 37°C. The incubation is needed to allow memory CD4 T-cells to respond to the TB antigen. The plasma is harvested after centrifugation to separate the plasma and the red cells to assess the concentration of IFN-γ by an enzyme-linked immunosorbent assay (ELISA).

Method for Quantiferon-TB Gold In-Tube Assay

Specimen. QuantiFERON-TB GIT uses the following collection tubes:

Nil control (gray cap with white ring)
TB antigen (red cap with white ring)
Mitogen control (purple cap with white ring)

Collection. For each subject, collect 1 ml of blood by venipuncture directly into each of the QuantiFERON-TB GIT blood collection tubes. The black mark on the side of the tubes indicates the 1-ml fill volume.

Antigens have been dried onto the inner wall of the blood-collection tubes, so it is essential that the contents of the tubes be thoroughly mixed with the blood after blood draw.

Incubation.

1. Incubate the tubes upright at 37°C for 16 to 24 h.
2. After incubation of the tubes at 37°C, harvesting of plasma is facilitated by centrifuging tubes for 15 min at 2,000 to 3,000 relative centrifugal force (RCF).
3. Plasma samples can be loaded directly from blood-collection tubes into the ELISA plate.
4. Alternatively, plasma samples can be stored prior to ELISA, either in the centrifuged tubes or collected into plasma-storage containers.

Reagents. Included within the QuantiFERON-TB GIT kit:

Microplate strips coated with murine anti-human IFN-γ monoclonal (2 × 96-well plates)
Human IFN-γ standard, lyophilized (contains recombinant human IFN-γ, 8 IU/ml when reconstituted, bovine casein, 0.01% wt/vol thimerosal) (1 × vial)

TABLE 2 Methodological characteristics of T-SPOT and QFT-GIT assays

Characteristic	T-SPOT-*TB*	QFT-GIT
Format	ELISPOT	ELISA
Assay time	PBMC isolation & setup: 0.5 h	Incubation at 37°C: 16–24 h
	Incubation at 37°C: 16–20 h	Testing: 3.5 h
	Testing: 6 h	
	Drying time: 4–16 h	
Specimen	Peripheral blood mononuclear cells	Whole blood
Instrumentation	Microplate washer	Microplate washer and reader
	Hemocytometer or hematology analyzer	Centrifuges
	Stereomicroscope or plate imager	
	Centrifuges	
TB antigens	ESAT-6, CFP-10	ESAT-6, CFP-10, TB7.7
Positive control (mitogen)	Phytohemagglutinin	Phytohemagglutinin
Units	Spot-forming units (SFU)	IU/ml IFN-γ
Equivocal zone	5–7 SFU	None
Positive result	≥8 SFU	≥0.35 IU/ml, and >25% of nil
Indeterminate	>10 SFU in Nil, or <20 SFU Mitogen	>8 IU/ml nil and/or <0.5 IU/ml

Green diluent (contains bovine casein, normal mouse serum, 0.01% wt/vol thimerosal) (1 × 30 ml)

Conjugate 100× concentrate, lyophilized (murine anti-human IFN-γ horseradish peroxidase [HRP], contains 0.01% wt/vol thimerosal when reconstituted) (1 × 0.3 ml)

Wash buffer 20× concentrate (pH 7.2, contains 0.01% wt/vol thimerosal) (1 × 100 ml)

Enzyme-substrate solution (contains H_2O_2, 3,3′,5,5′ tetramethylbenzidine) (1 × 30 ml)

Enzyme-stopping solution (contains 0.5M H_2SO_4) (1 × 15 ml)

Store kit refrigerated at 2 to 8°C.

Equipment and supplies.

Biohazard cabinet class II

Mechanical pipetting device

Sterile graduated 5- or 10-ml pipettes (1 pipette/patient)

37°C humidified incubator (5% CO_2 optional)

1 ml microtubes with caps in 96-well format racks for plasma storage (20 patients/rack)

QuantiFERON microplate shaker capable of speeds between 50 and 1,000 revolutions per min (RPM)

Calibrated variable-volume pipettes capable of delivering 10 to 1,000 μl with disposable tips

Multichannel pipette capable of delivering 50 μl and 100 μl with disposable tips

Centrifuge capable of centrifuging the blood tubes at least to 3,000 RCF (*g*)

Variable-speed vortex

Timer

Measuring cylinder, 1 or 2 liters

Deionized or distilled water (enzyme immunoassay [EIA] quality), 2 liters

Microplate washer (optional)

Microplate reader fitted with 450- and 620-nm (or 650-nm) filters

Protective clothing for handling potentially infectious material

Reservoirs (polypropylene)

Procedure.

1. All plasma samples and reagents, except for conjugate 100× concentrate, must be brought to room temperature (22 ± 5°C) before use.
2. ELISA PLATE. Remove strips that are not required from the frame, reseal in the foil pouch, and return to the refrigerator for storage until required. Allow at least two strips for the QuantiFERON-TB Gold IT standards and sufficient strips for the number of subjects being tested.
3. HUMAN IFN-γ STANDARD. Reconstitute the human IFN-γ kit standard with the volume of deionized or distilled water as indicated on the label of the standard vial, ensuring complete resolubilization. Mix gently to minimize frothing. Reconstitution of the standard to the correct volume will produce a solution with a concentration of 8.0 IU/ml.
   a. Use the reconstituted kit standard to produce a dilution series of eight IFN-γ concentrations.
   b. 300 μl of the kit standard to a tube labeled as Standard 1.
   c. 150 μl of green diluent to 7 tubes (labeled Standard 2–Standard 8).
   d. Perform serial dilutions by transferring 150 μl of each standard to the next tube. Mix each tube thoroughly before the next transfer.
   e. The undiluted kit standard serves as the highest concentration (Standard 1).
   f. Green diluent serves as the zero standard (Standard 8).
4. CONJUGATE (contains 0.01% wt/vol thimerosal). Reconstitute freeze-dried conjugate 100× concentrate with 0.3 ml of deionized or distilled water.
5. Add 50 μl of freshly prepared working-strength conjugate to each ELISA well.
6. Add 50 μl of test plasma samples to appropriate wells. Finally, add 50 μl each of the Standards 1 to 8. The standards should be assayed in at least duplicate.
7. Mix the conjugate and plasma samples/standards thoroughly using a microplate shaker for 1 min at 500 to 1,000 RPM.
8. Cover each plate and incubate at room temperature (22 ± 5°C) for 120 ± 5 min.
   a. Plates should not be exposed to direct sunlight during incubation.
   b. Deviation from specified temperature range can lead to erroneous results.
9. WASH BUFFER. Each plate (12 × 8-well strips) requires 1 liter of working-strength wash buffer. Dilute 1 part wash buffer 20× concentrate with 19 parts deionized or distilled water and mix thoroughly.
10. Wash wells with 400 μl of working-strength wash buffer. Perform wash steps at least six times.
11. Add 100 μl of enzyme-substrate solution to each well and mix for 1 min at 500 to 1,000 RPM using a microplate shaker.
12. Cover each plate with a lid and incubate at room temperature (22 ± 5°C) for precisely 30 min.
13. After 30 min, add 50 μl of enzyme-stopping solution to each well and mix by gentle agitation.

Read the absorbance of each well within 5 min of terminating the reaction using a 450-nm filter, with either a 620-nm or 650-nm reference filter. Absorbance values are used to calculate results.

Calculations. The QuantiFERON-TB GIT analysis software (version 2.13 or later) that is used to generate standard curves for IFN-γ and to calculate results for the patient values is available from Cellestis. The software performs quality control of the assay, generates a standard curve, and provides a test result from calculations performed on each plasma test based on the method of interpretation.

Interpretation Criteria QFT-GIT

The positive-control mitogen assesses the performance of the test by measuring the ability of T cells to produce IFN-γ. A low-mitogen result may indicate low T-cell counts or immunosuppression, or may also indicate improper handling of the specimen. A mitogen result less than 0.5 IU/ml will result in an indeterminate result.

The negative-control nil tube assesses the background IFN-γ levels in the patient. High-background IFN-γ can be seen in patients with recent viral illness or recent live-virus vaccination (i.e., measles, polio). High-background nil levels above 8 IU/ml will result in an indeterminate result.

The nil-tube IFN-γ value is subtracted from the TB-antigen IFN-γ value and mitogen IFN-γ value to determine their absolute numbers. A positive result consistent with previous exposure to *M. tuberculosis* is an absolute TB-antigen value of ≥0.35 IU/ml that is also greater than 25% of the nil value.

Preanalytical Sources of Variability and Quality Control Issues, QFT-GIT

During the sample-collection process, there are several possible sources of error or variability of the IFN-γ quantitative result. If any of the three blood draw tubes (nil, antigen, mitogen) are underfilled or overfilled from the recommended 1.0 ml, an incorrect measurement of the IFN-γ level will occur, changing the IFN-γ quantitative result and possibly the qualitative interpretation. Additionally, if there is incomplete mixing of the TB-antigen or mitogen tubes following the blood draw, there is a potential for a false-negative result in the antigen tube or an indeterminate result due to a low mitogen-tube response. Delays in incubation or processing also negatively impact the IFN-γ result.

Quality-control issues have been discovered with the QFT-GIT in two separate incidents. In November 2011, the Stanford Hospital and Clinics clinical microbiology laboratory noted a sharp increase in positivity rate in their QFT-GIT (6). They had previously instituted a daily surveillance program since 2010 for tracking positive rates. On investigation of the increase in positivity rate, all TB-antigen tubes giving false results were traced to a single lot number. Efforts undertaken by the laboratory and the manufacturer could not discover the root cause of the problem. The FDA was contacted and subsequently that particular lot number was recalled from all laboratories in the U.S.

The second incident involving quality control with the QFT-GIT was reported by the Veterans Affairs Palo Alto Health Care System (6). A sharp increase in the indeterminate rate was discovered on review of patient results. The source of error was traced to the transportation route of the blood draw tubes through the Panama Canal; it was discovered that there was heat damage to the mitogen peptides in the tubes, subsequently resulting in low mitogen results.

These isolated problems in reagent quality of the QFT-GIT highlight the need to institute a surveillance system to monitor and detect sudden changes in positivity and indeterminate rates, and also the need to conduct parallel testing of new lots with old lots to ensure quality control is maintained.

Reproducibility, Conversions, and Reversions: Proposal of an Equivocal Range for the QFT-GIT

The QFT-GIT does not have an FDA-approved equivocal range. Studies examining the reproducibility of the QFT-GIT have observed reversions and conversions of the QFT-GIT with frequencies ranging from 12% to 50% (7–9). Conversions and reversions are thought to be secondary either to biological factors such as within-subject fluctuations, laboratory artifact, or test-related error (10, 11). There has been no consensus for how to interpret the accuracy of the test in situations where there are conversions and reversions. Because of this variability, a gray zone has been suggested for persons with fluctuating results (12, 13). Most of the reversions and conversions in the studies occurred with IFN-γ levels between 0.35 and 0.69 IU/ml. Thanassi et al. (14) used receiver-operating-characteristic (ROC) analysis on serial QFT-IT results in 575 U.S. health care workers to find the separation point between those who test repeatedly positive and those who revert. Their recommendation was to retest low-risk individuals with initial QFT results <1.11 IU/ml.

Most reversions of QFT-GITs from positive to negative come to attention when the positive result is suspected to be a false positive and the clinician repeats the test. Reversions, however, may also occur spontaneously or after therapy. Reversions after therapy are thought to represent immune clearing of the infection. Studies have shown a decrease in quantitative results of IFN-γ responses with the treatment of LTBI. Studies, however, have not confirmed that LTBI treatment increases the reversion rate of IGRAs from positive to negative (15).

T-SPOT. *TB* Assay

For the T-SPOT.*TB* assay, 8 ml of whole blood is required and the assay must be performed within 8 h of blood collection. Alternatively, the manufacturer provides a reagent (T-Cell Xtend) which extends processing time to 32 h after blood collection. The T-cell-containing peripheral blood mononuclear cell (PBMC) fraction is separated from whole blood, counted, and inoculated into four separate microtiter plate wells (250,000 cells/well) provided in the T-SPOT.*TB* assay kit. The microtiter wells are precoated with antibodies against IFN-γ. Specific TB antigens (ESAT-6 and CFP-10) and mitogen (PHA) are also added.

Microtiter-plate wells are incubated 16 to 20 h at 37°C with 5% CO_2. During incubation, IFN-γ is released from activated T-cells and captured by monoclonal antibodies. The number of IFN-γ-secreting T-cells (represented as spot-forming units [SFU]) are detected by ELISPOT assay, an enzyme-linked immunospot assay that labels the IFN-γ-secreting T-cells as dark spots on the plate wells. After incubation, the wells are washed and a secondary conjugated IFN-γ antibody is added and incubated for 1 h. After another wash, substrate is added, which produces spots where the IFN-γ was secreted by the activated T-cells. The spots are counted using a magnifying glass or stereomicroscope.

Method for T-SPOT.*TB* Test

Specimen.

1. When using the T-SPOT.*TB* test without the use of T-Cell Xtend reagent, blood samples should be processed within 8 h of collection.
2. Samples may be collected into either sodium citrate or sodium heparin Vacutainer-CPT tubes with PBMCs separated in the tube.
3. Alternatively, blood samples may be collected into lithium-heparin tubes, with PBMCs being subsequently separated using standard separation techniques such as Ficoll-Paque or alternative methods to purify the PBMC fraction.
4. Blood-collection tubes containing the anticoagulant ethylenediaminetetraacetic acid (EDTA) should not be used.
5. If using Ficoll-Paque Plus, dilute the blood with an equal volume of RPMI-1640 medium (1 part blood to 1 part RPMI).
6. Layer carefully the diluted blood onto Ficoll-Paque Plus (2 to 3 parts diluted blood to 1 part Ficoll-Paque) and centrifuge at 1,000 RCF (*g*) for 22 min at room temperature (18 to 25°C).
7. When using the T-SPOT.*TB* test with T-Cell Xtend reagent, blood samples should be collected into lithium-heparin tubes. The T-Cell Xtend reagent

should be added prior to PBMC separation using standard separation techniques. Whole-blood samples should be stored at room temperature (18 to 25°C) between 0 and 32 h postvenipuncture with the use of T-Cell Xtend reagent.

8. Collect the white, cloudy band of PBMCs using a pipette and transfer to a 15-ml conical centrifuge tube. Bring the volume to 10 ml with prewarmed cell culture medium.
9. Centrifuge at 600 RCF (*g*) for 7 min. Pour off the supernatant and resuspend the pellet in 1 ml medium.
10. Bring the volume to 10 ml with fresh medium and centrifuge at 350 RCF (*g*) for 7 min.
11. Pour off the supernatant and resuspend the pellet in 0.7 ml cell-culture medium.

Reagents. Included within the T-SPOT.*TB* Kit:

1 microtiter plate: 96 wells, supplied as 12 × 8-well strips in a frame, coated with a mouse monoclonal antibody to IFN-γ.

2 vials (0.8 ml each) Panel A: contains ESAT-6 antigens.

2 vials (0.8 ml each) Panel B: contains CFP-10 antigens.

2 vials (0.8 ml each) positive control: contains phytohemagglutinin (PHA).

1 vial (50 μl) 200× concentrated conjugate reagent: mouse monoclonal antibody to the cytokine IFN-γ conjugated to alkaline phosphatase.

1 bottle (25 ml) substrate solution: BCIP/NBT plus solution.

Equipment and supplies.

8-well strip plate frame.

Biohazard cabinet class II.

Blood-collection tubes, such as Vacutainer CPT or heparinized tubes.

T-Cell Xtend reagent: whole-blood samples stored at room temperature (18 to 25°C) between 0 and 32 h postvenipuncture; can be processed with the use of T-Cell Xtend reagent.

Ficoll (if not using CPT tubes).

A centrifuge for preparation of PBMCs (capable of at least 1,800 RCF (*g*) and able to maintain the samples at room temperature (18 to 25°C) if using density centrifugation methods to separate the PBMCs).

Equipment and reagents to enable counting of PBMCs, either manually using trypan blue (or other appropriate stain) and a hemocytometer on a microscope or automatically using a suitable hematology analyzer.

A humidified incubator capable of 37 ± 1°C with a 5% CO_2 supply.

An automatic microtiter plate washer or an 8-channel or stepper pipette to manually wash plates.

Adjustable pipettes to cover a range of volumes from 1 to 1,000 μl (such as four Gilson pipettes capable of delivering volumes of 1–10 μl, 2–20 μl, 20–200 μl, and 100–1,000 μl) and sterile pipette tips.

Sterile phosphate-buffered saline (PBS) solution such as GIBCO 1× D-PBS (Invitrogen; catalogue no. 14040-133).

Distilled or deionized water.

A means of visualizing the wells or capturing a digital image of the well, such as a stereomicroscope, magnifying glass, or plate imager to allow counting of spots.

Sterile cell culture medium such as GIBCO AIM-V. Cell culture media should be prewarmed to 37°C before use with the T-SPOT.*TB* test.

Reagent preparation.

1. The vials of *M. tuberculosis* ESAT-6 antigens, *M. tuberculosis* CFP-10 antigens, and the positive control are supplied ready to use.
2. Prepare a 1:200 dilution working conjugate-reagent solution.
3. The substrate solution is supplied ready to use.

Cell counting and dilution. The T-SPOT.*TB* test requires 250,000 ± 50,000 PBMCs per well. A total of four wells are required for each patient sample; thus 1×10^6 PBMCs is required per patient. The number of *M. tuberculosis* T cells in the specimen is normalized to a fixed number of PBMCs.

1. Perform a PBMC count. Cells can be counted by a variety of methods, including manual counting using trypan blue (or other appropriate stain) and a hemocytometer, or using an automated hematology analyzer.
2. Calculate the concentration of PBMCs present in the stock cell suspension.

Plate setup and incubation.

1. The T-SPOT.*TB* test requires four wells to be used for each patient sample. An ESAT-6, CFP-10, nil control, and positive control well should be run for each individual patient sample. No standard curves are required.
2. Remove the precoated 8-well strips from the packaging, clip into a plate frame, and allow to equilibrate to room temperature. Remove the required number of strips only, reseal any remaining unused strips and the desiccant pouch in the outer foil packaging, and return to storage at 2 to 8°C.
3. Add 50 μl of AIM-V cell culture for nil, positive control, and CFP-10 or ESAT-6 to one of the four wells for each patient sample.
4. To each of the four wells to be used for a patient sample, add 100 μl of the patient's final cell suspension (containing 250,000 cells). Use a new tip for each individual patient's cells to avoid cross-contamination between wells.
5. Incubate the plate with the lid on in a humidified incubator at 37°C with 5% CO_2 for 16 to 20 h.

Spot development and counting.

1. Remove the plate from the incubator and discard the cell-culture medium.
2. Add 200 μl PBS solution to each well.
3. Discard the PBS solution. Repeat the well washing an additional 3 times with PBS.
4. Dilute concentrated conjugate reagent 200× in PBS.
5. Add 50 μl conjugate-reagent solution to each well and incubate at 2 to 8°C for 1 h.
6. Discard the conjugate and perform four PBS washes.
7. Add 50 μl substrate solution to each well and incubate at room temperature for 7 min.
8. Wash the plate thoroughly with distilled water to stop the reaction.

9. Allow the plate to dry. Allow 4 h drying time at 37°C or at least 16 h at room temperature.
10. Count and record the number of distinct, dark-blue spots on the membrane of each well.

Interpretation Criteria: T-SPOT.*TB* Test

As with the QFT-GIT, the positive-control mitogen assesses the performance of the test by measuring the ability of T-cells to produce IFN-γ and should be at least ≥8 SFU for the test to be valid. A low mitogen result may indicate low T-cell counts, immunosuppression, or improper handling of the specimen.

The negative-control nil tube assesses the background IFN-γ levels in the patient. High background IFN-γ levels of >10 SFU will result in an indeterminate result and can be seen in patients with recent viral illness or recent live-virus vaccination. When a patient's sample shows indeterminate results or borderline results (5 to 7 SFU), it is recommended that new blood samples be drawn and retested. If after retesting the results remain indeterminate and a technical error is ruled out, T-cell anergy may be a possible explanation. A positive result consistent with previous exposure to *M. tuberculosis* is a TB antigen value of ≥8 SFU.

Interpretation of Quantitative IGRA (QFT-GIT or T-SPOT.*TB*) Results

According to CDC recommendations, "both the qualitative results and the quantitative assay measurements for IGRAs should be reported" (16). However, in the absence of interpretive guidelines, the practice of reporting quantitative results can lead to false assumptions and misinterpretation. It is not clear whether higher IFN-γ levels correlate with greater risk of progression to active TB. There are two recommendations that should be followed with regard to the interpretation of quantitative IGRA results. First, there is not enough evidence at this time to use quantitative results for the purpose of therapeutic monitoring or to predict the risk of progression to active disease. Quantitative results, however, are useful for predicting the likelihood for reversion or conversion of test results when the IFN-γ response is in the gray zone (i.e., between 0.35 and 1.11 IU/ml; see discussion above).

Advantages and Disadvantages of IGRAs

IGRAs detect the presence of persistent cellular immune responses toward *M. tuberculosis* specific antigens ESAT-6, CFP-10, and TB7.7 (additionally for QFT-GIT), which are known to be absent in most NTM as well as in BCG strains. Therefore, there will be fewer false-positive reactions in patients previously vaccinated with BCG and those patients previously infected with NTM. There are, however, a number of NTM that are known or reported to cause a positive IGRA; these include *M. flavescens, M. marinum*, *M. kansasii*, *M. szulgai*, *M. xenopi*, and *M. gordonae*. It is important to note that these same patients may also have a positive PPD, though usually ≤10 mm. Since IGRAs detect the presence of *M. tuberculosis*-specific effector-memory T-cells, it cannot distinguish between latent or active disease. Clinical manifestations, culture, sputum microscopy, and chest X ray may be needed to confirm the diagnosis of active TB infection. As discussed earlier, the higher specificity of the antigens used in IGRAs may decrease the number of false-positive test results when investigating LTBI and, therefore, prevent further medical evaluations and treatment. Individuals being tested for LTBI need only present once to the testing facility for blood draw, increasing the likelihood that a diagnosis will be made. The *in vitro* assays have a rapid turnaround time and are standardized to decrease interperson variability when interpreting the results.

There are several disadvantages of performing IGRA testing that should be pointed out. IGRA testing requires drawing blood from individuals, which may be especially problematic in children. The QFT-GIT requires 3 ml of blood, whereas the T-SPOT.*TB* requires 8 ml. The testing needs to be conducted within a specific time period. The QFT-GIT needs to be incubated at 37°C by the blood-draw laboratory within 16 h after blood draw, spun down after 16 to 24 h of incubation, then sent (refrigerated) to a reference laboratory. With the T-SPOT.*TB*, the blood draw needs to be received by the reference lab and the T-cells need to be isolated within 8 h of the blood draw and processed. These tests are more technically demanding and have higher laboratory resource needs. Highly trained personnel are required along with access to reagents and laboratory instrumentation.

Direct and Indirect Costs of IGRAs versus TST

Two types of costs for IGRAs should be considered: direct costs and indirect costs. In a cost-effectiveness study of LTBI contact screening in the United Kingdom by Pooran et al. (17), QFT-GIT testing cost 54 EUR ($69 U.S. dollars), T-SPOT.*TB* cost €66 ($85 US), and TST cost €19.30 ($24 US). The main conclusion of the study was that although the direct costs of IGRAs are overall more than for the TST, a dual strategy of reflex-testing positive TSTs to an IGRA for confirmation was the most cost-effective strategy.

In a study by Shah et al. (18), in a low TB-prevalence setting in the U.S., the QFT-GIT cost $44 per test. They found in testing for LTBI that the dual strategy was, again, the most cost-saving algorithm. Numerous other studies have shown that IGRAs are more cost-saving than TST for certain groups such as close contacts, those infected with HIV, and foreign-born, regardless of time in the country. In conclusion, IGRAs lead to fewer false-positive results, and consequently to fewer chest X rays, fewer prescriptions of prophylaxis, and fewer clinic visits, leading overall to a more cost-effective diagnostic test either as a single test or dual-strategy test. Cost effectiveness values will increase in areas with a lower prevalence of LTBI.

Sensitivity and Specificity of IGRAs in the Diagnosis of LTBI

The ability to judge the accuracy of the TST and IGRAs has been complicated by the lack of a gold standard for LTBI. Sensitivity has been estimated by using culture-confirmed cases. Using culture as a gold standard is problematic since active disease and latent infection are two distinct disease conditions with very different clinical outcomes. More accurate estimates based on progression of LTBI to active TB are now being used. There are wide variations in sensitivity estimates for the QFT-GIT, T-SPOT.*TB*, and TST depending on the type of population studied and the type of study. When meta-analyses are conducted on a large number of studies, overall, the T-SPOT.*TB* tends to be more sensitive than QFT-GIT, whereas the QFT-GIT tends to be more specific. In an extensive review of a number of studies comparing the TST and IGRAs in patients with culture-confirmed TB, the overall sensitivities for T-SPOT.*TB*, QFT-GIT, and TST were 90%, 83%, and 89%, respectively (16) (Table 3). In the same study, the collective specificities for T-SPOT.*TB*, QFT-GIT, and TST were 88%, 99%, and 85%, respectively. Yet, in a number of studies involving patients who progressed to active

TB after exposure to active TB, the sensitivities have been widely variable, ranging from 40 to 100% (13). These results emphasize the caveat that a negative IGRA does not necessarily rule out the diagnosis of LTBI. IGRAs, especially the QFT-GIT, have a distinct advantage over TST in diagnosing LTBI in BCG-vaccinated populations, as the IGRAs do not give false positives in BCG-vaccinated patients. In a systematic review and meta-analysis by Pai et al. (19), the specificity of QFT-GIT in BCG-nonvaccinated and BCG-vaccinated populations was 99% and 96%, respectively (Table 3). The specificity for T-SPOT.*TB* and TST in non-BCG-vaccinated populations was 100% and 97%, respectively. In contrast, the specificity for T-SPOT.*TB* and TST in BCG-vaccinated populations was only 84.7% and 59%, respectively (Table 3). Therefore, in a low-risk, BCG-vaccinated patient with a positive TST and negative IGRA, it is reasonable to assume that the TST result is a false positive.

In the case of a patient with a negative TST and positive IGRA, if the individual is considered to be high risk, then the negative TST should not preclude further studies. Longitudinal studies suggest that the TST is more sensitive than the IGRA in high-risk populations (20). IGRAs, however, may be more sensitive than TST in detecting recent exposure.

Is There a Role of IGRAs in the Diagnosis of Active TB?

Active TB infection is diagnosed by evaluating the patient's medical history, physical exam, and chest X ray and by identifying *M. tuberculosis* by microbiologic techniques such as sputum-smear microscopy and/or culture, or by molecular techniques such as nucleic acid amplification. IGRAs have not been developed for the diagnosis of active TB. IGRAs were primarily developed to detect the cell-mediated immune response toward a set of recombinant *M. tuberculosis* antigens. Therefore, these tests cannot differentiate between active and latent TB infection.

However, in certain clinical circumstances—such as in patients with extrapulmonary TB, in patients who test negative for acid-fast bacilli in sputum and/or are negative on culture, in TB diagnosis in children, or in the differential diagnosis of NTM—IGRAs may provide useful supplementary information. Overwhelming active TB infection may, however, suppress the cellular immune response and cause a negative IGRA result.

In a meta-analysis assessing the accuracy of QFT-GIT, T-SPOT.*TB*, or TST in patients with a clinical suspicion of active TB disease, both culture-confirmed and nonconfirmed cases, the pooled sensitivities of the QFT-GIT, T-SPOT.*TB*, and TST were 80% (95% confidence interval [CI] 75–84%), 81% (95% CI 78–84%), and 65% (95% CI 61–68%), respectively (21). In the same meta-analysis, the specificity of IGRAs in the diagnosis of TB specificity was assessed in control groups who were considered to have a low risk of being infected with *M. tuberculosis*. The pooled specificities of the QFT-GIT, T-SPOT.*TB*, and TST were 79% (95% CI 75–82%), 56% (95% CI 56–62%), and 59% (75% CI 72–78%), respectively (21). Quantitative results from IGRAs have not been shown to have a predictive value for progression to active disease. Therefore, quantitative results should not be used for risk assessment for patients with a concern for active TB disease.

IGRAs in Immunocompromised Persons and HIV-Infected Patients

Immunocompromised patients, such as those who are receiving immunosuppressive drugs or individuals with HIV, represent a group of patients who are at a high risk of reactivating latent TB infection. Screening for LTBI is highly recommended for these groups of individuals. However, there are only a limited number of studies available on the accuracy of IGRAs in these high-risk groups. There are no U.S. data on the predictive value of IGRAs in HIV-infected patients, and poor concordance has been reported between TSTs and IGRAs in this population (22). Current CDC guidelines recommend treatment of LTBI in HIV-infected patients with either a positive TST or IGRA. Immunocompromised patients have been shown to have reduced IGRA responses compared to immunocompetent patients, with immunocompromised patients exhibiting a higher percentage of indeterminate results. It is recommended that IGRAs be performed as early as possible in the course of HIV infection, before a decline in CD4 T-cell counts occurs.

The positive-control mitogen tube will measure the ability of the patient's CD4 T-cells to produce IFN-γ. This function will be impaired with CD4 T-cell counts below 100/ml. False-negative or indeterminate IGRA results are commonly seen in HIV-infected individuals with advanced HIV infection and low CD4 T-cell counts. Studies have suggested that the T-SPOT.*TB* test may have less indeterminate results since a standardized number of cells per assay is used for lower CD4 T-cell counts, whereas the QFT-GIT test uses a standardized volume of blood per assay (23).

False-positive QFT-TB results have also been reported in HIV-infected patients. A study by Gray et al. in 2012 (24) observed that 80.5% of U.S.-born HIV-infected patients at low risk for TB exposure reverted to negative from positive in serial testing. Seventy-six percent of the reversions occurred in patients with an IFN-γ level of <1.0 IU/ml, which is consistent with the reversion rate observed in a number of previous studies of low-risk individuals with low-positive IGRA results (see discussion in previous section).

TABLE 3 Sensitivities and specificities of QFT-GIT, T-SPOT, and TST assays

Assay	Overall for LTBI (%)[a]		Non-BCG-vaccinated for LTBI[b] (%)	BCG-vaccinated for LTBI[b] (%)	Suspected active TB[c] (%)	
	Sensitivity	Specificity	Specificity	Specificity	Sensitivity	Specificity
QFT-GIT	83	99	99	96	80	79
T-SPOT.*TB*	90	88	100	84.7	81	56
TST	89	85	97	59	65	59

[a]Reference 16: meta-analysis of the overall accuracy of all three assays.
[b]Reference 19: specificity of all three assays in non-BCG- and BCG-vaccinated populations for LTBI.
[c]Reference 21: meta-analysis assessing the accuracy of all three assays in suspected active TB disease.

However, 24.2% of the HIV-positive patients who reverted to negative had IFN-γ IU/ml levels that were >1.0 IU/ml on initial testing. The authors of the study concluded that the positive predictive value of IGRAs is quite low when testing a large number of HIV-infected patients at low risk for TB. This study thus provided supportive evidence for the high rate of poor concordance between IGRAs and TSTs in HIV patients in the U.S. in general (22). They promoted the strategy of retesting positive IGRAs in HIV-infected patients with no TB exposure risks.

IGRAs in Children

A very limited number of studies exist describing the utility of QFT-GIT and T-SPOT.*TB* testing in children, especially for those aged <5 years. For this reason, and because rates of progression from latent infection to active disease are higher in infants and young children, extreme caution is warranted when using IGRAs in children aged <5 years. Lewinsohn et al. (25) observed that indeterminate rates for IGRAs were much more frequent in immunocompromised children and in young children <5 years of age. The authors also concluded that children ≥5 years of age can be tested with IGRAs for LTBI and that IGRAs may be used as an adjunct to other tests for active TB.

Although the majority of indeterminate results in children are thought to be due to a low mitogen response, the reasons for low mitogen responses in young children are not clear. The mitogen might not work well in young children as a result of a lack of immunologic maturity. Children ≥5 years are less likely to develop active TB or to have severe forms of the disease. Therefore, less caution might be required when implementing IGRA testing in these older children.

The sensitivity of IGRAs in children is expected to be comparable to TST. In one study of 28 children with culture-confirmed active TB who were aged 4 months to 7 years, estimates of sensitivity for TST, QFT-GIT, and T-SPOT.*TB* were comparable at 100%, 93%, and 93%, respectively ($P = 0.15$) (26). However, in a recent study performed in Africa by Machingaidze et al. (27), there was no clear evidence that IGRAs should replace TST for detecting LTBI in children. These investigators concluded that it may be best to use both tests in screening for LTBI. Sensitivity of the IGRA for TB disease was no different from TST, and a significantly reduced IGRA sensitivity was found in high-burden TB settings compared with low-burden TB settings. The specificity of IGRAs in children, however, should be expected to be high. In one study, QFT-GIT and T-SPOT.*TB* showed high specificity for *M. tuberculosis* infection even among children whose TST specificity was reduced to 22% because of NTM infections (26).

SEROLOGIC TESTS FOR ACTIVE TB INFECTION

The first attempt to diagnose active TB by serology was in 1898 by Arloing (28), who reported that sera from TB patients could agglutinate tubercle bacilli. Since the introduction of the ELISA methodology, there has been a considerable amount of interest in the development of serologic tests for the detection of active TB infection, particularly with regard to patients who are unable to produce adequate sputum, are sputum-smear negative, or are suspected of having extrapulmonary TB. Although the role of antibody-mediated immunity in the protection against *M. tuberculosis* is unclear, active *M. tuberculosis* infection often elicits the production of antibodies to several antigens that may be used as markers of active TB infection. Most researchers in the field agree that accurate serological tests for the diagnosis of active TB will require using multiple TB antigens (29, 30). Any single *M. tuberculosis* antigen is probably not sensitive enough to be used to cover the multiple-antibody profiles of active-TB patients. A number of companies have developed and marketed commercial tests for the serological detection of antibodies, mostly of the IgG class, typically using the ELISA technique.

Sensitivity and Specificity of Commercial TB Serological Tests

Commercially available TB serological tests have varied widely in accuracy, with reported sensitivities and specificities that range from 10% to 90% and 47% to 100%, respectively, depending on antigens used, number of subjects, study design, and geographic site (31).

Although recent studies have identified important problems in TB serodiagnostics, they have also identified several promising candidate antigens (32–35). Important methodological problems have been identified that are inherent with ELISA testing in general, including false-positive results due to autoimmune disease and false-negatives due to immunosenescence or immune deficiency (36). Despite their limitations, TB serologic tests could eventually have adjunctive value in smear-negative pulmonary and extrapulmonary cases. Testing for IgG antibodies to *M. tuberculosis* multiepitope recombinant antigens is offered only in a few reference laboratories and ELISA kits are available commercially.

URINE ANTIGEN TESTING FOR THE DIAGNOSIS OF ACTIVE TB INFECTION

M. tuberculosis urinary-antigen detection has been viewed as a possible future adjunctive test for the diagnosis of active TB infection, since it has the potential to overcome the limitations inherent with immune-based assays. The most studied *M. tuberculosis* urinary diagnostic assay detects the cell wall lipopolysaccharide lipoarabinomannan (LAM).

Simple lateral-flow versions of the LAM assay have been produced as point-of-care tests. The first clinical evaluation of the Determine TB-LAM (Alere, Waltham, MA) was conducted among HIV-infected patients in South Africa. The overall sensitivity was low (28.2%) but was highest in those with the lowest CD4 count (<50 cells/ml), with a sensitivity of 66.7% (37). In a second study from South Africa, two groups of patients were recruited: HIV-infected patients suspected of having TB and a control group of HIV-infected patients with a non-TB diagnosis (37). Sensitivity was 45% when compared to a gold standard that additionally incorporated clinical-radiological diagnoses with a positive response to TB treatment. Sensitivity increased to 71% when the results were combined with those of sputum-smear microscopy. Specificity, however, was poor, 66% when using a very faint positive band as a positive, but improved to 96% when a darker positive band was used. Cross-reactivity studies with the LAM ELISA system showed low-level cross-reactivity with *M. avium*, *M. kansasii*, and *M. fortuitum*.

In summary, the high specificity and moderate sensitivity of a urinary antigen LAM may be useful in the diagnosis of active TB in HIV-infected patients, especially those with advanced immunodeficiency. Further studies will be needed to evaluate the clinical indications and usefulness of the assay as an adjunctive TB diagnostic.

Mycoplasma: Immunologic and Molecular Diagnostic Methods

KEN B. WAITES, MARY B. BROWN, AND JERRY W. SIMECKA

49

Mycoplasmas and ureaplasmas are members of a unique group of organisms (class *Mollicutes*) that are characterized by their small genomes, lack of cell walls, sterols in cell membranes, and complex nutritional requirements. The role of *Mycoplasma* and *Ureaplasma* species in human diseases was largely underappreciated until recent years. As a result, most diagnostic laboratories ignored them. Because of their complex nutritional requirements as well as their adaptation to the host during infection, these fastidious organisms can be difficult and time-consuming to culture from patient samples. However, there are improved methods for detection, including PCR detection assays, serologic assays, and commercially available growth media, but these are still limited compared with the products for other organisms.

Several organisms in the class *Mollicutes* are associated with human disease. The best-known *Mycoplasma* disease in humans is *Mycoplasma pneumoniae* respiratory disease, and it remains a leading cause of respiratory illness worldwide. Some members of the *Mollicutes* are also significant causes of urogenital tract disease; these include *Mycoplasma genitalium*, *Ureaplasma* species, and *Mycoplasma hominis*. A number of other mycoplasma species occur in humans, which in some instances, may also contribute to disease. Thus, mycoplasmas are emerging as primary etiologic agents in a number of human diseases. Additional evidence supports their role in exacerbation of other diseases. As diagnostic approaches become better established and more frequently used by clinical laboratories, the impact of this unique group of infectious agents in humans is likely to become better appreciated.

The purpose of this chapter is to discuss the advantages and disadvantages of current molecular and serological diagnostic techniques for mycoplasmal and ureaplasmal infections. Established approaches to the detection of *M. pneumoniae*, *Ureaplasma* spp., *M. genitalium*, and *M. hominis* infections are discussed. In addition to immunologic and molecular-based methods for detection of these organisms, several molecular-based methods have been applied to typing clinical isolates for epidemiological purposes. Such procedures are not yet suitable or necessary for diagnostic purposes in a clinical setting. It is beyond the scope of this chapter to include descriptions of molecular typing systems, as this information has been summarized in other publications (1).

M. PNEUMONIAE

M. pneumoniae occurs endemically and epidemically in persons of all age groups. The most frequent clinical syndrome is tracheobronchitis, often accompanied by upper respiratory tract symptoms. Typical symptoms can persist for weeks to months and include hoarseness, fever, cough, sore throat, headache, chills, coryza, and general malaise (2). *M. pneumoniae* may occur in up to 20% of adults requiring hospitalization for community-acquired pneumonias in the United States and probably an even greater proportion of those not requiring hospitalization. The incubation period is 1 to 3 weeks, and spread throughout households often occurs. *M. pneumoniae* can persist in the respiratory tract for several months after initial infection and sometimes for years in hypogammaglobulinemic persons (2). Some people may experience extrapulmonary complications, including skin rashes, pericarditis, hemolytic anemia, arthritis, meningoencephalitis, and peripheral neuropathy (2).

Serology

Historically, serology was the most common laboratory means of diagnosis of *M. pneumoniae* respiratory tract infections. It has the advantages of not requiring viable microorganisms, of allowing easy acquisition of small amounts of serum for storage and testing, and of having the availability of many different commercially available assays in various formats. *M. pneumoniae* has both lipid and protein antigens, which elicit antibody responses in clinical infections that can usually be detected after about 1 week of illness, peaking at 3 to 6 weeks, followed by a gradual decline, allowing the use of several different serologic assays based on different antigens and technologies. Although serology is a historically common and useful approach to the diagnosis of *Mycoplasma* infection, its use alone has several potential disadvantages.

One disadvantage of serology is that both acute- and convalescent-phase sera collected 3 to 4 weeks apart need to be tested for IgM and IgG levels for the most accurate diagnosis of recent or current *M. pneumoniae* infection, especially in adults older than 40 years, in whom an IgM response may be minimal or absent, presumably because of reinfection (2). Infants younger than 6 months of age may also lack IgM production following acute *M. pneumoniae* infection. A 4-fold or greater rise in antibody titer indicates

doi:10.1128/9781555818722.ch49

a current or recent infection. The duration of the IgM response can be variable; it usually peaks after about 3 weeks and then gradually declines. However, IgM antibodies can last for several weeks to months in some cases, further complicating the interpretation of serologic data in diagnosis of acute M. *pneumoniae* infection and making it risky to base a diagnosis on the analysis of a single serum specimen. M. *pneumoniae* is primarily a pathogen of mucosal surfaces, and therefore IgA antibodies are produced early in infection. Serum IgA levels decrease quickly, since the half-life of IgA in serum is short. Thus, IgA may theoretically be more reliable and useful for diagnosis of acute infection than IgM. However, our experience is that IgA measured in sera from children and adults with pneumonia proven to be caused by M. *pneumoniae* by culture and/or PCR assay does not detect any more seropositive specimens than can be identified by a positive IgM. A Japanese study also did not find a significant advantage of IgA in detection of acute M. *pneumoniae* infection in children (3).

One of the first serologic indicators used in diagnosis of M. *pneumoniae* infection is the presence of cold agglutinins, which does not rely on *Mycoplasma*-specific antibody responses. Cold agglutinins are IgM antibodies that agglutinate human erythrocytes at 4°C. They occur in association with M. *pneumoniae* infection in about 50% of cases within a few days, and their levels remain elevated for about 6 weeks. One hypothesis is that cold agglutinins result from cross-reactive autoantibodies against the I antigen of human erythrocytes. Another is that they develop directly as a result of antigenic alteration of erythrocytes caused by M. *pneumoniae* infection.

Performance of a qualitative "bedside cold-agglutinin test" involves placing 1 ml of anticoagulated blood in a cup of crushed ice for several minutes and then visually examining it for agglutination. On warming, the agglutination will resolve, but repeating the cooling procedure can reproduce it. A positive test for a patient in whom mycoplasmal infection is strongly suspected may have some clinical value. A more precise test is to determine the cold-agglutinin titer by reacting 0.1 ml of doubling dilutions of patient sera with 0.1 ml of a 1% suspension of washed human type O erythrocytes in a microtiter plate and determining the highest dilution at which agglutination occurs after 30 min of incubation at 4°C. Titers of 64 to 128 or a 4-fold or greater rise in titer suggest a recent M. *pneumoniae* infection, and the magnitude of the cold-agglutinin response may correlate directly with the severity of pulmonary disease. Detection of cold agglutinins is generally not recommended for the diagnosis of M. *pneumoniae* infection since cold agglutinins are associated with a wide variety of conditions, such as viral infections and collagen vascular diseases, and, more importantly, M. *pneumoniae*-specific serologic assays are now widely available.

Complement fixation (CF) was the major diagnostic technique used to measure M. *pneumoniae*-specific serum antibodies for many years. Seroconversion, defined as a 4-fold change in titer, measured in paired sera collected 3 to 4 weeks apart and assayed simultaneously, provides the greatest diagnostic accuracy. However, CF measures mainly the early IgM response and is unable to differentiate the other antibody classes. In addition, CF has limited sensitivity and specificity because the glycolipid antigen mixture used is not specific for M. *pneumoniae* and may be found in other microorganisms, as well as human tissues and even plants. Cross-reactions with other organisms, most notably M. *genitalium*, are well recognized, and false-positive results due to cross-reactive autoantibodies induced by acute inflammation from other unrelated causes may occur. To help overcome the problem with cross-reactivity, confirmation of positive CF results using Western blotting can be done, but this adds to the time and cost. Commercial assays for detection of M. *pneumoniae* antibodies by Western immunoblotting are available in Europe but not yet in the United States.

Most clinical laboratories have replaced CF with techniques of greater sensitivity and specificity. Numerous assay formats have been developed over the past several years and sold as commercial kits. Commercial kits are often evaluated using CF as the reference method. However, considering its lack of antibody class distinction and its cross-reactivity with other microorganisms, CF is not really suitable as a reference standard. Many of these tests, however, have not been fully evaluated and compared. In addition, the extent to which newer commercial serologic assays for M. *pneumoniae* will cross-react with M. *genitalium* or other mycoplasmas was not established with certainty, but this seems less likely to be a problem than with CF.

In-depth discussions of various types of commercial M. *pneumoniae* antibody assays and comparative evaluations of several products are available in other publications (2, 4–8). Table 1 summarizes the most popular types of serologic assays used to detect M. *pneumoniae* infection that have been developed commercially. These are indirect immunofluorescence, particle agglutination, and enzyme immunoassay (EIA).

Experience with EIAs dates back to the 1970s, and these assays are now the most widely used techniques for measuring antibodies against M. *pneumoniae*. A review of Food and Drug Administration-approved diagnostic tests reveals at least a dozen different M. *pneumoniae* EIAs marketed in the United States over the past several years, all of which are described as having either moderate or high complexity according to Clinical Laboratory Improvement Amendment (CLIA) classification. EIAs are more sensitive for detecting acute infection than is culture and can be comparable in sensitivity to PCR, provided that sufficient time has elapsed since infection for antibody to develop, if paired sera are tested, and if the patient has a functional immune system. Although most EIAs are sold as 96-well microtiter plate formats, some can be obtained as breakaway microwell strips, which allow smaller numbers of sera to be tested economically.

Two EIAs are packaged as qualitative membrane-based procedures for the detection of single test specimens. These are truly rapid EIAs (taking 10 minutes or less) and are simple to perform. The Meridian Immuno*Card* (Meridian Bioscience, Inc., Cincinnati, OH) is an IgM-only assay that is simple to read and is especially useful for testing pediatric samples. The Remel EIA (Thermo Fisher Scientific, Inc., Waltham, MA) is another membrane-based assay that detects IgM and IgG simultaneously. As discussed above, there are limitations in interpreting the results of IgM-only assays when a single acute-phase specimen is tested due to the potential for delayed or absent IgM response in many persons. This is more of a reflection on the erratic humoral immune response against M. *pneumoniae* than on the performance of a specific assay type. Multiple investigations, involving adults as well as children, have shown that the Immuno*Card* sensitivity for detection of acute M. *pneumoniae* infection is well below 50%, but it improves considerably if convalescent sera are tested (5, 7, 9). Similar poor sensitivity has been documented for other IgM assays when testing is limited to the acute phase when a positive PCR assay was used to define infection (5). Likewise, a single IgG measurement has no diagnostic meaning for an acute infection and is useful

TABLE 1 Major commercial serologic test formats for *M. pneumoniae* in the United States

Assay format[a]	Antibodies measured	Equipment required	Comments and limitations
EIA	IgM, IgG, or IgA separately	Spectrophotometer/ EIA reader	EIAs are typically performed using a microtiter plate format in which antigens are adsorbed onto the polystyrene surface. Dilutions of test serum are added to the wells and incubated. Antibodies bound to the solid-phase antigen are visualized by using enzyme-labeled conjugates directed against the primary antibody and substrate read in a spectrophotometer. The amount of conjugate reacting is proportional to the levels of antibody present. EIAs have the advantages of requiring very small serum volumes (<100 μl), are adaptable to testing larger or small numbers of specimens, and can be made isotype specific.
Membrane EIA	IgM or IgG separately	None	Membrane EIAs are rapid, qualitative, point-of-care procedures designed for testing single-serum specimens. A permeable membrane or filter paper is impregnated with antigen to which serum is added. This step is followed by addition of anti-human IgG or IgM enzyme conjugate. Development of color after enzyme substrate is added constitutes a positive test. Lipemic or hemolyzed serum samples will interfere with results.
PA	IgG or IgM separately or simultaneously	None	PA tests utilize latex or gelatin as carrier particles coated with antigen that are incubated with test serum. If specific antibodies are present, the particles agglutinate, resulting in a visible reaction. PA products may provide qualitative results that can be visualized on a card or quantitative data read in a microtiter plate format. PA assays do not offer any advantages over other techniques such as EIAs or IFAs, except possibly their ease and simplicity of performance.
IFA	IgG or IgM separately	Fluorescence microscope	Antigen is fixed to glass slides. Specific antibody is detected in dilutions of test serum after staining with anti-human IgM or IgG fluorochrome conjugate. Results can be affected by the presence of rheumatoid factor and high *M. pneumoniae*-specific IgG antibody levels. Additional procedures to validate IgM results are needed in these settings. IFA provides quantitative data, but interpretation is very subjective.

[a]PA, particle agglutination; IFA, indirect immunofluorescence.

only in prevalence studies since the time of seroconversion cannot be determined. Although acute- and convalescent-phase sera should be tested quantitatively for both IgG and IgM for greatest diagnostic accuracy, the practical value of the qualitative single point-of-care tests offered by both kits is lost if paired specimens are required. Thus, these single point-of-care tests can be useful in some settings if the potential limitations are considered in the diagnosis. Csango et al. (10) concluded in their evaluation of 4 commercial EIAs sold in Europe that a substantial proportion of healthy adult blood donors were serologically positive for IgA, IgM, and/or IgG, suggesting the likelihood that these tests result in overdiagnosis of acute *M. pneumoniae* infections. Despite limitations on the analysis of a single serum specimen, many commercial kits provide interpretive criteria for single measurements of IgM or IgG. Such information should be interpreted with great caution. It is clear that there are potential problems with all of the commercial antibody tests used to detect the immune response to acute *M. pneumoniae* infection that have been evaluated in independent studies. For tests that have not undergone such comparisons, nothing is known about their diagnostic accuracies beyond what the manufacturer states in package inserts.

Molecular Biology-Based Techniques

The attention focused on nucleic acid amplification techniques (NAATs) such as PCR has largely eclipsed earlier interest in nonamplified antigen detection or DNA hybridization systems. Numerous studies since the late 1980s using simulated clinical specimens, animal models, and clinical trials have validated the ability of the PCR assay to detect *M. pneumoniae*, often in conjunction with serology and/or culture. The same types of clinical specimens that can undergo culture, such as throat swabs, nasopharyngeal swabs, sputum, and other sterile tissues or body fluids, can also be tested by the PCR assay. Additional advantages of PCR assays are that they can be used to detect mycoplasmas in tissue that has already been processed for histologic examination or in cultures that are contaminated. Furthermore, PCR assays generally require only one specimen, can be completed in 1 day, may give positive results earlier in infection than serology does, and do not require viable organisms.

Most PCR-based techniques are somewhat similar and do not differ in principle from PCR assays used for detection of other microorganisms. Although most approaches focus on amplifying sequences of genomic DNA, RNA-based amplification has also been used. Specific advantages of

RNA-based amplification techniques are the high sensitivity that can be achieved due to the large number of rRNA copies per mycoplasmal cell and the fact that its detection is more indicative of viable mycoplasmas in a clinical sample. NAATs for *M. pneumoniae* that are used in diagnostic laboratories have usually been developed in-house and have not been subjected to rigorous comparisons with culture, serology, or other NAATs. During the past few years, most newly described assays have utilized real-time detection as opposed to conventional gel-based PCR techniques. Numerous advantages exist for this newer technology, including greater sensitivity, lower risk of contamination-related false positives, shorter turnaround time, and the ability to provide quantitative results. Gene targets for PCR assays for detection of *M. pneumoniae* in clinical specimens have included 16S rRNA, *P1*, *tuf*, *parE*, *dnak*, *pdh*A, ATPase operon, CARDS toxin gene (*mpn372*), the non-coding repetitive element *repMp1*, and intracellular protease gene. Various detection systems have also been described (Table 2), and multiple types of instrumentation have been used. Both conventional and real-time nucleic acid sequence based amplification (NASBA) have also been used to detect *M. pneumoniae* RNA. There have been very few side-by-side comparisons to determine whether one assay format or gene target is better than another. Many of the evaluations that have been done compared PCR with culture and/or serology as a reference method and, predictably, yielded disparate results in some cases.

Over the past several years, various commercialized kits have become available in Europe for the detection of *M. pneumoniae* alone or in combination with other respiratory tract bacteria or viruses, either in mono or in multiplex formats. Two molecular-based NAATs are now FDA-approved for use in the United States. One of these is the illumigene Mycoplasma Assay (Meridian Bioscience, Inc., Cincinnati, OH). This loop-mediated isothermal amplification assay (LAMP) enables detection of *M. pneumoniae* in as many as 10 clinical specimens that can be tested simultaneously within 1 hour after extracted DNA is set up in the incubator/reader. This instrumentation, which does not require a thermocycler, can easily be incorporated into clinical microbiology laboratories that do not have extensive molecular diagnostic facilities. The second NAAT sold commercially in the United States is the multiplex Biofire Diagnostics FilmArray RP (BioFire Diagnostics, Salt Lake City, UT; recently merged with bioMérieux, Marcy l'Etoile, France). This kit detects nucleic acids in nasopharyngeal swabs for 20 respiratory tract pathogens, including *M. pneumoniae*, processing one sample at a time with results in about an hour. The BioFire Diagnostics FilmArray performance was shown to be comparable to real-time PCR for detection of *M. pneumoniae* in one study (11). This assay is also available in Europe. Additional technical information, primer sequences, and tabulations of various nucleic acid amplification assays according to respiratory specimen tested and further discussion of commercial NAATs are available in other recent publications on these topics (1, 12–15).

Comparison of various NAATs, mainly PCR assays, with culture has yielded varied results. In view of the enhanced analytical sensitivity of the PCR assay over culture, a positive PCR result together with negative culture can be easily explained. However, in a situation of a negative PCR assay with a positive culture, the presence of inhibitors or some other technical problem with the PCR assay must be considered. Interestingly, PCR inhibition may be more likely to occur with nasopharyngeal aspirates than with throat swabs, and sputum may be more likely to be PCR-positive than nasopharyngeal specimens, throat swabs, or throat washes. However, from a practical standpoint in sampling young children and many adults with fairly mild illness, sputum is not produced in *M. pneumoniae* infections, so nasopharyngeal or oropharyngeal samples may be the only specimen types available. Sometimes dilution of samples overcomes inhibition of PCR due to a reduction in inhibitors during the reaction, but this is at the cost of diminished sensitivity because the nucleic acid is diluted along with any inhibitors. Several commercial reagents with automated procedures for nucleic acid purification are effective in removing most inhibitors of amplification in PCR assays, and these appear to work as well as nonproprietary methods. Thus, the type of sample and its preparation can influence the ability to detect *Mycoplasma* infection using the PCR assay.

PCR results may not always correspond with serologic results. For example, elderly adults with pneumonia might have age-related impairment in immunity, resulting in low serologic responses after *M. pneumoniae* infection. The

TABLE 2 Examples of *M. pneumoniae* nucleic acid amplification assays

Gene target	Assay type	Detection format	Mono or multiplex	Reference

[b]NASBA, nucleic acid sequence based amplification.

same situation may occur with very young infants. A positive PCR test together with a negative serologic test could also mean that the specimen was collected too soon in the course of the illness to allow sufficient time for antibody to develop. Analysis of paired acute and convalescent sera might help resolve this situation. PCR results may also become negative within days following antibiotic treatment, whereas serologic results should remain positive for a longer time. It is not known with certainty whether there is a specific threshold quantity of *M. pneumoniae* in respiratory tract tissues that can differentiate colonization versus infection. Therefore, relying solely on a positive result by PCR may overestimate the clinical importance of *M. pneumoniae* as a pathogen if the population sampled has a high carriage rate, which sometimes occurs in children, or at a time when there is an epidemic ongoing in a given community and exposure rates would be elevated and because of the propensity of this organism to cocirculate with other bacterial and viral pathogens. Concern for spread of clinically significant macrolide-resistant *M. pneumoniae* has become a major issue because of its high prevalence in Asia and growing presence in the United States and Europe. Various real-time PCR assays to detect 23S rRNA mutations associated with macrolide resistance have been described and can be incorporated into a diagnostic scheme so that clinicians can be told whether an infection might be suitably treated with a macrolide antibiotic at the same time a positive PCR result for *M. pneumoniae* is provided (1, 13).

Published studies describing multicenter comparisons of various NAATs for *M. pneumoniae* detection (16, 17) reported significant variations in test performance among participating laboratories, making a strong case for an organized proficiency test program, which has been pilot-tested in Europe. Proficiency testing panels for NAATs for various pathogens, including *M. pneumoniae*, are also available through the College of American Pathology.

Recommended Diagnostic Approach

Clinical manifestations, radiographic presentation, and general laboratory tests are not sufficiently specific to allow the differentiation of *M. pneumoniae* infection from infections caused by other common microorganisms, and more specific laboratory methods are needed to confirm the diagnosis. This situation is complicated further by the fact that mycoplasmal respiratory infections often coexist with infections caused by several other respiratory pathogens. Most *M. pneumoniae* infections are relatively mild and amenable to management on an outpatient basis, so physicians may rely on clinical suspicion and provide empiric treatment. However, a microbiological diagnosis should be sought if illness is sufficient to warrant hospitalization, if there is unsatisfactory clinical response to initial antimicrobial therapy, if there are underlying comorbid conditions or immunosuppression that would make severe and disseminated disease more likely, or if significant extrapulmonary symptoms are present.

The ideal diagnostic strategy, especially in children, can take advantage of both serology for IgM and PCR, since culture is laborious, time-consuming, insensitive, and expensive and because serology or PCR alone can be problematic for reasons discussed above. If a single serological test is to be performed, the rapid EIAs mentioned earlier may be the most logical alternatives. The additional expense of performing two tests has to be considered along with the very limited availability of PCR assays in the United States.

M. GENITALIUM

M. genitalium is a very fastidious, slow-growing mycoplasma first identified in 1981 from the urethras of men with urethritis. Its role in human disease is now becoming more apparent, mainly as a result of epidemiological studies that have used PCR to detect infections. Despite the increased awareness of the pathogenic potential of *M. genitalium*, there are relatively few clinical isolates of the microbe because of its extremely fastidious nature. This mycoplasma is known to play a role in cervicitis and pelvic inflammatory disease in women and in urethritis in men.

Serology

A microimmunofluorescence assay for *M. genitalium* can detect antibody responses in men with nongonococcal urethritis and women with salpingitis (18). This method is rapid, reproducible, and quite sensitive and specific, with less cross-reactivity with *M. pneumoniae* than is seen with other methods. EIA protocols using lipid-associated membrane protein antigens were applied to population studies, and the results were confirmed by Western blotting (19). These antigens have limited cross-reactivity with *M. pneumoniae*, and the EIA platform is more amenable to large-scale testing than is Western blot analysis. However, these assays are not available outside of specialized research laboratories and therefore cannot be recommended for diagnostic purposes.

Molecular Biology-Based Techniques

Perhaps more than for any other mycoplasma, molecular biology-based techniques have played the critical and indeed defining role in diagnosis of *M. genitalium* infections. *M. genitalium* is notoriously difficult to culture, perhaps in part because of its ability to persist in the intracellular environment but also because of its fastidious growth requirements and extremely slow generation time (18 h). The anatomical sites that are sampled, preparation of DNA template material, and PCR approaches are basically similar to those used for other mycoplasmas. *M. pneumoniae* and *M. genitalium* are structurally and antigenically related, with 98% homology in their respective 16S rRNA, thus challenging development of specific diagnostic assays that can differentiate them, even though *M. pneumoniae* is much less likely to be found in the urogenital tract. Quantitative, rapid, real-time PCR assays for *M. genitalium* have utilized targets such as the MgPa operon, 16S rRNA, the 115-kDa gene, and *gap* encoding glyceraldehyde-3-phosphate dehydrogenase (20–24). Use of *gap* as a gene target overcomes some of the limitations identified for 16S rRNA and MgPa (1, 13). Since PCR-based assays are the primary means of *M. genitalium* diagnosis, it is essential that whichever type of procedure is employed should be stringently controlled and carefully monitored. There is a strong association between serology and PCR for *M. genitalium*, but the analytic sensitivity of a single PCR assay for *M. genitalium* will certainly vary according to the technique and gene targets that are used. Additional techniques such as transcription-mediated amplification (TMA) have been developed for detection of *M. genitalium*. Multiplex PCR-based systems for detection of *M. genitalium*, along with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and other urogenital mycoplasmas and ureaplasmas, are sold as kits in several European countries by multiple companies using various formats and instrument platforms. PCR assays have also been developed that can detect mutations mediating antimicrobial resistance in *M. genitalium* (1).

Recommended Diagnostic Approach

The lack of readily available molecular diagnostic testing for M. *genitalium* in clinical laboratories and the unavailability of culture or serology as alternatives has had the expected result that clinicians in the United States rarely request microbiological confirmation of infections suspected to be due to this organism. Some reference and specialty laboratories offer their own in-house PCR assays for this mycoplasma, but none of these assays are validated. Few comparative studies of different assay formats and gene targets have been performed, and no organized proficiency testing program is available. Given the rapid development of molecular-based tests for M. *pneumoniae* over the past few years in Europe and the introduction of two FDA-cleared tests, it seems possible that commercially available rapid diagnostic tests for M. *genitalium* may soon come to the United States as they have in Europe. Since M. *genitalium* is less commonly detected in the lower urogenital tract in the absence of clinical infection than is *Mycoplasma hominis* or *Ureaplasma* spp., when it is detected by PCR in the lower urogenital tract of a symptomatic individual, it should be considered clinically significant.

M. HOMINIS

Like *Ureaplasma* species and M. *genitalium*, M. *hominis* is associated with urogenital infections. However, unlike *Ureaplasma* species, detection of M. *hominis* in the vagina is of clinical significance since this microbe is a component of the suite of bacteria associated with bacterial vaginosis. M. *hominis* is also more closely linked to systemic diseases, including pyelonephritis, postpartum endometritis, arthritis, pericarditis, peritonitis, and wound infections in adults, as well as meningitis, bacteremia, and pneumonia in infants. Like *Ureaplasma* species, M. *hominis*, although somewhat slower growing, is relatively easy to cultivate and can be isolated using commercial SP4 agar and broth or 10B broth and A8 agar. Classic "fried-egg" colonies can be observed within 3 to 7 days.

Serology

As with the other urogenital mycoplasmas, no commercial serological assays are available in the United States. An EIA is based on lipid-associated membrane antigens and is more broadly cross-reactive among different M. *hominis* strains than are assays using cell lysates as antigens. Confirmation by immunoblot analysis is also appropriate. Seroepidemiology to determine exposure to M. *hominis* within a population can be done with a single serum sample. However, for diagnostic purposes, paired acute- and convalescent-phase sera are likely to be more informative. As is the case for ureaplasmas, clinical experience using serology for diagnosis of M. *hominis* infections is scant.

Molecular Biology-Based Techniques

The molecular biology-based techniques and considerations are essentially the same as for the other mycoplasmal species. Both multiplex PCR and real-time PCR assays have been developed, some of which are commercially sold in Europe but not in the United States at this time. PCR assays for M. *hominis* have mainly utilized 16S rRNA or 16S-23S intergenic spacer regions as gene targets (25, 26). Since heterogeneity may occur in the 16S rRNA gene of M. *hominis*, other targets, including *fstY*, *yidC*, *tuf*, and *rpoB*, have been developed (1, 13, 27–30). Microtiter plate hybridization assays used with M. *genitalium* and *Ureaplasma* spp. have also been employed for M. *hominis* (26, 31).

Recommended Diagnostic Approach

Since no serologic or molecular assays are available commercially in the United States, most clinical laboratories still depend on culture using specific procedures designed to recover these organisms. M. *hominis* is the easiest of the pathogenic human mycoplasma species to grow in culture using the appropriate methods. Use of Columbia blood agar or automated blood culture systems is discouraged because the number of false-negative results would be significant, and culture results would therefore be unreliable. Since M. *hominis* is a common inhabitant of the female cervix and male urethra, a positive PCR assay or culture may not be meaningful in the absence of clinical manifestations commonly associated with infections with this organism. However, an organism load exceeding 10^4 colony-forming units (CFU)/ml may be clinically significant. In addition, a positive culture or PCR from an extragenital site should be considered clinically significant.

U. UREALYTICUM AND *U. PARVUM*

Ureaplasma spp. are implicated in a number of human urogenital infections. *Ureaplasma* was proven to cause nongonococcal urethritis in experimental infection studies of humans. However, demonstrating their role in disease is complicated due to the high carriage rate of the microbe in the lower genital tract of asymptomatic persons. Colonization of the placenta and/or amniotic fluid with *Ureaplasma* spp. is also associated with histologic chorioamnionitis and premature birth. Importantly, colonization of developing fetuses *in utero* or preterm neonates is linked to the development of chronic lung disease and is associated with necrotizing enterocolitis, and the organisms can also cause neonatal bacteremia and meningitis.

Originally, human ureaplasmas were thought to consist of a single species with two biovars composed of 14 serotypes. *Ureaplasma* is now recognized as two species: *Ureaplasma parvum* (formerly biovar 1; serovars 1, 3, 6, and 14) and *Ureaplasma urealyticum* (formerly biovar 2; serovars 2, 4, 5, and 7 to 13). Although some serovars are more fastidious than others, most ureaplasmas are relatively easy to culture and develop classic colonies on A7 or A8 agar within 2 to 3 days, making culture the most common means for diagnosis used by clinical laboratories.

Serology

Although several EIA protocols have been published, no commercial product is available in the United States. The EIA does not differentiate between *U. parvum* and *U. urealyticum*, and other approaches, such as monoclonal antibody capture assays, microimmunofluorescence, growth inhibition, and metabolic inhibition, were used to detect serovar differences. As with M. *pneumoniae*, seroconversion, a 4-fold rise in titer, or change in subclass-specific response may be useful for epidemiological studies. However, serology has never been used to any significant degree for the diagnosis of ureaplasmal infections in a clinical setting, and assays have never been standardized.

Molecular Biology-Based Techniques

The same principles, limitations, and considerations that were discussed for M. *pneumoniae* also apply to the detection of *Ureaplasma* species. The most commonly tested samples from adults include urine, urethral swabs, semen, prostatic fluid, vaginal swabs, endocervical swabs, placental or endometrial tissues, amniotic fluid, and synovial

fluid. Synovial fluid has a particular problem in that some samples appear to be inhibitory for PCR assays, and therefore, false-negative results can occur. Due to high carriage rates, vaginal swabs are of limited clinical significance for *Ureaplasma*. In contrast, urethral swabs from males are more informative than are those from females due to lower carriage rates. In addition, first-void urine is a frequent sample used for PCR, but again there is the inherent caveat that first-void urine may reflect transient contamination rather than a clinically significant finding. Thus, the type of samples and carriage rates will impact interpretation of the results obtained.

The newest molecular biology-based tools using real-time PCR permit the identification of the individual species, although this is not essential for diagnostic purposes (1, 13). Ureaplasma-specific primers have been developed to target several different genes in real-time PCR assays; the most commonly used are the urease, multiple-band antigen (*mba*), and 16S rRNA genes, but other systems have been described based on the *U. UREALYTICUM*063 gene, which encodes a conserved hypothetical protein that is identical in all 4 serovars of *U. parvum* and *U. UREALYTICUM*R10_0680 that is conserved in all 10 serovars of *U. urealyticum* (13, 32) (Table 3). One approach incorporates hybridization with specific labeled probes to standard PCR reactants in a microtiter plate format (26, 31, 33). This system has the advantage of using a single primer pair to amplify the 16S rRNA target from the major genital mycoplasmal species, as well as the two ureaplasmal species, followed by a probe specific to each of the species. Multiplex PCR assays have been developed for several sexually transmitted microbes, including *U. urealyticum* and *U. parvum*, as well as *M. hominis*, *M. genitalium*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis* (1). Some are now sold commercially in Europe, but not in the United States. Multiplex PCR can also be used in combination with other techniques, including reverse line hybridization blotting (mPCR/RLB) and microarrays. The mPCR/RLB technique integrates multiplex PCR using biotin-labeled primer pairs or biotin-dNTPs to generate labeled PCR products that hybridize with highly specific, membrane-bound, amine-labeled oligonucleotide probes by reverse line blot hybridization. To visualize the hybridized PCR products, the membrane is incubated with peroxidase-labeled streptavidin and chemiluminescent detection liquid. Chemiluminescence results can be detected by a light-sensitive film or a lumino-imager. The mPCR/RLB technique has been used to develop assays that detect numerous respiratory pathogens, including *M. pneumoniae* and a variety of urogenital pathogens, including *Ureaplasma* spp., *M. genitalium*, and *M. hominis* (34–36). The microarray used for the detection of *Ureaplasma* spp. is based on immobilizing probes on a glass surface that hybridize to their complementary biotin labeled-DNA targets produced by a previous PCR procedure. The microarray is then incubated with gold-conjugated streptavidin. The interaction of biotin and streptavidin leads to silver precipitation visualized on the microarray. *In situ* hybridization (ISH) is a non-PCR-based molecular technique that has been specifically utilized for detection of ureaplasmas in lung tissue samples (37). Thus, there are a wide variety of molecular-based approaches that are developed to detect ureaplasmas in samples.

Recommended Diagnostic Approach

Since none of the serologic or PCR assays are available commercially in the United States, most diagnostic laboratories

TABLE 3 Examples of real-time PCR-based assays and gene targets for detection of urogenital mycoplasmas

Species	Gene target/ region	Analytical sensitivity (no. of genome copies or CFU/reaction)	References
U. urealyticum and *U. parvum*	16S rRNA	10 copies	50
U. parvum	Urease	5 copies	51
U. parvum	UU063	0.6 CFU	32
U. parvum	Urease	10 copies	52
U. parvum	Urease	1 CFU	53
U. urealyticum	Urease	10 copies	52
U. urealyticum	Urease	5 copies	51
U. urealyticum	Urease	3 CFU	53
U. urealyticum	UUR10_0680	0.8 CFU	32
M. genitalium	*gap*	5 copies	23
M. genitalium	16S rRNA	10 copies	54
M. genitalium	16S rRNA	1 copy	20
M. genitalium	16S rRNA	10 copies	55
M. genitalium	MgPa	<5 copies	22
M. hominis	16S rRNA	10 copies	56
M. hominis	*gap*	10 copies	28
M. hominis	*yidC*	7 copies	27
M. hominis	*fstY*	10 copies	29
M. hominis	*tuf*	100 copies	30

depend on the use of culture for detection of ureaplasmas in clinical specimens, because results can usually be provided within 2 to 3 days. The 10B broth and A8 agar used for culture are available commercially from various vendors. Even though PCR is clearly more sensitive than culture from an analytical perspective, it is considerably more expensive and much less practical for laboratories that may receive specimens on an occasional basis and particularly if they do not have molecular diagnostic facilities. A positive ureaplasma culture or PCR from the urethra or urine of men or women with symptoms consistent with urethritis, from prostatic fluid, or from an extragenital site in adults should be considered clinically significant. Similarly, if organisms are detected in samples from the lower respiratory tract in neonates with lung disease or from normally sterile sites such as the bloodstream or cerebrospinal fluid, these results should be considered clinically significant. *U. urealyticum* may be more pathogenic than *U. parvum* in some conditions, such as male urethritis, so it may be useful to identify the species present in these cases. However, no such associations have been consistently shown for other conditions.

Chlamydia and *Chlamydophila* Infections

ROSEMARY SHE

50

Chlamydiaceae is a unique family of bacteria which consists of small Gram-negative coccobacilli that are obligate intracytoplasmic organisms, typically causing infection in warm-blooded animals (1). The genus name *Chlamydia* first appeared in the literature in 1945 but was not fully recognized until 1956 (1, 2). The family had only one genus until 1999 when the genus *Chlamydophila* was added. However, the name *Chlamydophila* has not become widely adopted in the medical community, and *Chlamydophila* spp. are still commonly referred to as *Chlamydia* spp.

The diverse species of *Chlamydia* and *Chlamydophila* are unified by their characteristic two-stage developmental cycle, alternating between the elementary body and the reticulate body. The small (~ 0.3 μm), extracellular, and metabolically inactive elementary body infects eukaryotic cells. After being internalized, it develops within an inclusion body into the metabolically active reticulate body, which then undergoes multiple rounds of binary fission. The reticulate body is larger (~1 μm) and has a cell membrane resembling that of other Gram-negative bacteria. Within the host membrane-bound inclusion, it differentiates into elementary bodies, lysing the host cell and releasing infective organisms to repeat the cycle (3). Organisms in the *Chlamydiaceae* are reliant on the host cell for energy or ATP (4). Organisms in the *Chlamydiaceae* family cause several important and pervasive human diseases. *Chlamydia trachomatis* causes venereal and ocular disease and *Chlamydophila pneumoniae* causes respiratory infections. Rarely, *Chlamydophila psittaci* causes zoonotic infection in bird handlers.

C. TRACHOMATIS

Organism Description

The 20 genotypes and serovars of *C. trachomatis* are differentiated by their major outer membrane protein (MOMP). Serovars A to K are the most common and infect epithelial cells of the human genital tract and eye. L1, L2, L2a, and L3 serovars cause lymphogranuloma venereum (LGV) and infect mononuclear cells (5).

Clinical Disease

Chlamydia trachomatis is the cause of the most common reportable sexually transmitted infection in the United States (6). Serovars D to K have a predilection for the genital tract, where they can infect both the lower and upper genital tracts. The disease tends to be mild or asymptomatic in both males and females, but particularly in females. For this reason, annual screening is recommended in all sexually active females 25 years of age or younger, as well as in older women with risk factors such as new or multiple sexual partners. In males, the organism can cause urethritis and epididymitis (7). There are no recommendations for routine screening in males except in sexually active men who have sex with men (MSM) (8). In females, as the organism is capable of establishing chronic infection, it can further lead to complications such as chronic pelvic pain, pelvic inflammatory disease, tubal scarring, and ectopic pregnancy. In the MSM population, *C. trachomatis* is a major cause of proctitis and less commonly a cause of pharyngeal infection. *C. trachomatis* may also cause neonatal conjunctivitis and infant pneumonia (8).

Serovars A, B, Ba, and C cause trachoma, a leading cause of blindness worldwide that has recently been subject to intense eradication efforts. Infections frequently begin as a keratoconjunctivitis in children who then develop pathological scarring and blindness as adults. Recurrent infections are thought to sustain the inflammatory response (9).

LGV is more prevalent in developing countries but there has been a recent surge in rectal LGV among MSM in Western Europe and the United States (10). In the genital tract, the disease is characterized by formation of buboes and ulcers. LGV may also involve the rectum in those practicing anal sex. Untreated, the disease may result in scarring with subsequent lymphatic obstruction and elephantiasis of the genital region, rectal fistulas, or rectal stricture formation (5).

Laboratory Diagnosis

Recommended Laboratory Tests

For screening and diagnosis of genital tract infection caused by *C. trachomatis*, the Centers for Disease Control and Prevention (CDC) recommends nucleic acid amplification testing (NAAT). Vaginal and endocervical swabs and urine are acceptable for female patients. Urine or a urethral swab is collected for male patients. Urine specimens should be a first-catch 10 to 30 ml collection (8). Detailed screening recommendations are available elsewhere (8). Test of cure, such as may be done 3 to 4 weeks after initiation of therapy, is specifically not recommended by the CDC except in

doi:10.1128/9781555818722.ch50

pregnancy. The concern is that nucleic acid from nonviable organisms may be present and detectable by NAATs despite effective therapy, leading to false positive results. On the other hand, persistence of low-level infection may be difficult to detect and result in false-negative results. It is, however, recommended that retesting of newly infected patients be done 3 months after treatment. This follow-up testing is mainly to assess for reinfection, which increases the risk of complications (8).

For sexual abuse cases, legally acceptable testing will depend on the locality. Because of its superior specificity, chlamydial culture has long been considered the only acceptable test, until recently. Although not FDA-cleared for testing in children, NAAT has gained wider acceptance for testing in cases of suspected sexual abuse. When culture is not available and positive NAAT results can be confirmed by an alternate target, NAAT may be acceptable. Studies have been done on vaginal and urinary specimens from girls, but no recommendations are made for boys. It is important for laboratories to retain and not prematurely discard specimens tested for medicolegal reasons in the case that further testing is needed (8).

Specimen Collection

Swabs of the suspected site of infection are taken to collect cellular specimens. Besides genitourinary sources, eye, rectal, and throat swabs may be tested depending on the patient history. In LGV, an aspirate or biopsy of an affected lymph node may be examined or tested by culture or NAAT (if validated by the laboratory). In neonates, nasopharyngeal collection may be appropriate if respiratory *C. trachomatis* infection is suspected from vertical transmission.

Collection devices and transport media for *C. trachomatis* NAAT are test-specific and available from the manufacturer. Some kits are conveniently FDA-cleared for use on liquid-based Pap specimen media (i.e., BD SurePath or ThinPrep Autocyte) if aliquoted before cytology testing. For culture or antigen detection methods, specimens should be transported in sucrose-containing media such as 2-sucrose phosphate (2SP), M4, or universal transport media. In terms of timing of specimen collection for serologic testing, most patients develop detectable IgM and IgG response within 2 to 3 weeks (11).

Culture

Tissue culture for *C. trachomatis* is done with cells such as McCoy, Buffalo green monkey, or HeLa 229. The addition of 1% cycloheximide to the isolation media helps to optimize recovery; it is thought that cycloheximide inhibits host cell metabolism, thereby increasing availability of ATP for chlamydial organisms that may be present (12). Centrifugation yields 100- to 1000-fold more organisms with culture (4). The typical protocol is to centrifuge inoculated shell vials at 1,000 to 3,000 × *g* for 1 hour at 30 to 35°C (12). Blind passage of cells increases yield by 5 to 10% but must be balanced with increased labor, expense, and turnaround time (13). Blind stains should be done after 48 to 72 hours of incubation. Fluorescent antibodies, not Giemsa or other nonspecific stains, should be used (Fig. 1). Laboratories may choose to start with less expensive, genus-specific antibodies, and if positive, confirm with species-specific MOMP monoclonal antibodies (8).

Because of its poor sensitivity compared to NAAT, culture is not widely used or performed. The delay associated with specimen transport to an off-site laboratory can decrease recovery of these fastidious organisms (14). It is still of value in instances of medicolegal testing, when there is suspected failure of therapy requiring an isolate for susceptibility testing, or when non-genitourinary specimen types are not validated by the laboratory for NAAT (8).

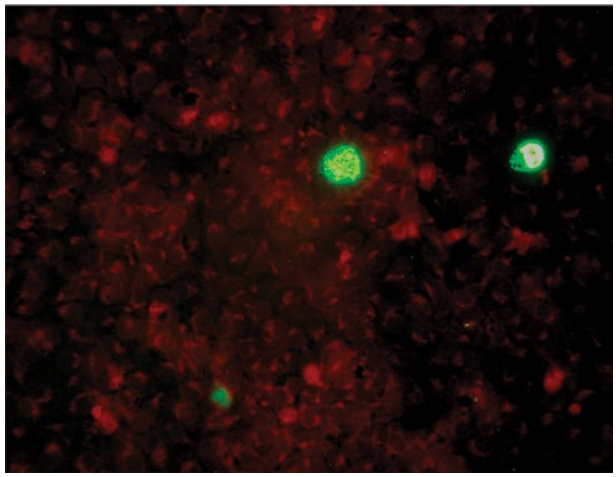

FIGURE 1 Example of culture positive for *Chlamydia trachomatis*, as confirmed by fluorescently labeled monoclonal antibody to chlamydial group antigens using reagents from Diagnostic Hybrids (Athens, OH).

Direct Antigen Detection

Older methods of direct antigen detection for *C. trachomatis* such as enzyme immunoassay and Giemsa staining are insensitive and not recommended for routine clinical testing (15). The classic intracytoplasmic inclusions of *Chlamydia* may occasionally be appreciated on histologic or cytologic specimens, but are not a reliable finding. Examination of lymph node tissue for LGV reveals somewhat nonspecific pathology, although in the appropriate clinical context it can suggest the correct diagnosis (16).

Direct fluorescent antibody testing for *C. trachomatis* involves detection of elementary bodies in smears of patient cells. It has limited utility but is an option when NAAT has not been validated and a rapid test would be helpful, e.g., for ocular sources. Although highly specific, its sensitivity is only 50 to 70% compared to that of NAAT (17).

Nonamplified nucleic acid detection methods used more widely in the past (i.e., Gen-Probe [Hologic] PACE 2 and Digene Hybrid Capture 2) also lack sensitivity compared to NAAT (18). The PACE 2 assay's only advantages are that it is inexpensive and FDA-cleared for use on conjunctival specimens.

Serology

Serologic diagnosis is challenged by cross-reactivity of antibodies between species of *Chlamydia* and *Chlamydophila*. It should not be used as the primary diagnostic modality for *C. trachomatis* infection. Antibody response may be delayed up to 1 month after infection, and elevated titers may be seen in the case of either current or past infection. If used, serologic testing for *C. trachomatis* is best done using paired specimens, e.g., collected in the acute and convalescent phases of illness. It may sometimes be useful in patients previously treated with antibiotics or patients with upper genital tract infection, in whom detection of the organism may be difficult (19). Serologic testing can also support the clinical presentation in the diagnosis of LGV (5, 8). Because LGV is an invasive infection, high titers, i.e., > 1:128, are usually

observed, but do not necessarily distinguish LGV from invasive infections caused by other serovars (5). Studies suggest that an elevated IgA titer may be useful in detecting anorectal LGV (20). Infants with suspected chlamydial pneumonitis may also benefit from serologic testing with an assessment for an IgM response (21).

Microimmunofluorescence (MIF) antibody testing is considered the gold standard for detection of chlamydial antibodies, although complement fixation and enzyme immunoassay (EIA) methods are also described. In MIF, formalin-fixed elementary bodies are spotted onto a glass slide for incubation with patient sera. This method is highly manual and technically complex and subjective. Subjectivity in interpreting endpoint titers and lack of interlaboratory agreement are some of the issues to consider (22). Most available serologic tests do not distinguish antibodies to LGV serovars from A to K serovars, but specialized testing for LGV serovars can be done at reference laboratories or research centers. Because elevated titers against *C. trachomatis* may result from cross-reactivity with related species, it is advisable to obtain titers against a panel of chlamydial species, e.g., *C. pneumoniae*, *C. psittaci*, and *C. trachomatis*, to ensure that the highest titer is to *C. trachomatis*. Interpretation of chlamydial antibody panels must be made carefully, taking into account the high incidence of both *C. trachomatis* and *C. pneumoniae* infection (23).

IgM antibodies by MIF testing appear to be less heterologous than IgG antibodies, but false positive titers may result from presence of rheumatoid factor or with Epstein Barr virus infection (24). Notably, a rise in IgM is observed after primary but not repeat exposure to *C. trachomatis*; therefore, single-point serology for *C. trachomatis* is difficult to interpret and rarely useful in sexually active individuals (25).

Molecular Testing

The standard of care for *C. trachomatis* screening and diagnosis from genital, pharyngeal, and rectal sources is NAAT (8). Numerous FDA-cleared methods are available and can suit different laboratory test volumes and workflow considerations (Table 1). The different methods include PCR, strand displacement amplification, and transcription-mediated amplification. Performance characteristics of these tests are roughly equivalent (26, 27). For testing in females, urine may be less sensitive than vaginal or endocervical swabs (28). The available assays can also target *Neisseria gonorrhoeae* in the same kit or platform. Although NAAT is recommended for diagnosis of rectal and pharyngeal infection, as of yet there has been no FDA clearance of such specimen sources (8). Performance will depend on laboratory validation of these sources according to Clinical Laboratory Improvement Amendments standards. The FDA-cleared NAATs are not approved for use in children, but NAAT has been shown to perform reliably in girls undergoing evaluation for sexual abuse, detecting all culture-positive cases and being able to be confirmed by secondary target testing. Recommendations are not made for boys (29). NAAT tests for *C. trachomatis* are designed to detect all serovars, but specific identification of LGV serovars requires specialized molecular tests available at some public health laboratories and the CDC.

The sensitivity of NAAT testing for *C. trachomatis* is indisputably superior to other available methods. The specificity approaches that of culture, but it is important that laboratories follow strict practices to minimize the possibility of contamination of the testing environment. Many of the FDA-cleared systems are considered closed environments, but laboratories should still monitor surfaces for contamination. Internal or amplification controls are either included or an available option among most FDA-cleared assays. Repeat or alternate target testing was once recommended to confirm positive results in low-prevalence areas. But because of evidence demonstrating a lack of overall benefit of this approach, it is no longer advocated for most circumstances (30).

Several NAATs target the cryptic DNA plasmid of *C. trachomatis* as this target is present in 7 to 10 copies per cell. Plasmid-deficient strains are rare as the plasmid appears to play a significant role in the virulence of the organism (31). It is noted that in 2006, a strain with a plasmid harboring a 377-base-pair deletion emerged in Sweden, with limited spread within Europe (32). Because of the deletion, the variant strain could not be detected by the Abbott m2000 PCR or the Roche AMPLICOR assays (33). Most current NAAT systems are designed to detect this variant.

C. PNEUMONIAE

Organism Description

Chlamydia strain TWAR was renamed *Chlamydia pneumoniae* in 1989, then 10 years later was reclassified into a new genus as *Chlamydophila pneumoniae* based on nucleic acid sequence analysis (34). It is distinct from *C. trachomatis* in several ways, such as having a characteristically pear-shaped instead of round elementary body. The organism is globally distributed and there is only one known serovar (22, 35).

Clinical Disease

C. pneumoniae is a common pathogen with a high population seroprevalence and is well described to cause atypical pneumonia, asthma exacerbation, tracheobronchitis, pharyngitis, laryngitis, and sinusitis (36). The prevalence among patients with community-acquired pneumonia is reported to be 6 to 22% (22). It is also known to cause sporadic outbreaks of respiratory tract infection (37). Prolonged duration of relatively mild respiratory symptoms is characteristic and may help differentiate it from other agents of respiratory tract infection (35, 38). *C. pneumoniae* commonly coinfects the respiratory tract with other pathogens, raising questions regarding its pathogenic role (39). Because it is believed to be capable of causing latent infection, it has been implicated in diverse extrapulmonary disease processes. *C. pneumoniae* has been associated with multiple sclerosis, Alzheimer's disease, and atherosclerosis, among other illnesses, although its exact role is still debated (40).

Laboratory Diagnosis

It is important to distinguish *C. pneumoniae* from other respiratory tract pathogens as treatment can differ. *C. pneumoniae* is an obligate intracellular organism best treated with a macrolide or tetracycline and not with beta-lactam drugs. Unfortunately, laboratory diagnosis in the outpatient setting, where most *C. pneumoniae* infections present, is infrequently undertaken due to poor availability of onsite testing. Diagnostic methods include culture, PCR, and serology, but *C. pneumoniae* suffers from a lack of a true gold standard for laboratory diagnosis. Culture requires extended incubation times and has a poor rate of recovery. PCR and serology are considered more reliable tests though performance is nonstandardized and laboratory dependent (22). Recent advances in technology may make molecular testing more readily available in the future.

TABLE 1 Select nucleic acid-amplified methods (FDA-cleared) for detection of *Chlamydia trachomatis* from clinical specimens

Kit name and manufacturer	Method	Gene target	FDA-cleared sources	Comments
APTIMA Combo 2, APTIMA CT; Gen-Probe (San Diego, CA)	Transcription-mediated amplification	23s rRNA	Male and female urine Endocervical, vaginal (clinician- or patient-collected), and male urethral swabs	Kit for alternate target testing available No internal control included PreservCyt solution, liquid Pap specimens also FDA cleared
GeneXpert CT/NG; Cepheid (Sunnyvale, CA)	PCR	Chromosomal DNA	Male and female urine Endocervical swab Patient-collected vaginal swab (in a clinical setting)	Clinical Laboratory Improvement Amendments – moderate complexity
ProbeTec ET (BD, Franklin Lakes, NJ)	Strand displacement amplification	Cryptic plasmid DNA	Male and female urine Endocervical and male urethral swabs Patient-collected vaginal swab (in a clinical setting)	SurePath and PreservCyt solution Liquid-based Pap media also FDA cleared
COBAS AMPLICOR CT/NG Test; Roche (Indianapolis, IN)	PCR	Cryptic plasmid DNA	Male and female urine Endocervical and male urethral swabs	PreservCyt solution Liquid Pap specimens also FDA cleared Does not detect Swedish variant with 377-bp deletion in cryptic plasmid DNA
RealTime CT/NG; Abbott Diagnostics (Santa Clara, CA)	PCR	Cryptic plasmid DNA	Male and female urine Endocervical, vaginal (clinician- or patient-collected), and male urethral swabs	Dual cryptic plasmid targets

Specimen Collection

C. pneumoniae has been isolated from a variety of body sites but the optimal specimen type has not been thoroughly examined. It is currently presumed that for respiratory tract infections, a variety of specimen types are acceptable, including sputum, nasopharyngeal swab, throat swab, tracheal specimens, and bronchoalveolar samples. One study found that nasopharyngeal swabs yielded more positive results for *C. pneumoniae* by PCR than throat, throat wash, or sputum samples, but could not rule out nasopharyngeal colonization unrelated to lower respiratory tract infection (39). It is best to use swabs with a Dacron tip and to avoid wooden shafts. For culture, specimens should be kept at 4°C and only frozen at –70°C if culture cannot be set up within 24 h (35, 41, 42). All specimens should be transported in 2SP, M4, or universal transport media. For NAAT assays, it is best to collect specimens as early in the course of disease as possible because sensitivity has been shown to decrease after the first week of illness (43). If collecting samples for serologic testing, it is important to note that IgM antibodies may not appear until 2 to 3 weeks after illness onset (11, 43). Paired IgG samples are required for diagnosis of acute infection, one taken during acute phase and one taken 6 to 8 weeks later (11).

Culture

Culture has been shown to be insensitive compared to serology or PCR for diagnosis of *C. pneumoniae* infection (39). Furthermore, it is a specialized test requiring tissue culture, and thus it is mainly limited to reference laboratories. Organisms lose infectivity during prolonged storage, which may explain why recovery in culture is inconsistent, especially in the reference laboratory setting (44). HEp-2 cells appear to be the most effective at cultivating *C. pneumoniae*, although use of other cells, such as HL or McCoy cells, has also been described (45). Centrifugation of specimen onto tissue culture monolayers enhances organism recovery (46). Organisms grow slowly and cultures may take up to one week. Passage of cells during the course of culture and blind stain using fluorescently labeled antibodies are recommended as these procedures enhance detection and identification (47). The CDC recommends at least two passages to optimize culture sensitivity (41).

Serology

Serologic assays for *C. pneumoniae*, which include MIF, complement fixation, and EIA, are criticized for their lack of standardization and their inability to provide a timely diagnosis (22, 48). The reader is referred to the 7th edition of this manual for more detailed information on the performance of serologic methods. MIF can be accomplished by using in-house laboratory preparations of chlamydial elementary bodies or by using commercial kits (e.g., from Labsystems [Vantaa, Finland], Savyon Diagnostics [Ashdod, Israel], etc.). Agreement between the various MIF tests is dependent on differences in antigen preparation, bacterial strains used, and interpretation of the stain (48). Nonetheless, MIF is considered the gold standard and is the serologic method recommended by the CDC (Fig. 2) (41). The *C. pneumoniae* MOMP is not species specific, and as already mentioned, there is substantial cross-reactivity between *Chlamydiaceae* antibodies (35). Therefore, as with *C.*

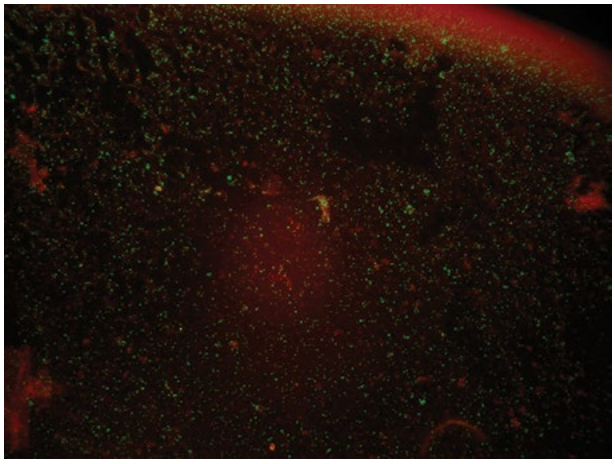

FIGURE 2 Example of a positive microimmunofluorescence (MIF) serologic reaction for *C. pneumoniae*. Bright green fluorescent dot-like staining highlights the elementary bodies which have reacted with the patient serum (100× magnification). Photo courtesy of Marc R Couturier.

trachomatis antibody testing, it is best to interpret antibody titers to *C. pneumoniae* in the context of antibody titers to other species of this family.

EIA or enzyme-linked immunosorbent assay (ELISA)-based methods are objective and less labor-intensive than MIF and thus may be a good alternative, although performance characteristics are kit dependent (43). Several kits, such as the Labsystems *C. pneumoniae* IgG EIA, the Medac sandwich ELISA (Medac, Wedel, Germany), and the Biopharm Elegance EIA (R-Biopharm, Darmstadt, Germany), have shown good correlation with MIF (49). False-negative results for some assays, including the SeroCP ELISA (Savyonn Diagnostics), Medac sandwich ELISA, and LabSystems EIA, have been noted in specimens with low IgG titers by MIF (50). False-positive results have also been documented, with one study showing cross-reactivity of the LabSystems EIA for *C. pneumoniae* IgG when high titers of *C. trachomatis* antibodies were present (51). In outbreak situations, a recombinant EIA (Medac) and the LabSystems EIA were found to be highly sensitive and specific when compared to MIF (52). While IgM by EIA or ELISA has been shown to aid in identifying cases during *C. pneumoniae* outbreaks, they are also less specific than IgG antibodies, with ~8% of asymptomatic healthy persons having positive results (50, 53).

Paired IgG serology results are recommended for a more reliable diagnosis of acute infection (41). A 4-fold or greater change in titer is considered diagnostic of recent *C. pneumoniae* infection. Given that paired samples should be drawn 6 to 8 weeks apart and that single-point serology is not recommended, an accurate serologic diagnosis of acute *C. pneumoniae* infection is retrospective. Admittedly, the prevailing clinical practice is to request single-point serology for the sake of convenience and a timely result. Clinicians should be advised that even high single-point titers (e.g., IgG ≥1:512 or IgM ≥1:16) are commonly seen in healthy, asymptomatic individuals (54).

When elevated, IgM antibodies for *C. pneumoniae* are considered indicative of acute infection. The utility of IgM is hampered by the fact that it may not be elevated early in the disease course or with reinfection. Rheumatoid factor has been shown to produce false-positive IgM results (11). During repeat infection, IgM may be low titer or absent, whereas IgG titers usually greatly increase within 1 to 2 weeks of reinfection (35).

Molecular Testing

Numerous laboratory-developed NAATs for *C. pneumoniae* have been described in the literature (39, 54). Early in disease onset, PCR has been shown to be highly sensitive and superior to culture and possibly more predictive of infection than serology in the outbreak setting (39). Nonetheless, in peer-reviewed studies there is great discrepancy in test results between NAAT, serology, and culture. Performance of NAATs as a whole is difficult to assess due to the lack of standardization and difficulty in defining a gold standard for *C. pneumoniae* infection. Interestingly, the positivity rate by PCR has not been as high as serology in multiple studies (22, 44). This may be related to sporadic occurrence of disease, timing of specimen collection, and lack of specificity of serologic testing, among other variables. Caution should be taken with interpreting NAAT results as *C. pneumoniae* is known to asymptomatically colonize the respiratory tract and can be shed for up to 8 weeks after infection (54).

Real-time PCR testing may be performed using commercially available analyte-specific reagents either in single-target format or multiplexed for simultaneous detection of other atypical bacterial pathogens of the respiratory tract. Reagents include those from Focus Diagnostics (Cypress, CA), ELiTech Molecular Diagnostics (Princeton, NJ), ARGENE (bioMérieux) (Durham, NC), Seegene (Seoul, Korea), and others. Recently, the FilmArray Respiratory Panel (BioFire Diagnostics Inc, Salt Lake City, UT) became the first FDA-cleared PCR assay with *C. pneumoniae* as one of the analytes on this sample-to-answer multiplexed assay. More convenient, affordable, and accurate test options for *C. pneumoniae* are still needed in the outpatient setting.

C. PSITTACI

Organism Description

The agent causing psittacosis was described as early as 1930 and eventually placed in the genus *Chlamydia* in 1966 (55). In 1999 it was reclassified as *Chlamydophila psittaci*. The species name is derived from the Greek for parrot, or psittakos. *C. psittaci* consists of eight serovars (34).

Clinical Disease

C. psittaci infects individuals who come in close contact with birds or bird secretions, such as pet shop keepers, poultry handlers, bird owners, and veterinarians. Infectious agents are found in the nasal discharge, feces, or tissues of the infected bird. In human cases, transmission is most common from infected birds of the parrot family but has also occurred with poultry and free-ranging birds (56). An average of 16 cases per year were reported to the CDC in the United States between 2000 and 2009 (57). This zoonotic illness known as psittacosis consists of influenza-like symptoms which uncommonly result in severe pneumonia. It is thought that many milder presentations go unrecognized or misdiagnosed (56).

Laboratory Diagnosis

Laboratory tests for diagnosis of psittacosis are performed only by a handful of reference laboratories. While numerous studies on diagnostic testing have been performed in birds, few have examined optimal test modalities in humans. Serologic testing and culture are used most commonly. As

with the other chlamydial species, MIF is considered to be the most reliable. A 4-fold increase in IgG between paired serum samples drawn 2 to 4 weeks apart, or an IgM titer elevated at least to 1:32, supports diagnosis. Because cross-reactivity is observed with other chlamydial species (23), it is best to obtain titers to *C. pneumoniae* and *C. trachomatis* concomitantly to be able to interpret results. The IgG titer to *C. psittaci* should also be highly elevated (≥1:128) to support the diagnosis (56).

C. psittaci may also be cultivated from respiratory or peripheral blood specimens (56). Centrifugation of the specimen onto the cell monolayer and treatment of cells with cycloheximide are shown to improve organism recovery (58). HeLa, McCoy, and mouse L cells have been used successfully (58, 59). Because of its low incidence, reference laboratories do not generally offer NAAT testing for *C. psittaci*. Testing may be performed by the CDC.

OTHER ZOONOTIC CHLAMYDIAL INFECTIONS

Besides *C. psittaci*, several other chlamydial species have been reported to cause rare, sporadic infections in people who come into contact with an infected animal. *C. psittaci* has, in fact, been separated into five species: *C. psittaci*, *C. pecorum*, *C. felis*, *C. abortus*, and *C. caviae*. *Chlamydophila felis*, which causes conjunctivitis and respiratory tract infection in cats, has been suggested to rarely cause human disease according to various case reports (60). *Chlamydophila abortus* infection causes abortion in sheep and other ruminants and has been reported to cause systemic infection and miscarriage in pregnant women (61). Testing for these zoonotic Chlamydiaceae is limited and done only in specialized reference laboratories.

The *Rickettsiaceae*, *Anaplasmataceae*, and *Coxiellaceae*

LUCAS S. BLANTON AND DAVID H. WALKER

51

Organisms belonging to the families *Rickettsiaceae*, *Anaplasmataceae*, and *Coxiellaceae* are a diverse group of intracellular bacteria that cause a variety of infections in humans. As in the case of the *Rickettsiaceae* and *Anaplasmataceae*, hematophagous arthropod vectors play a role in maintaining the agents in nature and transmit the agents to cause disease. *Coxiella burnetii*, the sole pathogen of the family *Coxiellaceae*, is a zoonosis spread to humans by the inhalation of contaminated aerosols. In the last 2 decades, there has been an emergence of new rickettsial and ehrlichial species as well as new syndromes attributed to species previously deemed nonpathogenic. The growing list of pathogens and syndromic illnesses adds a layer of complexity to their recognition. Additionally, the clinical manifestations of infections caused by these agents are protean and nonspecific. For these reasons, establishing an accurate and timely diagnosis is often difficult. Therefore, knowledge of available laboratory tests, their interpretation, and their shortcomings is crucial for the management of infections caused by these bacteria.

TAXONOMY

The order *Rickettsiales* consists of two families – *Rickettsiaceae* and *Anaplasmataceae* (Fig. 1). Members of both families are small obligately intracellular Gram-negative bacteria. The family *Rickettsiaceae* contains the genera *Rickettsia* and *Orientia*, both coccobacilli. Historically named *Rickettsia tsutsugamushi*, phenotypic and genotypic differences prompted the creation of the genus *Orientia* in 1995 (1). Rickettsiae implicated in human disease are divided into two main groups, the spotted fever group (SFG) and the typhus group (TG). The distinction between these groups is based on antigenic differences of the lipopolysaccharides, the presence of outer membrane protein A in the SFG, and phylogenetic relationships. Although the TG consists of two species, *R. prowazekii* and *R. typhi*, the SFG consists of over 20 named species and species candidates. The recent designation of a third group, the transitional group, classifies species that have variable serologic cross-reactivity and phylogenic placement between the SFG and TG. Members of the transitional group consist of *R. felis*, *R. australis*, and *R. akari* (2). *Orientia tsutsugamushi* is an antigenically diverse species with over 70 different strains. Although the genus has been traditionally recognized as consisting of only one species, a newly isolated strain has been proposed to be different enough to warrant classification as a separate species, *O. chuto* (3). The family *Anaplasmataceae* consists of five genera, *Ehrlichia*, *Anaplasma*, *Neorickettsia*, *Neoehrlichia*, and *Wolbachia* (4). These organisms are pleomorphic cocci that form inclusion-like clusters in host cell vacuoles. Whereas *Ehrlichia*, *Anaplasma*, *Neorickettsia*, and *Neoehrlichia* cause diseases in humans, *Wolbachia* is an endosymbiont of arthropods and filarial nematodes (5). *Coxiella burnetii* is the agent responsible for Q fever. As a small pleomorphic Gram-negative coccobacillus, it was once classified in the order *Rickettsiales*, but it is now classified in the order *Legionellales* (*Gammaproteobacteria*) (6).

EPIDEMIOLOGY

Rickettsiae have a worldwide distribution (Table 1). Those in the SFG cause disease in geographic locations that correspond to the ecological niches of their tick vectors. Although SFG rickettsioses have a variety of names, some of which are geographic, they do not necessarily reflect their full distribution. For example, Rocky Mountain spotted fever (RMSF), caused by *R. rickettsii*, is more prevalent in the southeastern and south-central regions of the United States than it is in the Rocky Mountain region. The organism also causes disease throughout the Americas with cases reported in Mexico, Costa Rica, Panama, Colombia, Brazil, and Argentina (7). *R. conorii* is a prevalent SFG organism with a distribution that includes the Mediterranean basin, Africa, and Asia. It is transmitted by the ubiquitous brown dog tick, *Rhipicephalus sanguineus*. Consequently, infection caused by *R. conorii* is known by several names: Mediterranean spotted fever (MSF), Marseilles fever, Kenya tick typhus, Israeli tick typhus, Astrakhan spotted fever, and Indian tick typhus. *Rickettsia slovaca* causes disease in Europe (8). Other SFG rickettsiae worth noting include *R. africae* and *R. parkeri*, which cause a relatively mild disease in sub-Saharan Africa and the Americas, respectively (9, 10).

Typhus-group organisms include *R. prowazekii* and *R. typhi*. *R. prowazekii* causes typhus, which is also known as epidemic typhus. The human body louse, *Pediculus humanus corporis*, is the vector responsible for transmission of *R. prowazekii* between infected humans. Lice become infected by feeding on rickettsemic patients prior to finding a new host. The new host becomes infected by either scratching *Rickettsia*-laden louse feces into the louse-bite site or by

doi:10.1128/9781555818722.ch51

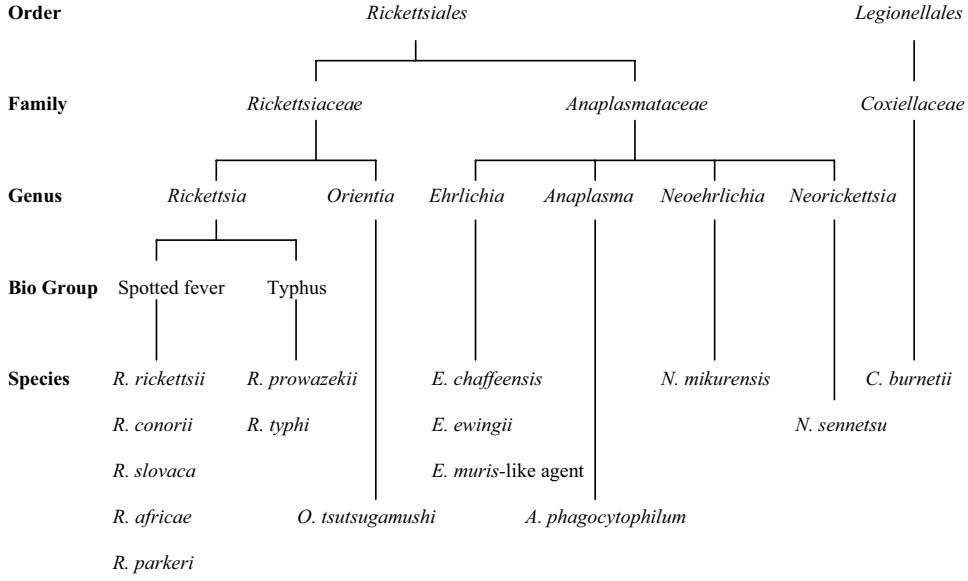

FIGURE 1 Taxonomy of representative human pathogens in the order *Rickettsiales* with the addition of *Coxiella*, formerly in the order *Rickettsiales*.

inoculating the organism into mucous membranes. After recovery, *R. prowazekii* may remain in a latent state and result in recrudescent infection later in life. This reactivation syndrome is known as Brill-Zinsser disease, and if reactivation occurs under conditions that promote louse infestation (e.g., extreme cold, poverty, war, overcrowding, poor hygiene), epidemics may occur. Louse-borne typhus is now an uncommon infection, but it still has a natural endemicity in the Peruvian Andes and has caused recent outbreaks in Burundi and Rwanda (11). A sylvatic cycle for the transmission of *R. prowazekii* exists in eastern North America, where *Glaucomys volans*, the southern flying squirrel, acts as an extrahuman reservoir for *R. prowazekii*. Infection is rare and occurs when humans are exposed to the feces of flying squirrel ectoparasites (12).

In contrast to infection caused by *R. prowazekii*, *R. typhi* infection occurs throughout the world and is especially prevalent in tropical and subtropical seaboard regions. Rats (*Rattus* sp.) are the primary reservoir, and their fleas (*Xenopsylla cheopis*) serve as vectors. This cycle is often responsible for disease in urban environments where rats thrive. In the United States, most cases occur in southern California and south Texas where a suburban cycle for transmission involves opossums and cat fleas (*Ctenocephalides felis*) as reservoirs and vectors, respectively (13).

O. tsutsugamushi is the causative agent of scrub typhus. The disease is endemic within the triangle-shaped region bound by northern Australia, Afghanistan, and the Primorje region of eastern Russia. Larval trombiculid mites (chiggers) maintain *O. tsutsugamushi* transovarially and transmit disease to humans while feeding. Rats are important in the maintenance of the chigger population. Transmission most frequently occurs in rural and suburban areas (14).

E. chaffeensis is the cause of human monocytotropic ehrlichiosis (HME). It is primarily transmitted by *Amblyomma americanum* ticks and occurs predominantly in the south-central and southeastern United States where these ticks are most prevalent. The organism is transtadially transmitted from one tick stage to another, but it is not transovarially maintained. Persistently infected white-tailed deer play a key role in maintaining the bacterium in nature by acting as a reservoir for acquisition of the infection by uninfected ticks. HME is likely vastly underdiagnosed (7). Other ehrlichiae of human importance include *Ehrlichia ewingii* and the recently described *E. muris*-like agent. *E. ewingii* is also transmitted by *A. americanum*. Most cases have been recognized in immunocompromised hosts (15). The *E. muris*-like agent has been recognized only in Wisconsin and Minnesota, with case descriptions suggesting an HME-like illness (16).

Similar to the aforementioned ehrlichioses, *Anaplasma phagocytophilum* is a tick-transmitted bacterium of the family *Anaplasmataceae*. This agent causes human granulocytotropic anaplasmosis (HGA). *Ixodes scapularis* is the vector responsible for transmission to humans. Infection occurs in the northeastern and upper midwestern United States and less often in California, in parallel to Lyme disease, which shares the same vector. HGA also occurs in northern Europe and Asia, where it is transmitted by other *Ixodes* species ticks (7).

Other members of the family *Anaplasmataceae* of human importance include *Neorickettsia sennetsu*, *Neoehrlichia mikurensis*, and *Wolbachia* sp. *N. sennetsu* causes a mononucleosis-like illness. It is believed to be acquired from the ingestion of infected uncooked fish in Japan, Malaysia, and Laos (17). *N. mikurensis* can cause severe and occasionally prolonged illness in immunocompromised persons or mild illness after exposure to *Ixodes ricinus* ticks in Europe or *I. persulcatus* and *Haemaphysalis concinna* ticks in Asia (18–23). Although the filarial endosymbiont *Wolbachia* does not directly cause human infection, the organism influences the pathogenesis of infections caused by their filarial hosts in human disease (5).

Coxiella burnetii is responsible for Q fever, a zoonosis transmitted to humans by the inhalation of contaminated aerosols. With the exception of New Zealand, *C. burnetii* causes disease throughout the world. The organism has been found in ticks and in a wide variety of animals where it is maintained (24). Cattle, sheep, and goats are important animal reservoirs (25). During the pregnancy of infected animals, the organism reactivates and increases in number within placental tissue. At the time of parturition, the

TABLE 1 Summary of representative human pathogens

Species	Disease	Distribution	Transmission	Target cells	Cellular location	LPS	C + G content (%)
R. rickettsii	RMSF	Americas	Tick bite	Endothelium	Cytosol	Yes	32.5
R. conorii	MSF	Europe, Asia, North Africa	Tick bite	Endothelium	Cytosol	Yes	32.4

[a]Currently unknown.

organism is shed and aerosolized (26). Therefore, those handling livestock are at higher risk for exposure (25).

PATHOBIOLOGY

Upon inoculation of *Rickettsia* sp., rickettsial surface proteins such as Omp B, Sca1, and Sca2 act as adhesins to promote attachment and induce entry into endothelial cells, their principal target cell. The SFG has an additional surface protein, OmpA, which also facilitates the host cell entry process. Within the cell, rickettsiae have transport mechanisms to take advantage of the host cell cytosol to provide necessary energy and nutrients (e.g., adenosine triphosphate, amino acids, and phosphorylated sugars). The SFG organisms are able to polymerize the host cell's actin filaments to mediate propulsion through the cytosol and invasion of neighboring cells. Organisms of the typhus group do not exhibit actin-based motility, but cause their host cell to burst, resulting in spread to other cells. The endothelial tropism of rickettsiae leads to the inflammation and vascular hyperpermeability that are responsible for the clinicopathologic features of rickettsioses (27).

The clinical spectrum of rickettsial infections varies from severe to mild, depending on the infecting pathogen. Of the SFG rickettsiae, *R. rickettsii* is the most pathogenic (untreated case-fatality rate of RMSF is 23%) while *R. africae*, the agent responsible for African tick bite fever (ATBF), has never been implicated in a human death (7). Typical manifestations of SFG rickettsial infection include fever, headache, myalgias, and rash. The rash of RMSF occurs in up to 90% of patients, is typically macular or maculopapular, and begins peripherally (wrists and ankles) before spreading proximally (28). Rash is also a frequent finding in MSF, and an eschar (a cutaneous lesion with a black necrotic center) is found in up to 72% of patients at the tick bite site (29). Infections with *R. africae*, *R. parkeri*, and *R. slovaca* are also associated with an eschar but cause milder illnesses compared to RMSF and MSF (8–10). In addition to an eschar usually occurring on the scalp, *R. slovaca* causes lymphadenopathy of the draining cervical lymph nodes, but seldom causes fever and rash.

Typhus-group rickettsioses have similar clinical manifestations as those caused by SFG rickettsiae. Both epidemic and murine typhus cause an undifferentiated febrile illness. The rash is typically macular or maculopapular and is first noted on the trunk prior to spreading to the extremities. Although clinical suspicion for a TG rickettsiosis is often prompted by the presence of rash, the sign may be subtle and difficult to detect in those with darkly pigmented skin. In those afflicted with epidemic typhus during a large outbreak in Burundi, rash was detected in only 20 to 40% (11). Rash is detected in 54% of those with murine typhus (30). Since outbreaks of louse-borne epidemic typhus often occur in the setting of great stress (e.g., wars, famine, and migration), the case-fatality rate may be quite high. The untreated case-fatality rate in the worst conditions of malnutrition is as high as 50% (11). In contrast, flying squirrel-associated typhus and murine typhus are generally less severe (12, 30).

O. tsutsugamushi infection follows the bite of a trombiculid mite, which releases *O. tsutsugamushi* from its salivary glands as it feeds on tissue fluids from the dermis. The organism enters cells by induced phagocytosis. The initial targets are likely dendritic cells, which phagocytose the pathogen and carry it to draining lymph nodes prior to its hematogenous spread. The primary target cells of *O. tsutsugamushi* are vascular endothelial cells and macrophages (31). As with infections caused by the aforementioned *Rickettsia* spp., scrub typhus is largely characterized by nonspecific symptoms (e.g., fever, headache, myalgia) that are often indistinguishable from symptoms caused by other endemic diseases, e.g., malaria, dengue fever, and leptospirosis. The finding of an eschar at the usually unrecognized mite bite site separates scrub typhus from these other infections. Patients often have tender draining lymph nodes proximal to the eschars. Severe manifestations such as pneumonia, prerenal azotemia, and meningoencephalitis may occur (14).

After inoculation by a feeding infected tick, ehrlichiae and *Anaplasma phagocytophilum* spread to the bone marrow and spleen where they infect their respective hematopoietic target cells. *E. chaffeensis* primarily infects monocytes and *A. phagocytophilum* infects neutrophils. These organisms reside in cytoplasmic vacuoles where they manipulate the host cell to promote their survival and evade host defenses, e.g., through the inhibition of phagosome-lysosome fusion. Clinical illness is a consequence of the host's immune system more than a result of direct cellular damage by the bacteria. For the most part, HME and HGA are clinically indistinguishable from infections caused by other species discussed in this chapter. Symptoms include fever, chills, headache, myalgia, and malaise. Physical examination is usually unremarkable, and unlike SFG and TG rickettsial infections, rash is an infrequent finding (up to 36% in those with HME). Laboratory abnormalities (leukopenia, thrombocytopenia, and hepatic-transaminase elevation) may suggest infection with these agents in the appropriate epidemiologic scenario. Although many patients experience mild illness, severe manifestations (septic shock, respiratory insufficiency, acute kidney injury, and, in HME, meningoencephalitis) may occur (32, 33).

C. burnetii-infected ruminants typically do not manifest illness. At the time of parturition, the heavily infected placenta sheds the organism (34). Viable bacteria can be found for weeks in the environment. After inhalation, the organism proliferates in the lungs followed by bloodstream invasion and eventual dissemination to other organs (35). *C. burnetii* undergoes phase variation in the laboratory. The phase I state is the form found in nature and reacts slightly with early sera and strongly with sera of chronically infected hosts. Phase II avirulent organisms occur after serial passage in embryonated chicken eggs or cell culture owing to deletion of genes for the synthesis of complete lipopolysaccharide. A stable form gives the organism the ability to survive in harsh environments (36).

The most frequent form of acute Q fever in humans is a self-limited nonspecific illness characterized by fever, chills, fatigue, and headache. In some areas, the relatively high percentage of seropositive individuals without previous history of severe febrile illness and outbreak investigation predicts that 60% of infections are asymptomatic. Pneumonia is often a feature of Q fever and may manifest as a spectrum of mild to severe manifestations. Incidentally discovered pulmonary infiltrates found on chest radiography are the most frequent pulmonary finding. Others may have symptoms of cough and pleuritic chest pain that mimic other causes of viral or atypical bacterial pneumonia. Rarely, severe progressive pneumonia leads to respiratory failure. Hepatitis is another manifestation of Q fever. It usually presents with hepatic transaminases elevated up to 3-fold the upper limit of normal in the setting of fever or pneumonia. A liver biopsy reveals granulomatous hepatic inflammation. An important manifestation of Q fever occurring as a chronic infection is endocarditis, which often afflicts those with preexisting valvular abnormalities. Associated signs and

symptoms include digital clubbing, pruritic rash, and hepatosplenomegaly (24).

LABORATORY DIAGNOSIS

As obligately intracellular organisms, laboratory isolation of the bacteria described in this chapter requires technical expertise and specialized facilities that are not readily available to most physicians and diagnostic clinical laboratories. Because of the ability of small inocula to cause illness when aerosolized, *Rickettsia* sp., *O. tsutsugamushi*, and *C. burnetii* require isolation to be carried out in a biosafety level-3 laboratory. Isolation of *Ehrlichia* and *Anaplasma* can be undertaken in a biosafety level-2 laboratory. Culture of these organisms may also require a significant amount of time for growth to occur when compared to more typical bacteria. This situation limits isolation as a method for diagnosis in acute infections (24, 36, 37). For these reasons, serologic methods are the mainstay of diagnosis for all infections described in this chapter. Unfortunately, serology can only confirm a diagnosis retrospectively, and results of such studies should not preclude prompt empiric therapy if such an infection is suspected. In the past several years, molecular methods such as PCR-based assays have become more refined and continue to show promise as a method for the diagnosis of infections caused by these organisms during the acute stage of illness. In the following sections, the current serologic and molecular methods of diagnosis are presented. Additionally, promising new techniques are discussed.

Immunodiagnosis

Rickettsia and *Orientia*

The gold-standard serodiagnostic method for diagnosis of RMSF is the indirect immunofluorescence assay (IFA). This method uses a fluorescein-labeled conjugate to detect serum antibodies bound to antigen (*R. rickettsii*-infected cells) fixed on a slide. The performance of IFA has greatly surpassed that of older methods, e.g., Weil-Felix, latex agglutination, and complement fixation (38). The test is available commercially and is also available through state health laboratories. Antigens used by various laboratories may differ in quality. Consequently, each laboratory should have its own cutoff titer, which it has validated as diagnostic for the population tested. As with infections caused by all the pathogens discussed in this chapter, the patient antibody response lags behind clinical illness. As a patient's illness progresses, a detectable antibody response follows. The sensitivity of IFA two weeks after the onset of illness is 94 to 100% (39). The timing of the IgM and IgG responses is similar in patients with RMSF. Antibodies of both isotypes increase simultaneously during the second week of illness (40). Since the appearance of IgM does not occur sooner, and IgM antibodies cross-react with nonrickettsial antigens more often than the IgG isotype, testing for IgM does not offer greater sensitivity or specificity during early illness. IFA testing for IgM is also affected by rheumatoid factor, necessitating the use of rheumatoid factor absorbent. Because IFA predictably fails to detect antibodies during the acute phase of illness, paired sera should be obtained during acute illness and after convalescence. Seroconversion or a 4-fold rise from acute-to convalescent-phase samples confirms the diagnosis (39).

Another commercially available and quite sensitive test for RMSF is the enzyme-linked immunosorbent assay (ELISA). The ELISA is sensitive, and its automation lends itself well to high-throughput applications. The subjective nature of reading IFA slides and requirement for a proficient microscopist is also avoided by using the ELISA technique (40). Because of the qualitative nature of ELISA, this assay is unable to quantify antibody titers. ELISA is therefore unable to monitor the change in antibody response over time. Like IFA, results depend on the particular laboratory, quality of the antigen, and threshold levels determined to yield a result considered reactive (39).

Other SFG rickettsioses can be diagnosed serologically as described above. Species belonging to this group induce antibodies that cross-react with antigens of other SFG members. Serum antibody titers are usually higher or the same when reacted with homologous antigens as compared to heterologous antigens. Therefore, it is helpful to use antigen prepared from *Rickettsia* species endemic to the area of interest. The micromethod format of the IFA is an efficient method to test for seroreactive antibodies to several different rickettsial antigens. This method may be useful in areas where several rickettsial species coexist and cause human diseases. The micro-IFA can detect antibodies to up to nine antigens within a single well containing multiple antigen dots (35).

The serodiagnosis of typhus-group rickettsioses is similar to that of RMSF and other SFG rickettsioses. IFA is the serologic method of choice (41). Antibodies may not be present during early illness, but almost all patients will have developed antibodies detected by IFA 2 weeks after the onset illness (30). Seroconversion or a 4-fold rise in antibody titer from the acute phase of illness to convalescence confirms the diagnosis of a typhus-group infection. As in the case with the SFG, the serologic response to infection with one species of the typhus group induces cross-reactive antibodies to the other species. Although a patient's clinical history and difference in IFA titers using both *R. prowazekii* and *R. typhi* antigens can offer clues to the offending agent, standard serologic methods may not establish a definitive species-specific diagnosis. *R. felis*, a flea-borne organism with features that resemble both the SFG and typhus groups, induces an antibody response that is variably cross-reactive with members of the typhus group and SFG organisms. Because *R. prowazekii* and *R. typhi* tend to burst cells during their propagation in cells, IFA slides using these organisms as antigen may show the presence of many extracellular organisms. Fluorescence of these small extracellular forms creates what has been described as a fine gold dust-like appearance, which is often mistaken for background fluorescence. IFA slides for the typhus group have been therefore considered as being more difficult to read than those of the SFG or *O. tsutsugamushi* (42).

The conventional methods of serodiagnosis are unable to distinguish a species-specific cause for a rickettsiosis. Whereas knowledge of the epidemiological situation in which the infection was acquired may be a helpful clue in typhus group infections, the diversity of the SFG renders it very difficult to determine a species-specific cause based on clinical and epidemiological assumptions. Although molecular methods or cultivation of the pathogen are the methods of choice for determining the exact etiologic agent implicated in an infection, a cross-absorption study can help determine a species-specific cause. Cross-absorption is performed by separately mixing the serum in question with the different bacterial antigens involved in the cross-reaction. This results in the disappearance of homologous and heterologous antibodies by Western blotting when absorption is carried out with the agent responsible for the disease. The disappearance of homologous antibodies by Western blotting occurs only when absorption is carried out with the

agent responsible for the cross-reaction. This technique is time-consuming. Although relatively straightforward for the distinction of two agents, cross-absorption becomes quite cumbersome when multiple rickettsial agents are in question and impossible when the actual agent is not included in the absorptions and reactions or has yet to be discovered (43).

Immunohistochemical staining of rickettsiae within formalin-fixed paraffin-embedded tissues is useful to demonstrate the presence of the offending agent prior to the patient's developing reactive antibodies (44). Prior to molecular methods, immunohistochemistry (IHC) was the only approach with the ability to reliably yield a diagnosis during acute illness. The technique can be performed on autopsy specimens including those from the skin, liver, spleen, lung, heart, kidney, and brain. In patients with RMSF, skin biopsy of the rash has a reported sensitivity and specificity of 70% and 100%, respectively (45). This technique can be used to detect other members of the SFG as well as those of the typhus group (46, 47). Of the SFG species causing eschars, such as *R. conorii*, *R. africae*, and *R. parkeri*, IHC can demonstrate the organism within eschar-biopsy specimens. The chance of demonstrating rickettsiae within tissues is greatest prior to or within 24 hours of antimicrobial administration (39).

The serodiagnostic methods of choice for the diagnosis of infection caused by *O. tsutsugamushi* (scrub typhus) include the indirect immunofluorescent and the immunoperoxidase assays. IFA has a high sensitivity and specificity, but as with the aforementioned rickettsioses, specific antibodies to *O. tsutsugamushi* are often absent during early illness (48). The use of the immunoperoxidase assay (IPA) yields comparable titers to those by IFA but holds a cost advantage, as it does not require a fluorescence microscope to view prepared slides (49, 50). Both the IFA and IPA are more sensitive than the Weil-Felix test (the first serologic test for the diagnosis of scrub typhus) and are much more specific (50). Over 70 strains of *O. tsutsugamushi* exist, and there is variable cross-reactivity among these strains. Therefore, prototype strains of *O. tsutsugamushi* (Karp, Kato, and Gilliam) are used in addition to local strains during the preparation of antigen for these assays. A definitive diagnosis can be established by demonstrating a 4-fold rise in antibody titer between acute and convalescent samples. Caution should be taken when using a single unpaired sample, as there is no consensus with regard to titer cutoff values to suggest recent infection. Each laboratory should base its cutoff titers on the local prevalence and titer of scrub typhus antibodies. In highly endemic areas, a titer as high as 1:400 may be appropriate (51). The reading of IFA and IPA slides and determination of endpoint titers are somewhat subjective. It appears that there is more inter-operator variability between microscopists with less experience than those with extensive experience (42).

Ehrlichia and *Anaplasma*

Serology remains the mainstay for the diagnosis of both ehrlichiosis and anaplasmosis. The IFA using *E. chaffeensis*-and *A. phagocytophilum*-infected cells is the method of choice for the serodiagnosis of HME and HGA, respectively. Slides incubated with sera reactive with the respective antigen will reveal morulae (characteristic mulberry-like microcolonies of bacteria) in the cytoplasm of cultured cells. Those living in areas where these diseases are endemic may have baseline serologic reactivity due to previous exposure to these or other antigenically related pathogens (52). It is therefore necessary to observe a 4-fold rise in titer by testing both acute-and convalescent-phase serum samples. In patients with HME, relatively few patients (22 to 44%) will demonstrate a reciprocal titer of at least 1:80 when tested in the first week of illness. After the first week of illness, the geometric mean titer rises sharply so that 68% of patient sera tested will yield a diagnostic titer. By week 4 or more of illness, all patients with HME should have seroconverted. The geometric mean titer peaks at 1:1280 in week 6 (53). Those with HGA have a slow early antibody response similar to those with HME; antibodies against *A. phagocytophilum* are detected in only 24 to 44% of patients in the acute stage of infection (54, 55). All patients with HGA will have seroconverted by the fourth week of illness (55).

Immunohistochemical analysis is an effective technique for the visualization of morulae within infected tissues. Whereas serodiagnosis requires the collection of convalescent sera to retrospectively confirm or refute a diagnosis, IHC can provide more timely results. The bone marrow, liver, lung, spleen, lymph nodes, kidneys, and adrenal gland have yielded positive results when collected at autopsy (56). Many of these tissues, such as the bone marrow, can be easily sampled during the course of a patient's workup and visually yield the presence of the organism. This technique uses formalin-fixed paraffin-embedded tissue incubated with biotinylated anti-*E. chaffeensis* antibodies followed by incubation with avidin-alkaline phosphatase (57).

Coxiella

As with infections caused by the aforementioned bacteria, acute Q fever is usually confirmed via serologic means. It is important to understand the host's immunoglobulin responses to the phase I and phase II antigens when interpreting serologic assays. In acute infection, IgM and IgG antibodies to phase II antigen appear prior to antibodies to phase I antigen. There is also a greater magnitude of antibody response to phase II antigen early after infection. Although the magnitude of IgM as measured in reciprocal titers to both phase I and II antigens decreases over time, these IgM antibodies may persist for several months (58) and even up to 2 years (59). IgG antibodies decrease over time but persist for life. In chronic Q fever, IgG-antibody titers to phase I antigens are quite high (60).

Several serologic methods for the detection of anti-*Coxiella* antibodies have been described. Techniques include microagglutination (61), complement fixation (62), microimmunofluorescence (63), and the ELISA (64). All of these methods are effective for the diagnosis of acute Q fever (65). The ELISA offers automation and the advantage of removing the subjectivity and inter-observer variation associated with IFA, but the sensitivity is not as high (66). The preferred and most frequently used serodiagnostic method in the United States is the indirect immunofluorescence assay, which is commercially available (67).

A 4-fold rise in phase II IgG titers by IFA from sera obtained during acute and convalescent stages of illness (separated by 3 to 6 weeks) confirms the diagnosis of acute Q fever, as almost all patients will have seroconverted by week 3 of illness (67). A single IgM titer to phase II antigen is not useful as a stand-alone test as the sensitivity in early disease is low and cross-reaction with other pathogens limits its specificity (68, 69). Early diagnosis and treatment of those with acute Q fever does not seem to prevent the IgG-antibody response (70). Paired samples should be sent to the same laboratory, and if possible, the acute-phase specimen should be frozen and sent with the convalescent specimen for simultaneous processing. This is to eliminate interlaboratory, interassay, and antigen variation (67).

Chronic Q fever can be diagnosed when the associated clinical picture is paired with the characteristic antibody profile. During chronic infection, IgG antibodies to phase I antigen are used to help confirm the diagnosis. The modified Duke Criteria, a diagnostic schema that includes clinical, microbiologic, and echocardiographic data for the diagnosis of endocarditis, includes a single phase I IgG-antibody titer of >1:800 or a single positive blood culture for C. *burnetii* as a major criterion. This, in combination with a second major criterion (echocardiographic evidence of endocarditis) or three minor criteria (predisposing heart condition, fever, vascular phenomena, immunologic phenomena), confirms a clinical diagnosis of Q fever endocarditis (71). Although the 1:800 cutoff value has been reported to be sensitive (100%) with a high positive predictive value (98%) (72), use of higher cutoffs such as 1:1,024 have been proposed based on follow-up studies of patients from large outbreaks in Europe (60, 73, 74). The Centers for Disease Control and Prevention recommend that the diagnosis of chronic Q fever can be demonstrated using a single phase I IgG titer of 1:1,024 in the setting of an identifiable chronic infection (endovascular infection, granulomatous hepatitis, chronic septic arthritis, osteomyelitis, or chronic pulmonary infection) (67).

Current serodiagnostic methods for Q fever are well established, but, as with most serologic tests, have limitations. The identification of novel seroreactive protein biomarkers is an attractive strategy for the development of safe and efficient diagnostic assays. Potential markers have been identified by immunoproteomic and microarray approaches (75, 76). The recombinant proteins corresponding to these immunoreactive antigens may aid in the development of new serologic tests. An enzyme-linked immunospot assay to measure C. *burnetii*-specific T-cell responses has been developed and shows promise as a useful diagnostic tool to identify an immunologic profile consistent with chronic Q fever (77).

Molecular Diagnosis

Rickettsia and *Orientia*

The use of PCR to amplify rickettsial DNA offers a rapid method to diagnose rickettsioses during acute infection. Prior to molecular methods, IHC was the only means of confirming a diagnosis early in disease. Conventional, nested, and real-time PCR techniques have been developed to amplify portions of various rickettsial genes. These methods can be used to detect rickettsial DNA within blood or tissue samples. Due to the intracellular endothelial tropism of organisms in the genus *Rickettsia*, few bacteria are found in the circulating bloodstream. This limits the sensitivity of PCR when performed on whole blood, except in late-stage or fatal cases (78, 79). The ability of PCR to detect organisms within biopsied tissue, such as the skin, makes these samples of much higher diagnostic yield when a rickettsiosis is suspected. Eschar biopsy specimens are also a good source for the detection of rickettsial DNA (35). The swabbing of eschars has also shown promise in the detection of rickettsial DNA. This technique uses a sterile saline-dipped swab rubbed onto the base of an unroofed eschar as a DNA-collection method. The swab is then placed in a tube with a small amount of saline for storage prior to processing (80). As in the case of culture and IHC methods, the sensitivity of PCR-based diagnosis decreases after the administration of effective antibiotics (39).

Screening for the presence or absence of rickettsial DNA within a sample can be achieved initially by using genus-specific primers designed to amplify conserved portions of genes encoding citrate synthase, OmpB, or the 17-kDa-antigen gene (78, 81, 82). Real-time PCR assays using primers and probes to detect these genes offer much greater sensitivity (83). If a sample screen detects target DNA, further analysis using primers to amplify OmpA, common to the SFG, can help delineate a SFG from typhus group infection.

For most clinical purposes, determination of a species-specific cause is not necessary after a rickettsial diagnosis is established, as treatment of these infections is identical. When identification of an infecting rickettsial agent is sought, the nucleotide-sequence analysis of PCR amplicons can reveal the exact causative agent. Since many primer sets amplify relatively conserved portions of genes encoding OmpA, OmpB, citrate synthase, and the 17-kDa antigen, it may be necessary to analyze portions of sequences from a gene fragment with sufficient diversity to identify the infecting species. An inexpensive alternative method to sequencing is restriction-fragment-length polymorphism (RFLP) analysis, which can be performed using products amplified from the aforementioned genes. The differentiation of rickettsiae can be achieved by using the endonuclease AluI for citrate synthase (82, 84) and the 17-kDa antigen gene PCR products (85). Digestion of an *ompB* PCR product using RsaI enables differentiation of several SFG rickettsiae (84). Finally, a primer set to amplify a portion of the *ompA* gene digested with a combination of endonucleases (RsaI, PstI, AluI, XbaI, and AvaII) can help identify most of the recognized SFG rickettsiae (86, 87).

O. *tsutsugamushi* DNA may be detected by PCR of whole blood, buffy coat, eschars, and other tissues to aid in the diagnosis of scrub typhus. Primers to amplify portions of a variety of genes have been described: the 56 kDa protein gene, 47 kDa protein gene, *groEL*, and 16S rRNA gene. Methods using conventional, nested, and real-time PCR techniques have been described. A nested PCR reaction to amplify a portion of the gene encoding the 56-kDa protein from eschars was 86% sensitive and 100% specific for the diagnosis of scrub typhus when compared to IFA as the gold standard test (88). Real-time PCR assays show promise of a high sensitivity as predicted from their ability to detect low copy numbers of O. *tsutsugamushi* in a variety of samples (89, 90).

Considering the nonspecific clinical presentations of rickettsioses and scrub typhus, they are undoubtedly mistaken for other prevalent febrile illnesses throughout the world. The development of inexpensive, reliable, and multiplexed point-of-care tests for the diagnosis of acute infections is a great need. Although attempts at PCR-based methods in resource-limited settings is troubled by cost and need for specialized equipment (91), reports of loop-mediated isothermal PCR assays show promise by offering an inexpensive and less technically demanding method for the amplification of pathogen DNA. Assays targeting the *ompB* and *groEL* genes of *Rickettsia* species and O. *tsutsugamushi*, respectively, have been described (92, 93).

Ehrlichia and *Anaplasma*

The presence of *Ehrlichia* within the bloodstream of those with acute infection makes PCR a useful tool during the early phases of these illnesses. In one study, PCR amplification of each of three targets (16S rRNA gene, the variable-length PCR target gene, and the *groEL* operon) was able to detect ehrlichial DNA in all cases of acute culture-proven HME (94). Techniques using conventional, nested, and real-time PCR and PCR with reverse-line blot hybridization have all been developed for the detection of *Ehrlichia* species (95–97). Quantitative real-time PCR offers the opportunity to detect

as few as one gene copy per reaction. The use of species-specific probes, rather than QuantiNova SYBR Green PCR (QIAGEN, Germantown, MD), has been demonstrated to increase species specificity (95). The pathogen can be detected from whole blood, buffy coat, cerebrospinal fluid, and tissue samples (56, 98, 99). PCR has demonstrated serum to contain ehrlichial DNA (97), but the yield of serum in those with HME is likely much lower than the aforementioned sources. The use of multiplexed assays may be of particular interest in regions where several pathogens coexist. A quantitative multiplexed real-time PCR assay using primers for the *Ehrlichia*-specific disulfide bond formation gene (*dsb*) has been developed to detect DNA of both *E. chaffeensis* and *E. ewingii* in human blood (100).

As in the case of ehrlichiosis, those with HGA have organisms circulating in the peripheral blood (within neutrophils) that are readily detected by PCR (101, 102). Utility of PCR is greatest during early illness. The likelihood of diagnostic PCR results diminish as the patient develops antibodies and clears the organism (103). The *A. phagocytophilum p44* gene is reported to be much more sensitive than targeting the 16S rRNA gene due to the presence of a large number of *p44* paralogs in the genome (104). A loop-mediated isothermal amplification assay targeting the *msp2* gene has been developed in hopes of offering molecular diagnostics to rural areas (105). In addition to use as a diagnostic tool, molecular methods have identified new pathogens causing human disease. Melt-curve analysis of a real-time PCR assay targeting the *groEL* heat shock protein operon found melt curves outside the typical range for *E. chaffeensis*, *E. ewingii*, and *A. phagocytophilum* in several patients with a syndrome resembling HGA and HMA. Further analysis revealed a novel organism, *Ehrlichia muris*-like agent, to be the pathogenic cause (16).

Coxiella

The molecular identification of *Coxiella* is performed with both conventional and real-time PCR methods. A variety of gene targets have been studied in these assays. Sensitivity and specificity may differ depending on the assay. It appears that real-time PCR assays targeting an insertion sequence with multiple genomic copies (IS1111) are quite sensitive (106). In the diagnosis of acute Q fever, an assay that detects the IS1111 target has been touted to have a sensitivity of 98% in those tested prior to the IgM phase II antibody response. With the progressive appearance of IgM and IgG antibodies, the ability to detect *Coxiella* DNA is lost (107). Since those with chronic Q fever may experience recurrent bacteremia, blood or serum should be sent for PCR when the diagnosis is suspected. PCR may also be performed on tissue from excised heart valves or other tissues taken from the site of infection (67). A loop-mediated isothermal-amplification assay has been developed, which may serve as a platform to offer a simple and cost-effective approach to support the molecular diagnosis of Q fever in resource-limited settings. Matrix-assisted laser desorption-time of flight (MALDI-TOF) mass spectrometry is a highly reproducible method that shows promise in the molecular diagnosis of Q fever by detecting protein markers consistent with a *C. burnetii* fingerprint (108).

INTERPRETATION

The protean manifestations of the diseases described in this chapter make a definitive clinical diagnosis difficult without the use of confirmatory laboratory testing. However, several important caveats need to be considered when interpreting the aforementioned serologic and molecular diagnostic assays. The unifying principle of utmost importance is to consider the results of these tests in the context of a clinically compatible syndrome. For reasons discussed below, positive test results obtained from those without a current or preceding compatible syndrome may be difficult to interpret accurately.

Because many of these infections go unnoticed and undiagnosed, there may be a substantial number of individuals residing in endemic areas with baseline antibodies to these agents. For example, up to 11% of healthy blood donors in Westchester County, New York, have been demonstrated to have antibodies reactive to *A. phagocytophilum* by IFA (52). A serosurvey of representative individuals throughout the United States found a seroprevalence of 3.1% to *C. burnetii* (109). This underscores the importance of demonstrating seroconversion or a 4-fold rise in titers in sera obtained during acute illness and convalescence. Unlike other organisms described in this chapter, *C. burnetii* may cause chronic forms of infection. The appropriate phase I IgG-cutoff value to support the diagnosis of chronic Q fever has been disputed and depends largely on local prevalence rates (60, 73, 74). All these points highlight the need to correlate serology with clinical findings.

Cross-reactivity of serum antibodies is also a concern when interpreting serologic data. The diversity of the genus *Rickettsia* exemplifies this. An infection with a SFG organism will induce an antibody response that will react to heterologous SFG antigens (35). Therefore, in the context of a serologic assay, infection with *R. parkeri* may appear no different than an infection with *R. rickettsii*. The prevalence of nonpathogenic or mildly pathogenic rickettsiae within ticks biting humans may contribute to confusing serologic results. The SFG species, *R. amblyommii*, is highly prevalent within the tick *Amblyomma americanum*, an aggressive and nondiscriminant feeder that frequently bites humans. Exposure to *R. amblyommii* and the resultant cross-reactivity of antibodies to *R. rickettsii* have likely contributed to the skyrocketing reported incidence of RMSF in the United States (7). Although cross-reactivity between SFG and TG rickettsiae may be present, the extent is less than that of species within the same group (35). It is also possible for sera to cross-react with other bacteria, such as *Legionella* and *Proteus* species (110). Serologic cross-reactivity not only exists among members of the genus *Rickettsia*, but also exists among strains of *O. tsutsugamushi* and among species in the genus *Ehrlichia*.

Finally, establishing a serologic diagnosis is retrospective. As mentioned above, the patient's antibody response generally lags behind the symptoms of early illness. It may take 2 or more weeks for detectable antibodies to appear. Many of these infections cannot be differentiated from one another clinically in their early stage, and since some of these infections, such as RMSF, have a high case-fatality rate, treatment should not be withheld while awaiting confirmatory serologic results. Even if clinicoepidemiologic data suggest exposure to an organism of mild virulence (as in the traveler to sub-Saharan Africa with suspected African tick bite fever), early appropriate treatment can quickly alleviate fever and other systemic symptoms.

PCR-based techniques have the potential to yield useful results during an acute illness. The ability of PCR to detect the presence of bacterial nucleic acids is highly dependent on the host-target cells. For example, rickettsiae, which primarily infect the vascular endothelium, do not cause sufficient rickettsemia to allow consistent PCR amplification of rickettsial DNA from whole blood. In contrast, the monocyte and neutrophil targets of *E. chaffeensis* and

A. phagocytophilum, respectively, allow relatively easy detection in whole blood or buffy coat preparations (39). Because of the variable sensitivities of these assays, the presence of PCR inhibitors in blood samples, and the effect of bacterial clearance in those treated early with antibiotics, negative PCR results do not definitively rule out infection or preclude the use of empiric antimicrobial treatment. Although PCR-based assays offer the ability to detect only a few organisms, these exquisitely sensitive techniques can generate false-positive results due to amplicon carryover from previous reactions. In laboratories processing many clinical samples without strict separation of processing, amplification, and analysis steps, PCR contamination can render results invalid. Melt-curve analysis of real-time PCR assays may allow the differentiation between true amplification of the target gene and non-specific DNA amplification.

The *Bartonellaceae*, *Brucellaceae*, and *Francisellaceae*

CHRISTINE M. LITWIN, BURT ANDERSON,
RENEE TSOLIS, AND AMY RASLEY

52

The three families of bacteria described in this chapter share several common characteristics despite the phylogenetic distance between the group that includes *Bartonella* and *Brucella*, from the *Alphaproteobacteria*, and the more distantly related *Francisella* in the *Gammaproteobacteria* class. All three genera are zoonotic bacteria with species capable of infecting both animals and humans and are fastidious with special growth requirements; many species among these three genera cause emerging infections in humans. The diversity of natural animal reservoirs for members of the genera *Bartonella* and *Brucella* are just now becoming fully defined and appreciated and are likely all around us. *Brucella* spp. and *Francisella* spp. are well-established as agents that warrant special attention and focus because of their potential for misuse and intentional release in acts of bioterrorism or biowarfare. This chapter briefly summarizes our knowledge of the taxonomy, epidemiology, and pathobiology of these zoonotic bacteria and describes the immunologic and molecular tools for the laboratory diagnosis of infections caused by these microbes.

TAXONOMY

Bartonella

The genera *Bartonella* and *Brucella* are classified within the order *Rhizobiales*, with *Bartonella* belonging to the family *Bartonellaceae* and *Brucella* to the family *Brucellaceae* (Fig. 1). There are currently 31 validated *Bartonella* species, 11 of which have been associated with human disease. Most reported cases of human infection involve *B. bacilliformis*, *B. henselae*, or *B. quintana*. However, *B. clarridgeiae*, *B. elizabethae*, *B. vinsonii* subsp. *berkhoffii*, *B. vinsonii* subsp. *arupensis*, *B. koehlerae*, *B. alsatica*, *B. rochalimae*, and *B. grahamii* have all been associated with infections in humans.

Brucella

Brucella species have traditionally been grouped according to their ability to transmit naturally within their zoonotic reservoir hosts. Six "classical" *Brucella* species, *B. abortus* (cattle), *B melitensis* (sheep and goats), *B. suis* (swine and some wildlife species), *B. canis* (dogs), *B. ovis* (sheep), and *B. neotomae* (desert wood rat) have been described, of which the first four are able to cause zoonotic infections in humans. Recently, new *Brucella* species have been isolated from marine mammals (*B. pinnepedialis* and *B. ceti)*, from voles (*B. microti*), and from a breast implant wound (*B. inopinata*) (1, 2). While a proposal to consider all of the *Brucella* species as subspecies of *B. melitensis* has been adopted by some databases such as the National Center for Biotechnology Information, the individual species names are considered by many to provide valuable biological information and continue to be used in the literature (3).

Francisella

Francisella tularensis is a small, highly pleomorphic, Gram-negative coccobacillus and the etiologic agent of tularemia. First isolated in 1911 in Tulare County, CA, the organism was ultimately assigned to a new genus named *Francisella*, in honor of Dr. Edward Francis, who detailed the human disease decades after the organism was first described (4). Over the past century, the taxonomy of *F. tularensis* has remained complicated and ever changing due to the expanding diversity of the genus *Francisella*. *Francisella* is the sole genus in the family *Francisellaceae*, falling within the class *Gammaproteobacteria*. *Francisella* contains two established species, *F. tularensis* and *F. philomiragia*, and several newly proposed species. *F. novicida* was recently reclassified as a subspecies within *F. tularensis* rather than a species (5). Currently, *F. tularensis* contains four recognized subspecies: *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *novicida*, and *F. tularensis* subsp. *mediasiatica* (Fig. 1) (6).

EPIDEMIOLOGY

Bartonella

Cats, and in particular kittens, serve as the natural host for *B. henselae*, the main causative agent for cat scratch disease (CSD). CSD can result from a cat scratch or bite. The cat flea, *Ctenocephalides felis*, plays a critical role in the horizontal cat-to-cat transmission of *B. henselae*. Zangwill et al. found that patients with CSD were more likely to have at least one kitten that was infested with fleas, to own a kitten 12 months or younger, and to have been scratched or bitten by a kitten (7). Rare cases of CSD occur after exposure to dogs, presumably from flea bites.

CSD has a worldwide distribution and is generally a disease of children and young adults, with 80% of cases occurring in children. It infrequently causes serious illness, with the severity and presentation of disease usually related to immune status.

doi:10.1128/9781555818722.ch52

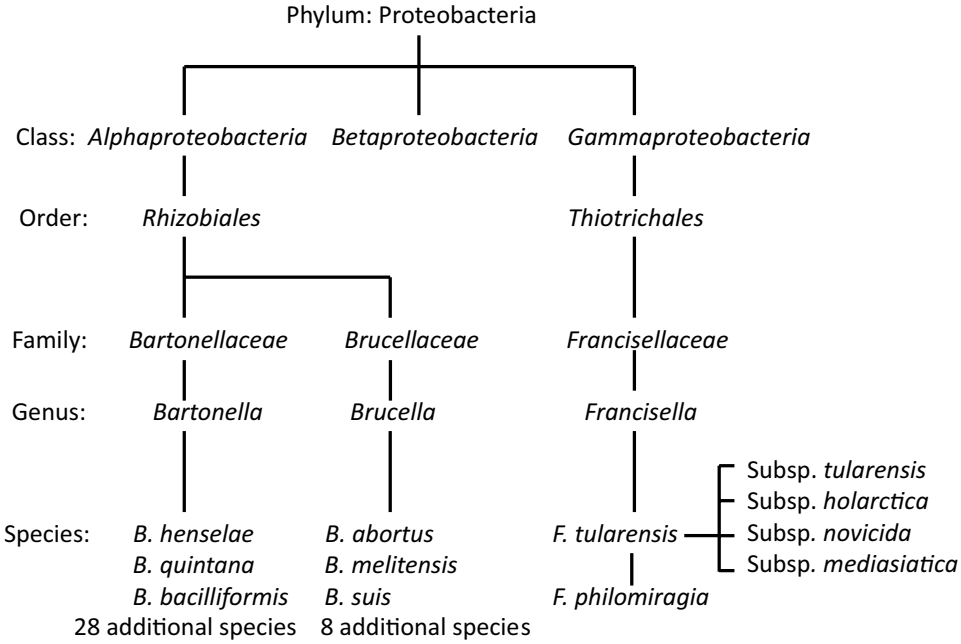

FIGURE 1 Taxonomy of the major human pathogens in the families *Bartonellaceae*, *Brucellaceae*, and *Francisellaceae*. Additional *Bartonella* spp. and *Brucella* spp. not shown here have also been associated with human disease but are not listed due to space constraints. Members of the *Bartonella* and *Brucella* genera are *Alphaproteobacteria*, while members of the genus *Francisella* are *Gammaproteobacteria*.

However, there have been accounts of severe disease such as endocarditis, persistent bacteremia, and bacillary angiomatosis reported in immune-competent individuals. On the other hand, CSD-like symptoms can also occur in immunocompromised patients and have been described in patients who have undergone solid organ transplantation. Contact with cats and previous valvular disease serve as the major risk factors for *B. henselae* endocarditis. HIV-infected patients with bacillary angiomatosis and bacillary peliosis caused by *B. henselae* also usually have an epidemiologic link to cat exposure.

During World War I, *B. quintana* infection became a major source of morbidity and mortality among soldiers and was commonly known as trench fever. Lice generally have been considered to be the major vector for *B. quintana* in classic trench fever. Three lice species, *Pediculus humanus* var. *capitis* (head louse), *P. humanus* var. *corporis* (body louse), and *P. humanus* var. *pubis* (pubic louse), can potentially transmit *B. quintana*. The body louse is felt to be the predominant vector. After World War II, reports of *B. quintana* infections were rare until infections with HIV were described. Both *B. henselae* and *B. quintana* can cause bacillary angiomatosis, especially in HIV patients. Homelessness, alcoholism, and body lice are now the major risk factors associated with contemporary *B. quintana* trench fever infections, bacteremia, and endocarditis (8).

Bartonellosis (or Carrion's disease) caused by *B. bacilliformis* is usually confined to limited areas of South America within the Andes, with the sand fly (*Lutzomyia verrucarum*) as the presumed vector in Peru. Occasional cases among travelers to other countries in South America such as Ecuador and Colombia suggests that other additional vectors may be involved in the transmission of *B. bacilliformis*.

Brucella

Brucellosis is a zoonotic infection with worldwide distribution. In the United States, brucellosis is mainly associated with travel to areas of endemicity such as the Middle East, the Balkan peninsula, Central Asia, and countries of Latin America, especially Mexico and Peru (9). However, in these areas, brucellosis is encountered frequently and is a significant cause of morbidity and disability, with an estimated 500,000 new cases annually.

The majority of brucellosis cases result from consumption of unpasteurized dairy products, especially goat's milk and cheese. In individuals with occupational exposure to *Brucella*-infected animals, infection may occur via mucosal or respiratory routes or via breaks in the skin. *Brucella* spp. can form highly infectious aerosols during manipulation of cultures in the laboratory, and for this reason, brucellosis is one of the most frequently reported laboratory-acquired infections (10).

Francisella

Tularemia is a zoonotic disease transmissible by inoculation, ingestion, or inhalation of *F. tularensis* (6). Clinical disease is caused largely by *F. tularensis* subsp. *tularensis* (type A strains), endemic in North America, and *F. tularensis* subsp. *holarctica* (type B strains), endemic in the terrestrial ecozones comprising the holarctic regions (6). The association of type A strains with lagomorphs and type B strains with rodents and aquatic environments is well described (6). Geographically, the distribution of type A and type B strains appears largely similar in the United States.

CLINICAL MANIFESTATIONS

Bartonella

The clinical syndromes associated with *Bartonella* species are varied and include CSD, cutaneous bacillary angiomatosis (BA), extracutaneous infection such as bacillary peliosis, fever with bacteremia, trench fever, and endocarditis (11).

CSD typically presents as a subacute regional lymphadenitis with an associated inoculation site due to a cat scratch or bite. With the originally described trench fever, symptoms are usually described as an abrupt-onset high fever, severe frontal or retro-orbital headache, rash, conjunctivitis, and bone and muscle tenderness, particularly involving the shins. In urban trench fever, the symptoms described above are present more variably and are less prevalent than in the initial description of the disease.

Disseminated infections by *B. henselae* or *B. quintana* have been reported in both immunocompetent and immunocompromised patients but are far more common in the latter group. In HIV-infected patients with BA, multiple cutaneous and interstitial subcutaneous nodules that contain bacteria are present. These nodular lesions have a unique histopathology characterized by proliferation of endothelial cells and angiogenesis, similar to that observed in the verruga peruana resulting from infection with *B. bacilliformis*.

B. bacilliformis causes Oroya fever and verruga peruana. The bacteremia of Oroya fever begins 3 to 12 weeks after a bite from an infected sand fly. The illness may range from mild to very severe. In severe cases, fever, chills, headache, sweating, aches, dyspnea, mental status changes, and seizure may occur. Verruga peruana occurs after organisms invade capillary endothelial cells and produce hemangioma-like nodules in the skin and mucous membranes. Verruga peruana can appear 2 to 8 weeks after the patient has apparently recovered from Oroya fever, although most patients do not have a previous history of febrile illness.

Brucella

Brucellosis is a febrile illness characterized by an acute or gradual onset of symptoms, including night sweats, fatigue, weight loss, lack of appetite, headache, and joint and muscle pain. In addition to constitutional symptoms, enlargement of the spleen, liver, or lymph nodes is present in a subset of patients; these result from localization of bacteria to the mononuclear phagocyte system. Focal complications of brucellosis are most frequent in the large, weight-bearing joints and in the spine; however, any organ may be affected. Brucellosis is difficult to diagnose, especially in areas where it is not endemic such as North America. The rare occurrence and nonspecific presentation of brucellosis in these areas often result in a failure of clinicians to consider brucellosis as a possible diagnosis.

Three species of *Brucella* have a high zoonotic potential: *B. melitensis*, *B. abortus*, and *B. suis*. *B. melitensis*, which has goats and sheep as its zoonotic reservoirs, is by far the most common cause of human infection and is most frequently acquired via consumption of unpasteurized goat's milk and cheese. *B. abortus* naturally infects cattle, and while some reports of foodborne infection exist, these appear to be less common than those caused by *B. melitensis*. Occupational infections with *B. abortus*, *B. melitensis*, and *B. suis* have been reported in veterinarians, farmers, abbatoir workers, and laboratorians. Human infection with a fourth species, *B. canis*, is infrequently reported and results from transmission from infected dogs (12).

Francisella

Six clinical forms of tularemia, caused mainly by *F. tularensis* subsp. *tularensis* and subsp. *holarctica*, have been described to date in which the type and severity of disease depend on the infecting strain, dose, and route of infection (13). Although disease caused by *F. tularensis* type A strains can be severely debilitating and even fatal, diagnoses of disease caused by less virulent strains remains problematic due to the nondescript nature of the symptoms.

Infection through the skin, following the bite of an infected vector or through direct contact with infected animals, results in ulceroglandular and glandular tularemia. Ulceroglandular tularemia is the most common clinical presentation. Nondescript flulike symptoms can occur abruptly following a relatively short incubation period (3 to 6 days). In the case of ulceroglandular disease, a localized ulcer develops at the site of infection. Subsequent bacterial dissemination from the inoculation site results in enlarged draining lymph nodes resembling the classic bubo associated with bubonic plague. Systemic dissemination can occur, yet this form of disease is rarely fatal. The clinical presentation of glandular tularemia is very similar, but the formation of an ulcer at the inoculation site does not occur (13). Oculoglandular tularemia is a rare presentation of disease in which the conjunctiva is the initial site of infection, usually as a result of inadvertent transfer of the bacteria present on an individual's fingertips to the eye.

Oral exposure can result in oropharyngeal or gastrointestinal tularemia, often via ingestion of infected foods or drinking water. Sore throat and enlarged tonsils and cervical lymph nodes often accompany oropharyngeal disease, while gastrointestinal tularemia is characterized by abdominal pain and mild diarrhea. If the infectious dose is high, an acute, potentially life-threatening disease marked by extensive ulceration of the bowel may ensue.

Typhoidal tularemia is a systemic form of disease, although the route of infection is unknown. Clinical presentation includes septicemia without lymphadenopathy or formation of an ulcer; mortality rates of 30 to 60% have been reported.

Inhalation of *F. tularensis* subsp. *tularensis* or subsp. *holarctica* can result in pneumonic tularemia, which can also develop as a secondary complication of ulceroglandular disease. Clinical presentation of pneumonic disease can vary widely and may or may not include ulcers, dry cough, and chest pain or be accompanied by pneumonia. Inhalational pneumonic disease is considered the most acute form of tularemia, with a reported case-fatality rate of approximately 40%. Naturally occurring cases of inhalation tularemia have been associated with agriculture and/or landscaping activities that promote the generation of infectious aerosols.

LABORATORY DIAGNOSIS

Bartonella

Microbiologic Culture

Since most *Bartonella* isolates require a 2-to 6-week incubation for primary isolation, routine bacterial culture methods usually do not allow *Bartonella* spp. to be detected. Specialized procedures are needed for the isolation of *Bartonella* from tissue and blood. Isolation and culture of *Bartonella* spp. are covered in detail in the 11th edition of the *Manual of Clinical Microbiology*.

Serology

Indirect Fluorescent Antibody Assay

Serology is used frequently for diagnosing infections with *Bartonella* spp., since culture is usually not feasible. The indirect fluorescent antibody (IFA) (14) assay is the most routinely used method for the detection of *B. henselae* and *B. quintana* antibodies. Originally developed by Regnery et al. (15), IFA uses a Vero cell cocultivated antigen to reduce the autoadherent nature of the bacterium.

Interpretation of test results. A positive IgM titer of ≥16 is indicative of acute infection. The use of IgM serology can be somewhat limited since the window of IgM production is often very early and minimal. Often, patients present to clinicians with symptoms (e.g., lymphadenopathy in CSD) and are tested long after IgM titers have reverted to negative (16).

A positive IgG titer of >1:64 is suggestive of recent infection. Stronger evidence of recent infection is a 4-fold or greater rise in IgG titer in acute-and convalescent-phase serum samples drawn at least 2 weeks apart. Serial measurements of antibody titers is highly recommended since antibody titers may remain high above controls for a year or more after infection. Initial titers of ≥1:64–256 are generally considered seropositive for *Bartonella* spp. infection. However, very high titers of ≥800 suggest a clinical diagnosis of *Bartonella* endocarditis.

Although there is widespread use of the IFA methodology, the assays often demonstrate wide variations in sensitivities and specificities in different in-house preparations and commercially manufactured IFAs. Numerous cross-reactivity issues have also been found with the IFA. Sensitivities for the IgM IFA assay vary between 54–98% and 69–96% for the IgG assay, according to numerous publications (17). Overall, the sensitivity of the IFA does not appear to be optimal, especially with the IgG assays.

Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA) is used by a few commercial laboratories for the detection of *B. henselae* antibodies (18, 19). Many in-house ELISA assays use *B. henselae* sonicated (whole-cell) proteins or outer membrane proteins fractionated by *N*-lauroyl-sarcosine (insoluble or soluble) (18). IgM ELISAs have been reported to also show wide variations in accuracy, with sensitivities and specificities ranging between 53–75% and 91–100%, respectively. IgG ELISAs tend to show sensitivities and specificities ranging from 28–77% to 91–94%, respectively (17).

A recombinant *B. henselae* 17-kDa antigen first described by Anderson et al. (20) has been developed into a commercial IgG ELISA with a reported sensitivity and specificity of 71.1% and 93.0%, respectively (21). An IgM-capture ELISA-based assay has also been developed using this antigen, with sensitivity and specificity values of 100% and 97.1%, respectively, based on comparisons with *B. henselae* IgM IFA IgM-negative and positive samples (19). IFA, indirect hemagglutination, and ELISA tests are available for the detection of antibodies to *B. bacilliformis*. Cutoffs for determining a positive, negative, or equivocal ELISA result vary with the manufacturer.

Interpretation of test results. Immunologic cross-reactivity as a result of conserved epitope recognition across species occurs frequently for many bacterial serological assays, including the *Bartonella* antibody assays. The first serological cross-reactivity between a *Bartonella* species and a heterologous pathogen was first reported in 1976 by Cooper et al. (22) when *C. burnetii* (Q fever) antibody-positive sera were discovered to cross-react and cause false-positive reactions with the hemagglutination test used in the diagnosis of trench fever (*B. quintana*).

Since that first publication, numerous cross-reactions have been cited with other bacterial and viral agents, including *Afipia felis*, *Anaplasma phagocytophila*, *Brucella* spp., *Chlamydophila pneumoniae*, *Chlamydia psittaci*, *C. trachomatis*, cytomegalovirus, Epstein-Barr virus, *Ehrlichia canis*, *Orientia tsutsugamushi*, *Rickettsia conorii*, *Rickettsia prowazekii*, *Rickettsia rickettsii*, and *Rickettsia typhi* (22–24). Studies using serologic assays other than the IFA, including ELISA, Western blot, immunoperoxidase staining, immunohistochemistry, and the passive hemagglutination test, have all described significant cross-reactivities, especially between *B. henselae* and *B. quintana* in patients with confirmed or suspected CSD or bacillary angiomatosis (22–24). Due to this high degree of cross-reactivity, most reference labs include both *B. quintana* and *B. henselae* in their antigenic panel of serologic assays. The degree of antibody reaction to either species in the IFA can then allow inference about which species might be responsible for a particular infection. The titer of the infecting organism is typically higher than the titer of the noninfecting organism. This is more important when the species can cause overlapping infections such as fever with bacteremia, endocarditis, or bacillary angiomatosis but is less important with CSD.

Other Immunological Methods

CSD typically produces primary inoculation papules followed a number of weeks later by lymphadenopathy, whereas bacillary angiomatosis produces cutaneous or subcutaneous angiomatous lesions. Microscopic evaluation of infected tissue using more specific immunohistochemistry, along with the Warthin-Starry (silver impregnation) stain, has been used to give a pathologic diagnosis of *Bartonella* spp. infection, especially in cases of CSD, bacillary angiomatosis, and endocarditis (25). Warthin-Starry stains have historically been the preferred method for the detection of *Bartonella* species. The use of this stain for diagnostic purposes is technically challenging due to the high background of silver precipitate in the tissue, which may result in false-positive diagnoses.

Lymph node removal or biopsy may be performed to determine the cause of lymphadenopathy or angiomatous lesion. The histologic findings of CSD (i.e., lymphadenopathy) may be nonspecific and the findings may be dependent on the stage of the disease. Nonspecific reactive follicular hyperplasia is usually seen early in disease. Later in disease, the lymph nodes develop stellate suppurative granulomas with acellular necrotic centers with a surrounding zone of histiocytes and an outer zone of plasma cells and lymphocytes. Immunoreactive bacteria are usually identified within the areas of necrosis in the suppurative granulomas. The typical angiomatous lesions of bacillary angiomatosis produce characteristic lobular proliferations of blood vessels histologically distinct from the granulomatous lymph node lesions of CSD. The immunoreactive bacteria are identified within the proliferative endothelial cells in the blood vessels. In patients with *Bartonella* endocarditis, clusters of bacteria are usually seen in an extracellular location in the fibrin deposits, mainly in the valvular vegetation.

As a rule, the immunohistochemical assay is performed on formalin-fixed, paraffin-embedded sections of embedded lymph nodes or biopsy tissue that are routinely sectioned to 5-mm-thick slices. A commercially available monoclonal antibody specific for *B. henselae* (clone H2A10; Biocare Medical, Concord, CA) is available. For the H2A10 clone, cross-reactivity tests were performed with *B. quintana*, *B. elizabethae*, *B. grahamii*, *B. taylorii*, *B. doshiae*, and *B. vinsonii* strains. Reactivity was obtained only with *B. henselae*.

A polyclonal rabbit antibody that does not differentiate between *B. henselae* and *B. quintana* can be used to detect CSD, bacillary angiomatosis, and peliosis hepatis. In a study by Caponetti et al. (25) on patients with suspected CSD, immunohistochemical analysis was positive in 25% of cases and PCR was positive in 38% of 22 patients with

lymphadenopathy and histopathological findings compatible with CSD. Overall, the diagnostic sensitivity of immunohistochemical analysis is low for the detection of *B. henselae* in tissue. PCR is slightly more sensitive than immunohistochemical analysis and should be performed on all cases negative by immunohistochemical analysis. Warthin-Starry seems to be the most sensitive test, but it is the least specific for *Bartonella* because of issues with background staining.

Molecular Diagnosis

PCR has played an important role in the association of *Bartonella* spp. with new disease syndromes. In fact, the initial association of *Bartonella* (then *Rochalimaea*) with bacillary angiomatosis resulted from the amplification and subsequent sequencing of 16S rRNA genes from the lesions of patients with bacillary angiomatosis (26). A similar approach, when applied to preparations of CSD skin test antigens, identified only the *B. henselae* 16S rRNA gene sequence, which provided compelling evidence that the delayed hypersensitivity reaction, used for many years to diagnose CSD, was elicited by a *B. henselae* antigen (27).

Currently, most applications of PCR in the clinical microbiology laboratory fall primarily into two areas. The first is the identification and strain typing of *Bartonella* isolates, a powerful tool for research microbiologists but somewhat impractical and time-consuming in the clinical laboratory since it relies on growth of the *Bartonella* isolates. The second is the detection of *Bartonella* DNA directly in clinical specimens. Recently, a strategy was described that combined enrichment culture in liquid media of bartonellae from clinical specimens, followed by PCR for detection and identification (28). PCR identification from clinical specimens is currently available only in a few select reference laboratories.

Initial approaches for PCR of *Bartonella* used primers to amplify all or part of the 16S rRNA gene coupled with sequencing (26, 29). However, the utility of the 16S RNA gene as a means of species identification is limited, as it is highly conserved among *Bartonella* spp. (30). Many other target genes have been used for PCR detection of *Bartonella*, including specific primers for serine protease (*htrA*) (31, 32); NADH dehydrogenase gamma subunit (*nuoG*) (33); RNA polymerase beta subunit (*rpoB*) (33); heme-binding protein A/Pap31 (*hbpA/pap31*) (34); the intergenic region between the 16S and 23S rRNA genes (35); and tmRNA (*ssrA*) (36). Newer approaches utilizing real-time PCR have been described which shorten the time to obtain results. Liberto et al. used real-time PCR to detect the *Bartonella bqtR* transcriptional regulator gene in blood specimens and demonstrated differential melting curves to specifically distinguish *B. henselae* from *B. quintana* (37). Diaz et al. utilized real-time PCR of the *ssrA* gene coupled with sequencing to differentiate among *Bartonella* species DNA amplified from blood specimens collected from wild and domestic animals (36). More recently, a two-step approach using real-time PCR of the *gltA* gene and pyrosequencing was applied to clinical specimens to detect and differentiate *Bartonella* species (38). However, currently, there is no consensus on the optimal approach to detect *Bartonella* DNA or RNA in clinical specimens, and a wide range of methods is employed by both commercial and reference laboratories.

Brucella

Microbiologic Culture

Definitive diagnosis of human brucellosis requires the isolation of *Brucella* spp. from clinical specimens such as blood, bone marrow, or joint aspirates. The success in obtaining positive blood cultures from patients varies, depending on the stage of the disease and the culture methods. In patients presenting acutely with brucellosis, between 40 and 90% of patients are culture positive, while in patients presenting with focal, chronic or recurrent infection, this decreases to 5 to 20% (39). Culture from bone marrow and lysis centrifugation have been shown to improve culture yields in patients with brucellosis. Methods for isolation and culture of *Brucella* spp. are detailed in chapter 47 of the *Manual of Clinical Microbiology*, 11th ed. (40), and a detailed comparison of yields from different culture methods can be found in reference 39.

Serology

Serum Agglutination Test (SAT)

Because of the long incubation time for primary culture, difficulty in reliable isolation of *Brucella* spp. from clinical specimens, and biohazards associated with culturing *Brucella* in the laboratory, serological assays are important tools for the rapid diagnosis of brucellosis. The humoral response to *Brucella* infection is dominated by antibodies specific for the O-polysaccharide moiety of lipopolysaccharide (LPS). During the early stage of primary infection, IgM predominates, while later during the course of infection, IgG and IgA can be detected (41). Early during the course of infection, serologic results may be negative, and if the patient's clinical presentation and history are consistent with brucellosis, it is important to perform a repeat serology test after 2 weeks (42). A shortcoming of all serological tests is the lack of standardization of the antigen preparations, and this can influence the sensitivity and specificity of these assays. Further, agglutination tests tend to lack sensitivity in patients with chronic or complicated brucellosis (39–43). For suspected infections with *B. canis* or with the veterinary vaccine RB51, which do not make the LPS O-antigen, serologic testing is not available.

The serum agglutination test (SAT), which detects IgM, IgA, and IgG responses to *Brucella* infection, is considered to be the definitive test because of its sensitivity and specificity. The test is performed by incubating a fixed volume and concentration of an inactivated *Brucella* cell suspension with doubling serial dilutions of serum for 24 h. The highest dilution with more than 50% of the suspension agglutinated is the titer.

Interpretation of test results. In areas of nonendemicity, an agglutination titer of ≥1:160, or a 4-fold rise in titers between acute-and convalescent-phase samples, is considered to be positive in symptomatic patients. In areas of endemicity, repeated exposure to *Brucella* or previous infection may lead to persistently elevated agglutination titers in the absence of an active infection, which must be considered when interpreting serology results. In the United States, because of the low number of suspected cases and the need for standardized assay conditions, the SAT is performed primarily by reference laboratories. A variation on this test, the microagglutination test (MAT), uses a microtiter format.

Rose Bengal Test

A second agglutination test, the Rose Bengal test, is a rapid slide agglutination test that utilizes a stained suspension of *B. abortus* buffered to a pH of 3.65 to inhibit nonspecific agglutinins (44). Rose Bengal is an inexpensive, simple, and sensitive test that can be performed rapidly in resource-limited settings.

Interpretation of test results. While studies with smaller numbers of samples have found the Rose Bengal test to have lower sensitivity than the SAT, a recent large-scale comparative study found that use of the Rose Bengal test with serum dilutions yielded a sensitivity and specificity similar to those of the SAT (45). While the Rose Bengal test performs well under optimal conditions, the varying sensitivity and specificity reported in the literature for this test has led to a recommendation by the World Health Organization that the results of the Rose Bengal test be confirmed by a second test method (46).

ELISA

Several commercial vendors offer ELISA kits for detection of *Brucella*-specific IgG and IgM, and in-house assays have been developed using *Brucella* antigen as well. ELISA has been reported to perform well in an area of endemicity (47). Further, it can be performed within a few hours and was shown to be superior to agglutination assays in diagnosis of chronic brucellosis (43). In an area of nonendemicity, IgM ELISA was reported to yield some false-positive results (48, 49). As a result, confirmation of positive ELISA results with serial sampling and a second test method, such as SAT, has been recommended (48).

Other Antibody Detection Assays

The Coombs test is used as a follow up to a negative SAT to detect incomplete, blocking, or non-agglutinating antibodies (50). In this test, the cell suspensions from the negative SAT are centrifuged. The resulting cell pellets are washed and incubated with anti-human IgG, then incubated to detect agglutination. The Coombs test is useful for complicated and chronic cases, in which it was shown to yield titers from 16-to 256-fold higher than the SAT (51). A second assay for the detection of nonagglutinating antibodies is the Brucellacapt (Vircell, Santa Fe, Spain), a commercially available immunocapture test for total anti-*Brucella* antibodies (52). This assay is simple to perform but was found to be inferior to the Coombs test for following small changes in antibody titer in chronically infected patients (53).

Interpretation of test results. Serologic tests continue to play an important role in diagnosis of brucellosis in the clinical laboratory. These assays are well suited for use in areas of endemicity because of their low cost and low degree of technical complexity. However, for each area, the appropriate cutoff for positive serology should be determined based on the regional prevalence of positive-serology *Brucella* spp. in the healthy population.

The interpretation of serologic test results for brucellosis requires consideration of the clinical presentation and the patient's detailed history, including possibility of zoonotic or occupational exposure to the agent. For patients with confirmed brucellosis, serological tests are used to monitor treatment progress. Declining antibody titers with antibiotic treatment are indicative of a good prognosis, while a rebound in titers suggests possible relapse or reinfection (43).

It should be emphasized that a single negative serology result is insufficient to rule out brucellosis. Since some patients may be seronegative at disease onset, paired serum samples taken at presentation and 2 weeks later should be compared and/or a second serologic test should be performed. *B. canis* and some of the newly described *Brucella* species differ in their LPS composition from the other zoonotic species and can therefore be missed using serologic assays based on LPS-containing antigen preparations from *B. abortus* or *B. melitensis* (54). A second instance in which serologic tests may fail to detect infection is occupational exposure to the veterinary vaccine strain RB51, which does not harbor the serodominant LPS O-antigen. In this case, high-risk exposures may warrant postexposure antibiotic prophylaxis (55).

In areas of endemicity, repeated exposure to *Brucella* spp., or past infection, may cause persistently high IgG titers in the absence of active infection. Since serology is based primarily on antibody responses to LPS, infections with bacteria that share epitopes on their LPS, including *Escherichia coli* O157, *Yersinia enterocolitica* O9, *Vibrio cholerae*, *Salmonella enterica* serotype Urbana, and *Francisella tularensis*, could elicit positive responses in the serological tests for brucellosis (56). However, in this case, the patient would not be expected to have the 4-fold increase in anti-*Brucella* titer between acute-and convalescent-phase sera that is required for a definitive diagnosis (43). In the United States, brucellosis is a reportable disease, and *Brucella* spp. are among the organisms that have been developed as bioweapons; therefore, a confirmed case of brucellosis in an individual with no history of exposure could prompt concerns of bioterrorism as well as a costly epidemiologic investigation by public health authorities (48). For this reason, a diagnosis based on serology in the absence of a positive culture result should utilize two independent test results and be prompted by a compatible clinical presentation and patient history.

Molecular Diagnosis

PCR has been shown to be a rapid and highly sensitive way to detect *Brucella* spp. DNA in serum and tissue samples (57). Multiple targets for PCR assays have been evaluated and have been shown to have differing levels of sensitivity. The 16S-23S rRNA spacer region, present in three copies in the genomes of *B. abortus*, *B. suis*, and *B. melitensis*, has shown promise as a diagnostic target; however, standardization is necessary. *Brucella* spp. DNA has been detected in circulation weeks to months after successful antibiotic treatment and resolution of symptoms, so a positive PCR result may not always be indicative of an active infection with *Brucella* spp. (58). PCR tests for the diagnosis of *Brucella* infection are offered only in a few reference laboratories and are not available commercially.

Francisella

Microbiologic Culture

Tularemia can be diagnosed by culturing the isolate from relevant clinical samples, by antigenic and molecular detection methodologies, and by serological analyses. *F. tularensis* is a notoriously fastidious organism that is difficult to culture, requires advanced containment laboratories, and is potentially hazardous to laboratory personnel, underscoring the challenges of recovery and culture of an isolate directly from clinical specimens. Isolation and culture of *Bartonella* spp. is covered in detail in the 11th edition of the *Manual of Clinical Microbiology*.

Serology

Serology relies on the presence of anti-*F. tularensis* antibodies and has been used historically for definitive diagnosis of tularemia, yet cross-reactivity has been observed (59). As such, most cases of tularemia are diagnosed qualitatively based on clinical presentation of symptoms compatible with tularemia coupled with semiquantitative serology.

Tube Agglutination and Microagglutination

During the course of infection, peak antibody responses typically occur during the end of the second week after

disease onset, at which point titers begin to decline slowly upon recovery from disease, although these antibody responses can be long-lived, having been shown to persist for years. Two agglutination methodologies, tube agglutination and microagglutination (MA), demonstrate marked sensitivity and specificity (59).

Interpretation of test results. When an individual presents clinically with symptoms compatible with tularemia, *F. tularensis* antibody titers of ≥160 during the acute phase of the disease support a presumptive tularemia diagnosis. Definitive tularemia diagnosis relies on a 4-fold rise in *F. tularensis* antibody titers between acute- and convalescent-phase sera, usually 2 to 4 weeks. While cross-reactivity has been reported at low titers with serum from patients with brucellosis or yersiniosis, the specificity of serology for tularemia is high. However, a titer ≥160 may also reflect past infection and may not be indicative of active disease (59), underscoring the importance of considering clinical symptoms in combination with serology for disease diagnosis.

ELISA

In addition to agglutination assays, a variety of ELISAs have been described, most of which use *F. tularensis*-derived LPS as antigen. ELISA detection methodologies have also been shown to achieve high degrees of sensitivity and specificity and also allow for the differentiation of antibody isotypes (60). More important, ELISA cannot distinguish past *F. tularensis* infections from current infections. A competitive ELISA (cELISA) assay was recently developed, based on the ability of serum antibodies to inhibit the binding of monoclonal antibodies (MAbs) directed against *F. tularensis* lipopolysaccharide antigens, and was reported to exhibit superior levels of sensitivity and specificity for serodiagnosis of human disease compared with the standard MA method (61).

More recently, a strategy termed *in vivo* microbial antigen discovery (InMAD) was reported for the identification of *F. tularensis* antigens that are shed into serum in mice during infection. While preliminary, such a strategy could ultimately lead to a more rapid diagnosis of *F. tularensis*, thereby facilitating timely, effective treatment of disease (62). In addition, recent efforts—comparing both commercially available and noncommercial immunochromatographic assay (ICA) (63) for tularemia diagnostics with the traditional, gold-standard MA assay—demonstrated that ICA achieved similar levels of sensitivity and specificity as MA, and the commercial ICA exhibited no cross-reactivity when screened against human immune and nonimmune sera. The ease of use of ICA indicates that this method could be more broadly adapted for tularemia diagnostics.

Immunological Methods

Immunofluorescence analysis has been broadly applied to detect *F. tularensis* in wild animal carcasses and laboratory necropsy specimens, but it has not been widely applied for the diagnosis of human tularemia due, in large part, to the lack of specialized reagents and media, the qualitative nature of the technique, and the inherently weak staining of *F. tularensis* using standard reagents.

The direct fluorescence antibody (DFA) assay, based on the use of fluorescein isothiocyanate (FITC)-labeled anti-whole cell *F. tularensis*, is a rapid and specific test used routinely for the identification of *F. tularensis* (type A and type B) by the Centers for Disease Control and Prevention. It should be noted that the DFA has sensitivity limitations, and in rare cases of infection caused by *F. philomiragia* or *F. tularensis* subsp. *novicida*, DFA results were negative (64, 65).

Molecular Methods

The development of molecular-based assays remains paramount both for the detection of *F. tularensis* and for the diagnosis of disease. Over the years, myriad PCR-based methodologies have emerged for tularemia diagnostics, and subsequent iterations of these assays have led to improved limits of detection and more rapid sample processing (66–68). PCR has been increasingly utilized to diagnose human disease, as culture of *F. tularensis* directly from human samples, long considered the gold standard for definitive diagnosis, remains challenging for the reasons mentioned above. The development of PCR assays for tularemia diagnostics have largely focused on targeting genes encoding the outer membrane lipoproteins Tul4 and FopA, as well as the *isfut2* insertion sequence element (69). Sequencing methodologies have recently been employed for the rapid identification of suspected isolates of *Francisella* species in clinical or environmental samples (70).

We would like to thank Christopher Polage for helpful discussions during the preparation of this section.

Mycotic and Parasitic Diseases

section I

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: THOMAS B. NUTMAN

Introduction

THOMAS B. NUTMAN

53

Combining the sections on parasitic and fungal infections into one unit stems not so much from the similarity between parasites and fungi but rather from their not being part of the infectious diseases mainstream. From a phylogenetic perspective, parasites (even the single-cell protozoa) differ from the fungi by a considerable evolutionary distance; interestingly, based on phylogenetic analyses, the differences between protozoan parasites and fungi are less significant than the differences between protozoa and helminth parasites.

Parasitic diseases are historically defined as infectious illnesses caused by unicellular protozoa or multicellular helminths distinct from viral, bacterial, or fungal etiologic agents. They are the special health care problem of tropical and subtropical countries, where their marked prevalence imposes major medical and economic burdens. These infections afflict billions of people worldwide and are responsible for millions of deaths every year. The importance of parasitic illness has received recent additional emphasis by the emergence of *Toxoplasma*, *Leishmania*, *Cryptosporidium*, and *Strongyloides* as pathogens in patients who are immunosuppressed.

Both protozoan and helminth pathogens have characteristically complex life cycles, often with two or more developmental stages present in the host during infection. Because each stage of parasite development may be antigenically distinct, protozoan or helminth infections are often characterized by a series of discrete immune responses that evolve at different times during the course of disease. Immune responses directed against a single stage may be circumvented by parasite differentiation. Each stage of parasite development may also entail a change in tissue trophism, introducing a compartmental feature to the immune responses. This temporal evolution of antigenic complexity and tissue trophism is unique to parasite immunology and further distinguishes this field from that of viral, fungal, or bacterial immunology.

Nevertheless, the immunology and molecular biology of fungal and parasitic infections converge at several levels. First, based on parasite and yeast genomics, many of the diagnostic antigens used for both parasitic and fungal infections are more specific now than heretofore. Moreover, since the diagnosis of mycotic infections cannot always be definitively addressed by culture or histology, the diagnosis of most parasitic infections has relied most commonly on the identification of the organism in appropriately collected specimens. At present, diagnoses of both mycotic and parasitic infections are most often based on immunologic and molecular methods of diagnosis.

Indeed, antigen detection immunoassays have been extraordinarily useful in diagnosing infections caused by *Aspergillus*, *Candida*, *Cryptococcus*, *Histoplasma*, and *Paracoccidioides* among the fungi and in parasitic infections caused by *Entamoeba*, *Giardia*, *Cryptosporidium*, *Wuchereria*, and *Plasmodium*. Many of these antigen detection systems have moved into the commercial arena and are available for use. In contrast, PCR-based assays, although definitive in many instances, are not in widespread use, but a number of multiplex platforms are becoming available for clinical microbiology laboratories, albeit at a significant cost.

Continued efforts to improve the predictive value (both positive and negative) of immunologically and molecularly based assays will remain the major goal of those interested in the diagnosis of both mycotic and parasitic infections. Although heralded as the new diagnostic gold standard, molecularly based assays are not yet in the mainstream. Notwithstanding the cost of molecular assays and issues related to quality control, the time required for sample preparation, PCR itself, and detection of the product suggests that other methods for diagnosis of fungal and parasitic infections are on the horizon, with the most hope placed on rapid antigen detection systems or nonisothermal DNA amplification.

Immunological and Molecular Approaches for the Diagnosis of Parasitic Infections

PATRICIA P. WILKINS AND THOMAS B. NUTMAN

54

Definitive diagnosis of parasitic infections is made by identification of parasites in properly collected specimens or in affected tissues. Microscopy for observation and identification of parasites is the laboratory method of choice for the diagnosis of some important parasitic infections, namely, malaria, babesiosis, and enteric parasitic infections. There are, however, important parasitic diseases that cannot be diagnosed by microscopic examination of clinical specimens. In infections such as angiostrongyliasis, schistosomiasis, paragonimiasis, and strongyloidiasis, parasites may be detected in stool or other specimens, but due to the limitations of intermittent shedding or sampling, direct observation of parasites is not sensitive or reliable. So, for these infections and others caused by parasites that are localized and sequestered in tissues, such as baylisascariasis, cysticercosis, echinococcosis, toxocariasis, toxoplasmosis, or trichinellosis, detection of specific antibodies is almost always required to confirm clinical suspicion.

Most parasitic infections induce a vigorous humoral immune response, so the presence of parasite-specific antibodies can be a valuable indicator of infection, especially if the patient has no prior history of exposure. The presence of specific antibodies, however, does not necessarily indicate current infection in a patient who resides or has recently lived in an area of endemicity. In general, detection of antibodies to parasitic antigens indicates infection at some indeterminate time and not necessarily acute or current infection. Parasite-specific antibodies may persist for as little as 6 months after infection or treatment or for many years, depending on the infecting parasite.

The humoral immune response usually precedes clinical manifestations for most parasitic infections; therefore, IgG is being produced by the time serological testing is considered, making collection of acute-phase serum specimens and the ordering of assays to detect parasite-specific IgM-based assays unnecessary. Detection of IgA and IgE alone is not informative, so tests for parasite-specific IgG are the primary tests that should be ordered. The notable exception to this is detection of *Toxoplasma*-specific IgM and IgA as indicators of acute neonatal toxoplasmosis. In some cases, detection of parasite-specific IgG4 has proven useful and more specific than detection of parasite-specific IgG (1–4). IgG4 detection has been shown to be particularly useful for the diagnosis of filarial infections (5). In many cases, if infection with a parasite is suspected and blood film, stool, or urine examinations are either not indicated or negative, then a serology test for parasite-specific Ig/IgG antibodies should be requested. If the test for parasite-specific IgG is negative, a positive IgM, IgA, or IgE result is generally a false-positive reaction and should be interpreted with caution.

Serological testing for parasitic diseases is limited to a few commercial laboratories in the United States (Table 1), with confirmatory testing available at the Centers for Disease Control and Prevention (CDC). Commercial laboratories and the CDC utilize a combination of test types: commercial kits that are approved or cleared by the U.S. Food and Drug Administration (FDA) for *in vitro* diagnostic use, commercial kits that are manufactured for research use only, and laboratory-developed tests. Federal regulations require that laboratories conduct rigorous evaluations when commercial kits designated for research use and laboratory-developed tests are adopted for clinical diagnosis. The levels of reliability of commercially manufactured kits vary widely, so suspicious results, both positive and negative, should be repeated or confirmed. Standardized proficiency testing surveys for serology tests for parasitic diseases are limited (Table 2). The participant summaries include information about the performance of specific kits, if applicable. This information can be used to inform specific test selection. Proficiency must be demonstrated by alternative assessments using split-sample testing of patient-derived material if commercially prepared challenges are not available.

Parameters for development and evaluation of tests used for clinical diagnosis are mandated by CLIA regulations and can be found in guidance documents published by the CLSI, CAP, and FDA. Optimally, determinations of test sensitivity, specificity, and precision should be made using specimens collected from patients with definitive diagnoses. Unfortunately, a definitive diagnosis is often not possible for parasitic infections caused by tissue-dwelling parasites, such as those causing toxoplasmosis, toxocariasis, or trichinellosis. Specimens from well-defined clinical cases may be used for evaluations of tests for these diseases. Panels should be prepared from specimens that represent the spectrum of clinical illness and should reflect the diagnostic dilemmas encountered in clinical practice. For example, immunodiagnosis is needed prior to surgery if echinococcosis is suspected. Accordingly, tests for *Echinococcus*-specific antibody should be evaluated using some specimens that were collected prior to surgery. Patients who have undergone

[a]Test offerings were gathered from review of the following laboratory Web pages (last accessed 1 September 2013): ARUP Laboratories (ARUP; http://www.aruplab.com); Focus Diagnostics (Focus; http://www.focusdx.com); Laboratory Corporation of America (LabCorp; http://www.labcorp.com); Mayo Medical Laboratories (Mayo; http://www.mayomedicallaboratories.com/); Parasitic Disease Consultants (PDC; http://www.parasitic.com); Quest Diagnostics, Nichols Institute of Valencia (Quest; http://www.questdiagnostics.com/); and PAMF, Palo Alto Medical Foundation, Palo Alto, CA (http://www.pamf.org/). A laboratory name in parentheses in the table indicates that the test is referred to that laboratory.

[b]Abbreviations: AC/HS, the test for differential agglutination of acetone (AC)-fixed tachyzoites versus that of formalin (HS)-fixed tachyzoites; IFA, indirect fluorescent antibody; EIA, enzyme immunoassay; IB, immunoblotting; FMI, fluorescent microsphere immunoassay; IC, immunochromatographic strip assay ; ELFA, enzyme-linked fluorescence assay; ICMA, immunochemiluminometric assay; dye test, Sabin-Feldman dye test; Diff Aggl, differential agglutination.

[c]IgE testing refers to allergen testing and is listed for completeness; clinical utility has not been demonstrated.

surgery for echinococcal liver cysts will almost always have detectable antibodies immediately after surgery; these same patients may have been seronegative prior to surgery. A test for echinococcosis that has been evaluated with specimens collected only postsurgery will have close to 100% sensitivity, but a test will have a lower sensitivity if it is evaluated with specimens collected before surgery. An understanding of test performance in the presurgery setting is important and, when available, provides a valuable basis for result interpretation to the clinician.

The antigen is generally the assay component which has the most influence on test sensitivity and specificity. Consideration of the specific parasite life cycle stage is critical when selecting antigens for immunodiagnosis. Ideally, antigens derived from the specific parasite stage seen in human infection are preferred over antigens that are present in all stages or only in intermediate hosts. For instance, diagnostic assays for schistosomiasis that utilize worm antigens theoretically detect infections earlier than those that utilize egg antigens (6). Other factors that affect test performance include the purity of the antigen and the solid phase used in the assay.

For decades, immunodiagnostic assays for parasitic infections were based on detection of antibodies to native parasite antigens present in crude parasite extracts. Over time, crude parasite materials have become more difficult to obtain as fewer laboratories maintain animal models of infection. Fortunately, the availability of recombinant antigens for the diagnosis of parasitic infections has increased. Recombinant-antigen-based assays have several advantages over existing technologies. In general, recombinant-protein-based assays are more specific because the cross-reacting molecules in the crude mixture are not present, but because recombinant-protein-based assays generally rely on one or just a few antigens, these methods may be less sensitive, since the full-scope extent of the humoral immune response

TABLE 2 CAP challenges for proficiency testing for parasitic infections[a]

Analyte	CAP panel code(s)	Challenge panel name	Grading method
Anti-*Toxoplasma* antibodies	VR3	Infectious disease serology	80% participant consensus
Anti-*Trypanosoma cruzi* antibodies	VM4	Viral markers	80% participant consensus
Anti-*Babesia* antibodies	TTD	Tick-transmitted diseases	80% participant consensus
Blood parasites for parasite identification in a parasite screen, namely, *Plasmodium*, *Babesia*, *Trypanosoma*, and microfilariae	BP	Blood parasite	80% participant consensus
Giardia for parasite identification in a parasite screen (parasitology, immunoassay), *Cryptosporidium* (immunoassay)	P, P3, P4, P5	Parasitology	80% participant consensus
Malaria antigen	RMAL	Rapid malaria detection	Educational challenge, not formally evaluated
Helminths	WID	Worm identification	Educational challenge, not formally evaluated

[a]Based on the 2014 CAP surveys.

is not measured. The use of recombinant proteins eliminates the need for crude parasite materials. Therefore, the development of recombinant-protein-based assays for diagnosing parasitic infections should be less expensive to manufacture and consequently may make reliable methods more available to reference, commercial, and hospital laboratories.

In addition to antibody detection assays, antigen detection assays are commonly used to confirm the diagnosis of parasitic infections. This is especially true for enteric protozoal infections, as detection of parasite antigens is indicative of current infection and testing can be completed in a short amount of time by most technicians. Many antigen detection systems are commercially available for the intestinal parasites *Cryptosporidium parvum*, *Entamoeba histolytica*, *Giardia lamblia*, and *Trichomonas vaginalis*. Antigen detection tests are also increasingly considered for the diagnosis of malaria. These tests will be discussed in detail below.

Detection of parasite nucleic acids by PCR is now available for diagnosing many parasitic infections. In general, parasite DNA can be detected in the same specimen type used for direct parasite detection; however, some fixatives typically used for parasitological examination, especially formalin, interfere with the DNA amplification process, making some fixed specimens unsuitable for PCR analyses. For a more comprehensive presentation of available molecular methods, we refer readers to a recently published text on molecular methods for parasitic disease diagnosis (7).

Although immunodiagnosis and antigen and nucleic acid detection methods are important laboratory tools used to establish a diagnosis for many parasitic infections, definitive diagnosis is made by visualization and identification of the parasite. For detailed procedures and information about the morphological identification of parasites of clinical importance, see the CDC website DPDx, http://dpd.cdc.gov/dpdx/, and other texts dedicated to classical parasitology (8, 9).

Finally, this review chapter will focus on the most frequently used methods for detection of parasite-specific antibodies that are currently used for the diagnosis of parasitic diseases in the United States. Experimental antibody detection tests may be discussed if they add insight into test selection or result interpretation. For some diseases, testing is not available in the United States. Although the CDC can recommend international laboratories where testing may be available, their results generally cannot be reported by referring laboratories, since international laboratories are not CLIA approved. Results from international laboratories may be treated as results from research tests. The terms "sensitivity" and "specificity," as used here, refer to diagnostic sensitivity and diagnostic specificity, or the ability of the test to detect diseased cases and truly negative cases, respectively.

SPECIMEN REQUIREMENTS

Specimens for Antibody Detection

Serum and plasma are acceptable specimens for virtually all serological tests that are used for parasitic-disease diagnosis. For toxocariasis and toxoplasmosis, aqueous and vitreous eye fluids may be tested when accompanied by a serum specimen. For central nervous system infections, such as cysticercosis or toxoplasmosis, cerebrospinal fluid (CSF) accompanied by a serum specimen may be tested. In general, acute- and convalescent-phase specimens are not required; valid results generally can be obtained by testing only one specimen because many parasitic infections have progressed past the acute stage when initially considered. Sera may be stored for up to a week with refrigeration prior to shipment but should be frozen if storage for a longer period is anticipated. Specimens for serological testing may be shipped at room temperature.

Specimens for Antigen Detection

Fresh or preserved stool samples are acceptable for most antigen detection testing for enteric protozoa, but refer to the specific manufacturer's recommendations in the package insert, as exceptions do exist. Venous blood collected in EDTA and fingerstick blood samples are acceptable specimens for testing using rapid malaria diagnostic tests. Generally, fresh specimens are preferred for molecular testing; however, stools fixed in polyvinyl alcohol (PVA) may be acceptable. Formalin-fixed specimens are not acceptable for molecular testing. Refer to the testing laboratory's specific shipping requirements before shipping specimens for antigen and molecular testing.

AFRICAN TRYPANOSOMIASIS

African sleeping sickness or human African trypanosomiasis (HAT), caused by *Trypanosoma brucei gambiense*, is diagnosed using a 3-step laboratory algorithm: screening, diagnostic confirmation, and staging (10). Detection of specific antibodies is the best method for screening; diagnostic confirmation and staging require examination of CSF for trypanosomes. The card agglutination test for trypanosomiasis (CATT/*T. b. gambiense*) is the most reliable test available for initial serological screening (11–13). The CATT utilizes whole, fixed, Coomassie blue-stained trypanosomes that react with serum IgG or IgM antibodies to form a visible precipitate. False-positive results can occur in patients with malaria and other parasitic diseases, including transient infection with nonhuman trypanosomes. Rare false-negative results have been reported and may be the result of infection with trypanosomes that lack the surface antigen (LiTat 1.3) used in the CATT assay. Positive CATT results must be confirmed by microscopic detection of trypanosomes in lymph node aspirates, blood, or CSF. If trypanosomes are present and HAT is confirmed, classification of HAT into the first (hemolymphatic) or second (meningoencephalitic) stage of the disease is recommended before treatment (14).

The CATT is available through the World Health Organization, Geneva, Switzerland, or the National Reference Centre for Parasitology (NRCP) in Montreal, Canada (https://www.mcgill.ca/tropmed/services/national-reference-centre-parasitology/immunodiagnostic-service).

AMEBIASIS CAUSED BY *ENTAMOEBA HISTOLYTICA*

Several protozoan species in the genus *Entamoeba* infect humans, but not all are pathogenic. *Entamoeba histolytica* is associated with both intestinal and extraintestinal infections. Antibody detection is most useful in patients with extraintestinal disease, i.e., amebic liver abscess, when organisms are not generally found upon stool examination. Antigen detection and PCR may be useful adjuncts to microscopic diagnosis especially for differentiating between pathogenic and nonpathogenic *Entamoeba* infections (15).

The serological tests for diagnosing amebiasis detect antibodies to antigens present in crude soluble extracts of axenically cultured organisms. Enzyme immunoassays (EIA) are most frequently used, but indirect hemagglutination assays (IHA) are also available in some laboratories. Various EIA kits are manufactured commercially, making serology available in most specialty laboratories and at larger research hospitals. EIA kits detect antibodies specific for *E. histolytica* in approximately 95% of patients with extraintestinal amebiasis, 70% of patients with active intestinal infections, and 10% of asymptomatic patients with intestinal *E. histolytica* infections. If antibodies are not detectable in patients with an acute presentation of suspected amebic liver abscess, a second specimen should be drawn 7 to 10 days later. If the second specimen does not show seroconversion, other agents should be considered. Detectable *E. histolytica*-specific antibodies may persist for years after successful treatment, so the presence of antibodies does not necessarily indicate acute or current infection. The specificity of the EIA that utilize culture-derived parasites is 95% or higher. Detection of *E. histolytica*-specific IgM antibodies has been reported but is not reliable; the sensitivity of the IgM tests is only about 65% in patients with invasive disease. Several commercial EIA kits for antibody detection are available in the United States.

Immunodetection of *E. histolytica* antigens in fecal specimens may be used to distinguish the morphologically identical pathogenic *E. histolytica* and nonpathogenic *Entamoeba dispar*. Several FDA-cleared kits for antigen detection of the *E. histolytica*/*E. dispar* group are available in the United States (Table 3). These assays detect the galactose-inhibitable adherence protein, which is necessary for pathogenesis, and have excellent sensitivity and specificity. Assays that detect the *E. histolytica*-specific antigen require a fresh or frozen stool sample instead of a fixed sample; stool has to be collected specifically for this test.

Differentiation of *E. histolytica* and *E. dispar* DNA can also be made by PCR. This assay is available in some commercial laboratories, in state public health laboratories, and from the CDC. Contact information for specific state health laboratories is available at the Association of Public Health Laboratories website, http://www.aphl.org.

AMEBIASIS CAUSED BY FREE-LIVING AMEBAE

Granulomatous Amebic Encephalitis

Granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris* is best diagnosed by immunoperoxidase or immunofluorescent staining of parasites in tissue sections. Electron microscopy and observation of parasites in wet preparations of CSF have also been used successfully, although *Acanthamoeba* or *Balamuthia* is rarely found in CSF (16). Methods to detect *Balamuthia*-specific antibodies have been reported, but their usefulness in clinical diagnosis is unproven (16, 17).

Primary Amebic Meningoencephalitis

Primary amebic meningoencephalitis (PAM) is a rare and devastating infection of the brain caused by a single free-living ameba species, *Naegleria fowleri*. Because of the rapid progression of PAM, immediate diagnosis is required; immunodiagnosis is not useful. Like GAE, PAM is diagnosed by observation of parasites in CSF and biopsy specimens.

PCR methods that can differentiate all three free-living amebae discussed here have been developed and used successfully to diagnosis GAE or PAM (18).

ANGIOSTRONGYLIASIS

Immunodiagnostic tests for the detection of antibodies to *Angiostrongylus cantonensis*, which may cause eosinophilic meningitis, or *Angiostrongylus costaricensis*, the causative agent of abdominal angiostrongyliasis, are not commercially available (19). Serological testing is currently offered in a few laboratories worldwide; contact the Division of Parasitic Diseases & Malaria, CDC, at dpdx@cdc.gov for information on the availability of diagnostic testing.

TABLE 3 FDA-cleared tests for detection of parasite antigens[a]

Organism(s) and kit name	Manufacturer	Assay type[b]
Cryptosporidium, *Giardia*, and *Entamoeba histolytica*		
Triage Micro parasite panel	Alere	ICT
Cryptosporidium and *Giardia*		
Cryptosporidium/*Giardia* direct fluorescent antigen assay	IVD Research	DFA assay

(http://www.ivdresearch.com); Meridian Bioscience, Inc. (http://www.meridianbioscience.com); Thermo Scientific (http://www.thermoscientific.com/); Sekisui Diagnostics (http://www.sekisuidiagnotics.com); and TechLab, Inc. (http://www.techlab.com).

[b]DFA, direct fluorescent antibody; ICT, immunochromatographic card test; EIA, enzyme immunoassay.

A recently developed PCR test for *A. cantonensis* can be performed at the CDC for cases of acute eosinophilic meningoencephalitis. Clinical sensitivity is yet to be defined, but a positive result can be interpreted with confidence, whereas a negative result does not rule out angiostrongyliasis (20).

BABESIOSIS

Natural transmission of *Babesia microti* occurs primarily in the coastal areas of the northeastern United States and in Minnesota and Wisconsin. Rare human infections with *Babesia duncani* in California, Washington, Missouri, and Kentucky have occurred (includes strains formerly known as *Babesia* WA-1, WA-2, CA-5, and CA-6), *Babesia* CA-1, CA-3, and CA-4, and *Babesia divergens*-like organisms, which are antigenically distinct from *B. microti* (21). Because *Ixodes scapularis*, the primary tick vector of *B. microti* in the United States, also transmits the causative agents of Lyme disease and ehrlichiosis, dual and triple infections of *B. microti*, *Borrelia burgdorferi*, and *Ehrlichia* may occur (22, 23). Tick vectors for the other human *Babesia* species in the United States have not been described.

Diagnosis of *Babesia* infection should be made after microscopic review of thick and thin Giemsa-stained blood smears. Antibody detection tests are useful, however, for identifying infected individuals with very low levels of parasitemia (such as asymptomatic blood donors in transfusion-associated babesiosis), for posttherapy diagnosis after parasitemia is no longer detectable, and for discrimination between *Plasmodium falciparum* and *B. microti* infection in cases that cannot be differentiated by blood film examination.

The indirect fluorescent antibody (IFA) test using *B. microti* parasites as the antigen detects antibodies in 88 to 96% of patients with *B. microti* infection (24). IFA antigen slides are prepared using washed, parasitized erythrocytes produced in hamsters. Patients' antibody levels generally rise to ≥1:1,024 during the first weeks of illness and decline gradually over 6 months to levels of 1:16 to 1:256, but antibodies may remain detectable at low levels for a year or more. Antibodies produced in response to other tick-borne infections do not cross-react. Cross-reactions may occur in sera from patients with malaria.

Babesia microti, *B. duncani*, and *B. divergens* are antigenically distinct, and minimal cross-reactivity is seen with heterologous *Babesia* antigens; generally, antibody levels are highest with the homologous *Babesia* antigen. Therefore, a negative *B. microti* antibody result for a patient exposed on the West Coast may be uninformative and testing using a

B. duncani-specific test should be considered. There is a high level of background reactivity in the *B. duncani* IFA assay (25) that is not well understood, and this has led to false-positive results in the *B. duncani* IFA assay for patients who are not infected with this species. Positive *B. duncani* IFA results for patients with no history of exposure to ticks on the West Coast and no history of transfusion should be considered with caution and confirmed at the CDC. IFA assays for *B. microti* and *B. duncani* are available at the CDC and from commercial laboratories, and *B. microti* and *B. duncani* IFA antigen slides are also available commercially. IFA assays for infections caused by the *B. divergens*-like parasites are available at the CDC, after consultation.

B. microti PCR assays are available in several commercial laboratories and at the CDC. PCR is at least as sensitive as microscopy, but the persistence of *Babesia* DNA is variable, ranging from 3 weeks posttherapy to 3 or more months in untreated patients. Antibody detection is the initial test of choice for the detection of *B. microti* infection in asymptomatic infected blood donors or in patients posttherapy, because it is more sensitive than microscopy or nucleic acid detection in these situations. If *Babesia* organisms are observed and serology tests are negative, blood specimens should be collected in EDTA for species determinations made by DNA sequence analysis at the CDC (21).

BAYLISASCARIASIS

Baylisascariasis is a severe infection requiring immediate diagnosis. Histological sectioning of infected tissues is informative if parasites can be observed in the tissue sections, but organisms may not be present in the sections obtained, so negative results do not rule out infection. Immunodiagnostic methods have been the most reliable method for laboratory diagnosis. Antibodies can be detected in serum or CSF using an immunoblot assay that detects antibodies to a recombinant protein, repeated antigen 1 (rRAG1) (26). The rRAG1 immunoblot does not detect cross-reacting *Toxocara* antibodies and therefore represents an important improvement in testing over previously used EIA (27).

Because of the small number of cases reported to date, specimens are not available in sufficient quantity for robust calculations of sensitivity for any of the immunodiagnostic methods described for baylisascariasis. Serological testing for baylisascariasis using rRAG1-based immunoblotting is available at the CDC or the National Reference Center for Parasitology in Montreal, Canada.

CHAGAS' DISEASE

Infections with *Trypanosoma cruzi* may occur throughout Central and South America. During the acute stage of illness, blood film examination generally reveals the presence of trypomastigotes. During the chronic stage of infection, parasites are rare or absent from the circulation and immunodiagnosis is the method of choice for determining whether the patient is infected. Although differentiating between acute and chronic infection is very important in determining the necessity for therapy, serology cannot be used to make this distinction. A positive antibody response indicates only infection at some unknown time and not specifically acute infection.

When Chagas' disease is suspected in patients with HIV/AIDS, it is important to differentiate chagasic brain lesions from those caused by *Toxoplasma*. Serological tests as well as direct examination of CSF for parasites and PCR should be performed. Negative serology results can rule out Chagas' disease in these patients, especially in patients with no history of intravenous drug use (28). In contrast, serological tests may be negative for patients who are immunosuppressed due to organ transplantation (29, 30).

A variety of serological tests for the diagnosis of Chagas' disease are used throughout Latin America, where the greatest experience exists. Diagnosis usually requires positive results from at least two different serological methods (31). A laboratory algorithm that uses EIA methods for screening, followed by confirmatory testing if screening tests generate positive results, has been proposed. Serological methods include IHA, IFA assays, complement fixation, EIA, immunoblotting, and radioimmunoprecipitation (32–38). These assays detect antibodies that react with parasite antigens found in crude trypanosome extracts or in the excretory-secretory (ES) products of cultured parasites or recombinant proteins (39). An immunoblot which detects antibodies that react with the ES antigens of a trypomastigote fraction, TESA blotting, has been proposed as a reliable confirmatory test (40, 41).

The IFA assay, an EIA, and TESA blotting are employed at the CDC. IFA antigen slides are prepared from a suspension of epimastigotes, and crude soluble antigens of epimastigotes are used in EIA. Although the IFA assay is sensitive, cross-reactivity occurs with sera from patients with leishmaniasis. The sensitivities (93 to 98%) and specificities (99%, excluding patients with leishmaniasis) of EIA that use crude antigens are similar to those of the IFA assay. EIA kits utilize a variety of antigens, either crude parasite lysate, recombinant proteins, or a combination of both. The sensitivities and specificities of the EIA kits vary widely (39). Two FDA-cleared kits are available in the United States for clinical diagnosis (Table 4). In the United States, the radioimmunoprecipitation assay has been used as a confirmatory test for blood donor screening (36). It is important to recognize that a test that is FDA cleared for blood donor screening does not imply clearance or approval for *in vitro* diagnostic use.

Molecular detection of *T. cruzi* DNA is most useful for cases of transfusion or transplant transmission or for congenital Chagas' disease. Laboratory exposures can also be monitored using PCR. At the CDC, molecular detection of *T. cruzi* DNA is performed using a combination of three real-time PCR assays (42). Acceptable specimen types are EDTA blood (minimum of 2.2 ml), heart biopsy tissue (in saline or paraffin embedded), and, in cases of suspected cerebral involvement, CSF. Using PCR to detect *T. cruzi* DNA in EDTA blood is appropriate only when the parasitemia is expected to be high, such as in the acute phase of the infection or if reactivation of chronic Chagas' disease due to immunosuppression is suspected.

In the United States, specific laboratory testing to confirm Chagas' disease may be required before release of drugs that are available only under an investigational new drug (IND) application.

CRYPTOSPORIDIOSIS

Microscopic identification of *Cryptosporidium* parasites and detection of antigen in stool specimens are the current diagnostic tests of choice. Antigen detection methods provide sensitivity that is equal to or greater than microscopy. Table 3 lists 11 commercial products (two direct fluorescent antibody [DFA] tests, four EIA, and five rapid tests) that are FDA cleared (approved) for diagnosis of cryptosporidial infections. Seven of the kits are combined tests for *Cryptosporidium* and *Giardia*, and one test detects *Cryptosporidium*,

TABLE 4 Commercially available FDA-cleared kits for detection of parasite specific antibodies[a]

Organism and company, test	IgG kit(s)	IgM kit(s)

NA, not applicable.

[b]Access, Vidas, Advia, Liaison, and Vitros are automated laboratory systems.

Giardia, and *E. histolytica*. The most sensitive (99%) and specific (100%) method is the DFA test, which identifies oocysts in concentrated or unconcentrated fecal samples by using a fluorescein isothiocyanate-labeled monoclonal antibody (43). A combined DFA test for the simultaneous detection of cryptosporidial oocysts and *Giardia* cysts is available; however, this method did not perform better than routine microscopy in a recent study (44).

Four commercial EIAs are available in the microplate format for the detection of cryptosporidial antigen in fresh or frozen stool samples and also in stool specimens preserved in formalin, merthiolate-iodine-formalin, or sodium acetate-acetic acid-formalin fixatives. Concentrated or PVA-treated samples are unsuitable for testing with antigen detection EIA kits. The kits are reportedly superior to microscopy (especially acid-fast staining), and their results show good correlation with those of the monoclonal antibody-based DFA test. In head-to-head studies comparing multiple kits in clinical settings, sensitivities ranged from 70% to 100%; specificities are typically high, 99% to 100% (43, 45–47). Laboratories which use these EIA kits need to be aware of potential problems with anecdotal reports of false-positive results and take steps to monitor a kit's performance (48).

Four rapid immunochromatographic assays are available for detection of *Cryptosporidium* antigens alone or in combination with *Giardia* or *Giardia* and *E. histolytica* (Table 3). These tests are easy to use and provide results for more than one organism in a single reaction device. Initial evaluations indicate sensitivity and specificity comparable to those of microplate assays (or EIA) (43).

PCR tests are available in commercial laboratories and at the CDC for detection of *Cryptosporidium* DNA in stool specimens (49). These tests are highly sensitive and specific but require either fresh stool specimens or stools collected in PVA. Formalin-fixed stools are not acceptable for molecular studies.

Tests for the detection of *Cryptosporidium*-specific antibodies are not currently recommended due to a lack of sensitivity and specificity. Serological tests have been reported for *Cryptosporidium*, but their use should be limited to epidemiological studies.

CYCLOSPORIASIS

Cyclosporiasis in humans is caused by *Cyclospora cayetanensis*. Currently, the most practical diagnostic method of diagnosis is identification of oocysts in stool specimens. The sediment from concentrated stool specimens can be examined microscopically with different techniques: wet mounts (by conventional light microscopy, which can be enhanced by UV fluorescence microscopy or differential interference contrast) or stained smears, using modified acid-fast stain or a modified safranin stain. If cyclosporiasis is suspected, these special tests should be ordered specifically, as classical ova and parasite examination may not detect *Cyclospora*. Tests for antibody detection for cyclosporiasis have not been developed to date. Sensitive and specific PCR tests are available and can be used to detect parasite DNA in stool specimens (50). Molecular tests require either fresh stool specimens or stools collected in PVA. Formalin-fixed stools are not acceptable for molecular studies.

CYSTICERCOSIS (LARVAL *TAENIA SOLIUM*)

Diagnosis of neurocysticercosis (NCC), caused by the larval stages of *Taenia solium*, is established using a combination of imaging and serological results. Today, the CDC enzyme-linked immunoelectrotransfer blot (CDC-EITB) assay and EIA are the antibody detection test formats most frequently used for the diagnosis of NCC.

The CDC-EITB assay, which utilizes partially purified *T. solium* antigens, is the immunodiagnostic test of choice for confirming a presumptive clinical and radiologic diagnosis of neurocysticercosis (51). Briefly, the CDC-EITB assay is an immunoblot test that detects antibodies to one or more of seven lentil lectin-bound glycoproteins (LLGP) present in an extract of *T. solium* cysts. It has a sensitivity superior to that of any other test yet evaluated.

In the original description of the assay, serum specimens from 97% of 108 confirmed parasitological cases of cysticercosis had detectable antibodies (52). No serum samples from 376 patients with other microbial infections contained antibodies that reacted with any of the *T. solium*-specific antigens. After several decades of use, the most important factors identified as determining positive immunoblot reactions are the numbers and stage of development of cysticerci. Cumulative clinical experience has confirmed that in patients with multiple (more than two) lesions, the test has a sensitivity of more than 95% (51). However, seropositivity in biopsy-confirmed patients with single, enhancing parenchymal cysts was <50%; in clinically defined patients with a single cyst but who were not biopsied, sensitivity was 70%. Seropositivity in the sera and CSF of patients with multiple but only

calcified cysts was 82% and 77%, respectively. Seropositivity in the sera and CSF of patients with intraventricular neurocysticercosis was 93% (single cyst) and 95% (two or more cysts). In all patients, regardless of their clinical presentation, the immunoblot assay is 10% more sensitive with serum than with CSF specimens: consequently, there is no need to obtain CSF solely for use in the immunoblot assay.

The specificity of the CDC-EITB assay using LLGP is remarkable (virtually 100%), with only rare anecdotal reports of false-positive results documented (53, 54). However, in one study, only 2 of 13 patients with antibodies to only the gp50 protein were associated with a clinical diagnosis of neurocysticercosis; seven cases had other final diagnoses (55). Therefore, in patients for whom the suspicion of neurocysticercosis is low, reactivity to the gp50 protein alone should be interpreted with caution.

Other EITB tests, or immunoblot methods, have been described (56) and are manufactured and offered by commercial laboratories (Table 1). These other EITB methods do not necessarily utilize the LLGP antigen extract used in the CDC-EITB assay, so interpretation of results from these other tests should be made carefully, recognizing that the performance attributes of the CDC-EITB assay may not apply to other immunoblot-based methods (57).

EIA methods continue to be used extensively for clinical diagnosis, mainly because of their technical simplicity. In general, EIA methods are reliable if CSF, not serum, is tested. Many EIA have high rates of false positivity (with specificities ranging from 81% to 97%) and false negativity (with sensitivities ranging from 62% to 93%) compared to the CDC-EITB assay (58–61); results should be confirmed using the CDC-EITB assay if they are deemed inconsistent with the clinical picture (62).

Serology is not useful for evaluating the outcomes and prognoses in patients treated with anthelmintics (63). However, recent studies showed that antigen detection may be useful in cases for monitoring NCC patients with live parasites. Antigen was detected more frequently in CSF than in serum, so CSF is the preferred specimen type for NCC antigen testing (64–66). Antigen testing is available at the CDC for management of specific cases after consultation.

It is important to note that the presence of *T. solium* ova or tapeworm segments in stool specimens does not diagnose NCC but rather taeniasis (infection with the adult tapeworm stage of the parasite). Identification and treatment of taeniasis are important public health measures that can prevent NCC. Follow-up with family members associated with cases of NCC reported to the Los Angeles County Health Department from 1988 to 1991 demonstrated at least one active tapeworm carrier among family contacts of 22% of locally acquired cases and 5% of imported cases (67).

ECHINOCOCCOSIS

Immunodiagnostic tests can be very helpful in the diagnosis of echinococcal disease, and they should be used before surgery (68, 69). However, the clinician must have some knowledge of the characteristics of the available tests and the factors associated with false results. False-positive reactions may occur in persons with other helminthic infections, cancer, and chronic immune disorders. Negative test results do not rule out echinococcosis because approximately 10% of patients with cysts are seronegative (70). The presence of detectable antibodies is dependent on the physical location, structural integrity, and viability of the larval cyst. Cysts in the liver are more likely to elicit an antibody response than cysts in the lungs, and, regardless of localization, antibody detection tests are least sensitive in patients with intact hyaline cysts. Cysts in the lungs, brain, and spleen are associated with decreased or nondetectable antibody levels, whereas those in bone appear to elicit a detectable immune response. Fissuration or rupture of a cyst is followed by an abrupt stimulation of antibody production. A patient with senescent, calcified, or dead cysts is generally found to be seronegative.

Detection of *Echinococcus*-specific IgG4 antibodies has been shown to be more sensitive than detection of total IgG and has been associated with progression of cystic echinococcosis (71, 72). Specific IgG4 is not specifically measured by any of the kits available today, but next-generation assays may exploit detection of IgG4.

Molecular tools are used primarily for isolate or strain identification for epidemiological purposes and not for clinical diagnosis.

Cystic Echinococcal Disease (*Echinococcus granulosus*)

EIA and immunoblotting are sensitive tests for detecting antibodies in the sera of patients with cystic echinococcal disease; sensitivity rates vary from 60 to 90%, depending on the characteristics of the cases. Crude hydatid cyst fluid is generally employed as the antigen. At present, the best available serologic diagnosis is obtained by using combinations of tests. EIA are used to screen all specimens; a positive reaction is confirmed by immunoblotting. Although these confirmatory assays give false-positive reactions with sera from 5 to 25% of persons with neurocysticercosis, the clinical and epidemiological presentation of neurocysticercosis patients should be rarely confused with that of cystic echinococcosis.

Antibody responses have also been monitored as a way of evaluating the results of treatment, but with mixed results. Following successful radical surgery, antibody levels decline and sometimes disappear; antibodies rise again if secondary hydatid cysts develop. Antibody levels do not consistently decline following chemotherapy. Consequently, the usefulness of serology to monitor the course of disease is limited; imaging techniques provide a more accurate assessment of the patient's condition.

Alveolar Echinococcal Disease (*Echinococcus multilocularis*)

Immunodiagnostic tests utilizing specific *E. multilocularis* antigens are available, but tests developed for the detection of *E. granulosus* antibodies can also be used, although *E. granulosus*-based immunoblot assays detect only 50% of *E. multilocularis* cases. EIA that use affinity-purified or recombinant forms of several *E. multilocularis* antigens, Em2, Em10, or Em18, are available in Europe and can detect specific antibodies in more than 95% of alveolar cases (73–76). Em18 is highly specific, so if positive results are obtained, a diagnosis of alveolar echinococcosis can be made. Tests for *E. multilocularis* infection are not presently available in the United States but may be in the immediate future. As in cystic echinococcosis, antibody detection tests are more useful for postoperative follow-up than for monitoring the effectiveness of chemotherapy.

FASCIOLIASIS

The acute manifestations of human fascioliasis may precede the appearance of eggs in the stool by several weeks; immunodiagnostic tests may be useful for early indication of *Fasciola* infection as well as for confirmation of chronic fascioliasis when egg production is low or sporadic and for

ruling out "pseudofascioliasis" associated with ingestion of parasite eggs in sheep or calf liver.

The current test of choice for immunodiagnosis of human *Fasciola hepatica* infection is an EIA that uses ES antigens combined with confirmation of positive results by immunoblotting (77, 78). Antibodies specific to *Fasciola* may be detectable within 2 to 4 weeks after infection, which is 5 to 7 weeks before eggs appear in stool. The sensitivity of the Falcon assay screening test (FAST) system enzyme-linked immunosorbent assay (FAST-ELISA) was reported to be 95%, while the sensitivity of immunoblotting using 12-, 17-, and 63-kDa antigens appeared to be 100%. Cross-reactivity may occur in the FAST-ELISA with serum specimens of patients with schistosomiasis. Antibody levels decrease to normal 6 to 12 months after chemotherapeutic cure and can be used to predict the success of therapy. More recently, an EIA that measures antibodies to a recombinant cathepsin L-protease has been developed (78). This assay reports greater than 99% sensitivity and 99% specificity and is available in the NRCP in Canada.

In the United States, specific laboratory testing to confirm fascioliasis may be required before release of drugs that are available only under an IND application. Testing for fascioliasis is available at the NRCP in Montreal, Canada.

FILARIAL INFECTIONS

Among the eight filarial species that commonly infect humans, the four most likely to be pathogenic are three blood-borne filariae—*Brugia malayi, Wuchereria bancrofti*, and *Loa loa*—and the skin-dwelling parasite *Onchocerca volvulus*. For each of these infections and the other filariae (*Mansonella perstans*, *Mansonella ozzardi*, *Mansonella streptocerca*, and *Brugia timori*) demonstration of the parasite or parasite DNA by PCR (microfilariae in the blood or skin or adult parasites in tissue samples) remains the gold standard for definitive diagnosis. Nevertheless, diagnosis can be elusive not only because occult infections (low parasite burdens) occur but also because microfilariae (for most *Brugia* and *Wuchereria* organisms at least) are nocturnally periodic.

Lymphatic Filariasis (*Wuchereria bancrofti* and *Brugia* spp.)

A definitive diagnosis of lymphatic filariasis can be made only by detection of *Wuchereria bancrofti* and *Brugia* species parasites and hence can be difficult. Adult worms localized in lymphatic vessels or lymph nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 μm) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the region of endemicity involved. Many infected individuals do not have microfilaremia, and definitive diagnoses in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: one is an ELISA and the other a rapid-format immunochromatographic card test. Both assays have sensitivities that range from 96 to 100% and specificities that approach 100% (79, 80). There are currently no tests for circulating antigens in Brugian filariasis.

PCR-based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed (81). A number of studies indicate that this diagnostic method has a sensitivity equivalent to or greater than those of parasitologic methods, detecting patent infection in almost all infected subjects.

Immunologically based diagnostics which measure IgG responses against crude extracts of *Brugia* or *Dirofilaria* worms have traditionally suffered from poor specificity. Extensive cross-reactivity is found in the sera of individuals infected with closely related helminth parasites and even certain protozoal parasites. Further, it is difficult to differentiate previous infection or exposure to the parasite (aborted infection) from current active infection; most residents of regions where filariasis is endemic are IgG antibody positive. Nevertheless, such serologic assays for IgG antibody have a definite place in diagnosis, as a negative assay result effectively excludes past or present infection. The prominent role of antifilarial antibodies of the IgG4 subclass in filarial infection has led to the development of serodiagnostic assays based on antibodies of this subclass. Antifilarial IgG4 assays have improved specificity (82), but positive assays may still be seen in uninfected individuals living in areas of endemicity and in those infected with other filarial species (e.g., *O. volvulus*, *L. loa*, and *Mansonella* spp.). More recently, a *Wuchereria bancrofti*-specific recombinant antigen (named Wb123) has been identified and used in both IgG4- and IgG-based immunoassays (ELISA, Luciferase immunoprecipitation assays, Luminex) for more-specific screening applications, with the understanding that, again, these antibody-based assays cannot distinguish between current and previous infections (83–85).

In cases of suspected lymphatic filariasis, examination of the scrotum or the female breast using high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of men infected with *W. bancrofti*.

Confirmation of serological results obtained at commercial laboratories is usually required for release of therapeutics (e.g., diethylcarbamazine) administered under an IND application.

Onchocerciasis

Definitive diagnosis of onchocerciasis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip or in the anterior chamber of the eye using a slit lamp. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2 to 4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be visualized by low-power microscopy.

Because detection of parasites in the skin is invasive and insensitive, immunodiagnostic assays have been sought. IgG antifilarial antibody assays, while positive in individuals with onchocerciasis, suffer from the same lack of specificity and positive predictive value seen in the blood-borne filarial infections. The combined use of three groups of recombinant antigens provided sensitivities and specificities that approach 100% for the serological assessment of onchocerciasis (86, 87). Although no recombinant antigen test is available commercially, an experimental rapid card test that detects IgG4 antibodies in serum or whole blood to the Ov-16 recombinant antigen has been shown to have

>90% sensitivity and specificity (88, 89) and should be available commercially in mid- to late 2014. Antigen detection methods for use on serum/plasma or urine specimens are theoretically feasible, but prototypes have lacked both specificity and sensitivity.

Assays using PCR to detect onchocercal DNA in skin snips are now in use in filariasis research laboratories and are highly sensitive and specific (90, 91).

Loiasis

Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye or from a subcutaneous biopsy specimen from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are now available in filariasis research laboratories (and a few clinical microbiology departments) and are highly sensitive and specific.

Antifilarial IgG and IgG4 may be useful in confirming the diagnosis of loiasis in visitors to areas of endemicity who have suggestive clinical symptoms or unexplained eosinophilia; however, currently available methods using crude antigen extracts from *Brugia* or *Dirofilaria* species do not differentiate between *L. loa* and other filarial pathogens. The utility of such testing in populations living where the disease is endemic is limited by the presence of antifilarial antibodies in up to 95% of individuals in some regions. A *Loa*-specific recombinant antibody (Ll-SXP-1) has been tested; IgG4 antibody-based assays have been found to be >95% specific, but with limited (50%) sensitivity (92). When used with a luciferase immunoprecipitation system format, the Ll-SXP-1 test has been shown to provide a high degree of both sensitivity and specificity (93).

Confirmation of serological results obtained at commercial laboratories is usually required for release of therapeutics (e.g., diethylcarbamazine) administered under an IND application.

GIARDIASIS

Giardia lamblia is the most common human intestinal protozoal pathogen in the United States and is an important cause of diarrhea in children and adults. Outbreaks of disease are common within day care centers as a result of person-to-person contact and may also occur in communities as a result of drinking water contaminated by infected-human or -animal feces. Infected persons often excrete cysts intermittently, so multiple stools collected over at least several days must sometimes be examined to detect the parasite. Tests for antibody detection of *Giardia* infection are available at commercial laboratories but are not currently recommended because of a lack of sensitivity and specificity. Highly sensitive and specific PCR tests are available and can be used to detect parasite DNA in stool specimens (94). Molecular tests require either fresh stool specimens or stools collected in PVA. Formalin-fixed stools are not acceptable for molecular studies.

Table 3 lists 12 FDA-cleared (approved) kits for diagnosis of giardiasis (two DFA tests, five EIA, and five rapid tests). DFA assays that employ fluorescein isothiocyanate-labeled monoclonal antibody for detection of *Giardia* cysts may be purchased in a combined kit for the simultaneous detection of *Giardia* cysts and *Cryptosporidium* oocysts. Both the sensitivity and the specificity of these kits were 100% compared to those of microscopy. They may be used for quantitation of cysts and oocysts and thus may be useful for epidemiologic and control studies.

Five commercial EIA are available in the microplate format for the detection of *Giardia* antigen in fresh or frozen stool samples and also in stool specimens preserved in formalin, merthiolate-iodine-formalin, or sodium acetate-acetic acid-formalin fixatives. Concentrated or PVA samples are not suitable for testing with EIA kits. EIA kit sensitivity rates were recently reported as ranging from 94 to 100%, while all specificity rates were 100% (63, 95).

Five rapid immunochromatographic assays are available for the detection of *Giardia* alone or in combination with *Cryptosporidium* or *Cryptosporidium* and *E. histolytica*. These offer the advantage of short test times and multiple results in one reaction device. Initial evaluations indicate a sensitivity and specificity comparable to those of previously available tests.

GNATHOSTOMIASIS

Immunodiagnostic tests for the detection of antibodies to *Gnathostoma* are not available in the United States. If gnathostomiasis is suspected, contact the CDC at dpdx@cdc.gov for information on the availability of diagnostic testing.

LEISHMANIASIS

Diagnostic testing for leishmaniasis should include examination of bone marrow aspirates and tissue impression smears and culture for parasite isolation followed by isoenzyme analysis or molecular tests for species determination. If visceral leishmaniasis is suspected, antibody detection tests can be a useful adjunct to clinical findings. In contrast, the sensitivity of antibody tests for cutaneous leishmaniasis is poor, as most infections do not induce a detectable circulating antibody response to the parasite; serological testing in not recommended for cases of cutaneous leishmaniasis.

The IFA tests and EIA are used for the detection of antibodies to *Leishmania* (96). IFA slide antigens are prepared from cultured epimastigotes of various *Leishmania* species, while EIA antigens are usually crude solubilized epimastigotes. These procedures can differentiate leishmaniasis from other clinically similar conditions but cannot determine the species of *Leishmania*. Cross-reactions also occur in patients with antibodies to *T. cruzi* (Chagas' disease). Antibody detection tests can be a useful because test sensitivity is >95%. A recombinant protein, K39, has been used in rapid immunochromatographic card tests and EIA formats to detect *Leishmania*-specific antibodies with success in immunocompetent patients (97); however, the sensitivity is greatly reduced (~20%) in HIV-infected patients (98). More recently, another recombinant protein, rK28, has been evaluated in a limited study and has been shown to perform better than K39 in both EIA and a rapid diagnostic test (RDT) format (99).

Recently, molecular methods have been developed for discrimination of *Leishmania* species (100). This method is based on PCR amplification followed by DNA sequencing analysis of the *Leishmania* ITS2 fragment. The method was shown to be highly concordant with culture/isoenzyme analysis, and results can be obtained within days, compared to the weeks required for culture.

In the United States, specific laboratory testing to confirm leishmaniasis may be required before release of drugs that are available only under an IND application.

MALARIA

Diagnosis of malaria is based on microscopic review of thick and thin Giemsa-stained blood smears. Serological tests for

malaria antibodies are not recommended for diagnosing malaria except in a few specific instances: (i) testing a febrile patient suspected of having malaria who is repeatedly blood smear negative, (ii) diagnosing cases of suspected tropical splenomegaly syndrome, and (iii) screening blood donors involved in cases of transfusion-induced malaria. IFA tests and EIA are available in commercial laboratories in the United States (Table 1).

IFA tests for malarial antibody detection are 97% sensitive and 99% specific, but the presence of antibodies indicates that infection occurred at some time in the past and does not necessarily indicate current infection (101). Antibodies may persist for years, especially in cases from areas where malaria is endemic. Interestingly, antibody titers decreased significantly after treatment (within 6 months) in troops after their return from Vietnam, suggesting that antibodies may not be long lived in naive hosts (102). Although multiple IFA tests are frequently performed using IFA slides prepared from *Plasmodium falciparum*, *Plasmodium vivax*, or *Plasmodium malariae* parasites, determination of the infecting *Plasmodium* species should not be inferred from IFA titers.

There are many RDTs for the detection of *Plasmodium* antigens in blood or serum available outside the United States. One RDT has been cleared by the FDA for *in vitro* diagnostic use in the United States (Table 4). The BinaxNOW malaria test detects the histidine-rich protein 2 (HRP-2) of *P. falciparum* and lactate dehydrogenase, a pan-malarial parasite antigen. Carefully review the package insert for test interpretation. Recently, some *P. falciparum* isolates from Peru and nearby countries that lack the HRP-2 protein and thus produce false-negative results in the BinaxNOW malaria RDT were identified (103). Microscopic examination of Giemsa-stained blood films should be performed for all cases regardless of RDT results to determine the species of *Plasmodium* identified and to quantify the parasitemia as well as to rule out false-negative results from infections with HRP-2-negative strains. More information about the BinaxNOW malaria RDT is available at http://www.cdc.gov/malaria/diagnosis_treatment/rdt.html.

PCR is a sensitive method for diagnosing malaria (104) and is available in commercial laboratories, some state public health laboratories, and at the CDC. If malaria is suspected, submit blood smears for morphological examination and EDTA blood for PCR. The blood smears should be examined first for the presence of parasites. If malarial parasites are observed and the species is determined, the diagnosis is complete. However, if parasites are not observed or if parasites are observed but the infecting species cannot be determined morphologically, PCR can then be performed. PCR should also be ordered if cerebral malaria is suspected, as it is more sensitive than blood film examination for the diagnosis of cerebral malaria. *Plasmodium* DNA generally becomes nondetectable within a week of antimalarial chemotherapy.

For more information about malaria and its diagnosis, visit http://www.cdc.gov/malaria.

PARAGONIMIASIS

Pulmonary paragonimiasis is the most common presentation of patients infected with *Paragonimus* spp., although extrapulmonary (cerebral, abdominal) paragonimiasis may occur. Detection of eggs in the sputum or feces of patients with paragonimiasis is often difficult; therefore, serodiagnosis may be helpful in confirming infections and for monitoring the results of individual chemotherapy.

Both EIA and immunoblot tests are used for immunodiagnosis of paragonimiasis. The immunoblot assay for antibody detection performed with a crude antigen extract of *Paragonimus westermani* has been in use at the CDC since 1988 (105). Positive antibody reactions, based on demonstration of reactivity with an 8-kDa antigen, were obtained with serum samples of 96% of patients with parasitologically confirmed *P. westermani* infection. Specificity was ≥99%; of 210 serum specimens from patients with other parasitic and nonparasitic infections, only 1 serum sample from a patient with *Schistosoma haematobium* reacted. Antigens present in *P. westermani* extracts may also be useful for the diagnosis of infections with other *Paragonimus* species, such as *P. kellicotti*, but species-specific tests may be more sensitive (106, 107). Serological methods for clinical diagnosis are available only at the CDC at this time.

SCHISTOSOMIASIS

Antibody detection can be useful to indicate schistosome infection in patients who have traveled in areas of schistosomiasis endemicity if schistosome eggs cannot be demonstrated in fecal or urine specimens. The test sensitivities and specificities of the many tests reported for the serologic diagnosis of schistosomiasis vary widely and are influenced by both the type of antigen preparation used (crude, purified, adult worm, egg, cercarial) and the test format.

At the CDC, a combination of tests with purified adult worm antigens are used for antibody detection (108, 109). All serum specimens are initially tested by FAST-ELISA using *Schistosoma mansoni* adult microsomal antigen (MAMA). A positive reaction indicates infection with *Schistosoma* species. The sensitivity of the FAST-ELISA is 99% for *S. mansoni* infection, 95% for *Schistosoma haematobium* infection, and >50% for *Schistosoma japonicum* infection. The specificity of this assay for detecting schistosome infection is 99%. Because test sensitivity with the MAMA is reduced for species other than *S. mansoni*, immunoblots of the species appropriate to the patient's travel history are also tested to ensure antibody detection of *S. haematobium* and *S. japonicum* infections. Infections caused by *Schistosoma mekongi* can be detected using *S. japonicum* immunoblotting (110), and *Schistosoma intercalatum* can be diagnosed using *S. haematobium* blotting. The number of serum specimens from confirmed cases of *S. mekongi* and *S. intercalatum* is limited, so sensitivity cannot be calculated. Immunoblots with adult worm microsomal antigens are species specific, and so a positive antibody reaction indicates the infecting species. The presence of antibody is indicative only of schistosome infection at some time and cannot be correlated with clinical status, worm burden, egg production, or prognosis.

Immunodiagnostic tests offered in commercial laboratories utilize *S. mansoni* antigens. It is important to note that these assays may have limited sensitivity to detect infections caused by other schistosome species.

Detection of schistosome antigens in serum and urine has been suggested as an indicator of cure after chemotherapy. These techniques are being used in control programs in Africa, but antigen detection tests for clinical use are not yet available in the United States (111). Similarly, quantitative stool or urine exams can be performed, but their limits of detection are usually not adequate to monitor cure.

STRONGYLOIDIASIS

Immunodiagnostic tests for strongyloidiasis are indicated when the infection is suspected and the organism cannot be demonstrated by duodenal aspiration, string tests, or repeated examinations of stool. Antibody detection tests

should use antigens derived from *Strongyloides stercoralis* filariform larvae for the highest sensitivity and specificity. A variety of different EIA are currently available, and many have reported sensitivities in the range of 90 to 95% (112–116). Although some *Strongyloides* EIA perform well, with good sensitivity and specificity, other tests may be unreliable, neither sensitive nor specific. Cross-reactions in patients with most filarial infections and some other nematode infections may occur (117). Several limitations are recognized: approximately 5 to 10% of individuals infected with *Strongyloides* are seronegative, and a single antibody test result cannot be used to differentiate between past and current infection. A positive test warrants continuing efforts to establish a parasitological diagnosis followed by anthelmintic treatment. Suspicious results, positive or negative, which are not consistent with clinical presentation, should be confirmed in a reference laboratory.

The sensitivity for detecting *Strongyloides*-specific antibodies in immunocompromised patients is variable depending on the type or cause of immunosuppression. Reactivity in patients with HIV/AIDS or human T cell leukemia virus type 1 (HTLV-1) infection or hematological malignancies may be reduced (118, 119). Immunocompromised persons with disseminated strongyloidiasis usually have detectable IgG antibodies despite immunosuppression (120). Transplant recipients may be seronegative.

Serologic monitoring may be useful in the follow-up of treated immunocompetent patients; antibody levels decrease markedly within 6 months after successful chemotherapy, but the decrease is less dramatic in patients from areas of endemicity or in those who have been infected for years (121, 122).

The use of a recombinant protein, NIE, shows promise for improving the serodiagnosis of strongyloidiasis. In one evaluation, in immunocompetent persons, the assay demonstrated 97% sensitivity and 100% specificity; seropositivity was not associated with *Ascaris* or hookworm coinfections (116).

TOXOCARIASIS (LARVA MIGRANS)

Antibody detection tests are the best means of confirmation of a clinical diagnosis of visceral larva migrans (visceral toxocariasis), ocular larva migrans (ocular toxocariasis), and covert toxocariasis, the most common clinical syndromes associated with *Toxocara* infections (123, 124). The currently recommended serologic test for toxocariasis is an EIA that utilizes larval-stage antigens extracted from embryonated eggs or released *in vitro* by cultured infective larvae (125). *Toxocara canis* excretory-secretory antigens are preferable to larval extracts because they are convenient to produce and because an absorption-purification step is not required to obtain maximum specificity. *T. canis* excretory-secretory antigens prepared from *T. canis* larvae also detect antibodies produced during *Toxocara cati* infections (126).

Evaluation of the true sensitivity and specificity of serologic tests for toxocariasis in human populations is not possible because very few patients who have been definitively diagnosed exist. This inherent problem results in underestimations of sensitivity and specificity. Evaluation of the *Toxocara* EIA in groups of patients with presumptive diagnoses of visceral larva migrans or ocular larva migrans (OLM) indicated sensitivities of 78 and 73%, respectively, at an antibody titer of ≥1:32. When the cutoff titer for OLM cases was lowered to 1:8, sensitivity was increased to 90%. Further confirmation of the specificity of the serologic diagnosis of OLM can be obtained by testing aqueous or vitreous humor samples for antibodies. Specificity has been reported to be >90% at an antibody level of ≥1:32.

When interpreting the serologic findings, clinicians must be aware that a detectable antibody level may not necessarily indicate current clinical *Toxocara* infection. In addition, in most human populations, a number of those tested have positive EIA antibody levels that apparently reflect the prevalence of asymptomatic toxocariasis. In a recent study, approximately 14% of the U.S. population was determined to be seropositive, with the percentage varying according to age, race, and socioeconomic status (127).

TOXOPLASMOSIS

Numerous immunodiagnostic tests are available at commercial laboratories for toxoplasmosis diagnosis and are used to distinguish acute versus chronic toxoplasmosis. Commercial laboratories offer testing for *Toxoplasma*-specific IgG and IgM using kits that are FDA cleared or approved (Table 4). Additional tests, such as the Sabin-Feldman dye test, the test for differential agglutination of acetone (AC)-fixed versus formalin (HS)-fixed tachyzoites (AC/HS test), and an IgG avidity test, as well as tests for *Toxoplasma*-specific IgA and IgE, are used to try to establish the time of infection. The College of American Pathologists offers *Toxoplasma* antibody proficiency testing as part of the Infectious Disease Serology survey (Table 2). The participant summary includes information about the performance of the different kits that can be used to inform specific test selection. Commercial kit comparison studies indicated that most kits perform comparably in detecting *Toxoplasma*-specific IgG antibodies but vary markedly in detecting *Toxoplasma*-specific IgM antibodies (128). To help evaluate the accuracy of commercial *Toxoplasma* antibody test kits, the CDC created a *Toxoplasma* serum panel, the CDC 1998 *Toxoplasma* human serum panel, that contains known positive and negative sera. The FDA now requires that any new commercial test kit intended to measure *Toxoplasma* antibodies performs adequately based on results obtained using this panel (129), which is available from the CDC.

The Clinical and Laboratory Standards Institute has published a guideline entitled *Clinical Use and Interpretation of Serologic Tests for* Toxoplasma gondii to assist clinical microbiologists and physicians in interpreting serological tests for toxoplasmosis (130). EIA or IFA tests for IgG and IgM antibodies are the tests most commonly ordered. Patients should be initially tested for the presence of *Toxoplasma*-specific IgG antibodies to determine their immune status. A positive IgG titer indicates infection with the organism at some time. If more precise knowledge of the time of infection is necessary, then an IgG-positive person should have an IgM test performed by an IgM capture EIA. A negative IgM test essentially rules out infection in recent months. A positive IgM titer combined with a positive IgG titer may be suggestive of recent infection. However, *Toxoplasma*-specific IgM antibodies may be detected by EIA for as long as 18 months after acute acquired infection.

If a patient is tested initially for both *Toxoplasma*-specific IgM and IgG antibodies, the results will sometimes be positive for IgM but negative for IgG. A positive IgM result with a negative IgG result in the same specimen should be viewed with great suspicion. A follow-up serum specimen then should be collected 2 weeks after the first and tested together with the first specimen if possible. If the first specimen was drawn very early after infection, the patient should have highly positive IgG and IgM antibodies in the second sample. If the IgG is negative and the IgM is positive in

both specimens, the IgM result should be considered to be a false-positive result and the patient can be considered to be uninfected.

If the patient is pregnant, an IgG avidity test should then be performed. A high-avidity result in the first 12 to 16 weeks of pregnancy (with time dependent upon the commercial test kit) essentially rules out an infection acquired during gestation. A low-IgG-avidity result should not be interpreted as indicating recent infection, because some individuals have persistent low-IgG-avidity antibodies for many months after infection. Suspected recent infection of a pregnant woman should be confirmed prior to intervention by having samples tested at a toxoplasmosis reference laboratory, such as the Toxoplasmosis Serology Laboratory, Palo Alto Medical Foundation, Palo Alto, CA (http://www.pamf.org). Newborn infants suspected of having congenital toxoplasmosis should be tested by both an IgM- and an IgA-capture EIA. Detection of *Toxoplasma*-specific IgA antibodies is more sensitive than IgM detection in congenital infections.

Toxoplasma-specific IgG antibody levels in HIV-AIDS patients often are low to moderate, but occasionally no specific IgG antibodies can be detected. Because toxoplasmosis in HIV-AIDS patients and in patients with other immunodepressed disease states typically represents activation of a previously latent infection, tests for IgM antibodies are generally negative.

Detection of *T. gondii* DNA by PCR is useful for diagnosing congenital, ocular, and central nervous system toxoplasmosis and reactivation disease. PCR performed on amniotic fluid is especially useful to establish early diagnosis of congenital toxoplasmosis (131, 132).

TRICHINELLOSIS

The immunodiagnostic test for trichinellosis that is currently used in the United States is an EIA that detects antibodies specific to *Trichinella spiralis* ES products produced by cultured larvae (133). The TSL-1 group of larval secretory antigens is conserved in all species/isolates of *Trichinella* and thus can be used to detect infection in animals or people infected with any of the species of *Trichinella* currently recognized. Positive antibody reactions are detectable at some time during infection in serum samples of 80 to 100% of patients with clinically symptomatic trichinellosis. *Trichinella*-specific antibodies typically are detectable between 3 and 5 weeks after infection but may take as long as 60 days postinfection to develop (134, 135). As a result, serology may not be useful for diagnosing acute cases. Multiple serum specimens should be drawn several weeks apart to demonstrate seroconversion in patients whose initial specimen was negative. Positive serology results are ultimately seen in 80 to 100% of patients with clinically symptomatic trichinellosis. The antibody response is affected by the infecting dose of larvae: the higher the infecting dose, the sooner specific antibodies will develop. IgG, IgM, and IgE antibodies are detectable in many patients; however, tests based on IgG antibodies are most sensitive. Antibody levels peak in the second or third month postinfection and then decline slowly for several years. Antibody tests that utilize *T. spiralis* ES antigens can be used to detect human cases of trichinellosis caused by other *Trichinella* species (136, 137).

TRICHOMONIASIS

Trichomoniasis, an infection caused by *Trichomonas vaginalis*, is a common sexually transmitted disease. Diagnosis is made by detection of trophozoites in vaginal secretions or urethral specimens by wet-mount microscopic examination, culture, or detection of parasite antigens or nucleic acid. The sensitivities of the assays compared to that of culture were reported as 60% for wet mounts, 86% for DFA tests, 80% for the Affirm VP test, 78.5% for the OSOM rapid test, and 78% for the XenoStrip rapid test (138, 139). The DFA test, the nucleic acid probe test, and two rapid antigen detection tests are available commercially (Table 4). Antibody detection methods are not used for clinical diagnosis. PCR methods are also available to detect parasite-specific nucleic acids.

Serological and Molecular Diagnosis of Fungal Infections*

MARK D. LINDSLEY

55

Analysis of the signs and symptoms of disease, in conjunction with an evaluation of available epidemiologic information and the results of modern imaging procedures, can often provide a presumptive clinical diagnosis of a fungal infection. However, the clinical presentation of many mycotic diseases is nonspecific, and a presumptive diagnosis must therefore be confirmed by appropriate laboratory tests. A definitive diagnosis of fungal disease is usually based upon the isolation of the etiologic agent in culture and/or microscopic demonstration of the organism in histopathologic or other clinical specimens. Unfortunately, these laboratory methods are insensitive and often unsuccessful, despite repeated sampling efforts. In the absence of positive microscopy or culture, immunologic and molecular tests offer alternative laboratory procedures to aid in the diagnosis of a mycotic disease. Advances in molecular diagnostic methods and the commercial introduction of new antigen and antibody detection tests hold promise for an earlier and more specific diagnosis than previously possible. Antibody detection tests are often helpful for the diagnosis of fungal infections. For example, when acute- and convalescent-phase serum specimens are tested, seroconversion from negative to positive or a 4-fold rise in antibody titer is considered to be diagnostic.

Despite recent advances in the production of purified antigens using biochemical and recombinant techniques, many antigens used in antibody detection tests possess cross-reactive epitopes that are shared among different fungal genera or which cross-react with entirely different classes of microorganisms. To rule out possible false-positive results, several serologic tests must be performed with a battery of antigens (including those from antigenically related genera).

Likewise, mycotic infection is not definitively excluded by negative antibody results, which may be a result of obtaining the specimen before the antibody response can be detected. In this instance, an examination of serial serum specimens to detect temporal changes in titer may be helpful. Furthermore, no or low antibody production may be the result of an altered immune response in some immunocompromised individuals.

Patients who are immunosuppressed are very susceptible to many fungal infections in which false-negative antibody assay results are common. Non-antibody-dependent diagnostic assays, such as detection of fungal antigens, are not dependent on a functioning immune system and may therefore allow diagnosis early in the infectious episode, before an antibody response occurs. Fungal antigens such as β-1-3-D-glucan, galactomannan, and glucuronoxylomannan, the capsular polysaccharide antigen of *Cryptococcus*, are very stable and have long half-lives in a patient's specimen. Assays for the detection of these antigens are often very sensitive.

Nucleic acid-based tests also offer the promise of increased sensitivity and specificity compared to conventional diagnostic tests in both immunocompromised and immunocompetent patients. Nucleic acids, once extracted from clinical materials, can be amplified using PCR or other DNA or RNA amplification technologies. An advantage of molecular diagnostic tests is the capacity to identify the infecting organism to the species level and to detect mixed as well as single-organism infections. However, whereas amplification technologies may provide greater test sensitivity and specificity for the above reasons, these advantages are counterbalanced by the concomitant increased risk of sample contamination resulting in false positivity and a loss of specificity. Moreover, the extraction of fungal DNA or RNA from clinical materials is not a straightforward or standardized process at present. The rigid fungal cell wall can be difficult to penetrate and may result in a reduced DNA yield. In these instances, isolation of extracellular DNA may be helpful; however, the presence of DNases in the specimen may affect the assay sensitivity. Also, procedures used to remove inhibitors of the PCR assay may cause loss of target DNA, thereby reducing test sensitivity. Many DNA-based tests have been developed in single laboratories and are quite successful; confirmation of the usefulness of these technologies awaits multicenter clinical evaluations.

It is important to note that the performance of the different methods discussed is not mutually exclusive. Combinations of methods often provide an increase in diagnostic sensitivity. When available, a combination of antibody and antigen assays can result in enhanced sensitivity. Likewise, the use of DNA and antigen assays may improve diagnostic sensitivity.

This chapter is divided into two sections. The first section provides the methods used for the diagnosis of fungal infections. The second section describes the most

*This chapter contains information presented by Mark D. Lindsley, David W. Warnock, and Christine J. Morrison in chapter 66 of the 7th edition of this *Manual*.

TABLE 1 Commercially available antibody detection tests for fungal diseases

Disease and test[a]	Specimen	Antigen	Interpretation	Sensitivity	Specificity	Source(s)[b]
Aspergillosis						
CF	Serum	Culture filtrate from *A. fumigatus*	Titer of ≥1:8 is strong evidence for *Aspergillus* infection; seroconversion or ≥4-fold increase in titer between acute- and convalescent-phase sera confirms diagnosis	Aspergilloma: 79% ABPA: 46% Invasive pulmonary or disseminated: 20%	95–100%	IMMY
EIA	Serum	Purified recombinant *Aspergillus* proteins	<5 AU[c], negative; 5–<10 AU, intermediate; ≥10 AU, positive	CAP: 90.2–94.1% ABPA: 92.3%	Colonized but not infected: 54.3–84.0% No pulmonary disease: 99.5–100%	Bio-Rad
ID	Serum	Culture filtrate from *Aspergillus* spp.[d]	≥1 line of identity indicates aspergilloma, ABPA, or IA; ≥3 lines of identity is strong evidence for aspergilloma	ABPA: 50–61% Aspergilloma: 80–93%	97–100%	Gibson, IMMY, Meridian, Microgen
Blastomycosis						
CF	Serum	Purified A antigen	Titer of ≥1:8 is presumptive evidence of infection; titer of ≥1:32 is strong presumptive evidence of recent infection; seroconversion or ≥4-fold increase in titer between acute- and convalescent-phase sera confirms diagnosis	Disseminated: 50% Localized: 33%	97–100%	IMMY
EIA	Serum	Proprietary mixture of purified yeast-phase antigens	EIA units: <1.0, negative; 1.0–<1.5, indeterminate; ≥1.5, positive	83.3–100%	100%	IMMY
ID	Serum	Purified A antigen	Presence of A band suggests recent infection	Disseminated: 85% Localized: 33%	100%	Gibson, IMMY, Meridian
Candidiasis						
EIA	Serum	Purified mannan from *C. albicans*	<5 AU, negative; 5–<10 AU, intermediate; ≥10 AU, positive; >20 AU, dilute serum 1:4 and retest	*C. albicans*: 71–88% Other *Candida* spp.: 25–77%	63–94%	Bio-Rad Candida Ab
	Serum, plasma	Purified mannan from *C. albicans*	<5 AU, negative; 5–<10 AU, intermediate; ≥10 AU, positive; >80 AU, dilute serum 1:10 and retest	62.5%	65.0%	Bio-Rad Candida Ab Plus
ID	Serum	Culture filtrate and cell lysate of yeast-phase *C. albicans*	≥1 line of identity is positive for the presence of antibody; seroconversion or increase in number of lines suggests systemic infection; the greater the number of lines, the more severe the infection in immunocompetent patients	58–94%	94–98%	IMMY, Gibson
IFA	Serum	Germ tubes of *C. albicans*	Titer of ≥1:640 suggests invasive candidiasis	78–85%	85–100%	Vircell
Coccidioidomycosis						
CF	Serum, CSF	Culture filtrate (coccidioidin)	Titer of ≥1:2 is positive for acute pulmonary disease; titer of ≥1:16 suggests disseminated disease	Acute pulmonary: 75% Disseminated: 98%	80–95%	IMMY, Meridian

EIA	Serum, CSF	Mixture of purified TP and CF antigens to detect IgM or IgG, respectively	Absorbance values: <0.150, negative; 0.150–<0.200, indeterminate; ≥0.200, positive	IgM only: 74% IgG only: 92% IgM and IgG: 97%	IgM only: 96% IgG only: 97% IgM and IgG: 94%	Meridian
	Serum	TP antigen-coated wells (IgM), CF antigen-coated wells (IgG)	For both CF and TP antigens (EIA units): <1.0, negative; 1.0–<1.5, indeterminate; ≥1.5, positive	92.5%	Normal population: 98.3% Other fungal infections: 95.2%	IMMY
IDCF	Serum, CSF	Culture filtrate (coccidioidin)	Band of identity with reference serum indicates active infection	77%	100%	IMMY, Meridian, Gibson
IDTP	Serum	Heat-treated culture filtrate (coccidioidin, 60°C, 30 min)	Band of identity with reference serum indicates active infection	75–91%	—[e]	IMMY, Meridian
LA	Serum	Heat-treated coccidioidin-coated latex particles	≥2+ agglutination is positive for the presence of antibody; must confirm with ID and/or CF	65–70%	93%	IMMY, Meridian
Histoplasmosis						
CF	Serum, CSF	Mycelial culture filtrate (histoplasmin)	Titer of ≥1:8 is presumptive evidence for infection; titer of ≥1:32 is strongly presumptive for infection	21%	81–99%	IMMY, Meridian
	Serum, CSF	Yeast cell suspension	Titer of ≥1:8 is presumptive evidence for infection; titer of ≥1:32 is strongly presumptive for infection	82%	81–88%	
ID	Serum, CSF	Mycelial culture filtrate (histoplasmin)	M band indicates acute or chronic histoplasmosis (observed in 75% of patients); H and M bands indicate acute histoplasmosis (observed in 20% of patients); positivity for H and/or M band indicates *Histoplasma* meningitis	65–100%	89–100%	IMMY, Meridian, Gibson
EIA	Serum	Inactivated *Histoplasma* antigen	EIA units: <0.9, negative; ≥0.9–≤1.10, equivocal; >1.0, positive	58.0–82.4%	88.0–93.3%	Focus Diagnostics
LA	Serum	Mycelial culture filtrate (histoplasmin)	Titer of ≥1:16 is presumptive evidence of active or very recent infection	Acute: 97–100% Chronic: 46–96%	97% 97%	IMMY
Paracoccidioidomycosis						
ID	Serum, CSF	Mycelial culture filtrate (contains gp43 and other antigens)	Band of identity with reference serum indicates active infection	94%	95–99%	IMMY
		Ag7		84%	99%	
Sporotrichosis						
LA	Serum	*Sporothrix* antigen	Titer of ≥1:8 is presumptive evidence of sporotrichosis	Disseminated: 100% Articular: 86–100% Pulmonary: 73–87% Cutaneous: 56–93%	100%	IMMY

[a]For abbreviations, see the text.
[b]Vendor contact information is given at the end of the chapter.
[c]Arbitrary units compared to a standard curve.
[d]Detection of precipitins to *A. fumigatus*, *A. flavus*, *A. nidulans*, *A. niger*, or *A. terreus* was performed separately.
[e]Insufficient data.

TABLE 2 Commercially available antigen detection tests for fungal diseases

Disease and antigen test[a]	Specimen	Antigen detected	Interpretation	Sensitivity	Specificity	Source(s)[b]
Aspergillosis						
EIA MAb (EBA-2)[c]	Serum (boiled)	Galactomannan	EIA index: ≥0.5 units, positive; detection limit, 1 ng/ml	60–100%	78–99%	Bio-Rad
Candidiasis						
EIA MAb (EBCA-1)	Serum (boiled)	α-(1,2)-Oligomannosides	<0.25 ng/ml, negative; ≥0.25 to <0.5 ng/ml, intermediate; ≥0.5 ng/ml, positive	Overall, 52%; *C. albicans*, 53–60%; other *Candida* spp., 20–70%	85–100%	Bio-Rad Candida Ag
Mab (EBCA-1)	Serum, plasma		<62.5 pg/ml, negative; ≥62.5 to <125 pg/ml, intermediate; ≥125 pg/ml, positive	69.6%	93.5%	Bio-Rad Candida Ag Plus
LA PAb	Serum (not boiled)	Uncharacterized heat-labile *C. albicans* antigen	Titer of ≥1:4 suggests invasive candidiasis	Titer of 1:4, 48–81%; titer of 1:8, 2–59%; titer of 1:16, 59%	Titer of 1:4, 80–97%; titer of 1:8, 93–95%; titer of 1:16, 98%	Ramco
Cryptococcosis						
EIA PAb	Serum, CSF	Capsular polysaccharide antigen	Visual: definite yellow color, positive Spectrophotometric: <0.100 OD, negative; ≥0.100–<0.150 OD, intermediate; ≥0.150 OD, positive Detection limit: 0.63 ng/ml	96–100%	93–99%	Meridian
MAb	Serum, CSF	Capsular polysaccharide antigen	≤0.265, negative; >0.265, positive Detection limit: serum, 5.3 ng/ml; CSF, 1.7 ng/ml	100%	99.8%	IMMY
LA PAb	Pronase-treated serum; CSF (boiled)	Capsular polysaccharide antigen	≥2+ agglutination is positive; titrate positive sera; titer of ≥1:8 is strongly suggestive evidence for infection	93–100%	93–98%	IMMY, Meridian
LFA MAb	Serum, CSF	Capsular polysaccharide antigen	Positive, control and test band visible; negative, only control band visible	98–100%	94–100%	IMMY
LA MAb (E1)	Urine; pronase-treated serum, CSF, BAL fluid	Glucuronoxylomannan	Any agglutination indicates positivity; titrate positive sera; detection limit, 50 ng/ml	Overall, 92%; urine, 93%; serum, 85%; CSF, 100%; BAL fluid, 100%	Overall, 98%; urine, 97%; serum, 100%; CSF, 100%; BAL fluid, 100%	Bio-Rad
Panfungal[d]						
Modified *Limulus* amebocyte assay	Serum	(1,3)-β-D-Glucan	Negative, <60 pg/ml; indeterminate, 60–79 pg/ml; positive, ≥80 pg/ml	100%	90%	Associates of Cape Cod

[a]For abbreviations, see the text.
[b]Vendor contact information is given at the end of the chapter.
[c]Clone name in parentheses.
[d]Detects species of *Candida*, *Aspergillus*, *Pneumocystis*, *Fusarium*, and *Trichosporon asahii* but not *Zygomycetes* or *Cryptococcus* spp.

extensively evaluated or routinely used tests for the serodiagnosis of mycotic infections. Commercially available antibody and antigen detection tests are listed in Tables 1 and 2; vendor contact information is provided at the end of the chapter. Specific details regarding the clinical indications for test application and the mechanics of test performance are presented in the body of the text. Experimental antigen and antibody detection tests and molecular biological tests are reviewed briefly in the text.

Abbreviations. ABPA, allergic bronchopulmonary aspergillosis; AC, anticomplementary; AU, arbitrary units; BAL, bronchoalveolar lavage; BDG, (1,3)-β-D-glucan; CAGTA, *Candida albicans* germ tube-specific antibodies; CF, complement fixation; CH_{50}, amount of complement required for 50% hemolysis; CNPA, chronic necrotizing pulmonary aspergillosis; CSF, cerebrospinal fluid; EIA, enzyme immunoassay (fluid or solid phase); ELISA, enzyme-linked immunosorbent assay; FDA, Food and Drug Administration; GM, galactomannan; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplant; IA, invasive aspergillosis; ID, immunodiffusion in an agarose gel; IDCF, immunodiffusion variation to detect antibody to the CF F antigen in patients with coccidioidomycosis; IDTP, immunodiffusion variation to detect antibody to the tube precipitin antigen in coccidioidomycosis; IFA, immunofluorescent antibody; Ig, immunoglobulin; ITS, internal transcribed spacer region of the rRNA gene; LA, latex agglutination; LFA, lateral flow assay; MAb, monoclonal antibody; OD, optical density; PAb, polyclonal antibody; PCP, *Pneumocystis* pneumonia; QC, quality control; RBCs, red blood cells; SOT, solid-organ transplant; SRBCs, sheep erythrocytes; TP, tube precipitin; VBD, veronal-buffered diluent; WB, Western blotting.

METHODS USED FOR THE DIAGNOSIS OF FUNGAL INFECTIONS

Immunodiffusion

Theory

The ID assay is a solid-phase assay based on the liquid tube agglutination assay in which, when solubilized antigen and antibody are combined at equimolar concentrations, a "latticework" complex is formed, producing a visible precipitate denoting a positive result. The ID assay is performed by placing antigen and antibody in opposing wells formed in an agar matrix. The reagents diffuse into the agar matrix, and when equimolar concentrations are achieved, the latticework is formed and a visible precipitin line, or band, is visualized as the positive result. A seven-well format is used in the performance of this procedure (Fig. 1).

Sample Requirements

Serum or CSF may be used in the ID test. Because the reported sensitivity of the ID test is low early in infection, patients with negative serum reactions during the acute phase of infection should have additional sera drawn 3 to 4 weeks later to detect the development of precipitin bands that would indicate seroconversion and recent infection. Concomitant evaluation of patient specimens by using the CF test is also recommended.

Materials

Plexiglas matrix (3-mm-diam wells) with 17 patterns of seven wells each

Plastic petri dish, 15 by 100 mm

Agar medium (see below for formulation)

Spatula, 1-mm tip (flattened)

Organism-specific reference antigen

Aspergillus: genus-specific antigen

Species-specific antigens: *A. fumigatus*, *A. niger*, *A. flavus*, *A. terreus*

Histoplasma: histoplasmin

Blastomyces: *Blastomyces* A antigen

Coccidioides: *Coccidioides* IDCF antigen (F antigen), *Coccidioides* IDTP antigen

Paracoccidioides: yeast antigen

Organism-specific reference antisera

Humidified chamber

Light box with indirect backlighting

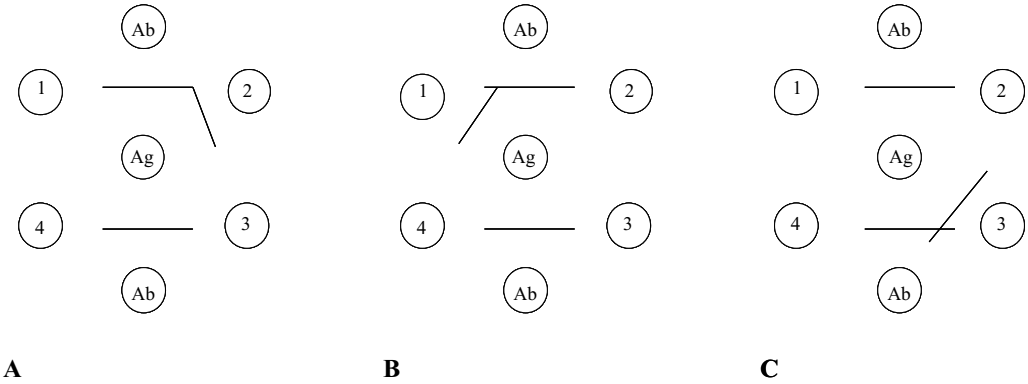

FIGURE 1 Examples of ID results observed when a seven-well agar gel pattern is used. (A) Band of identity (patient 2); (B) band of partial identity (patient 1); (C) band of nonidentity (patient 3). Ag, reference antigen; Ab, reference antiserum; 1 to 4, patient test sera. A standard reference band is shown midway between the antiserum-containing wells and the central antigen-containing wells in all three panels.

Agar Medium: *Aspergillus* Formulation

Stock barbital buffer (pH 8.6), 0.05 M, made up to 500 ml.

Sodium diethylbarbiturate	5.16 g
Diethylbarbituric acid	0.92 g
Sodium acetate	2.05 g

Store at 4°C. Buffer is stable for 2 months. Discard if bacterial growth develops.

Phenolized medium.

Noble agar (or equivalent)	1.00 g
Phenol, liquefied	0.25 ml
Stock barbital buffer (above)	25.0 ml
Distilled water	to 100 ml

Heat until the agar is completely dissolved.

Agar Medium: Dimorphic Pathogen Formulation

Phenolized medium.

Sodium chloride	0.9 g
Noble agar (or equivalent)	1.0 g
Sodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$)	0.4 g
Phenol, liquefied	0.25 ml
Glycine	7.5 g
Distilled water	to 100 ml

Autoclave the mixture at a pressure of 15 lb/in^2 for 10 min. The final pH of the medium should be 6.3 to 6.4.

Larger volumes of agar can be produced and divided into aliquots in smaller containers for later use. Store at 4°C. Aliquots can be reliquefied in a boiling water bath or microwave set at low power.

Procedure

Making Agar ID Plates

1. Using a pipette, place 6.5 ml of molten (60 to 75°C) agar into a petri dish (15 by 100 mm) and allow to solidify for at least 2 h.
2. Overlay the first agar layer with 3.5 ml of molten (85 to 90°C) agar and immediately place the Plexiglas matrix on top of the liquid agar.
3. Plates may be used 30 min after the agar has solidified or may be stored for up to 1 week at 4°C in a humidified chamber.

Preparing and Inoculating ID Plates

1. Number each seven-well pattern on the bottom of the dish (not on the template).
2. Place plates on a dark background to facilitate well filling.
3. Carefully remove the excess agar from the upper section of the template wells with the pointed end of the spatula.
4. Place the reference serum in the top and bottom wells of each pattern and place the patient's test sera in the four lateral wells (Fig. 1). Note, wells should be filled with the proper reagent, but overfilling and accidental mixing of well reagents should be avoided.
5. At this step, with assays for antibodies against *Aspergillus*, *Blastomyces* A antigen, or *Coccidioides* IDTP antigen, the plate should be covered and incubated at room temperature for 30 min before going on to step 6. For all other assays, preincubation is not necessary and you can proceed directly to step 6.
6. Place the reference antigen in the center well of each pattern. All wells must be examined for air bubbles.
7. If bubbles are observed, they should be broken by being gently pierced with toothpicks. Separate toothpicks should be employed for each different antigen and antibody solution.
8. Place closed plates on a level surface in a humidified chamber and incubate them at 25°C for 48 h.

Reading of ID Plates

1. Remove the Plexiglas matrix by gently pressing the sides of the petri dish. Place Plexiglas matrix in a 10% solution of bleach for 15 min, and then wash and rinse.
2. Gently wash the agar surface with water and finish by adding enough water to sufficiently cover the agar surface.
3. Cover the petri dish and incubate it for 10 to 30 min, allowing the ID band to intensify.
4. Read ID reactions using a light box with indirect lighting and record visible reactions.
5. Very carefully, remove the upper layer of agar overlay by gently sweeping the surface with a cotton swab.
6. Wash the remaining agar with water to remove excess agar from the upper layer.
7. Cover the agar with a minimal volume of water.
8. Examine the plate for lines of identity between test and reference wells.

Interpretation

1. Visible ID bands must be present between the antigen and reference antisera for each seven-well pattern inoculated.
2. The lack of ID bands between the antigen and reference antisera invalidates the results of the sera for that pattern, and the test must be repeated.
3. Four results may be observed for the ID reactions with patient sera (Fig. 1).
   a. No band present: negative reaction. Note, this reaction can occur in the event of antibody excess. If the index of suspicion for infection is great, serum dilutions should be performed.
   b. Band of identity: patient serum precipitates an antigen with identical specificities.
   c. Band of partial identity: patient serum precipitates an antigen that possesses common but not identical antigen determinants.
   d. Band of nonidentity: patient serum precipitates an antigen with no antigenic determinant in common; precipitation occurs with a component of the antigen preparation that is different from that with which the specific reference antisera reacts.
4. A band of identity is considered a positive reaction. Bands of partial and nonidentity are bands of unknown significance.
5. Patient serum must react with the homologous reference antigen to form a line of identity with the reference band to be considered positive.

Notes for the Performance of the ID Assay

1. Some antigenic extracts (particularly *Aspergillus)* contain C substance, and this can react with C-reactive protein in the serum of some patients with inflammatory disease.

The resulting complex forms a precipitate, which may be erroneously interpreted as the presence of anti-*Aspergillus* antibodies. This false-positive reaction is easily eliminated if the test plates are soaked in 5% sodium citrate for 45 min before being read. In addition, C substance generally produces lines of nonidentity with reference antisera.

2. When using in-house-prepared antigen and/or reference antisera, the reagents must be titrated to determine the optimum concentration for use in the assay. For example, to determine the optimum concentration of antigen, serial dilutions of antigen are sequentially placed in the 6 wells surrounding the center well. The center well receives the reference antisera at the previously determined optimum concentration. Read the ID reactions after incubation for 48 h at room temperature. The optimum concentration is that which places the ID band equidistant between the antigen and antibody well.

3. The sensitivity of the ID assay is sometimes compromised due to the presence of antibody below the level of detection of the assay. Concentration of serum 4- to 8-fold increases the concentration of antibody in the serum and subsequently the sensitivity of the assay. Concentration can be performed through evaporation using a Savant SpeedVac (Thermo Scientific; Waltham, MA) or an Amicon/Centricon centrifugal filter device (EMD Millipore; Billerica, MA).

Commercial ID Test Procedures

Kits and/or individual reagents for the ID assay are available for purchase from several vendors, as listed in Table 1.

Materials

Reagents purchased commercially necessary to perform this assay are as follows:

1. Precast agar medium available using different formulations
   a. Agarose
   b. Cleargel (IMMY); note, Cleargel plates are not to be used with rabbit antiserum
   c. Well sizes can vary between vendors which require a variable amount of reagents and patient serum to perform the assay
2. Organism-specific reference antigen
3. Organism-specific reference antisera (purchase twice the volume of antisera as antigen, since two wells are used for the reference antisera to one of antigen per 7-well pattern) (Fig. 1)
4. Humidified chamber
5. Light box with indirect backlighting

Procedure

Performance of the ID procedure using commercial reagents should follow the procedure as described in the vendor's package insert. Briefly, the inoculation of the ID plates and reading of the ID reactions are identical to those listed above. Inoculated agar plates are placed in a humidified chamber. Positive results are reported after 24 h of incubation, and negative results are reported after 72 h of incubation.

Interpretation

Refer to the manufacturer's package insert for the interpretation of the results using commercial reagents.

Notes for Performance of Commercial ID Assays

1. Commercial antigens and antibodies should be used with the agar plates provided by the vendor.

2. An advantage with precast agar medium is, unlike the method described above, there is no Plexiglas template that obscures the view of precipitin band formation. Therefore, the ID bands can be visualized regularly; positive reactions can be determined after 24 h and negative results can be monitored throughout the entire 72 h of incubation.

Complement Fixation Assay

Theory

Complement is a series of lytic proteins that binds to antibody/antigen complexes and ultimately causes the lysis of cells by embedding into and disrupting the cell membrane. The CF assay takes advantage of the complement binding or "fixing" to antibody/antigen complexes. Antigen specific for the disease in question is combined with the patient serum along with a known quantity of complement. Specific antibody in the patient serum, if present, binds to the antigen. Complement binds to the antibody/antigen complex, reducing the amount of active complement in the mixture; the greater amount of antibody present, the greater the number of antibody/antigen complexes formed and the greater the reduction of active complement. In patients with no antibody present in their serum (seronegative patients) antibody/antigen complexes are not formed, and subsequently, there is no reduction of active complement in the mixture.

The amount of active complement present in the mixture is measured using antibody-coated RBCs as an indicator system. The greater percentage of RBCs lysed, the greater amount of active complement present in the mixture. Total lysis of the RBCs indicates the lack of antibody present in the patient serum. No lysis of the RBCs indicates a large amount of antibody present in the patient serum. Methods and assay interpretation are detailed below.

The advantage of the CF test is that it provides a quantitative measurement of the amount of antibody present in the test specimen. To assess disease progression or treatment efficacy, the titer for a given early (acute-phase) specimen can then be compared to the titer of a later (convalescent-phase) specimen as measured by the respective increase or decrease in antibody titer. For accurate comparisons, serially acquired specimens must be tested in parallel during the same assay.

The disadvantages of the CF test are as follows: (i) it is a relatively complex, labor-intensive assay that should be performed by only highly trained technical staff; (ii) accuracy depends on constant, complex QC standardization or titration of test reagents (hemolysin, complement, SRBCs) each time a new lot of reagent is obtained; and (iii) specimens may possess AC activity (i.e., patient serum fixes or destroys complement in the absence of any added antigen), making test results in these wells uninterpretable.

If infection by one of the dimorphic pathogens is suspected, it is important to include antigens for each of the dimorphic pathogens when performing CF because cross-reactivity can occur at low antibody titers. Furthermore, overlap of the areas of endemicity for *Histoplasma*, *Blastomyces*, and *Coccidioides* and the ease of travel between zones of endemicity may confound the diagnosis. *Paracoccidioides* antigen should also be included when there is a history of travel to Central or South America.

Because of the complexity of the procedure, only an abbreviated description of the CF test is outlined below. Readers are directed to a more detailed protocol (1) or a modified version, available from Immuno-Mycologics for use with their reagents. No commercial kits are available

for the CF test, but antigens, antisera, and other reagents can be purchased individually from the commercial sources listed in Table 1.

Sample Requirements

Serum, peritoneal fluid, or CSF may be used in the CF test. Serum is most often tested in cases of suspected acute fungal infections. CSF may be used to detect localized antibody production if meningitis is suspected. Other body fluids are examined in cases of suspected disseminated disease. Acute-phase sera should be obtained after the onset of symptoms, and convalescent-phase sera should be collected 3 to 4 weeks later and tested in parallel to identify changes in titer compared to the titer obtained for the acute-phase sera. To remove any red or white blood cells, CSF should be centrifuged before being tested. Sera and CSF are heated at 56°C for 30 min immediately prior to use to inactivate endogenous complement activity.

Serum and CSF can be stored at 4°C for 72 h or stored for longer periods in frozen aliquots at −20°C or colder in a nondefrosting freezer. Repeated freezing and thawing of the samples, which can reduce reactivity, should be avoided.

Unacceptable Specimens

1. Plasma. Blood collected with any anticoagulant is an unacceptable specimen for the CF assay.

2. Excessively pigmented specimens. As the results of the CF assay are measured by the hemolysis of red blood cells, excessively hemolyzed specimens can interfere with test interpretation. Slightly pigmented specimens may be used because the color will be diluted out during sample processing and titer determination which will not interfere with test interpretation.

3. Excessively lipemic specimens. Lipids should be removed with a 0.45- to 0.8-μm-pore-size filter attached to a syringe (Millipore Corp.).

Materials

Antigens and reference antisera may be purchased from Immuno-Mycologics, Inc., or from Meridian Diagnostics, Inc. Other key materials, listed below, may be purchased from vendors that sell biological products (e.g., Lonza, Walkersville, MD; Rockland Immunochemicals, Inc., Gilbertsville, PA; TCS Biosciences Ltd., Buckingham, United Kingdom; and Colorado Serum Company, Denver, CO).

Equipment

pH meter
Centrifuge with microtiter plate carriers
Incubator (37°C)
Glass serologic tubes (15 by 125 mm and 12 by 75 mm)
Pipettes (1, 5, and 10 ml)
Water baths (37 and 56°C)
Refrigerator
Microtiter equipment
25- to 50-μl multichannel pipetter
U-bottom polystyrene microtiter plates
Reading mirror (concave)

Procedure

Reagent Preparation and Standardization

1. Gelatin solution. Make a 0.05% (wt/vol) solution of gelatin in deionized H_2O and heat to 100°C. Allow it to cool to room temperature, and use it to dilute 5× VBD to 1×. The shelf life of the 0.5% gelatin water solution is 7 days at 4°C.

2. VBD. VBD is prepared and stored as a 5× stock solution. The working 1× VBD solution is prepared by diluting the 5× stock solution of VBD to 1× with 0.05% gelatin-water solution. The 1× VBD is used throughout the test procedure as a reagent diluent. The pH of the 1× VBD must be between 7.3 and 7.4; if it is not, prepare new 1× VBD from the 5× stock. Do not adjust the pH of the 1× VBD. If the pH of the 1× VBD is continually out of range, obtain new 5× buffer. Keep the 1× VBD on ice during the assay. The shelf life of 1× VBD is 24 h at 4°C.

3. SRBCs, supplied in Alsever's solution. SRBCs must be washed three times with 1× VBD by gentle centrifugation on the day the CF test is to be performed (final working concentration, 2.8% [vol/vol] in 1× VBD). If red pigment remains after three consecutive washes, the SRBCs are too old and too fragile for use. A fresh lot of SRBCs should be obtained (SRBCs should be between 5 and 28 days old at the time of use). The shelf life of the stock SRBCs in Alsever's solution is 1 month, whereas the shelf life of washed and diluted SRBCs in 1× VBD is 24 h.

4. Hemolysin. Hemolysin (complement-fixing, anti-SRBC antibody) is used to "sensitize" (i.e., coat with antibody) the SRBCs, allowing them to be lysed in the presence of complement. To determine the optimal concentration of hemolysin for the sensitization of SRBCs, serially dilute hemolysin in 1× VBD in 15- by 125-mm glass tubes (1:1,500, 1:2,000, 1:2,500, 1:3,000, 1:4,000, and 1:8,000) and titrate it against multiple dilutions of guinea pig complement (1:300, 1:350, and 1:400 [see item 5 below]). After adding SRBCs and incubating them in a water bath at 37°C for 1 h, centrifuge tubes and determine the percent hemolysis in each tube by comparison to a standard curve (color standards) constructed from differing proportions of hemoglobin and 0.28% SRBCs (percent lysis = 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100). Plot the percent hemolysis against the hemolysin dilution, and identify the second dilution on the plateau of the graph. This hemolysin dilution is optimum to sensitize SRBCs for complement titration, antigen titration, and serum tests. Hemolysin must be titrated each time a new lot of SRBCs or hemolysin is obtained. The shelf life of the stock hemolysin (a 1:100 dilution of hemolysin in VBD containing 0.2% phenol) at 2 to 8°C is up to 1 year.

5. Guinea pig complement. Reconstitute guinea pig complement into single-use glass vials, and freeze at −70°C until ready to use. Storage in plastic vials will cause a reduction of complement activity over time. The complement must be subjected to titer determination before each use.

Titration of guinea pig complement. (Note: during this procedure, the stock complement, VBD, and further complement dilutions must be kept on ice, unless otherwise instructed. Tubes and flasks should be made of glass and kept on ice while performing the procedure.)

a. Remove an aliquot of complement from the −70°C freezer and thaw on ice.
b. Keep complement and subsequent dilutions on ice, unless otherwise instructed.
c. Serially dilute complement with VBD (1:200, 1:250, 1:300, 1:350, and 1:400) in 12- by 75-mm glass test tubes and add 0.20, 0.25, 0.30, and 0.40 ml of each complement dilution to 0.60, 0.55, 0.50, and 0.40 ml of VBD, respectively.

d. Then add 0.20 ml of sensitized SRBCs (see below) to the tubes, shake the mixture, and incubate the tubes in a 37°C water bath for 30 min (shake again after 15 min and return the tubes to water bath).
e. Remove the tubes, and centrifuge the cells. Determine the percent hemolysis compared to the color standards.
f. Calculate the ratio of lysed to unlysed cells (lysis ratio = lysed/[100 − lysed], i.e., 10/[100 − 10] = 0.111).
g. Using log-log graph paper, plot the volume of complement added to the tubes (0.20, 0.25, 0.30, and 0.40) against the lysis ratio. For valid analysis, the lysis ratio values of the two lower complement concentrations (0.2 and 0.25) must be less than 1, and the lysis ratio values of the two higher complement concentrations (0.30 and 0.40) must be greater than 1.
h. With a ruler, join the two points plotted for the two lowest volumes of complement and do the same for the two highest volumes. Draw a line connecting the midpoint of one line to the midpoint of the other line.
i. From the point where this line intersects the vertical line at 1 on the *x* axis, draw a horizontal line to the *y* axis on the left. This is the volume, in milliliters, that contains 1 CH_{50} unit. Multiply this value by 5 to obtain the equivalent of 5 CH_{50} units.

6. Sensitized SRBCs. While gently swirling the flask, slowly add an equal volume of SRBCs to an equal volume of the optimum concentration of hemolysin (determined as described in item 4 above). Incubate the mixture for 15 min in a 37°C water bath before use.

CF Test

1. All reagents (hemolysin, complement, SRBCs, and VBD) must be optimally standardized as described above before the test is used with patient samples or the positive control.

2. Using cold VBD, prepare a 1:8 dilution of the following samples in plastic screw-cap tubes: patient sample, positive control, and negative control. Samples may also be diluted 1:2 instead of 1:8 or may be diluted more than 1:8 during repeat testing to detect lower or higher antibody titers, respectively.

3. Heat the diluted sera for 30 min in a 56°C water bath, and cool to room temperature.

4. Label the microtiter plates as shown in Fig. 2.

5. Pipette 25 μl of cold VBD into the wells of rows B to H of columns 1 to 12 of the patient plate(s) (Fig. 2A) and columns 1 to 9 of the control plate (Fig. 2B).

6. Add 50 μl of heat-inactivated patient sera to wells 1 to 6 of row A for patient 1 and wells 7 to 12 of row A for patient 2. Add 50 μl of control sera to the appropriate wells in row A of the control plate that correspond to the appropriate antigen.

7. Using a multichannel pipette, serially pass 25 μl of serum sequentially from row A through row H and mix. Remove 25 μl from the wells in row H and discard (25 μl of serially diluted sera should remain in all wells).

8. Dilute fungal antigens to the appropriate concentration as determined by the antigen titration assay performed for that lot of antigen. Add 25 μl of diluted antigen to wells A through H of the appropriate columns as follows:

a. *Histoplasma* mycelial antigen (histoplasmin) to columns 2 and 8 on patient plate(s) and column 2 of the control plate.
b. *Histoplasma* yeast antigen to columns 3 and 9 on patient plate(s) and column 3 of the control plate.
c. *Blastomyces* A antigen to columns 4 and 10 on patient plate(s) and column 5 on the control plate.
d. *Coccidioides* culture filtrate antigen (coccidioidin) to columns 5 and 11 on the patient plate(s) and column 7 on the control plate.
e. *Paracoccidioides* antigen in columns 6 and 12 on the patient plate(s) and column 9 on the control plate.

9. Add 25 μl of cold VBD to columns 1 and 7 on the patient plate(s) and columns 1, 4, 6, and 8 on the control plate to control for serum activity in the CF test.

10. Thaw guinea pig complement on ice, and dilute with cold VBD in a glass container to the concentration determined by the complement titration assay. Allow to stand on ice for at least 20 min, but use within 2 h.

11. Add 50 μl of diluted complement to all patient specimen wells and columns 1 to 9 of the control plate.

12. A complement "back titration" is performed with each assay to determine the accuracy of the complement titration/dilution. On the control plate, add 50 μl of cold VBD to rows A to F in columns 11 and 12.

a. Add 100 μl of diluted complement to wells A to F of column 10. Serially transfer 50 μl of diluted complement from wells A to F of column 10 to wells A to F of column 11 and then to wells A to F of column 12. After gently mixing the content of the wells of column 12, remove 50 μl of diluted complement and discard.
b. Add 50 μl of cold VBD to wells 10 to 12 in row A. In wells 10 to 12 of rows B to F, add 25 μl of cold VBD.
c. Add 25 μl of diluted antigen from step 8 to the appropriate wells in rows B to F of columns 10 to 12.

13. Finally, add 100 μl of cold VBD to wells 11 and 12 of row H. Each well should now contain a total volume of 100 μl.

14. Mix the contents of the wells for 5 to 10 s on a vibrating microtiter plate shaker.

15. Place plates at 2 to 8°C for 15 to 18 h. Cover the plates to prevent evaporation (an unused plate can serve this function; plates can be placed in stacks of five to eight plates).

16. Place VBD and SRBCs on ice and store at 2 to 8°C for use in the following steps.

17. As the incubation period in step 15 concludes, sensitize SRBCs are sensitized as described above; add 25 μl of sensitized SRBCs to all wells of the patient and control plates.

18. Mix the contents of the wells for 5 to 10 s on a vibrating microtiter plate shaker.

19. Cover the plates, and incubate them at 37°C for 30 min. Stack the plates no more than two high.

20. Centrifuge the plates for 5 min at 400 to 450 × *g*.

21. Read the plates for percent hemolysis compared to the color standard.

Reading and Interpretation of CF Reactions

1. Control sera must display the titer recommended by the manufacturer (or the typical titer for laboratory-derived control sera) ± 1 dilution. If not, the sera must be repeated for the particular antigen.

2. The complement back titration controls should display 95 to 100% lysis in column 10, 90 to 100% lysis in column 11, 30 to 50% lysis in the VBD control well (A of

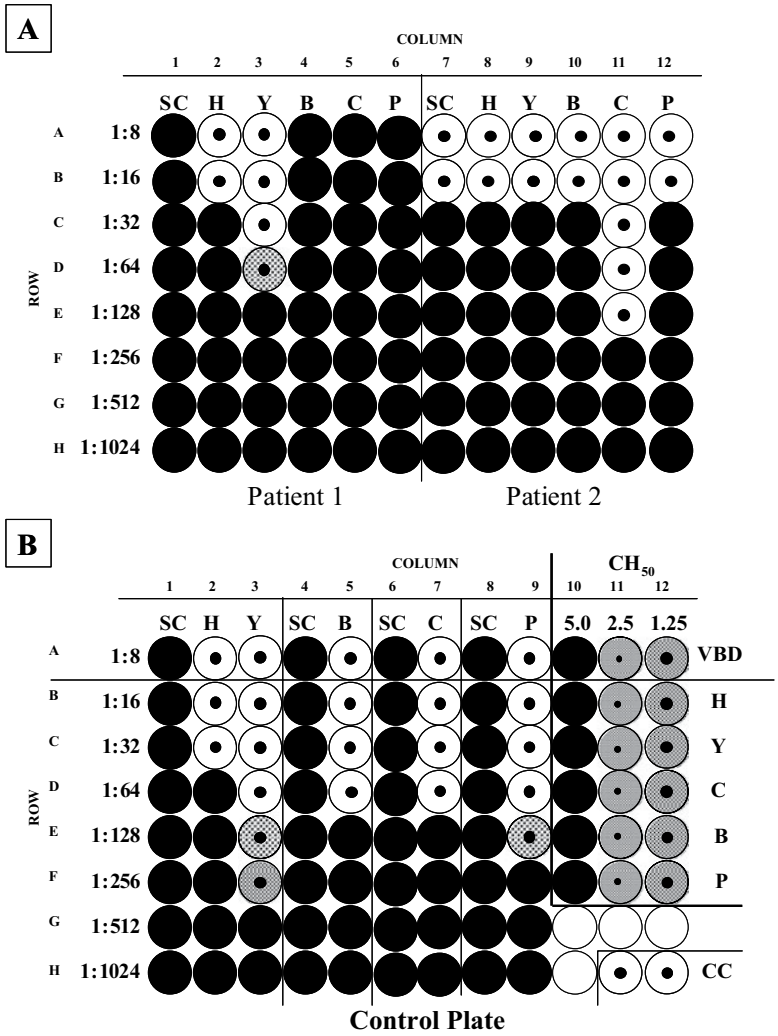

FIGURE 2 Diagram displaying organization of the microtiter plates and results for the CF assay. Solid circles, 100% lysis; shaded circles, 30 to 90% lysis; open circles, 0% lysis. SC, serum control wells receiving buffer in place of antigen; H, column receiving *Histoplasma* mycelial histoplasmin antigen; Y, column receiving *Histoplasma* yeast antigen; B, column receiving *Blastomyces* antigen; C, column receiving *Coccidioides* coccidioidin antigen; P, column receiving *Paracoccidioides* yeast antigen; CC, cell control; CH_{50}, amount of complement required for 50% lysis of SRBC. (A) Patient plate. Patient 1 demonstrates serum that is positive for *Histoplasma* antibodies with a 1:16 titer against mycelial histoplasmin antigen and a 1:64 titer against *Histoplasma* yeast antigen. Patient 2 displays serum that contains an AC titer of 1:16. However, because antibodies to coccidioidin are present at a titer that is >2 dilutions beyond the AC titer, the patient CF result is AC 1:16, *Coccidioides* 1:128. (B) Control plate. Columns 1 to 9 depict the reactivity of the control sera to specific fungal antigens. Columns 10 to 12, rows A to F, depict the results of the back titration of complement in CH_{50} units (5, 2.5, or 1.25) in the presence of fungal antigens or the VBD buffer control. Columns 11 and 12, row H, depict the cell control wells that receive SRBC only.

column 12), and 0 to 50% lysis in the antigen control wells (B to F of column 12). The cell control wells (H 11 to 12) should display no lysis (0%).

3. Wells with patient or control serum that display ≤30% lysis are considered positive. The dilution at which the last well of serially diluted serum displays ≤30% lysis is the antibody titer for that sample. Serum control wells should display >70% lysis.

4. Serum that displays ≤70% lysis in a serum control well is considered AC at that serum dilution, and results cannot be interpreted for that dilution (Fig. 2A, patient 2). AC activity often disappears as the serum is serially diluted. A patient's serum may contain an antibody titer that is greater than that of the AC activity. In this case, a titer of the fungal antigen can be interpreted and reported (i.e., a patient serum with AC activity that ends at a serum dilution of 1:8 and with a positive antibody to *Coccidioides* antigen observed at a 1:64 dilution can be reported as AC at 1:8 and positive for antibody to *Coccidioides* at 1:64). Parallel testing of serum using the ID assay can help to resolve antibody detection in serum that contains AC activity, as ID results are not affected by AC. However, ID tests may not be as sensitive as the CF test. Also, all of the QC measures described in the text under "Reagent Preparation and Standardization" above must be followed for optimal operation of the test.

Latex Agglutination

Theory

The LA test is a qualitative slide agglutination assay using latex particles to detect antibodies or antigen of interest. Antigen-coated latex particles measure antibody levels, and antibody-coated particles measure the presence of antigen in the specimen. Like the ID assay, the LA test depends on the formation of latticework structures to agglutinate the latex particles, resulting in visible clumping. Results are graded according to the level of agglutination (1+ to 4+ agglutination) observed for a particular dilution of serum. If a patient specimen contains an excessive quantity of antigen or antibody, a false negative, or prozone effect, may occur. In these instances, dilution of the patient specimen may reveal the positive reaction.

Commercial Methods—Antibody Detection

The assay is rapid and simple to perform, and no special equipment is needed. Commercial sources are listed in Table 1. The LA test yields results in a matter of minutes and may be used with sera giving AC activity in the CF test.

Sample Requirements

Blood should be collected into tubes that contain no anticoagulant, since anticoagulant can interfere with test performance. Specimens can be held at 2 to 8°C for up to 72 h before being tested but must be placed at −20°C or colder for long-term storage. Specimens should not be stored in frost-free freezers because repeated freezing and thawing can affect test results. Serum must be heat inactivated at 56°C for 30 min before being tested.

Performance of the LA assay procedure using commercial reagents should follow the procedure as described in the vendor's package insert. Briefly, serum and latex particles are placed on a reaction card provided by the manufacturer, mixed using a separate applicator stick for each serum to avoid cross contamination of samples, and placed on a rotary shaker or rotated by hand for the recommended time and speed. The reaction card is immediately examined macroscopically for signs of agglutination.

Agglutination is graded as follows: negative, a homogeneous suspension of particles with no visible clumping; 1+, fine granulation against a milky background; 2+, small but definite clumps against a slightly cloudy background; 3+, large and small clumps against a clear background; 4+, large clumps against a clear or very clear background. An agglutination grade of 2+ or greater is considered positive.

Avoid freezing of the latex particle suspension, since this can result in granularity, leading to false-positive results. Materials should not be allowed to dry on the slide.

Commercial Methods—Antigen Detection

The LA test for antigen detection is a noncompetitive direct-binding slide agglutination test to detect fungal antigens in clinical samples by employing latex particles adsorbed with an antigen-specific detection antibody (monoclonal or polyclonal). Specimens can be screened using a single dilution; positive samples are subsequently diluted serially to obtain an end point titer (2–4).

Sample Requirements

1. Various vendors provide kits for antigen detection for latex agglutination. Follow the requirements listed in the kit's package insert, as they vary as to the specimens for which they are approved. For cryptococcosis, most tests are approved for serum and CSF; some are also approved for BAL fluid. Plasma may not be used.

2. For serum, most kits recommend pretreatment with pronase before testing to disrupt antigen/antibody complexes. Pronase must be inactivated with pronase inhibitor or by boiling prior to use.

3. For CSF, heat in a boiling-water bath for 5 to 10 min as directed by the manufacturer. Pronase treatment of CSF is generally not recommended but was reported to increase LA titers by 2 to 3 dilutions in 14 (20%) of 70 CSF specimens tested (5).

4. BAL fluids should be treated with pronase prior to assay.

Performance of the LA assay procedure for antigen detection using commercial reagents should follow the procedure as described in the vendor's package insert. The procedure for antigen detection is the same as for antibody detection described above except that specimens are heat inactivated and/or pronase treated to remove immune complexes prior to use. An agglutination grade of 2+ or greater is considered positive. However, a 1+ reaction may be the result of a prozone effect as a result of excess antigen present in the specimen. If suspected, the assay should be repeated after serially diluting the specimen.

If desired, samples with a positive result upon initial screening can be diluted for end point titer determinations using serial 2-fold dilutions up to 1:1,024; greater dilutions may be required if testing determines that the specimen is still positive at the 1:1,024 dilution.

Enzyme Immunoassay

Theory

The EIA is a sensitive, solid-phase immunoassay that is used for the detection of either antibody or antigen. For antibody detection, a specific antigen, coated on the surface of a plastic microtitration well, binds or immobilizes specific antibody present in the patient's serum. The addition of an enzyme-labeled anti-human antibody results in the formation of an antigen/antibody/enzyme-labeled antibody complex. After the addition of the enzyme's substrate, a positive reaction is indicated by a color change measured spectrophotometrically.

Antigen is detected by coating the microtiter wells with a polyclonal or monoclonal antibody to the specific antigen. Antigen in the patient specimen is immobilized by the coating antibody and is detected by the addition of an enzyme-labeled antibody specific for the antigen. As with the antibody assay, the presence of enzyme is demonstrated by the addition of the appropriate substrate. While this method is very sensitive, often more sensitive than other methods, the specificity is variable depending on the specificity of the reagents employed in the assay. While several enzyme/substrate combinations can be used, horseradish peroxidase-tetramethylbenzidine is most frequently used.

EIA for Detection of Antifungal Antibody

EIAs available commercially for the detection of antifungal antibodies in patient specimens are detailed in Table 1. The kit contains all necessary reagents and microtiter plates precoated with antigen. Microtiter plates are composed of eight-well strips so that the entire plate does not have to be used at one time. Unused microwells must be placed back inside the foil ziplock pouch provided and sealed immediately to protect them from moisture.

A detailed stepwise procedure can be found in the package insert included with each kit. Briefly, all reagents should be brought to room temperature prior to performing the

assay. Diluted specimens are added to the antigen-coated microtiter plate, followed stepwise with a peroxidase-conjugated anti-human antibody and substrate solution. Each step is followed by an incubation and washing of the microwells using a plate washer. Plates are read spectrophotometrically at 450 nm or at 450/630 nm, if a dual-wavelength plate reader is available.

To reduce assay background, it is essential that excess wash buffer is removed after each wash by forcefully inverting the microtiter plate onto a paper towel until no more moisture is seen on the paper towel. Care must be taken that the microtiter well strips do not come loose from the microtiter well frame.

EIA for Detection of Fungal Antigen

Assays available commercially for the detection of fungal antigens in patient specimens are listed in Table 2. Such assays include the Platelia assays for *Aspergillus* GM antigen and for *Candida* antigen (BioRad) and a variety of tests for cryptococcal antigen. As with the antibody assay above, detailed stepwise procedures can be found in the package insert included with each kit. The methods are essentially the same as that for the EIA for antibody detection. The major difference between the two assays is that the wells of the microtiter plate are coated with antigen-specific antibody instead of antigen.

Lateral Flow Assay

Theory

The LFA is a rapid, low-complexity, immunochromatographic assay in which diluted serum/CSF travels by capillary action along a filter test strip to a sector containing immunogold-conjugated antibody. If antigen is present, antibody/antigen complexes form, continue to travel down the test strip, and are finally trapped by a line of immobilized anti-antigen antibodies. A red/purple line appears, resulting from the accumulation of immunogold particles and signifying a positive reaction. LFA results are available in 10 min.

Sample Requirements

Acceptable specimens are nonhemolyzed serum and aseptically collected CSF. Store specimens at 2 to 8°C for up to 72 h. For longer periods, store below −20°C. Do not repeatedly thaw and refreeze. If shipping is required, specimens should be maintained at 2 to 8°C or below −20°C.

Materials

The LFA kit contains all reagents necessary to perform the test. The kit is stored at room temperature (22 to 25°C).

Details of the procedure can be found in the kit package insert. Briefly, the patient specimen and specimen diluent are combined in a reaction tube, followed by placement of the LFA strip into the tube. After a 10-min incubation, the results are observed.

Interpretation

1. Positive: a line of any intensity visible on the LFA strip at the test position, plus a strong positive line at the control position.
2. Negative: a strong positive line at the control position on the LFA strip with no visible line at the test position.
3. Invalid test: no line present at the strip control position. The results are invalid and the test should be repeated.

Panfungal Detection Using 1,3-β-D-Glucan Assay

Theory

BDG is a component of the cell wall of all fungi except the Mucormycetes, and only low levels of BDG are released from *C. neoformans* (6). BDG activates factor G, a coagulation enzyme found in horseshoe crab amoebocyte lysates. Once activated by BDG, the enzyme cleaves a chromogenic substrate (*t*-butyloxycarbonyl-Leu-Gly-Arg-*p*-nitroanilide) included in the test, releasing *p*-nitroanilide. The free *p*-nitroanilide can then be quantitated with respect to a glucan standard. Two methods have been employed to measure the reaction, a colorimetric method and a turbidimetric method.

Two species of horseshoe crab, the North American horseshoe crab (*Limulus polyphemus*) and the Asian horseshoe crab (*Tachypleus tridentatus*) have been used in the production of BDG assays. The FDA-approved Fungitell assay (Associates of Cape Cod, East Falmouth, MA) uses the amoebocyte lysate from *Limulus polyphemus* and employs the colorimetric method. Alternative colorimetric (Fungitec G Test MK [Seikagaku Kogyo Co., Ltd., Tokyo, Japan] and BGSTAR β-glucan test [Maruhua, Tokyo, Japan]) (7) and turbidimetric (Wako-WB003; Wako Pure Chemical Industries, Ltd., Osaka, Japan) (8) forms of amoebocyte lysate assays are available in Japan (9).

Materials Required

The kit provides all necessary reagents

Pipette tips, must be glucan free

13- by 100-mm borosilicate glass test tubes, must be glucan free

Certified glucan-free tips and tubes can be purchased from the kit manufacturer

Spectrophotometer, capable of maintaining a temperature of 37°C and capable of dual-wavelength monitoring at 405 and 490 nm with a dynamic range up to at least 2.0 absorbance units

Computer with appropriate kinetic assay software

Specimen Requirements

Sterile serum samples should be placed in a container that is free of interfering levels of BDG and stored at 2 to 8°C before assay or frozen at <-20°C. False-positive results have been observed in specimens from patients undergoing hemodialysis when certain cellulose dialysis membranes are used (10, 11). Treatment with fractionated blood products such as serum albumin and immunoglobulins (12) have also resulted in false-positive results. Likewise, care must be taken with subjects or specimens exposed to glucan-containing gauze. Surgical gauzes and sponges can leech high levels of BDG that may contribute to a contamination-based transient positive result, as has been observed in postsurgical patients (13). In these cases, sera should be drawn 3 to 4 days after final exposure (hemodialysis or surgical exposure to BDG-containing sponges and gauze).

Procedure

Note, the outside wells of the microtiter well plate are not used in this assay. When first performing the assay, it is recommended to test patient sera and glucan standards in triplicate. As the use of the assay becomes more familiar and results more consistent, the assay can be performed in duplicate. During the procedure, avoid the use of gauze or other glucan-containing material which may contaminate

the specimen or assay. Use suitable protective clothing and powder-free gloves when handling patient specimens.

The Fungitell assay is quantitative, which measures the reaction from the patient specimen compared to the reaction of serially diluted glucan standard (measuring 31.25 to 500 pg/ml). For a detailed description of the procedure, refer to the package insert that is provided with the assay kit. Briefly, the patient specimen is initially treated with an alkaline reagent (equal volumes of 0.25 M KOH and 1.2 M KCl), converting triple-helix glucans that may be present in the serum into more-reactive single-stranded glucans (14, 15). This reagent also prevents false-positive and false-negative results by inactivating serine proteases and serine-protease inhibitors (16). The patient specimen is combined with the alkaline reagent in the microwell and incubated for 10 min in the spectrophotometer, preheated to 37°C. At the end of the incubation period, the standards and negative controls are added to appropriate wells of the microtiter plate and the Fungitell reagent (a BDG-specific LAL) is added to all reagent-containing wells. The microtiter plate is placed into the spectrophotometer (37°C) and shaken for 5 to 10 s with the lid on, and the plate is read at 405 to 490 nm, with the lid removed, for 40 min at 37°C. The spectrophotometer is set to collect data using the kinetic data point, reading the result as frequently as allowed by the software and instrument over the 40-min period of the test, and plotted using "linear/linear" or equivalent.

Interpretation

Negative, <60 pg/ml

Indeterminate, 60 to 79 pg/ml

Positive, ≥80 pg/ml

The accuracy of the assay is up to 500 pg/ml. For accurate results, specimens for which results are greater than 500 pg/ml must be diluted and retested. Results are multiplied by the dilution factor for the final result.

SERODIAGNOSIS OF FUNGAL INFECTIONS

Aspergillosis

Clinical Indications and Diagnostic Rationale

Patients with ABPA, pulmonary aspergilloma (fungus ball), or CNPA and immunocompetent patients with obscure pulmonary or sinus infections should be tested for *Aspergillus* antibodies. ABPA should be considered in patients with asthma, transient pulmonary infiltrates, and peripheral eosinophilia. Pulmonary aspergilloma occurs when *A. fumigatus* or other *Aspergillus* species colonize preexisting cavities of tuberculosis, sarcoidosis, or bronchiectasis. Assays to detect antibodies to *Aspergillus* species should be applied in such cases (see below; Table 1). Antibody testing has been suggested by some to play a role in the diagnosis of IA in nonneutropenic, high-risk SOT recipients. The sensitivity of such testing may be low, however, requiring repeated testing to detect the antibody response.

The commercial antigen detection test for IA (Platelia; Bio-Rad) detects circulating cell wall GM from medically important *Aspergillus* species (see below; Table 2) (17). The GM EIA may be used as a screening tool for high-risk patient populations such as allogeneic HSCT recipients. The European Organization for Research and Treatment of Cancer/Mycoses Study Group (EORTC/MSG) consensus group now includes a positive GM result as one of the factors in the definition of probable and possible fungal infections (18).

The website www.aspergillus.org.uk offers a listing of *Aspergillus* diagnostic tests approved for use in the United States and in Europe.

Antibody Assays for the Diagnosis of Aspergillosis

Serologic results can be helpful for the diagnosis of aspergillosis, but results from these assays should be used in conjunction with other diagnostic procedures including culture, histopathologic examination of biopsied tissues, and radiologic evidence of infection.

Immunodiffusion

The ID test is effective and specific for diagnosing aspergillosis in immunocompetent persons, and individual reagents can be purchased from several different sources (Table 1). Precipitins can be found in over 90% of patients with aspergillomas and in 70% of patients with ABPA or CNPA (19). Only serum samples that produce a line or lines of identity with reference serum from a patient with a proven case of human aspergillosis are considered positive in the ID test. Although one or two precipitins may occur when serum from patients with any clinical form of aspergillosis is used, the presence of three or more bands is usually associated with either aspergilloma or CNPA. Pulmonary fungus balls can also be produced by *Pseudallescheria boydii* and by other fungi; noninfectious conditions or other abnormalities may also be misinterpreted as aspergillomas on chest radiographs. In such cases, the *Aspergillus* ID test is usually negative. However, the ID test may also be negative in some patients with aspergillosis who are receiving long-term antifungal or corticosteroid therapy.

Complement Fixation

Reagents for the detection of anti-*Aspergillus fumigatus* antibodies by CF are available commercially (Table 1). While the specificity of the assay is very good, the sensitivity has been reported to be low for tests using cell homogenate antigens and to be variable (20 to 79%) for tests employing culture filtrate antigens (20). Few laboratories now use the CF test for the diagnosis of aspergillosis.

Enzyme Immunoassay

A commercial EIA (Platelia Aspergillus IgG; Bio-Rad, Redman, WA) for the diagnosis of aspergillosis using purified recombinant antigens has recently become available for the detection of antibodies in serum or plasma. In immunocompetent patients (329 sera) diagnosed with noninvasive aspergillosis, including ABPA (164 sera) and chronic pulmonary aspergillosis (16 sera), the sensitivity of the assay was 92.3% and 90.2 to 94.1%, respectively (21). The specificity was measured using sera from control patients suspected of having noninvasive aspergillosis but where aspergillosis was ruled out (114 sera) and was found to be 67.2 to 84.0%. Sera (n = 222) from noninfected persons displayed a specificity of 99.5 to 100%. Further reports will be needed to determine the usefulness of this assay.

Antigen Assays for the Diagnosis of Aspergillosis

Enzyme Immunoassay

A commercial monoclonal sandwich EIA to detect circulating serum GM antigen is effective in diagnosing IA in the immunocompromised host (Platelia *Aspergillus* EIA; Bio-Rad, Inc.), and it detects the disease approximately 1 week before clinical signs of infection. This assay uses a rat MAb, EB-A2, as both the capture and detector antibody for the (1,5)-β-D-galactofuranose residues of GM, an outer

cell wall component found in the most clinically important species of *Aspergillus*. The detection limit of this assay is 1 ng of GM per ml (Table 2) (22, 23).

Serum specimens may be collected at regular intervals before suspicion of infection and collected serially during the infectious episode. A 300-μl volume of patient serum is consumed each time the test is performed. Because the test may need to be repeated more than once and because some sample loss occurs during immune complex removal (precipitation of serum proteins during boiling in the presence of neutral disodium EDTA), at least 1 ml of patient serum is required for testing. The FDA has recently approved the use of BAL specimens in the GM assay. BAL fluids from lung transplant patients with proven or probable cases of IA demonstrate a sensitivity of 81.8% (24). Specificities in lung transplant patients not colonized with *Aspergillus* were 95.8 and 96.6% when using cutoffs of 0.5 and 1.0, respectively.

Results are expressed as an index (i.e., the ratio of the OD of the test sample to the OD of the mean cutoff control serum provided in the kit). An index of ≥0.5 is considered a positive result, and an index of <0.5 is considered a negative result. Positive results obtained with the Platelia *Aspergillus* EIA should be interpreted in conjunction with other diagnostic procedures including culture, histopathologic examination of biopsied tissues, and radiologic evidence of infection. For all positive samples, it is recommended that a second aliquot of the same sample be retested and a new sample collected from the same patient be tested in a follow-up procedure. In the absence of positive culture or histopathology, if tests for serum GM are repeatedly positive in patients at risk for IA, such results may be interpreted as a probable *Aspergillus* infection. On the other hand, negative test results do not rule out a diagnosis of IA. Even in cases of culture-proven or histopathologically proven IA, not every serum sample from each patient is expected to be positive.

Neonatal or pediatric serum samples have been reported to give a higher rate of false-positive results, and this may be related to the finding that the EB-A2 MAb used in the test reacts with components found in infant milk formulas and with the lipoteichoic acid of a common neonatal gut commensal, *Bifidobacterium bifidum*. False-positive test results may also occur in patients receiving piperacillin-tazobactam and amoxicillin-clavulanic acid antibiotics, since these agents also react with the EB-A2 MAb in vitro. Positive test results in such individuals should be interpreted with caution and confirmed by other diagnostic means. Other fungal genera, including species of *Histoplasma*, *Penicillium*, *Alternaria*, and *Paecilomyces*, have demonstrated reactivity with the EB-A2 MAb used in the Platelia *Aspergillus* test and could cause false-positive test results. Other possible reasons for false-positive results have been suggested, including reactions with cyclophosphamide and/or adsorption of dietary GM through a damaged intestinal wall.

Reduced detection of GM may occur in patients with chronic granulomatous disease or hyper IgE (or Job's) syndrome or in those with IA who are receiving antifungal therapy (25). Sera from such patients giving negative results should be retested. False-negative results have also been attributed to limited invasion of blood vessels by the organism or to especially high antibody titers in the host.

Lateral Flow Assay

Recently, an *Aspergillus* LFA was developed using MAb JF5, which is specific for a protein epitope on a glycoprotein antigen (26). In a guinea pig model of IA, the LFA was shown to be more sensitive and specific than the GM and BDG assays (27). In hematology patients with IA (28), LFA was more sensitive and specific than GM: 81.8 versus 77.3% and 98.0 versus 91.5%, respectively. The authors found that PCR was more sensitive (95.5%) but less specific (96.6%) than LFA. The combination of PCR and LFA provided the best sensitivity (100%) and specificity (100%). There is no commercial source for this assay, and it is still considered experimental.

1,3-β-D-Glucan

Several reviews regarding the diagnosis of invasive aspergillosis using nonculture methods, including the detection of BDG, have recently been published (29–31). Sensitivity and specificity for the diagnosis of IA are approximately 70 to 71% and 82 to 87%, respectively (29, 30), and 77 and 85%, respectively, for invasive fungal infections in general (32). Combining BDG detection with the GM assay further enhances the diagnostic capabilities of both assays to 80 to 88% sensitivity and 98 to 100% specificity (29, 33, 34).

Immunohistochemistry

Aspergillosis may also be diagnosed histopathologically by observing in biopsy tissue the typical dichotomous, branched, septate hyphae after Grocott's methenamine silver or periodic acid-Schiff staining (35). However, other filamentous fungal agents may appear similar morphologically to *Aspergillus*. A murine MAb, WF-AF-1, directed against a cell wall fraction of *A. fumigatus*, is commercially available (AbD Serotec, Raleigh, NC) for the immunohistochemical diagnosis of major *Aspergillus* species in tissues (36). After the tissue is deparaffinized and antigen cross-linking is disrupted, the tissue is stained using a standard immunohistochemistry method (36). The primary mouse MAb is placed on the slide followed by a secondary, anti-mouse antibody conjugated with a fluorescent or enzymatic label. If a fluorescent label is used, the slide is now ready to be examined using a fluorescence microscope with the appropriate filters specific for the fluorescent label. If an enzymatic label is used, the slide is next treated with a substrate solution specific for the enzyme label. The substrate reacts with the enzyme, forming a colored precipitate which is deposited on the tissue in places where the antibody is located, and can be detected using a bright field microscope.

Blastomycosis

Clinical Indications and Diagnostic Rationale

Blastomyces dermatitidis is a thermally dimorphic fungus that has a range of endemicity from the upper Midwestern states of the United States extending east and northeast through the St. Lawrence River Valley. While recent outbreaks suggest that exposure may occur in more urban environments, and with less active outdoor exposure (37, 38), the classic mode of infection is inhalation of conidia of disturbed moist soil, most frequently in relation to watershed areas and nearby waterways (39, 40). Infections may resolve spontaneously or slowly progress as a slow indolent process. Dissemination to multiple organs including bone, skin, and genitourinary system may occur. Antibody detection tests for blastomycosis should be performed with sera from patients showing signs of suspected acute pulmonary blastomycosis, especially if they reside in or have recently traveled to geographic areas where blastomycosis is endemic (40). Symptoms of acute pulmonary blastomycosis include a nonspecific respiratory infection characterized by fever, chills, productive cough, myalgia, arthralgia, pleuritic chest pain, and weight loss. Antibody detection tests should also be performed with sera from patients presenting with symptoms of chronic pulmonary blastomycosis, which are similar

to those of tuberculosis and include productive cough, hemoptysis, night sweats, malaise, weight loss, and low-grade fever. Antibody detection can be helpful when lesions are present on the skin, a common site of dissemination, and for monitoring CSF specimens from patients with suspected blastomycotic meningitis.

Immunocompromised patients are predisposed to severe forms of the disease, which can relapse and are often associated with a high mortality rate. Up to 40% of AIDS patients with blastomycosis have central nervous system disease that manifests as either meningitis or brain lesions. Others have presented with a septic shock-like syndrome. Experimental antigen detection tests, should they prove to be sensitive and specific, would be helpful for the diagnosis of disseminated blastomycosis in immunocompromised patient populations whose antibody responses may be limited or variable.

Antibody Assays for the Diagnosis of Blastomycosis

Substantial improvement in the serodiagnosis of blastomycosis can be attributed to the use of a purified surface antigen of *Blastomyces dermatitidis* called the "A antigen" by one group of investigators (41) and WI-1 by another group (42); both are released from the yeast form of *B. dermatitidis* by autolysis and are recovered from culture filtrates. Immunologically, the A antigen and WI-1 are related in that antibodies directed against the WI-1 antigen recognize the A antigen and vice versa. The A antigen has a molecular mass of 135 kDa and is glycosylated, whereas the WI-1 antigen is a 120-kDa protein that is not glycosylated.

ID test kits and reagents to conduct the ID and CF tests are commercially available (Table 1) for the detection of anti-*B. dermatitidis* antibodies. The A antigen is now incorporated into most commercially available kits and is also supplied as a reagent for in-house ID and CF testing.

Immunodiffusion

A positive reaction in an ID test using the purified A antigen is specific and diagnostic for blastomycosis. However, a negative ID test does not rule out a diagnosis of blastomycosis, since this test has been reported to be negative in 10% of patients with disseminated infection and over 60% of patients with localized disease.

Complement Fixation

Initial CF assays for the diagnosis of blastomycosis used a crude yeast antigen which resulted in unsatisfactory sensitivity and specificity. With the incorporation of purified A antigen into the CF assay, the specificity improved markedly from initial reports of 30 to 87% (43–45) to 97 to 100% (43, 45). However, the sensitivity still remains unsatisfactory for the diagnosis of disseminated infection (50%) or localized infection (33%) (43). Although the CF test is still in use, its sensitivity is poor and much reduced compared to the ID test, and it is therefore not discussed in further detail here.

Interpretation. The ID test performed using a *B. dermatitidis* yeast-form culture filtrate containing the A antigen is highly specific for blastomycosis. A positive reaction denotes a recent or current infection with *B. dermatitidis*. Positive reactions can therefore be the basis for immediate treatment of the patient without parallel testing for coccidioidomycosis or histoplasmosis. Negative test results, however, do not exclude a diagnosis of blastomycosis because the sensitivity of the ID test has been reported to range from 33% for localized infection to 88% for disseminated disease. In the absence of a positive A precipitin band or in cases where the CF test is positive for blastomycosis but the ID test is negative, patients should be examined extensively for evidence of infection with other endemic fungi as well as with *B. dermatitidis* (especially because the areas of endemicity for blastomycosis and histoplasmosis overlap and cross-reactivity can occur).

In patients where a high suspicion for blastomycosis exists, testing of an additional serum drawn 3 to 4 weeks after initial sampling may be necessary to detect the development of an A precipitin band indicating seroconversion and recent infection. In addition, sera should be drawn at 3-week intervals and examined by CF and ID tests with *B. dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* antigens. Such testing may detect increases in CF titers to a causative organism other than *B. dermatitidis* or the development of precipitin bands diagnostic for blastomycosis, histoplasmosis, or coccidioidomycosis. In established cases of blastomycosis, the disappearance of the precipitin line is evidence for a favorable prognosis. The serologic response, however, is often not as rapid as the clinical response.

Enzyme Immunoassay

A commercial EIA (*Blastomyces* antibody enzyme immunoassay; IMMY) using a proprietary mixture of fungal yeast-phase antigens has recently been developed. The manufacturer reports a sensitivity of 83.3% compared to positive CF titers at ≥1:8 and 100% at ≥1:16. Sensitivity and specificity are 100% compared to ID. This assay looks very promising given the less than desirable results of the ID and CF assays. Independent evaluation of this assay has not been reported at this time.

Antigen Assay for the Diagnosis of Blastomycosis

Enzyme Immunoassay

A double-antibody sandwich EIA employing rabbit polyclonal antibodies to detect an uncharacterized antigen from *B. dermatitidis* in urine, serum, CSF, BAL fluid, and other body fluids is available only through a commercial reference laboratory (MiraVista Labs, Indianapolis, IN). Test sensitivity was reported to be 89 and 100%, respectively, for the detection of urinary antigen in the disseminated and pulmonary forms of blastomycosis (46). Little or no cross-reactivity was observed when specimens obtained from healthy volunteers or from patients with aspergillosis, candidiasis, coccidioidomycosis, or cryptococcosis were used, but significant cross-reactivity occurred when specimens from patients with disseminated histoplasmosis (96%), paracoccidioidomycosis (100%), or penicilliosis marneffei (70%) were used (46). Because the areas of endemicity for blastomycosis and histoplasmosis overlap, additional tests are required to obtain a specific diagnosis. The assay has recently been converted to a quantitative assay in which the result from the patient specimen is evaluated against a standard curve derived from serial dilutions of *B. dermatitidis* galactomannan isolated from the pooled urine of blastomycosis patients (47). The sensitivity of the assay on average is 89.9% but ranged from 88.2% in patients with only extrapulmonary involvement to 92.3% in patients with isolated pulmonary involvement. However, the assay continues to cross-react with 95.6% of samples from histoplasmosis patients. Patients with paracoccidioidomycosis and penicilliosis marneffei were not evaluated with the updated version. Individual case reports have shown that the assay appears to correlate well with confirmed cases of blastomycosis.

The use of the *Blastomyces* antigen test in outbreak investigations has displayed only a low success rate for the diagnosis of blastomycosis (37). The lack of sensitivity in this

case may reflect the delay in patient presentation until after the antigen in urine is cleared.

Candidiasis

Clinical Indications and Diagnostic Rationale

Candida albicans and other *Candida* species are part of the normal microbiological flora of humans, often found on the skin and in the respiratory and gastrointestinal tracts. Disease ranges from superficial cutaneous/mucocutaneous infections to severe disseminated infections. Tests for *Candida* antibodies have been extensively evaluated but remain of uncertain usefulness in the diagnosis of invasive forms of candidiasis. The clinical utility of these tests has been hampered by false-positive results in patients who are colonized with *Candida* species or who have superficial infections as well as by false-negative results in immunocompromised patients, who produce small or variable quantities of antibodies. Those most at risk for these infections include neutropenic cancer patients, HSCT and SOT recipients receiving immunosuppressive agents, and patients receiving critical care, particularly those in adult surgical and neonatal intensive care units. On the other hand, in immunocompetent patients, seroconversion from antibody negative to antibody positive may be diagnostically helpful. A decision to treat a patient with antifungal drugs must not be based on serologic data alone, however, but rather should be made after consideration of all available clinical and laboratory data.

Antibody Assays for the Diagnosis of Candidiasis

Immunodiffusion

ID tests to detect antibodies to *Candida* species have been applied using sera from patients with acute disseminated candidiasis, chronic hepatosplenic candidiasis, or localized deep-organ candidiasis (e.g., endocarditis). Patient serum containing antibodies that react with homogenate antigens of *C. albicans* in the ID test may produce one or several lines of identity. Systemic candidiasis should be suspected when serial serum specimens demonstrate seroconversion (i.e., when negative antibody test results become positive) or show temporal increases in the number of precipitins. ID kits are commercially available (Table 1).

The ID test for antibodies has good specificity (94 to 98%) but has variable sensitivity, ranging from >90% for confirmed cases of invasive candidiasis in immunocompetent hosts to much lower in more localized or superficial infections (Table 1).

Interpretation. Sera from candidiasis patients, which react with homogenate antigens of *C. albicans* in the ID test, may produce between one and seven precipitin bands. Seroconversion from negative to positive or an increase in the number of positive bands may be a strong indication for the diagnosis of systemic candidiasis. Negative results do not rule out the diagnosis of candidiasis. The serum may have been obtained too early, before the generation of antibodies. Serial specimens can be obtained every 2 to 3 weeks to observe seroconversion.

Enzyme Immunoassay

An EIA to detect antibodies to circulating mannoprotein, a major cell wall component of *Candida* species, is commercially available in some countries but not in the United States (Platelia *Candida* Antibody; Bio-Rad). The assay uses a four-point calibrator range (2.5 to 20.0 AU) that is created through user-developed dilutions. Clinical evaluations of the test with sera from patients with invasive candidiasis demonstrated that the test specificity ranged from 63 to 94% but the test sensitivity ranged from 25 to 88%, depending on the identity of the infecting *Candida* species (the lowest sensitivity occurred for detecting *C. parapsilosis* infections, and the highest occurred for detecting *C. albicans* infections) (Table 1).

An updated version of the antibody EIA was recently developed (Platelia Candida Ab Plus; Bio-Rad), allowing measurement of antibody levels in either serum or plasma. Prediluted assay calibrator reagents are provided which form a five-point curve with a broader range (0 to 80 AU/ml). Sensitivity and specificity for the diagnosis of candidiasis are maximized when combining the results of the antimannan antibody assay with the *Candida* mannan antigen assay (see below).

The production and use of recombinant proteins as antigens has recently displayed promise for the serodiagnosis of candidiasis. A panel of four recombinant *Candida* antigens was evaluated in an EIA format for the detection of anti-*Candida* antibodies in serum of systemic candidiasis patients (48, 49). A combination of these assays displayed a sensitivity of 96.6% and specificity of 95.6% (37). It has been suggested that the use of a panel of recombinant *Candida* antigens improves utility in the diagnosis of candidiasis, as antibody titers to individual antigens vary during infection (49). EIAs using recombinant enolase and fructose-bisphosphate aldolase (50) for the diagnosis of candidemia were 72 and 95% and 87 and 93% sensitive and specific, respectively. Combining the results of both assays resulted in a sensitivity and specificity of 90 and 91%, respectively. There are no commercial sources for assays using recombinant antigens for the serodiagnosis of candidiasis, and they are still considered experimental.

IFA Assay

An IFA assay to detect antibodies to *C. albicans* is available commercially (Table 1). The assay detects antibodies to the germ tubes of *C. albicans* cells (CAGTA) and has a sensitivity and specificity of 76 to 94% and 95 to 100%, respectively (51). In a study of nonneutropenic intensive care unit patients, mortality rates were significantly lower in patients that developed CAGTA (52). A significantly larger number of patients with invasive candidiasis displayed CAGTA antibodies compared to uninfected or colonized patients. Combining the results of CAGTA and BDG resulted in a sensitivity of 87% and a specificity of 94 to 100% (50, 53, 54).

Antigen Assays for the Diagnosis of Candidiasis

Antibody detection tests have limited sensitivity for the diagnosis of invasive candidiasis in immunocompromised patients because antibody production may be limited due to the suppressed immune response. Furthermore, antibody that is present may be bound to antigen present in the sera. Therefore, antigen detection assays have been developed to aid in diagnosis in these cases. Among these are tests to detect heat-labile antigens by reverse passive LA (Cand-Tec test; Ramco Laboratories, Inc., Stafford, TX) and heat-stable *Candida* cell wall mannan by EIA (Platelia *Candida* Ag EIA; Bio-Rad Laboratories, Inc.).

Latex Agglutination

The Cand-Tec test has been commercially available for many years. The nature of the antigen is unknown, but its susceptibility to heat (56°C), pronase, 2-mercaptoethanol, and sodium periodate treatment suggests that it may be a

glycoprotein. Test sensitivity varied widely among studies (2 to 59%), whereas test specificity ranged from 93 to 95%, using a threshold titer of ≥1:8. A threshold titer of ≥1:4 resulted in a somewhat increased sensitivity (41 to 81%) and a specificity of 80 to 97% (55–57) (Table 2).

Enzyme Immunoassay

The Platelia *Candida* Ag (Bio-Rad Laboratories) (Table 2) is a commercial double-antibody sandwich EIA antigenemia detection test that can be conducted as either a quantitative (results are compared to a standard curve) or a qualitative (results are expressed as an index relative to the calibrator serum) test. This assay uses a rat MAb, EB-CA1, as both the capture and detector antibody for α-(1,2)-linked oligomannosides, outer cell wall components of most clinically important species of *Candida* (58). The assay is not available in the United States. The quantitative assay uses a four-point calibration curve (0.25 to 2.0 ng/ml) from which the patient antigen concentration is calculated. The Platelia *Candida* Ag EIA has an overall sensitivity of 52% and a specificity of 85 to 95%.

An updated version of the *Candida* antigen EIA has recently become available (Platelia Candida Ag Plus; Bio-Rad) which measures antigen levels in both serum and plasma. Prediluted assay calibrator reagents are provided and form a five-point curve with a broader range (0 to 500 pg/ml). The Platelia *Candida* Ag Plus EIA has an overall sensitivity of 62% and a specificity of 98 to 99%. The reduced sensitivity is due to the extremely low sensitivity of the assay in detecting infections due to *C. parapsilosis*, *C. krusei*, and *C. guilliermondii* (59). Sensitivity and specificity for the diagnosis of candidiasis is maximized when combining the results of the anti-mannan antibody assay with the *Candida* mannan antigen assay.

Sample requirements. Serum and/or plasma (i.e., EDTA, heparin, or citrate anticoagulants) specimens should be collected serially during the infectious episode. If the test is to be used as a screening tool in high-risk patient populations, such as SOT recipients and critical care patients, sera may also be collected at regular intervals before any symptoms develop. Mannan is found in the serum in low nanogram-per-milliliter concentrations and is rapidly cleared from the circulation, necessitating frequent sampling of patients during periods of high risk. Therefore, the use of multiple serum specimens, collected at least twice per week, increases test sensitivity.

Strict compliance with the prescribed 100°C temperature for the boiling water bath is essential for success of the test. A negative control serum (no mannan), a calibrator serum (containing 2.0 ng of mannan per ml and the concentration from which to prepare a standard curve for the quantitative assay or from which to dilute to 0.5 ng for the qualitative assay), and a positive control serum (containing between 0.5 and 1.5 ng of mannan) are included in each kit. Results are expressed in nanograms per milliliter extrapolated from the standard curve (quantitative assay) or as an index (semiquantitative assay; i.e., the ratio of the OD of the test sample to the OD of the mean calibrator serum provided in the kit). In both test modes, OD values for the calibrator, for the four points comprising the standard curve (quantitative mode), and for the positive and negative controls must be within their designated ranges.

Interpretation. Serum samples with a mannan concentration of less than 0.25 ng/ml are considered negative, serum samples with a mannan concentration of between 0.25 and 0.5 ng/ml are considered intermediate, and serum samples with a mannan concentration greater than or equal to 0.5 ng/ml are considered positive. Range points used to plot the standard curve do not allow precise determination of mannan concentrations above 2.5 ng/ml, and strongly positive sera should be diluted 1:5 (vol/vol) with negative serum and retested. Positive results obtained with the Platelia *Candida* Ag test should be interpreted in conjunction with other diagnostic procedures including culture, histopathology of biopsied tissues, and radiographic evidence of infection. Negative test results do not rule out a diagnosis of invasive candidiasis. Even in cases of culture or histopathologically proven candidiasis, not every serum sample from each patient is expected to be positive.

The EB-CA1 MAb is specific for an α-linked mannopentose common to all *Candida* species (60), but test sensitivity varies depending upon the *Candida* species being detected. For example, in a retrospective study conducted on 106 patients (366 sera) residing in various hospital wards (surgery, hematology, intensive care, burns, and others) and from whom *Candida* species were isolated from the blood or other sterile body sites, the overall sensitivity of the EIA was 52%. For infections with specific *Candida* species, however, sensitivities were 70% for *C. tropicalis*; 50 to 58% for *C. kefyr*, *C. albicans*, and *C. glabrata*; 38% for *C. parapsilosis*; and only 20% for *C. krusei*. The moderate sensitivity exhibited by the test does not provide an optimum negative predictive value for diagnosing invasive candidiasis. However, because the overall specificity of the EIA is so high (98%), a positive result obtained with samples from patients at risk suggests infection.

1,3-β-D-Glucan Assay

BDG has been evaluated for utility in the diagnosis and prognosis of patients with candidiasis. In a study of patients in a surgical intensive care unit, the sensitivity of BDG to detect invasive candidiasis on the day of diagnosis was 87% with specificity of 73% (61). In 3 patients, however, the BDG became positive 4 to 8 days prior to diagnosis. BDG may be more useful in determining the prognosis of the infection. Serial samples from invasive candidiasis patients showed a decline in BDG levels in successfully treated patients compared to those with treatment failure that resulted in increased levels of BDG (62, 63).

Coccidioidomycosis

Clinical Indications and Diagnostic Rationale

Coccidioides species are thermally dimorphic fungi that are endemic to the desert southwestern United States, northern Mexico, and parts of Central and South America. While infections in many cases are asymptomatic, symptomatic infection is known as Valley fever, a severe pulmonary disease in immunocompetent persons and sometimes fatal, disseminated infection in immunocompromised individuals. *Coccidioides* is found in dry desert soil and when disturbed by manmade or natural forces, the coccidioidal arthroconidia are aerated and infection is initiated upon inhalation of the arthroconidia. Serologic tests should be considered whenever patients display signs and symptoms of coccidioidomycosis and have lived in or traveled to areas where *C. immitis* (California) or *C. posadasii* (Arizona, New Mexico, Utah, Texas, Mexico, and Central and South America) are endemic. Coccidioidin, a liquid culture filtrate of *Coccidioides immitis*, is the antigen upon which the serologic assays are based. The antigen is prepared from cultures grown in synthetic asparagine-glycerol salt medium (64). Serologic assays do not distinguish between the two species of *Coccidioides*.

Tests to detect anti-*C. immitis* antibodies are of proven usefulness for the diagnosis and management of coccidioidomycosis. One of the original serologic methods for the diagnosis of this disease was the TP test which detects IgM antibodies reactive against a heat-stable, carbohydrate-containing component in coccidioidin. However, this assay is rarely used today. Current serologic test formats include ID (IDTP and IDCF), LA, CF and EIA. The IDTP and LA assays measure predominantly IgM, IDCF and CF predominantly measure IgG, and the EIA measures both IgG and IgM.

The CF and TP assays were the original, liquid-phase assays that used unheated coccidioidin (containing F antigen) and heated (60°C, 30 min) coccidioidin. Through the heating process, the predominant F antigen is inactivated, revealing the heat-stable TP antigen. These assays were subsequently converted to solid-phase ID assays: IDCF and IDTP.

Antibody Assays for the Diagnosis of Coccidioidomycosis

Immunodiffusion

The ID test format can be used to simultaneously detect IgM (IDTP) and IgG (IDCF) antibodies. Both the IDTP and the IDCF tests are performed using separate seven-well ID patterns. Positive control IDTP and IDCF sera are placed in independent wells and are tested against patient sera using optimally diluted heated (for IDTP) or unheated (for IDCF) coccidioidin. Lines of identity between patient sera and positive reference sera, corresponding to reactive IgM (for IDTP) and IgG (for IDCF) antibodies, can then be observed for positive cases of early or late disease, respectively (65). Serum demonstrating AC activity, making CF test results difficult to interpret, can be successfully used in the ID test. In addition, the ID test is more specific than CF and may help resolve CF cross-reactivity issues often encountered among the endemic mycoses during CF testing. Commercial sources for ID kits and reagents for use in ID tests are listed in Table 1.

Sample requirements. Serum from symptomatic patients may give negative or indeterminate test results early in infection. Additional serum from such patients should be obtained 3 to 4 weeks later, and the tests should be repeated. CSF should be obtained and tested in parallel with serum specimens from patients presenting with signs and symptoms of meningitis. The sensitivity of the IDTP and IDCF tests can be increased by 4- to 8-fold concentration of serum prior to testing. Serum can be concentrated by evaporation *in vacuo* (Speed-Vac; Thermo Fisher Scientific, Waltham, MA) or by the use of centrifugal ultrafiltration devices (Centricon; Millipore, Billerica, MA). Concentration of test serum may be especially helpful to improve IDTP detection of low levels of IgM antibodies present early in infection or to improve IDCF detection of IgG antibodies in specimens from patients with chronic disease.

Interpretation. *IDTP.* Observation of a band of identity in the IDTP assay indicates that the patient is in the early stages of coccidioidomycosis. Of patients with coccidioidomycosis, 75% develop a detectable IDTP antibody response as early as 1 week after the onset of symptoms and 91% are positive within 3 weeks. Negative test results, however, do not exclude a diagnosis of coccidioidomycosis. In the absence of a positive precipitin band, or in cases where the CF test is positive but the IDTP test is negative, patients should be examined extensively for evidence of infection with another endemic fungus as well as with *C. immitis*. In addition, sera should be drawn at 3-week intervals and examined using CF and ID tests with *B. dermatitidis*, *C. immitis*, and *H. capsulatum* antigens to detect increases in CF titer specific for infection with one of the endemic fungi or to detect the development of precipitin bands diagnostic for blastomycosis, histoplasmosis, or coccidioidomycosis. IDTP antibodies may not be detected in immunosuppressed patients with disseminated coccidioidomycosis (66). False-positive IDTP reactions have been reported to occur in 15% of sera obtained from cystic fibrosis patients in the absence of a positive culture for *C. immitis* (67). A positive IDTP test can also rarely indicate the presence of chronic pulmonary cavities. Although infrequent, a positive result using CSF in the IDTP test indicates the presence of acute meningitis. IDTP-reactive antibodies may also occur in cases of disseminated coccidioidomycosis; 347 (48%) of 722 patients with disseminated infections demonstrated reactivity to this antigen, and in some cases, patient sera were reactive for up to several years (68). Persistence of IDTP-reactive antibodies (along with positive CF titers) may therefore be an indication of disease severity.

Interpretation. *ICDF.* Observation of a band of identity in the IDCF assay is presumptive evidence that the patient had recent or chronic coccidioidomycosis. IDCF-reactive antibodies can usually be detected within 2 to 6 weeks after the onset of symptoms. Occasionally, a band of nonidentity may be observed very close to the ID well containing the patient's serum. This band may represent the presence of reactive IgM antibodies; in such cases, the IDTP test should be performed.

Although the IDCF test is generally not performed as a quantitative test, it can be used in this manner after serial dilution of patient serum to obtain an end point titer. Titers obtained by using the quantitative IDCF test are not identical to titers obtained from the CF test, but the observed trends are comparable (titers of each will rise or fall in parallel). Results using specimens collected longitudinally may show differences in the intensity of bands or in banding patterns which have prognostic value. On the other hand, IDCF-reactive antibodies may not be detected in immunosuppressed patients with disseminated coccidioidomycosis (66).

Latex Agglutination

The LA test is a simple and rapid method, using particles adsorbed with heated coccidioidin, to measure early antibody production corresponding to that detected by the TP or IDTP tests. The LA test is a qualitative slide agglutination assay in which antibodies to *C. immitis* present in patient specimens bind to the antigen-coated latex particles and are graded according to the level of agglutination observed for a particular dilution of serum. The assay measures predominantly IgM antibodies and therefore is used to diagnose early coccidioidomycosis. Commercial sources are listed in Table 1.

Interpretation. Agglutination of 2+ or greater is considered a positive test result, indicating early or primary coccidioidomycosis. The LA test is more sensitive than the IDTP test but is less specific; 5 to 10% false-positive rates have been reported (69, 70). Therefore, a positive LA result with undiluted serum or CSF must be confirmed by ID and/or CF testing (65). This false-positivity rate is greater if sera have been diluted before testing. Therefore, the LA test cannot be used as a quantitative test and results which are positive by this method must be confirmed by the IDTP test. The

LA test, however, may yield a positive result earlier than the IDTP test. False-negative LA results may occur in specimens from immunocompromised patients. Also, 10 to 30% of individuals with culturally or serologically (CF or ID) positive results may demonstrate a negative or 1+ reaction in the LA test, limiting the test's negative predictive value. Such test negativity is thought to be related to the rapid rise and fall of IgM levels early in infection.

Complement Fixation

The CF assay, using unheated coccidioidin antigen, detects antibodies predominantly of the IgG subtype. Sera from approximately 98% of patients with disseminated infection are positive in the CF test within 2 to 6 weeks after the onset of illness. The CF-reactive antibodies typically disappear within 6 months after onset but can persist in disseminated or chronic infection. An advantage to the use of the CF test for the diagnosis of coccidioidomycosis is that it is a sensitive assay which provides quantitative results. Testing serial specimens to detect rising or falling antibody titers can reveal the progression or regression of illness (65, 71) and the response to antifungal therapy. The major disadvantage of the CF assay is that it is a laborious and time-consuming test that requires experienced personnel for optimum performance. No commercial CF test kit is available, but reagents for in-house use can be obtained from the vendors listed in Table 1.

Sample requirements. The CF test may be performed with serum and CSF. Pleural, peritoneal, and joint fluids (in conjunction with serum) may also be tested when the corresponding anatomical sites are thought to be involved. Concentration of sera before performance of the CF test can be useful in the detection of chronic cases of coccidioidomycosis which might otherwise be missed.

Interpretation. A CF titer to coccidioidin at any dilution should be considered presumptive evidence for *C. immitis* infection. Sera giving titers of 1:2 to 1:8 in the CF test that are also positive in the IDCF test reflect currently active or recent infection. CF titers of >1:16 generally indicate extrapulmonary dissemination, whereas titers of 1:2 or 1:4 usually indicate early, residual, or meningeal coccidioidomycosis. However, titers of 1:2 and 1:4 have also been obtained when sera from patients without coccidioidomycosis were used. The parallel use of the IDCF test and the CF test can therefore help confirm or refute the significance of low titers. Negative serologic test results do not exclude a diagnosis of coccidioidomycosis. Patients with clinical presentations consistent with coccidioidomycosis whose sera give negative or low CF titers should be retested at 3- to 4-week intervals; all sera should then be tested in parallel to detect any increases in titer or to detect seroconversion. Approximately 5% of all CSF specimens from patients with coccidioidal meningitis are negative in the CF test. Sera from patients with chronic cavitary coccidioidomycosis may also frequently be negative.

Enzyme Immunoassay

The Premier *Coccidioides* EIA (Meridian Diagnostics, Inc.) is a qualitative test to determine the presence of anti-*Coccidioides* IgG and IgM antibodies in serum or CSF by using microtiter plates coated with a mixture of purified CF and TP antigens. Antibodies in serum or CSF are detected colorimetrically after addition of peroxidase-labeled, class-specific, anti-human IgM or IgG. The assay detects IgG and IgM antibodies separately, but maximum test sensitivity is achieved by using results from the detection of both IgG and IgM antibodies (Table 1). It is recommended that any positive result in the EIA be confirmed by the ID assay.

Interpretation. Absorbance values of ≥0.200 are considered positive, and values of <0.150 are considered negative. Specimens with absorbance values between 0.150 and 0.199 are defined as indeterminate, and testing must be repeated. A new specimen should be obtained from any patient whose original specimen gives repeatedly indeterminate results. Because the test uses a mixture of TP and CF antigens to coat microtiter plate wells, it does not distinguish between antibodies reactive to one antigen or the other. The kit may be used to detect reactive antibodies of a single class (IgG or IgM); however, optimum test sensitivity is obtained by using results for both Ig classes. Attempts to operate the Premier *Coccidioides* EIA as a quantitative test have not given results that correlate precisely with titers obtained by the conventional CF test. Nonetheless, the EIA has been used as a qualitative test in a series of evaluations and has been demonstrated to have an estimated sensitivity of 95 to 100%, a specificity of 96 to 99%, and positive and negative predictive values of >95% (72–74). There have been some reports questioning the specificity of the IgM result, particularly in cases that are IgG negative. While the manufacturer reports a 4 to 6% false-positivity rate in IgM-only positive patients, others report 18% and as high as 82% false-positivity rates (75–77). It has been suggested that IgM-positive results from patients with a high suspicion of infection are less likely to be false positives (76, 78). Therefore, positive EIA test results should be confirmed by IDTP and IDCF assays. The standard CF test should be employed in cases where there is concern about possible extrapulmonary dissemination (79).

Enzyme Immunoassay

Another commercial EIA for the antibody diagnosis of coccidioidomycosis has recently become available (Omega *Coccidioides* antibody EIA; IMMY) which uses a mixture of recombinant and native antigens. In contrast to the previous EIA, this kit provides 196 wells (2 plates). The wells from one plate are coated with CF antigen and the others with TP antigen. In comparison to complement fixation, the assay is 92.5% sensitive and 98.7% specific in a "normal" population. The specificity was 78.6%, with 16.7% indeterminate and 4.8% (2/42) false positive, using sera from patients with other fungal infections. These results were reported by the manufacturer. Studies to determine the efficacy of this assay by independent laboratories have not yet been reported.

Interpretation. Results are reported in EIA units which are calculated by dividing the absorbance reading from the patient serum by the absorbance reading from an internal calibrator control provided by the manufacturer. Results of <1.0 are considered negative and ≥1.5 are considered positive. Results of ≥1 to <1.5 are indeterminate.

Antigen Assays for the Diagnosis of Coccidioidomycosis

Enzyme Immunoassay

A commercial antigen assay for the detection of *Coccidioides* antigens in urine (*Coccidioides* antibody EIA) is offered as a fee-for-service assay at a commercial reference laboratory (MiraVista Laboratories, Indianapolis, IN). The assay has been shown to be 70.8% sensitive (80). Polyclonal capture antibodies for this assay were produced by injecting

rabbits with a mixture of purified *Coccidioides* galactomannan and formalin-killed mold. The specificity of the assay was 99.4% when compared to healthy individuals and patients with nonfungal infections. There was a 10.7% cross-reaction with other endemic molds.

Cryptococcosis

Clinical Indications and Diagnostic Rationale

Cryptococcus neoformans and *C. gattii* are yeasts that are ubiquitous in nature. While infection can occur in immunocompetent persons (81), cryptococcosis is most often associated with HIV infection or other immunocompromising disorders. Antibody assays are generally not considered helpful in the diagnosis of cryptococcosis, as most individuals have been exposed and have seroconverted early in life (82). However, serologic tests to detect *C. neoformans*/*C. gattii* antigens are an indispensable tool for the rapid diagnosis of pulmonary, meningeal, or disseminated forms of cryptococcosis and should be considered for immunosuppressed patients with signs and symptoms of a subacute meningitis or meningoencephalitis. In HIV-infected persons, headache and fever are common, but overt neurological symptoms and signs are unusual. In HIV-negative persons, headache may be common, but fever is often minimal or absent until late in the course of the infection. A subset of HIV-negative persons infected with *C. gattii* preferentially develop pulmonary disease instead of neurologic disease.

Antigen assays for the diagnosis of cryptococcosis have been developed using a variety of formats including LA, EIA, and most recently, the LFA. The *Cryptococcus* LA test to detect capsular polysaccharide in CSF and serum of patients infected with *C. neoformans*/*C. gattii* is one of the most reliable diagnostic tests in immunomycology. The EIA provides more objective end points with equivalent sensitivity and is more amenable to large numbers of specimens. A new assay based on lateral flow technology has been developed for the detection of capsular antigen. All three assays are designed to detect antigen in serum and CSF and are commercially available (Table 2). The selection of the method to use is dependent upon the laboratory's specimen load and equipment available. The LA and LFA are less amenable to large specimen loads.

Antigen Assays for the Diagnosis of Cryptococcosis

Latex Agglutination

The LA test is a noncompetitive direct-binding slide agglutination test to detect *C. neoformans*/*C. gattii* antigens in clinical samples. Latex particles adsorbed to anti-*C. neoformans* antibodies are employed and can be used to screen specimens for positivity, and positive samples can subsequently be diluted serially to obtain an end point titer (2–4). There are multiple commercial sources for LA tests to detect cryptococcal antigen, including those which adsorb latex particles with PAbs (Latex-Cryptococcus antigen test [Immuno-Mycologics, Inc.], CALAS [Meridian Diagnostics]) or with mouse anti-glucuronoxylomannan MAb (Pastorex Crypto Plus; Bio-Rad Laboratories) (Table 2). Results and end point titers vary among LA tests from different manufacturers, and reagents are not interchangeable. Generally, tests detect both *C. neoformans* and *C. gattii* infections. Similar sensitivities were reported for the MAb-based LA test compared to the two PAb-based LA tests using sera obtained from patients with culture-confirmed cryptococcosis (4). Unlike the PAb-based tests, the MAb-based LA test is recommended for use with BAL fluid and urine specimens as well as with serum and CSF (4).

Before running the assay, sera should undergo a pronase treatment step and CSF specimens should be boiled for 5 to 10 min to remove interfering substances which may cause false reactions in the LA assay. False-negative reactions may occur as the result of immune complex formation resulting from patient antibody masking the antigen epitopes recognized by the antibody-coated latex particles. On the other hand, the presence of rheumatoid factor in serum can result in a false-positive reaction. Rheumatoid factor, an anti-IgG autoantibody, can cause false agglutination by cross-linking the IgG antibody-coated latex particles.

Also, specimens containing a high concentration of cryptococcal antigen may show false-negative reactivity due to prozone effect, where excessive antigen inhibits the agglutination reaction, displaying weak or no agglutination. In cases where negative or weak reactions are observed but cryptococcosis is strongly suspected, the specimen should be retested after dilution (1:10 and 1:100) in glycine-buffered saline. Rarely, false-negative results may occur when sera from patients infected with poorly encapsulated strains of *C. neoformans* are tested. Such strains produce insufficient amounts of polysaccharide antigen to be detected and give false-negative results.

Latex particles should not be frozen, since this can result in granularity, leading to false-positive results; excessive hand rotation during observation may also lead to misinterpretation of results. False-positive reactions have also been reported to occur as the result of inadequate removal of detergent from the surface of reusable glass ring slides used for the LA test. Detergent can be removed by soaking slides in 10% bleach followed by thorough washing with distilled water. Rare false-positive results may be caused by the presence of contaminating hydroxyethyl starch, by nonspecific reactivity found in the serum of HIV-infected patients, and by cross-reactions with serum from patients infected with *Capnocytophaga canimorsus* or *Trichosporon asahii*.

Periodically, the sensitivity of the latex particles coated with anti-cryptococcal globulin should be tested by titration against purified capsular polysaccharide antigen included in the kit. Pronase provided in the kit must be stored frozen in aliquots after initial reconstitution to eliminate exposure to repeated freezing and thawing and subsequent loss of enzyme activity. Also, at least once per month, an aliquot of frozen pronase should be examined for proteolytic activity by testing, in parallel, goat anti-rabbit globulin (PAb-based systems) or goat anti-mouse globulin (MAb-based systems) that have and have not been pronase treated before use. The untreated pronase control must demonstrate agglutination of 2+ or greater, and the pronase-treated control must demonstrate agglutination of less than 1+ in the reaction.

Interpretation. The LA test to detect *C. neoformans* antigen has both diagnostic and prognostic value. A positive LA reaction at a titer of 1:4 or less using CSF, serum, or urine from an untreated patient is suggestive of cryptococcal infection, whereas titers of 1:8 or greater usually indicate active cryptococcosis (strong presumptive evidence). Antigen is detected in the CSF of over 90% of patients with untreated meningeal cryptococcosis. On the other hand, a negative serum antigen test result does not exclude a diagnosis of cryptococcosis, particularly if only a single specimen has been tested and the patient continues to have symptoms consistent with cryptococcal infection.

In HIV-negative patients, the antigen titer is usually proportional to the extent of infection. Whereas increasing titers reflect progressive infection and a poor prognosis, declining

titers generally indicate a favorable response to chemotherapy and progressive recovery; failure of the titer to fall during therapy suggests inadequate treatment. High initial titers of antigen (1:1,024 or greater) in the serum or CSF prior to treatment indicate a poor prognosis, and high titers at the end of treatment often predict later relapse. In contrast, HIV-positive patients may manifest elevated titers that decline very slowly even in the face of clinical improvement, whereas an unchanged or increased titer in the CSF of these patients is often associated with clinical and mycological failure to respond to treatment. Positive CSF antigen tests, despite no recovery of viable cryptococci from the CSF, may indicate persistent release of capsular antigen from dead as well as from living cells or may indicate slow elimination of capsular antigen from the CSF rather than ongoing infection.

Enzyme Immunoassay

The Premier Cryptococcal Antigen test (Meridian Diagnostics, Inc.) is a double-antibody sandwich EIA for the detection of cryptococcal polysaccharide antigen in patient serum and CSF. Rabbit polyclonal anti-*C. neoformans* antibodies, adsorbed onto the surface of microtiter plate wells, are used to capture cryptococcal polysaccharide antigen found in the serum and CSF of patients with cryptococcosis. Peroxidase-labeled detector MAbs are applied, and plates are read visually or spectrophotometrically after the addition of peroxide and a colorimetric substrate. Its sensitivity has been reported to be equivalent to or somewhat better than that of the LA test produced by the same manufacturer, and it does not require serum to be heat inactivated or pretreated with pronase to remove immune complexes or rheumatoid factor, nor does it require that CSF be boiled before testing (2–4). The EIA is not subject to prozone effects and has also been reported to detect cryptococcal antigen earlier, and at lower concentrations, than does the LA test (2). LA titers and EIA titers are not equivalent but generally follow the same trend (i.e., both titers increase and decrease in parallel).

Sample requirements. Serum and CSF samples may be tested, but urine may not be tested. Sample preparation of CSF and serum for the EIA consists only of centrifugation to remove any cells or other particulate matter. Pretreatment of specimens is not recommended by the manufacturer. However, samples that have previously been pronase or heat treated (56°C for 15 min) may be used in the screening assay but should not be tested in the semiquantitative test mode, since such treatment may alter EIA titration results. Therefore, it is recommended that all serial specimens from a given patient be pronase or heat treated in the same manner and that all samples be assayed in parallel when monitoring patients for disease changes or response to drug therapy; earlier specimens collected as part of these series should be aliquoted and frozen if stored for longer than 72 h at 2 to 8°C.

Procedure. A detailed stepwise protocol can be found in the package insert included with each kit. The EIA can be performed in one of two modes: (i) as a screening assay examining a patient specimen at a single concentration and designed solely for the differentiation of positive from negative specimens, and (ii) as a semiquantitative assay where the patient specimen is serially diluted (starting at 1:2) to obtain an end point titer. An analysis of a series of specimens collected longitudinally can be used to monitor relative changes in antigen levels in serum and CSF for the evaluation of patient progress and to monitor the efficacy of drug therapy. Specimens from the same patient should be assayed in parallel, in the same run, for accurate comparisons between time points.

Interpretation. For the screening assay, results can be recorded either visually or spectrophotometrically. For visual reading: negative, colorless well; positive, definite yellow color in well. For spectrophotometric reading with a single wavelength (OD_{450}): negative, <0.100; indeterminate, ≥ 0.100 and <0.150; positive, ≥ 0.150. For spectrophotometric reading with a dual wavelength ($OD_{450/630}$): negative, <0.070; indeterminate, ≥ 0.070 and <0.100; positive, ≥ 0.100. Tests giving indeterminate results should be repeated; if the results are still indeterminate, a second specimen should be obtained and tested. Extremely strong reactions may produce a purple precipitate, but these samples are considered positive.

If the 1:2 dilution of the specimen yields an OD of <0.100 when using the semiquantitative method, the assay should be repeated using an undiluted sample. A negative result does not preclude a diagnosis of cryptococcosis, especially if only a single specimen has been tested and if the patient shows symptoms consistent with the disease. The sensitivity of the EIA was reported to be 93% for serum and 100% for CSF (3), whereas the specificity of the EIA was reported to be 97% (83).

A new commercial EIA is available for the detection of cryptococcal antigen (ALPHA cryptococcal antigen enzyme immunoassay; IMMY) and has recently been approved by the FDA. The manufacturer-reported positive and negative agreements for serum were 98.5% and 97.7% and those for CSF were 93.5% and 99.2%, respectively, compared with the Premier EIA. In an evaluation with 118 sera and 15 fungal culture filtrates, the specificity was 96.1%; *Paracoccidioides* culture filtrates were positive 67% of the time. An independent comparison of the ALPHA cryptococcal antigen enzyme immunoassay to other cryptococcal antigen assays (84) reported a 100% sensitivity and a 99.8% specificity when compared to the consensus result of the other assays. Limitations of this study were the low number of positive patients evaluated and that specimens from patients with other fungal infections were not examined.

Lateral Flow Assay

The latest methodology for use in fungal serology is the LFA (IMMY). Cryptococcal antigen LFA is a rapid, low-complexity assay with results available in 10 min. Compared to EIA, the sensitivity and specificity are 96 to 100% and 96 to 100%, respectively (85, 86). Similar sensitivity and specificity values were also seen when LFA was compared to LA and culture (87). The limit of sensitivity of the cryptococcal LFA is 1 ng/ml for serotypes A and B and 4 to 16 ng/ml for serotypes C and D (88). The use of cryptococcal antigen LFA shows tremendous promise. The assay is inexpensive and does not require significant laboratory infrastructure or refrigeration. Currently, the incidence of infection is greatest in the more underdeveloped areas of Africa and Southeast Asia. Needing no cold chain for shipment to the end user, the LFA can be provided to the most remote areas of these continents. The potential to detect antigen prior to onset of symptoms may reduce morbidity and mortality through the initiation of earlier treatment (89, 90).

Histoplasmosis

Clinical Indications and Diagnostic Rationale

Histoplasma capsulatum is a thermally dimorphic fungus that is endemic to the Mississippi and Ohio River valleys of the

United States and parts of Central and South America. *Histoplasma* is found particularly in soil that has been enriched with bird or bat guano. Therefore bat-infested caves and highly frequented bird roosts are locations with high endemicity of infection. In the absence of culture or microscopic evidence of infection, the primary methods used to diagnose histoplasmosis are the ID, CF, and LA antibody detection tests and EIA to detect *H. capsulatum* antigen. Antibodies in primary pulmonary infections are generally demonstrable within 4 weeks after exposure to the fungus or, frequently, when symptoms appear. Serologic tests for histoplasmosis should be applied to clinical specimens (serum, peritoneal fluid, CSF, or urine) from patients with respiratory illness, hepatosplenomegaly, signs of extrapulmonary systemic infection, or meningeal involvement. The patient's residence, travel, and occupational history is useful as a guide to the application of these tests.

Antibody Assays for the Diagnosis of Histoplasmosis

Immunodiffusion

The ID procedure detects *H. capsulatum* precipitins directed against the immunodominant H and M glycoprotein antigens present in histoplasmin (91, 92). In the immunodiffusion reaction, the M band is found closer to the antigen well and the H band is found closer to the antiserum well. The ID test is a useful screening procedure or adjunct to the CF test for the serologic diagnosis of histoplasmosis. In contrast to the CF test, the ID test is generally performed as a qualitative rather than a quantitative test. The ID assay is generally more specific but less sensitive than the CF test, so that when both assays are employed, the overall sensitivity and specificity to detect histoplasmosis are quite good (85%). Because of this enhanced specificity, the ID test provides a more accurate diagnosis than the CF test, particularly in samples that display CF cross-reactivity to other fungal diseases. The ID test may also help to resolve the diagnosis in cases where the CF results are made uninterpretable by AC activity in the test sample.

Interpretation. In the ID test, the M band is demonstrated with serum from patients with acute or chronic pulmonary histoplasmosis and is frequently the first to appear in patients with acute disease (4 to 8 weeks after exposure). A positive M band is considered presumptive evidence of *H. capsulatum* infection and may be attributed to active or previous disease. Antibodies to the H antigen are specific for active disease but occur in fewer than 20% of cases; they usually disappear within the first 6 months of infection and are seldom, if ever, found in the absence of M precipitins. The demonstration of both the M and H precipitin bands in serum is highly suggestive of active histoplasmosis. Seroconversion from no bands to the presence of an M or H band is strong evidence for recent infection. The detection of M and H precipitins in CSF specimens indicates meningeal histoplasmosis (93). Precipitins can frequently be detected in the CSF of patients with meningeal histoplasmosis before *H. capsulatum* is detected by culture and when cultures are sterile.

Complement Fixation

The CF test is very sensitive, but the current incorporation of unpurified antigens reduces test specificity. Cross-reactions may occur with sera from patients with blastomycosis, coccidioidomycosis, and other mycoses. Sera from patients with leishmaniasis may cross-react in the CF test with *H. capsulatum* yeast-form antigens. It is generally recommended that both the ID and CF tests be performed to obtain maximum sensitivity and specificity. Use of the histoplasmosis ID and CF tests in parallel, with histoplasmin as the antigen, results in an overall sensitivity of approximately 85%. The CF and ID tests are also useful in diagnosing meningitis caused by *H. capsulatum* (93).

CF tests can be valuable in the diagnosis of acute, chronic, disseminated, and meningeal histoplasmosis. The CF microtitration procedure (1) yields information of both diagnostic and prognostic value. Over 90% of patients with culture-proven histoplasmosis demonstrate a positive CF test if serum is collected and tested at 2- to 3-week intervals during infection. For the serodiagnosis of histoplasmosis, the CF assay incorporates two different antigen preparations: "histoplasmin," a soluble filtrate of mycelial-phase broth cultures (containing the H and M antigens), and *Histoplasma* yeast antigen, a suspension of merthiolate-killed, whole yeast-form cells. Histoplasmin is produced by harvesting and filtering the supernatant from *H. capsulatum* cultures grown at 25°C for approximately 4 to 5 weeks in Smith's synthetic asparagine broth on a gyratory shaker at 150 rpm (94). The optimal dilution for each antigen is determined by a block titration. These antigens may also be purchased commercially (Table 1). The CF assay is more sensitive (82% versus 21%) but less specific (88% versus 99%) when yeast cells rather than mycelial antigens are used. Antibodies to yeast cells are usually the first to appear and the last to disappear after resolution of infection. However, antibodies produced during infection with other fungi such as *Coccidioides* or *B. dermatitidis*, and with bacterial infections such as tuberculosis, may react with the yeast antigen and give false-positive results (95). Antibodies to the yeast antigen usually appear within 4 weeks after exposure, whereas antibodies to the mycelial antigen occur later and have titers which are considerably lower. In contrast, histoplasmin titers are usually higher when serum from patients with chronic histoplasmosis is used.

Interpretation. CF test results can be difficult to interpret because cross-reactions or nonspecific reactions with the yeast or histoplasmin antigens are often encountered. In such instances, titers usually range between 1:8 and 1:32 and occur mainly against yeast-form antigen. Many serum samples from culture-proven cases of histoplasmosis, however, give titers in the same range. Consequently, titers of 1:8 and greater with either antigen are generally considered presumptive evidence of histoplasmosis. Titers above 1:32 or rising titers offer strong presumptive evidence of infection. The probability of infection increases in proportion to the CF titer.

On the other hand, one cannot rely solely on CF titers above 1:32 as a means of diagnosis because false-positive reactions of similar magnitude may occur in patients with other endemic mycoses. For example, the first serologic response noted in a patient with histoplasmosis may be obtained only with *B. dermatitidis* antigen. Some patients with histoplasmosis may demonstrate antibodies against the antigens of *H. capsulatum*, *B. dermatitidis*, and *C. immitis* or may demonstrate antibodies to only some of these antigens or to none. Furthermore, a lack of immunologic response does not exclude histoplasmosis, particularly when only one specimen has been tested and when the clinical picture strongly suggests a pulmonary mycosis. For example, in cases of disseminated or terminal histoplasmosis, humoral antibody responses may or may not be positive. In contrast, the CF test is usually positive when CSF specimens obtained from patients with chronic meningitis are used; titers in such cases may range from 1:8 to 1:128.

Increases or decreases in titer of 4-fold or greater are significant indicators of disease progression or remission, respectively. However, culture, clinical, and other laboratory data should also be considered in assessing the patient's prognosis or making treatment decisions. Occasionally, in some patients, positive titers decline slowly and persist long after the patient has been cured. The significance of persistently elevated or fluctuating CF titers is unclear, as is the effect of antifungal treatment on antibody clearance.

Latex Agglutination

The histoplasmosis LA test is a rapid, semiquantitative test that uses latex particles sensitized with histoplasmin for the detection of agglutinating antibodies against *H. capsulatum*. This assay measures predominantly the IgM subclass of antibodies and therefore is most useful in the early diagnosis of acute histoplasmosis. A positive LA test result can be obtained as early as 2 to 3 weeks after exposure and has been reported to have an overall sensitivity (including both acute and chronic forms of the disease) of 62% and a specificity of 97% (96). Antibody to *H. capsulatum* present in the patient's specimen binds to the antigen-coated latex particles, resulting in visible clumping. Results are graded according to the level of agglutination observed for a particular dilution of serum. The assay is rapid and simple to perform, and no special equipment is needed. Histoplasmin-sensitized latex particles are available commercially prepared (Table 2).

The histoplasmosis LA test is satisfactory for the detection of acute primary infections but may yield negative results for sera from persons with chronic histoplasmosis (96). It is particularly valuable in the detection of early disease. Because of the transitory nature of the agglutinins, the LA test cannot be considered a replacement for the CF test.

Interpretation. The LA test yields results in a matter of minutes and may be used with sera giving AC activity in the CF test. Although the LA test may be negative with sera from persons with chronic histoplasmosis or from immunosuppressed individuals, it is an excellent presumptive test aiding in the early diagnosis of acute histoplasmosis. A titer of 1:16 or greater is presumptive evidence of infection, and a titer of 1:32 or greater is considered strong presumptive evidence for active or very recent infection. Although a positive LA test result can be demonstrated as early as 2 to 3 weeks after infection by *H. capsulatum*, false-positive results can occur with other systemic mycoses. It is therefore recommended that results be confirmed by using ID or other laboratory tests. Low-titer results from single specimens should especially be interpreted with caution. In such cases, the test should be performed with another specimen collected 4 to 6 weeks later.

Enzyme Immunoassay

Attempts to replace the CF test with an EIA format have been frustrated because of cross-reactive carbohydrate moieties found on the immunodominant H and M antigens (97, 98). Periodate treatment of the M antigen before use in an immunoblot format, however, was reported to remove most of the cross-reactivity and increase the test specificity to 91% (98, 99). Recently, an ELISA for the early diagnosis of histoplasmosis was described in which purified native histoplasmin was compared to its deglycosylated counterpart (100). Deglycosylation resulted in an increase in test specificity from 93 to 96%; more surprisingly, the test sensitivity also increased from 57 to 92% (98–100). The sensitivity of the assay was 100% for patients with acute histoplasmosis and mediastinal histoplasmosis. However, sensitivity was reduced in other forms of histoplasmosis: 90% in chronic disease, 89% for disseminated disease, and 86% in disseminated disease in HIV-infected patients (101). An EIA for histoplasmosis antibodies using "inactivated" histoplasmin antigen to coat microtiter wells is commercially available (Histoplasma DxSelect; Focus Diagnostics). According to the manufacturer, when compared to CF titers of $\geq$1:8, the assay has 82.4% sensitivity and 88% specificity. When compared to CF titers of $\geq$1:32, specificity is improved to 93.3%; however, sensitivity was reduced to 58%. There are currently no independent reports evaluating the performance of this commercial assay.

Antigen Assays for the Diagnosis of Histoplasmosis

Enzyme Immunoassay

EIA for detecting *Histoplasma* antigen in urine and serum is useful for diagnosing disseminated histoplasmosis, particularly in AIDS patients (102). Antigen detection is less effective in diagnosing histoplasmosis in immunocompetent patients with self-limited disease or in cases of chronic pulmonary disease (103). Although less sensitive for the diagnosis of primary disease than disseminated disease, the test can be useful for diagnosis in the early stages of acute pulmonary disease (first 3 to 4 weeks after onset), permitting appropriate therapy to be initiated sooner.

An EIA to *Histoplasma* antigen uses polyclonal rabbit antisera against formalin-killed yeast forms of *H. capsulatum* as both the capture and detector antibody (103). This test is performed as a fee-for-service reference test (MiraVista Diagnostics, Indianapolis, IN, www.miravistalabs.com). The antigen detected is poorly defined but is believed to be a galactomannan based on its stability to heat (100°C for 30 min) and its reduced reactivity after passage through a concanavalin A affinity column (99, 104). Antigen can be detected very early in disease (during the first 2 weeks after the onset of symptoms), and then its level rapidly declines in self-limited disease. It can be detected for longer periods in cases of disseminated disease. The MiraVista assay has undergone various revisions of specimen and assay performance since it was first designed. Acceptable specimens include urine, serum, plasma, CSF, and BAL fluid. CSF and serum are initially pretreated with EDTA to dissociate antigen/antibody complexes. Results are reported quantitatively through comparison to a standard curve made from antigen serially diluted from 19.0 to 0.4 ng/ml (105). Significant EIA cross-reactivity has been reported for the other endemic mycoses, particularly blastomycosis, paracoccidioidomycosis, and penicilliosis marneffei.

The use of the antigen assay, however, may not be the most sensitive assay with all patient populations. A multicenter study (106) compared the efficacy of detecting antigen in urine to conventional antibody detection for the diagnosis of histoplasmosis. The antigen assay was more sensitive for the diagnosis of disseminated infection in immunocompromised patients (69 to 84% [antibody] versus 92 to 94% [antigen]). However, in immunocompetent patients with disseminated or localized pulmonary infections, antibody diagnosis was more sensitive (86 to 100% [antibody] versus 39 to 80% [antigen]). Therefore, diagnostic sensitivity and specificity of these assays are dependent upon the particular population that is being tested. Therefore, test results must be interpreted in light of the clinical presentation and the patient's history of travel to or residence in areas of endemicity in conjunction with other laboratory results, including those for antibody detection and for culture.

Recently, another commercial antigen assay has been developed and is available for purchase (*Histoplasma* antigen enzyme immunoassay; IMMY). This assay uses rabbit polyclonal antibodies for antigen detection and was stated by the manufacturer to have a sensitivity and specificity of 80.9% and 98.7%, respectively. However, an independent report showed much lower values (62% and 79%, respectively) (107). A new version of this assay uses monoclonal antibodies for antigen detection and provides a much better sensitivity and specificity (90.5% and 96.3%, respectively) (107, 108).

Paracoccidioidomycosis

Clinical Indications and Diagnostic Rationale

Paracoccidioides brasiliensis is a dimorphic fungus whose endemic range is found in parts of Central and South America. Infection is found most frequently in persons 30 years or older and most commonly in men. Primary infection occurs in the lungs as observed through abnormal chest X rays but is often asymptomatic. Secondary manifestation can be observed in the mucous membranes, reticuloendothelial system, skin, adrenals, and other organs. Serologic tests for paracoccidioidomycosis should be performed on specimens from patients with symptoms of chronic disease or who present with ulcerative lesions of the mucosa (oral, nasal, or intestinal) or the skin. A history of travel to or residence in Latin America in conjunction with typical clinical signs should raise suspicion for paracoccidioidomycosis. Serologic tests are useful for the rapid presumptive diagnosis of paracoccidioidomycosis, particularly for diagnosing cases of disseminated disease and for monitoring the response to treatment.

Antibody Assays for the Diagnosis of Paracoccidioidomycosis

Immunodiffusion

The ID test is simple to perform and is among the most specific procedures available (reported sensitivities, 84 to 94%; reported specificity, 99%). The ID test employing concentrated yeast-form culture filtrate antigens and reference sera is 100% specific and has a sensitivity of 94% when sera from patients with paracoccidioidomycosis are tested. The major diagnostic precipitin is a 43-kDa glycoprotein referred to as gp43 (also known as E_2 or A) and is found in 95 to 98% of patients with paracoccidioidomycosis (109, 110). Commercial mycelium-phase *P. brasiliensis* culture filtrate antigens, containing gp43 and other antigens are available from IMMY (Table 1).

Interpretation. The ID test is valuable for the diagnosis of acute or chronic pulmonary infection and disseminated paracoccidioidomycosis. The greatest number of precipitin bands has occurred when sera from patients with lung involvement or disseminated disease have been used; up to three precipitin bands have been observed (111). A major diagnostic precipitin is consistently found in the sera of patients with paracoccidioidomycosis, which reacts with a soluble, specific *P. brasiliensis* antigen. Band 1, which appears closest to the antigen-containing well, is thought to contain gp43 on the basis of immunochemical analysis. The precipitin that reacts with the gp43 antigen has been observed to occur in 95 to 99% of sera from patients with active paracoccidioidomycosis and can be found in patient serum for longer periods following infection than the other two major serum precipitins; the latter disappear during a favorable response to treatment. The positive predictive value of a positive ID test result is 100%.

Complement Fixation

CF tests that use unpurified antigens have a similar sensitivity to the ID (87%) but are less specific (68%) (112). Therefore, the ID test should be performed in conjunction with the CF test. The CF test detects antibodies in 80 to 96% of patients with paracoccidioidomycosis. CF antibodies are diagnostic, but CF test results with *P. brasiliensis* yeast-form culture filtrate antigens are not always specific, and cross-reactions may occur when sera from patients with other endemic mycoses, particularly histoplasmosis, are used. These cross-reactions are infrequent and occur mainly at titers of 1:8 or below. Nonetheless, concomitant use of the CF and ID tests allows a correct serodiagnosis of paracoccidioidomycosis in over 98% of cases. No commercial reagents for CF are available.

Culture filtrate antigens of *P. brasiliensis*, referred to as paracoccidioidin, are prepared by growing *P. brasiliensis* in a tryptic soy broth-dialysate medium supplemented with glucose, ammonium sulfate, and vitamins (113). Yeast-form shake cultures of three stock isolates of *P. brasiliensis* are grown singly at 35°C in this medium for up to 4 weeks. Consult references 112 and 114 for isolate selection. The culture filtrate from each isolate is dialyzed, concentrated 10-fold, and mixed in equal volumes with those from the other isolates. The optimal dilution for each antigen pool is determined by titration with low- and high-titer CF-positive sera from human paracoccidioidomycosis cases or by the use of ID tests with precipitin-positive sera. References 111 and 114 give details of the kinetics of *P. brasiliensis* antigen production during growth and discuss alternative growth media.

Interpretation. CF titers of ≥1:8 are considered presumptive evidence of paracoccidioidomycosis. However, 85 to 95% of patients with active disease have titers of ≥1:32. Low CF titers are usually associated with localized disease or involvement of the mononuclear phagocyte system, whereas high titers are found in patients with pulmonary lesions or multifocal disease. Sera from young children with disseminated paracoccidioidomycosis are an exception and ordinarily show low or negative CF reactivity. Serial CF determinations are prognostic in that a decreasing titer generally indicates effective therapy, whereas relapses are accompanied by increasing titers. High and fluctuating titers suggest a poor prognosis. Low levels of CF antibodies may persist long after the patient is cured.

Experimentally, other approaches have also been explored for the detection of antibodies to *Paracoccidioides*. A WB method (115) used to detect antibodies against gp43 in patient sera showed an increase in sensitivity when compared to ID (80% versus 95.5%). However, specificity was better with ID. Another approach evaluated the use of latex agglutination assay for the diagnosis of paracoccidioidomycosis (116). Using serum, the LA assay was 73% sensitive and 79% specific. However, when the serum was first pretreated with a citrate buffer for dissociation of immune complexes, sensitivity and specificity of the assay improved to 90% and 90%, respectively (116).

Penicilliosis Marneffei

Clinical Indications and Diagnostic Rationale

Penicillium marneffei is a thermally dimorphic fungus endemic only to portions of Southeast Asia. Disseminated infection with *P. marneffei* is observed almost exclusively in

immunocompromised patients who either live in or have traveled through Southeast Asia. Recent taxonomic evaluation has determined that *P. marneffei* is closely aligned with the genus *Talaromyces* and renaming this mould to *Talaromyces marneffei* has been proposed (117). However, as *P. marneffei* is still most frequently used in the literature, the name *P. marneffei* will continued to be used in this section to avoid any confusion.

Diagnosis of *P. marneffei* infections relies mainly on culture and/or histopathologic identification. Serologic tests for the diagnosis of *P. marneffei* infections should be considered for use with patients who have lived in or traveled to Southeast Asia and who display symptoms of intermittent fever, marked weight loss, nonproductive cough, and debilitation. About 60 to 70% of patients present with multiple papular lesions, some of which show a central necrotic umbilication resembling molluscum contagiosum. Other presenting signs include hepatosplenomegaly, generalized lymphadenopathy, anemia, and thrombocytopenia. These symptoms may be confused with those of other fungal infections such as histoplasmosis or cryptococcosis as well as with those of tuberculosis. No commercial serology assays are currently available in the United States.

A major antigenic protein of *P. marneffei*, Mp1p, has recently been cloned and expressed in the yeast *Pichia pastoris* (118). Rabbit polyclonal antibodies and mouse monoclonal antibodies were subsequently produced against the recombinant protein for the development of antigen capture assays using either the MAb or PAb as capture antibodies and the MAb as the detector antibody. An antibody EIA was also produced using the recombinant antigen to coat the microwells for a microtiter plate. Evaluation of each assay was performed with sera from confirmed penicilliosis marneffei cases and control sera. Sensitivity and specificity of the antigen detection assays were 55% and 99% compared to 75% and 99% using the PAb and the MAb as capture antibodies, respectively. While the antibody assay was equally as specific (98%), the sensitivity was only 30%. A combination of antigen and antibody assays improved the diagnostic sensitivity to 85% with the MAb antigen assay and 100% with the PAb antigen assay, with a 98% specificity for both.

Pneumocystosis

Clinical Indications and Diagnostic Rationale

The cause of pneumocystis disease in humans has recently been reclassified as *Pneumocystis jirovecii* (119). Until 1988, these organisms were widely thought to be protozoa, but comparative DNA sequence analysis demonstrated that *Pneumocystis* strains were phylogenetically more closely related to the fungi (120). The route of transmission of *P. jirovecii* is not understood, but seroprevalence studies have suggested that exposure occurs in early childhood. It was hypothesized that the strains acquired during first exposure persisted in the lungs in a dormant state throughout life and became active on subsequent immunosuppression of the host (119, 121). However, this hypothesis has recently been challenged, and it has been suggested that *P. jirovecii* organisms are frequently acquired and cleared by the immune system in immunocompetent hosts and do not persist (122).

Pneumonia caused by *P. jirovecii* (PCP) is rare in immunocompetent adults but is a leading cause of illness and death in individuals with impaired immunity including malnourished or premature children, persons with AIDS, SOT recipients, and patients receiving long-term corticosteroid therapy. It is often described as interstitial plasma cell pneumonia; histopathologic studies of patients' lungs typically show alveolar interstitial thickening and the presence of a frothy eosinophilic exudate in the lumina. The clinical presentation in children is characterized by cyanosis, mild cough without fever, and, in severe disease, intercostal retractions. In contrast, adults with PCP frequently present with dyspnea, nonproductive cough, chest tightness, night sweats, and an inability to breathe deeply. Tachypnea and low-grade fever often occur, but hemoptysis is rarely present. Adults with CD4 counts below 200 per μl are at increased risk for PCP, and persons with AIDS have a more insidious progression than those who are immunosuppressed but HIV negative. Extrapulmonary pneumocystosis has been reported in 1 to 3% of postmortem examinations of patients known to have pulmonary infections (123, 124) and most often involves the lymph nodes (44%) and the spleen, bone marrow, and liver (33%). Infection at multiple extrapulmonary sites is associated with a rapidly fatal outcome (123, 124).

The laboratory diagnosis of pneumocystosis depends largely on the use of Gomori methenamine silver, calcofluor white, Gram-Weigert, toluidine blue-O, or fluorescent antibody staining of lung biopsy specimens, induced sputum, or BAL fluid specimens to detect the cyst form of the organism and the use of Giemsa stain to detect the trophozoite form or clusters of cysts containing intracystic bodies. Specific anti-*Pneumocystis* MAbs have been developed that can detect not only the cyst form of the organism but also the significantly more abundant trophozoite form (125, 126). The sensitivity of the MAbs with either induced sputum or BAL fluid specimens has been reported to be similar to or somewhat greater than that of conventional staining methods.

Indirect and direct immunofluorescent assays employing MAbs have most commonly been used for the detection of *P. jirovecii* in induced sputum and in BAL fluid samples; however, less frequently, these reagents have also been used for tissue diagnosis (127–129). MAbs directed against *Pneumocystis* for use in direct or indirect staining procedures are available commercially from Axis-Shield Diagnostics (Dundee, United Kingdom), Bio-Rad Laboratories, Inc., Chemicon International, Inc. (Temecula, CA), and Meridian Diagnostics. Other immunologic methods including counterimmunoelectrophoresis, ELISA, WB, and LA tests have also been developed experimentally and are discussed in more detail below. Finally, the increased sensitivity of molecular biology-based diagnostic methods may allow a minimally invasive procedure, such as oral washings (130), to be sufficient for diagnostic purposes.

The serologic diagnosis of pneumocystosis has proven to be difficult because most humans become seropositive for *Pneumocystis* antibodies at an early age and are exposed to the organism multiple times throughout life. Therefore, the detection of serum antibodies may not correlate with true infection. In addition, conflicting results have been obtained, primarily because different test methods have been used (LA, WB, ELISA, and indirect immunofluorescence), a variety of antigen sources have been employed (rat versus human), and the antigens used have been purified to different degrees (column purified or recombinant).

Other tests include the detection of antigens ranging from 35 to 45 kDa, as well as a 95-kDa major surface glycoprotein antigen, in BAL fluids (131). WB analysis demonstrated that the 35- to 45-kDa antigen was found in 88% of the BAL fluids tested, whereas the 95-kDa antigen was detected in only 49% of specimens. Recent analysis of sera from HIV-infected patients show that those infected with PCP contain much higher antibody titers to a recombinant protein that is part of the major surface glycoprotein (Msg), particularly MsgC, when compared to HIV-infected

patients without PCP (132). It has also been demonstrated that health care workers who care for HIV-infected PCP-positive patients are also more likely to have antibodies to MsgC (133, 134).

A recent meta-analysis of 12 studies analyzed the usefulness of BDG in the diagnosis of *Pneumocystis* infection which included the use of any of the commercially available BDG assays. The study concluded that BDG in PCP patients was 96% sensitive and 84% specific (135). Another particularly useful study showed that a decrease in BDG levels following treatment strongly correlated with a favorable outcome (136).

Sporotrichosis

Clinical Indications and Diagnostic Rationale

Sporothrix schenckii organisms, while found worldwide, are found in the soil and plants of tropical and subtropical regions of North, Central, and South America. The disease sporotrichosis is a subdermal infection that begins after a skin injury where the fungal conidia are implanted resulting in ulcerated, verrucous, or erythematous nodules which may spread locally through the lymphatics. Rarely, a pneumonitis can occur if conidia are inhaled. Dissemination may occur in both immunocompetent and immunosuppressed individuals.

Serologic tests for sporotrichosis may be applied to sera from patients with skin lesions, subcutaneous nodules, bone and joint lesions, lymphadenopathy, or pulmonary disease and to CSF from patients with undiagnosed chronic meningitis. The disease should be suspected in individuals whose work brings them into contact with soil, plants, timber, plant materials, or sphagnum moss. Cutaneous sporotrichosis is more common in adults than in children, and extracutaneous disease is found more often in men older than 30 years. Although not common, disseminated infection is more likely to occur in immunosuppressed than immunocompetent individuals.

Serologic tests are sometimes helpful for the diagnosis of the extracutaneous or systemic forms of sporotrichosis. A slide agglutination test to detect anti-*Sporothrix schenckii* antibodies has been demonstrated to be the most useful method. This test has been reported to have sensitivities of 100, 86, 73, and 56% for disseminated, articular, pulmonary, and cutaneous disease, respectively, and a specificity of 100% (137). Antibodies are most probably directed toward a peptido-L-rhamno-D-mannan, localized in the outer layer of the *S. schenckii* cell wall. Comparable sensitivity for the detection of *S. schenckii* antibodies has not been reported for an ID test format.

Antibody Assays for the Diagnosis Of Sporotrichosis

Latex Agglutination

The LA test is a semiquantitative slide agglutination assay in which *S. schenckii* antigen-coated latex particles are used to detect antibody to *S. schenckii*. The assay is rapid and simple to perform and requires no special equipment. A commercial kit is available from IMMY (Table 1).

Interpretation. LA titers of 1:8 or greater are considered presumptive evidence of sporotrichosis. False-positive reactions have, however, been noted at titers of 1:8 when sera from patients with nonfungal infections were used. Sera from patients with localized cutaneous, lymphocutaneous, or extracutaneous sporotrichosis may display titers ranging from 1:8 to 1:512. An increasing titer or a sustained high titer indicates pulmonary sporotrichosis. The test has limited prognostic value, since antibody levels may show little change during and after convalescence. Slide latex agglutinin titers of >1:8 with CSF are considered presumptive evidence of meningeal sporotrichosis.

Mucormycosis

Clinical Indications and Diagnostic Rationale

The primary agents of mucormycosis in the order Mucorales include species of *Lichtheimia*, *Apophysomyces*, *Cunninghamella*, *Mucor*, *Rhizopus*, *Rhizomucor*, and *Saksenaea*, and those in the order Entomophthorales include *Conidiobolus* and *Basidiobolus* (104, 138). The major risk factors for mucormycosis are neutropenia, uncontrolled diabetes mellitus, other forms of metabolic acidosis, and burns. Other contributing factors include corticosteroid use and treatment with deferoxamine. Although ID tests have been successfully used to detect antibodies in patients with active mucormycosis (97, 139), these methods have not been extensively evaluated.

Immunohistochemistry

In tissue, these organisms are difficult to differentiate and appear as sparsely septate, irregularly branched, broad, ribbon-like hyphae (138, 140). A murine MAb, WSSA-RA-1 (141), directed against somatic antigens of *Rhizopus arrhizus* (*oryzae*), has been reported to react specifically with *Lichtheimia corymbifer* (*Absidia corymbifera*), *R. arrhizus* (*oryzae*), and *Rhizomucor pusillus* when applied as an immunoperoxidase histopathology stain; this reagent is commercially available (AbD Serotec; Raleigh, NC). The method used for staining is the same as that for *Aspergillus* and can be found in the section above.

MOLECULAR METHODS FOR FUNGAL DETECTION

DNA-based methods have been used extensively to identify fungi from biological specimens in culture. However, DNA-based identification methods for isolate identification are outside the scope of this chapter; for the description of molecular methods used for identification of fungal cultures, the readers are referred to CLSI document MM18-A (142).

Methods for direct detection and diagnostics of fungal DNA in biological specimens remain experimental and can be divided into two major groups based on the method that is used for DNA detection and identification, such as (i) PCR amplification using universal fungal primers followed by DNA sequencing and (ii) real-time PCR amplification using species-specific molecular probes.

Panfungal PCR with universal fungal primers is most frequently used for diagnostics when the exact agent of infection is unknown. For this procedure, total DNA is extracted from the biological samples and amplified using panfungal primers specific to portions of the rRNA gene locus, such as ITS1, ITS2, and/or portions of the 28 rRNA gene (143). The PCR products are then visualized, purified, and sequenced. The fungus is identified by comparing the DNA sequence with those in the GenBank or other fungal databases (MycoBank, www.mycobank.org; Fusarium-ID, http://isolate.fusariumdb.org). The advantage of this approach is that it can be used to amplify and detect pathogens for which molecular probes have not been developed. For example, recently this method was used to detect and identify DNA of *Exserohilum rostratum* in fluids and tissues from an outbreak of fungal meningitis

and other infections associated with contaminated steroids (144). This approach is also frequently used for detection/identification of fungi in formalin-fixed paraffin-embedded tissues (145, 146).

Real-time PCR with species-specific molecular probes can be used for detection/identification when the agent of infection is already known or strongly suspected. The advantage of real-time PCR is that this method is more sensitive than conventional PCR. However, the disadvantage is that molecular probes used for identification are targeted toward specific species and would miss other pathogens that might be causing infection. In addition, because real-time PCR does not include a DNA sequencing step, extensive testing is required to ensure the specificity of the probes. Converse to the panfungal PCR method described above, probes and PCR primers for real-time PCR are often designed to amplify unique regions of DNA. Some of the studies where real-time PCR has been used for detection of fungal infections include *Aspergillus fumigatus* in sera of patients with suspected invasive aspergillosis (147, 148), *Pneumocystis jirovecii* in respiratory samples of non-AIDS patients (149, 150), *Candida* sp. DNA in blood of neonatal patients (151–153), and *Coccidioides* sp. in respiratory specimens of suspected cases of Valley fever (154, 155).

Regardless of the method that is used for the detection of fungal DNA, one of the most challenging aspects of molecular detection is obtaining sufficient amounts of fungal DNA from the patients' specimens. This procedure is complicated by (i) the presence of thick cell walls that need to be disrupted to release fungal DNA from cells prior to extraction and (ii) excess human DNA that competes with fungal DNA when using extraction columns. To release fungal DNA from hyphae, cell walls can be mechanically disrupted by bead beating (147, 148), sonication, or shaking or enzymatically digested using protease (156) or lyticase (145). Once the fungal cell walls are fragmented, a variety of DNA purification methods can be used. Some studies have compared such methods (148). As an alternative, free circulating fungal DNA can be concentrated and purified using methods developed for extraction of viral DNA from body fluids, such as the QIAamp UltraSens virus kit (Qiagen). Furthermore, when fungal DNA is extracted from formalin-fixed paraffin-embedded tissue scrolls, removal of paraffin and rehydration of specimens need to be performed (145, 146).

Viral Diseases

section J

VOLUME EDITOR: JOHN L. SCHMITZ
SECTION EDITORS: RICHARD L. HODINKA AND JOHN L. SCHMITZ

Introduction

JOHN SCHMITZ

56

It is probably not unreasonable to say that the clinical virology laboratory has experienced the greatest amount of change of any clinical pathology laboratory since the last edition of this *Manual*. The traditional virology laboratory, as found in many larger hospital-based facilities, often no longer exists, having been replaced by molecular diagnostics. Accordingly, the first chapter in this section now covers rapid and molecular diagnostic methods as well as the traditional diagnostic procedures that still pertain. Rarely are culture or antigen detection methods still in regular use. Likewise, the ability to detect low copy numbers of viral nucleic acids, as well as the ability to accurately quantify the amount of virus present based on nucleic acid amplification, has limited the practical application of serologic methods to immune status testing, with a few well-known exceptions. There are many obvious benefits associated with the adoption of molecular diagnostics for viral infections, such as an increase in the diagnostic sensitivity. In addition, these technologies allow for the rapid deployment of tests for newly described viral pathogens. Quantitative methods facilitate diagnosis and allow prognostic application and facilitate patient management. This is not to say that serologic methods have been stagnant. There has been increasing adoption of avidity-based testing for chronic viral infections to facilitate the differentiation of primary infection from reactivation.

As viral diagnostic methods have evolved, so has this section of the 8th edition of this *Manual*. Several important revisions have been made, the most significant of which concerns HIV. Rather than an entire section, a single chapter on HIV diagnosis now details the application of the recently adopted new HIV diagnostic algorithms and no longer addresses viral load testing or genotyping.

Further changes include the combination of three chapters from the 7th edition into one authoritative discussion of respiratory viruses. The measles and mumps and rubella chapters likewise have been merged because they stress a common theme; since these three childhood viruses are easily managed by vaccination, serology remains important to identify unvaccinated or nonimmune individuals. Finally, the remaining chapters in this section offer the current state of the art concerning herpes simplex virus; varicella-zoster virus; Epstein-Barr virus and cytomegalovirus; human herpesviruses 6, 7, and 8; parvovirus B19; viral hepatitis; viral agents of gastroenteritis; arboviruses; hantavirus; rabies virus; human T-cell lymphotropic virus types 1 and 2; and prions.

Immunologic and Molecular Methods for Viral Diagnosis

MARIE LOUISE LANDRY AND YI-WEI TANG

57

Tremendous strides have been made in viral diagnosis in the past decade. Many infections are now treatable and, for optimum effect, antivirals must be started early. For hospitalized patients, rapid and accurate viral diagnosis is essential not only for patient management, but for infection control and prevention of nosocomial transmission. The impact of seasonal and pandemic influenza on morbidity and mortality of all ages has received increasing attention in both the medical literature and the popular press. Emerging, highly virulent viruses such as severe acute respiratory syndrome (SARS) coronavirus (CoV), Middle East respiratory syndrome CoV, and avian influenza H5N1 and H7N9 have also heightened concerns. Lastly, immunosuppressed and other vulnerable populations at risk for serious or life-threatening viral infections continue to increase. In response to these needs, there has been an explosion in viral diagnostic test development.

Tests are now available that can provide results within minutes of sample collection for some viruses and within hours for others, thus significantly shortening the time to diagnosis over conventional culture and serologic methods. In the past, on-site availability of viral diagnosis was limited by the need for cell culture facilities and expertise. Now, with simple-to-use, FDA-cleared immunologic and molecular tests, viral diagnosis has become more widely available and has entered the mainstream of diagnostic testing.

This chapter will present a practical approach to the rapid diagnosis of acute viral infections, focusing on the advantages and limitations of common methods and, importantly, the availability of new molecular methods. Routine serology and conventional cell culture techniques will not be covered, but details can be found in other texts (1).

VIRAL DIAGNOSTIC METHODS

The methods used for diagnosis of acute viral infection can be generally grouped according to the following strategies: (i) direct detection of viral proteins or particles in clinical specimens; (ii) biochemical amplification of nucleic acid in clinical samples; (iii) biologic amplification of infectious virus in culture followed by early detection of viral antigens in the infected cells; and (iv) detection of an IgM antibody response to viral infection. The test of choice may vary with the virus and the circumstance (Table 1).

Immunoassays historically have provided the most rapid results, with the most common antigen detection tests consisting of only one step, no reagent additions, and 10 to 20 min of incubation. Rapid cell culture methods, with incubation times of only 1 to 2 days followed by monoclonal antibody (MAb) staining, provide efficient detection of multiple viruses. Nucleic acid amplification techniques (NAATs) have been significantly shortened by more rapid thermocycling and real-time detection strategies. Some provide "on-demand" or "random-access" testing.

Whereas conventional culture and electron microscopy can detect the unexpected, immunologic and molecular methods detect only the specific agent(s) sought. However, multiplex strategies can now detect multiple viruses associated with a particular syndrome in a single reaction and more quickly, and thus have led to replacement of culture methods in many situations.

IMMUNOLOGIC METHODS

Direct Detection of Viral Antigens in Clinical Specimens

With direct antigen detection methods, the target is not amplified; thus, these tests are inherently less sensitive than culture or NAATs. Nevertheless, immunoassays are still widely used for influenza, respiratory syncytial virus (RSV), and rotavirus antigens, due to ease of use, cost, ability to accommodate single to multiple samples, rapid time to result, point-of-care (POC) capability including use in resource-poor or remote areas, and potential impact on patient management (Table 2). However, during the 2009 H1N1 influenza pandemic, the suboptimal sensitivity of rapid influenza diagnostic tests (RIDT) received a great deal of attention (2). This has led to a renewed focus on improving sensitivity of simple antigen assays. As molecular methods become more user-friendly and less expensive, antigen immunoassays must become more sensitive if they are to remain relevant.

Immunofluorescence

Immunofluorescence (IF) is by far the most demanding antigen detection technique and requires careful attention to detail throughout. When done well, it is an excellent test. When done poorly, it is neither sensitive nor specific. First, cells are applied to slides by touch prep, by pipette, or by cytocentrifugation. After fixation in acetone, methanol, or

doi:10.1128/9781555818722.ch57

TABLE 1 Application of various methods for rapid diagnosis of acute or primary viral infections[a]

Commonly encountered virus	Immunologic				Comments
	Viral antigen	Rapid culture	IgM	Molecular: NAAT	
Adenovirus	+	++	NA	+++	DFA suboptimal for adenovirus; rapid antigen assays available for enteric adenovirus in stool; rapid culture may require longer incubation than 2 days for optimal sensitivity; NAAT can be falsely negative or falsely low due to genome diversity
Arboviruses[b]	NA	NA	+++	++	Serology is primary diagnostic method for encephalitis-associated arboviruses; NAAT is commercially available only for WNV and dengue
Coronavirus	NA	NA	NA	+++	NAAT for common respiratory CoV is available as part of some commercial multiplex respiratory virus panels
Cytomegalovirus	++	++	+/−	+++	CMV pp65 antigenemia can be used to monitor viral load; rapid culture useful for congenital CMV urine or saliva, BAL, and tissue biopsy samples; quantitative NAAT most common method for viral load; while IgM can be useful in diagnosis of primary infection in normal hosts, it lacks specificity
Enterovirus and parechovirus	NA	++/−	NA	+++	NAAT preferred for CNS enterovirus infection; separate NAAT required for parechovirus detection
Epstein-Barr virus	NA	NA	+++	+++	Serology is test of choice for routine diagnosis; NAAT useful for virus-related tumors; quantitative NAAT useful for monitoring viral load in blood of transplant recipients; ISH can be used on tumor biopsies
Hepatitis A virus	NA	NA	+++	NA	Serology is the standard diagnostic test; false-positive IgM common in low-prevalence areas
Hepatitis B virus	+++	NA	+++	+++	Detection of specific viral antigens and antibodies allows for diagnosis and for monitoring the course of infection; NAAT used to monitor therapy and determine genotype
Hepatitis C virus	NA	NA	NA	+++	Serology is used for diagnosis; qualitative NAAT used to confirm active infection; quantitative NAAT used to monitor response to therapy; genotyping helps determine duration of therapy
Herpes simplex virus	++	++	Not reliable	+++	IFA used for rapid detection in skin/mucous membrane lesions or tissue specimens; NAAT is test of choice for CNS infection and used for other sample types as well; serology, including HSV-2-specific serology, used to determine prior infection
Herpesvirus 6	NA	NA	+	+++	NAAT test of choice for diagnosis; MAbs available to differentiate virus isolates and for IHC; serology can document primary infection in children
Human immunodeficiency virus	++	NA	++	+++	Serology is primary diagnostic method; rapid antibody testing becoming more widely available; proviral DNA and plasma RNA tests used to diagnose neonatal infection; quantitative RNA tests used to guide therapy and monitor response
Human metapneumovirus	++	++	NA	+++	NAAT is the test of choice for diagnosis; DFA and shell vial culture rapid and fairly sensitive; conventional culture difficult
Human T-cell lymphotropic virus	NA	NA	NA	+++	Serology is primary diagnostic method; NAAT useful for virus identification in HTLV Western blot-positive but untypeable specimens
Influenza virus	+/++	++	NA	+++	Rapid antigen tests widely used but suboptimal in sensitivity and specificity; DFA and rapid culture more sensitive; NAAT most sensitive and increasingly available; serology useful for epidemiological studies or retrospective diagnosis

(Continued on next page)

TABLE 1 Application of various methods for rapid diagnosis of acute or primary viral infections[a] *(Continued)*

Commonly encountered virus	Immunologic				Comments
	Viral antigen	Rapid culture	IgM	Molecular: NAAT	
Measles virus[b]	NA	NA	+++	+++	Serology most useful for diagnosis and determination of immunity; isolation only useful if attempted early (prodromal period to 4 days post-rash); NAAT done at CDC
Mumps virus[b]	NA	++	++	+++	Serology used most commonly for diagnosis and determination of immunity; NAAT done at CDC
Norovirus	NA	NA	NA	+++	NAAT challenging due to strain variability; reagents for antigen detection not commercially available
Parainfluenza virus	NA/++	++	NA	+++	IFA most common rapid detection method; NAAT more sensitive than isolation but not widely available, except as part of multiplex panel
Papillomavirus	NA	NA	NA	+++	NAAT test of choice for detection and genotype differentiation. Cytopathology useful for diagnosis; serologic diagnosis of exposure not available
Parvovirus	NA	NA	++	+++	Serology used to diagnose acute B19; NAAT test of choice for amniotic fluid or fetal tissue and for individuals who cannot mount an antibody response or who present early, before antibody has developed; NAAT can be used to detect human bocavirus
Polyomavirus	Kidney or brain tissue	NA	NA	+++	NAAT test of choice, but genetic variability can lead to falsely low or negative results; JCV DNA detection in CSF used for presumptive diagnosis of PML; BKV DNA quantification in plasma/urine used for pre-emptive diagnosis of PVAN; IHC and EM useful for biopsy tissues
Respiratory syncytial virus	+/++	++	NA	+++	Rapid antigen tests, such as DFA, more sensitive than culture; NAAT most sensitive, especially in adults
Rhinovirus	NA	NA	NA	+++	NAAT much more sensitive than culture; cross-reaction with enteroviruses can occur
Rotavirus	++	NA	NA	+++	Direct antigen detection useful for diagnosis; NAAT testing now commercially available as part of panels
Rubella virus[b]	NA	NA	+++	+++	Serology used for diagnosis of acute infection and immunity; NAAT most sensitive, but not commercially available; isolation useful for postnatal rubella if attempted early (prodromal period to 4 days post-rash); in CRS, virus can be isolated for weeks to months after birth
Varicella-zoster virus	++	+	Not reliable	+++	DFA and NAAT are most commonly used tests; rapid culture less sensitive than DFA; conventional culture insensitive; serology most useful for determination of immunity

[a]Key: +++, most sensitive and rapid; ++, moderately sensitive; +, least sensitive; −, not sensitive; NA, not available for routine clinical use in hospital or commercial laboratories. Pathology and tissue stains not included. Abbreviations: BAL, bronchoalveolar lavage; BKV, BK virus; CNS, central nervous system; CRS, congenital rubella syndrome; EM, electron microscopy; HTLV, human T-cell lymphotropic virus; IFA, immunofluorescent assay; IHC, immunohistochemistry; ISH, *in situ* hybridization; JCV, JC virus; PML, progressive multifocal leukoencephalopathy; PVAN, polyomavirus-associated nephropathy; WNV, West Nile virus.

[b]Additional specialized tests available at CDC and possibly other public health laboratories.

formalin, the cells are overlaid with antibodies labeled with fluorophores. After incubation and washing to remove unreacted antibodies, slides are examined under a fluorescence microscope. Free virus cannot be detected by IF microscopy; rather, viral proteins that accumulate during viral replication are visualized in infected target cells. IF is commonly performed on cell smears from skin lesions and nasopharyngeal (NP) aspirates or swabs, and has also been successfully applied to peripheral blood leukocytes (PBL). Advantages of IF include the opportunity to assess the quality of the sample (i.e., presence of an adequate number of target cells for a valid result), to discern specific from nonspecific staining patterns, to detect a single infected cell, and, in contrast to other immunoassays, to test one sample for multiple viral pathogens in a single cell spot. It can be applied to single or multiple samples, and per-test reagent costs are generally less than for other methods. Time to result is typically 1 to 2 hours.

Clinical utility of IF has been enhanced by reducing total time to as little as 25 min (D^3 FastPoint, Diagnostic Hybrids), by using cytocentrifugation to enhance slide quality (3), and by combining antibodies with different fluorochrome labels

TABLE 2 Uses and limitations of immunologic detection methods for viral antigens[a]

Method	Common clinical applications	Time required	Uses	Limitations
Direct antigen detection				
Immunofluorescence	RSV, influenza A and B, parainfluenza 1–3, adenovirus, HMPV in respiratory cells; VZV and HSV in skin-lesion smears; CMV in leukocytes	0.5–2 h	Can evaluate quality of sample, characteristic staining pattern and morphology; can detect a single positive cell, multiple pathogens in single sample, or quantitate CMV load in leukocytes; can test single or multiple samples; can run test multiple times a day; more sensitive than other antigen tests	Requires significant expertise and training; endpoints subjective; needs good sample with adequate cells; requires fluorescent microscope with good-quality objectives; cytocentrifuge desirable
Microwell, tube, or bead EIA	Rotavirus, HBV, fourth-generation HIV test	2–4 h	Suitable for large test volumes, batch testing; breakaway strips for smaller sample size; cheaper per test reagent costs; objective endpoints, computerized data analysis, automated format	Sensitivity varies with virus and kit used; neutralization test needed to detect nonspecific reactions; multiple controls processed with each run; EIA reader and washer, multichannel pipette required
Membrane EIA	RSV, influenza	15–30 min	Simple format, minimal training required; can test single or multiple samples, and run test multiple times a day; no major equipment	Relatively expensive per test reagent cost; nonspecific reactions difficult to detect; single agent detected
Latex agglutination	Rotavirus, enteric adenovirus	30 min	Simple format, no major equipment; suitable for single-sample testing	Subjective; weak positives difficult to read; nonspecific reactions; not as sensitive as EIA
Lateral flow immunoassay	Influenza, RSV, fourth-generation HIV test	10–20 min	Simple format, add sample, no reagent additions; no major equipment required; suitable for single-sample testing; many CLIA-waived tests for POC or resource-poor areas	Subjective unless reader used; weak positives difficult to read; some transport media may give spurious results
Rapid culture[b]				
Shell vial centrifugation culture	CMV, VZV, HSV, RSV, influenza A and B, parainfluenza 1–3, adenovirus, HMPV, enterovirus	16–48 h	Centrifugation enhances infectivity; characteristic staining pattern enhances specificity; can detect a single positive cell; can detect multiple viruses in one culture by combining two cell cultures in one shell vial and staining with pool of antibodies; detects replicating and not latent virus	Cell culture toxicity and contamination can reduce sensitivity; requires infectious virus; labor-intensive; need expertise in cell culture and IF; tissue culture facilities, centrifuge, fluorescent microscope required
Immune response				
IgM antibody	Parvovirus B19, EBV, arboviruses including West Nile virus, HBV, HAV, rubella, measles, mumps, CMV, HIV	1–4 h	Valuable when virus detection methods not available and/or disease is immune mediated and IgM antibodies detectable at clinical presentation; economical screening test	Compromised hosts and neonates may not have detectable antibodies; heterologous antibody rises can occur; appearance of IgM can be delayed until week 2 of illness; rheumatoid factor and IgG may interfere

[a]All rapid methods except electron microscopy are limited to the detection of suspected viruses; direct antigen tests do not amplify the target, thus are less sensitive than culture and NAATs.

[b]Limited to viruses that grow in commonly available cell cultures.

in one reagent to simultaneously detect and differentiate multiple viruses in the same cell spot (4). The dual fluorophore approach has been used to simultaneously test for herpes simplex virus (HSV) and varicella-zoster virus (VZV) in skin lesion samples, and influenza A and RSV in respiratory epithelial cells (SimulFluor Millipore). For a more comprehensive respiratory virus screen, a pool of MAbs to seven or eight common viruses (RSV; influenza A and B; parainfluenza types 1, 2, and 3; adenovirus; and human metapneumovirus [HMPV]) can be used without compromising test sensitivity. With D3 Ultra DFA (Diagnostic Hybrids), either the RSV or influenza A MAb is labeled with a yellow-gold fluorophore, and the remaining MAbs are labeled with green fluorescein. If the screen is positive with a green fluorescein-labeled MAb, additional slides must be stained with dual or single reagents to determine the infecting pathogen.

The essential prerequisites for accurate IF testing are an experienced and well-trained microscopist, sensitive and specific reagents, a fluorescence microscope with high-quality objectives, and a sufficient and steady flow of samples to develop and maintain expertise. IF works best in settings that allow re-collection of inadequate specimens. Established criteria for interpretation must be strictly followed, and results should be validated initially and intermittently thereafter by culture or other methods. IF staining can be more sensitive than culture for detection of RSV in NP aspirates, VZV in skin lesions, and cytomegalovirus (CMV) in blood leukocytes, but is variable for other viruses or sample types, ranging from 60% to 95% compared to culture (5, 6). IF is a labor-intensive, manual method, highly operator dependent, and not amenable to automation or high-volume testing. Most reagents now use the faster direct fluorescence staining method (i.e., the primary antiviral antibody is labeled) and are referred to as direct immunofluorescence assays (DFA).

Reasonable sensitivity, speed, and multiplex capability make DFA an attractive alternative to culture, particularly for respiratory viruses in pediatric patients. DFA has also been shown to reduce antibiotic use and lead to reduced hospitalization costs (7, 8). However, NAAT tests, such as BioFire FilmArray with 1-hour time to result, detect more pathogens, provide more sensitive results, and require less expertise than DFA. Although DFA is less expensive than NAAT, its use has decreased (9).

EIA

Enzyme immunoassay (EIA) employs an enzyme label and a colorimetric substrate and is the main test format in clinical laboratories for the detection of antibodies. In indirect EIA for antigen detection, antiviral antibody is immobilized on a solid support, sample is added, and viral antigen, if present, binds to the antibody. A second enzyme-labeled antibody is added, followed by addition of a substrate that usually generates a colorimetric signal. The reaction can be detected visually or with a spectrophotometer. Whereas IF microscopy can only visualize viral antigens produced in infected cells, EIA detects both cell-associated and cell-free antigens in clinical samples. Therefore, EIA can be used for noncellular samples, such as serum and stool. However, with EIA one cannot assess the quality of the sample and cannot distinguish nonspecific reactions unless a neutralization or blocking antibody test is done. EIA using microtiter plates is well suited to automated, high-volume batched-sample testing, with results analyzed by computer. Samples may be held until a sufficient number are available for testing and assay times are 2 to 4 hours. Alternatively, rapid membrane EIA in single sample cassettes with 15- to 30-min assay times can be performed multiple times a day as needed.

EIA for detection of viral antigens has been most successful when high titers are present in clinical samples and is most useful for viruses that do not grow in routine cell cultures, such as rotavirus, hepatitis B virus (HBV), and HIV (10, 11). Membrane EIA was widely used for influenza and RSV, especially in pediatric patients, until replaced with lateral flow assays. EIA has been less successful for other pathogens, such as HMPV. Although readily implemented in laboratories without virology experience, EIAs may not be commercially available for the desired pathogen or in the preferred format.

CLIA

In the chemiluminescence immunoassay (CLIA), a chemiluminescent label combined with a trigger reagent produces light. Random access instruments using CLIA are beginning to replace batch testing of blood samples by EIA. Testing can be performed "on demand" throughout operating hours, as samples arrive in the laboratory. Time to result is generally 1 hour. Compared to EIA, CLIA is more sensitive, has a lower background, and has a greater dynamic range.

An important advance in the diagnosis of acute HIV infections is the fourth-generation HIV screening test that combines IgM and IgG detection with detection of HIV-1 p24 antigen. Once antibody develops, p24 is bound in immune complexes, but prior to the appearance of antibody, p24 antigen is a sensitive marker for acute HIV infection. Currently one fourth-generation HIV EIA (Bio-Rad Genetic Systems), one CLIA (Abbott Architect), and one lateral flow immunoassay (Alere) are FDA cleared in the United States, although numerous fourth-generation HIV tests have long been used in Europe (11).

Latex Agglutination

The advantages of latex agglutination assays include simplicity, speed, and lack of expensive equipment. Antiviral antibody bound to latex beads is mixed with sample. If antigen is present, the beads clump or agglutinate, which can be seen by eye. When the specimens contain large amounts of viral antigen, agglutination assays can be used with acceptable results. This would include rotavirus and enteric adenovirus in stools of infants with gastroenteritis (12). When antigen is present in great excess, however, a prozone reaction can occur, leading to a false-negative result. This can be detected by repeating the test at a higher sample dilution. Limitations are lack of sensitivity, subjective interpretation of results, and difficulty reading borderline samples.

LFIA

In a lateral flow immunoassay (LFIA) for antigen detection, a sample is applied to a device or a strip and antigen, if present, binds to labeled antiviral antibodies. Antigen-antibody complexes move along the test strip by capillary action until bound by capture antibodies at the distal end of the strip, giving rise to a visible band. Whereas EIA involves a series of reagent additions, incubations, wash steps to remove unreacted materials, addition of substrate, and stop reagent, LFIA requires addition of sample only and provides results in 10 to 20 min that are comparable to EIA. Almost all rapid influenza and RSV tests are currently LFIA. These tests can be used at the point of care and have been shown to affect management (13). Both membrane EIA and lateral flow assays must be read within 5 to 10 min of assay completion for valid results. It should be noted that kit performance can be adversely affected by the transport media used. Media with gelatin such as M4 RT (Remel), especially when cold, can impair flow and lead to spurious results (false positives and false negatives). Like EIA, LFIA requires high viral load in

the sample for a positive result and thus performs best in infants and young children. Rapid influenza diagnostic tests (RIDT), predominantly LFIA, received increased scrutiny during the 2009 influenza pandemic and their inadequate sensitivity was widely recognized. Furthermore, detection of circulating influenza strains varies year to year, affecting kit performance.

To improve sensitivity, several rapid influenza and RSV LFIA tests utilize a fluorescence label, instead of the standard colloidal gold, and a small reader. Two readers (3M by Focus Diagnostics and Sofia by Quidel) are walkaway, provide a printout, and can be interfaced to the laboratory information system (LIS) (2, 14–16). One reader (Veritor, Becton Dickinson) is less expensive but is not walkaway (17). RIDT false positives are a significant problem when influenza prevalence is low. Due to the public health implications of influenza and advantages of having a simple POC test, the Centers for Disease Control and Prevention (CDC) has begun to monitor performance with currently circulating strains and has encouraged manufacturers to prioritize improved performance. Research into improving labels and enhancing sensitivity are a priority (18). For an update on use of RIDT, consult the CDC website at http://www.cdc.gov/flu/professionals/diagnosis/.

POC tests combining viral antigen with IgM and IgG antibody detection have been recently developed for HIV (Determine, Alere) and for dengue viruses (19).

Rapid Detection of Viruses in Culture by Immunologic Methods

Conventional virus isolation typically requires inoculation of multiple cell lines in roller tubes, followed by daily microscopic examination of cell monolayers for virus-induced cytopathic effects (CPE), which can take days to weeks to appear. The expertise required and the delay in virus detection limit the impact of conventional culture on patient therapy and management.

Rapid Culture

In contrast, rapid cultures involve centrifugation of samples onto cell monolayers in shell vials or multiwall plates, then fixation of cells after 16 to 48 hours of incubation, followed by staining with virus-specific MAbs to detect viral proteins in infected cells. Rapid culture for CMV utilizes one cell line, usually a human fibroblast, and staining with a MAb to CMV immediate-early antigen (20).

To detect a spectrum of viruses in conventional culture requires inoculation of multiple cell lines. To simplify the process for rapid cultures, two to three cell lines have been combined into one vial, and after sample inoculation and incubation for 1 to 2 days and up to 5 days, the cell monolayer is stained with a pool of antibodies to potential viral pathogens (21, 22). There are a variety of mixed cell cultures to choose from (Diagnostic Hybrids), depending on whether herpesviruses, respiratory viruses, or enteroviruses are sought (Table 3). The training time for personnel to become competent at interpreting IF staining in shell vial cultures is much shorter than required for conventional CPE or DFA of clinical samples.

Detection of Antibody Response to Virus Infections

In general, rapid diagnosis of acute viral infections in a timeframe to impact patient management relies on detection of the virus itself. Antibody develops in response to viral replication and therefore appears later. Nevertheless, in some virus infections, antibody detection remains the initial test of choice for several reasons.

IgM

IgM detection is primarily useful when viral detection methods are not readily available or are too slow to give clinically useful results, or when patients present coincident with the appearance of IgM. Examples include arboviruses and rubella, measles, and mumps viruses. In most infections, IgM antibodies can usually be detected within 5 to 7 days of clinical symptoms, but may require up to 2 weeks.

Third- and fourth-generation HIV tests that detect both IgM and IgG provide an earlier diagnosis than provided by first- and second-generation tests, which detected only IgG (11). Likewise, some hepatitis C virus (HCV) antibody tests detect both IgM and IgG and reduce the seronegative window after initial infection.

For some virus infections, the clinical symptoms prompting medical attention are immune mediated; therefore, IgM is usually detectable when the patient first presents. Examples include hepatitis A virus (HAV), HBV, parvovirus B19, and Epstein-Barr virus (EBV). Antibodies to several distinct viral antigens provide useful information regarding the stage of HBV and EBV infections.

Limitations of IgM testing include variability in test methods, weak or undetectable antibody responses in immunocompromised patients or neonates, heterologous IgM responses, interference by IgM-class rheumatoid factor (RF), competition between IgG and IgM antibodies leading to false positives and false negatives, failure to detect IgM due to timing of sample collection, persistence of IgM in some chronic viral infections, and frequent absence of IgM in reinfections or reactivations. For CMV, IgM antibody

TABLE 3 Mixed-cell cultures available commercially[a]

Culture type	Cell culture composition	Viruses targeted by staining[b]	Other potentially recoverable viruses
R-mix	Mink lung (Mv1Lu) and A549	RSV; influenza A and B; parainfluenza 1, 2, and 3; adenovirus (antibody pool); HMPV (separate antibody)	HSV, VZV, CMV, enterovirus
R-mix Too	MDCK and A549	Same as R-mix, except not susceptible to SARS CoV	HSV, VZV, enterovirus
H&V Mix	African green monkey kidney (strain CV-1) and MCR-5 cells	HSV-1 and 2, VZV	CMV, mumps, measles, RSV, rotavirus, SV40, rhinovirus, adenovirus, enterovirus
Super E-mix	BGMK-hDAF and A549	Enterovirus	HSV, VZV, adenovirus

[a]Diagnostic Hybrids, a Quidel Company. Table modified from reference 2. Abbreviations: A549, human lung carcinoma; BGMK, Buffalo green monkey kidney; BHK, baby hamster kidney; MDCK, Madin-Darby canine kidney; MRC-5, human diploid fibroblasts; SV40, simian virus 40.

[b]IF staining is at 1 and 2 days for mixed cells except Super E-mix, for which staining at 2 and 5 days is recommended.

increases with age in seropositive individuals, presumably due to subclinical reactivation. Cross-reactions between anti-parvovirus, rubella, and measles IgM are a particular problem if one is investigating a rash in pregnancy.

Methods to remove RF or interfering IgG prior to testing have been developed. While the best approach has been use of the IgM-class capture-assay format to improve specificity (23), background subtraction may still be necessary (24). Nevertheless, false-positive IgM results are common and can lead to inappropriate care. Although a positive IgM result may be the first indication of the viral pathogen, IgM tests are not definitive, but require confirmation by detection of virus or seroconversion of IgG or, for arboviruses, the more specific plaque-reduction neutralization test. The relative intensity of IgM and IgG reactivity (i.e., high IgM and low or negative IgG), followed by a rise in IgG over time, increases the likelihood of a true result. False-positive IgMs are a particular problem when the disease prevalence is low, as is commonly seen with HAV IgM in the U.S. population. The use of synthetic peptides to replace virion antigen-based immunoassays may reduce, but not eliminate, interference by RF, nonspecific reactions, and cross-reactivity.

MOLECULAR METHODS

Recent advances in nucleic acid amplification, detection, sample processing, and extraction techniques have enabled increased adoption of molecular tests for the diagnosis and monitoring of viral infections (2, 25–27). Molecular viral testing offers several advantages, including rapid detection of outbreaks and newly emerging strains or genotypes, identification of resistant viral pathogens, and the ability to correlate viral load with disease severity, all of which contribute to timely therapeutic decisions and early infection-control interventions. For discussion, molecular techniques can be divided into four main categories based on the numbers of targets detected and the diagnostic purpose. Table 4 provides an overview and comparison of commercial molecular *in vitro* diagnostic devices (IVD) that have been cleared by the U.S. FDA for detection, quantification, and genotyping of viral pathogens in clinical virology. Details and updates concerning these devices are available from the FDA website (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm330711.htm#microbial). In addition to IVDs, laboratory-developed tests (LDT) and commercial analyte-specific reagents (ASR) are used in laboratories with molecular expertise that are capable of validating and troubleshooting these tests for clinical use.

Monoplex Assays

Conventional PCR includes three steps: sample extraction, target nucleic acid amplification, and amplicon detection. Real-time amplification methods greatly accelerated the transition to NAATs in clinical laboratories and have become the main platform for detection and identification of viral pathogens. In real-time PCR, nucleic acid amplification and amplicon detection occur simultaneously in a closed tube, thus shortening time to result and reducing cross contamination.

Numerous LDTs using molecular technologies have been in the forefront of the effort to implement rapid and sensitive detection methods. One of the first molecular assays used successfully for clinical diagnosis was PCR for detection of HSV in cerebrospinal fluid (CSF) (28). PCR quickly became the test of choice when studies demonstrated that CSF PCR was equivalent to culture of brain tissue for diagnosis of HSV encephalitis and meningitis (28, 29). Interestingly, after almost a quarter of a century, probably due to market size, there were no FDA-cleared commercial HSV assays designated for CSF specimens until Simplexa HSV 1 & 2 was approved in 2014. In contrast, quite a few commercial NAATs are now available for detection and identification of HSV in skin and mucosal lesions (30). Among them, MultiCode-RTx HSV 1 & 2 (Luminex Corp), PROBETEC HSV (Becton Dickinson), and IsoAmp HSV (Quidel) are FDA-cleared IVD (30).

TABLE 4 FDA-cleared molecular methods for detection, quantification, and genotyping of viral pathogens[a]

Testing method	Viruses covered	TAT	Applications	Limitations
Monoplex	Adenovirus, CMV, dengue viruses, enterovirus, HCV, HSV, HMPV, HPV, influenza, and WNV	0.5–4 hours	Virus detection and infection diagnosis	"One stone for one bird"; limited test capacity; cannot be used as a test-of-cure
Multiplex[b]	Respiratory panel: adenovirus, bocavirus, coronavirus (4 species), influenza A and B, HMPV, parainfluenza 1, 2, 3, and 4, RSV, enterovirus, and rhinovirus Gastroenteritis panel: rotavirus, norovirus	1–8 hours	"One stone for many birds"; enhance diagnostic yields; reveal mixed infections	Slightly decreased sensitivities; cross-reaction can occur
Quantification	CMV, HIV, HBV, HCV	4-8 hours	Viral load determination; predict disease; monitor therapeutic response	Not ideal for diagnosis or confirmation; lack of inter-lab standardization
Genotyping	HCV, HPV, HIV, influenza	6–48 hours	Predict antiviral resistance; direct therapeutic regimens and prognosis; foresee means of spread of infection	Unknown and emerging mutations; indirect clinical correlation

[a]In addition to FDA-cleared IVD kits, commercial analyte-specific reagents are available for many viruses. Abbreviations: TAT, test turnaround time; WNV, West Nile virus.

[b]In addition to viral pathogens, these multiplex panels may cover nonviral pathogens; see companies' product inserts for details.

Studies have shown the superior sensitivity of real-time PCR-based assays compared to other assays for the detection of respiratory viruses (2, 27). Recent FDA approval of a number of commercial molecular assays for influenza virus testing has prompted many laboratories to discontinue culture or RIDT (2). Devices that have received FDA clearance include Human Influenza Virus Real-time RT-PCR Detection and Characterization Panel (CDC, Atlanta, GA), Xpert Flu (Cepheid, Sunnyvale, CA), Simplexa Flu A/B & RSV test (Focus Diagnostics, Cypress, CA), Liat Influenza A/B Assay (IQuum, Marlborough, MA), Autus Influenza A/B RG RT-PCR Kit (Qiagen, Inc., Germantown, MD), and Influenza A+B Assay (Quidel Corporation, San Diego, CA) (31). It merits mention that influenza-diagnostic test performance can be adversely affected by viral genetic and antigenic changes and should be re-assessed annually. Variability in sensitivity and specificity of the same test in different settings highlights the need for each laboratory to ensure optimal procedures and work with clinicians to improve sample quality (32).

Recently, the FDA has accelerated its clearance pace for a variety of viral pathogens (33). In addition to HSV and influenza, the FDA has cleared real-time PCR-based devices for adenovirus, CMV, dengue virus, enterovirus, HBV, HCV, HIV, HMPV, RSV, human papillomavirus, (HPV), and West Nile virus (33).

The monoplex assay will likely be the main platform for urgent, random-access, low-throughput assays such as POC testing that can be performed at home, in the workplace, at pharmacies and physician's offices, outpatient clinics, emergency rooms, or at the bedside of patients. POC test development has been driven by the need to make rapid, evidence-based, clinical, and therapeutic decisions at or near the site of patient care (30). While currently there are no FDA-approved molecular assays that can be used in a POC setting, considerable effort has been expended in developing POC devices including Xpert (Cepheid), Liat (IQuum), illumigene (Meridian Biosciences, Madison, WI), and iNAT (Alere Scarborough, Scarborough, ME).

Multiplex Assays

Multiplex design enables simultaneous detection and identification of multiple viral agents in a single reaction. Relative simplicity, powerful multiplexing capabilities, and high-throughput detection make multiplex assays most attractive for screening and detection of a panel of respiratory viruses. These methods are able to identify multiple pathogens more rapidly and with greater sensitivity than culture. This is particularly important in immunocompromised hosts. In addition, multiplex assays provide potent tools to detect mixed infections. Multiplex assays with relatively high throughput will likely become the main platform for batched specimens.

Multiplex reverse-transcriptase (RT)-PCR-based detection of respiratory viral pathogens has become part of the routine diagnostic algorithm in clinical laboratories over the past 5 years (25, 34) and several systems are commercially available. Some are rapid but low-throughput, whereas others use slower, conventional PCR assays, but with higher throughput. Examples include the FilmArray Respiratory Panel from BioFire Inc., the Infiniti Respiratory Viral Panel from AutoGenomics, Inc., the Jaguar system from HandyLab, Inc., the Multi-Code-PLx respiratory virus panel from EraGen Biosciences, the NGEN Respiratory Virus ASR from Nanogen, the ResPlex II assay from Qiagen, the Seeplex respiratory virus detection assay from Seegene, Inc., the eSensor Respiratory Virus Panel from GenMark Diagnostics, Verigene Respiratory Virus Nucleic Acid Test from Nanosphere, and the xTAG Respiratory Viral Panel from Luminex Molecular Diagnostics (25, 31, 34–36). Among them, the BioFire FilmArray Respiratory Panel, the GenMark eSensor Respiratory Virus Panel, the Nanosphere Verigene Respiratory Virus Nucleic Acid Test, and the Luminex xTAG Respiratory Viral Panel have been cleared by FDA.

With the success of multiplexing molecular detection in the respiratory arena, one would anticipate that highly multiplexed molecular assays will soon become a reality for detection of gastroenteritis pathogens (37). Indeed, progress has been made in the past few years on this front and there are a few multiplex RT-PCR-based commercial assays available for multi-target detection and identification in a single sample for gastroenteritis. Seegene's Seeplex Diarrhea ACE Detection detects diarrhea-causing viruses and/or bacteria directly from stool and rectal swab (38). A FilmArray GI Panel has been developed by BioFire to detect a panel of pathogens including adenovirus genotypes 40/41, human astrovirus, norovirus GI/GII, rotavirus A, and sapovirus. The xTAG Gastrointestinal Pathogen Panel (Luminex) using the xMAP Technology platform detects and identifies 11 pathogens including adenovirus 40/41, rotavirus A, and norovirus GI/GII and has become available as an IVD recently in the U.S. (39). The overall assay turnaround time is approximately 5 hours with bead-based detection on either the Luminex 100/200 or MAGPIX instruments.

Opening of postamplification tubes and subsequent pipetting steps in some test systems that use conventional PCR increase the risk for intra- and inter-run contamination. Careful attention should be paid to contamination control measures including the re-establishment of dedicated post-amplification laboratory space, which had become unnecessary in the real-time PCR era. Simultaneous testing for all possible pathogens is an efficient means to obtain a conclusive result and improves etiologic diagnosis (35, 36, 40). Assaying for all potential pathogens may also yield crucial information regarding coinfections or secondary infections (41). However, one study from the Netherlands indicated that implementation of multiple molecular assays for the etiologic diagnosis of lower respiratory tract infections increased the diagnostic yield considerably, yet did not reduce antibiotic use or costs (42). Thus, the clinical relevance and cost-effectiveness of simultaneous multi-pathogen detection and identification strategies merit further investigation.

Quantitative Assays

One of the first applications of NAAT in virology included quantitative detection of HIV, followed by assays to detect HBV and HCV. Over time, these assays have progressed from conventional to real-time methods with increased automation and have been extensively evaluated and shown to be essential to monitor and guide patient management. Calibration can be performed using a calibrator within each reaction or by comparing the quantitative results versus those generated using a stored calibration curve. The precision and linear range of viral loads can be measured precisely across the observed concentration range in plasma or serum collected from infected persons.

HIV infection results in lifelong viral persistence. In chronically infected patients, the HIV-1 RNA viral load in the plasma together with CD4 T cell numbers are the two routine laboratory markers used to guide antiretroviral therapy (ART) initiation, monitor treatment effectiveness, determine clinical progression, and modify treatment regimens. An HIV-1 RNA level below the detection limit is indicative of excellent adherence by patients and ART efficacy (43). Commercially available devices, including COBAS AmpliPrep/TaqMan HIV-1 (Roche), VERSANT

HIV-1 RNA (Siemens), NucliSens HIV-1 RNA QT (bioMerieux), and RealTime m2000 HIV-1 (Abbott Molecular), have been cleared by the FDA.

Abbott Molecular, Roche, and/or Siemens provide FDA-cleared devices for HCV and/or HBV viral load determination in plasma or serum (26, 44). Development of a World Health Organization (WHO) standard has resulted in the use of international units (IU) per milliliter and has improved agreement between assays (45). With the exception of the branched-DNA quantitative assay, the analytical sensitivity of these assays approaches limits of detection as low as 12 IU/ml (44). The highly sensitive quantitative data are used to help determine the rate of sustained virologic response (46).

Real-time PCR-based assays are commonly used for diagnosis and monitoring of CMV viral load in hematopoietic stem cell and solid organ transplant recipients (47, 48). Subsequent to CMV, quantitative viral load testing has been extended to monitoring other viruses in various transplant groups, including EBV, BK virus, and adenoviruses (49). However, the biggest challenge associated with the use of these mostly LDT quantitative assays is the inability to compare viral load results obtained across laboratories due to differences in genomic target (single versus multi-copy genes), extraction methods (manual versus automated), and detection platforms and the lack of international standards and calibrators (50). These limitations have made the establishment of quantitative thresholds for treatment difficult to establish (51, 52). However, the variability in viral loads measured across methods might be solved for some viruses with the recent introduction of the first WHO international standards for CMV (51) and EBV (52), as well as the availability of the first FDA-approved commercial real-time quantitative assay from Roche for monitoring of CMV viral loads (53).

Genotyping Assays

Genotyping is defined broadly here as assays that provide sequence or genotype, track disease outbreaks, provide strain resistance data and/or treatment prognosis, and determine the method or source and means of spread of infection. A variety of commercial tests, based on PCR coupled with sequencing, matrix probe hybridization, or electrospray ionization/mass spectrometry (ESI-MS), are available for genotype determination (43, 54, 55).

HIV-1 drug resistance tests—which include genotyping assays to detect known resistance-associated nucleotide mutations in the viral genome—and phenotype assays to detect viral replication in the presence of antiretroviral drugs have become routine in the management of patients receiving ART. Genotypic drug resistance testing has been recommended by the International AIDS Society-USA panel as an important tool to guide changes in therapy, the overall direction of therapy, and more recently, the initiation of therapy. There are currently two FDA-approved commercial drug resistance assays: (i) the TruGene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Siemens Healthcare Diagnostics, Tarrytown, NY), and (ii) the ViroSeq HIV-1 Genotyping System (Abbott Molecular, Des Plaines, IL) (55). Both systems generate reverse transcriptase and protease gene sequences following RT-PCR amplification. TruGene HIV-1 was recently discontinued by Siemens but will be made available through RTT Molecular Dx (Buford, GA). LDT-PCR assays coupled with sequencing have been used to detect antiviral drug resistance-related mutations such as those in CMV (UL97 mutations) (56) and influenza viruses (neuraminidase gene) (57).

HCV genotyping is widely used to determine therapy duration in conjunction with baseline viremia and viral load kinetics during treatment. A wide variety of technical platforms are available, including PCR followed by strip-based reverse hybridization, PCR followed by Sanger sequencing, and real-time PCR (58). All of these assays use the 5′ untranslated region (UTR) as their primary target, which has difficulty reliably differentiating between genotypes 1 and 6, as well as between subtypes, such as 1a and 1b. To remedy this, a second target region (core or NS5b) has been added to some of the 5′ UTR-based assays (59). Two complications impact current genotyping assays. First, multiple genotypes have been detected in intravenous drug users, and current population-based sequencing assays may miss minor genotype populations (60). The other complication is the presence of recombinant HCV isolates; current assays likely do not detect recombinants (61). Next-generation sequencing is predicted to provide more accurate HCV genotyping in these complicated settings (62). Currently, the Abbott RealTime HCV Genotype II, which differentiates genotypes 1, 1a, 1b, 2, 3, 4, and 5, is FDA-cleared to aid in determining the appropriate approach to treatment (63).

Recently, HPV vaccines have demonstrated effectiveness in preventing type-specific persistent infection and disease. To monitor the impact of vaccine implementation strategies, determine type-specific persistence, and evaluate the clinical significance of coinfection with multiple genotypes, type-specific results are desirable (64). Most established HPV typing assays are based on consensus PCR to amplify the relatively conserved L1 gene region with hybridization, restriction enzyme digestion, or sequencing of the amplicon to determine type(s) (65). Recently, several solid or liquid microarray-based techniques have been reported for simultaneous detection and typing of HPV (54). Currently, there are four FDA-approved tests for detection of HPV in endocervical specimens. Among them, the Cervista HPV 16/18 (Hologic, Inc.) and the Cobas HPV Test (Roche) are the two FDA-cleared devices providing limited HPV genotyping information (33, 65). Microarrays have also been used to characterize and type other viral pathogens, including rotavirus, norovirus, astrovirus, and HBV (66–68). The PLEX-ID Flu Assay (Abbott Molecular Inc., Des Plaines, IL), which incorporates multilocus PCR and ESI-MS, has been recently cleared by FDA to detect and differentiate influenza A 2009 H1N1, seasonal H1N1, H3N2, and influenza B in nasopharyngeal swab specimens (37).

TEST SELECTION, VALIDATION, AND MONITORING

Selecting which tests to offer in the laboratory has become more challenging as each diagnostic method has advantages and limitations (Table 1). An assessment and understanding of clinical needs, including communication with clinicians, is essential. In what settings would intervention, either therapeutic or preventive, be benefited by a laboratory diagnosis? Is targeted diagnosis of one or two agents acceptable, or is a test that detects multiple pathogens needed? Turnaround time, anticipated test volume, personnel expertise, fit with laboratory workflow, cost, equipment needed, number of tests available on the platform, etc. should be carefully considered. In smaller hospital laboratories, testing may be limited, whereas in laboratories serving large tertiary care hospitals, multiple methodologies are commonly available and algorithms for test use should be in place.

Once a test is selected, it is important to establish how the test functions in the setting into which it will be introduced, and not to rely on manufacturer's claims in the package insert or publications from other institutions. If the test does not function as anticipated, the reasons should be investigated (e.g., poor sample collection, transport media used, improper test procedure, different patient population, lack of technical expertise, etc.) and corrective action should be taken or a more suitable method employed. Each test offered should be monitored and periodically re-evaluated to assess its performance and to determine whether it continues to serve the needs of patients and physicians. For DFA and in-house amplification methods in particular, the pitfalls are many and careful monitoring of results is critical. Genetic and antigenic variability and genetic change can be a problem with any virus, but particularly with influenza viruses. Commercial kits provide many advantages, but primer and probe sequences are proprietary and can become outdated over time. Users should be aware that molecular tests can miss high-positive samples due to primer or probe mismatches. In critical situations when the molecular diagnosis is questioned, retesting with a different molecular assay may be warranted. Monitoring clinical correlation for test results and seeking feedback from clinicians are best practices that should be ongoing.

SUMMARY AND CONCLUSIONS

The choices for rapid viral diagnosis continue to increase. A variety of test formats are available, from walk-away automated systems to single-specimen immunoassays read visually. The number and types of techniques chosen will vary with the individual viruses, laboratory expertise, and clinical needs, and will continue to change as both test methods and antiviral therapy evolve. Laboratories must establish and monitor the performance of each test in their hands and their patient population. To provide clinically relevant, cost-effective, and accurate information for patient management, it is important to work with clinicians to establish priorities, improve sample collection, and seek clinical correlation and feedback.

Efforts to improve the sensitivity of simple immunoassays are underway. NAATs continue to evolve at a dazzling rate, with increasing automation, high-volume throughput, random access capability, faster time to result, and highly multiplexed test capability. With increasing demand, manufacturers are now motivated to seek FDA approval for their products, which in turn has increased adoption of NAAT in clinical laboratories.

NAATs are now the standard against which other methods are judged. Yet NAAT reagent costs are higher than other methods and equipment can be costly. To facilitate implementation, some facilities restrict more expensive NAATs to the patient groups that will benefit most from a viral diagnosis. Although we can detect more viruses more quickly, the significance of a positive result may sometimes be unclear in the individual patient. Outcomes research is urgently needed to provide guidance to both laboratories and clinicians on the cost-effective use of viral diagnostic tests to improve outcomes in diverse patient groups and clinical settings.

Herpes Simplex Virus

D. SCOTT SCHMID

58

Human infections with herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) are common throughout the world. HSV infection can cause a variety of illnesses depending on the anatomic site infected, whether it is a primary or recurrent infection, and the immune status of the person infected. Persons at risk for serious or prolonged active HSV infection are those with eczema, severe burns, or immunosuppressive conditions, such as organ transplant patients or HIV-infected persons. Primary infection occurs in individuals who have not previously been infected with either HSV-1 or HSV-2. Primary infections may be subclinical or mild enough to be unrecognized in a majority of cases, whereas clinically apparent infections comprise a wide array of presentations, ranging from mild pharyngitis or cutaneous infections to severe generalized disease and, on rare occasions, death (1). HSV-1 has a greater propensity to cause oral infections and is typically acquired during childhood. The most frequent manifestation of primary HSV-1 infection in children is gingivostomatitis. Primary HSV-1 infection in adolescents and adults usually manifests as pharyngitis or tonsillitis. Conjunctivitis, keratitis, vesicular eruptions of the skin, herpes whitlow, and encephalitis occur much less frequently. While the most common manifestation of sexually acquired HSV-2 is genital disease, both HSV-2 and HSV-1 can cause genital infection. HSV is the most common cause of genital ulcer disease in developed countries. In recent years, HSV-1 has been more frequently implicated as the etiologic agent (1). Complications of HSV-2 infection include aseptic meningitis and other neurological complications, extragenital lesions, and disseminated infection. Neonatal herpes is caused by mother-to-child transmission of HSV-1 or HSV-2 *in utero*, during the birth process, or during the neonatal period. Infants infected during delivery or postpartum present in one of three ways: (i) disease localized to the skin, eyes, or mouth; (ii) central nervous system disease with or without skin, eye, or mouth disease; or (iii) disseminated infection. HSV-1 seroprevalence in the United States declined about 7% from 1999 to 2004 and from 2005 to 2010, with roughly 60% of persons being HSV-1 seropositive among 40- to 49-year-olds (2). HSV-2 seroprevalence in the United States increased by more than 50% between the mid-1970s and the mid-1990s but then began to decline; in 2005 to 2010, the estimated seroprevalence was 25% in 40- to 49-year-olds (2).

As with all human herpesviruses, HSV-1 and HSV-2 establish a lifelong latent infection following primary infection, in this instance by colonizing sensory neurons of either the trigeminal or the lumbosacral ganglia (1, 3). Reactivation from either site may result in subclinical or clinical disease, both with viral shedding. Recurrent infection in the form of fever blisters or, rarely, ocular herpes occurs in up to 40% of HSV-1-seropositive people (1, 3). Genital eruptions may recur in one-third to two-thirds of individuals infected with HSV-2 (1, 3); reactivation is less frequent with genital HSV-1 than with genital HSV-2 infection. Recurrent infections are frequently subclinical and, as such, may result in unrecognized virus transmission, including neonatal infection (4, 5). A previous oral HSV-1 infection does not protect a person against a genital HSV-2 infection; however, persons with prior HSV-1 infection who are subsequently infected with HSV-2 frequently experience a less severe clinical course (1).

CLINICAL INDICATIONS

A presumptive clinical diagnosis of HSV infection can frequently be made from the appearance of cutaneous or mucosal lesions alone; however, given the large differential diagnoses for genital ulcer disease, laboratory confirmation of the infection should always be sought. The serologic results obtained after waiting to collect and test an appropriately timed convalescent-phase serum sample offer little guidance for therapy in the clinical management of most patients. The definitive diagnostic method is HSV type-specific PCR (1, 6), which has largely supplanted other methods, e.g., viral culture, direct fluorescent-antibody assay (DFA), and the Tzanck smear. HSV PCR has been shown to be substantially more sensitive than virus culture (2- to 4-fold more sensitive) in a head-to-head comparison (7). Culture is valuable primarily because it provides a viable isolate for further study, but this is unlikely to be a paramount consideration in most clinical settings. Some patients suspected of having HSV encephalitis may have negative PCR results, in which case parallel testing of serum and cerebrospinal fluid (CSF) for HSV antibody should be considered (8–10). A CSF-to-serum HSV antibody index of >2 (10) or an antibody titer in CSF that exceeds 6% of the titer in serum strongly suggests intrathecal production of HSV-specific antibody and recent central nervous system infection. Tests for HSV antibody may also be helpful in the diagnosis of HSV infection in immunosuppressed patients

doi:10.1128/9781555818722.ch58

with prolonged fever of unknown etiology and infants with undiagnosed congenital disease.

Procedures for the determination of type-specific antibody to HSV are most useful in epidemiologic, clinicopathologic, and natural history studies (1, 2, 6, 11, 12). Serologic confirmation of HSV-2 infection may alert physicians to the need for prophylactic treatment of severely immunosuppressed patients and guide physicians in their discussions of acyclovir therapy, the risk of recurrence, and ways to decrease the risk of HSV transmission with contacts. An accurate diagnosis for persons with mild or unrecognized clinical manifestations also aids in infection control and in issues associated with pregnancy (5, 13). The prenatal detection of specific HSV antibodies indicates which women may be at risk of transmitting HSV-1 or HSV-2 to their infants at delivery, although the presence of IgG antibody does not inform when active HSV shedding occurs in the genital tract. Conversely, a negative result indicates that a woman may be at risk of acquiring HSV-1 or HSV-2 during pregnancy, particularly if her partner is positive (5, 13). Finally, HSV-1 and HSV-2 PCR testing should be considered part of the rule-out diagnosis for suspected cases of bioterrorism-related smallpox (14, 15).

SPECIMEN COLLECTION

Clinical specimens for HSV-1 or HSV-2 culture can be obtained by swabbing skin lesions that have been unroofed. Polyester swabs with synthetic applicator sticks should be used, as cotton swabs with wooden sticks may complicate nucleic acid extraction and PCR testing. Culture may also be successfully performed with specimens of aspirated vesicular fluid or CSF. Direct detection methods require swabbing the base of unroofed lesions to ensure that infected epithelial cells are collected. In patients with disseminated HSV, peripheral blood mononuclear cells may be useful as specimens for either culture or PCR. For PCR or electron microscopy (EM) detection, scabs from crusted-over lesions are excellent specimens, but they are not useful for virus culture or direct detection methods. Specimens for PCR may be stored under dry conditions for extended periods at ambient temperature without substantial loss in specimen quality. In contrast, swabs collected for direct detection methods should be immersed in a small volume of isotonic transport medium and, ideally, tested within 24 h of collection. Virus isolation in cell culture is far more likely to succeed if specimens are inoculated immediately after collection.

VIRUS ISOLATION

Collected specimens are quite labile and must be transported to the laboratory and processed without delay. It is advisable to use several different HSV-susceptible cell lines, such as HEp-2, Vero-E6, and RD, to maximize the chance for successful culture. Inoculated cells should be checked daily for 7 days (incubated at 37°C, 5% CO_2) for the appearance of cytopathic effect. Positive wells should be used to reinoculate conventional tissue culture for additional conformational testing.

ELECTRON MICROSCOPY

EM is not commonly used as a method for diagnosing HSV infection, since individual species of the herpesvirus family are indistinguishable on the basis of virion morphology. It is chiefly used today by specialized pathology laboratories as an initial screening tool to narrow probable etiology. Suitable specimens for EM include dried smears of material from lesions (which can be resolubilized and placed on a copper grid), vesicular fluid, and scabs that have been ground in water. The chief limitations of this method are its relative insensitivity (the sensitivity is low compared with those of methods other than virus isolation) and the nonspecific result produced. EM is capable of identifying an agent as a member of the herpesvirus family on the basis of its distinctive morphology, but individual species cannot be discriminated on the basis of morphology. The method can be rendered specific by using type-specific monoclonal antibodies coupled to electron-dense particles.

PCR METHODS

Serological methods are not useful for detecting current HSV infection or viral shedding, and culture is relatively insensitive even when performed under optimal conditions. HSV-specific PCR has now been clearly established as the method of choice for the direct detection of active HSV infection (1, 16), whether due to primary infection, reactivation, or reinfection. HSV PCR of CSF has also largely supplanted brain biopsy as the method of choice for diagnosing herpes encephalitis (17), although as previously mentioned, HSV PCR-negative results can often be resolved by measuring HSV-specific intrathecal antibody synthesis. A variety of different methods have been described, including single-agent methods (17, 18), multiplex methods (16, 19), and real-time PCR (7). In studies directly contrasting the performance of PCR with that of culture, direct fluorescent-antibody assay, and other techniques, PCR is invariably more sensitive and at least comparably specific. The most frequently used target genes for type-specific PCR are the glycoprotein D (gD) and gB genes, although reported methods have also targeted the thymidine kinase, gG, UL42, DNA polymerase, and ICP27 genes. The highly conserved DNA polymerase gene has been used most frequently for consensus PCR methods that amplify all recognized human herpesviruses. As commercial PCR formats for clinical diagnosis have become more widely available, the use of PCR in clinical settings for routine diagnosis has become increasingly common. It is the most sensitive and specific method available for the detection of HSV in a wide variety of specimens. Since atypical HSV-1 and HSV-2 disease was, as with varicella, historically misdiagnosed as smallpox prior to eradication, HSV PCR is also recommended as part of a testing panel to exclude smallpox used as a bioterrorist weapon. It must also be kept in mind, however, that not all PCR methods are created equal. Direct comparisons of various formats have sometimes revealed substantial differences in the performance standards. In addition, care should be taken to ensure that substances potentially inhibitory to PCRs are eliminated during DNA purification.

DIRECT DETECTION METHODS

Tzanck (Giemsa) Smear

The Tzanck smear technique is not in common use currently, having been replaced by more sensitive and specific type-specific HSV PCR protocols. Smears of material from mucocutaneous lesions can be dried on glass microscopic slides, stained with Giemsa reagent, and examined for the presence of cellular anomalies (syncytia, cytoplasmic ballooning, intranuclear inclusions). These anomalies are observed in all alphaherpesvirus infections and as such do not provide a specific diagnosis.

Direct Fluorescent-Antibody Assay

For the DFA, the same type of clinical specimen as for the Tzanck smear is used, except that the test sample is suspended in transport medium. Cellular matter is then pelleted by centrifugation, and the pellet is washed and resuspended in a small volume. The cell suspension is spotted onto glass slides, thoroughly air dried, fixed in ice-cold isopropyl alcohol, and stained with fluorescent antibodies specific for HSV-1 or HSV-2. If monoclonal antibody reagents are used in the protocol, it is preferable to use more than one type-specific antibody for each agent, since an individual epitope may be missing due to mutations in some circulating strains. Variations of this method include the use of shell vial monolayers that are first inoculated with specimen and then examined with HSV-specific fluorescent-antibody reagents.

There is also a commercially available enzyme-linked virus-inducible system that takes advantage of a genetically engineered reporter cell line. The cell line includes a hybrid gene that is induced by the HSV UL39 gene product to express bacterial galactosidase. Cells infected with HSV undergo a colorimetric change with the addition of the substrate. Type specificity is determined by use of fluorescent antibodies. As with conventional DFA, this method is considerably less sensitive than HSV-specific PCR.

SERODIAGNOSTIC TESTS

Enzyme immunoassays (EIA), immunoblotting, the indirect fluorescence assay, and the neutralization assay have had the widest application for serodiagnosis and serosurveys. Radioimmunoassays (3) are rarely used because current EIA and immunoblotting procedures fulfill the same purpose and avoid the problem of using and disposing of radioisotopes.

Type-Specific Antibody Tests

The extensive cross-reactivity between HSV-1 and HSV-2 prevents accurate delineation of type-specific antibody with standard antigen preparations (1, 3, 4, 20). Early efforts to devise type-specific serologic assays met with limited success, and none of these formats is currently regarded as reliable. The discovery of a type-specific protein, gG, and the crafting of assays using gG1 and gG2 have largely resolved the problem of discriminating antibodies to HSV-1 and HSV-2 (20, 21). This approach concomitantly solved the problem of cross-reactivity to the other human alphaherpesvirus, varicella-zoster virus (VZV), since no gG protein is encoded in the VZV genome. A variety of protocols based on the use of gG have been developed over the years, including Western blotting (22, 23), monoclonal antibody blocking EIA (24), indirect IgG enzyme-linked immunosorbent assay (ELISA) (25), and capture ELISA (26). A number of comparisons of the performances of commercial type-specific EIA have been conducted, and several excellent commercial gG type-specific assays are now available. There are still some marketed methods that rely on techniques like antigen cross-absorption, but these methods do not reliably discriminate HSV-1 and HSV-2 antibody (27). Excellent reviews of the history of the development of type-specific and gG-based assays have been published by Bergström and Trybala (20) and Ashley (28). gC of HSV-1 was initially believed to be type specific but was later found to have epitopes that cross-react with HSV-2 antibodies (3, 23). Subsequently, gG1 and gG2 were discovered and shown to be type-specific targets for the human immune response by an immunodot EIA (24), immunoblot assays (1, 3, 12), and EIA (5, 25). The availability of these type-specific recombinant or purified proteins from commercial sources (29–31) has now made possible large-scale testing of human sera in a variety of type-specific formats. HSV-2-specific monoclonal antibodies have also been used to directly bind gG2 to microtitration plates and detect HSV-2 antibodies by EIA (6). Although the immune response to gGl and gG2 is not immunodominant, sufficient antibodies to these proteins are made within a month postinfection (29) that gG assays can usually determine the HSV-1/-2 infection history of a patient.

Immunoblotting

The immune response to HSV can be finely dissected by the immunoblot assay as developed by Ashley and colleagues (3, 29). Briefly, the proteins of HSV-1 and HSV-2 recovered from lysed infected cells are separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), transferred to a nitrocellulose substrate, and reacted with human sera. Bound antibody is detected with a peroxidase-conjugated anti-human IgG and a substrate with an insoluble colored product. In each test, one HSV-2 nitrocellulose strip is incubated with a monoclonal antibody that identifies the 92-kDa band of gG2 as a positive control. Sera with predominant reactivity on the HSV-1 strip and no reaction with the gG2 band on the HSV-2 strip have only HSV-1 antibodies. Sera with predominant reactivity on the HSV-2 strip, including the gG2 band, have HSV-2 antibodies. Sera with both profiles reveal an infection history by both viruses. Sera with atypical or equivocal results, without a clear 92-kDa gG2 band on the HSV-2 strip, are adsorbed separately with HSV-1 and HSV-2 antigens, and each aliquot is retested with both HSV strips. The immunoblot assay described by Ashley (28) is a highly sensitive and specific assay for HSV type-specific antibodies. Control sera with known reactivity for HSV-1 and HSV-2 are required. Since immunoblot assays include multiple HSV proteins that detect a range of both type-specific and type-common antibodies, they remain the standard by which other type-specific assays are evaluated (20, 21).

A modification of this approach using baculovirus-expressed gG1 and gG2 has also been described (25). Abundant quantities of HSV gG1 and gG2 have been produced in insect cells by use of a baculovirus expression system (12, 32). Insect cells infected with recombinant baculovirus expressing gG1 or gG2 are harvested and disrupted under conditions that release the proteins. The partially purified proteins are separated by SDS-PAGE, transferred to nitrocellulose, and incubated with test and control sera. This method has been extensively compared with other HSV antigen-specific methods and has high specificity and sensitivity (12, 32).

Immunodot EIA

Lee et al. (11) purified gG1 and gG2 antigens with immunoaffinity columns prepared with HSV type-specific murine monoclonal antibodies for an immunodot EIA performed on nitrocellulose disks in 96-well microtitration plates that required very little antigen. The assays are developed using an enzyme immunoaffinity colorimetric reaction. This is a high-throughput technique that has been instrumental in determining population-based seroprevalence rates for HSV-2 in the United States (2).

Commercially Available Type-Specific Assays

A number of commercially available gG2-based EIA have been evaluated against serum samples from persons with culture-confirmed HSV-1 and/or HSV-2 infection (8, 27, 30) or by using gG-based Western blotting as a gold standard (33, 34). With some variation, nearly all of these methods

performed with acceptably high specificity and sensitivity compared with those of the gold standards of HSV culture and gG-based Western blotting. Some caution is advised in the interpretation of slightly positive results (possible false-positive results), and such samples should be further evaluated with a confirmatory test. At least two rapid point-of-care tests for the detection of HSV-2 antibody are also commercially available; both have been evaluated against immunoblot assays and were shown to perform with excellent sensitivity (29, 35). The sensitivity and specificity of the tests in comparison with the immunoblot results were in the 90 to 95% range. Timing in the collection of sera is important because it was shown that the median time for the point-of-care kit HSV-2 test and the immunoblot assay to become positive after the onset of symptoms was 13 days, and only 80% of the samples were positive at the end of 4 weeks. Almost all of these methods that use HSV gG have shown good agreement when evaluated with specimens from cross-sectional studies (21). A study in which samples were collected serially over a 2-year period from Thai military recruits found that the serologic status of some individuals determined by gG assays changed from positive to negative over time (12). The inaccuracy was found in four separate assays, and the variation was not confined to the same specimens with each assay. In some cases, the loss of positivity may be associated with weakly positive specimens. It is suggested that testing of cohort specimens from population-based studies in addition to clinical ones should be part of any assay evaluation scheme (12). Commercial gG-based methods have also been developed based on technologies other than standard ELISA, including flow cytometry and lateral-flow, gG peptide-based, and luciferase immunoprecipitation.

Neutralization Assay

Several neutralization methods have been described but have not been adopted for routine clinical use and have been used only sporadically in studies of HSV epidemiology (36–39).

IgG Avidity

Methods for measuring the avidity of the IgG response to HSV-2 have been reported in the literature and, as with neutralization, have not been extensively used to characterize responses on a population level in the literature (40, 41). It has been proposed that the method would serve a useful routine diagnostic role in the assessment of relative risk for neonatal HSV infection (40, 42).

ELISpot Assay

ELISpot methods for detecting gamma interferon (43) and tumor necrosis factor beta (44) have been developed to evaluate the HSV-specific T cell response. While these methods have been used to generate useful information about the T cell response to HSV, they are probably too cumbersome in their current form to be adopted for routine clinical use.

Interpretation

Infection with either type of HSV gives rise to humoral and cell-mediated immune responses that, while capable of neutralizing HSV and destroying virus-infected cells, do not eliminate latent infection or prevent recurrent disease. Humans produce antibody to the structural components of the virus, namely, the envelope, capsid, and internal proteins, as well as soluble virally encoded proteins not included in the virion. A majority of persons are HSV-1 seropositive by 29 years of age (1). Consequently, evidence of antibody against HSV-1 or HSV-2 in a single serum sample by any serologic test, with the exceptions of an IgM-specific antibody assay (25, 45) and the avidity assay described below (46), provides no information about the time of onset of infection or reactivation. Serologic diagnosis of active infection with either virus type depends on demonstration of a significant increase in antibody titer. The two HSV types share many epitopes that give rise to extensively homologous antigens (1, 3, 4), and a major portion of the antibody produced in response to a primary infection is cross-reactive to these shared epitopes. Virus culture or type-specific serologic tests, many of which are now commercially available (29–31), must be performed to determine whether an individual has been infected with HSV-1, HSV-2, or both. Primary infection with either HSV type is documented by testing for seroconversion in paired serum samples (consisting of an acute-phase serum sample collected as close as possible to the onset of illness and a convalescent-phase serum sample collected 10 days to 3 weeks later) by any of the type-specific serologic tests. Evidence for primary infection can also be documented using an IgG avidity assay. An HSV IgG avidity assay was found to distinguish primary HSV infections from nonprimary HSV infections for as long as 100 days after the onset of infection (46). Detection of HSV-specific IgM in the absence of other evidence is proof of recent exposure (primary infection, reactivation, or reexposure) but does not demonstrate a primary infection (45).

The immune response to recurrent infection or reinfection with either HSV type is much more complicated and depends on the number, frequency, and type of previous infections as well as the severity of the subsequent infection. After primary HSV infection, antibody levels may decline and then be boosted by subsequent recurrences or infection with the heterologous type. Patients who experience severe recurrences, particularly those associated with systemic or neurologic symptoms, may have a significant rise in antibody levels. On the other hand, most adults with recurrent localized HSV-1 or HSV-2 lesions show stable, typically high titers (1, 3) in the neutralization test, complement fixation test, and many EIA (45). Initial infection with HSV-2 in persons previously infected with HSV-1 (or vice versa) usually causes a significant rise in the level of antibodies to both the shared HSV antigens and the specific antigens of the infecting type. The only human herpesvirus that shows significant cross-reactivity with HSV-1 and HSV-2 is VZV. Paired serum samples from patients with recent VZV infection who have preexisting HSV antibody may sometimes show a rise in the level of antibodies to HSV-1 and HSV-2 in nonspecific tests (6). A similar rise in the level of antibody to VZV may occur in patients with recent HSV infection who have prior antibody to VZV. This concern has been eliminated with the adoption of type-specific serologic methods that use gG as the antigen source, since VZV does not encode a gG protein.

The findings and conclusions in this report are those of the author and do not necessarily represent the official views of the Centers for Disease Control and Prevention.

Varicella-Zoster Virus

D. SCOTT SCHMID

59

Varicella-zoster virus (VZV) is a readily contagious alphaherpesvirus that commonly causes two distinct exanthematous illnesses. Primary infection with VZV causes varicella, known colloquially as chicken pox, which is characterized by a generalized vesicular rash typically accompanied by fever and other nonspecific symptoms. VZV establishes a lifelong latent infection in the dorsal root ganglia during the first infection, and it can reactivate decades later to cause zoster, also called shingles, a dermatomally distributed and often painful vesicular rash (1, 2). A number of zoster patients present with postherpetic neuralgia, characterized by severe pain that may persist for long periods after the rash has resolved. Some rare complications of zoster include encephalitis, conjunctivitis, keratitis and other eye disorders, Ramsey-Hunt syndrome, neurogenic bladder, and transverse myelitis.

Most varicella cases are mild in nature and resolve without serious sequelae. Varicella may be complicated by bacterial infections, pneumonia, encephalitis, cerebellar ataxia, hepatitis, thrombocytopenia, and nephritis. Studies have shown that patients with recent varicella have a 40-fold greater risk of developing severe group A streptococcal disease. Populations at increased risk for serious VZV disease include immunocompromised adults and children, VZV-seronegative adults, pregnant women, and newborn infants (2). Prior to the introduction of the varicella vaccine, complications of varicella infections resulted in approximately 100 deaths and 10,000 hospitalizations each year in the United States (1–3).

A live, attenuated varicella vaccine was approved for use in the United States in 1995 and is recommended for routine immunization of children and for susceptible adolescents and adults (4). National coverage for the vaccine in the United States is now greater than 90% for children, and a proportionate reduction in varicella incidence has been observed, with evidence of herd immunity (5, 6). A mild rash can occasionally occur in the first 2 to 6 weeks after vaccination, and breakthrough infections by wild-type VZV strains sometimes occur in vaccinated patients, usually causing less severe disease than a typical primary infection. The vaccine virus establishes latency and can reactivate to cause herpes zoster, albeit less frequently than the wild-type virus. The observation of varicella outbreaks among children in highly vaccinated populations (7–10) led to the recommendation of a second dose of varicella vaccine for children, to be administered at 4 to 6 years of age (4). A more potent preparation of Oka vaccine (zoster vaccine) was shown in a large clinical trial to reduce the risk of herpes zoster by 50% and that of severe zoster and postherpetic neuralgia by more than 60% (3). The zoster vaccine was recommended for routine immunization of adults of ≥60 years of age in 2008 (11).

When varicella was commonplace in the United States, laboratory testing to verify varicella or zoster was generally unnecessary, since both varicella and zoster could readily be diagnosed by a clinician. The dramatically reduced incidence of varicella, together with the increasingly common occurrence of modified disease and zoster among vaccinated persons, has made laboratory confirmation of VZV infection and discrimination of the vaccine strain from the wild-type virus increasingly important. Serology has limited usefulness for the confirmation of acute infection, and among various direct virus detection methods, VZV PCR has emerged as the most reliable method for confirming VZV infection. VZV PCR methods designed to both detect the virus and distinguish the vaccine strain (Oka) from wild-type viruses in vaccinated persons have been developed but are currently available only in a few government, academic, and corporate laboratories. Screening of persons at high risk of varicella for susceptibility is important and can be accomplished using most available serologic methods, even those that are insufficiently sensitive to consistently detect vaccine seroconversion. This is particularly true for adults (e.g., for health care workers), in whom varicella tends to be more severe than it is in children. Persons who have been immunized with varicella vaccine are presumed to be protected; documentation of vaccine seroconversion is not recommended, since most methods are unable to reliably detect it. In many cases of VZV neurologic disease, VZV DNA is undetectable in the cerebrospinal fluid. In those instances, detection of synthesis of intrathecal immunoglobulin can be used to confirm the etiology. Routine varicella immunization has led to a >90% reduction of the incidence of varicella, and young physicians are less likely to encounter cases of varicella; this is further complicated by the increased likelihood of encountering disease that does not meet the conventional case definition for varicella. Consequently, effective monitoring of the changing epidemiology of this virus will depend critically on reliable diagnostic testing. Furthermore, laboratory services are essential for the identification of

doi:10.1128/9781555818722.ch59

susceptible health care workers or other individuals at high risk for exposure to varicella or zoster. Varicella vaccine is recommended for all susceptible adults; those at elevated risk for VZV exposure should receive special consideration for vaccination (4, 12).

In the aftermath of several instances of deliberate release of anthrax as a bioterrorism agent, there was heightened concern about a deliberate release of smallpox. Since varicella was the disease most commonly mistaken for smallpox during the eradication program, a recommendation was made that VZV PCR testing should be performed as part of the rule-out diagnosis for suspected cases of bioterrorism-related smallpox (13, 14).

GENETIC STABILITY OF VZV

A variety of techniques, including complete genomic sequencing, have revealed that the VZV genome is highly conserved. Only about 0.1% of the nucleotides vary among individual strains of VZV, and the sequence diversity is distributed randomly throughout the genome. Thus far, nine distinct circulating VZV clades have been identified from clinical VZV isolates around the globe, three of which are provisional pending more complete genetic information (15–17; my unpublished observation). Notably, VZV clades have been shown in several publications to have distinctive geographic distributions, perhaps driven by a combination of climate and immigration patterns (18–20). Clades 1 and 3 dominate in North America, Europe, and Australia, with smaller numbers of clade 4 viruses in the same regions; clade 2 dominates in Asia; and clade 5 dominates in Africa. The attenuated vaccine strain (Oka) is derived from a Japanese clade 2 strain that has only 42 base-pair differences from the parental strain. Vaccine preparations are now known to contain a mixture of strains, and only four of the vaccine markers—all of which are located in open reading frame 62 (ORF62)—are relatively fixed in all vaccine strains (21). The mutations responsible for vaccine attenuation have not yet been determined, however. Limited as it is, the genetic variability can affect the performance of serological assays, particularly those involving the use of VZV-specific monoclonal antibodies (MAbs).

METHODS

Specimen Collection

Laboratory diagnosis of VZV infection requires the identification of the virus or one of its products in skin lesions, tissues, or fluids from the patient. In the absence of suitable specimens for direct detection, VZV infection can be confirmed with serum or plasma by evidence of seroconversion or by a fourfold or greater increase in IgG titer between acute- and convalescent-phase sera. Primary VZV infection in an unvaccinated person can also be confirmed by detection of low-avidity VZV IgG in a single serum sample, which is dependent on the production of sufficient levels of VZV IgG by the patient. Direct detection techniques are preferable and include isolation of the virus in tissue culture, direct immunofluorescence staining of cells obtained from lesions, and detection of the virus genome by techniques based on PCR. Among these techniques, PCR-based detection methods are easily the most sensitive. Suitable clinical samples for VZV testing include smears or swabs of vesicular fluid, skin scrapings, crusts, cerebrospinal fluid, and various tissues obtained by biopsy or at autopsy. Vesicular lesions may be sampled by unroofing a vesicle with a sterile needle and then vigorously swabbing the base of the lesion with a sterile swab, applying enough pressure to collect epithelial cells without causing bleeding. Collection of infected epithelial cells from the base of the lesion is important because the majority of VZV virions are cell associated. It is best to use swabs made from synthetic materials, as it may be difficult to elute virus from cotton swabs, porous wooden sticks may absorb the extraction buffer, and substances in wood may inhibit PCR. To avoid contamination, each swab must be placed directly into a separate tube and labeled. Vesicular fluid can also be collected onto a glass slide and air dried (again, taking care that specimens are placed in separate containers to avoid contamination). For virus isolation, vesicular fluid may be collected in sealed capillary tubes; however, VZV is extremely sensitive to heat and desiccation, making isolation difficult under the best of circumstances. Ideally, vesicular fluid should be inoculated into cell culture immediately upon harvesting. Samples may be frozen at −80°C for several days prior to culture, but this procedure results in a significant loss of infectivity. Crusts are also outstanding specimens for PCR detection of VZV DNA; they may be collected in sterile tubes or plastic bags. Refrigeration is preferred for smears to be examined for viral antigen, but air-dried specimens for PCR can be kept at ambient temperature indefinitely.

Virus Isolation

VZV can be isolated from vesicular fluids of patients with zoster or varicella following the onset of rash as long as new vesicles erupt, but culture of VZV from respiratory secretions or biopsy specimens is rarely successful. Crusts do not contain infectious virus. Various tissue cell lines can be used to culture VZV from vesicular fluid, including human fetal diploid lung or kidney cells, human embryonic lung fibroblasts (MRCS or WI38), human melanoma (MeWo) cells, and human lung fibroblasts. Primary embryonic guinea pig cells will support VZV propagation but are generally less productive than human cells. Sufficient cell culture medium must be used to maintain the culture for 10 to 14 days without change. Several studies have shown that even under optimal conditions, virus isolation is significantly less sensitive than direct immunodetection or PCR for the detection of VZV. VZV produces a distinctive specific cytopathic effect (CPE) in cell monolayers. In human lung fibroblasts, the CPE is characterized by discrete football-shaped foci of different sizes and consists of rounded and swollen cells. The CPE most often appears between 4 and 7 days into culture but may manifest as early as day 3 or as late as day 14 after inoculation. If VZV-specific CPE has not appeared after a week to 14 days, it may be useful to passage the inoculated cultures. CPE may develop even if the amount of vesicular fluid in the capillary tube is barely discernible to the naked eye, if the specimens are obtained within the first 2 days of rash. Confirmation of VZV-specific CPE may be obtained, if necessary, by staining with a fluorescein-labeled specific antibody.

Preliminary identification of VZV can be made on the basis of the characteristic CPE, which is usually more focalized and progresses significantly more slowly than the CPE from herpes simplex virus (HSV). However, the definitive identification of VZV requires additional testing with immunological assays or PCR. Specific identification of a VZV isolate can be made by demonstrating its ability to interact with reference sera from patients who have had a clinically diagnosed case of varicella or with a VZV-specific MAb. Human sera used for identification of VZV should be free of antibodies against other human herpesviruses that may

cross-react with VZV proteins due to structural homology (e.g., HSV-1 and HSV-2). VZV-specific MAbs are commercially available and are the preferred reagents, since they significantly increase the sensitivity and specificity of detection compared with those for human serum or polyclonal serum produced in animals. Specific VZV identification can be accomplished by direct or indirect immunofluorescence staining of infected cells. Due in part to the fragility of VZV, viral culture is substantially less sensitive than PCR. In one study, only 44% of samples from PCR-confirmed cases were successfully cultured (22).

Direct Examination of Material from Skin Lesions

Scrapings of vesicular lesions obtained with a scalpel blade or the beveled edge of a microscope slide can be examined for giant cells or intranuclear inclusions by staining with Giemsa reagent (Tzanck smear). Staining for examination for inclusions must be performed properly, using specific methods for this purpose, or specimens may yield false-negative results. It should be recognized that the presence of intranuclear inclusions or multinucleated giant cells is not specific for VZV; similar changes are seen with HSV. Thus, the method is limited to identifying the presence of an alphaherpesvirus. The method is also not as sensitive as PCR (22). Direct fluorescent-antibody staining appears to have good sensitivity and specificity, although its performance is also substantially inferior to that of PCR (23). Staining of the scrapings with conjugated anti-VZV MAbs can enable specific identification. A number of MAbs are available for this purpose, although more than one MAb reagent should be used, since false-negative results have been obtained due to VZV strains lacking the specific target epitope. Specimens must be collected with care; scraping of unroofed lesions must be sufficiently vigorous to ensure the collection of infected cells, but the specimen should contain as little blood as possible, since this can produce false-negative results. Crusts cannot be used for direct detection methods.

Electron Microscopy

Vesicular fluids, crusts that have been ground in water, or skin lesion sections can be examined by electron microscopy (EM). Good results can be obtained with air-dried smears of fluids prepared on glass microscope slides, which can be resolubilized and transferred to a grid. This method is useful only for the identification of herpesviruses as a family; it does not facilitate the identification of VZV. The finding of a virus with a morphology characteristic of herpesviruses identifies the etiological agent as a member of the *Herpesviridae* and serves to distinguish it from orthopoxviruses and other agents. Specificity can be accomplished through the use of a specific antibody conjugated to an electron-dense material, such as colloidal gold. EM is somewhat insensitive, as it is capable of reliably detecting virions only at relatively high concentrations. It has been estimated that more than a quarter of direct-fluorescent-antibody-positive specimens may give negative results by EM. EM was also shown to be considerably less sensitive than PCR in a head-to-head comparison (24). The availability of PCR methods with superior performance and no requirement for costly equipment has greatly reduced reliance on EM as a diagnostic tool for this purpose. EM is now employed most frequently as a preliminary screening tool for case patients with diseases of unknown etiology.

PCR

PCR is the most accurate and sensitive method for VZV detection and differentiation. In addition, virus isolation and culture are time-consuming, and viral DNA is much more stable than infectious virus. Accordingly, quite apart from its superior performance specifications, PCR is the much preferred method for confirming the presence of VZV in a specimen. PCR is particularly useful for confirming mild VZV disease in vaccine recipients or patients in the late stages of varicella, when crusted lesions contain no viable virus. Amplification and analysis of targeted VZV DNA regions form the method of choice for discriminating vaccine from wild-type VZV isolates. For routine laboratory diagnostic purposes, the best materials to use are vesicular fluids or swab samples collected with capillaries or swabs, scrapings dried onto glass slides, or crusts from lesions. For disseminated disease, VZV DNA can be detected in various tissues, including the lungs, liver, kidneys, skin and adrenal glands, trigeminal ganglia, and dorsal root ganglia. The viral genome can also sometimes be detected in peripheral mononuclear cells, cerebrospinal fluids, bronchoalveolar lavage fluids, breast milk, oropharyngeal swabs, throat swabs, peripheral blood mononuclear cells, and nasal secretions. In some specific situations, VZV DNA can be found in other tissues, such as the synovial fluid of patients with arthritis; intraocular fluids, corneal scrapings, and tear films of patients with retinal necrosis; temporal bone sections from patients who had herpes zoster oticus; and amniotic fluid, fetal tissues, and the placenta during neonatal varicella. There has also been some success at detecting VZV DNA in environmental samples, which is a potentially useful tool for evaluating outbreaks whose index case has already resolved (25, 26). The VZV PCR protocols available commercially or through testing laboratories are generally designed for DNA detection only, but several laboratories have designed PCR strategies for both VZV DNA detection and vaccine and wild-type strain discrimination. These include methods that rely on restriction fragment length polymorphism (27), real-time fluorescence resonance energy transfer (28), and TaqMan real-time PCR (26, 29, 30). All of these methods share a strategy for detecting one or more single nucleotide polymorphisms that are (i) unique to the Oka vaccine or (ii) unique to the clade 2 subvariant from which the Oka vaccine was derived. Reliance on single nucleotide polymorphisms in the latter category is no longer sufficient by itself, since wild-type clade 2 viruses with the parental Oka profile have now been isolated in the United States (31). Currently available commercial VZV PCR methods perform with excellent sensitivity and specificity if only the detection of VZV DNA is desired.

Serologic Testing

Serologic testing is useful primarily for determining susceptibility to VZV in outbreak settings or as a screening tool for persons at high risk of exposure or severe disease. As a diagnostic tool, in cases where suitable specimens for direct detection by PCR are unavailable, IgG testing of acute- and convalescent-phase sera can be used to confirm seroconversion to VZV or to provide evidence for suspected breakthrough infection. Acute-phase serum should be obtained as soon as possible after the onset of illness, and the convalescent-phase serum should be obtained 4 to 6 weeks after onset. A variety of methods are available to determine whether there are significant rises in the level of VZV-specific serum immunoglobulin; however, all must be performed in an endpoint dilution format. Assay formats used for simple determination of VZV serostatus include enzyme-linked immunosorbent assay (ELISA), assay of fluorescent antibody to membrane antigen (FAMA assay), latex bead agglutination assay, and lateral flow assay. Each of these test formats has limitations, which are discussed in greater detail

below. Measurements of IgM antibody in individuals with known recent exposure to VZV are inconsistent, and the detection of IgM may reflect primary infection, reinfection, or reactivation. IgM testing cannot be used to confirm a primary infection.

Commercial Serologic Tests

A number of commercial products for the detection of VZV antibodies have been marketed in recent years. These include ELISA, latex bead agglutination, and flowthrough membrane-based enzyme immunoassay (EIA) methods. Serum, plasma, or in some instances whole blood can be tested. In general, these assays are designed to detect IgG antibodies. A number of these methods have been compared against various gold standard methods and can vary considerably in their performance specifications (32–34; unpublished data). None of them is as reliable as either glycoprotein-based ELISA (gpELISA) or FAMA tests, particularly for detecting seroconversion in VZV-vaccinated persons. One study revealed that the latex bead agglutination test can be prone to false-positive results (35). Most commercial methods are sufficiently reliable to identify unvaccinated health care workers and other persons at high risk for exposure to VZV. As with HSV, the use of VZV serologic methods to detect VZV-specific intrathecal antibody synthesis can be used to confirm the etiology of neurological illness, for which viral DNA is detectable in only about a third of cases (36–38).

FAMA Assay

The FAMA assay is one of the most sensitive assays for the detection of VZV antibodies when it is performed in an experienced laboratory. It has been recognized for some time as one of several tests sufficiently sensitive and specific to reliably detect VZV antibodies in vaccinated individuals. In part, the enhanced sensitivity of this assay may be attributable to the preservation of the natural three-dimensional configuration of VZV glycoproteins expressed on the surfaces of infected cells. Chemical fixation of infected cells inevitably results in modifications of surface antigen structures, and this generally leads to a decrease in assay sensitivity. The FAMA assay can be used in various formats to detect any of the major classes of specific immunoglobulin. While this method can be quite powerful, accurate interpretation of results is somewhat subjective, and extensive experience is needed to perform the method reliably. An adaptation of the FAMA assay to an objective flow cytometric readout resulted in a slightly diminished sensitivity and specificity of the method (39). The FAMA assay is not available commercially.

gpELISA

Merck and Company developed a highly sensitive and specific ELISA method predicated on the use of a purified, concentrated solution of VZV glycoproteins. It is another method that, like the FAMA assay, reliably detects seroconversion in response to VZV vaccination, and it was used for the large efficacy trial of the Varivax Oka vaccine. The method is not currently available commercially and has been performed routinely only by a few laboratories that have obtained supplies of the purified glycoproteins from Merck and Company through material transfer agreements. Direct comparison between the FAMA assay and gpELISA reveals that they have comparable levels of performance, and the ELISA method has the advantage of being easily performed (my unpublished data). A commercially available purified VZV glycoprotein preparation (Virusys Corporation, Tarrytown, MD) was recently shown to perform indistinguishably from the Merck antigens, provided that a custom-ordered normal tissue control antigen is used to subtract background reactivity (my unpublished observation). Hopefully this development will lead to a commercially available VZV gpELISA in the near future.

TRFIA

A time-resolved fluorescence immunoassay (TRFIA) was developed in England and was shown in a pilot study to have performance specifications comparable to those of gpELISA (32). A subsequent study provided additional support for the performance specifications of the method (33). The method has the advantage of performing comparably to gpELISA without relying on highly purified and concentrated glycoprotein antigen preparations. Rather, crude lysate from VZV-infected cells is used as an antigen source. One drawback is that it requires the use of a fluorometric reader, which may be too costly compared with conventional spectrophotometers. As with gpELISA and the FAMA assay, TRFIA is not currently commercially available and has not been reviewed or approved by the FDA.

NT Tests

The presence of neutralizing antibodies in serum can be detected by using a neutralization (NT) assay based on reductions of plaque formation by titrated VZV preparations pretreated with serum (40). VZV is aggressively cell associated in tissue culture, making the production of cell-free virus preparations with reliable titers problematic. The Oka vaccine is relatively cell-free and can be used as a virus reagent for these protocols, although it is important to determine an accurate titer before use. NT assays for VZV will likely prove helpful for evaluating the duration of protective immunity among vaccine recipients. They may also be useful for identifying the primary neutralization targets for VZV. There are no clear recommendations or standardized data for the evaluation of neutralizing antibody for VZV. A high-throughput NT method using a semiautomated protocol is in development at the CDC and is currently being validated.

Antibody Avidity

Evaluations of antibody avidity are straightforward to perform and can provide useful insights into the relative maturity of immunoglobulin responses to VZV (41). As such, they provide the only reliable laboratory test for primary VZV infection, other than measuring seroconversion in acute- and convalescent-phase sera. A recent study indicated that 14% of adult health care workers who received a two-dose regimen of varicella vaccine were still producing low-avidity IgG, and half of the recipients with no detectable IgG seroconverted upon receiving a third dose, with the production of low-avidity antibody (41). This suggests that a substantial fraction of adults may either respond to varicella vaccine with suboptimal T cell engagement or fail to establish B cell memory. Determination of antibody avidity is based on the separation of low- and high-avidity antibodies by using chemicals that disrupt hydrogen bonding in immunoassays (EIA) or immunofluorescence assays. Chemicals used for this purpose include guanidine hydrochloride, diethylamine, isothiocyanate, and urea. Calculations of the avidity results have been approached in several ways historically. Most commonly, avidity is expressed as the percent ratio of antibody titers or EIA absorbance values, with and without dissociation. Avidity results based on endpoint titration, with and without denaturant, are considered to be the "gold standard" for avidity determination. An IgG

avidity method has been developed at the CDC and is now being validated for inclusion under the Clinical Laboratory Improvement Amendments (CLIA).

INTERPRETATION

PCR-based methods are more sensitive and informative than the other methods, since they are agent specific and also can be designed to discriminate the vaccine strain from wild-type isolates. Moreover, real-time single-tube methods and more rapid DNA extraction have greatly reduced the turnaround time required to obtain a result. Serologic testing is not a preferred method for confirming an acute infection, as paired acute- and convalescent-phase sera are required and greatly delay test results. In addition, significant rises in titer between acute-phase and convalescent-phase sera are not always observed. For determination of susceptibility, a properly standardized and specific method is essential. Serologic assay specificity trumps sensitivity as a consideration if the goal is to determine susceptibility to varicella in persons at high risk of VZV exposure. Passively acquired antibody may also yield false-positive test results, and immunocompromised patients may have lower levels of antibody that may be difficult to detect in some immune patients if the test used is too insensitive.

OTHER CONSIDERATIONS

Serologic Testing

There have been several reports of inappropriate management of patients due to false-positive reactions (35, 42). While this is the greatest concern in settings where susceptible adults are at high risk of VZV exposure, it is also clear that the majority of VZV serologic assays currently available fail to consistently detect seroconversion in response to vaccination. In some public health organizations, this has led to unnecessary multiple vaccinations of the same individual. The use of serology to confirm seroconversion in response to vaccination is not recommended; rather, persons who have received the recommended two-dose regimen are presumed to be immune. Suitable normal tissue control antigens in an ELISA are essential to reduce the risk of false-positive test results, although such controls are generally not included in commercially available assays. New methods are commonly validated by comparing their performances with that of an established method that is itself inevitably inaccurate, since no method is perfect. Ideally, a set of well-defined samples (e.g., pre- and postvaccination sera from toddlers) should be evaluated by receiver operating characteristic analysis rather than being compared to another method, however well the "gold standard" assay is thought to perform. Samples for VZV test validation that are seronegative with a high degree of confidence are difficult to obtain. Sera from seronegative susceptible individuals with no reported history of varicella can be used to standardize an assay, although vaccine recipients increasingly fail to develop detectable antibody titers as determined by some methods and might inadvertently be selected. The establishment of optimal cutoff values for seropositivity will ideally employ a combination of evaluation criteria (e.g., receiver operating characteristic analysis of sensitivity and specificity, reproducibility with the same operator, and reproducibility between operators). VZV IgM test results are difficult to interpret. IgM antibody capture assays are preferred because they avoid the obfuscating effect of rheumatoid factor and are the most effective means for eliminating all of the IgG in serum specimens. IgM kits that rely on absorbents to remove IgG are commercially available, but they may not succeed in removing all of the IgG from a specimen. In addition, extensive studies of sera from persons with documented recent exposures to VZV indicate that VZV IgM antibodies are inconsistently detectable even in persons with PCR-documented infections. Finally, since naïve B lymphocytes are constantly replenished, IgM is inevitably produced on every exposure to antigen. As such, IgM assays are not able to establish primary infection and cannot distinguish infection from VZV reinfection or reactivation.

The findings and conclusions in this chapter are those of the author and do not necessarily represent the official views of the Centers for Disease Control and Prevention. The use of product names in this chapter does not imply their endorsement by the U.S. Department of Health and Human Services.

Epstein-Barr Virus and Cytomegalovirus

HENRY H. BALFOUR, JR., KRISTIN A. HOGQUIST, AND
PRIYA S. VERGHESE

60

Epstein-Barr virus (EBV; also known as human herpesvirus 4 [HHV-4]) and cytomegalovirus (CMV; also known as HHV-5) logically belong in the same chapter. Both of these human herpesviruses are major pathogens for the immunocompromised host, and both are capable of causing disease during primary infection, reactivation, or superinfection. They, along with BK polyomavirus, are the feared viral triumvirate that complicates hematopoietic cell transplantation (HCT) or solid organ transplantation. This chapter emphasizes recognition of EBV and CMV diseases and focuses on the clinical relevance of laboratory findings.

EBV

Background and Biology

EBV was discovered in 1964 by Epstein et al., who visualized it by electron microscopy of suspension cultures of African Burkitt's lymphoma cells (1). Four years later, EBV was conclusively linked to infectious mononucleosis, which is its most common clinical manifestation (2).

EBV, whose systematic name is HHV-4, is one of the eight human herpesviruses recognized to date. The EBV virion has a double-stranded linear DNA genome of approximately 170 kb surrounded by a protein capsid. Mature virions vary in size from 120 to 180 nm in diameter. A protein tegument lies between the capsid and the lipid envelope, which carries embedded glycoproteins that are important for cell tropism, host range, and receptor recognition. The EBV genome of about 85 genes has been described in detail (3).

EBV is classified as type 1 or type 2 (also referred to as type A or type B), based on sequence variation in the EBV nuclear antigen (EBNA) genes EBNA-2, -3A, -3B, and -3C (4). The pathogenic potentials of the two types are not clearly differentiated. EBV type 1 predominates in most areas of the globe. Genetic diversity exists at other gene loci, especially in the latent membrane protein 1 gene (5). However, the link between strain variation, disease, and geographic distribution is unclear (6).

EBV invades and maintains itself in the host through interactions between infected B lymphocytes and infected oropharyngeal epithelial cells (7). EBV infects B cells by binding of its viral gp350 protein to CD21 (8, 9). EBV gp42 then interacts with B cell HLA class II molecules and triggers fusion with the host membrane. To infect oral epithelial cells, which lack CD21, the EBV transmembrane glycoprotein BMRF-2 interacts with β1 integrins (10), and the EBV envelope glycoproteins gH/gL trigger fusion by interacting with integrin αvβ6 or αvβ8 (11). Endocytosis of the virus by vesicles and fusion of the virus with the vesicle membrane release the nucleocapsid into the cytoplasm. Once the viral nucleocapsid is dissolved, the genome is transported to the nucleus, where it is replicated by DNA polymerases. Viral DNA polymerase accomplishes linear viral replication, which occurs during the lytic phase of the viral life cycle. There are three temporal classes of viral lytic gene products (immediate early [IE], early [E], and late [L]), as reviewed by Tsurumi et al. (12). BZLF1 and BRLF1 are some of the IE products that further act as transactivators of the viral lytic program. Activation of lytic replication or reactivation from latency is key to transmission. The early products (e.g., BNLF2a) have a wide array of functions, including replication, metabolism, and blockade of antigen processing, while late products tend to be structural proteins, such as the viral capsid antigens and gene products used for immune evasion (e.g., BCRF1). An important consequence of EBV infection in B cells is to activate their growth program and trigger differentiation into memory B cells via the germinal center reaction. Infected memory B cells are released into the peripheral circulation, resulting in detectable levels of virus in the blood. The number of infected B cells decreases over time after the onset of symptoms of primary infection, but these cells are never entirely eliminated.

Latency is the state of persistent viral infection without active viral proliferation. EBV establishes latency in the memory B cell compartment, and possibly also in epithelial cells. It is generally thought that EBV genomes in latently infected B cells exist as episomes (13), although it is possible that they also exist as integrated DNA (14). Memory B cells do not express EBV proteins during latency and hence cannot be recognized by the host's immune system (15).

Reactivation of EBV is thought to occur when B cell receptor stimulation by antigens not related to EBV induces memory B cells to differentiate into plasma cells, which are capable of initiating active viral replication (16). Viral progeny can then infect new B cells and epithelial cells, rendering the host infectious to other persons.

Humans are the only natural hosts for EBV. Primary infection occurs in the oral compartment in adolescents and

doi:10.1128/9781555818722.ch60

young adults, who most often acquire the virus from deep kissing (17). We presume that primary infection in young children is also acquired by the oral route, but this has not been documented conclusively.

Besides oral transmission, EBV has been acquired from blood transfusions (18) or from transplanted hematopoietic cells (19) or solid organs (20), and such infections can be life-threatening, especially among recipients who were EBV naive before transplantation (21). Several reports of intrauterine transmission of EBV have been published, but none has been substantiated by appropriate viral laboratory data.

The overall prevalence of EBV antibody, indicative of past infection, varies widely by geographic location (22–24). Primary EBV infection occurs at a younger age among persons from lower versus higher socioeconomic backgrounds (25) and among non-Hispanic whites versus non-Hispanic blacks or Mexican Americans (26). Acquisition of EBV by young children indicates that it can be transmitted without deep kissing. However, this does not rule out saliva as the source of EBV, because young children commonly share objects that they put in their mouths.

Healthy people continue to shed EBV for many months after their acute infection and are potentially capable of transmitting it (27, 28). Because such virus "donors" are asymptomatic and hence not considered as sources of infection, they often go unrecognized. For the most part, shedding becomes intermittent rather than continuous several months after the primary infection. Hadinoto et al. reported that EBV is shed continuously in the saliva at relatively stable levels over short periods (hours or days), but quantities vary as much as 4 to 5 $\log_{10}$ copies over months or years (7). This suggests that a person's likelihood of transmitting EBV fluctuates over time.

Indications for Laboratory Tests and Their Interpretation

Table 1 outlines recommended tests for the diagnosis and management of various states of EBV infection, which are discussed in some detail below.

Documentation of Past EBV Infection

Documentation of past infection is most commonly done to determine the dose and duration of antiviral prophylaxis after solid organ transplantation or HCT. EBV-naive recipients usually receive a longer course of posttransplant prophylaxis than recipients who have previously experienced an EBV infection. As shown in Table 1, the best single test for documenting a past EBV infection is detection of IgG antibodies against the viral capsid antigen (VCA) of EBV. There are various platforms for this test, with the most widely used being an enzyme immunoassay (EIA). Indirect immunofluorescence assay (IFA) used to be the criterion standard method until assays suitable for high throughput, such as EIAs, were perfected (29). Detecting IgG antibodies against EBNA-1 can distinguish past from subacute infection, because EBNA-1 IgG antibodies generally do not develop until 3 months or longer after primary infection. However, they are not as sensitive as VCA IgG antibodies for documenting a previous EBV infection. Among subjects who experienced primary EBV infections while being monitored prospectively, 82/82 (100%) developed VCA IgG antibodies, whereas 67/74 (91%) subjects became EBNA-1 IgG positive (17; unpublished data). Patterns of EBV-specific antibody responses associated with various stages of infection are shown in Table 2.

Description of Primary EBV Infection and Diagnostic Approaches

Primary EBV infections, especially those in children under the age of 10 years, often go undiagnosed, either because they are entirely asymptomatic or because they do not present as the typical infectious mononucleosis syndrome. A clinical dilemma for making the correct diagnosis in children is that point-of-care laboratory tests, which are essentially all heterophile antibody assays, may be falsely negative (30, 31). Hence, even infections in children suspected of having EBV infection might not be confirmed. Primary EBV infection may not be recognized in adolescents and young adults, either, but 90% of these patients report some symptoms, especially sore throat, if seen shortly after the onset of infection (17), and the infection can be diagnosed with appropriate laboratory tests.

Infectious mononucleosis was named in 1920 by Sprunt and Evans, who used the term to describe a syndrome that resembled an acute infectious disease accompanied by atypical large peripheral blood lymphocytes in the peripheral blood (32). We now understand that these atypical lymphocytes, also called Downey cells, are activated CD8 T lymphocytes that are responding to EBV-infected B cells. Interestingly, EBV, the major cause of infectious mononucleosis, was not identified until 44 years after infectious mononucleosis was recognized as a distinct disease (1).

It is important to emphasize that the diagnosis of infectious mononucleosis cannot be made on clinical grounds alone. The illness most often begins insidiously, with vague malaise followed several days later by fever, sore throat, swollen cervical lymph nodes, and fatigue. Some patients experience an abrupt influenza-like onset, with fever, chills, body aches, and sore throat. Hepatitis, documented by abnormal liver function tests, is seen in 80% of cases and thus should be considered part of the acute disease rather than a complication. Liver involvement is subclinical in 90 to 95% of patients, but the remainder develop jaundice, and a few of them complain of tenderness in the right upper quadrant of the abdomen that is likely due to hepatic swelling with pressure on the liver capsule. Eyelid edema, which gives the patient a slit-eyed appearance and may be accompanied by facial puffiness, is a valuable clinical finding that is unique to primary EBV infection (33). Unfortunately, eyelid edema is present in only 10% of cases (34).

The median duration of infectious mononucleosis is 10 days (17), which is much longer than those of most acute viral illnesses. Recovery is gradual, and it may take months for the patient to feel entirely well (35). Fatigue interferes with productivity and quality of life and is usually the last symptom to resolve.

The severity of primary EBV infection increases with age, and adults older than 40 years of age are especially prone to serious illness (36, 37). They have more prolonged fever and more serious hepatic involvement but less noticeable lymphadenopathy than younger patients.

A flare-up of symptoms before the acute illness ends occurs occasionally (38). However, recurrences or "second cases" of infectious mononucleosis, documented by laboratory evidence of active EBV infection after recovery from the acute illness, are very uncommon. Hoagland reported no recurrences in his series of 200 patients, most of whom were hospitalized during their acute illness, according to military policy (39). We have had just one laboratory-documented recurrence among 132 subjects who acquired infectious mononucleosis between the ages of 16 and 26 years (Balfour, Jr., unpublished data).

TABLE 1 Recommended laboratory tests for diagnosis and management of EBV infections[a]

Indication	Recommended test	Alternative test	Comment(s)
Documentation of past infection	VCA IgG antibody test	EBNA-1 IgG antibody test	A small percentage of patients (~3%) never develop EBNA-1 antibody.
Detection of primary EBV infection (acute)	Heterophile antibody test	VCA IgM antibody test	Heterophile antibody testing may be negative in children of <4 years of age and may not become positive in older children and adults until 10 days after onset of symptoms.
Detection of primary EBV infection (subacute)	Tests for VCA IgM and IgG antibodies		This is usually considered to be 3 weeks to 3 months after primary infection.
Monitoring posttransplant EBV infections	Blood viral load measurement		The matrix tested in most centers is whole blood, but some prefer plasma. Serial testing at the same center is important.
Diagnosis of PTLD	ISH of biopsy material for detection of EBER	Blood viral load measurement	The PTLD risk has been shown to increase significantly with the peak whole-blood viral load.
Diagnosis of oral hairy leukoplakia	Diagnosis usually based on clinical findings without lab tests	ISH of lesion swab or biopsy specimen for detection of EBV DNA	EBV is actively produced under these conditions and usually responds to antiviral agents, such as acyclovir or ganciclovir.
Diagnosis of EBV central nervous system infection	PCR of cerebrospinal fluid		A positive result, regardless of quantity, should initiate a thorough neurologic evaluation, including imaging.
Diagnosis of EBV-associated cancers	ISH of biopsy material for detection of EBER		EBV-associated cancers include nasopharyngeal carcinoma, Hodgkin's lymphoma, endemic Burkitt's lymphoma, gastric carcinoma, and leiomyosarcoma.
Diagnosis of EBV-associated lymphoproliferative diseases in nonimmunocompromised hosts[b]	Determination of antibody profile of primary EBV strain and phenotype of infected cell type	Clonality analysis	CAEBV is the most common form.

[a]Abbreviations: CAEBV, chronic active EBV; EBER, EBV-encoded RNA; EBNA, EBV nuclear antigen; ISH, *in situ* hybridization; PTLD, posttransplant lymphoproliferative disorder; VCA, viral capsid antigen.
[b]These include CAEBV, hematophagocytic lymphohistiocytosis, severe mosquito bite allergy, and hydroa vacciniforme.

Complications of primary EBV infection may be due to tissue-invasive viral disease or to immune-mediated damage. Many complications have been associated with infectious mononucleosis, but nearly all of them are uncommon or rare (40, 41). Complications reported in ≥1% of cases are airway obstruction, meningoencephalitis, hemolytic anemia, thrombocytopenia, and maculopapular rash (34). Splenic rupture is a rare but serious complication that excludes athletes from contact sports for various lengths of time.

The correlations between time of primary infection, disease expression, immune responses, and viral loads are shown in Fig. 1. EBV infects the host approximately 42 days before the onset of overt symptoms. The first laboratory indicator of primary infection is oral viral shedding, which can occur as early as 2 weeks before the onset of symptoms. This is not a good test for diagnosis of acute primary EBV infection, because essentially all persons ever infected by EBV shed virus intermittently from the oral compartment. The next indicators of primary infection arise almost simultaneously. They are development of VCA IgM antibodies, development of heterophile antibodies, and viremia. These may be detected as early as 7 days before symptoms develop. Viremia, found in approximately 75% of patients, is short-lived in most cases but may persist for up to 6 months in unusual instances (17, 28).

A heterophile antibody test is the practical choice for the diagnosis of acute infectious mononucleosis (Table 1),

TABLE 2 EBV infection category according to patterns of EBV-specific antibody tests[a]

Infection category	Presence of antibody		
	VCA IgM	VCA IgG	EBNA-1 IgG
Common patterns			
Never infected (naive)	−	−	−
Acute primary infection	++	−	−
Subacute primary infection	++	+	−
Convalescent-phase primary infection	±	++	±
Past infection (>6 months old)	−	+++	+++
Unusual patterns			
Past infection (>6 months old)	−	+++	−
Past infection (>6 months old)	−	−	++

[a]Symbols for presence and semiquantitation of antibody response: −, no antibody response; ±, equivocal result; +, low positive response; ++, moderate positive response; +++, strong positive response.

because of its simplicity and relatively low cost (42). Heterophile antibody tests use various mammalian erythrocytes to detect IgM class antibodies that are present during the generalized immune upregulation that characterizes acute primary EBV infection. Paul and Bunnell discovered heterophile antibodies in 1932 (43), which they defined as "having the capacity to react to certain antigens, which are quite different from, and phylogenetically unrelated to the one instrumental in producing the antibody response [in this case EBV]."

Heterophile antibody tests do have drawbacks. As mentioned above, children 4 years of age or younger may not develop heterophile antibodies during primary EBV infection (31). Thus, the heterophile antibody test may be falsely negative for young children. Second, heterophile antibodies are nonspecific and may be present in infections not caused by EBV or in malignancies or autoimmune diseases (44, 45). Finally, these antibodies may persist for a year or more and therefore are not always diagnostic of an acute EBV infection (46).

If the clinical impression is primary EBV infection but heterophile antibodies are absent, we recommend testing for the following three EBV-specific antibodies: anti-VCA IgM, anti-VCA IgG, and anti-EBNA-1 IgG. The category of EBV infection can then be assigned as naive (never infected), acute (1 to 3 weeks old), convalescent (4 weeks to 6 months old), or past (>6 months old), as shown in Table 2. The criterion standard for measuring these antibodies used to be IFAs, but assays with a higher throughput that are less labor-intensive, such as EIAs, have essentially supplanted them (29).

Examination of a peripheral blood smear may be helpful, especially when antibody results are inconclusive. In acute primary EBV infection, large atypical lymphocytes (also known as Downey cells) may constitute 10% or more of the total lymphocyte population (47). We now understand that these are $CD8^+$ cytotoxic lymphocytes, most of which are probably reacting against EBV-infected B cells (48).

IgG antibody against VCA is first detected at different times during the course of primary EBV infection, depending on the target antigen used in the test. If the target antigen is EBV p18, which is the antigen reagent in the Diamedix EIA, the antibody response starts about 10 days after the onset of illness. If it is p23, the VCA IgG antibody response may be seen as early as the first few days of illness. The EBNA-1 antibody response develops slowly and normally is not detected until at least a month after the onset of symptoms (17). Because of its late appearance, the presence

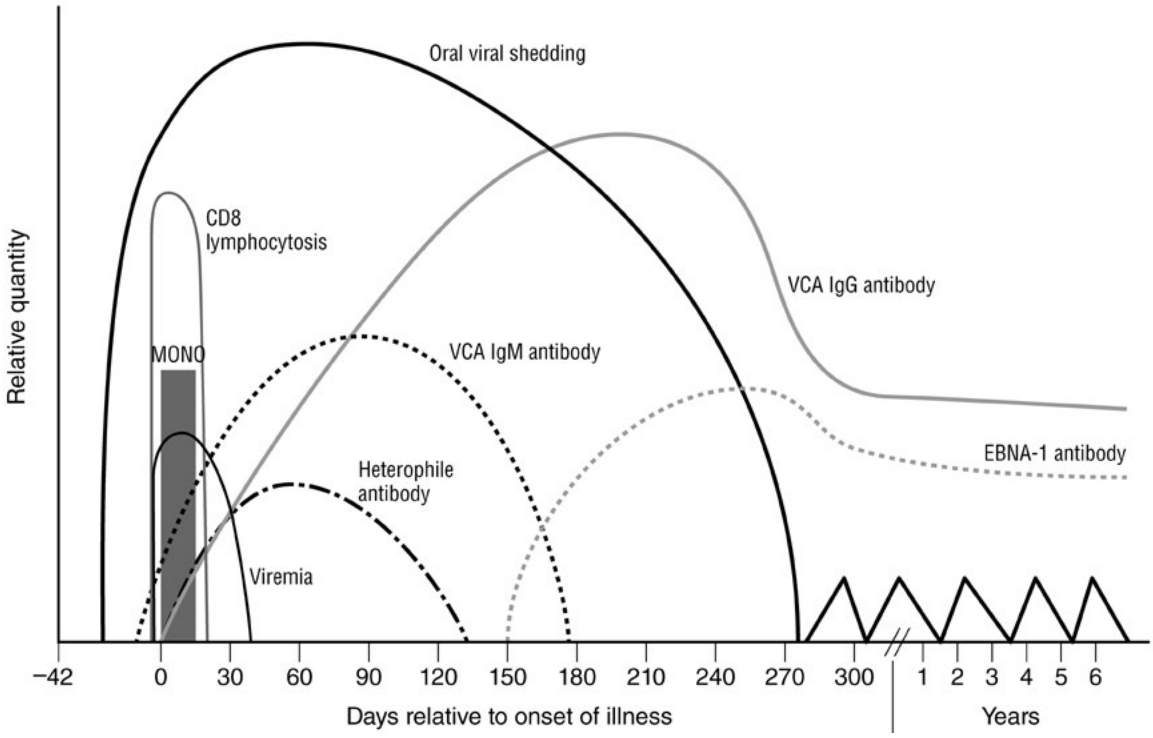

FIGURE 1 Correlations between time of primary infection, disease expression, immune responses, and viral loads.

of EBNA-1 antibody is useful for distinguishing past from recent or subacute infections. Also, EBNA-1 antibody indices are significantly elevated in patients with multiple sclerosis compared with matched controls (49).

Monitoring Infections in the Immunocompromised Host

EBV infections in immunocompromised patients are best evaluated in the laboratory by serial measurements of the blood viral load (Table 1) (50, 51). Most assays employ a DNA template, and the matrix tested is usually blood, so EBV blood viral loads are also referred to as EBV DNAemia. While there are options in terms of platforms, volumes, probes, and targets, a multicenter comparison of different real-time PCR assays suggested that if samples are tested at one center on the same platform, real-time PCR is a precise technique for measuring viral load. However, substantial quantitative differences were found when samples were tested in different laboratories (52). A WHO quantitative calibration standard is now available, which should improve interlaboratory variability (53).

At a number of institutions, viral loads of >4,000 copies/ml of whole blood (54, 55) or steadily rising levels often prompt a reduction of immunosuppression and initiation of specific treatment for solid organ transplant recipients. The threshold triggering an intervention is lower for hematopoietic cell transplants (usually ~1,000 copies/ml). The best matrix to use for monitoring EBV infections has been a subject of debate. Some centers consider EBV in plasma to be more indicative of active infection (56), but the majority favor whole blood (57, 58). Copy numbers in plasma are usually 10- to 100-fold lower than those in concomitant whole-blood samples. The diagnosis of posttransplant lymphoproliferative disorder (PTLD) requires a tissue diagnosis, but some centers consider rising blood viral loads, especially those exceeding 100,000 copies/ml, to be consistent with PTLD (Table 1) and treat patients accordingly (59).

An unusual manifestation of EBV infection, oral hairy leukoplakia (OHL), is seen mainly in patients with HIV/AIDS but occasionally occurs in individuals not infected with HIV. OHL lesions are characterized as white, nonremovable plaques most commonly seen on the lateral borders of the tongue. These can usually be diagnosed clinically and do not require laboratory confirmation. In atypical instances, *in situ* hybridization (ISH) to detect EBV DNA in incisional biopsy tissue or lesion swabs may be used to make the diagnosis (60). Because OHL plaques are the result of active EBV replication, they often regress during antiviral therapy (61).

Central Nervous System Infections

Cerebrospinal fluid testing by PCR is the method of choice to diagnose EBV infection of the central nervous system (Table 1). A positive result, regardless of quantity, should initiate a thorough neurologic evaluation, including imaging.

EBV-Associated Cancers

EBV is best identified by examination of biopsy or surgical samples of cancer tissue by using immunohistochemical (IHC) approaches (Table 1). ISH to detect EBV-encoded RNA transcripts (EBERs) is the criterion standard for detecting EBV in tissue (62). PCR is the technique of choice for detecting and quantifying EBV in body fluids and can also be used to quantify the virus in tissue samples (63). Diagnosis and monitoring of therapy of nasopharyngeal carcinoma by noninvasive sampling techniques, such as quantification of EBV DNA in bronchial brushings, are under investigation (64, 65).

EBV-Associated T or NK Cell Lymphoproliferative Diseases

A subset of patients do not recover from primary EBV infection because they develop clonal proliferation of EBV-infected T or NK cells. The majority of these individuals are Japanese, with a median age of onset of 8 years (66). These patients have no prior evidence of immune dysfunction; therefore, this group of diseases has been referred to as EBV-associated lymphoproliferative diseases in nonimmunocompromised hosts. There are four clinical categories: chronic active EBV, hematophagocytic lymphohistiocytosis, severe mosquito bite allergy, and hydroa vacciniforme. These conditions are life-threatening, with an overall mortality of 40 to 50%. The diagnosis is based on documentation of a primary EBV infection followed by determination of the phenotype of the infected cells by immunobead separation or ISH followed by flow cytometry. Viral clonality may also be assessed by Southern blot analysis using an EBV terminal repeat probe. Most patients' EBV-infected cells are monoclonal.

Laboratory Methods

Methods in Clinical Use

Methods are presented in order of relative clinical value for both methods in clinical use and research methods with potential clinical application.

Detection of Heterophile Antibody

There are numerous commercial kits that detect heterophile antibodies (also referred to as monospot tests). Our laboratory employs the Acceava Mono test, which is an immunoassay using a qualitative membrane strip for the detection of heterophile antibodies in anticoagulated whole blood, plasma, or serum. The membrane strip is coated with a bovine erythrocyte antigen extract at the test line on each strip. Diluent and a specimen sample are added in the proper dilution to a small tube, and the strip is placed into the solution, which migrates up the membrane strip. A colored line appears in the test strip if heterophile antibodies are present. No colored line in the test strip area indicates a lack of heterophile antibodies. Each strip contains a control to show that proper volumes and wicking of the sample are present.

Detection of EBV-Specific Antibodies (VCA IgG, VCA IgM, and EBNA-1 IgG) by EIA

A number of commercial assays are available for detection of EBV-specific antibodies. We use the semiquantitative Diamedix platform, which has proven to be quite reliable. We have published three studies in which the EBV-specific antibody responses correlated closely with clinical findings for primary EBV infection and EBV loads (17, 28, 67). Serum is the preferred matrix, but plasma is acceptable. For the detection of EBV VCA IgG, VCA IgM, and EBNA-1 IgG antibodies, recombinant VCA antigen or recombinant EBNA-1 antigen is bound to plastic microwells. A cutoff calibrator, negative and positive controls, and diluted patient serum samples are pipetted into the microwells for incubation. A diluent is supplied for the IgG or IgM antibodies and is not lot specific. The specimen and diluent are used at a 1:21 ratio for IgG testing and a 1:101 ratio for IgM testing. If EBV antibodies are present in the sample, they will bind to the antigen coating the wells, forming an antigen-antibody

complex. Other antibodies that may be in the specimen are eliminated through aspiration or "flicking" of the sample in the wells and then washing of the wells with a prepared wash solution. A kit-specific conjugate (horseradish peroxidase-labeled anti-human IgG or IgM) is added to the wells to bind to the antigen-antibody complex. Unbound conjugate is removed through aspiration or "flicking" and washing. A substrate solution of 3,3′,5,5′-tetramethylbenzidine is then added to the well for incubation. The substrate is converted to the end product by a bound enzyme. The reaction is stopped with 1 N H_2SO_4. The absorbance at 450 nm of the end product is measured by using a spectrophotometer (with reference band reading at 630 nm). The amount of color produced is relative to the quantity of antibody in the specimen.

Some laboratories prefer an antibody capture assay, especially for detection of VCA IgM antibodies. The major advantage of this method is enhanced specificity. The procedure involves coating wells with an anti-human IgM antibody that "captures" the patient's antibody. VCA antigen and an anti-EBV antibody conjugate are then added, followed by a color substrate to visualize the bound enzyme.

Detection of EBV DNA by PCR

Detection and quantification of EBV DNA by PCR currently form the criterion standard for monitoring EBV infections and disease posttransplantation. DNA is extracted from the sample through a series of washes with buffers of various salt concentrations. Membranes are ruptured using protease enzymes, and DNA is removed from cellular and extracellular debris during DNA extraction by using columns that loosely bind DNA. The DNA is washed off in a final step with a salt solution. Both in-house and commercial assays are in use, and a number of EBV DNA targets have been designed, including BNRF-1, BALF-5, and EBNA-1. We employ an in-house TaqMan assay with an amplicon that is a 71-bp segment of the EBNA-1 gene. TaqMan technology for the determination of viral load uses fluorescently labeled probes that lie between specific primers. Each probe is labeled on its 5′ end with a reporter dye that allows for product detection during amplification and is labeled on its 3′ end with tetramethylrhodamine or another quencher dye to reduce the unbound fluorescence signal and prevent the probe from acting as a primer. Probes attach to their complementary DNA sequence targets, and when the PCR proceeds, the fluorescence signal is released at a rate relative to the quantity of EBV DNA in the sample. Most assays are run for 40 to 45 thermocycles. The cycle threshold is reached sooner when the sample contains large amounts of EBV DNA and later when smaller quantities are present. The controls that we use include serial dilutions of Namalwa cells (these contain two copies of EBV DNA per cell), no template, and six quantitative amplicon standards calibrated to contain 10^2, 10^3, 10^4, 10^5, 10^6, and 10^7 copies of EBV/ml. Patient samples are run as a pair, with one well containing an internal control to ensure that the sample does not inhibit detection of DNA. The best matrix to use for monitoring chronic EBV infections is still in question. As discussed above, whole blood is preferred by many centers, whereas some test plasma.

In Situ Hybridization

ISH is an IHC technique to detect and localize a target sequence in samples that have been treated to fix the target in place and to facilitate access of the probe to the area of interest. ISH is the method of choice to diagnose tissue-invasive EBV disease. The assay is quite sensitive if probes designed to bind to EBV-encoded RNAs (EBER-1 and EBER-2) are employed, because latently infected B lymphocytes contain ~10^6 copies of EBERs/cell, which aggregate in the nucleus. Commercial reagents are available from several manufacturers. Controls should include EBER-positive and -negative specimens.

Detection of EBV EA IgG Antibody

Antibody against EBV early antigen (EA) can be detected in serum or plasma by use of an EIA, IFA, or immunoblotting. Henle et al. identified two distinct patterns of immunofluorescence staining, diffuse and restricted, using sera from patients with infectious mononucleosis, Burkitt's lymphoma, and nasopharyngeal carcinoma (68). The more common diffuse pattern antigen (EA-D) is encoded by the BMRF-1 gene and is characterized by nuclear and cytoplasmic staining. The restricted pattern antigen (EA-R), encoded by the BHRF-1 gene, consists of cytoplasmic aggregates of various sizes without nuclear staining. Both patterns can be seen in the same cell. In early infectious mononucleosis, the predominant pattern was EA-D, but later on, EA-D and EA-R became nearly equal. Nasopharyngeal carcinoma patients dominantly showed the EA-D pattern, whereas sera from Burkitt's lymphoma patients most frequently contained EA-R. The clinical utility of EA testing is questionable today. It is not sensitive for diagnosing acute infectious mononucleosis because only 60 to 80% of patients are positive (29). It is not specific for reactivation of EBV because healthy blood donors have been found to be positive for serum EA IgG antibodies (69).

Detection of EBV IgA Antibody

The EBV IgA antibodies purported to have clinical application are VCA IgA and EA IgA. They have practical value only for diagnosis and management of patients with nasopharyngeal carcinoma (70). The sensitivity and specificity of VCA IgA antibody detection appear to be superior to those of EA IgA detection for the diagnosis of nasopharyngeal carcinoma (71). VCA IgA antibody has been proposed as a marker of reactivation. However, it is not specific, as VCA IgA antibodies have been reported for 74% of primary EBV infections and have also been seen in 13% of healthy subjects (72).

Research Methods with Potential Clinical Application

Immunoblotting

Immunoblotting can include immediate early, early, and late EBV antigens on one test strip, which may permit evaluation of the relative stage of EBV infection by use of a single serum or plasma sample (73). Our virology research laboratory uses the Mikrogen line blot immunoassay system, which provides a choice of reagents for detection of IgA, IgG, and IgM class antibodies and IgG antibody avidity. Briefly, highly purified recombinant EBV antigens are fixed onto nitrocellulose membrane strips. The test strips are incubated with the diluted sample, and specific antibodies attach to the EBV antigens on the test strip. Unbound antibodies are then flushed away by a wash procedure. In the second step, the strips are incubated with anti-human immunoglobulin antibodies (IgG, IgA, and/or IgM), which are coupled to horseradish peroxidase. Unbound conjugate antibodies are then flushed away by a wash procedure. Specifically bound antibodies are detected by a staining reaction

catalyzed by the peroxidase. If an antigen-antibody reaction has taken place, a dark band will appear on the strip at the corresponding point. Each test strip contains three control bands. The reaction control band, at the upper end of the test strip, must show a reaction for every serum/plasma sample. Next on the strip is the conjugate control (IgG, IgA, or IgM), which is used for verification of the antibody class detected. If, for example, the test strip is used for the detection of IgG antibodies, the conjugate control IgG must show a clearly defined band. Finally, there is a cutoff control. The intensity of the antigen-antibody bands produced by the test sample must exceed that of the cutoff control in order to be called positive.

EBV Culture

The classic way to isolate EBV is to incubate body fluid or tissue samples with fresh umbilical cord B cells. The cells are observed for 6 weeks for evidence of transformation, which includes persistent proliferation, mitotic figures, large vacuoles, granular morphology, and cell aggregation. There is little value in performing this labor-intensive assay that takes weeks to give results, because molecular techniques, especially nucleic acid detection, are available and are much more sensitive than viral culture for identification and quantification of EBV.

Neutralization Assays

Neutralization assays are important for evaluation of antibody responses to candidate EBV vaccines. These used to rely on viral culture in human lymphocytes, with comparison of endpoint dilutions of infectivity or transformation. A streamlined neutralization assay was recently described in detail by Sashihara et al. (74). They elegantly showed that antibody titers against EBV gp350 correlated tightly with neutralization of infectivity. The neutralization assay is based on coincubating Raji cells (a Burkitt's lymphoma cell line) with B95-8 cells (cotton top tamarin lymphocytes transformed by EBV from an infectious mononucleosis subject) that contain green fluorescent protein. The green fluorescent protein-positive Raji cells indicate infection and are enumerated by flow cytometry after a 3-day incubation period. The ability of antibody to inhibit Raji cell infection can be quantitated by serial dilution of the plasma or serum specimen.

Assays of EBV-Specific T Lymphocytes

The two most popular methods to identify and study EBV-specific T lymphocytes are HLA-peptide tetramer (75) and gamma interferon (IFN-γ) enzyme-linked immunosorbent spot (ELISPOT) (76) assays. An extensive list of $CD4^+$ and $CD8^+$ T cell epitopes derived from EBV proteins has been identified (77) and facilitates the use of these assays. Measuring virus-stimulated IFN-γ production, typically by ELISPOT assay, is a very sensitive and specific means to detect virus-specific T cells and is used widely to study EBV-specific $CD4^+$ and $CD8^+$ T cells. By using mixtures of peptides from different viral proteins and different HLA alleles (78, 79) or by using EBV-infected lymphoblastoid cell lines from patients' own B cells (80), ELISPOT assays can be quite comprehensive and do not require knowledge of the HLA type of the individual. Nonetheless, not all virus-specific T cells produce IFN-γ, and if T cells become exhausted due to overstimulation, they may fail to produce IFN-γ (79, 81). This is particularly problematic for detection of EBV during acute infection. Identification of virus-specific T cells by use of HLA-peptide tetramers avoids this issue.

During acute infection, large numbers of tetramer-binding (EBV-specific) $CD8^+$ T cells are observed in the peripheral blood (77, 80, 82), as well as $CD4^+$ T cells, to a lesser extent (83). However, since our knowledge of EBV epitopes and the alleles that present them is not exhaustive, neither ELISPOT assays nor tetramers can identify all of the EBV-specific T cells in an individual. Nonetheless, the pattern of expansion and contraction of tetramer-binding T cells over time after primary infection is generally similar to that of total $CD8^+$ T cells in peripheral blood (17). Some studies have estimated the total number of pathogen-specific T cells during infection by assessment of cell surface activation markers, such as CD38 and HLA-DR, assuming that these activated T cells are pathogen specific (84). However, our study clearly showed that "bystander" $CD8^+$ T cells (those specific for other viruses) become activated during acute EBV infection as well (48). Although it remains challenging to precisely determine the fraction of T cells that are specific for EBV, it is clear that the $CD8^+$ T lymphocytosis observed during acute EBV infection is unusually large and that this effect is not as pronounced for $CD4^+$ T cells.

Finally, HLA-peptide tetramers can be combined with flow cytometric analysis of cytokine production, cell cycle markers, cytolytic proteins, activation/memory/exhaustion markers, and survival proteins. These types of studies have provided great insight into the kinetics and character of the T cell responses to different EBV epitopes (77) but are not yet being employed to distinguish pathogenic versus protective responses in the clinical setting.

Detection of Encapsidated versus Naked EBV DNA

Whether circulating cell-free DNA is encapsidated in virions or exists as fragments of naked DNA may be important for managing patients with EBV-related malignancies. It is thought that fragments of naked EBV DNA are released from tumor cells undergoing apoptosis, whereas encapsidated EBV DNA reflects lysis of cells undergoing active EBV replication (13). If most of the DNA is encapsidated, signaling ongoing viral replication, then antiviral therapy might be effective. On the other hand, naked DNA may be a measure of tumor cell burden, and its disappearance after a transient increase following radiation or chemotherapy could be a positive prognostic factor signifying destruction of cancer cells.

Ryan et al. developed a test to distinguish encapsidated from naked EBV DNA (85). Their assay is based on the observation that viral capsids protect EBV DNA from degradation by DNase I. The assay measures the EBV load by real-time TaqMan PCR before and after exposure to DNase I. A marked reduction in viral copy number after DNase I treatment indicates that the sample contains mostly or all naked EBV DNA.

Clonality Analysis

During lytic replication, EBV forms linear intermediates of different sizes produced by random cleavage between the variable-number terminal repeats in the viral genome. If malignant transformation occurs, the same fused terminal repeat pattern is inherited by all progeny of the original malignant cell. Clonality analysis involves digestion of EBV DNA with a restriction endonuclease, such as BamHI, that does not cut the genome within the terminal repeats. The fragments containing the terminal repeats are detected by Southern blotting using specific probes. If the EBV-infected

cell population is monoclonal, the fragments have a single size and appear as a single band when visualized by staining or autoradiography. Multiple bands indicate oligoclonality or polyclonality, which implies a less aggressive disease.

CMV

Background and Biology

CMV has a very distinct cytopathology that was first described by the German pathologist Hugo Ribbert at a medical meeting in Bonn in 1881 (86). Similar cells with eccentrically placed nuclei containing a central nuclear body surrounded by a clear halo were identified in the lungs, kidneys, and liver of an 8-month-old stillborn fetus (87). The first indication that these cells with intranuclear inclusions were related to viruses rather than to protozoa, as previously believed, occurred in 1925, when similar cells were discovered in a man with herpes zoster and herpes genitalis (88, 89).

In 1950, Wyatt et al. reviewed the published data on conditions associated with this unique cytopathology, added six cases of their own, and concluded that "the etiologic agent of the disease is a specific virus [and] the morphology and cytology of the inclusion-bearing cells is pathognomonic of the disease" (90). In addition, renal tubules were identified as a uniform site of involvement, and thus a cytological preparation from the urinary sediment of a suspected case patient became the first successful diagnostic test for what was now being called "cytomegalic inclusion disease" (91). In 1953, electron microscopy revealed 199-nm particles in the clear halo around the intranuclear inclusion, consistent with a viral etiology (92). After Enders et al. discovered how to grow human cells in culture (93), for which they received the Nobel Prize in 1954, CMV was isolated in cell culture by independent laboratories (94–96). The virus was then available for the laboratory studies that provided the data presented below.

CMV, whose systematic name is HHV-5, is one of the eight human herpesviruses recognized to date. CMV is a prototypic member of the betaherpesvirus subfamily, and its DNA genome is approximately 230 kb long, the largest among known human viruses, and consists of unique long (UL) and unique short (US) segments, each of which is flanked by inverted repeats (RL and RS). Most of the approximately 200 genes encode proteins, but some express only noncoding RNAs, including approximately 14 microRNAs. The central portion of the UL region contains clusters of core genes that have homologs in other herpesviruses, such as genes encoding DNA polymerase, glycoprotein B (gB), and glycoprotein H (gH), whereas the remainder of the genome contains genes primarily found only in betaherpesviruses or unique to human CMV. By convention, CMV genes are named by their position within the genome, although some also have additional descriptive names. For example, UL54 (the 54th gene in the UL region, according to the original report of the CMV strain AD169 sequence) is the DNA polymerase gene (97).

Following initial infection, a complex set of nonspecific and humoral host responses attempt to limit CMV replication, but the virus has lived in its human host for a very long time and has evolved successful evasion strategies. The interaction between CMV and the host immune system is complex, since the virus itself can cause suppression or enhancement of host immune responses and can infect the lymphoid system. Nonspecific host defense mechanisms include NK cells and IFNs. In humans and murine models, NK cell deficiency has been linked to severe CMV disease (98), and NK cells have been shown to lyse cells infected with CMV (99). At least seven genes are able to modulate, and in many cases inhibit, NK cell function (100). The production of IFN-α and -β is an important part of the defense against murine CMV in the early stages of infection. In humans, too, CMV infection prompts cellular membrane sensors, such as the lymphotoxin beta receptor, to initiate the production of antiviral cytokines such as IFN. However, virion factors, such as pp65 (ppUL83) and viral proteins made soon after infection, repress this response by interfering with steps in the activation of IFN regulatory factor 3 and NF-κB. CMV then exerts a multipronged attack on downstream IFN signaling. CMV has multiple genes involved in blocking the function of IFN-induced effectors (101).

Adaptive T cell responses are critical for keeping the virus inactive. Restoration of $CD8^+$ and $CD4^+$ T cells is a strong correlate of control of the virus after transplantation (102, 103). Adoptive transfer of CMV-specific T cells protects against clinical reactivation (104).

In antibody-positive humans, a strikingly large proportion (10% or more) of circulating T lymphocytes target CMV, and the proportion of CMV-specific T cells tends to increase with age, which supports the hypothesis that CMV contributes to immune system exhaustion and dysfunction associated with aging (105). However, our understanding of these inflammatory memory CD8 T cells is incomplete, and they alternatively may serve an essential protective role (106). Antibodies in CMV-infected individuals have been useful for establishing immune status. Although it has long been thought that only antibodies to gB or gH neutralize the virus, other viral genes, including UL128, UL130, and UL131A, also mediate entry into endothelial and epithelial cells.

Like other herpesviruses, once the primary infection is brought under control by the host immune response, CMV persists in a state of cellular latency in which infected cells are not producing any infectious virus or are replicating it at a very low level, below the threshold of current detection methods. The latent virus retains the complete genome, with the potential to start producing virus at any time. The site of CMV latency has been thought to possibly be circulating leukocytes. During kidney transplantation, donors are thought to transmit CMV via the organ, which is undoubtedly contaminated with leukocytes. However, since CMV has a propensity to reactivate within the transplanted organ, perhaps parenchymal cells harbor latent virus.

CMV replication and the host immune system are in a delicate balance, such that even relatively minor perturbations, such as pregnancy or admission to an intensive care unit, allow CMV reactivation, often without overt CMV disease (107). Moreover, subtle effects of subclinical reactivation or quiescent CMV infection might contribute to chronic immune system dysfunction and predispose individuals to other illnesses, including infections by other microbes (108).

Clinical Relevance

CMV is a ubiquitous virus, and infections are usually asymptomatic and acquired relatively early in life. The high frequency of CMV antibody in the general population without previous overt disease suggests that CMV infection is fairly frequent. Transmission occurs during direct contact with body fluids. Once a person is infected, the virus establishes lifelong latency, with periodic reactivations usually resulting in asymptomatic shedding of virus. Unfortunately, CMV infection is not always asymptomatic. CMV is the most common cause of congenital infections that result in

sensorineural hearing loss and psychomotor retardation, with a 5 to 10% mortality rate (109). The birth prevalence of congenital CMV is 0.64%, with 11% of these infants being symptomatic (110). Symptoms can include jaundice, hepatosplenomegaly, hydrops, thrombocytopenia, anemia, microcephaly, seizures, and chorioretinitis. Even asymptomatic infants remain at risk for later symptoms, such as sensorineural hearing loss (109). CMV may also be a cause of antenatal stillbirth (111). In immunocompetent adults, CMV can cause a self-limiting mononucleosis syndrome, and in immunocompromised patients, it can present with mild to severe organ involvement that may be fatal. Moreover, even subclinical CMV viremia has been associated with deterioration in kidney function in kidney transplant recipients (112, 113) and, more recently, was cited as a risk factor for cardiovascular disease in transplant recipients (114). Breakthrough infections occur despite routine viral prophylaxis with valganciclovir for 3 to 12 months posttransplantation in all transplant recipients (115).

Laboratory Methods

Methods in Clinical Use

Since CMV disease can have nonspecific clinical manifestations, laboratory confirmation is essential for diagnosis. A summary of the laboratory tests for diagnosis and management of CMV infections is provided in Table 3.

Nucleic Acid Amplification Tests

The sensitivity of PCR technology to detect minute amounts of viral nucleic acid in clinical samples has made this the preferred method of CMV diagnosis, particularly after solid organ transplantation or HCT, when timely diagnosis is of the essence. Nucleic acid amplification tests (NATs) can detect CMV nucleic acid in a variety of samples, including blood, cerebrospinal fluid, respiratory samples, and aqueous or vitreous humor fluid, but the matrices most often tested are whole blood and plasma. Since the vast majority of CMV NATs are developed and validated by

TABLE 3 Laboratory tests for diagnosis and management of CMV infections

Test	Indication	Comment(s)
NAT against DNA	Detects active or latent CMV infection	Detects latent DNA, making it a good qualitative test but less useful clinically, since it is sensitive but not specific
NAT against RNA	Detects active CMV infection	RNA intermediates are mainly produced during active replication, so the test is specific for acute CMV but has reduced sensitivity, since RNA is easily degradable.
qNAT	Useful for diagnosis, risk assessment, and therapeutic guide for active CMV infection	The test is sensitive and specific and is the most clinically utilized and useful test for detection of CMV infection or disease.
Non-PCR amplification	Detects active CMV infection	Based on signal amplification and is therefore less sensitive and less utilized clinically
Histopathology	Diagnosis of tissue-invasive or compartmentalized disease	While very specific for disease, it requires an invasive procedure or biopsy for specimen retrieval. In addition, atypical features may overlap the features of other viral diseases.
ISH/IHC	Diagnosis of tissue-invasive or compartmentalized disease	More sensitive and specific than histopathology but still requires an invasive procedure or biopsy for specimen retrieval
Viral culture	Useful for samples not suitable for molecular testing	Although very specific, it has a reduced sensitivity, long turnaround time, and laborious method.
pp65 antigen testing	Diagnoses active CMV infection	This is a rapid test, but it utilizes a laborious method with subjective interpretation. In addition, there is an increased risk of false-negative results in cases of severe leukopenia.
Antibody testing	Useful for risk stratification of transplant patients for CMV disease, detects past infection	Denotes past or recent infection but is not useful for initiating or monitoring the response to therapy
IgG avidity assay	Detects recent primary infection	Not commercially available in the United States

each performing laboratory, results are not interchangeable given the different limits of detection, assay characteristics, and levels of precision and accuracy. The U.S. FDA recently approved a CMV NAT called the CAP/CTM CMV test (Roche) for viral load monitoring in patients receiving antiviral therapy for CMV disease.

In most CMV NATs, the target nucleic acid is CMV DNA, which accounts for their high sensitivity, since DNA is very stable over time. However, since latent viral DNA is also detected by this test, its specificity is reduced. This concern led to the development of a CMV NAT to detect RNA, since RNA intermediates are produced mainly during active replication. But since RNA molecules are readily degraded, the sensitivity of the test is lowered.

CMV NAT can be developed as a qualitative test, but this is less useful than quantitative testing, whose results are reported as absolute values per volume of specimen. Quantitative NAT (qNAT) allows for CMV disease risk assessment, since higher initial and peak viral loads or a rapid rise in viral load is associated with a higher risk of CMV disease development (116, 117) and more severe CMV disease. qNAT also guides the initiation and duration of preemptive therapy for prevention of CMV disease and allows rapid and sensitive diagnosis of CMV disease so that prompt therapy can be initiated. The effectiveness of antiviral therapy for CMV disease, treatment duration, risk of relapse, and risk of antiviral resistance can be assessed by qNAT.

Non-PCR amplification methods based on signal amplification rather than direct detection of CMV DNA or RNA are less sensitive and therefore less utilized clinically.

Histopathology

While histopathology remains the reference standard for the diagnosis of tissue-invasive CMV disease, it requires an invasive procedure/biopsy to obtain tissue samples. Therefore, many clinicians rely on a NAT coupled with compatible clinical signs and symptoms to make a diagnosis of CMV disease. However, in the case of compartmentalized or localized CMV disease, blood testing may be negative for CMV. Histopathology is critical in such cases. Testing for allograft biopsy pathology is also useful if transplant rejection is a diagnostic consideration for patients with CMV viremia. Histopathologic features of CMV infection are classic and include cellular and nuclear enlargement with amphophilic to basophilic cytoplasmic inclusions. But since there are sometimes atypical features that may overlap the presentation of other viruses, ISH or IHC testing is a useful confirmatory test. ISH testing uses CMV-specific DNA probes that bind to viral DNA in the cellular material, while IHC testing uses a monoclonal/polyclonal antibody against early CMV antigen. This increases the sensitivity and specificity of histopathology as a diagnostic test for CMV disease.

Viral Culture

Viral culture is highly specific and can be done using a conventional plaque assay or the more rapid shell vial centrifugation culture system. Isolation of CMV from most clinical samples is highly predictive of CMV disease. The exception is recovery of CMV from the urine, saliva, or stool samples of antibody-positive recipients, in which case the shedding is usually of no clinical consequence. The utility of CMV culture is limited by its low sensitivity, labor-intensiveness, and long turnaround time. The shell vial centrifugation method has a shorter turnaround time because the cultured cells are stained with monoclonal antibodies to detect immediate early antigen production during CMV replication, allowing diagnosis in as little as 2 days. Viral culture is useful mainly when samples are not suitable for molecular testing. Viral culture used to be required for phenotypic drug resistance testing, but molecular genotypic assays are now the methods of choice.

Antigen Testing

The CMV antigenemia assay uses monoclonal antibodies to detect CMV lower matrix phosphoprotein pp65 antigen, a structural late protein expressed in CMV-infected leukocytes during early CMV replication. The result is reported as the number of positive cells per total number of cells counted and generally signifies active CMV infection. This test is rapid and is easier to perform and more sensitive than viral culture, and it can detect CMV infection earlier than viral culture. The degree of pp65 antigenemia can be used to pre-emptively treat patients to prevent CMV disease, since it is correlated with the risk of subsequent CMV disease, although this is not absolute. The number of pp65-positive leukocytes usually declines during successful antiviral therapy, and persistence may indicate suboptimal dosing or drug resistance.

Despite all these potential uses, it is labor-intensive and manual, unlike CMV NATs, and blood must be processed rapidly to optimize sensitivity. In addition, the interpretation of the test is subjective, making interlaboratory standardization difficult. Since the test relies on a sufficient number of polymorphonuclear leukocytes, false-negative results may occur in patients with severe leukopenia. Therefore, the CMV NATs by PCR described above are considered by most to be more sensitive and can detect CMV much earlier than the pp65 antigenemia test.

Antibody Tests

Serologic tests that detect CMV IgM and IgG antibodies are widely available from commercial laboratories. Enzyme-linked immunosorbent assay is the most commonly used antibody method, but various fluorescence, indirect hemagglutination, and latex agglutination tests are also available. These tests are performed to detect current active CMV infection or past infection in immunosuppressed persons at risk for reactivation of CMV infection.

In the field of transplantation, knowledge of donor and recipient antibody statuses allows stratification of the risk for CMV disease. The highest-risk antibody category is donor positive and recipient negative (D+R−), moderate-risk categories are D+R+ and D−R+, and the lowest-risk category is D−R− (118). Recommended viral prophylactic regimens often vary depending on the risk category. In addition, lack of antibody development by 6 months may be useful for identifying patients at risk for late-onset CMV disease (119, 120). Antibody testing may also be performed to detect CMV infection in newborns.

The presence of antibodies to CMV indicates a current or past infection but does not determine when the primary infection occurred. However, if tests performed on paired acute- and convalescent-phase sera show a 4-fold rise in CMV IgG antibody and CMV IgM antibody is present, or if CMV is cultured from a urine or oral sample, then an active CMV infection is probable.

The detection of CMV IgM antibody by itself is not diagnostic of primary CMV infection because both CMV reactivation and exogenous reinfection may elicit a CMV IgM antibody response.

IgG avidity assays, which measure antibody maturity, can detect recent primary CMV infection. During primary

infection, the body produces low-avidity IgG, followed 2 to 4 months later by high-avidity IgG. Therefore, finding low-avidity antibodies suggests that the patient has had a recent primary CMV infection.

Research Methods with Potential Clinical Application

Delayed recovery of CMV-specific T cells predicts the risk of progressive CMV infections in transplants (121), and therefore it is of great interest to develop methods to quantify and characterize such cells. Like the case for EBV, the most widely used research methods to do this utilize HLA-peptide tetramers and functional assays that measure IFN production or degranulation (122). Many CD4 and CD8 T cell epitopes have been identified for CMV, which facilitates these approaches. CMV-specific T cells in healthy seropositive individuals exhibit a "late differentiation" phenotype ($CD45RA^+$ $CD27^-$) and lower overall frequencies of naive T cells (123). This phenotype is not observed following infection with other herpesviruses, such as herpes simplex virus (124) or EBV (48), suggesting that CMV is unique in eliciting memory T cells with this phenotype. Interestingly, this phenotype was associated with control of viral reactivation, and in patients with uncontrolled reactivations, this phenotype did not develop (125). In contrast, chronic viral replication can impair T cell responses through exhaustion via programmed death 1 (PD-1) (126). Increased expression of PD-1 was observed on CMV-specific CD8 T cells with active CMV replication (127), and antibody-mediated blockade restored function (128, 129). Expression of PD-1 and cytotoxic T lymphocyte-associated antigen 4 on CMV-specific CD4 T cells was also recently demonstrated to be a specific phenotype associated with CMV viremia in transplant recipients (130).

For measurements of functional responses, T cells are typically stimulated with viral antigens, and cytokines such as IFN-γ, tumor necrosis factor alpha, and interleukin-2 are measured using the enzyme-linked immunosorbent assay-based QuantiFERON-CMV assay, an ELISPOT assay, or flow cytometric intracellular staining (131, 132). Quantitative decreases of specific immunity are associated with symptomatic CMV infection (132–134), and a failure to reconstitute CMV-specific immunity soon after the onset of CMV viremia is associated with higher peak viral loads (135). Also, by examining cytokine production and degranulation in CMV-specific T cells, Krol and colleagues observed that IFN-γ and interleukin-2 double-producing CD8 T cells were present in patients who controlled CMV reactivation, whereas CD8 T cells that produced IFN-γ alone were present in noncontrollers (136).

For all these reasons, phenotypic and functional analyses of CMV-specific T cells are promising approaches to predict CMV reactivation episodes (137), and several studies have begun to report on the comparative precision and reproducibility of the different assays (135, 137–141). It is very likely that in the future, such assays will serve as a guide to treating patients at risk of developing progressive CMV disease.

Human Herpesviruses 6, 7, and 8

RICHARD L. HODINKA

61

Herpesviruses 6, 7, and 8 are the most recently described members of the human herpesvirus family. Like other herpesviruses, they have the ability to establish a latent or persistent infection following primary infection, and reactivation may occur in healthy and immunocompromised people in response to different stimuli. A variety of methods are available or under development for the laboratory diagnosis of each virus, including viral isolation in cell culture, demonstration of viral antigens or nucleic acids in body fluids or tissues, and serology for detection of virus-specific antibodies. This chapter focuses on the immunologic and molecular diagnosis and monitoring of infections with human herpesvirus 6 (HHV-6), HHV-7, and HHV-8, and provides information on the unique features of the epidemiology and biological and clinical characteristics of these viruses.

HHV-6

Introduction

HHV-6 is a lymphotropic virus which was discovered in 1986 in cultures of lymphocytes from patients with lymphoproliferative disorders and AIDS. Since that time, much has been learned about the biology, epidemiology, clinical features, and diagnosis of HHV-6, and a number of comprehensive reviews have been published (see references 1 to 6 for examples of reviews).

HHV-6 is similar in morphology to other known human herpesviruses but is genetically and serologically distinct (Table 1). The completed virion has a diameter of 160 to 200 nm and consists of an internal core containing double-stranded DNA of approximately 160 to 170 kb and an icosahedral nucleocapsid surrounded by a tegument and a protein-spiked envelope. The virus has a primary cell tropism for mature $CD4^+$ T lymphocytes but also infects $CD8^+$ T cells, natural killer (NK) cells, monocytes, macrophages, megakaryocytes, epithelial cells, endothelial cells, fibroblasts, and neural cells. CD46 has been identified as part of the cellular receptor for infection; this marker is expressed on the surfaces of many human cell types, leading to the broad cellular tropism of HHV-6. Viral replication occurs in the nucleus of the host cell, and the viral envelope is acquired during maturation within cytoplasmic vacuoles before budding of the completed virus from the host cell membrane.

The DNA genome of HHV-6 differs from that of other human herpesviruses by both restriction mapping and nucleic acid hybridization and is unique in that it has a significantly lower guanine-plus-cytosine content at 43 to 44%. Regions of sequence homology between HHV-6 and cytomegalovirus (CMV) have been identified, and HHV-6 is now classified with CMV among the betaherpesviruses. Together with HHV-7, it is a member of the genus *Roseolovirus*. Genetic polymorphism among different isolates of HHV-6 exists, and evidence suggests that HHV-6 isolates form two distinct but very closely related groups (variants A and B) that differ in molecular, biological, and clinical properties. Most isolates of HHV-6 from patients with symptomatic primary infections have been of variant B. Variant A has been isolated or detected only rarely in children with primary HHV-6 infection, with the exception of African children with febrile illnesses. Both variants have been isolated from immunocompromised individuals, including AIDS patients, transplant recipients, and patients with leukemia; dual infections with both variants also have been described. Variant A is seen more frequently in patients with human immunodeficiency virus (HIV) infection, and it may be more neurotropic than variant B. Otherwise, an etiologic role for variant A in causing disease has not been clearly identified. Recently, HHV-6A and HHV-6B have been formally classified as distinct virus species by the International Committee on Virus Taxonomy.

The HHV-6 genome has a coding capacity of approximately 100 to 120 proteins, and a number of polypeptides ranging in size from 30 to 220 kDa, including six or seven glycoproteins, have been identified. A 101-kDa nucleocapsid protein was found to be highly reactive with human sera by Western immunoblotting and appears to be a specific marker for HHV-6 infection. A set of five monoclonal antibodies has been developed and used to identify nine proteins designated gp105 and gp82; gp116, gp64, and gp54; gp102; p41 and p110; and p135.

A unique feature of the DNA genome of HHV-6 is that it can integrate into the subtelemeric region of host cell chromosomes in approximately 1% of the human population (see references 7 and 8 for reviews). This chromosomally integrated form of HHV-6 DNA is passed from parent to child through the germline, and both HHV-6A and HHV-6B can integrate into the chromosomes. Because the viral genome can be found in every human somatic and germ cell in the body, individuals with chromosomally integrated HHV-6 will have very high levels of HHV-6 DNA in blood and tissues.

TABLE 1 Biological characteristics of HHV-6, HHV-7, and HHV-8

Characteristics	HHV-6	HHV-7	HHV-8
Family *Herpesviridae*			
Subfamily	*Betaherpesvirinae*	*Betaherpesvirinae*	*Gammaherpesvirinae*
Genus	*Roseolovirus*	*Roseolovirus*	*Rhadinovirus*
Properties			
Genome (linear double-stranded DNA)	~159 kb; encodes 110–120 proteins	~145 kb; encodes at least 70 proteins	~165 kb; 97 genes identified
DNA relatedness (% homology)	CMV (66%)	HHV-6 (50-60%)	Herpes saimiri (51%), EBV (39%)
Species/strains	Species HHV-6A, HHV-6B	Unknown	HHV-8 strains A, B, and C
Cell tropism *in vitro*	$CD4^+$ T lymphocytes, NK cells, macrophages, $CD8^+$ T cells, megakaryocytes, neural and epithelial cells	$CD4^+$T lymphocytes	$CD19^+$ B lymphocytes, spindle cells, endothelial cells
Virus interactions	EBV, CMV, HIV, parvovirus B19, human papillomaviruses	HHV-6, CMV, HIV	EBV, HIV

The clinical consequences of this are not fully understood, and chromosomal integration is often mistaken for active infection and unnecessarily treated with antiviral drugs.

Similar to cases of CMV and Epstein-Barr virus (EBV) infection, infections with HHV-6 are common and often mild or inapparent; however, HHV-6 is now recognized as the causative agent of roseola (roseola infantum, exanthem subitum, sixth disease) in children aged 6 months to 3 years (see reference 9 for a review). The disease presents with an onset of high fever (39 to 40°C) for 3 to 5 days that resolves abruptly and is followed by the appearance of an erythematous, blanching, maculopapular, nonpruritic rash beginning on the neck or trunk and spreading to the face and other areas of the body. The rash usually lasts for 1 to 3 days, and there are no subsequent desquamation or pigment changes. Recovery is usually rapid and without complications. Interestingly, most cases of acute primary HHV-6 infection in young children do not result in an illness recognizable as roseola. Studies have revealed that acute viremic HHV-6 infection accounts for 14% of febrile children younger than 2 years seen in an emergency room, most of whom have a nonspecific febrile illness without a rash. Other clinical manifestations of primary infection include rash without fever, fever of >40°C, intussusception, bulging of the anterior fontanelle, lymphadenopathy, hepatitis, an infectious mononucleosis-like syndrome, inflamed tympanic membranes, myocarditis, aseptic meningitis, meningoencephalitis, and encephalitis (see references 10 to 14 for reviews). Febrile seizures are a common complication of roseola; approximately one-third of all febrile seizures in childhood have been attributed to HHV-6 infection. Primary infection in adults is rare but may result in prolonged lymphadenopathy, hepatitis, encephalitis of variable severity, or an illness resembling infectious mononucleosis. Reactivated infection in healthy persons is asymptomatic. It remains to be fully established whether HHV-6 causes or contributes to disease in immunocompromised hosts, although reactivation of clinical importance in recipients of hematopoietic stem cell and solid-organ transplantation has been associated with isolated fever, hepatitis, leukopenia, delayed engraftment, neurologic dysfunction, skin rashes resembling graft-versus-host disease, bone marrow suppression, and interstitial pneumonitis (see references 15 to 20 for reviews). Also, reactivation of HHV-6 has been associated with the pathogenesis of drug-induced hypersensitivity syndrome or drug rash with eosinophilia and systemic symptoms syndrome. Evidence suggests that HHV-6 infection may contribute to disease progression with HIV type 1 (HIV-1) and may interact with other viruses, such as CMV, EBV, parvovirus B19, and human papillomaviruses, to affect their behavior and exacerbate disease. HHV-6 has also been associated with a number of other diseases in patients in whom elevated titers of HHV-6 antibody have been detected and from whom replicating virus was isolated and/or viral antigens or DNA was found. The role of the virus in most of these clinical settings, however, remains unproven and controversial.

HHV-6 is a ubiquitous virus, and humans are the only known natural host (Table 2). The mode of transmission of the virus is poorly understood but presumably requires direct, personal contact. Virus has been identified in saliva, peripheral blood mononuclear cells (PBMC), cervical and vaginal secretions, urine, and various tissues, including skin, lymph nodes, liver, spleen, heart, lungs, kidneys, and brain. HHV-6B, but not HHV-6A, actively replicates in the salivary glands of children and adults, making oral secretions the most likely source of transmission for this species. Intrauterine or perinatal transmission has been suggested. Congenital infections with HHV-6 have been described to occur in 1% of births; infected infants are asymptomatic at birth, in contrast to the acute febrile illnesses observed with primary postnatal infection (3). In this study, species A was responsible for one-third of the congenital infections, whereas species B was observed in all postnatal infections. The incidence of antibody to HHV-6 is high throughout the world, although variation in seroprevalence based on age and the serologic method employed has been reported. Newborn infants have titers of antibody to HHV-6 that are comparable to those in adults, suggesting passive transfer of transplacental maternal antibodies. With the loss of maternal antibody, the seroprevalence to HHV-6 decreases significantly by 4 to 6 months of age but subsequently rises to 90% at the end of

TABLE 2 Epidemiologic and clinical characteristics of HHV-6, HHV-7, and HHV-8

Characteristics	HHV-6	HHV-7	HHV-8
Epidemiology			
Distribution	Worldwide	Worldwide	Worldwide
Natural host	Human	Human	Human
Transmission	Oral secretions (HHV-6B only); possible blood and urine; intrauterine and perinatal transmission	Oral secretions; possibly blood and urine	Predominantly sexual contact; possibly oral secretions and blood; transplanted allograft
Seroprevalence	90% or greater	80–90%	0–25% in healthy American and European blood donors; higher in some African and Mediterranean populations; 75–95% of KS patients
Population affected	Infants (0–3 yr), organ transplant recipients	Infants (1–5 yr)	Homosexual or bisexual HIV^+ males or their sexual partners; Mediterranean males; Africans; organ transplant recipients
Incubation period	9–10 days	Unknown	Unknown
Attributable clinical illnesses	Exanthem subitum, infantile febrile illnesses without rash, rash without fever, febrile seizures, infectious mononucleosis-like illness in adults, posttransplantation and central nervous system diseases, hepatitis, drug-induced hypersensitivity syndrome/ drug rash with eosinophilia and systemic symptoms, malignancies	Exanthem subitum, infantile febrile illnesses without rash, febrile seizures, other neurologic events in children, pityriasis rosea (?)	KS, multicentric Castleman disease, primary effusion lymphoma, herpesvirus inflammatory cytokine syndrome

the first year of life. By 3 years of age, almost 100% of individuals have antibody to HHV-6; immunity is maintained throughout childhood, adolescence, and early adulthood but may decline after 40 years of age and then rise to high titers following increased rates of reactivation in elderly persons. With the exception of HHV-7, no significant serologic cross-reactivity between different herpesviruses and HHV-6 has been detected.

Immunology of HHV-6 Infection

The host response to HHV-6 infection is thought to involve both humoral and cell-mediated immunity. Children with exanthem subitum develop an immunoglobulin M (IgM) response on day 4 of illness, and the response peaks between 7 and 14 days and declines over a period of 1 to 2 months. In addition, IgM antibodies to HHV-6 can persist for extended periods after a primary infection and can reappear in reactivated infections. IgG appears on day 7 of illness, peaks at approximately 4 weeks, and persists for long periods.

The role of cell-mediated immunity in HHV-6 infections is less well defined. However, the virus appears to have the ability to modulate or alter the expression of a number of cytokines and immune activation molecules. Increased levels of alpha interferon (IFN-α) have been found during the febrile phase of exanthem subitum, while an increase in NK cell activity has been observed during the exanthem period. *In vitro* infection of PBMC with HHV-6 decreases the expression of interleukin 2 (IL-2) and cell proliferation, upregulates NK cell cytotoxicity, and induces the synthesis of the soluble cytokines IFN-γ, IL-1β, tumor necrosis factor alpha, and IL-15. The virus can downregulate CD3, CD46, and CXCR4 expression and upregulate the chemokine receptor CCR7 in infected T cells and can stimulate IL-10 and IL-12 expression in monocytes and macrophages. Also, HHV-6 infection of transformed T-cell lines *in vitro* results in an enhanced susceptibility to apoptosis. The significance of these immunomodulating properties to the interaction of infected T cells with other components of the immune system and to the pathogenesis of the virus is unclear. Macrophages are infected with HHV-6 following primary infection and may serve as a reservoir for reactivation of the virus.

Clinical Indications

Although a diagnosis of exanthem subitum in a child can be made on the basis of clinical presentation alone, laboratory confirmation is needed to detect atypical and more severe manifestations of HHV-6 infection and to more clearly define the role of HHV-6 in other childhood illnesses and in diseases of adults and immunocompromised persons (see references 21 and 22 for reviews). Various diagnostic methods can be used, including viral isolation in cell culture, demonstration of viral antigens or nucleic acids in body fluids or tissues, and serology for detection of virus-specific antibodies (Table 3).

Immunologic Diagnosis

Antigen Detection

Immunohistochemistry

Monoclonal antibodies suitable for the direct detection of HHV-6 antigens by immunofluorescence have been developed and employed with tissue samples (1). Some are

TABLE 3 Diagnostic methods for HHV-6, HHV-7, and HHV-8

Method	HHV-6	HHV-7	HHV-8
Virus culture	PBMC grown in primary culture or cocultured with CBC or donor PBMC; culture in continuous T-cell lines (HSB-2, MOLT-3, Sup-T1, J-Jhan, MT-4, ET62); spin amplification shell vial assay	PBMC grown in primary culture or cocultured with CBC or donor PBMC; culture in continuous T-cell line (Sup-T1)	Not available; $CD19^+$ B cells, BB19 papillomavirus-transformed endothelial cells, and adenovirus-transformed human kidney epithelial cell line 293 have been used to attempt culture without success
Antigen detection	Immunohistochemistry (IHC), EIA	IHC	IHC
Antibody detection	IgG and IgM by IFA, ACIF, EIA, NT test, and immunoblotting; IgG antibody avidity assay	IgG and IgM by IFA, EIA, NT, and immunoblotting	IgG by IFA using latent or lytic cells; IgG by EIA using whole-virus lysates and recombinant proteins; immunoblotting using latent and lytic recombinant proteins
Nucleic acid detection	Qualitative and quantitative real-time PCR from whole blood, PBMC, plasma, serum, and CSF; multiplex assays with other herpesviruses; reverse transcriptase PCR for mRNA transcripts	Qualitative and quantitative real-time PCR from whole blood, PBMC, plasma and serum; multiplex assays with other herpesviruses	Qualitative and quantitative real-time PCR; tissues, whole blood, PBMC, plasma, serum; urine, saliva, bone marrow, semen

available commercially and react with HHV-6A and/or HHV-6B, although discrimination of the two species is not necessary for clinical purposes. HHV-6 antigen has been demonstrated in biopsy material from allografts of kidney transplant patients, lung tissue from bone marrow transplant recipients with interstitial pneumonitis, cervical lymph nodes of patients with histiocytic necrotizing lymphadenitis and lymphoma, oligodendrocytes from patients with multiple sclerosis, abortive villous tissues from spontaneous abortions, patients with AIDS, and the salivary and bronchial glands of latently infected individuals. Productive infection of tissues with HHV-6 can be detected by using monoclonal antibodies reactive against the structural protein p101 of species B and the structural protein gp82 of species A. More recently, an HHV-6 antigenemia assay similar to that described for detecting CMV has been developed to monitor active HHV-6 infection in liver and allogeneic stem cell transplant recipients (23, 24). This immunohistochemical method involves the cytocentrifugation of purified PBMC onto microscope slides followed by the detection of HHV-6-specific early and structural antigens by monoclonal antibodies and indirect immunoperoxidase staining. The significance of the results from immunohistochemical testing is still unclear, and the results must be further validated and correlated with clinical findings and data obtained from other laboratory tests.

EIA

A commercial antigen capture enzyme immunoassay (EIA) has been developed for the detection of HHV-6 antigens directly from clinical specimens (25). The assay is based on the gp116-gp64-gp54 antigen and is specific for HHV-6 species A and B. The EIA has a sensitivity similar to that of viral culture from plasma obtained from children with exanthem subitum. Additional studies are needed to determine the utility of this EIA for rapid diagnosis of HHV-6 infection and for monitoring of HHV-6 activity in the immunocompromised host. The EIA has the advantages of being relatively simple and inexpensive to perform relative to culture or nucleic acid detection methods.

Viral Identification in Conventional Cell Culture

HHV-6 can be isolated from PBMC grown in primary culture or by cocultivation of these cells with stimulated cord blood cells (CBC) or donor PBMC (26) and has been considered the reference method for the diagnosis of active infection. Saliva and other body fluids and tissues can be cocultured with activated donor cells for isolation of the virus as well. The optimal time for collection of specimens from children with roseola is during the febrile phase, before the development of rash. Infected PBMC show a specific cytopathic effect, with intracytoplasmic and intranuclear inclusion bodies appearing within 7 to 10 days. The cytopathic effect on primary isolation can be subtle and difficult to recognize, and virus production from infected cells should be confirmed by detection of viral antigens, *in situ* hybridization, or electron microscopy. Viral antigens can be detected by indirect immunofluorescence assay (IFA), anticomplement immunofluorescence (ACIF), or EIA with commercially available reagents or kits. IFA staining reveals a characteristic granular nuclear and cytoplasmic fluorescence in infected cells. The sensitivity and specificity of immunologic reagents for confirmation of viral growth have not been extensively studied, and it is recommended that appropriate antigen and antibody controls be used when attempting to identify infected cells. HHV-6 infects a number of established continuous T-cell lines, most notably HSB-2, MOLT-3, Sup-T1, J-Jhan, MT-4, and ET62, which are used mainly to grow virus following primary isolation. The two species can be differentiated in culture by their growth in different cell lines; species B strains of HHV-6 do not replicate in HSB-2 cells, and species A strains do not replicate in MOLT-3 cells. The described culture methods are insensitive, slow, and labor-intensive and require a high level of technical expertise. Their routine use in clinical laboratories is quite limited and they are primarily performed for research purposes.

Spin Amplification Shell Vial Assay

The human diploid lung fibroblast line MRC-5 has been reported to support primary virus isolation and has been used

in a centrifugation-assisted shell vial amplification assay for the detection of the immediate-early antigen of HHV-6 from PBMC of patients (27). Panspecific polyclonal and monoclonal antibodies to the immediate-early antigen of species A and B of HHV-6 and monoclonal antibodies specific to either species A or B are commercially available; they stain the nucleus of infected MRC-5 cells as early as 12 h after infection and give maximum staining within 48 to 72 h of infection. In the assay, PBMC are obtained from heparinized whole blood by Ficoll-Hypaque density gradient centrifugation, washed once with Hanks' balanced salt solution, and resuspended in 1 ml of RPMI 1640 medium supplemented with 10% fetal bovine serum, 20 mM HEPES, and 2 μg of Polybrene per ml. MRC-5 cells are grown to confluency on 12-mm-diameter round coverslips in 1-dram (3.7-ml) vials and inoculated with 0.5 ml of specimen to each of two vials. After inoculation, the vials are centrifuged at 800 × *g* for 45 min at 25°C, and then 1.5 ml of RPMI 1640 medium is added as described above. The cultures are incubated at 37°C for 48 to 72 h, fixed in cold (−20°C) acetone for 10 min, and stained by IFA. Uninfected and HHV-6-infected monolayers are included as negative and positive controls, respectively. The monolayers are counterstained with Evans blue. Coverslips are scanned at magnifications of ×200 to ×250 with a fluorescence microscope, and specific staining is confirmed at ×400 to ×630. Staining of immediate-early antigen occurs in the nucleus of an infected fibroblast and appears as a speckled or an even matte green fluorescence. The spin amplification shell vial assay has the important features of being more rapid and less labor-intensive than conventional culture, but the sensitivity and specificity of this assay are not well defined.

In general, positive culture results are most useful to diagnose primary infection but can be difficult to interpret for immunocompromised hosts and during reactivation of the virus, when the presence of the virus may be unrelated to the clinical presentation. As with conventional cell culture, spin amplification cultures have limited utility and are not routinely used in most clinical laboratories.

Antibody Detection

A number of tests have been developed for the serodiagnosis of HHV-6 infection, of which IFA, ACIF, EIA, and the neutralization (NT) test have been most commonly employed (see references 1 and 26 for reviews). The method that is chosen depends on the volume of specimens, turnaround time, cost, equipment needs, ease of performance, reagent availability, and levels of assay sensitivity and specificity. Some commercial reagents and kits are available from a limited number of manufacturers. Overall, variation in the rates of seropositivity for HHV-6 appears to be related to the assay systems and the need for standardization of methods and reagents. The use of different cutoff values and serum dilutions and the method of preparing antigen substrates for individual assays can have a marked effect on the percentage of serum specimens that are determined to be positive for antibody to HHV-6. Overall, higher rates of seropositivity are observed when either NT or EIA is used than when the less sensitive method of IFA is used.

Collection and Storage of Specimens

Serum is the specimen of choice for most serologic assays, although plasma can normally be used as well. A total of 1 to 2 ml of serum should be collected from clotted blood. The serum should be refrigerated at 4°C shortly after collection and during transport to the laboratory. If an extended delay in transport or testing of a specimen is anticipated, the specimen should be frozen to at least –20°C. Freeze-thawing of specimens that have been frozen should be avoided. A single serum specimen is required to determine the immune status of an individual or to detect IgM-specific antibody. Paired serum specimens, collected 2 to 3 weeks apart, are required for the diagnosis of a current or recent HHV-6 infection when specimens for IgG antibody are examined. The acute-phase serum should be obtained as soon as possible after the onset of illness. The most useful results are obtained by submitting acute- and convalescent-phase sera together to be tested simultaneously.

Methods

IFA

The IFA is the most widely used method for detecting antibodies to HHV-6. Initially, IFAs were found to be both insensitive and nonspecific, in part because of the use of infected CBC as a source of antigen but also because of variations in the criteria used for positive results. With the preparation of HHV-6 antigen in continuous T-cell lines, such as HSB-2, MOLT-4, and J-Jhan, and following improvements in the definition of seropositivity, IFAs have become increasingly more sensitive and reliable.

In the IFA, HHV-6-infected cells are spotted onto wells of Teflon-coated slides, allowed to air dry completely, and then fixed in cold (–20°C) acetone for 10 min. Fixed slides can be used immediately or stored at 4°C for short periods or at –20 to –70°C for extended times. Serial dilutions of patient and positive and negative control sera are added to individual wells, and the slides are incubated at 37°C for 30 min in a humidified chamber. The slides are then washed two or three times in phosphate-buffered saline (PBS), and an appropriate dilution of fluorescein-labeled anti-human IgG or IgM is added to each well. The slides are again incubated at 37°C for 30 min in a humidified chamber, washed two or three times in PBS, counterstained with Evans blue, and air dried. Coverslips are mounted in buffered glycerol (pH 8.0), and the slides are examined at magnifications of ×200 to ×400 under a fluorescence microscope. The presence of HHV-6 antibodies in the serum is determined by the observation of positive fluorescence within infected cells. Antigen substrate slides can be purchased commercially, and some manufacturers provide kits that contain all the necessary reagents for staining, including diluted conjugated antibody, wash buffer, mounting fluid, control sera, and substrate slides. When testing for HHV-6-specific IgM antibodies, serum samples should be appropriately treated before the test, to decrease the incidence of false-positive results due to interfering rheumatoid factor or false-negative results caused by high levels of specific IgG antibodies blocking the binding of IgM to HHV-6 antigen.

ACIF

The ACIF test is an immunofluorescence assay that has been developed to reduce the nonspecific fluorescence observed when CBC are used in the IFA. It also has the added advantage of enhancing the fluorescent signal from positive cells. As with IFA, HHV-6-infected cells are spotted onto wells of Teflon-coated slides, allowed to air dry completely, and then fixed in cold (–20°C) acetone for 10 min. Sera are heat inactivated at 56°C for 30 min, and serial dilutions are added to individual wells. The slides are incubated at 37°C for 30 min in a humidified chamber and then washed two or three times in PBS. HHV-6-specific antibody bound to the infected cells is detected by incubating the slides with a source of complement at 37°C for 30 min in a humidified

chamber, washing the slides in PBS, and then incubating the slides with fluorescein-conjugated anticomplement antibodies for a final 30 min at 37°C. The slides are washed, counterstained, air dried, mounted in buffered glycerol (pH 8.0), and examined at magnifications of ×200 to ×400 under a fluorescence microscope. The presence of nuclear and cytoplasmic fluorescence within infected cells indicates positivity for antibodies to HHV-6.

EIA

EIAs for the determination of HHV-6 antibodies have been developed. HHV-6-infected and uninfected HSB-2 cells are harvested by centrifugation and disrupted by one of several methods, such as sonication in glycine buffer (pH 9.5) for 30 s, solubilization in Tris-Triton X-100 buffer, or cycles of freezing and thawing. Polystyrene 96-well microtiter plates are then coated with optimal dilutions of antigen by overnight adsorption of the antigen at 4°C. Coated plates can be stored at –20°C for extended periods. Prior to use, the plates are washed three times in PBS-0.05% Tween 20 and the wells are blocked for 30 min with PBS containing 1% bovine serum albumin. Diluted patient serum and controls are added to antigen wells of infected and uninfected cells, and the plates are incubated for 1 h at 37°C. The plates are then washed three times with PBS-Tween 20, and bound antibody is detected by reaction with an enzyme-conjugated anti-human IgG or IgM antibody at 37°C for 1 h. After washing is performed as described above, a substrate is added, and the plates are incubated for 30 to 45 min at room temperature. Following color development, the reaction is stopped and the absorbance of each well is read with a spectrophotometer. The results are calculated by subtracting the absorbance in wells containing uninfected cell antigen from the absorbance in wells containing infected cell antigen. The main advantages of the EIA are that it is rapid and more sensitive than the IFA and the results can be evaluated in an objective manner. In addition, the EIA is applicable to large numbers of specimens, and the potential for automation is excellent. Kits that detect HHV-6 IgG and IgM antibodies are now commercially available, although the performance characteristics of these reagents have not been fully elucidated. A μ-capture EIA has been developed to enhance the specificity for the detection of HHV-6-specific IgM antibody in human sera (28).

NT Assay

Neutralizing antibodies to HHV-6 are determined in the NT assay by mixing serial two-fold dilutions of patient sera in microtiter plates with an equal volume of cell-free virus containing $10^{2.5}$ 50% tissue culture infective doses per 0.1 ml. After 1 h of incubation at 37°C, 2×10^5 HSB-2 or MOLT-4 cells or CBC are added to each well, and the cultures are maintained for 7 days at 37°C. The antibody titer is determined as the reciprocal of the highest dilution of serum that completely prohibits the observation of viral cytopathic effect or the detection of antigen by IFA. The NT assay has a sensitivity and a specificity that are comparable to those of EIA, but the method is cumbersome, labor-intensive, and less suited to a routine diagnostic laboratory.

Antibody Avidity Assay

An indirect immunofluorescence antibody avidity test has been used to distinguish primary from past infections with HHV-6 (29). Since the binding of an antibody increases with time after exposure to an antigen, a primary antibody response to HHV-6 infection would be of much lower avidity than an antibody response that had occurred in the more distant past or following viral reactivation. By using urea to disrupt hydrogen bonds following binding of HHV-6-specific IgG antibody to antigens in the immunofluorescence assay, low-avidity antibody-antigen reactions are preferentially dissociated and differentiated from high-avidity antibody-antigen reactions. This test has been successfully used to diagnose primary HHV-6 infection in children with rashes and to distinguish primary from secondary antibody responses in solid-organ transplant recipients.

Other Serologic Tests

Western immunoblots and radioimmunoprecipitation are other serologic assays that are used to measure antibody to HHV-6. These assays have been used mainly in research settings to identify and analyze the role of specific proteins in the immune response to HHV-6. More recently, a microwell-adapted immunoblot system using recombinant antigens has been developed to distinguish specific antibody responses to HHV-6A and HHV-B (30).

Molecular Diagnosis

The diagnosis of HHV-6 infection is increasingly being made by the amplification of viral DNA by molecular methods (see references 31 and 32 for reviews), and PCR is now considered the reference method used by most clinical laboratories worldwide. Many in-house and some commercial qualitative assays have been developed and have been shown to be sensitive and specific for the diagnosis of HHV-6 infection. Multiplex conventional and real-time PCR assays for the simultaneous detection and differentiation of HHV-6 species A and B and HHV-7 also have been described (33, 34), although it is not clinically necessary to discriminate between the two species of HHV-6. Amplification has been performed with a number of different primer pairs, including those from the immediate-early antigen 1 and 2, large tegument protein (U31), DNA polymerase, U22, U65-U66, and U67 regions of the HHV-6 genome. PCR has been used successfully to qualitatively detect HHV-6 DNA in a variety of clinical specimens from solid-organ and hematopoietic stem cell transplant recipients; children with roseola, acute febrile illnesses, encephalitis, and other clinical manifestations of primary HHV-6 infection; AIDS patients; and individuals with less common forms of HHV-6 infection. However, qualitative PCR for HHV-6 diagnosis cannot reliably distinguish between active disease and asymptomatic infection or latency, and HHV-6 DNA can often be detected in saliva and, to a lesser extent, in blood of healthy individuals. Measuring the level of HHV-6 DNA appears to be necessary to predict and diagnose HHV-6 disease, particularly in immunocompromised individuals such as transplant recipients with illnesses that may be associated with reactivation of the virus or that are possibly caused by another pathogen. Consequently, conventional and real-time quantitative PCR assays have been developed (35–39) and used to monitor the levels of HHV-6 DNA in a variety of different body fluids and tissues of both healthy subjects and selected patient populations. Similar to the diagnostic paradigm for CMV, these assays may be useful to associate HHV-6 infection with disease, to predict and monitor disease progression, to assess the efficacy of antiviral drugs, and to facilitate our understanding of the natural history and pathogenesis of this virus. Currently, there is a definite need for traceable and commutable international reference HHV-6 DNA standards for institutional comparison of results, since significant variability in HHV-6 quantification has been observed between laboratories (40). As with CMV, viremia is considered to be the best predictor of disease, and quantitative measures of HHV-6 DNA in PBMC,

plasma, serum, or whole blood have proven useful for the continued surveillance and management of transplant recipients. When testing transplant recipients, it is more important to monitor the relative changes in DNA levels from serial blood specimens collected over time, since absolute HHV-6 DNA levels or breakpoints for symptomatic disease have not been determined. It may also be important to monitor both plasma and PBMC fractions of blood or to use whole blood, since it has been reported that both HHV-6 species A and B are detected in plasma but only species B can be found in PBMC of patients after bone marrow transplantation (41). In general, whole blood is considered to be the most practical specimen of choice for the detection of HHV-6 viremia by PCR (42). Plasma has been shown not to be as sensitive as whole blood or PBMC for detecting HHV-6 and may not be as useful to distinguish between active viral replication and chromosomal integration since HHV-6 DNA in plasma may reflect the presence of infected blood cells rather than circulating virus particles indicative of active infection (43, 44).

Reverse transcriptase PCR assays for the detection and quantification of specific HHV-6 mRNA transcripts that are expressed only during active infection have been used as a substitute for quantitative measures of DNA in blood to assist in identifying patients at greatest risk for developing symptomatic infection (45, 46). These assays have targeted immediate-early, early, and late gene transcripts and may prove to be more specific and applicable to correlate detection with active disease. In a recent study, reverse transcriptase PCR was shown to accurately distinguish between primary HHV-6 infection, chromosomal integration of HHV-6, and latent HHV-6 infection. Alternatively, qualitative detection of HHV-6 in cell-free specimens such as serum or plasma can be diagnostically useful in supporting a causal relationship between active HHV-6 infection and disease (47).

Antiviral Susceptibility Testing

Resistance of HHV-6 to ganciclovir is extremely rare, but has been reported in a patient with AIDS and in recipients of solid organ and hematopoietic stem cell transplantation (48). Mutations in the U69 and/or U38 genes confer resistance to ganciclovir. Both culture-based phenotypic assays and PCR-based molecular genotypic assays have been described to measure the susceptibility of HHV-6 to antiviral drugs, although neither system is currently available for use in a clinical setting.

Interpretation of Results

The ubiquitous distribution of HHV-6 throughout the world, its latency in a variety of cell types, and the integration of the complete HHV-6 genome into the human genome complicates the interpretation of laboratory studies, and a combination of methods may be required to confirm the relationship of HHV-6 infection with various diseases. Also, most diagnostic methods for HHV-6 are not fully developed; the sensitivity, specificity, and positive and negative predictive values of each assay have not been systematically evaluated in controlled, prospective studies; and reagents have only more recently been made available to diagnostic laboratories through commercial sources.

In general, conventional and spin amplification culture-based assays for growth of HHV-6 from specimens have limited utility and little to no impact on clinical decision making due to their overall lack of sensitivity and technical difficulties in performing these assays. Serologic testing is most useful for diagnosing primary infections with HHV-6 in children with acute illnesses and for studies of the epidemiology, clinical pathology, and natural history of the virus. For interpretation of serologic tests, a history of seroconversion from a negative to a positive IgG antibody response to HHV-6 between acute- and convalescent-phase sera or the presence of IgM or low-avidity IgG in a single serum sample during a primary infection helps establish HHV-6 as the causative agent. If a serum sample from early in an illness contains HHV-6 antibodies and a four-fold or greater rise in titer is demonstrated in a second specimen taken several weeks later, a diagnosis of recent infection due to reactivation or reinfection can be made. If acute- and convalescent-phase sera are both positive for HHV-6 antibody but the antibody titer is unchanged, the result is interpreted as HHV-6 infection at some time in the past. Screening a single serum specimen for IgG antibody to HHV-6 can also provide evidence of previous exposure to the virus and assists in identifying individuals at risk for HHV-6 infection.

The use of serologic techniques to establish the presence of active HHV-6 infection can be problematic; the detection of HHV-6-specific IgG or IgM antibodies may not always indicate primary infection, and in the setting of reactivation or latent infection, conventional serologic studies have limited value in establishing an association with disease. Increased titers of IgG to HHV-6 may occur during infections with other herpesviruses, such as CMV, EBV, or HHV-7, and the relative importance of each virus in producing disease may be difficult to determine. Variations in the detection of HHV-6-specific antibodies have been observed and may be related to the methods and reagents used. The use of insensitive assays may inappropriately indicate that HHV-6 infection has been excluded or that a positive seroconversion had occurred when, in fact, this may represent an inability to detect low levels of antibody during reactivation. Assays should also be extensively evaluated for specificity to detect potential cross-reactivity with other herpesviruses. Results of serologic tests for IgM antibody should be interpreted with caution; IgM antibody can appear in both primary and reactivated HHV-6 infections and can persist for extended periods after a primary infection. Also, some children may not develop detectable IgM responses during primary infection. A recognized technical problem with HHV-6 IgM assays is the occurrence of false-positive and false-negative reactions due to high levels of competing rheumatoid factor and HHV-6-specific IgG.

In the immunocompromised host, the use of direct detection methods to diagnose HHV-6 disease is most beneficial for patient care. To implicate HHV-6 as the cause of an illness, laboratory confirmation of active disease in an appropriate clinical setting is required. However, the proper selection of methods for the diagnosis and monitoring of HHV-6 disease is a challenge. Differentiation between primary, latent, or reactivated infection or chromosomally integrated HHV-6 can be difficult and may require that more than one assay be used. Quantitative measures of HHV-6 DNA may provide a rapid diagnosis of active disease, identify patients at risk of developing disease, assess the progression of disease, and possibly direct the initiation of antiviral therapy in most patients, while detection and quantification of specific HHV-6 mRNA transcripts may also be necessary to differentiate active disease in individuals suspected of having chromosomally integrated HHV-6. Of note, in the small percentage of individuals who have chromosomally integrated HHV-6, viral loads are persistently high in specimens such as whole blood, plasma, PBMC, saliva, urine, and hair follicles and other tissues in the absence of viral replication, and viral loads of $>1 \times 10^6$ copies/ml in whole blood or 1×10^4 copies/ml in plasma are strongly suggestive of chromosomally integrated HHV-6 DNA rather than active infection (7, 8).

However, these values are not absolute, and overlapping viral loads have been observed in children during primary infections and in immunocompromised patients with symptomatic reactivated infections. Such levels are normally transient and will decline with time in the latter populations, while serial testing of patients with chromosomally integrated HHV-6 DNA will show persistently high HHV-6 viral loads. Also of concern is the fact that in patients with chromosomally integrated HHV-6 DNA who have acute neurologic presentations and a cerebrospinal fluid (CSF) pleocytosis due to other pathogens, a CSF PCR for HHV-6 DNA may be incidentally positive and not be a true reflection of central nervous system disease with this virus. Recently, a droplet digital PCR assay has been developed which appears to accurately identify chromosomally integrated HHV-6 DNA in cellular patient specimens by determining the ratio of HHV-6 to cellular DNA; a ratio of 1:1 of virus to human genomes confirms the diagnosis (49). Lastly, testing of hair follicles or nails by real-time PCR can also be used to confirm the presence of chromosomally integrated HHV-6 since only individuals with HHV-6 DNA integrated into the host chromosome have detectable HHV-6 DNA in these tissues (50, 51). However, receipt and processing of these types of specimens in a clinical laboratory is unusual.

The lack of well-defined, commercially available reagents and standardized methods and controls has made the interpretation of laboratory results for HHV-6 more difficult. Whenever possible, serologic diagnoses of HHV-6 infection should be confirmed by virus isolation or suitable direct detection methods. To implicate HHV-6 as the cause of certain diseases, it may also be necessary to use methods that measure active virus replication, since the qualitative detection of virus or viral DNA may simply indicate the presence of the virus in a latent state. A more accurate assessment of the involvement of HHV-6 in a given disease may be provided by the detection of cell-free viral DNA in serum or plasma by PCR, by qualitative or quantitative amplification of specific HHV-6 mRNA transcripts, by detection of viral antigen expression in tissues or PBMC by immunohistochemistry or *in situ* hybridization, or by quantitative assessment of the viral load by DNA PCR.

HHV-7

Introduction

HHV-7 was first isolated in 1989 from PBMC of a healthy individual (52) and belongs to the genus *Roseolovirus* (Table 1). In contrast to HHV-6, little is known about the prevalence, biology, and pathogenesis of this virus. HHV-7 is morphologically identical to other herpesviruses but, like HHV-6, is characterized by having a tropism for $CD4^+$ T lymphocytes, by causing infection early in life, and by being ubiquitous, with a seroprevalence rate of more than 85% in U.S. and European populations (see references 5, 11, 21, and 53 for reviews). Lower rates of seropositivity in Japan have been reported. After primary infection, HHV-7 can persist in the host in a latent state and reactivation can occur. Primary infection in children is thought to occur somewhat later in life than primary infection by HHV-6, usually after 24 months of age and by 5 years of age, although higher rates of seropositivity have been reported at a younger age (54). Salivary glands appear to be a main site of viral replication for HHV-7 as the virus is frequently and consistently isolated from the saliva of infected individuals, and transmission is likely to occur from contact with respiratory secretions. HHV-7 has also been detected in breast milk, PBMCs of most healthy adults, cervical secretions, bone marrow, cerebrospinal fluid, and bronchoalveolar lavage fluid. Seroconversion to HHV-7 antibody positivity is a separate and distinct event from production of antibody to HHV-6. The virus can be grown in PBMC or CBC and shows a characteristic cytopathic effect of membrane blebbing and large, refractile multinucleated giant cells indistinguishable from the cytopathic effect of HHV-6. A single continuous T-cell line (Sup-T1) can support the growth of HHV-7 with variable success. In general, HHV-7 has a narrower cell tropism and its growth in culture is more cell associated, less cytopathic, and slower than HHV-6. The virus is closely related to HHV-6 but has been shown to be genetically and immunologically distinct. Unlike for HHV-6, genetic variants have not been described for HHV-7. The linear, double-stranded DNA of HHV-7 is approximately 145 kb and has no homology to that of EBV, herpes simplex virus, or varicella-zoster virus and has limited homology to that of CMV. Therefore, HHV-7 has been classified as a member of the subfamily of betaherpesviruses with HHV-6 and CMV. Virus particles of HHV-7 measure 170 nm and contain an icosahedral nucleocapsid surrounded by a tegument and an envelope containing virus-encoded glycoproteins. Western immunoblot analyses of viral proteins reveal different patterns for HHV-6- and HHV-7-infected cells, although monoclonal antibodies to HHV-6 can cross-react with HHV-7-infected cells. The HHV-7 genome has the capacity to code for 84 different proteins and a number of viral proteins have been identified, ranging in size from 30 to 136 kDa.

The clinical spectrum of disease caused by HHV-7 is poorly understood. Most infections are asymptomatic, but HHV-7 has been associated with up to 10% of roseola cases and, as with HHV-6, primary infection is thought to be responsible for febrile seizures and other neurologic events in children (Table 2) (see reference 55 for a review). The virus also has been isolated from patients with a chronic viral syndrome and occasionally in children with a nonspecific febrile syndrome without rash. No viruses other than HHV-7 were isolated in these cases, and a seroconversion to HHV-7 but not HHV-6 positivity was documented. There is some evidence to suggest that HHV-7 also may play an etiologic role in pityriasis rosea. Little is known about disease caused by HHV-7 in immunocompromised patients, although reactivation of the virus in bone marrow and solid-organ transplant recipients is common (see reference 16 for a review). The glycoprotein CD4 is a critical component of the receptor on the surface of T lymphocytes for HHV-7; it has been shown that a selective and progressive downregulation of the expression of CD4 in HHV-7-infected T cells leads to a marked reciprocal interference of HIV infection, although the clinical significance of this interaction is unknown. Infection of PBMC with HHV-7 enhances NK cell cytotoxicity by induction of IL-15. HHV-7 also may interact with other herpesviruses, leading to the reactivation of HHV-6 and CMV. Reactivation of HHV-7 has been reported to be a cofactor for the progression of CMV disease in renal transplant patients infected with CMV, and isolated cases of encephalitis, meningitis, myelitis, and optical neuritis have been reported following stem cell transplantation.

Immunologic and Molecular Diagnosis

The methods for laboratory diagnosis of HHV-7 are essentially identical to those for diagnosis of HHV-6 (Table 3) and currently include the direct examination of clinical specimens for viral antigens by immunohistochemistry (56) or viral nucleic acids by *in situ* hybridization and PCR (35,

57), virus identification in cell culture (52), and detection of antibodies against the virus (54). An HHV-7 antigenemia assay similar to that described above for HHV-6 has been developed for the detection of HHV-7 early and late antigens in PBMC isolated from recipients of liver and allogeneic stem cell transplants (23). The serodiagnosis of HHV-7 infection can be made by IFA, EIA, and Western immunoblot assays, using HHV-7-infected cells as an antigen source. Seroconversion to HHV-7 antibody positivity, as determined by IFA, is independent of that to HHV-6 antibody positivity and is diagnostic for primary infection. An antibody response to HHV-7 is induced only by HHV-7 infection, since neither seroconversion nor a significant rise in the titer of antibody to HHV-7 can be detected following primary infection with HHV-6. Conversely, seroconversion to HHV-7 antibody positivity can cause a simultaneous rise in the titer of antibody to HHV-6. This is thought to be due to the ability of HHV-7 to induce a response of memory B cells against HHV-6 cross-reactive antigens or to be due to reactivation of HHV-6 during infection with HHV-7. HHV-6 antibodies are not protective against HHV-7 infection, since seroconversion to HHV-7 antibody positivity can occur in the presence of high titers of antibody to HHV-6. The presence of antigenic cross-reactivity between HHV-6 and HHV-7 should be considered when performing serologic assays; it may be necessary to preadsorb patient sera to infected cells for specific determination of titers of antibody to each virus. Antibody assays based on an 89-kDa protein or glycoprotein B of HHV-7 also have been developed and do not appear to cross react with antibodies to HHV-6. More recently, an HHV-7 antibody avidity assay has been developed and validated and used in conjunction with the HHV-6 avidity test described above to detect and distinguish primary from past infections with either HHV-6 or HHV-7. In addition, dual primary HHV-6 and HHV-7 infections have been confirmed by using these assays.

Both conventional and real-time PCR assays have been described for the detection of HHV-7 DNA from clinical specimens. As with HHV-6, qualitative PCR assays are not able to differentiate active disease from asymptomatic infection or latency, and HHV-7 DNA is frequently found in saliva and PBMC of healthy individuals. To this end, PCR assays for quantitating HHV-7 DNA from whole blood and mononuclear and polymorphonuclear cells in infected individuals have been developed and are being evaluated for the ability to correlate the viral load of HHV-7 with clinical disease and response to antiviral therapy, and to facilitate studies of the epidemiology of the virus (35, 42, 58, 59).

The interpretation of laboratory results for HHV-7 is similar to that described for HHV-6 and is confounded by a paucity of commercially available reagents and, as with HHV-6, by the ubiquitous nature of this virus. In addition, caution is needed in interpreting the results of serologic studies because of the cross-reactivity of HHV-7 with HHV-6 and because of the ability of HHV-7 to reactivate other members of the herpesvirus family. With serologic evidence of dual infection, it may be difficult to determine the relative importance of each virus in causing disease. Virologic methods, including viral culture, rapid direct detection of antigens and/or nucleic acids, and serology, must be combined with a clinical assessment of the patient to provide a reliable determination of HHV-7 infection and to establish a clear relationship between infection and human disease. It may also be necessary to monitor viral load or other measures of active virus replication to help in our understanding of the natural history and pathogenesis of this virus.

HHV-8

Introduction

Using the molecular technique of representational difference analysis, HHV-8, also termed Kaposi's sarcoma (KS)-associated herpesvirus, was first identified by Chang et al. (5) in 1994 in more than 90% of KS tissues obtained from patients with AIDS. Subsequently, HHV-8 has been detected in patients with all forms of KS from all parts of the world, including AIDS-related or epidemic KS and classic KS in older men of Mediterranean and Eastern European origin, HIV-1-negative African endemic KS of adults and children, and KS in persons with iatrogenic immunosuppression, most often organ transplant recipients (see references 60 to 65 for reviews). HHV-8 also has been detected in other lymphoproliferative disorders such as AIDS-related primary effusion lymphomas (formerly called body cavity-based lymphomas) and multicentric Castleman disease and in KS-associated herpesvirus inflammatory cytokine syndrome (66, 67). In addition, HHV-8 has been implicated in the pathogenesis of other diseases, including multiple myeloma, sarcoidosis, angiosarcoma, non-KS skin lesions (including squamous and basal cell carcinomas) of immunocompromised patients, and multiple sclerosis. However, numerous follow-up studies using PCR-based and serologic assays have failed to corroborate the original findings, making it unlikely that HHV-8 is associated with these latter disorders. Little is known about primary HHV-8 infection in healthy individuals, and the diseases associated with this virus are thought to be more probably due to viral reactivation. Primary infection in immunocompetent children may be associated with fever and a maculopapular rash and severe clinical manifestations, including marked fever, splenomegaly, pancytopenia, lymphoid hyperplasia and occasionally rapid-onset-KS among immunocompromised solid organ transplant recipients and HIV-infected individuals.

The biology, epidemiology, and pathogenesis of this virus are still not fully understood, but significant advances have been made over the years (see references 60, 61, and 68 to 70 for reviews). HHV-8 is classified as a gammaherpesvirus in the genus *Rhadinovirus* and has sequence homology to the simian virus herpesvirus saimiri and EBV (Table 1). These viruses establish persistent, latent infection and are associated with immortalization and transformation of cells and play an important role in the development of malignancies. The replicative form of the HHV-8 genome is approximately 165 kb in length, and 97 genes have been identified. Several genes have homology to human genes, such as those encoding cyclin D (a cell cycle inducer), various cytokines, and Bcl-2 (a blocker of apoptosis). Expression of these genes may help explain the association of HHV-8 with cell transformation and the development of tumors. Viral replication may be affected by interaction with other viruses such as HIV-1 and EBV, since body cavity lymphoma cells are frequently coinfected with EBV and tumors associated with HHV-8 are often seen in persons infected with HIV-1. It also has been demonstrated that HIV-1 can increase HHV-8 replication in a body cavity lymphoma cell line. Genetic diversity exists among viral isolates of HHV-8, resulting in the identification of strains A, B, and C; strain A has been found mainly in patients with AIDS-associated or classical KS, while strains B and C are seen more often among African patients. The virus has a broad cell tropism and can infect $CD19^+$ B lymphocytes, the flat endothelial cells lining vascular spaces, macrophages, and the perivascular spindle cells of KS lesions. Its distribution is worldwide, although it is not ubiquitous in most populations and

there is considerable variation in its prevalence, which is related to the geographic and demographic distribution of KS (Table 2). The precise modes of transmission are unknown. Based on the epidemiology of HHV-8, however, it is thought to be transmitted through sexual contact, predominantly among homosexual and bisexual HIV-1-positive males or their sexual partners. Likely sources of infection for sexual transmission are semen and possibly female genital secretions; HHV-8 DNA has been found in the semen of male AIDS patients and in cervicovaginal specimens from HHV-8-seropositive women. Although HHV-8 DNA has yet to be found in feces, sexual practices involving oral-anal contact may be a risk factor for homosexual transmission. HHV-8 also has been detected in oral secretions and PBMC of HIV-1-infected males and in the blood of an apparently healthy blood donor following multiple donations. Widespread horizontal transmission from oral secretions may be responsible for the high rate of HHV-8 infection in areas where KS is hyperendemic. However, the transmission of HHV-8 by blood or the respiratory route in populations at low risk for KS is likely to be uncommon. Transmission through organ transplantation has been documented and is of concern for this patient population.

Immunologic and Molecular Diagnosis

The laboratory diagnosis of HHV-8 infection is possible using molecular methods such as PCR or using serologic assays (Table 3) (see reference 71 for a review), although the clinical need for testing has not been defined. These methods have been used mainly to study the epidemiology of HHV-8 and to investigate the relationship between HHV-8 and the pathogenesis of various diseases. Assays are currently available only in research laboratories, and there are few commercial sources of reagents.

PCR is the primary method used for the direct detection of HHV-8 from tissues, from body fluids such as serum, plasma, urine, saliva, bone marrow, and semen, and in PBMC from infected individuals. The most widely used primers are those originally described by Chang et al. (72) and are specific for the highly conserved 233-bp region of the KS330Bam fragment (open reading frame [ORF] 26). Other useful primer sets have been evaluated and include those that amplify gene sequences of ORFs 8, 25, 37, 65, 72, 73, 75, K5, and K6. Quantitative conventional (73) and real-time (74–78) PCR assays have been developed to measure the HHV-8 viral load in PBMC, plasma, or tissues of individuals with AIDS-associated KS, classical KS, AIDS-related primary effusion lymphomas, and multicentric Castleman disease and organ transplant recipients. These assays may be useful to determine the exact mode(s) of transmission of the virus, to assist in the diagnosis of KS and other diseases associated with HHV-8 infection, to identify those individuals at highest risk of disease, to predict the progression to and development of KS, and to assess the efficacy of different therapeutic regimens. It has been shown that individuals with HHV-8-related diseases have more HHV-8 DNA in either plasma or PBMC than do persons without disease, but the level of HHV-8 DNA in plasma is significantly higher than that in PBMC. Quantitation of HHV-8 in plasma, therefore, may be more accurate for evaluating the risk of HHV-8 disease progression and the efficacy of therapy.

Attempts to culture HHV-8 have met with great difficulty, and current methods are labor-intensive and impractical for diagnostic use. Nevertheless, $CD19^+$ B cells, the human papillomavirus-transformed endothelial cell line BB19, and the adenovirus-transformed human kidney epithelial cell line 293 have been used to grow virus from KS spindle cells, fluids from body cavity lymphomas, and filtered cell culture fluids from $CD19^+$ cells positive for HHV-8. However, continual replication in these cell lines has not been successful. Monoclonal antibodies specific to HHV-8 have been described and are currently being used to localize HHV-8 in infected cells and tissue by immunocytochemistry and flow cytometry. These antibodies are not widely available for diagnostic use.

Serologic testing for HHV-8 can be done by a variety of formats, including IFA, EIA, and immunoblot assays. Similar to serologic tests for EBV, these assays have been designed to detect antibody responses to HHV-8-specific antigens expressed during latency or lytic infection. Antigens currently used in HHV-8 serologic assays include purified viral particles, whole cells, or isolated nuclei prepared from HHV-8-infected cell lines derived from body cavity-based lymphomas, whole-cell lysates, recombinant viral proteins, and synthetic peptides.

IFAs for measuring HHV-8-specific antibody responses from patient sera are usually done with HHV-8-infected whole cells fixed onto slides as the substrate. The cell lines BC-1 and HBL-6, which are latently infected with HHV-8 and coinfected with EBV, were originally used to develop some of the first IFAs for the detection of HHV-8 antibodies against nonstructural latent antigens of the virus, particularly the latency-associated nuclear antigen (LANA). Antibody cross-reactivity is of primary concern with assays that use cells infected with both HHV-8 and EBV; cell lines such as BCP-1 and BCBL-1, which are infected with HHV-8 alone, are now being used in most whole-cell IFAs to minimize cross-reactions with antibodies to other herpesviruses. For measurement of antibodies to lytic antigens by IFA, HHV-8-infected cell lines are treated with phorbol esters or sodium butyrate. This results in the chemical induction of a lytic cycle of viral replication and the expression of lytic antigens that usually correspond to structural viral proteins. When using IFA, the presence of stippled immunofluorescence in the nuclei of uninduced cells is representative of an antibody response to LANA, while antibodies against HHV-8 lytic antigens are measured by observing fluorescence as diffuse cytoplasmic staining, spots in the nucleus, or localized to the membrane of the induced cells. A monoclonal antibody-enhanced IFA (mIFA) has been described and uses a mouse monoclonal antibody and induced or uninduced BCBL-1 cells for detecting antibodies to latent and lytic HHV-8 antigens. Although IFAs can be used to detect a range of antibody responses to various latent and lytic proteins of HHV-8, the procedures are labor-intensive and subjective, requiring considerable experience and critical evaluation to ensure reliable results. Extensive quality control is also needed to monitor the appropriate expression of lytic antigens in induced cells and to prepare the substrate slides.

EIAs have been developed that use whole viral lysates as antigens for detecting HHV-8 antibodies. The whole-virus EIA is designed to detect IgG antibodies to nonstructural and most structural HHV-8 antigens; it uses a viral lysate prepared from sucrose gradient-purified whole virions obtained from the cell line KS-1. More recently, recombinant proteins of the lytic viral capsid antigen from ORF 65 or peptides corresponding to a fragment of the minor capsid protein from ORF 26 have been used in the development of HHV-8 serologic EIAs.

Immunogenic latent (encoded by ORF 73 [LANA]) and lytic (encoded by ORFs 65, K8.1, K8.1A, and K8.1B, and ORF 26) proteins have also been recombinantly expressed and used in immunoblot assays (79). Reactions to LANA on immunoblot assays are seen as a high-molecular-mass

doublet of 226 and 234 kDa. The ORFs corresponding to K8.1 encode HHV-8-specific envelope glycoproteins of 35 to 40 kDa. As a whole, the performance characteristics of these immunoblot assays have not been fully established.

With most of the available serologic assays, HHV-8-specific antibodies have been detected in the majority of individuals with KS, AIDS-related primary effusion lymphomas, or multicentric Castleman disease. Among persons infected with HIV-1, the seroprevalence for HHV-8 is highest in HIV-1-infected homosexual males, indeterminate in intravenous drug users and persons infected through heterosexual contact, and lowest in hemophiliacs, women, and children. It also has been shown that seroconversion to HHV-8 antibody positivity precedes the progression to KS and predicts the subsequent appearance of KS lesions in HIV-1-infected individuals. In the general population, the highest seroprevalence rates for HHV-8 are seen in sub-Saharan Africa and Mediterranean countries, while rates in northern European, North American, and Southeast Asian countries are relatively low.

In several studies done to compare the various HHV-8 antibody assays (79–81), good assay correlation was obtained when testing sera from individuals with KS. The most significant discrepancies between assays were observed when determining the seroprevalence of HHV-8 in high-risk groups without KS or in groups at minimal risk for HHV-8 infection, such as blood donors. While the different methods showed similar antibody trends within the various epidemiological and population groups, they did not always agree. Considerable variation in sensitivity and specificity was observed from one assay to another when testing individual serum specimens within defined panels of sera from different populations. This appears to be related to the choice of assays, the use of different serum dilutions and cutoff values, the selection and preparation of antigen(s) used, and the lack of standardized methods and reagents. In general, the mIFA using lytic antigens identifies the highest number of individuals with HHV-8-specific antibodies, while assays based on latent antigens or individual HHV-8 proteins and peptides are less sensitive. The specificity of the lytic mIFA has been questioned because this assay detects HHV-8 antibodies in a much higher percentage of healthy blood donors and the results have not been corroborated by other assays. However, it is still unknown whether the lytic mIFA is just more sensitive or truly detects cross-reactive antibodies. In general, nonspecific reactions have been found to occur when IFAs are performed with sera at dilutions of <1:40, particularly if the cells used as an antigen source were chemically induced. Dilutions as high as 1:100 or 1:160 have been recommended to avoid such reactions, but such dilutions also may lead to false-negative results. Single-antigen assays do not appear to detect all antibody responses to infection with HHV-8, but use of these tests has demonstrated that individuals may differ in their abilities to recognize different HHV-8 proteins and that different antibody profiles can develop during the course of HHV-8 infection (81). It is clear that no one assay is completely sensitive and specific, and that combinations of several assays or combinations of several antigens in a single assay may be required to accurately determine the seropositivity to HHV-8, particularly in the general population (81). Zhu et al. (79) have shown that IFA antibody positivity to both latent and lytic antigens followed by confirmation with an immunoblot assay using a panel of latent and lytic immunogenic recombinant antigens provides a reliable, sensitive, and specific measure of HHV-8 antibodies. More recently, a luciferase immunoprecipitation assay has been developed that can measure profiles of antibody responses against multiple latent and lytic HHV-8 antigens (82). Significant differences in antibody levels were observed between patients with KS, multicentric Castleman disease, and primary effusion lymphoma when using this assay, possibly reflecting altered protein expression and/or differences in immune recognition among these diseases.

Until serologic assays are extensively evaluated and better standardized, their utility for diagnosing HHV-8 infection and for determining the immune status of an individual is limited and the interpretation of results is difficult. As with HHV-6 and HHV-7, it may be necessary to correlate serologic results with direct antigen and/or nucleic acid detection and to quantify the HHV-8 viral load to reliably detect infection and to establish a clear relationship between infection and human disease.

Parvovirus B19

STANLEY J. NAIDES

62

Autonomous parvoviruses capable of helper-virus-independent replication have been isolated from many animal species. The human serum parvovirus B19 was accidentally discovered in 1975 in healthy donor blood used in the development of hepatitis B virus surface antigen diagnostic tests. To date, three B19-type genotypes have been described: types 1 (B19), 2 (A6/K71), and 3 (V9). Disease variation has not been reported amongst the three genotypes (1–3). Bocavirus, another parvovirus, has been associated with pulmonary infection (4). PARV4 has been identified in a parenteral drug abuser, but human disease causation has not been confirmed (5, 6). Recently, a proposal was submitted to the International Committee on Taxonomy of Viruses to reclassify B19 as primate erythroparvovirus type 1. The most frequent clinical presentation of B19 infection is erythema infectiosum, or fifth disease, a common childhood exanthem. Application of sensitive molecular biological and immunological methods to viral diagnosis has allowed recognition of the ever-expanding spectrum of clinical presentation (7).

BIOLOGICAL, CLINICAL, AND EPIDEMIOLOGICAL FEATURES

Physicobiochemical Characteristics

B19 and its variants are currently members of the *Erythrovirus* genus, subfamily *Parvovirinae*, family *Parvoviridae*; the genus contains members of the family that infect mammalian hosts and are autonomous in their ability to replicate in host erythroid precursors. Parvovirus B19 is one of the smallest (18 to 26 nm in diameter) DNA viruses known to infect humans. It forms nonenveloped icosahedral virions. The single-stranded genome contains approximately 5,600 nucleotides (8) and has double-stranded palindromic hairpin termini. B19 encapsidates a single copy of genome. Progeny virus populations are represented by equal numbers of virions containing positive- or negative-sense DNA.

B19 employs a simple coding strategy. A single strong promoter at map unit 6 initiates transcription for both a left-handed nonstructural protein region and a right-handed structural protein region (9). The nonstructural protein, NS1, is approximately 74,000 Da and is encoded between nucleotides 435 and 2448. NS1 is a helicase that provides the "nickase" activity for reduction of replicative DNA forms to progeny virus DNA that can be packaged into the virion and may also play a role in the assembly of viral DNA into mature capsids during viral replication. NS1 causes apoptosis in replication-permissive erythroid precursor cells as well as in nonpermissive cells, e.g., hepatocytes (10, 11).

Both structural proteins, VP1 and VP2, are encoded in the same open reading frame by nucleotides at positions 2444 to 4786 and 3125 to 4786 and are 84,000 and 58,000 Da, respectively. VP2 transcription is initiated at an alternate start site at nucleotide 3125 (12). Small proteins measuring 7.5 kDa and 11 kDa, respectively, are encoded in the capsid region, but their function has not been well defined.

Pathogenesis and Pathology

Experiments on healthy volunteers provided a detailed picture of the natural history of B19 infection in the normal host (13). When B19 viremic plasma was inoculated into the nostrils of previously seronegative individuals, B19 was first detected in recipient serum by day 6 postinoculation. Viremia lasted up to 7 days, with the peak occurring on days 8 and 9 postinoculation. During this period, B19 DNA appeared in nasal and oropharyngeal secretions but virus was not detected in urine or stool. Approximately 11 days postinoculation, high-titer anti-B19 immunoglobulin M (IgM) antibody developed, followed by the appearance of anti-B19 IgG antibody. Volunteers with a significant level of preexistent anti-B19 antibody did not show any evidence of viremia or anti-B19 IgM response. During the viremic phase, some of the subjects had a flulike illness with malaise, myalgia, and transient fever. Coincident with the onset of viremia, reticulocytosis was absent and remained so for up to 10 days. Viremia was cleared with the onset of the anti-B19 IgM antibody response, which was associated with the second phase of clinical illness, characterized by rash, arthralgia, and arthritis (13). The cell receptors for B19 have been reported to be the neutral glycosphingolipid globoside, which is widely distributed in various cell types (14–16). α_5 β_1-Integrins and Ku80 may serve as coreceptors (17, 18). Endothelial cell uptake may occur by anti-B19 IgG-bound C1q via C1q receptor on endothelial cells (19). Cell injury occurs by NS1-mediated host cell DNA damage and resulting apoptosis and downstream events (10, 20–24).

During natural infection, the incubation period may vary from 6 to 18 days, with a maximum of 28 days. By the time most patients present, usually with rash, polyarthralgia,

doi:10.1128/9781555818722.ch62

and/or polyarthritis, an anti-B19 IgM response has begun and the patients are not infectious. An exception is the patient with aplastic crisis, who typically presents during the viremic phase. Usually, anti-B19 IgM is present for up to 2 to 3 months postinfection, after which its level may wane. Specific IgG response to B19 is long-lived. Approximately 50% of the adult population has anti-B19 IgG antibodies (25).

Clinical Manifestations

The clinical spectrum of parvovirus B19 infection may be classified by common (Table 1) and uncommon (Table 2) presentations.

Nearly half of infected children and adults have subclinical or asymptomatic infection. Erythema infectiosum, or fifth disease of childhood, is the best-known manifestation of B19 infection. Children aged 4 to 7 years are typically infected as they enter school, but children as young as 1 year of age and adolescents may present with fifth disease. Prodromal symptoms are often mild. The majority of the children have the hallmark rash characterized by bright red "slapped cheeks." The rash may also appear on the torso and extremities. It may recur after sun exposure, hot bath, or physical activity. Usually the exanthem is a lacy, reticular, "fish net," or blotchy macular or maculopapular eruption, but occasionally it is vesicular or hemorrhagic. Other symptoms usually are mild and include sore throat, headache, fever, cough, anorexia, vomiting, diarrhea, and arthralgia. Children presenting with rash usually have serum anti-B19 IgM antibody present at presentation. Uncommon dermatological manifestations include vesiculopustular eruption, purpura with or without thrombocytopenia, and a "socks-and-gloves" erythema. Erythema infectiosum may also be encountered in adults in whom the rash tends to be more subtle and the bright red slapped-cheeks symptom is often absent; the flu-like symptoms may be more severe in adults.

Approximately 10% of children with erythema infectiosum have associated arthritis and arthralgia. In adults, the polyarthralgia and joint swelling tend to be more prominent (26–28). The arthropathy typically appears as an acute, moderately severe, symmetric, peripheral polyarthritis. The joints most frequently affected include the metacarpophalangeal joints, proximal interphalangeal joints, wrists, knees, and ankles. The duration of these symptoms is usually brief (approximately 10 days), but one-third of patients continue to have persistent joint symptoms 2 to 3 months after onset of the disease. About half of patients who have chronic parvovirus arthropathy meet the criteria of the American Rheumatism Association for a diagnosis of rheumatoid arthritis (27). Patients may have transient expression of autoantibodies, usually in low to moderate titer, including rheumatoid factor, anti-DNA, antilymphocyte, antinuclear, anticardiolipin, and antiphospholipid antibodies (28, 29). Unlike rheumatoid arthritis, there is no major histocompatibility HLA DR4 predisposition to B19 arthropathy (30, 31). The pathogenesis of B19 arthropathy has not been fully elucidated. In patients with chronic B19 arthropathy, B19 DNA may be found in bone marrow aspirates and in synovial biopsy specimens, suggesting B19 viral persistence in apparently immunocompetent individuals (32–34). B19 DNA has been detected in the normal synovium of young adults by using sensitive PCR techniques (33, 34). One group reported B19 DNA and capsid protein in rheumatoid synovium (35). Coculture of B19-positive rheumatoid synovium with normal cells increased tumor necrosis factor alpha production, a finding typical of rheumatoid arthritis; the group suggested that B19 may be a causative agent of rheumatoid arthritis, a provocative suggestion that remains to be confirmed (35). Others observed that inoculation of normal synovial fibroblasts with B19 virus induces a cartilage matrix invasive phenotype more typical of rheumatoid arthritis synoviocytes (36). Transgenic mice expressing B19 nonstructural protein, NS1, are prone to developing polyarthritis (37).

Fetal parvovirus B19 infection presents as fetal or congenital anemia, hydrops fetalis, spontaneous abortion, or stillbirth. In some cases, fetal infection is asymptomatic and self-limited. During B19 infection *in utero*, virus infects fetal erythroid progenitor cells, causing maturation arrest and severe anemia. The resulting hypoxia causes high-output cardiac failure with fluid accumulation in body cavities and generalized edema of the fetus. B19 may also infect the fetal liver, spleen, kidneys, heart, lungs, thymus, adrenal glands, skeletal muscle, eyes, and placental tissue (7, 10, 38).

Individuals with inherited or acquired conditions causing a decrease in reticulocyte production or shortened erythrocyte survival may develop aplastic crisis during an acute B19 infection. These predisposing conditions include iron deficiency; congenital dyserythropoietic anemia; α- and β-thalassemias; hereditary spherocytosis, stomatocytosis, or elliptocytosis; deficiencies in the production of erythrocyte enzymes such as glucose-6-phosphate dehydrogenase, pyruvate kinase, pyrimidine-5′-nucleotidase; sickle cell disease;

TABLE 1 Common clinical presentations of parvovirus B19 infection

Asymptomatic infection
Aplastic crisis
Erythema infectiosum (fifth disease)
Hydrops fetalis
Arthropathy, acute and/or chronic
Chronic or recurrent bone marrow suppression in immunocompromised individuals

TABLE 2 Less common clinical presentations of parvovirus B19 infection

Skin
Vesiculopustular eruption
Henoch-Schönlein purpura
Thrombotic thrombocytopenic purpura
Socks-and-gloves syndrome
Hematological
Anemia
Thrombocytopenia
Leukopenia
Benign acute lymphadenopathy
Hemophagocytic syndrome
Cardiovascular
Polyarteritis nodosa
Wegener's granulomatosis
Myocarditis
Liver
Hepatocellular enzyme elevations
Hepatitis
Non-A, non-B, non-C, non-E, non-G fulminant liver failure
Nervous system
Paresthesias
Meningitis
Sensorineural hearing loss

chronic autoimmune hemolytic anemia; antibody-mediated autoimmune hemolytic anemia; paroxysmal nocturnal hemoglobinuria; virus-associated hemophagocytosis; and blood loss. In healthy individuals, B19 causes transiently decreased reticulocyte production, but this is not usually clinically evident (39, 40).

Chronic or recurrent bone marrow suppression with anemia, thrombocytopenia, and/or leukopenia has been found in patients with immune compromise including Nezelof's syndrome; those who had undergone prior chemotherapy for lymphoproliferative disorders including acute lymphocytic leukemia, chronic myeloid leukemia, Burkitt's lymphoma, acute lymphoblastic lymphoma, myelodysplastic syndrome, astrocytoma, and Wilms' tumor; those with human immunodeficiency virus infection and AIDS; and those who were receiving immunosuppressive therapy for bone marrow or organ transplantation. In immunocompetent hosts, anti-B19 IgM and acute-phase IgG antibody recognize antigenic determinants on VP2 and may last for 2 months or more. Convalescent-phase anti-B19 IgG antibody recognizes determinants on VP1 (40). VP1 differs from VP2 by containing unique N-terminal determinants absent from the shorter VP2 (12). Patients with congenital or acquired immunodeficiencies fail to produce convalescent-phase IgG antibodies to VP1, and their serum is unable to neutralize B19 *in vitro* (40). These individuals have less intensive viremia than that experienced during acute infection or aplastic crisis, but viremia may be recurrent or chronic and associated with recurrent or chronic suppression of one or more bone marrow-derived lineages, causing anemia, leukopenia and/or thrombocytopenia. Since IgG seroprevalence in the adult population is approximately 50%, neutralizing activity to B19 is present in commercially available pooled immunoglobulin. Administration of commercial immunoglobulin with anti-B19 activity to patients with immunodeficiency who have chronic B19 infection and cytopenias is effective in clearing B19 infection and allowing bone marrow recovery (41).

Several uncommon presentations of B19 infection have been described, including idiopathic thrombocytopenia purpura, transient erythroblastopenia of childhood, Diamond-Blackfan anemia, encephalitis, aseptic meningitis, brachial plexus neuropathy, paresthesias, neuralgic amyotrophy, and motor weakness. Unusual rheumatologic presentations attributed to B19 infection include systematic vasculitis, Henoch-Schönlein purpura, Kawasaki's disease, polyarteritis nodosa, adult Still's disease, fibromyalgia, and systemic lupus erythematosus. Parvovirus B19 has also been associated with hepatitis, acute fulminant liver failure, myocarditis, mononucleosis-like syndrome, Koplik's spots, and pneumonia (7, 10, 39, 41–44).

Epidemiology

Parvovirus B19, genotype 1, has a worldwide distribution. Genotypes 2 and 3 tend to be found in Europe and Africa (1–3). B19 infection occurs in all age groups throughout the year in epidemics or as sporadic cases. The peak incidence is seasonal, occurring predominantly in late winter and early spring. Serological studies show that B19 has usually infected 2 to 15% of children under the age of 5 years, 15 to 60% of school-age children (5 to 19 years old), and 30 to 60% of adults. The highest rates of natural infection (50 to 60%) were observed during outbreaks of erythema infectiosum or B19-induced aplastic crisis (45, 46).

Natural transmission of B19 occurs mostly via respiratory secretions or vertically from mother to fetus. Recently, transmission via transfusion of blood and blood products was reported. The frequency of contamination of blood obtained from single donors usually ranges from 1 in 30,000 to 1 in 50,000 donations. However, the frequency of contamination of pooled clotting-factor concentrates can be much higher (47).

LABORATORY DIAGNOSIS

Cell Culture

A major limitation in studies of B19 has been the absence of appropriate cell lines permissive for the virus. Attempts to detect B19 virus in standard cell cultures have not been successful. Several investigators use cell cultures of erythroid origin for B19 propagation. B19 infection of primary cell cultures of erythroid precursors derived from human fetal liver and bone marrow or of human megakaryocytic leukemic cell lines has been successful. However, cultivation of B19 in these cell cultures is not routine, and the viral yield tends to be low. Attempts to use animals, including anthropoid primates, for modeling B19 infection have been unsuccessful.

Electron Microscopy

Standard electron microscopy methods of negative staining allow the examination of a liquid sample dried on an electron microscopy grid that had been previously coated with a thin layer of plastic, followed by staining with phosphotungstic acid or uranyl acetate. Electron-dense material accumulates around viral particles, giving a bas relief appearance or negative-contrast image (Fig. 1).

Specific viral identification may be confirmed by immunoaggregation with polyclonal or monoclonal anti-B19 antibodies (immunoelectron microscopy [IEM]), or by immunogold labeling. However, successful IEM requires the absence of excess endogenous anti-B19 antibody in the sample. In serum samples, "bare" virions are present only in the very early stages of infection before specific antibody develops. IEM may be useful when used with nonserum body fluids or tissues in which anti-B19 antibody is not present in high titer. After incubation of the sample with specific antiserum or anti-B19 monoclonal antibody, centrifugation, and negative staining, the aggregated virions can be seen by electron microscopic examination.

Combined pseudoreplica-immunochemical staining may be more useful, even in the presence of endogenous anti-B19 antibody, since even a few antigenic sites may be adequate to allow the labeling of B19 by specific anti-B19 monoclonal antibodies. Virus can be detected in various body fluids by this method (38). In the pseudoreplica technique, a sample is absorbed into an agarose block, leaving viral particles on the surface. The agarose is then overlaid with a plastic film, which, after hardening, is floated off the agarose, inverted, applied to a support grid, and negatively stained. Combined pseudoreplica-immunochemical staining uses second-stage gold-conjugated labeling antibodies to detect first-stage anti-B19 monoclonal antibody before negative staining. Examination of viral particles with specific colloidal-gold-conjugated antibodies permits species identification. Otherwise, it may be difficult to discriminate B19 virions from other nonenveloped icosahedral viruses of a similar size, such as enteroviruses, on the basis of morphology alone. B19 may be present as "full" particles with the contrast stain excluded, or stain may enter the capsid, giving the appearance of an "empty" shell (Fig. 1). Although these methods have high specificity, they require special equipment and experienced examiners and are labor-intensive, rendering them suboptimal for routine diagnosis (38).

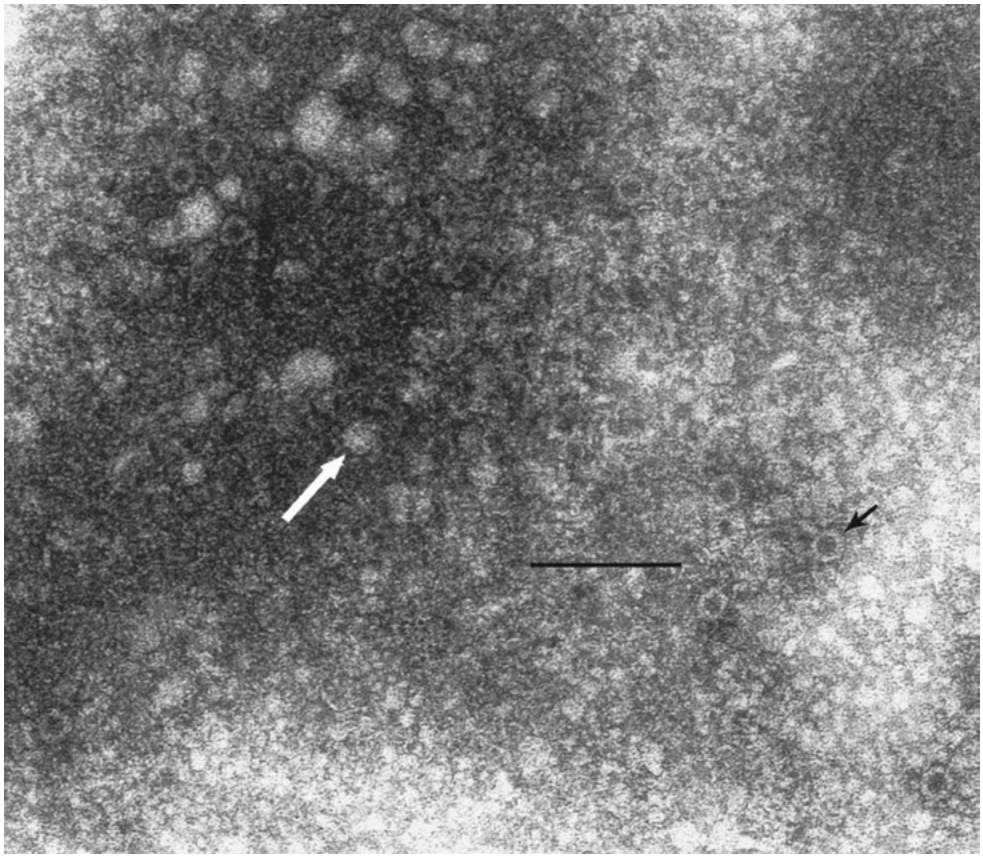

FIGURE 1 Electron micrograph of serum from a patient with sickle cell disease and aplastic crisis, showing full (white arrow) and empty (black arrow) nonenveloped, icosahedral viral particles measuring ~23 nm in diameter, visualized by negative staining with uranyl acetate. Bar, 100 nm (original magnification, ×196,000). Reprinted from reference 26 with permission of the publisher.

Immunoassays

Immunofluorescence assay, radioimmunoassay (RIA), and enzyme-linked immunosorbent assay (ELISA) have been used to detect both B19 antigen and specific anti-B19 antibody. The indirect immunofluorescence assay was successfully applied to the cellular localization of B19 antigen in tissue and cell culture samples but has not found wide clinical application. Several RIA and ELISA systems were developed for detecting B19 antigen and anti-B19 IgM and IgG antibody. Prior to laboratory cloning and production of recombinant capsid proteins, native virus from viremic patients served as an antigen source (Fig. 2A) (48, 49). Briefly, for antibody capture RIA or ELISA to detect anti-B19 IgM or anti-B19 IgG, microtiter plates (solid phase) are incubated overnight to coat the wells with anti-human IgM (μ-chain specific) or anti-human IgG (γ-chain specific) antibody, respectively. After the plates have been washed with phosphate-buffered saline containing a low concentration of nonionic detergent to prevent nonspecific aggregation, the serum to be tested for antibody is added. After incubation and washing with buffer, a high-titer B19 viremic serum without endogenous anti-B19-specific antibodies is added as an antigen source; an antigen-negative control serum may be added to parallel wells to detect nonspecific reagent cross-reactivity. Detection of such cross-reactivity may be necessary to avoid false-positive results for patients presenting with autoantibodies such as rheumatoid factor (27). After overnight incubation and washing with buffer, murine monoclonal antibody with anti-B19 activity is added. After nonadherent anti-B19 murine monoclonal antibody is washed off, anti-mouse class-specific antibody labeled with ^{125}I (RIA) or peroxidase (ELISA) is added. After incubation and washing, radioactivity is counted or color developer is added in the presence of hydrogen peroxide, and the reaction is stopped with 2 M H_2SO_4.

If the RIA or ELISA is used for detection of antigen, a defined serum with high-titer anti-B19 IgM is added instead of patient serum. After incubation and washing, the serum to be tested for virus is added instead of known viremic serum. In the antigen capture assay, parallel wells with an anti-B19 IgM negative control capture serum and parallel wells with appropriate virus negative control sample (e.g., normal serum, body fluid, and cell lysate) must be added to detect nonspecific reagent cross-reactivity. In both the antibody capture and antigen capture assays, test wells must be compared to background wells for a given sample (27).

Identification of a stock of high-titer viremic serum without endogenous anti-B19 antibody for use as antigen in immunoassays (Fig. 2A and B) requires significant effort. B19 virus in a panel of candidate antigen sources may be detected by screening antigen capture RIA or ELISA (Fig. 2C) and confirmed by molecular detection of B19 DNA. Screening may be performed for sera candidates by PCR methods, and positive samples may be tested in an antibody capture assay to eliminate those with endogenous anti-B19 antibody.

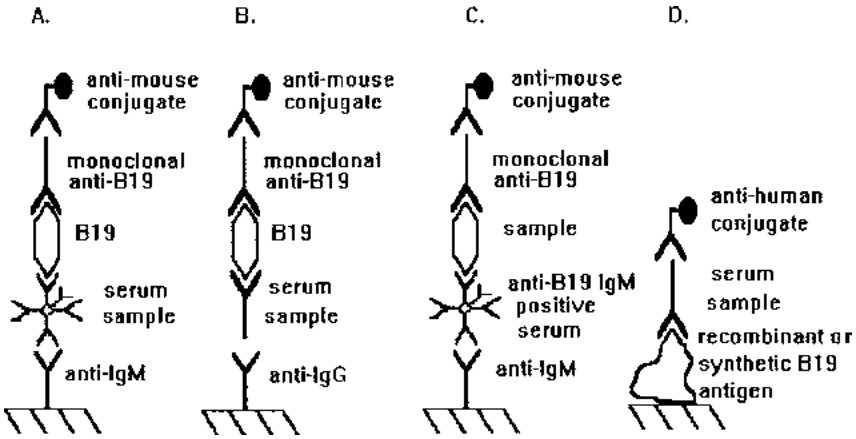

FIGURE 2 ELISA-based tests showing antibody capture ELISA for anti-B19 IgM antibody (A), antibody capture ELISA for anti-B19 IgG antibody (B), antigen capture ELISA for B19 virus (C), and recombinant or synthetic B19 antigen-based ELISA for detection of B19 antibody (D).

To overcome the problem of limited access to antigen for diagnostic testing, a number of commercially available antibody capture ELISA assays were developed using recombinant VP2 (Fig. 2D). VP2 protein expressed in Chinese hamster ovary cells, bacteria, or baculovirus expression systems spontaneously self-assembles into empty capsids (10, 50–54).

Antibodies to genotypes 1 and 3 may be detected equally well by using ELISAs targeting B19 or V9, respectively (47).

Methods for Detection of B19 Nucleic Acid

B19 DNA may be detected by hybridization with cDNA probes, riboprobes (synthetic RNA), or synthetic oligonucleotide probes. Hybridization may be performed directly on tissue or cells by *in situ* hybridization allowing localization of viral DNA. Disrupted virus-containing sample or extracted DNA may be blotted onto a nitrocellulose or nylon membrane before being hybridized with B19-specific probe. Numerous modifications of this basic approach have been used to detect B19 in body fluids, blood products, tissue, and cell culture extracts. Nonradioactive labels for probes may be used for safety and long shelf life. B19 DNA has been detected in serum by using a digoxigenin-labeled RNA probe to hybridize with target DNA, followed by capture of the hybrid onto a solid phase (microtiter wells) previously coated with a second anti-B19 oligonucleotide probe to an unhybridized portion of the B19 target DNA; an alkaline phosphatase-conjugated antidigoxigenin antibody and chemiluminescent substrate allow the detection of B19 DNA on a scintillation counter.

PCR-based technologies offer exquisite sensitivity and the ability to detect B19 DNA in different types of clinical specimens. Various oligonucleotide primers directed against sequences in both the nonstructural and viral capsid protein genes have been used (55–58). PCR is more sensitive than traditional dot blot hybridization; the use of an internal radiolabeled probe to detect amplification product by Southern analysis is still more sensitive than dot blot hybridization. Many investigators have now reported the use of PCR to detect B19 in fetal and adult tissues, body fluids, blood products, and cell cultures. However, PCR detection of B19 DNA in clinical samples is not problem free. The most common problem is the presence in clinical samples of inhibitors of *Taq* polymerase (56). Different approaches to avoid this problem have been used, including controlled heating of the sample, detergent extraction of DNA, and the use of a second round of amplification with nested primers. In antigen capture or immunoadherence PCR, virus is adhered to PCR tubes precoated with anti-B19 monoclonal antibody, and after incubation and washing, the PCR mixture (containing primers, deoxynucleoside triphosphates, and *Taq* polymerase) is added, virions are disrupted by heating, and viral DNA is amplified. This approach avoids nonspecific inhibition and provides high sensitivity and specificity (34, 38). While PCR primers and conditions may be optimized to preferentially amplify genotypes 2 and 3, B19-specific assays detect most isolates of genotypes 2 (A6/K71) or 3 (V9) (58).

Interpretation

Molecular testing for B19 DNA in serum is helpful during the viremic phase in acute infection. Viremia is accompanied by constitutional symptoms of fever, chills, and malaise, but once arthralgia, arthritis and/or rash appears in immunocompetent individuals, standard PCR methods are typically negative. However, immunocompromised patients may have chronic viremia or intermittent viremia for years. A positive PCR test confirms a B19 infection in any setting, but in acute infection viremia is typically 10^{11} virions or more per mL (39). In chronic infection in immunocompromised patients, viremia may be as low as 10^3 virions per mL (59). Initial PCR screening methods had analytical sensitivity of as little as 5 virions per mL (60).

When immunocompetent individuals present with arthralgia, arthritis and/or rash, they typically have B19 IgM. B19 IgG is often present, but if not present initially, it usually appears within a few days. Sensitivity for B19 IgM detection at this time using commercially available kits is essentially 100%. Specificity ranged between 94.2 and 98.5% in patients with other acute infections or autoimmune diseases (61).

DISEASE PREVENTION AND THERAPY

Parvovirus B19 infection is widespread in the community. It is therefore difficult to prevent exposure and to control the spread of infection. Community and household contacts are frequently asymptomatic. Hospital exposures may occur. However, isolation of viremic patients may decrease the level of exposure (46).

Specific antiviral therapy has not been identified. In general, patient management is symptomatic and supportive.

Patients with acute aplastic crisis may require blood transfusion. Adults with chronic B19 arthropathy are managed with nonsteroidal antiinflammatory drugs (27). Fetal transfusion *in utero* may be required to support the fetus during B19 infection complicated by severe anemia; fetuses transfused *in utero* and surviving the aplastic crisis have been born without apparent long-term sequelae (38). Immunocompromised patients who lack neutralizing anti-B19 antibodies and who present with manifestations of persistent B19 infection benefit from commercial intravenous immunoglobulin (41). Intramuscular immunoglobulin for prophylaxis following B19 exposure has not been adequately evaluated (55). Specific antiviral chemotherapy for parvovirus B19 has not been demonstrated.

Respiratory Viruses

DAVID J. SPEICHER, MOHSIN ALI, AND MAREK SMIEJA

63

Respiratory viruses are among the most common acute viral infections affecting humans and contribute appreciably to school and to work absenteeism. Globally, acute respiratory tract infections (ARTI) cause frequent morbidity and mortality among children under the age of 5 years, and are a major health care burden (1). Among the very young and the very old, as well as those with chronic medical conditions, respiratory viruses contribute substantially to medical visits, prescription of antibiotics and antivirals, hospitalizations, and deaths.

Most ARTI are caused by viruses, such as human metapneumovirus (hMPV), respiratory syncytial virus (RSV), influenza viruses (IFV), parainfluenza viruses (PIV), adenoviruses (AdV), human rhinoviruses (HRV), human bocavirus (HBoV) and human coronaviruses (HCoV), but bacteria also contribute to similar clinical syndromes. However, the etiology of up to 70% of ARTI remains unknown from a laboratory perspective (2). The diagnosis, prevention, and therapy of respiratory viruses, particularly influenza, has been a major imperative for virology laboratories, public health departments, and international public health authorities such as the World Health Organization. Therefore, this chapter discusses the common viruses manifesting as ARTI in humans, the clinical syndromes, and how these pathogens can be diagnosed. The explosion of knowledge regarding the etiologic agents involved has expanded faster than the methods to ascertain whether they are causal or colonizers and has far outstripped the ability to develop preventive or treatment methods. In coming years, the anticipated development of new vaccines and antiviral drugs for the more important respiratory viruses will increase the need for prompt diagnosis.

The recognition of new species of HRV (i.e., rhinovirus C, with ≥50 genotypes), HCoV (i.e., HCoV-NL63, HCoV-HKU1, and MERS-CoV), HBoV, and polyomaviruses (i.e., WUPyV, KIPyV, and BKPyV) suggests that our knowledge is accelerating. Nevertheless, the majority of adults with ARTI, and as many as half of the children, do not have an etiologic diagnosis. The large number of undiagnosed ARTI is due to inefficient application of suitable detection methods, inadequate sampling methods or delay in obtaining diagnostic specimens, and the limitations on viral testing in many laboratories. Most respiratory viruses cause similar clinical symptoms, from fever and myalgia to abdominal pain and respiratory symptoms (3). In mild to moderate disease there may be no perceived clinical need to make a specific etiologic diagnosis, thus hampering development and availability of appropriate diagnostics. Conversely, the recognition that these agents may play a more severe or more chronic role in the immunocompromised patient has necessitated the development of improved testing.

Diagnostic testing has improved markedly over the past 20 years. Previous detection methods included serology and isolation of viruses by cell culture, but neither is optimal for all respiratory viruses because they are cumbersome, require large turnaround times (up to 10 days to diagnose influenza), and are insensitive. As well, many viruses, such as HCoV, are fastidious (4). Immunochromatic methods for detecting virus-specific antigens are much faster than culture, providing results in minutes, and may provide acceptable diagnostic test accuracy, particularly in children and during known influenza or RSV circulation. Furthermore, newly developed molecular methods are faster than culture and more accurate than either culture or antigen detection, and thus are replacing traditional methods and have enhanced the laboratory diagnoses of respiratory viruses. These changes have enabled diagnosis of a broader group of viruses, with consequent challenges in interpretation of certain viruses and of multiple viral infections. Finally, the advances in viral diagnosis have not been accompanied by a parallel improvement in the diagnosis of bacterial respiratory infections. Since viral and bacterial infection may coexist, diagnosis of a viral infection does not necessarily rule out a clinically important and treatable bacterial coinfection. As a result, the role of viruses as the sole cause of many respiratory syndromes remains controversial, and unnecessary antibiotic prescriptions for viral syndromes remain common.

Clinicians will increasingly demand rapid, accurate, and broad-spectrum diagnostic testing for viruses, particularly for hospitalized patients. In choosing which diagnostic tests to offer, the laboratory director will need to balance clinical needs against the plethora of testing modalities, the different technical and capital costs required, and the changing clinical utility of these tests in driving antibiotic and antiviral use, patient isolation and other infection control treatments, and in forecasting prognosis. Ultimately, the cost-effectiveness of providing an accurate diagnosis in different clinical settings will affect the provision of appropriate services. These are likely to be a combination of point-of-care molecular tests or enhanced sensitivity

doi:10.1128/9781555818722.ch63

immunochromatographic assays to aid in making immediate decisions (such as hospital admission or use of influenza antiviral drugs), combined with high-throughput, batched multiplex syndromic panels (for making a definitive viral diagnosis for a broader number of viruses).

TAXONOMY AND DESCRIPTION OF AGENTS

The majority of respiratory viruses are RNA viruses: nonenveloped, positive-sense single-stranded RNA viruses (e.g., HRV); enveloped, negative-sense single-stranded RNA viruses (e.g., IFV and PIV); nonenveloped, negative-sense single-stranded RNA viruses (e.g., RSV and hMPV); or enveloped positive-sense RNA viruses (e.g., HCoV). The minority are DNA viruses, such as the nonenveloped double-stranded AdV, the nonenveloped single-stranded HBoV, or the enveloped human herpesviruses (HHVs).

Orthomyxoviruses: Influenza A, B, and C

Influenza viruses, belonging to the family *Orthomyxoviridae*, are the most clinically important respiratory viruses due to their role in severe lower respiratory tract infections (LRTI), explosive outbreaks and epidemics, and in occasional global pandemics. Influenza viruses are spherical or filamentous, enveloped, single-stranded RNA viruses containing seven or eight separate segments of RNA. These viruses attach to human respiratory epithelium via sialic acid residues, are internalized, and multiply in the cell nucleus. The hemagglutinin antigen (HA) is expressed on the viral envelope, interacts with cell surface receptors in attachment, and is a major target of the body's immune defenses. Vaccines against influenza A and B target the HA. The neuraminidase (NA) facilitates viral release from infected cells to enable subsequent new generations of infections and is inhibited by commonly used antiviral drugs such as oseltamivir and zanamivir. The M2 ion channel, which enables viral entry, is a target of the drugs amantadine and rimantadine and is found only in influenza A but not in influenza B (5). Only influenza A causes pandemics, usually due to a genetic reassortment of HA and NA subtypes to confer a novel virus for which humans have limited immunity. Both influenza A and B cause seasonal outbreaks, whereas influenza C causes milder disease that is rarely specifically diagnosed.

Paramyxoviruses: RSV, hMPV, and PIV-1 to -4

The family *Paramyxoviridae* is a large family of negative-sense, single-stranded RNA viruses that cause measles, mumps, and respiratory infections. The associated respiratory viruses include RSV (subfamily *Pneumovirinae*, genus *Pneumovirus*), hMPV (genus *Metapneumovirus*), and four PIV types (PIV-1 and PIV-3 belong to the genus *Respirovirus* while PIV-2 and PIV-4 belong to the genus *Rubulavirus*). This group of viruses is the most clinically important after influenza. RSV is named after its propensity to cause syncytia formation in cell culture and is a common cause of childhood infections and hospitalizations. hMPV was discovered in 2001 and has four subtypes with a different subtype predominating in each year (6). PIV types 1 to 4 cause similar respiratory diseases but are generally less severe than RSV.

Picornaviruses: HRV and EV

The small, nonenveloped, positive-sense, single-stranded RNA viruses in the order *Picornavirales*, family *Picornaviridae*, genus *Enterovirus*, include the respiratory pathogens HRV and enterovirus (EV). Some authors refer to human enteroviruses with the abbreviation HEV, which is also used for hepatitis E virus and, as such, is ambiguous. Further confusion arises from the reclassification of HRV into the genus *Enterovirus*, with recognition of three rhinovirus species (A, B, and C), and five enterovirus species (A to E). HRV causes outbreaks of upper respiratory tract infections (URTI), as rhinovirus A and B infect respiratory epithelial cells via the ICAM-1 or LDL-receptors. The receptor for rhinovirus C viruses is unknown. HRVs are acid labile and grow best at 33°C. The EVs cause gastrointestinal, respiratory, and systemic diseases. The EVs have a larger genome than HRV, use a wide variety of receptors for cell entry, and are acid stable.

Coronaviruses: HCoV

Members of the family *Coronaviridae*, genus *Coronavirus*, are large (120 to 160 nm), roughly spherical, enveloped viruses, which carry a positive-sense-strand RNA genome approximately 30 kb in length. The name "coronavirus" is derived from the crown-like appearance of these viruses when examined using electron microscopy. This appearance is due to an envelope studded with long, petal-shaped spikes of glycoprotein (7, 8). Four HCoVs are in circulation.

HCoV-OC43 and HCoV-229E were initially identified in the 1960s and are responsible for up to 30% of common cold symptoms but have received little attention as serious human pathogens (7, 9, 10). HCoVs were overlooked in diagnosis because they were thought to only cause outbreaks of URTI and are difficult to culture (11). This view was dramatically altered in November 2002 when the newly identified severe acute respiratory syndrome (SARS) CoV was associated with severe pneumonia in more than 8,000 people, contributing to over 800 deaths worldwide (12, 13). Since the outbreak of SARS-CoV, two novel HCoVs (HCoV-NL63 and HCoV-HKU1) have been discovered in association with LRTI. Research has also shown that HCoVs have a marked seasonal distribution (14, 15). HCoV-NL63 was first isolated from a 7-month-old child suffering from bronchiolitis, conjunctivitis, and fever in April 2004 in the Netherlands and was placed in group 1 based on genetic similarity to HCoV-229E (16). Since the discovery of HCoV-NL63, a seasonal distribution has been identified among HCoV-OC43 and HCoV-NL63 which peaks during late winter (15, 17, 18). HCoV-HKU1 was initially discovered as a codetection of severe LRTI in two patients in Hong Kong in January 2005 and has since been found to cause community-acquired pneumonia in winter and spring with a 2.4% incidence (19–21). HCoV-HKU1 has been classified as a group 2 HCoV based on genomic analyses (22). More recently, the Middle Eastern respiratory syndrome (MERS) CoV was identified in 2012 in the Netherlands from a Saudi Arabian patient who died with severe respiratory illness.

DNA Respiratory Viruses: AdV, HBoV, and Others

The nonenveloped AdV is a double-stranded DNA virus containing 51 serotypes. These are small viruses that multiply in the cell nucleus and invade respiratory epithelium and the gastrointestinal tract as well as the systemic circulation and heart.

HBoV is a single-stranded DNA virus which was the first member of the family *Parvoviridae*, genus *Bocaparvovirus*, to cause disease among humans and has been suggested to cause respiratory and gastrointestinal disease in children (23). There are four known serotypes. Infections often occur as dual infections together with another respiratory virus (21).

Newly described polyomaviruses (WUPyV, KIPyV, and BKPyV) have been associated with respiratory disease symptoms (24, 25). Their role remains undefined.

Other DNA viruses causing respiratory disease include the HHVs, particularly cytomegalovirus (CMV), but also varicella-zoster virus (VZV). CMV is more commonly recognized in the immunocompromised host. HHV-6 and HHV-8 have also been associated with respiratory symptoms.

Other Viruses and Bacteria

Other RNA viruses such as measles and mumps can cause respiratory symptoms. Bacteria such as *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* and *Mycoplasma pneumoniae*, while not viruses, overlap clinical syndromes caused by viruses and may be diagnosed in virology and molecular laboratories. *C. pneumoniae* is an obligate intracellular bacterium infecting respiratory epithelial cells. *Mycoplasma* spp. are cell-wall-free bacteria infecting the upper and lower respiratory tract. Both are sensitive to antibiotics, and, as part of the differential of upper and lower respiratory tract infection, both are included in some viral multiplex panels for laboratory detection. Finally, *Bordetella pertussis*, the bacterium that causes whooping cough, presents initially as URTI ,with antibiotics being effective only if started during the "catarrhal" stage of illness. Some molecular respiratory panels include *B. pertussis* as a target.

EPIDEMIOLOGY, TRANSMISSION, AND PATHOGENESIS

Respiratory viruses cause acute, self-limited infections spread person to person via infected hands, infected objects in the environment (fomites), large droplets from sneezing or coughing, and potentially via small-particle aerosols. Incubation times vary from as little as 10 hours for HRV, to 1 to 4 days for influenza, and up to 14 days for AdV and HCoV.

The transmission of respiratory viruses is highly seasonal in temperate and subtropical climates but may be year-round in tropical climates. In temperate and subtropical climates, influenza, RSV and other paramyxoviruses, and HCoVs predominate in the winter and spring. In North America, influenza is most common between December and April, whereas HRV is present year-round but peaks in the spring and early fall, and EV is most common in the summer months. In Australia, the "cold and flu season" starts as the prevalence of influenza peaks from late June to early August (early to mid-winter in the Southern Hemisphere) and is followed with a peak in HCoV prevalence in August (late winter), when they can be detected in 22% of specimens tested (15). The epidemic peak of hMPV is from August (late winter) to November (late spring) with a change in predominant viral genotype seen in most years (26). Seasonality also differs by serotypes (e.g., PIV-1 versus PIV- 3), and there are both synergistic and potentially antagonistic relationships between viruses. Seasonality may reflect effects of temperature, humidity, and indoor exposure, as well as lower vitamin D levels in winter months. In North America, peaks of HRV in September have been associated with school return and spread among children.

Most respiratory viruses multiply initially in the upper respiratory tract, in respiratory epithelial cells in the nose, nasopharynx, oropharynx, tonsils, or trachea. HRV is characterized by infection of only small numbers of epithelial cells, and symptoms may result from inflammatory cytokines.

CLINICAL SIGNIFICANCE

Respiratory virus infections may be asymptomatic or symptomatic and may affect the upper respiratory tract and its related structures, the lower respiratory tract, the gastrointestinal tract, or occasionally other organs.

Asymptomatic or minimally symptomatic illness may occur with most respiratory viral infections and can be detected by asymptomatic seroconversion or as an incidental finding with testing of asymptomatic study subjects in epidemiologic studies or volunteer inoculation studies. Community cohort studies have demonstrated asymptomatic infection with influenza or HRV, with rates of asymptomatic infection estimated at 15 to 20% for influenza and up to 80% for HRV (27). Asymptomatic infection and/or prolonged carriage after initial infection likely occurs with most respiratory viruses, thus complicating the interpretation of causality when a virus is detected.

The most common symptomatic presentation of respiratory viruses is URTI, also known as the common cold. Nasal congestion, rhinorrhea, sneezing, coughing, and/or throat irritation occur for 1 to 9 days, with shedding of virus for 3 to 7 days and resolution of symptoms generally in about 10 days. Neutrophils are present in nasal secretions, along with mucous and water. While HRV is the most common cause of URTI, all respiratory viruses can cause URTI and may be clinically indistinguishable. AdV, influenza, or HCoV may be more commonly associated with fever in the context of URTI, but HRV and EV can also be associated with fever—particularly in young children.

Pharyngitis and tonsillitis may be viral (especially HRV, but also influenza, AdV, HCoV, and other respiratory viruses) or bacterial (especially *Streptococcus pyogenes*, also referred to as group A *Streptococcus*). Viral sore throat is more likely to be accompanied by nasal congestion and cough, whereas fevers and painful lymphadenopathy favor a bacterial etiology. Persisting symptoms may be a manifestation of primary Epstein-Barr virus infections (i.e., acute mononucleosis).

Otitis media, or infection of the middle ear, is more common in the setting of acute viral infection and may be due to the virus itself (as evidenced by isolation of virus from middle ear fluid), bacterial (as with *Streptococcus pneumoniae*), or a bacterial complication of an initial viral infection. AdV, which affects the tonsils and adenoids, may obstruct the Eustachian tubes that aerate the middle ear and may predispose the patient to a bacterial middle ear infection.

Sinusitis is common with concurrent URTI, and the infection may be referred to as "rhinosinusitis." The contiguous respiratory epithelium covers the nasal, pharyngeal, and sinus surfaces, and a large proportion of HRV and other viral URTI involve nasal and sinus cavities even in uncomplicated infections. Bacterial sinusitis may result later, often after 7 to 10 days, with exacerbation of fevers, sinus congestion, and nasal discharge.

Laryngitis, or inflammation of the larynx, may be viral, bacterial, or noninfectious. PIV, RSV, influenza, HRV, and AdV have all been associated with laryngitis, as have *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae*. These are usually self-limited and accompanied by other signs of URTI or LRTI.

Influenza-like illness (ILI) is a syndrome characterized by upper and potentially lower respiratory tract symptoms. A combination of fever, abrupt onset of cough, and new-onset sore throat characterize ILI, which may also involve constitutional symptoms of muscle aches, tiredness, and loss of appetite. The diagnosis of ILI is not highly sensitive for influenza infections, which may present as URTI or pharyngitis

without fevers or as LRTI (see below) without fever, particularly in the elderly, nor is ILI specific for influenza, but it may be due to any respiratory virus including HRV. ILI remains a key tool for tracking potential influenza in the community, and, when influenza outbreaks occur, ILI incidence is a useful epidemiologic measure. From a health-care perspective, screening emergency departments and clinic patients for ILI enables timely testing and infection control in order to prevent infection of other patients and staff.

LRTI is a broad term for symptoms and clinical signs of infection below the level of the larynx. Infections of the trachea (tracheitis), bronchi (bronchitis), and smaller airways (bronchiolitis) are primarily due to viral infections, including influenza, PIV, RSV, hMPV, HCoV, and AdV. Infections of the lung parenchyma, or pneumonia, are often of bacterial origin, although pneumonia may be a mixed viral and bacterial infection or a sole viral infection. Increasingly, HRV is being recognized as a cause of lower respiratory tract infection, particularly in young children, the elderly, and those with immune deficiencies such as bone marrow or solid organ transplantation, chemotherapy, or advanced infection with the human immunodeficiency virus type 1 (HIV-1).

Bronchitis/tracheitis is common with influenza and other respiratory viruses and causes cough, pain on tracheal pressure, and exacerbation of preexisting chronic respiratory diseases such as asthma or chronic obstructive pulmonary disease (COPD). The presentation may be exacerbation of asthma or COPD. COPD exacerbations are often accompanied by increased sputum production suggestive of a bacterial infection, and physicians will often treat with antibiotics since tests do not clearly rule out bacterial infection.

Croup, or laryngotracheobronchitis, is a common ARTI caused by PIV and other respiratory viruses. It affects young children, who develop acute difficulty with breathing out and develop a characteristic "seal-like" barking cough. Children are often brought to an emergency department and may require observation, with treatments consisting of oxygen and antiinflammatory corticosteroids for moderate to severe disease. The disease is self-limited and mortality is rare.

Bronchiolitis is an acute and potentially life-threatening illness and can be particularly severe in young children and premature infants or in infants with heart or lung disease. Bronchiolitis is characterized by fever, rapid and labored breathing, difficulty with oxygen exchange (resulting in lower oxygen saturation), and wheezing. RSV is the most common cause, although hMPV, PIV, and HRV can also cause bronchiolitis. Virtually all children are infected with RSV by 2 years of age, as evidenced by seroprevalence studies, and younger children are more likely to develop severe disease. RSV causes bronchiolitis and may require hospitalization. Severe disease may lead to intensive care unit admissions with therapies that include intravenous hydration, bronchodilators, antibiotics, oxygen, and even intubation and mechanical ventilation. Intravenous or inhaled ribavirin may be used in severe disease, although its effectiveness remains controversial. No vaccine is available for prevention of RSV, but RSV immunoglobulin is used to prevent severe disease among infants under the age of 2 years who are at high risk of developing severe RSV bronchiolitis and pneumonia. Risk groups include premature infants and those with severe heart or lung disease. RSV immunoglobulin is given monthly throughout the RSV season in a given community. While effective for preventing disease, RSV immunoglobulin is not effective for treatment once symptoms are established. Development of effective antivirals is currently being researched and is a high priority for the medical community.

Episodes of wheezing with respiratory viral infections in young children may be labeled as reactive airway disease, as airways in the young child do not have sufficient smooth muscle to cause bronchospasm characteristic of asthma. However, children with severe RSV or HRV bronchiolitis/reactive airway disease are more likely to manifest with childhood asthma by 6 years of age, although the role of these viruses in causing—as opposed to unmasking—asthma remains unclear. In younger children, all respiratory viruses can cause asthma exacerbations, including live attenuated influenza vaccine (which is not recommended for children with moderate to severe asthma). In older children and in adults, both HRV and EV are common causes of asthma exacerbations. In the late summer and fall of 2014, a serotype of Enterovirus, EV-D68, was associated with an outbreak of asthma exacerbations in hospitalized children in Kentucky, Colorado, and Canada (28). EV-D68 had been previously associated with similar outbreaks in the Philippines and in the Netherlands. The virus was first identified in California in 1962, and the cause for its recent increased activity is unknown.

Pneumonia is an infection of the lung parenchyma, with fluid, pus, and often bacteria in the alveoli affecting oxygen exchange by the lungs. Patients may need oxygen, fluids, hospital admission, and occasionally mechanical ventilation. In industrialized countries, pneumonia is a rare cause of death in children but remains a common cause of death in the elderly and immunocompromised. Viral pneumonia occurs with influenza and with most respiratory viruses and may be severe and result in diffuse lung white-out and severe difficulty with oxygen transport. Viruses such as influenza also predispose to bacterial pneumonia, often *Streptococcus pneumoniae*, *Staphylococcus aureus*, or *Streptococcus pyogenes*. *Haemophilus influenzae*, first associated with pneumonia during the H1N1 influenza pandemic of 1918, is now a rare cause of pneumonia since the onset of childhood vaccination against *H. influenza* type B (29, 30).

In 2009, a novel reassortment of animal and human viruses resulted in the pandemic H1N1 virus that originated in Mexico. Within 3 months, the pH1N1 virus spread worldwide and rapidly infected populations including children and adults. While the elderly were relatively spared and overall hospitalizations and deaths were lower than in the H3N2 years, there was an excess of deaths in children and young adults. Overall, the combined category of influenza and pneumonia remains the eighth most common cause of adult death in the United States, and the prevention, diagnosis, and treatment of influenza remain key health priorities.

Prevention of influenza includes annual vaccination of at-risk groups, such as young children, the elderly, and those with heart, lung, or immune diseases. Health care workers are recommended for vaccination to prevent hospital-based outbreaks. Universal vaccination of all children over 6 months of age, and of all adults, has long been recommended in jurisdictions such as the Province of Ontario and has recently been recommended in the United States by the Centers for Disease Control and Prevention (31). Universal influenza vaccination has been associated with a reduction in hospitalizations and complications among the elderly. A vaccination strategy targeting children was shown to reduce infection in the elderly in Japan, and more recently in a cluster-randomized clinical trial in Canada (32), the key role of children in spreading influenza in the community was demonstrated. Antiviral prophylaxis and treatment of

influenza includes amantadine and rimantadine, which are rarely used today because of drug resistance, and the neuraminidase inhibitors oseltamivir, zanamivir, and peramivir. Used early, these drugs are highly effective for the prevention or treatment of influenza (33).

Other influenza strains also occasionally cause human disease. In 1998, a novel H5N1 avian influenza virus infected 18 people in Hong Kong and was controlled by the culling of millions of birds. Since 2003, H5N1 continues to circulate among birds, with sporadic zoonotic infections of humans from bird markets or from direct exposure to dead birds. Person-to-person spread has only rarely been documented, and a total of 844 cases and 449 (53%) deaths have been recorded as of July 2015 (34). The most affected countries have been Egypt, Indonesia, and Vietnam, each with over 100 human cases. Other novel influenza viruses have infected humans exposed to bird markets in China, such as H7N9 in 2013 to 2015. Both H5N1 and H7N9 human cases have occasionally been imported into North America.

In 2002/2003, a novel CoV in China caused SARS, which affected 8,800 people in 29 countries and resulted in over 800 deaths (12, 13). The lungs and gastrointestinal tract were heavily infected in those who died and underwent autopsy. Diagnosis was complicated by the nonspecific nature of the illness, the frequent absence of virus in upper respiratory tract samples, and the delay to seroconversion among infected patients. Serology or molecular testing of lower respiratory tract specimens was helpful in making the diagnosis. Treatment was supportive, and the pandemic was controlled with careful infection control and other public health measures.

In 2012, a novel CoV was associated with severe respiratory disease in Saudi Arabia. Since then, MERS-CoV has infected over 1,000 people in Saudi Arabia and the Middle East, with occasional importation and secondary spread in the United States, United Kingdom and elsewhere. Serologic studies in Saudi Arabia suggested that 0.15% of surveyed people had serologic exposure to disease, with higher rates among shepherds (35). In June 2015, an outbreak in South Korea affected 186 patients, with 36 deaths, with at least three generations of infections (36). As of July 2015, over 16,500 South Koreans were transiently in quarantine, with concern for the potential of a much broader MERS-CoV outbreak.

Respiratory viruses can also contribute to extrapulmonary disease. In young children, respiratory viruses can also cause nausea, vomiting, and diarrhea. Extrapulmonary disease is also common with EV and AdV, with occasional involvement of the central nervous system (enterovirus meningitis, encephalitis, and acute flaccid paralysis), heart (myocarditis), liver (hepatitis), or muscle (myositis). Influenza, particularly influenza B, has been associated with myositis.

The respiratory illness in 2014 due to EV-D68 was also associated with neurologic disease, including acute flaccid paralysis—mimicking poliomyelitis—during the same time period. Virus was demonstrated in respiratory secretions in half of the examined children but could not be detected either in cerebrospinal fluid or in stools (37).

COLLECTION, TRANSPORT, AND STORAGE

Whom To Test

When considering testing, the first consideration is the patient. A young child, an elderly patient, or an immunocompromised patient would be at high risk for respiratory virus infections including severe disease or chronic/complicated disease. If admitted to hospital, they would be a potential source of infection for staff, visitors, and other patients. Any individual who is part of an institutional outbreak should be tested to guide prevention and treatment strategies. Travelers may warrant testing for exotic causes of their illness but will benefit from standard testing as well. Knowledge of worldwide outbreaks such as MERS-CoV in Saudi Arabia and other Middle Eastern countries, or H7N9 influenza in China, may direct specific testing and will require higher biosafety levels for specimen collection, transport, and laboratory testing.

When To Test

The second issue becomes when to test, although timing is often dictated by the point of contact between the patient and the medical system. Generally, viruses are shed from the upper respiratory tract for 3 to 7 days with many respiratory viral infections, but may be shed longer with certain viruses or in certain hosts (the young, the elderly, and the immunocompromised). Certain specimen types (e.g., nasopharyngeal swab [NPS]) may be positive early in the disease but do not rule out LRTI later in the disease. Similarly, transient viremia has been noted with influenza and with other viral infections, but blood is not commonly used as a direct test for infections in general. Wherever possible, samples should be obtained early in the disease, and certainly within the first 3 to 5 days of symptom onset. Children and the immunocompromised may shed viruses for weeks and may be tested if clinically relevant to guide decisions regarding etiology, isolation, and treatment. Testing for unusual infections such as novel influenza hemagglutinin serotypes may include acute and convalescent sera, although such testing requires prolonged turnaround time and is rarely helpful in treatment and infection control decisions for the patient.

Choice of Specimen Type

The next issue is the specimen type. Most commonly used specimens include NPSs and nasopharyngeal aspirates (NPAs). Nasal/mid-turbinate swabs (38), nasal washes, throat swabs or washes, and lower respiratory tract samples (tracheal aspirates or bronchoalveolar lavage samples) may all be submitted for respiratory virus testing. Choice of specimen type will involve decisions regarding the patient population (children versus adults, outpatients versus inpatients), the skills of the collecting nurse or physician, or the preference for self-collection or parental-collection of samples. In general, nasopharyngeal swabs or aspirates are the specimens of choice for acute diagnosis, with the exception of intubated patients, in whom supplementation with a lower respiratory tract specimen (such as bronchoalveolar lavage) is recommended (39). However, a lower respiratory tract specimen should not substitute for an upper respiratory tract specimen, as the latter is generally more sensitive.

Choice of Swab Type

Flocked swabs may be preferred to conventional nylon swabs and have been shown to be superior in collecting more respiratory epithelial cells and more infected cells (40). Viral transport media enable preservation of virus for antigen testing, culture, or molecular detection, and certain commercial media have demonstrated stability at room temperature for up to 3 weeks (41). Unless the stability characteristics of the viral transport medium are known, however, refrigeration of the sample at 2 to 8°C and processing of the sample within 48 hours are recommended. Samples can be stored for a prolonged period at −70°C but may be less stable to storage at −20°C.

Test Ordering

Test orders for respiratory virus detection may be limited (e.g., influenza alone by rapid antigen detection), expanded (e.g., influenza, PIV, RSV, hMPV, and AdV by direct fluorescent antibody and rapid shell vial culture), or comprehensive (multiplex PCR for 12 to 22 viruses and bacteria). These may be offered by setting (more limited for outpatients, more comprehensive for inpatients), patient comorbidities (immunocompromised), travel history, or physician ordering preference. However, the complexity of the ordering algorithm may be confusing and delay appropriate diagnosis, whereas an unrestricted policy of ordering comprehensive multiplex panels is costly and may result in overdiagnosis of incidental viral shedding unrelated to the current illness.

Test Utility

A diagnostic test for respiratory viruses may decrease the number of ancillary tests performed, affect decisions to admit a patient to the hospital, alter the degree of respiratory isolation required, and influence the choice of antiviral and antibacterial treatments for an overall cost savings (42). However, as respiratory viruses and bacteria may coexist, the cost savings may be exaggerated, as most physicians will continue to prescribe antibiotics in the setting of proven respiratory viruses amongst patients admitted to the hospital. Thus, in a retrospective review, 90% of adult inpatients with laboratory-confirmed influenza received antibiotics in our hospital, whereas, disturbingly, only 30% received antivirals (43). During known influenza activity in the community, we advise starting all admitted or high-risk patients with influenza-like illness on appropriate antiviral drugs, and discontinuing antivirals if subsequent batched multiplex PCR (generally available within 6 to 12 hours) proves negative for influenza A or B. Antibiotics are used for clinical or radiographic suspicion of pneumonia or for suspected bacteremia/sepsis.

Preanalytic Quality Control

Minimization of the number and types of swabs and transport media distributed throughout a hospital system may enable better inventory and quality control. Viral transport media may require refrigeration or be stable at room temperature, and many have a pH-dependent indicator dye to identify acid and unusable media in addition to an expiry date. In the future, as molecular testing replaces antigen and culture testing, simpler transport media enabling optimized molecular testing may extend shelf life and facilitate inventory and quality control. However, methods such as culture will still be required on a proportion of patients to enable characterization of a random sampling of influenza isolates each year, for travelers or others potentially exposed to novel influenza strains, or for phenotypic antiviral testing. One option may be to use molecular specific transport media routinely and to take additional specimens for culture when epidemiologic risk factors dictate the need.

Biohazard

Sample collection may entail a biohazard to the medical personal collecting the specimen as well as to laboratory personnel processing the sample. Thus, NPS and NPA collection may cause sneezing or coughing, with potential droplet and even aerosol spread of the virus to mucous membranes including the conjunctiva. Appropriate droplet precautions, including a gown, surgical mask, and eye protection, should be worn by clinical personnel when taking a nasopharyngeal specimen. Where a biosafety level 3 or higher pathogen is suspected (e.g., MERS-CoV, H5 influenza), enhanced biosafety during collection and laboratory processing will be required. Respiratory virus collection should be avoided altogether among patients with a suspected biosafety level 4 pathogen such as Ebola virus.

DIRECT FLUORESCENT ANTIBODY TESTING AND RAPID SHELL VIAL CULTURE

Conventional tube culture was the mainstay of respiratory virus diagnostics for many years. Both primary and continuous cell lines were used, including green monkey and rhesus monkey kidney cells, MDCK cells, A535, mink lung cells, or embryonal lung cells. These cells required considerable expertise to maintain and interpret and were time consuming, requiring daily examination and maintenance and taking 5 to 10 or more days to grow and identify viruses. Cytopathic effect of the viruses on the cell line, hemagglutination, or monoclonal antibody staining was used to verify detection of a virus. Tube culture methods continue to be used by some reference laboratories to prepare control material and to grow viruses for antigen characterization. However, they are generally impractical for clinical laboratories requiring a diagnosis to aid individual patient treatment or infection control.

Many clinical laboratories replaced conventional tube culture with rapid shell vial culture, in which one or more cell lines are placed below a cover slip, with a centrifuged patient sample, and incubated for 24 to 48 hours. The sample is then stained with a monoclonal antibody conjugated to FITC, and typical intranuclear or intracytoplasmic apple-green fluorescence is identified under a UV microscope.

Antigen detection using pools or individual monoclonal antibodies is available for influenza A, B, PIV-1, -2 and -3, RSV, hMPV, AdV, and EV. Commercial mixes of two or more cells are available, such as R-Mix, R-Mix-Too, or E-Mix shell vials (Diagnostic Hybrids). Antigen can be detected in a primary sample prior to culture, known as direct fluorescent antibody (DFA), enabling rapid identification in 90 to 120 minutes. Negative specimens are then inoculated into shell vial culture, and staining is repeated after 24 and 48 hours of culture, as described above.

The sensitivity of DFA is ~75% compared with culture, with a lower yield if insufficient numbers of respiratory epithelial cells are visible on the slide. Insufficient quantity would be reported, with an indication on the report that a negative could be a false-negative due to poor specimen adequacy. True sensitivity of DFA/culture, compared with a molecular test reference standard, is approximately 10% lower. The specificity of DFA approaches 100% but requires specialized equipment and experienced laboratory technologists. The requirement for fluorescent microscopy limits the daily throughput, although a result can be available as soon as 90 minutes after the specimen arrives in the laboratory.

Today, some laboratories may continue providing DFA/shell vial culture for respiratory virus detection, particularly for patients who are less urgent or in whom influenza has been excluded by molecular tests (described in "Molecular Tests for Respiratory Viruses" below).

IMMUNOCHROMATOGRAPHIC ASSAYS FOR INFLUENZA

Rapid methods for the identification of influenza and RSV have involved the detection of antigen using specific monoclonal antibodies raised in animals. Detection from an NPS

with a rapid immunochromatographic assay can be done in as little as 10 minutes, potentially enabling rapid institution of antiviral therapy and infection control procedures. Furthermore, monitoring of respiratory specimens in aggregate can identify when influenza is highly active. These assays are considerably less expensive than current multiplex molecular panels.

A representative sampling of currently available antigen assays is summarized in Table 1. The sensitivity of these assays is highly variable (44). Sensitivity of 60 to 90% compared with conventional or shell vial culture has been documented but depends on the patient's age (child versus adult), specimen type (NPS or NPA versus nasal swabs), duration of illness, and sensitivity of the reference standard (culture versus molecular). Compared with molecular reference standards, which are more sensitive than culture, antigen detection is appreciably less sensitive analytically and clinically. During pH1N1, it was estimated that rapid antigen detection had a very poor sensitivity of 20 to 40% (45).

Specificity of rapid antigen testing, however, is quite high at >90%, and the positive predictive value is >90% during influenza season. Thus, during known circulation of influenza in a community, a positive rapid antigen test would confirm the presence of influenza. However, at times without circulating influenza, the positive predictive value (which is a function of prevalence) would be much lower, and a second method (such as culture or molecular testing) would be required to verify the presence of influenza.

Two new, higher-sensitivity influenza assays have been cleared by the U.S. Food and Drug Administration (FDA): the Sofia Influenza A+B fluorescent immunoassay (Quidel Corp) and the BD Veritor Systems Flu A+B (46–49). These use analyzers that improve reliability, use signal-amplification methods, and incorporate algorithms to improve the sensitivity of the immunochromatographic influenza assays. These take 10 to 15 minutes to give results and are low-complexity assays requiring minimal sample preparation. These offer 80 to 90% sensitivity and 90 to 95% specificity, with higher sensitivity for children versus adults and for influenza A versus influenza B. The BD Veritor is low complexity and Clinical Laboratory Improvement Amendments (CLIA)-waived for NPSs and nasal swabs. The Sofia Influenza A+B is CLIA-waived for NPSs or nasal swabs but is classified as moderate complexity for NPAs or washes. Quidel has also introduced a Sofia RSV assay.

In settings in which viral load is high, such as early disease in children, these assays are likely to perform adequately. They are rapid, simple, and appreciably cheaper than molecular assays. However, among adults, or with any genetic drift in the virus, these assays may perform suboptimally. In a point–counterpoint, Dunn and Ginocchio argue for and against the use of these rapid immunochromatographic assays (50).

Antigen assays may still have a role in the diagnosis of infected children (particularly if not requiring hospital admission), in outbreaks (in which a single positive would suggest that the entire outbreak is due to the same infection), and in remote communities (in which a single viral infection may predominate, and knowledge of the circulation of influenza or RSV would enable appropriate decision making and treatment in other community members). Thus, an "ecologic" or "cluster" diagnostic tool, with imperfect abilities to diagnose (especially to exclude illness) in an individual, may still be highly useful in these particular group settings.

If antigen-based tests are to be used for influenza diagnosis, the two newer, higher-sensitivity tests would be preferred. Testing children during known influenza activity, or multiple individuals involved in an outbreak, may be a cost-effective use for these assays. However, decisions on treatment and isolation for individual patients, particularly for adults with comorbidities and among inpatients, should ideally rely on the more sensitive molecular diagnostics, described below. The FDA has proposed annual retesting for influenza assays, and these assays should not be relied upon for novel influenza strains until adequate validation has been performed.

Rapid immunochromatographic assays, including the newer, higher-sensitivity Sofia assay from Quidel, are also available for RSV. As with influenza antigen detection assays, both low-complexity immunochromatographic assays, as well as more complex enzyme immunoassays that are more amenable to high-throughput batch processing, are

TABLE 1 Reported ranges of sensitivity and specificity of a representative selection of influenza rapid antigen detection kits[1]

Kit (manufacturer)	Targets		Sensitivity (%)	Specificity (%)
	Flu A	Flu B		
Actim Influenza A&B (Medix Biochemica)	X	X	65–77	99–100
BD Veritor System for Flu A+B (Becton-Dickinson)	X	X	70–94	99–100
BinaxNOW Flu A and Flu B (Alere)	X	X	44–65	92–100
BinaxNOW Influenza A&B (Alere)	X	X	4–82	92–100
Directigen Flu A (Becton-Dickinson)	X		61–100	85–100
Directigen Flu A+B (Becton-Dickinson)	X	X	22–80	92–100
ESPLINE Influenza A&B-N (Fujirebio)	X	X	23–91	72–100
FLU OIA (BioStar)	X	X	41–93	83–95
QuickVue Influenza Test (Quidel)	X	X	22–96	75–100
QuickVue Influenza A+B Test (Quidel)	X	X	4–75	84–100
SD Bioline Influenza (Standard Diagnostics)	X	X	45–70	98–100
Sofia Influenza A+B FIA[2] (Quidel)	X	X	62–98	96–100
ZstatFlu (ZymeTx)	X	X	37–96	77–97

[2]FIA, fluorescent immunoassay.

available. Sensitivities are reported at 70 to 90%, although a study comparing a rapid assay with PCR found only 41% sensitivity (51).

MOLECULAR TESTS FOR RESPIRATORY VIRUSES

Molecular tests for respiratory viruses have been extensively developed since 2005. Uniplex or multiplex testing for influenza A alone, A and B, or for influenza and RSV, has been instituted by many clinical virology laboratories around the world, using laboratory-developed tests (LDTs), published primers from the Centers for Disease Control and Prevention, commercially available analyte-specific reagents (ASRs), or commercially available *in vitro* diagnostic kits for diagnosis of one or more respiratory viruses. Use of molecular diagnostics greatly accelerated after the pandemic H1N1 influenza of 2009, at which time nonmolecular methods were found to have poor sensitivity.

Most of these LDTs, ASRs, and multiplex kits require manual or automated nucleic acid extraction, followed by reverse transcription (RT), amplification (usually using PCR), and then detection of amplicon using gels, real-time instruments and SYBR Green intercalating dyes, or specific hydrolysis probes. These methods generally take 3 to 8 hours, are moderately or highly complex, and are most appropriate for a skilled molecular laboratory. Unidirectional, three-phase workflows with separate reagent preparation, amplification, and detection areas are essential to prevent false positives from specimen or amplicon contamination (52). Contamination has also been minimized by the use of closed tubes and uracil-*N*-glycosylase as well as proper training of laboratory staff.

There are a number of FDA-approved molecular assays for the diagnosis of influenza A and B (Table 2). Many of the approved assays can differentiate influenza A from B, and can also differentiate influenza A H1, H3, and pandemic H1 subtypes (53). Three of the listed assays detect both influenza and RSV, whereas four diagnostic kits (from three manufacturers) were multiplex panels for a larger number of viral targets.

Most assays are RT-PCR assays requiring initial nucleic acid extraction followed by amplification and detection. Most assays take 4 to 8 hours to results. Two exceptions are the Cepheid Xpert for influenza A and B, with or without RSV, and the Alere iNAT Flu A/B assay (54). The Cepheid assay is cartridge-based, with self-contained extraction and multiplex PCR on a dedicated, expandable instrument.

TABLE 2 Representative molecular assays for influenza cleared by the U.S. FDA[a]

Product (Manufacturer)	Targets			Specimens	Time	Complexity
	Flu A	Flu B	Other			
iNAT Flu A/B (Alere)	X	X		Nasal	0.25 h	Low[b]
CDC RT-PCR	X	X		NS, NPS, NA, BAL	4 h	High
Xpert Flu (Cepheid)	X	X		NPS, NA, NW	1 h	Moderate
Xpert Flu/RSV	X	X	RSV	NPS, NA, NW	1 h	Moderate
eSensor Respiratory Viral Panel (GenMark)	X	X	RSV, PIV, hMPV, AdV, RV	NPS	8 h	High
FilmArray Respiratory Panel (BioFire/ BioMérieux)	X	X	RSV, PIV, hMPV, HRV/ EV, AdV, HCoV	NPS	1 h	Moderate
IMDx Flu A/B (Abbott)	X	X		NPS	8 h	High
Prodesse ProFlu (Hologic)	X	X	RSV	NPS	4 h	High
Prodesse ProFAST	X	X		NPS	4 h	High
Influenza A+B (Quidel)	X	X		NPS, NS	4 h	High
Artus Influenza A/B (Qiagen)	X	X		NPS	4 h	High
Verigene Respiratory Virus (Nanosphere)	X	X	RSV	NPS	4 h	Moderate
xTAG Respiratory Viral Panel (Luminex)	X	X	RSV, PIV, MPV, RV, AdV	NPS	8 h	High
xTAG Respiratory Viral Panel FAST (Luminex)	X	X	RSV, MPV, RV, AdV	NPS	6 h	High

[a]Adapted from reference 53. BAL, bronchoalveolar lavage; NA, nasal aspirates; NPS, nasopharyngeal swabs; NW, nasal wash.
[b]CLIA-waived.

Amplicon is identified with real-time detection in about one hour, and the instrument can be expanded to take a small, medium, or large number of cartridges simultaneously. The Alere iNAT is even faster; using a rapid isothermal molecular amplification method, this CLIA-waived, low-complexity assay for Influenza A and B requires only 15 minutes to results. Sensitivity was similar to culture, although more extensive evaluation versus the "gold standard" RT-PCR methods is needed. Nevertheless, such "point-of-care" molecular assays appear attractive, particularly in settings where immunochromatographic assays are currently used, such as in physicians' offices or emergency departments. While most diagnostic tests are approved for various specimen types, the Alere is approved for nasal swabs, which may be the most practical and easily obtained specimen in the outpatient setting.

The development of multiplex commercial panels started with the introduction of the TM Bioscience (now Luminex) xTAG Respiratory Viral Panel (RVP), which detects influenza A (with subtyping of H1 and H3), influenza B, RSV (subtyping of A and B), hMPV, PIV 1 to 4, HRV/EV, AdV, and four HCoV (NL63, 229E, OC43, and HKU1) (55). As with many uniplex PCR assays, the xTAG RVP assay required initial extraction of sample (via the bioMérieux NucliSENS easyMag), followed by reverse transcription and multiplex PCR, and then followed by hybridization to tagged oligonucleotide beads. Detection used the Luminex-100 with dual lasers. The process was highly complex and required 8 hours to run. A newer version of the assay, RVP FAST, decreased run time to 6 hours.

The eSensor Respiratory Viral Panel from GenMark detects influenza A and B (with subtyping A into H1, H3, and pandemic H1); RSV (subtype A or B), PIV 1 to 3, hMPV, AdV, and HRV. The assay takes approximately 8 hours and is of high complexity.

The final FDA-cleared assay is considerably less complex and much faster. The FilmArray from BioFire (now part of bioMérieux) is a self-contained, nested RT-PCR assay for influenza A (H1, H3, pandemic H1), RSV, PIV 1 to 4, hMPV, HRV/EV, AdV, and HCoV (HKU1 and NL63). This is a moderate-complexity assay requiring 2 minutes to set up and 1 hour to results. Each instrument processes one sample at a time and is best suited for ongoing, small-volume testing near the point of care. With one-hour turnaround time, the results can be used to influence antiviral treatment, admission, and isolation decisions. However, a large number of instruments are needed to run multiple specimens, and the tests are more expensive than many other molecular platforms.

A comparison of Luminex RVP and RVP FAST, GenMark eSensor, and BioFire FilmArray found sensitivity of 84 to 98% and specificity of 99 to 100%. Adenovirus and influenza B were the most likely to be false negative (56).

Other multiplex PCR diagnostic kits have been developed by Seegene and Qiagen and have CE-mark approval for sale in the European Community.

PHENOTYPING, GENOTYPING, ANTIVIRAL SUSCEPTIBILITY

While culture is increasingly rare in the clinical virology laboratory, it will continue to be used in some academic research laboratories and in reference laboratories. Culture continues to be important for the characterization of influenza for vaccination preparation and for phenotypic characterization of antiviral sensitivity. Neutralization assays for serologic testing also require culture of the relevant virus. However, molecular methods for both virus characterization and drug susceptibility are increasingly performed with Sanger sequencing of partial and whole genomes.

Antiviral susceptibility testing remains important for monitoring influenza antivirals. Between 2007 and 2009, increasing resistance to oseltamivir in seasonal H1N1 viruses was found, as well as amantadine resistance of H3N2. Subtyping was essential in severely ill, hospitalized patients to guide therapy and prophylaxis. Since 2009, amantadine resistance of all influenza A (influenza B is naturally resistant), but only minimal resistance to oseltamivir or zanamivir, has been seen. Resistance may emerge during treatment of severe disease, particularly among the immunocompromised, and can be measured with phenotypic or genotypic testing. The signature mutation for H1N1 is H275Y, but other mutations could also contribute to antiviral resistance. Resistance testing is primarily performed at reference laboratories by sequencing of the neuraminidase gene (57).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The result of a respiratory virus molecular or immunochromatographic test may indicate the presence of virus (nucleic acids or antigen). The detection of virus does not prove that the virus is the cause of the current respiratory symptoms, nor does it exclude the coinfection of multiple viruses or concurrent bacterial infections. Thus, results will need to be interpreted in the appropriate clinical context. Multiplex PCR has demonstrated frequent coinfection with multiple viruses, particularly in children. Detection of more than one virus has unknown clinical consequences but may be of value to prevent cohorting of children with multiple viruses.

While a positive result indicates the presence of virus, as long as all quality controls are adequate, a negative or nonreactive result does not entirely rule out the absence of a viral infection. This is true particularly for the antigen-based assays, which have lower analytical sensitivity compared with molecular assays, and particularly in adults or in patients several days after symptom onset. However, even in children, inadequate collection of specimen could lead to false negatives. Inadequate extraction or inhibition would also lead to false negatives. These are controlled with most molecular assays by the addition of exogenous nucleic acid, such as MS2 phage, to the sample prior to extraction. Detection of MS2 will then control for extraction, reverse transcription, as well as amplification.

With individual tests, each can be reported as positive, negative, or indeterminate. For indeterminate results, a protocol is required for resolving these, which may include repeat testing before the report is finalized, reflexing to supplementary tests, or requesting a repeat or alternative sample.

For assay panels with a long list of tested analytes, a potential issue is how to report all of the results. A report in which each analyte is listed, and a "positive" or "negative," would be the simplest solution. However, clinicians may object to a long list of results, and a positive result may not be quickly apparent from a cursory glance at the report. An alternative is to report as "positive" for the individual viruses detected, or "negative for all tested viruses," and to list all the viruses tested at the bottom of the report. The latter solution may be clearer for clinicians to interpret. Some infections, such as influenza, are reportable to public health authorities, and this should be documented on the report as well.

The assay used for testing should be reported, whether an LDT, ASR, or commercial IVD. The source of the material, and version of the test, should be specified. Laboratories should consider assigning version codes to protocols using LDTs and ASRs, and should include a comment regarding the target of the assay. Finally, comments are added such as "Positive for rhinovirus/enterovirus by PCR. This assay does not distinguish rhinovirus from enterovirus. Please request additional testing if clinically relevant." Additional testing is then offered if enterovirus typing is clinically relevant.

Antigen-based assays, culture, or qualitative molecular assays would be reported as positive/negative or as detected/not detected. However, many LDTs, ASRs, and commercial assays will give a continuous outcome measure such as a cycle threshold or viral load. In the absence of a clear clinically important interpretation, these should generally not be reported. However, we choose to report these verbally to the infectious-diseases consultant in settings of apparent serial testing and nonresponse, as a marker for potential antiviral resistance for infections such as influenza.

All molecular tests are run with internal controls such as MS2, which indicate extraction, reverse transcription, and amplification. The presence of target indicates generally adequate extraction, reverse transcription, and amplification, but cannot rule out target-specific or relative (incomplete) inhibition of the reaction. Most current methods do not include a method for ascertaining specimen adequacy, which was done by laboratories using DFA by noting whether adequate epithelial cells were seen. While molecular methods are more tolerant of poor sample collection, validated methods for ascertainment of sample adequacy, such as measurement of beta-actin or GAPDH DNA or RNase P, may help identify inadequate specimens, although thresholds for specimen adequacy have not been well established. Ideally, multiplex assays will include a specimen-adequacy marker, such that an inadequate concentration could be reported as "Inadequate specimen collected, which may result in false negative results. Please repeat if clinically necessary."

Laboratories conducting respiratory virus testing must be attuned to regional and global outbreaks with novel strains of virus and must be aware of whether their current tests are capable of detecting currently circulating strains. Assays prone to changing diagnostic accuracy may require annual recertification by the FDA in the future; such recertification may be less important for molecular diagnostics which are capable of detecting broad targets such as influenza A matrix gene.

THE FUTURE OF RESPIRATORY VIRUS TESTING

Laboratory-developed and commercial assays are utilizing extraction-free methods and exploring the potential of alternate enzymes and isothermal conditions, such as loop-mediated isothermal amplification or helicase-dependent amplification. These may be faster and cheaper than conventional and real-time PCR-based molecular tests, although they currently have severe limitations for multiplexing targets. There will likely be many new assays available using the "molecular point of care" model of near-patient rapid testing.

Further into the future, chips and microarrays will be increasingly used for broad testing of viruses, bacteria, fungi, and parasites. Nucleic acids are applied to microarrays, and the hybridized products are detected. The very broad range of detection is offset by the expense and limited analytical sensitivity of these systems, but improvements are likely in the next few years and these methods may eventually be feasible in the clinical virology laboratory.

Finally, viral metagenomics with "shotgun" sequencing of all nucleic acids in a given clinical sample may obviate the need for pathogen-specific diagnostic testing. Rather, extraction of a specimen followed by amplification and sequencing of all nucleic acid material, using next-generation sequencing instruments such as the Thermo Fisher Scientific Ion Torrent or Illumina HiSeq, will enable identification of all potential infections in a sample. Currently, these methods remain highly complex, requiring extensive preparation and postanalysis bioinformatics manipulation, and analytical sensitivity remains inferior to uniplex or multiplex PCR. However, these methods will continue to develop and will increasingly supplement detection in a multiplex test-negative sample, where clinically relevant.

The development of respiratory virus diagnostics in the past decade has been dramatic, and the pace of change is accelerating. The dominance of rapid antigen detection and rapid culture has largely been replaced by molecular testing for influenza alone or with multiplex panels for various respiratory viruses. Molecular testing has been demonstrated to be more sensitive than antigen detection or culture, compatible with high specimen throughput, and more adaptable to new viruses and to new variants of old viruses.

The coming years are likely to see further development of uniplex assays, limited panels, and large multiplex panels. One type of test will be a new point-of-care rapid molecular test, performed in the emergency department or in a core laboratory and available in time to influence treatment and hospitalization decisions. Conversely, there will continue to be a need for high-throughput, batched testing for large numbers of viruses. On a more limited basis, reference laboratories will continue to use viral culture or more complex molecular methods for characterization of novel viruses and viral strains and for elucidation of antigens for vaccination and mutations for drug resistance.

Most importantly, the improved detection of viruses will drive a greater demand for effective prevention and therapy, which in turn will mandate improved detection. Currently, effective prevention and treatment strategies exist only for influenza. Laboratory directors should pay attention to the development of vaccines or drugs for common infections such as RSV or HRV, both common causes of morbidity and occasional mortality in young children and in the elderly. The demand for rapid testing will further accelerate in the future when specific antivirals are available.

Measles, Mumps, and Rubella Viruses

DIANE S. LELAND AND RYAN F. RELICH

64

Measles virus, also called rubeola, and mumps virus are both RNA viruses of the family *Paramyxoviridae*, subfamily *Paramyxovirinae*; measles is in the *Morbillivirus* genus, and mumps virus is in the *Rubulavirus* genus. Rubella virus is also an RNA virus but is a member of the *Togaviridae* family. These three viruses, despite differences in their families and genera, are often considered together because the epidemiology of the infections they produce in humans and the preventive measures used against them are similar for all three. Measles and rubella, both of which produce rash-associated illness, and mumps, which typically infects the parotid glands, were all included among the expected illnesses of childhood in the United States prior to the introduction of vaccination programs in the late 1960s. Measles epidemics involving 500,000 to 700,000 cases occurred every 2 years (1), approximately 180,000 cases of mumps were reported annually (2), and approximately 58,000 rubella cases that included 60 congenital rubella syndrome (CRS) cases (3) were seen annually.

Individual vaccines for mumps (Mumpsvax, licensed in 1967), measles (Attenuvax, licensed in 1967), and rubella (Meruvax, licensed in 1969), all from Merck and Company, Inc., started the downward trend in numbers of infections. With the licensing of the first measles/mumps/rubella (MMR) vaccine in 1971, the epidemiology of measles, mumps, and rubella virus changed dramatically, with the number of cases in the United States decreasing rapidly throughout the 1970s and 1980s. In 1986 and 1987 in the U.S., there was a brief resurgence of mumps cases that peaked at 8,000 to 12,000 cases. A similar resurgence in the number of measles cases occurred from 1989 to 1991, peaking at nearly 30,000 cases. Resurgences were attributed to susceptible populations of children under 5 years of age residing in urban settings and to an accumulation of underimmunized children born between 1967 and 1977 (1).

Following measles and mumps resurgences, a two-dose schedule was implemented for the MMR vaccine in the United States. The first dose is given between 12 and 15 months and the second between 4 and 6 years of age (4). Although measles was declared eliminated from the U.S. in 2000, sporadic outbreaks continue to occur due to importation of infection from areas of the world in which measles remains endemic (5). Sporadic outbreaks are also seen with mumps, with infections sometimes seen in fully vaccinated individuals, although there is no longer endemic transmission of measles, mumps, or rubella in the U.S.

With the decrease in incidence of measles, mumps, and rubella, the demand for diagnostic services has changed. Although previously diagnosed on clinical grounds alone, these infections are now so rare that they are not readily recognized by physicians. Likewise, they may occur in underimmunized individuals or in immunocompromised individuals, in whom typical clinical signs and symptoms are absent. Laboratory-based confirmation of infection is essential to ensure an accurate diagnosis (6), but most hospital diagnostic laboratories do not offer testing to confirm current infection, focusing instead on immune-status evaluations. Each of these viruses continues to present unique epidemiologic and diagnostic challenges, so measles, mumps, and rubella viruses are discussed separately in the pages that follow.

MEASLES

Measles is a leading cause of vaccine-preventable death among children around the world, having killed approximately 139,000 people in 2010, most younger than 5 years old (7). Although seldom fatal in developed countries, measles is especially deadly in resource-challenged countries where death rates may reach 10 to 30% among young children, most of whom have not received vaccine (7). In the U.S., measles cases decreased to an average of 63 cases per year between 2000 and 2007 but increased in 2008 to the highest level in more than a decade; half of the cases were in children whose parents had refused to have them vaccinated. During 2011, there were 222 measles cases in the U.S., 200 of which were associated with importations from other countries and occurred in unvaccinated individuals (8). In the first 3 months of 2013, England experienced 587 confirmed measles cases, which is twice the number in the same period the previous year. Experts describe these cases as "the 'legacy' of unvaccinated children in the 10 to 16 age bracket who missed out on vaccination in the late 1990s and early 2000s when there was widespread concern over the now discredited link between autism and the MMR vaccine" (9).

Measles virus causes classic 7-day measles. In measles infection, after 1 to 2 weeks of incubation, fever, rhinorrhea, cough, and conjunctivitis appear, followed by a maculopapular rash and Koplik spots (1- to 3-mm red spots with a bluish-white speck in the center located on the buccal mucosa—pathognomonic for measles). The rash usually lasts

doi:10.1128/9781555818722.ch64

7 days, and recovery is rapid and complete. The complications of measles may include otitis media, lower respiratory infections, confusion, and seizures. Subacute sclerosing panencephalitis (SSPE) is believed to be a persistent measles infection of the central nervous system. Onset is 4 to 7 years after the initial measles episode and is characterized by personality changes, mental deterioration, involuntary movements, and muscular rigidity, invariably ending in death (1). The incidence of SSPE has been estimated as 1 per 11,000 measles cases (10). However, SSPE has been largely eliminated in countries like the United States in which measles has been reduced to low levels for more than a decade.

Transplacental transfer of antibodies traditionally provided protection from measles for infants for 6 months or longer after birth. Currently, the level of transplacental antibody is lower at birth, and infants are more susceptible because mothers whose measles immunity is vaccine induced have lower levels of antibodies. By 6 months of age, only 18% of infants born to vaccinated mothers were shown to have protective levels of measles antibodies; this is in contrast to the 50% of infants born to naturally infected mothers (11). Premature infants (<32 weeks gestation and weighing less than 1,000 g) may demonstrate seronegativity of 45% for measles, with further deterioration of immunity over the next 3 months, resulting in seronegativity of 94% for measles (12).

Interestingly, despite the lower measles-specific antibody levels following vaccination compared to those after natural infection, antibody in vaccinated individuals has been shown to persist (13). Measles antibody has been detected in two-dose MMR recipients 26 to 33 years after vaccine administration, with 92% of these individuals showing antibody at protective levels. Measles occurs very rarely in vaccinated individuals.

DIAGNOSTIC STRATEGIES FOR MEASLES

For measles, both current infection and immune status may need to be determined. For confirmation of current infection, virus isolation in culture, detection of viral RNA by reverse transcriptase polymerase chain reaction (RT-PCR), or confirmation of measles-specific IgM is needed. Throat or nasopharyngeal swabs are usually the preferred sample for virus isolation and RT-PCR, although urine may also contain virus (14). Oral fluids, buccal swabs, and blood are sometimes used in testing. Measles virus can be isolated in Vero/hSLAM cells. These are Vero cells transfected with a plasmid encoding the gene for human signaling lymphocyte activation molecular (hSLAM) protein, which is a receptor for both wild-type and laboratory-adapted strains of measles. Measles virus produces the cytopathic effect of syncytium formation in these cells (15). These cells are available to World Health Organization (WHO) laboratories. Measles virus may also proliferate in B95a cells, another cell type not used routinely in most hospital laboratories. Virus isolation typically takes several days or weeks.

Efficient and timely molecular testing by real-time RT-PCR performed directly on the specimen is likely the most effective approach for detecting current infections. Several RT-PCR methods have been developed (16–19), including one that simultaneously detects measles and rubella RNA (20). Sensitivities and specificities vary among methods, with typical lower limits of detection estimated as 10 (18) to 20 (19) copies per reaction. Specificity has been confirmed by testing with samples positive for respiratory viruses (respiratory syncytial virus, influenza A and B, and human metapneumovirus) (18, 19), mumps (18, 19), and enteroviruses (19). Some RT-PCR methods also provide quantitation and genotyping information. In addition to the types of samples listed previously, lysates of measles-infected cells dried onto filter paper can be used for molecular testing (15).

Detection of measles-specific IgM in blood or oral fluid is another accepted method for laboratory confirmation of suspected cases. In natural measles infection (in an unimmunized host), IgM is detectable initially within 3 to 4 days of appearance of clinical symptoms and persists for 8 to 12 weeks. IgM is most effectively detected between day 4 and 28 after the onset of rash; in the first 72 hours after the appearance of the rash, up to 30% of tests for measles IgM may be falsely negative (14). Enzyme immunoassay (EIA) methods for measles IgM detection in serum have been estimated to have a false-positive rate of 4%, with false-positives occurring in patients with parvovirus B19 and rubella (21, 22).

A significant increase in IgG between two samples, one collected at or near the time of the rash and the second collected 2 weeks later, can be confirmation of current infection. IgG is detectable within 7 to 10 days of the onset of symptoms, is maintained at high levels for years, and remains detectable for life. Confirmation of current measles infection by IgG measurements is slow and may be complicated by obtaining samples at the appropriate intervals.

Measles infection in vaccinated individuals is rare but presents a diagnostic challenge. Clinical signs and symptoms may be different from those seen in unvaccinated individuals, and laboratory confirmation of infection is more complicated. IgM and the virus itself may be difficult to detect. IgG avidity determinations may be useful in these cases to differentiate measles IgG produced in the new infection from IgG related to previous immunization. Commercially available measles-specific IgG assays can be modified to determine IgG avidity and have shown 91.9% sensitivity and 98.4% specificity in differentiating low-avidity (new infection) IgG from high-avidity (previous immunization) IgG (23). Avidity determinations, in addition to measurement of measles-neutralizing antibody levels, may be needed to confirm infection in previously vaccinated individuals (21). Unfortunately, at this writing, measles avidity assays remain as research or investigational tools. Further standardization of control materials and implementation of guidelines for use are needed (25).

Testing for measles immune status, rather than for current infection, is the focus of most hospital laboratories. Although antibodies are produced against various measles proteins, protection is most closely correlated with antibodies to the measles virus hemagglutinin (H) protein. Most assays use whole virus or viral extract antigens that will detect antibodies of various specificities, but most detect antibodies against the measles H proteins effectively.

The most widely used methods in measles antibody detection are EIA, indirect immunofluorescence (IFA), and multiplex bead fluorescence immunoassays (FIA) that simultaneously detect IgG antibodies to measles, mumps, rubella, and varicella zoster viruses. EIAs, IFAs, and FIAs can be designed to detect either IgG or IgM. U.S. Food and Drug Administration (FDA)-cleared EIA, IFA, and FIA kits are readily available commercially, and testing is not difficult to perform. Most EIAs and FIAs are fully automated, so they are optimal for large-volume testing. The IFAs are performed manually and require expertise for microscopic evaluation and interpretation.

Complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), and plaque reduction neutralization (PRN) are seldom used in diagnostic laboratories

but may be available at reference or research facilities. PRN can be modified to allow a comparison of IgM and IgG levels, as well as to measure total (IgG + IgM) response. The other methods detect total response and do not distinguish between IgG and IgM. CF, HI, NT, and PRN assays are more complicated, requiring a variety of reagents and considerable expertise on the part of the technologist. These are used primarily for difficult cases that are not resolved with routine testing methods.

Comparisons of IgG or total antibody (IgM and IgG together) levels can be achieved with IgG-specific EIA, IFA, and FIA or by total antibody detection by CF, HI, NT, or PRN. With assays performed in serial 2-fold dilutions, a 4-fold increase in antibody level between acute- and convalescent-phase samples confirms infection. With methods such as EIA that are not performed in serial dilutions, the manufacturer must provide guidelines for defining significant differences in antibody level. No standardized interpretation is available for these assays. EIA results show very good correlation with HI and PRN in testing of paired serum samples to detect rises in IgG (14).

The laboratory confirmation of SSPE is less straightforward. Measles virus often cannot be isolated due to its defective nature, and antibodies are detectable but in abnormally high quantities. A comparison of antibody levels in serum and cerebrospinal fluid (CSF) shows greater elevations in the CSF than in the serum (26).

Most commercially available FDA-cleared EIAs, IFAs, and FIAs have shown acceptable sensitivity and specificity for immune status determinations. However, endpoints of these assays are usually set to maximize confidence in positive results, causing these methods to yield false-negative results in low-titered immunity (26). In situations where very low levels of antibody are suspected, testing for measles antibodies by the NT, HI, or PRN assays—performed at a reference or research laboratory—may be needed.

TECHNOLOGY FOR MEASLES TESTING

Molecular Methods

After the appearance of the measles rash, RT-PCR methods are often able to detect measles virus for 3 to 4 days beyond the time of successful virus isolation. Typical samples such as nasal pharyngeal swabs, oral fluids, and blood can be tested. Oral fluid sampling devices which include a preservative for stabilizing IgM should not be used for collection of RT-PCR samples (14). None of the measles RNA real-time RT-PCR assays are FDA-cleared for *in vitro* diagnostic testing, but several published methods have been shown to be effective. Most of these use TaqMan technology to detect measles RNA alone (16–19) or in combination with rubella RNA (20). The multiplex assay detects measles and rubella RNA in a single tube as effectively as individual RT-PCR for measles alone or rubella alone. Primers and probes for the multiplex assay are based on highly conserved regions of the complete measles nucleoprotein (N) gene sequences available in GenBank; the assay has a lower limit of detection of 100 copies per reaction. A multiplex RT-PCR has been developed that identifies the RNAs of measles virus, rubella virus, parvovirus B19, enterovirus, human herpes virus type 6 (HHV-6), and human herpes virus type 7 (HHV-7). Infections with each of these viruses can be accompanied by a "measles-like rash." In 26 patients clinically diagnosed with measles, measles virus was detected in only eight; parvovirus was detected in two, HHV-6 in three, and HHV-7 in one (27).

Serologic Methods

Sample requirements: The specimen collection guidelines are similar for most serologic assays: collect whole blood, separate serum, store the serum in the refrigerator (2 to 8°C) for up to 48 h, and freeze the serum (−20°C) if testing will be performed after 48 h. For most methods, heat inactivation of the serum (incubation at 56°C for 30 min) is not required. Some methods specify that heat-inactivated samples cannot be used. In general, contaminated, hemolyzed, lipemic, or icteric specimens should not be used.

An alternative to serum collected by venipuncture is whole blood obtained by finger stick or heel prick, spotted on Whatman filter paper, air dried, sealed in air-tight packets, and stored at 2 to 8°C. Venous blood collected by venipuncture may also be spotted on filter paper and stored. Following elution and dilution of the dried blood sample, commercial EIAs may be used to test the sample. Results of EIA testing for measles IgG and IgM from dried blood spots have shown excellent correlation with those of fresh serum or plasma testing (28–31). Storage of blood spots for up to 24 months without significant change in antibody testing results has been demonstrated, although storage for 6 months or less is recommended (32). Prior to testing, the dried blood is eluted from the filter paper using phosphate buffered saline (PBS) with Tween 20 at room temperature for 30 minutes. The eluted sample is then diluted in PBS containing 5% fat-free milk powder before testing by EIA (28).

EIA

Most diagnostic laboratories use FDA-cleared, commercially supplied measles antibody EIA testing systems and follow protocols provided and validated by the manufacturer. The typical configuration involves an antigen-coated solid phase (often microwells). The antigen may be an extract of cells infected with virus (often Edmonston strain for measles) or a recombinant protein. Testing is performed either manually or with an automated system. All controls are supplied by the manufacturer to ensure accuracy and reproducibility. Most EIAs detect only IgG, but IgM-specific EIAs are available. IgM-specific assays may include a serum pretreatment step to eliminate interference from virus-specific IgG and rheumatoid factor or an "IgM capture" step featuring microwells coated with antibodies against human IgM. In the first step of a capture assay, patient's serum is added to the antibody-coated microwell, and any IgM present in the sample is bound or captured. In subsequent steps, reagents are added to confirm that the captured IgM is, indeed, specific for the virus. Most large reference laboratories list measles-specific IgM testing in their menus.

IFA

IFA can be used for measles antibody detection. Written procedures, along with proper reagents and controls, are included with each FDA-cleared commercial product, and manufacturer's guidelines must be followed. Like the EIAs, most IFAs are designed to detect IgG antibodies but can be used for IgM detection. As described above for IgM-specific EIAs, IgM-specific IFA testing is preceded by a serum pretreatment step to aid in eliminating interference from IgG and rheumatoid factors.

FIA

Automated FIA technology is comparatively new to the diagnostic laboratory. Sets of tiny polystyrene beads are dyed various shades of color with fluorescent dyes, and each bead set is coated with a particular antigen. Beads from each set

are combined in a single reaction vessel to which the patient's serum is added. Following incubation and washing, a fluorescein-labeled antibody (either antihuman IgG or antihuman IgM) is added that binds to patient's IgG or IgM that bound to the antigen on the bead during the first incubation. After washing to remove unbound conjugate, beads are analyzed (up to 20,000 per second) by a dual-beam laser system. One laser identifies the bead set (by color of the bead), and the other laser measures bound conjugate to determine if the patient's antibody bound to the antigen on the bead surface. One multiplex bead FIA by BioRad Inc, the BioPlex 2200, features an FDA-cleared multiplex assay that simultaneously detects antibodies to measles, mumps, rubella, and varicella antibodies. The system is totally automated.

CF

CF depends on the binding of antibodies to the viral antigen to make antigen–antibody complexes that bind complement, thus making it unavailable for lysis of sensitized indicator red blood cells. CF is a lengthy and cumbersome method of antibody detection, requiring multiple reagents and an overnight incubation period (33–35). Few diagnostic laboratories currently use this method for measles antibody determinations because the EIAs, IFAs, and FIAs are more sensitive and so much easier to perform.

NT

Virus NT measures the capacity of serum antibody to neutralize live virus, thus preventing it from infecting susceptible cell cultures. NT testing requires laboratory facilities suitable for management of live, infectious viruses and cell cultures. The virus must be quantitated prior to the start of the assay, and cell cultures are observed to determine the result (36). This method is sometimes considered the reference method against which other assays should be compared because neutralizing antibodies, which are the type of antibody considered protective for infection, are measured.

HI

An overview of the HI test for measles (and mumps) antibodies is presented below. A detailed procedure was published previously (26, 37).

Antigens

Commercially purchased measles and mumps virus hemagglutinating antigens are used. Antigen suspensions must be treated to break up antigenic particles and titrated to determine a challenge dose of two 50% hemagglutinating units.

Erythrocytes

For measles antibody testing, African green, Patas, or rhesus monkey erythrocytes are used. For mumps antibody testing, chick, goose, or monkey cells are used.

Specimen Preparation

Serum, plasma, or CSF may be used. Nonspecific inhibitors of agglutination must be removed from serum or plasma by treatment with saturated ammonium sulfate, and nonspecific agglutinins must also be removed by mixing inhibitor-free sample with packed erythrocytes. CSF is usually free of nonspecific inhibitors and agglutinins.

Performance of the Test

A U-bottom microwell plate may be used to prepare serial 2-fold dilutions (from 1:2 to 1:2,048) of test serum. Add prepared, titrated hemagglutinating antigen to serum dilutions, incubate, and add a 0.5% erythrocyte suspension to all wells. Allow erythrocytes to settle. Read for hemagglutination.

IgG and IgM titers can be determined separately in a series of three titrations. The first is carried out as described above. The second titration uses serum that has been extracted with *Staphylococcus aureus* protein A, and the third titration is conducted on sera that have been further treated for 30 min with 0.2 volume of 1 M 2-mercaptoethanol. The IgG level is the difference between the arithmetic titers of the first two tests, and the IgM level is the difference between those of the second and third tests. IgG3 and IgA remain in the third test.

PRN

The PRN assay is used for detecting measles antibodies only. An overview of the PRN test is presented below. A detailed procedure was published previously (26, 37).

Challenge Virus

Use a low-pass measles virus (previously titrated).

Cell Cultures

Use Vero cells grown to confluence in 24-well (16-mm-diameter) plates.

Performance of the Test

Mix portions of serial dilutions of inactivated serum with an equal volume of virus containing 125 PFU. Incubate mixtures for 1 h at 37°C. Inoculate this mixture into cell cultures drained of their medium. Incubate cultures for 1 h at 37°C. Replace the inoculum with agarose overlay. Incubate for 4 to 7 days, with timing determined by plaque formation. Remove the overlay, stain the cells with neutral red diluted in cell culture medium, and count. A 50% reduction in plaque count, relative to controls, is considered the endpoint.

INTERPRETATION OF MEASLES TESTING

Isolation of measles virus in culture or the presence of measles RNA in clinical samples is the preferred approach for confirming current or very recent infection or vaccination. If the serologic approach is used for diagnosis of current or very recent infection, serum is tested for measles IgM. The presence of IgM indicates current or recent experience with the virus, either through infection or vaccination. Timing of collection of samples for IgM testing relative to onset of symptoms is important for accurate detection. Both false-positive and false-negative results are possible.

Interpreting a positive IgM result from a person with suspected measles can be difficult if the person has recently received measles vaccine. Because measles-specific IgM may appear as early as 8 days after vaccination and persists for at least 8 weeks after primary vaccination, IgM-positive results obtained during this time should not be assumed to confirm infection (38). IgM is not produced routinely upon revaccination of those previously immunized but may be detected following clinical measles in these individuals (1). An absence of IgM does not rule out measles infection. Samples collected within 72 h after onset of rash may not yet contain detectable IgM, and IgM may not be produced in infection of those previously immunized (1).

A significant increase in IgG level between acute- and convalescent-phase samples is also indicative of infection or vaccination but may be seen in those with a history of natural infection or vaccination when they are again exposed

to the virus. Failure to detect a significant increase between acute- and convalescent-phase samples in infection may occur if the samples are collected too long after the onset of symptoms. This approach is slower than the other approaches and is, thus, the least desirable.

The U.S. Centers for Disease Control and Prevention (CDC) currently recommends collection of respiratory specimens for culture or RNA testing and blood for serologic testing in suspected measles cases. Clinical and epidemiological information should also be considered in the final interpretation of test results (25).

Most measles serologic testing in U.S. laboratories is for determination of immune status. Testing of a single serum sample for measles IgG is sufficient for this purpose. A positive (antibody detected) result by any of the many U.S. FDA-cleared methods correlates with immunity.

MUMPS

Mumps virus causes the infection known simply as "mumps," which typically involves swollen parotid glands. This infection is clinically unapparent in 25 to 30% of cases, is typically mild, and is characterized by slightly elevated temperature and enlargement of one or both parotid glands. Complications of mumps include meningoencephalitis (up to 15% of cases) and, in postpubertal individuals, orchitis (20 to 30% of males) and oophoritis (7% of females) (39). Mumps remains common throughout much of the world.

Although numbers of mumps cases in the U.S. diminished rapidly with the success of the MMR vaccine, isolated outbreaks continue to occur. Only 231 mumps cases were reported in the United States in 2002 (40), but the largest U.S. outbreak in 2 decades occurred in the Midwestern states in 2006 (41). More than 6,500 cases were involved in this outbreak, and a high percentage of the cases had received two doses of mumps vaccine. Waning immunity and incomplete vaccine-induced immunity to circulating wild-type virus were suspected as causes (41). The overall estimate of mumps antibody seroprevalence in the U.S. in 1999 through 2004 was 90%, which is the lower end of the level of immunity (90 to 92%) needed to achieve herd immunity (42).

During 2009 and 2010, another mumps outbreak occurred in the U.S involving 3,502 cases of mumps (43). As with the 2006 outbreaks, a high percentage of infected individuals had received either one (14%) or two (76%) doses of the MMR vaccine, so waning of vaccine-induced protection against mumps was again suggested as a contributing factor. It was also concluded that the level of immunity required to protect against clinical mumps may depend on the size of the inoculum of virus involved in the exposure, indicating that a particular antibody titer versus protection from infection is not absolute (43). However, there is evidence that individuals with lower antibody titers are more likely to become infected (44).

At this writing, the incidence of mumps has returned to its pre-2006 outbreak levels, but it remains unclear whether a change in the vaccine itself or in vaccine administration schedules will be needed to prevent future outbreaks in the United States. Mumps remains common throughout much of the world, usually infecting 6- to 10-year-old children in the spring in unvaccinated populations.

Similar to measles antibodies, mumps antibodies transplacentally transferred from vaccinated mothers are at lower levels at birth, and infants are more susceptible to infection than in the prevaccine era when mothers experienced natural infection. Premature infants may demonstrate seronegativity of 55% for mumps, with further deterioration of immunity over the next 3 months, resulting in seronegativity of 100% for mumps (12).

DIAGNOSTIC STRATEGIES FOR MUMPS

Both current infection and immune status may need to be confirmed for mumps. Virus isolation, RNA detection, and detection of mumps-specific IgM are evidence of current infection. Saliva, blood, urine, and CSF are suitable specimens for virus isolation and RNA testing. Mumps virus proliferates in several cell lines routinely used in viral diagnostic laboratories, including primary monkey kidney, human neonatal kidney, HeLa, and Vero cells. Better proliferation may be obtained in B95a and Vero/hSLAM cells, but these lines are not available at most diagnostic laboratories. The process of virus isolation is slow, and reagents may not be available for confirmation at most laboratories.

Molecular techniques are the method of choice for confirmation of current infection. The assays are more sensitive than virus isolation in culture and can provide sequence information needed for genotyping. RT-PCR methods can detect mumps RNA in oral fluids, CSF (45, 46), saliva/throat, and urine specimens (45, 47). There are currently no FDA-cleared molecular assays for mumps detection.

Mumps IgM is detectable initially within 3 to 4 days of appearance of clinical symptoms and persists for 8 to 12 weeks. Detection of mumps-specific IgM is one of the ways to confirm current infection. However, there is cross-reactivity of mumps antibodies and antibodies against other related viruses (human parainfluenza viruses, types 1, 2, 3, and 4 and others), so falsely positive results may be encountered. Samples collected too soon after infection may be falsely negative in IgM testing.

Mumps IgG is detectable within 7 to 10 days of the onset of symptoms, is maintained at high levels for years, and remains detectable for life. Confirmation of a significant increase in antibody level between two samples collected 2 weeks apart supports current infection, but—as seen in mumps IgM assays—increases in IgG may be seen in patients infected with related viruses. In general, cross-reactivity with related viruses can be ruled out by testing for antibodies to the related viruses in parallel with mumps virus antibody testing. The greatest increase in antibody level should identify the true infection. Given the lack of serologic test specificity, virus isolation and RNA detection in clinical samples remain the most effective ways to confirm infection in unvaccinated individuals.

Confirmation of current mumps infection in previously infected or immunized individuals is very difficult. Virus isolation and RNA detection have been recommended for mumps diagnosis in these individuals. Buccal swabs should be procured early (within 3 days of parotitis onset), as the duration of viral replication is likely to be shorter in these hosts. Virus isolation in culture or RNA detection can be variable, presumably due to low viral loads. IgM is not consistently observed in this situation, so it is not a reliable indicator of recent infection. IgM may be produced weakly or not at all in a secondary immune response. In a recent outbreak, mumps virus IgM antibodies were detected in fewer than 15% of mumps virus-infected persons who were previously immunized, and 95% of these patients were positive for mumps virus IgG (48). The CDC provides guidance online for mumps testing in both previously vaccinated and unvaccinated individuals (http://www.cdc.gov/mumps/lab/qa-lab-test-infect.html).

Because standard diagnostic tests for mumps that detect virus or virus-specific antibody perform inconsistently for

individuals with prior immune exposure via either immunization or natural infection, an alternate approach has been developed. Detection of activated mumps-specific antibody-secreting memory B cells (ASCs/plasmablasts) by EIA has been shown to be a more reliable test (49). ASCs are detectable in circulation only following recent activation by antigen. In testing for ASCs, peripheral blood mononuclear cells are cultured in the presence of polyclonal mitogens, and the ASCs are detected by exposure to viral antigen. Trials with this method detected mumps ASCs in recently MMR-vaccinated individuals and in those with clinical mumps during a mumps outbreak. Detection of ASCs appears to be more sensitive for longer periods of time than RT-PCR or IgM EIA and may be useful for diagnosing mumps cases that cannot be confirmed with standard methods and for testing asymptomatic case contacts in an outbreak. Interestingly, mumps ASCs appear to be produced in lower numbers than measles or rubella ASCs, suggesting that mumps infection may not generate robust B-cell memory (49).

As with measles, most mumps antibody testing in the United States involves immune status determinations using FDA-cleared, commercially available EIA, IFA, and FIA test kits. Because these methods may yield falsely negative results in low-titered immunity, NT and HI assays for mumps antibodies may be needed but are available only at reference or specialty laboratories.

TECHNOLOGY FOR MUMPS TESTING

Molecular Methods

At present, there are no FDA-cleared methods for mumps RNA detection, but high-quality reagents are available. Two RT-PCR assays have been developed and standardized by the CDC, with information available online. Step-by-step procedures are provided and commercial sources of reagents are identified for one standard RT-PCR that detects the SH gene of mumps virus (http://www.cdc.gov/mumps/downloads/lab-rt-pcr.doc) and for one real-time RT-PCR assay (http://www.cdc.gov/mumps/downloads/lab-rt-pcr-assay-detect.doc). Molecular assays are more sensitive than virus isolation in culture and can provide sequence information for the coding region of the SH gene that is needed to determine the viral genotype. Laboratories with advanced molecular assay capabilities may be able to offer mumps detection by RT-PCR, but most routine virology laboratories rely on mumps virus isolation as the standard method for diagnosing mumps virus infection.

Serologic Methods

As presented above for measles serologic methods, serum sample collection, processing, and storage are similar for most serologic assays. Blood spotted onto Whatman filter paper can be eluted and tested for mumps antibodies. Results of EIA testing for mumps (28) IgG and IgM from dried blood spots have shown excellent correlation with those of fresh serum or plasma testing. Protection from infection is most closely correlated with antibodies to the mumps virus hemagglutinin/neuraminidase (HN) protein. Most assays use whole virus or viral extract antigens that will detect antibodies of various specificities, but most detect antibodies against the mumps HN proteins effectively.

EIA, IFA, and FIA

FDA-cleared, commercially available EIA, IFA, and FIA kits are used by most laboratories for mumps antibody testing (as described above for measles EIA). Most EIAs and FIAs use either an extract of cells infected with Enders strain of mumps virus or a recombinant protein as the antigen in the system. IFA methods use mumps-infected cells fixed on a microscope slide as the antigen. Various configurations are available and may test for IgM alone, IgG alone, or IgM and IgG together. An IgM-capture EIA was used recently for detection of mumps virus IgM (48).

CF, NT, and HI

CF, NT, and HI can be used to detect mumps antibodies. All are cumbersome technologies seldom used in routine laboratories. The CF technique can be used with two different mumps virus antigens, V and S. Antibodies against the S antigen appear earlier and rise quickly, in contrast to the antibodies to the V antigen, which appear later. The presence of both V and S antibodies is thought to signal a recent past infection, while V antibodies alone signal a long-past infection (50). A detailed procedure for mumps virus antibody HI testing was published previously (26, 37). The NT method was described above for measles antibody detection (36).

INTERPRETATION OF MUMPS TESTING

As with measles virus infection, isolation of mumps virus or the presence of mumps RNA in clinical samples is evidence for current or very recent infection or vaccination. However, the interpretation of mumps antibody testing results is less straightforward than that of measles. Mumps IgM maybe detected, along with significant increases in IgG, in patients infected with related viruses such as the paramyxoviruses. In general, cross reactivity with related viruses can be ruled out by testing for these antibodies in parallel with mumps antibody testing. The greatest increase in antibody level should identify the true infection. Virus isolation and RT-PCR are the most accurate methods for resolving this issue. Interpretation of mumps serology can be obscured in patients previously vaccinated. Various therapeutic treatment regimens such as chemotherapy may result in a decrease in seropositivity for measles and mumps. Additional precautions in interpretation of testing results in diseases of low prevalence such as mumps are presented at the end of this chapter.

Testing for mumps IgG by various U.S. FDA-cleared methods is used to determine mumps immune status. Detection of IgG in a single serum sample is indicative of immunity.

RUBELLA

Rubella virus is the cause of a contagious, acute infectious disease called rubella, which is often colloquially referred to as German measles and 3-day measles. The rubella virus is principally transmitted by contact with infectious respiratory secretions and through inhalation of droplet nuclei, but vertical transmission is also possible. In symptomatic postnatal infections, the disease is characterized by mild fever, lymphadenopathy of suboccipital, postauricular, and posterior cervical nodes, and a discrete maculopapular rash that follows an incubation period averaging 16 to 18 days (range 10 to 21 days). Some patients may also experience conjunctivitis, arthralgia or arthritis (51). The disease is most often self-limited and without postinfectious sequelae, but rare complications including encephalitis (52, 53), polyradiculoneuritis (53), and thrombocytopenia (54) have been reported. Infection of pregnant women with rubella virus can lead to potentially devastating

consequences for the fetus. Congenital rubella syndrome has been associated with miscarriages, stillbirths, and a host of birth defects that include developmental delays, cataracts, hearing impairment, and congenital heart disease, among others. The risk of CRS appears to be greatest if infection occurs during the first trimester of gestation, and the risk declines after 12 weeks gestational age, with rare defects presenting in fetuses at risk of infection equal to or older than 20 weeks gestation.

The implementation of stringent vaccination campaigns such as The Measles and Rubella Initiative (http://www.measlesrubellainitiative.org/), a multicollaborator global partnership geared toward the eradication of measles and rubella, has essentially eliminated the endemic spread of rubella virus in the Americas. However, cases are still reported in many regions of the Western Hemisphere as a result of importation of cases from areas of endemicity. In other parts of the world, the disease remains endemic and, in 2012 alone, approximately 94,000 cases were reported to the World Health Organization by reporting countries (55).

Strict infection control precautions are mandatory to avoid transmission of the highly infectious rubella virus. Studies have demonstrated the presence of rubella virus in nasopharyngeal secretions 1 week prior to and 2 weeks following rash onset in postnatal cases. Because infected infants can remain infectious for 1 year or longer, enrollment of these children in daycare should be avoided, and isolation precautions should be implemented when they present to healthcare institutions (47).

DIAGNOSTIC STRATEGIES FOR RUBELLA

For rubella, laboratory testing to confirm acute or recent rubella infection, CRS, and immune status is needed. Immune status testing is straightforward and widely available at most diagnostic laboratories. As described above for measles and mumps immune status determinations, a single serum sample collected at random and tested by a rubella IgG-specific method such as EIA or FIA is all that is needed.

For diagnosis of current postnatal infections, serologic testing for rubella virus-specific IgG and IgM is the usual approach, although virus isolation in culture and detection of rubella virus RNA are useful. For serologic testing, a serum sample should be collected as soon as possible (within 7 to 10 days) after onset of illness and another collected 2 to 3 weeks later. If IgM antibodies are detected in the first sample, a diagnosis of rubella infection is supported; however, persons infected with parvovirus, those demonstrating the heterophile antibodies of infectious mononucleosis, or those who test positive for rheumatoid factors may have false-positive results for rubella IgM. Follow-up testing for these other analytes should be done if a false-positive rubella IgM result is suspected (57). A negative rubella IgM test may be encountered if the sample is collected before day 5 after rash onset, and testing should be repeated on another sample collected later. A significant increase in IgG levels between the first and second sample supports current rubella infection. Assays for IgG avidity can aid in distinguishing between recent and past rubella infections, with low avidity associated with recent primary infection and high avidity associated with past infection. These assays are most often performed in reference laboratories.

For investigation of rubella infection in pregnant women, rapid and accurate diagnosis is imperative. For patients who develop clinical signs, serum should be collected immediately and tested for the presence of anti-rubella IgM by EIA (58, 59). If a rubella IgM test result is positive in a woman with no history of illness and low or no risk of exposure to rubella, additional laboratory evaluation should be completed (57).

In current postnatal infection the virus can be isolated in culture. Virus shedding is greatest up to day 4 after rash onset, but virus may be isolated 1 to 2 weeks after rash onset. Throat swabs are the specimen of choice for isolation, although virus can be isolated from nasal, urine, and cataract specimens (57). RT-PCR provides a result more quickly than viral culture. Detection of rubella RNA confirms current infection. RT-PCR can be performed on the same specimens used for virus isolation.

Isolation of rubella virus in culture is not routinely performed since most diagnostic laboratories lack both the expertise and the technical capacity for it. In addition, rubella virus culture is quite slow, so most laboratories have abandoned cultivation-based methods in favor of faster and less challenging approaches such as serologic and nucleic acid amplification assays. For culture, many cell lines are permissive for rubella virus infection and include African green monkey kidney (AGMK), BHK21, RK-13, and Vero (51, 60). Detection of rubella virus in infected cell cultures has historically proved difficult because of the lack of apparent cytopathology in first-passage wild-type virus cultures. Interestingly, assays exploiting the fact that the rubella virus infectious cycle interferes with the replication of cytopathogenic enteroviruses have been devised to improve rubella virus detection. However, these assays are beyond the technical capability of most clinical laboratories. The availability of high-quality reagents and easily reproducible assays, such as viral antigen-specific IFAs and PCR, has replaced these older methods for detecting rubella virus in cell cultures. Also, reverse transcription-loop-mediated isothermal amplification (RT-LAMP) has been used for the detection of rubella virus RNA in media from infected cell cultures (61). The CDC provides guidance online for culture-based detection of rubella virus using Vero cells (http://www.cdc.gov/rubella/lab/ifa_protocol.html).

Diagnostic tests used to confirm CRS include serologic assays, isolation of the virus, and detection of rubella virus by RT-PCR. A positive IgM result in the infant's cord blood or serum supports the diagnosis of CRS. In CRS, IgM antibody is expected to persist for 6 to 12 months but may not be detectable until at least 1 month of age. Infants with symptoms suspicious for CRS but testing negative for IgM shortly after birth should be retested at 1 month of age (57). Persistence of rubella IgG beyond 6 months of age also supports CRS. The virus may be isolated from the throat and urine of CRS infants, but chances for isolation are best in samples collected before 5 months of age (57). Molecular detection by RT-PCR and molecular typing are recommended because epidemiologic information is needed to track rubella in the U.S. By comparing virus sequences from new cases with sequences from other cases, the origin of particular virus types in this country can be tracked (56).

Historically, serologic diagnosis of postnatal rubella and CRS as well as demonstration of immunity to rubella has been performed by a number of methods, including EIA, FIA, IFA, CF, HI, passive hemagglutination (PHA), latex agglutination (LA), hemolysis in gel, radioimmunoassay, and a variety of IgM detection assays. However, FDA-cleared, commercially available EIAs for detection of IgG and IgM are used by most laboratories for rubella antibody testing.

TECHNOLOGY FOR RUBELLA TESTING

Molecular Methods

Currently, there are no FDA-cleared assays for the detection of rubella virus RNA in clinical specimens. However, numerous laboratory-developed assays have been extensively evaluated for detection of viral RNA from clinical samples, including conventional and real-time reverse transcription-PCR methods (57) that test for rubella virus alone or in multiplex with other analytes. Specimens from which rubella RNA can be detected include blood, CSF, nasal and throat swabs, and urine (57).

Serologic Methods

Sample requirements: As discussed above for serologic methods for measles and mumps, serum sample collection, processing, and storage are similar for most rubella serologic assays. In addition, detection of anti-rubella virus IgM and IgG has been successful using eluates from dried blood spots (29). In general, sera should be rejected if they are grossly lipemic, icteric, contaminated, or hemolyzed. For many EIAs, heat-inactivated specimens should also be rejected. Always follow assay manufacturer guidelines for the collection, processing, and storage of specimens for rubella serology.

EIA and FIA

As with measles and mumps serology, most diagnostic laboratories use FDA-cleared commercial EIA testing systems for the detection of antibodies produced against rubella virus. These assays are perhaps the most inexpensive, widely available, and most commonly used assays for detection of anti-rubella IgM and IgG. All commercial systems are solid-phase (often microwells, beads, microparticles, or filters) capture assays that detect antibodies to rubella virus capsid and/or envelope antigens in serum or other clinical specimens (e.g., oral fluid). Both manual and automated rubella EIA testing platforms are available, and many of the tests are either quantitative or semiquantitative and have built-in controls.

IFA

IFA assays can be used for detection of antibodies against rubella. Historically, chronically infected rhesus monkey kidney cells (LLC-MK2 cells) fixed to glass slides have served as the solid-phase antigen (62) to which aliquots of patient sera are added followed by fluorescein isothiocyanate-conjugated antihuman secondary antibodies. Other sources of rubella antigen, including purified viral proteins, have also been used for IFA assays. Because IFA assays are read visually using a fluorescence microscope, subjective interpretation of results is possible. As with any other diagnostic test, controls should always be run in parallel with patient specimens to ensure validity of results and to provide standards for comparison.

CF and HI

CF testing for rubella antibody detection is performed by a standard technique (33). An excellent overview of HI testing for rubella antibodies has been published previously (63).

PHA and LA

PHA and LA assays use either erythrocytes or latex particles as carriers for rubella virus antigens in the test system. Anti-rubella antibodies react with rubella antigen coated on the particle to cause agglutination. Antibodies produced against both structural and nonstructural viral proteins usually remain measurable for years following natural infection or immunization. PHA is performed in a V-shaped microwell plate, and hemagglutination appears as a dispersed settling of erythrocytes within a plate well. Formation of an erythrocyte button in the bottom of the microwell is interpreted as negative. LA methods, which are routinely performed on slides, are read macroscopically for clumping of coated latex particles by rubella antibodies. Both PHA and LA have largely been replaced by EIA for detection of rubella antibodies.

INTERPRETATION OF RUBELLA TESTING

The isolation of rubella virus or the presence of rubella virus RNA in clinical samples, including those from infants with suspected congenital rubella, indicates current or very recent infection. Demonstration of a 4-fold rise in anti-rubella antibody titers in paired sera also indicates current or recent infection with rubella virus.

Because the incidence of rubella virus infection in the Western Hemisphere is very low, the majority of positive rubella IgM tests most likely represent false-positive results that must be confirmed by additional methods (57). Infection with other viruses and the presence of cross-reacting IgM class antibodies and rheumatoid factors have been shown to produce biological false-positive results (64, 65). If there is a likelihood that these substances may be present, additional testing, such as antibody avidity testing, is needed to confirm rubella infection. Care should also be taken when interpreting rubella serology data from pregnant women exposed to rubella; the CDC has constructed an algorithm to facilitate the serologic evaluation of such patients (available at http://www.cdc.gov/vaccines/pubs/surv-manual/chpt14-rubella.html#f20).

Interpretation/Applications of Laboratory Results in Diseases of Low Prevalence

Even assays of high specificity will have a low positive predictive value in populations with low prevalence (less than 1%) of infection, making a high percentage of positive results "false-positives" (66). This precautionary note fits well with the current status of measles, mumps, and rubella infections in the United States, suggesting that a single positive laboratory value should be carefully scrutinized. Thorough clinical histories and confirmatory laboratory testing are warranted in order to differentiate true- from false-positive laboratory findings. For example, a single positive measles IgM result should be supported/confirmed with follow-up measles IgG testing to demonstrate seroconversion from negative to positive or a significant increase in IgG titer. Also, in such cases, detecting viral RNA in clinical samples would give the necessary confirmation and would do so more quickly than monitoring the IgG level.

Viral Hepatitis

HUBERT G. M. NIESTERS, ANNELIES RIEZEBOS-BRILMAN,
AND CORETTA C. VAN LEER-BUTER

65

The term "hepatitis" refers to the inflammation of the liver, and in this chapter the five so-called major or primary viruses that cause this inflammation are described. These are the viruses hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis delta virus (HDV), and hepatitis E virus (HEV). In Table 1, the characteristics of these hepatitis viruses are described. Although there are also secondary viruses that can infect the liver and cause hepatitis, such as cytomegalovirus, Epstein-Barr virus, herpes simplex virus 1, and enterovirus, the five primary viruses account for at least 95% of hepatitis virus infections. They primarily cause an infection of the liver and may infect other organs, while the secondary viruses infect the liver only during the course of a systemic infection.

The initial diagnosis of hepatitis is based on biochemical parameters that give information on the function and integrity of the liver. Alanine aminotransferase (ALT) and aspartate transaminase (AST) are the most important enzymes and are easy to measure in serum because their levels are indicators for hepatocellular damage and inflammation. But these biochemical parameters do not give any information about the presence of viruses involved, since damage to the liver may also be caused by other routes, like medication or autoimmune hepatitis.

Clinically, hepatitis can be divided into acute infection and persistent or chronic infection. The latter is defined as infection lasting >6 months as established by the presence of the surface antigen of HBV, known as HBsAg, or by the detection of viral RNA in the case of a chronic or persistent HCV infection. In some immunocompromised patients, HEV can also cause a chronic infection. Symptoms can also be variable, from mild, subclinical infection without jaundice to fulminant infection, as well as chronic hepatitis. Fulminant hepatitis is a rare form of acute hepatitis associated with liver failure and may lead to death of the patient or the need for liver transplantation. A summary of the different forms of viral hepatitis is given in Table 2. The immune system plays a very important role in the pathogenesis of these viruses, because the immune system attacks the infected hepatocytes, which express viral antigens. Therefore, in those individuals in whom the immune system is suppressed, the manifestation of the infection can be less severe and less obvious. Also, in an infection that occurs prenatally or perinatally, as in many cases of HBV, the immune system does not attack the infected hepatocytes and the infection is very likely to become chronic. The immune system is crucial for clearing the viral infection, and thus it is obvious that in patients who are immunosuppressed, whether by HIV infection or immunosuppressive treatment, it is more difficult to cure the infection.

Both HAV and HEV are transmitted mainly by the fecal-oral route, while HBV (potentially accompanied by HDV) and HCV are blood-borne viruses (see Table 1). This implies that these viruses can be transmitted through activities in which blood is exchanged (e.g., medical procedures, tattooing, sexual contact, bites, and exchange of infected needles). In particular, HBV can persist with a high viral load in chronically infected individuals.

In general, HBV and HCV are the only viruses that can become chronic, although in the immunocompromised host (e.g., an organ transplant patient), HEV also has the ability to result in a chronic infection.

The importance of the five major hepatitis viruses (HAV, HBV, HCV, HDV, and HEV) is high due to their impact on global health issues. Billions of people are or have been in contact with one of these five viruses, and hundreds of millions are chronically infected with HBV or HCV. For HEV, the World Health Organization (WHO) estimates that every year ~20 million people are infected, with 3 million symptomatic cases and 56,600 HEV-related deaths. The numbers for HBV are even higher, with 240 million people chronically infected and 780,000 persons dying every year from HBV-related disease. HDV is actually a companion virus of HBV in some areas of the world. For HCV, it is estimated by the WHO that 180 million people are chronically infected, with 500,000 HCV-related deaths annually. For HAV, these figures are not completely known, but in developing countries ~90% of children are infected at a young age due to poor sanitation and unclean and unsafe drinking water. Generally, HAV does not cause a chronic disease and fatal cases are rare.

Because globally so many people are at risk of contact with a hepatitis virus, it is logical that diagnostic laboratories are involved in the detection of these viruses. With the availability of vaccines for HAV, HBV, and soon HEV, as well as different antiviral strategies to combat viruses like HBV and HCV, diagnostic laboratories are involved in monitoring treatment options and in the quantitation of viral genomes during different intervention strategies using molecular diagnostic assays, real-time genome amplification and detection, and sequencing strategies to understand the epidemiology as

doi:10.1128/9781555818722.ch65

TABLE 1 Characteristics of the five primary hepatitis viruses

Virus	Nucleic acid	Type of infection	Route of transmission	Incubation period (days)	Antigens
HAV	RNA	Self-limiting	Fecal-oral	15–45	HAV antigen
HBV	DNA	Self-limiting or persistent	Parenteral, other	40–180	HBsAg, HBcAg, and HBeAg
HCV	RNA	Self-limiting or persistent	Parenteral, other	15–150	HCV antigen
HDV	RNA	Self-limiting or persistent	Parenteral, other	30–50	HDV antigen
HEV	RNA	Self-limiting	Fecal-oral	15–60	HEV antigen

well as resistance against antivirals. But it must also be noted that one of the difficulties with the primary hepatitis viruses is the inability to grow them in culture for diagnostic purposes, and therefore serology and molecular methods are the only diagnostic instruments that laboratories have. Although this was a drawback in the earlier days of diagnostics, these methods are now common in clinical virology.

GENERAL CHARACTERISTICS OF DIAGNOSTIC PROCEDURES

Diagnostic procedures can be handled using serology or molecular methods. During the last decade, molecular technologies have been implemented in laboratories worldwide, although there are different regulations in different countries and continents. Serological markers can be analyzed using automated systems, and for most targets, including HAV, HBV, and HCV, these systems are generally available. The assays must be Food and Drug Administration (FDA) cleared/approved in the United States and CE-IVD marked in Europe, using serum and plasma as the materials of choice. Serum and plasma are readily available. There is a marked difference between CE-IVD-marked and CE-marked assays; in the latter case more attention is given to the manufacturing of the assays, while in CE-IVD as well as in FDA-cleared/approved assays, more information should be provided on the analytical and clinical performance and utility of the assays.

In the case of HEV serology, a number of serum- and plasma-based assays are available, used mostly in Europe and Asia; in Europe these serological assays are CE marked. Performance of the different assays varies, resulting in different epidemiological outcomes as well as differences in diagnostic decisions. They need to be used in laboratories with special interest and expertise in hepatitis. A similar situation exists with serological assays for HDV; they are of greater interest in specific cases or regions where HDV is more prevalent and less available in routine diagnostic laboratories.

TABLE 2 Clinical forms of hepatitis

Name	Clinical signs
Acute hepatitis	Typically associated with jaundice (icteric phase) and seroconvalescence. Infection will resolve.
Fulminant hepatitis	Severe infection with hepatic failure. High mortality.
Subclinical hepatitis	No jaundice, no clinical signs. Antibodies demonstrable in serum. Will resolve. Example: HEV.
Chronic hepatitis	Infection of the liver for a period of >6 months (rule of thumb). Caused by HBV (age dependent) and HCV. Chronic inflammation of the liver and higher risk for necrosis, fibrosis, and HCC. Chronic infections of HEV are described in specific patient groups.

Molecular methods have changed tremendously in recent decades. With the development of real-time detection systems for HBV and HCV, more information has become available for understanding the pathogenesis of these viruses. At the same time, diagnostic tools to monitor the effect of treatment using antiviral agents have become accessible to monitor the development of antiviral resistance, to characterize the genotype of the virus for epidemiological reasons, and to acquire insight into the route of transmission. Initially, these assays were used by laboratories with interest in hepatitis, but now they are more common in more and more laboratories worldwide. With the availability of WHO international standards for these viruses, the standardization of these molecular—mostly real-time-based—assays has made huge progress, although differences in genotype detection can sometimes still be a challenge. All of these assays can be used with serum or plasma, but it is of importance that the blood taken is handled quickly for transport to the laboratory and stored at low temperatures. These assays are also FDA cleared/approved and CE-IVD marked, and some of them can be used for the detection of these viruses in blood donations.

The use of molecular methods for detection of the other hepatitis viruses, meaning HAV, HDV, and HEV, is less common, and these assays are performed mainly in specialized reference laboratories or centers specializing in the treatment of hepatitis-infected patients. These viruses can be detected in both serum and plasma; however, HAV and HEV are also detectable in fecal samples. This can be used to understand how long treatment in the case of HEV infection should be continued; however, no clear guidelines are currently available.

Aside from detection, further characterization of these viruses is performed mostly in specialized laboratories, like the determination of the genotype and subtype, relevant for assessing treatment options for HBV and HCV. Now that sequencing technologies, including next-generation sequencing, are becoming more readily available, it is expected that this genetic characterization will be performed in more laboratories in the near future.

Diagnostics and Quality Control

Whether an assay is FDA cleared/approved, CE-IVD marked, or CE marked, the laboratory has to validate or verify the performance of the assay itself, and there might be special requirements in different countries or U.S. states. Laboratories have to be accredited or certified, and these regulations by official agencies will become more stringent in the years to come. Important parts of these regulations include quality assurance of the diagnostic performance in laboratories,

participation in proficiency programs, risk analyses, and dedicated responsibilities for the people involved in the complete workflow. Taking regional differences into account, different guidelines are available and continuously updated. Laboratories therefore will have to select the suitable guideline and make quality control and accreditation efforts accordingly. The ISO 15189:2012 guideline for medical laboratories is available in a number of countries.

HEPATITIS A VIRUS

HAV is a very small, nonenveloped, icosahedral RNA virus (size, ~27 to 32 nm) with a single-stranded and linear, positive-sense RNA genome. This RNA genome is ~7,500 bases in length and has only one open reading frame (ORF), two untranslated regions (UTRs) at the 5′ and 3′ ends, and a poly(A) tail. It is the prototype virus of the *Hepatovirus* genus within the *Picornaviridae* family. The virus is present worldwide and is more common in developing countries, where ~90% of the population may have been exposed to it. It has a tropism for the liver and is thermally very stable.

All human HAV strains belong to only one serological group; however, genetic analysis has shown that there are as many as six distinct genotypes, which correlate with geographic origin. Genotype I is the most common type worldwide, and in particular genotype IA.

Pathogenesis

The virus has an average incubation time of 30 days, with a range between 15 and 45 days. The prodromal period is normally 4 to 6 days and is characterized by nonspecific symptoms, like general malaise, vomiting, abdominal pain, loss of appetite, and headache. Transmission is via the fecal-oral route, and therefore poor hand hygiene and bad sanitation are strong contributing factors for exposure. It is estimated that ~1.5 million cases are reported annually worldwide. Transmission through water, food, and food additives is well known. Food may not only become contaminated during preparation, but contamination may also occur via HAV-contaminated water or ice. Alternatively, shellfish caught in HAV-contaminated water is a source of infection, particularly if contaminated sewage is dumped into the water. Person-to-person transmission is rare but may occur under poor hygienic circumstances.

Most infections are self-limiting, with no long-term sequelae or chronicity of the infection. An HAV infection may be more symptomatic in older patients due the maturity of the immune system, and fulminant hepatitis due to an acute HAV infection may occur, often accompanied with fever over 40°C, possibly resulting in liver transplantation or death (1). HAV infections occur outside the developing world in outbreaks surrounding a common source, or sporadically when visitors acquire the infection in countries where the virus is more prevalent. The virus can also be transmitted sexually, and epidemiological data have identified particular risk groups in which the virus can be easily transmitted (2, 3).

The virus invades the liver and subsequently replicates extensively in hepatocytes. As a result of this replication, huge amounts of virus are produced and the hepatocytes are damaged, resulting in the release of several biochemical markers in serum like ALT and to a lesser degree AST, which roughly correlates with the severity of the disease. No extrahepatic replication sites for HAV are clearly identified. Virus is already shed into the gastrointestinal tract towards the end of the incubation period, before clinical symptoms are observed; fecal shedding is at its highest just before the onset of clinical symptoms, and HAV RNA may be detected in feces for up to several months (4). During the prodromal phase, nonspecific symptoms may occur, like vomiting, abdominal pain, malaise, loss of appetite, headache, and fever, as well as some constipation and diarrhea. These symptoms disappear with the onset of jaundice; however, in 15% of cases, no prodromal symptoms are observed. The icteric phase that follows is marked by symptoms accompanying jaundice, such as scleral icterus, dark brown urine, clay-colored stool, and interestingly, a clearly decelerated heart rate. The icteric phase typically lasts for up to 3 weeks.

Viremia is present from a few days before and during the early acute phase of the infection when ALT and AST are high. The level of viremia is estimated to parallel the shedding of the virus in stool, albeit at a lower magnitude. But blood, serum, or plasma may be used to detect the viral RNA during the onset of disease using molecular amplification methods. The viral RNA can also be detected in stool samples. The typical course of the immunological events in symptomatic patients is described in Fig. 1, in which the similarity between HAV and HEV infections is depicted.

Diagnostics for HAV: Serology

Serological testing is necessary to distinguish an HAV infection from other viral infections and noninfectious causes

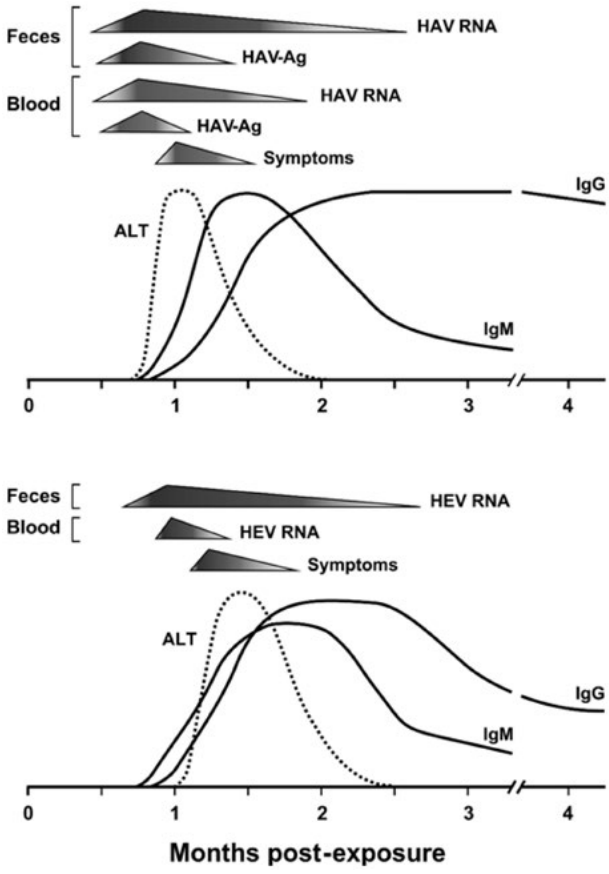

FIGURE 1 Typical course of the virological and immunological manifestations of HAV (top) and HEV (bottom). Neither of these viruses results in a chronic infection in the immunocompetent host. Infections with both viruses are in most cases asymptomatic. The virological parameters for both viruses are very similar. Both viruses are transmitted through the fecal-oral route.

of hepatitis, like autoimmune diseases or toxicity caused by medication or drugs. At the onset of symptoms, anti-HAV IgM antibodies are present in almost all patients, as well as viral RNA which can be detected in stool and in blood (serum or plasma) samples. The IgM antibodies disappear in about 3 to 6 months, but in some cases of relapsing hepatitis A, these IgM antibodies can be detected for a period of up to 1 year. One should keep in mind that IgM antibodies might not be caused by an acute HAV infection, although commercial assays to detect anti-HAV IgM antibodies are very sensitive and specific, nearly 100%. The detection of anti-HAV IgG antibodies coincides in most cases with the appearance of anti-HAV IgM antibodies, but the comparison of these two classes of antibodies has no added diagnostic value. If the anti-HAV IgM antibody titer is very low in a patient with a fulminant liver failure, one needs to confirm that the infection is truly caused by HAV. This could warrant an amplification-based RNA detection assay on stool or serum or plasma. Serum is usually available and so might be the first choice for additional diagnostics. In general, one must remember that the diagnostics for acute HAV infection must be carefully considered based on a single serological assay, but should always be viewed in correlation with the clinical data, like the onset of symptoms like jaundice, as well as the elevated biochemical parameters (ALT and AST). Furthermore, it is also important to determine whether there is a risk factor for this infection, e.g., shellfish consumption, travel to developing countries, or homosexual contact. For an algorithm of laboratory tests for HAV infection, see Table 3.

Diagnostics for HAV: Molecular Detection

Molecular detection methods are based on real-time amplification of viral RNA by PCR, enabling the detection of a few copies per reaction. Molecular detection is useful for epidemiological purposes and to supplement the diagnosis of an HAV infection when, for instance, the IgM ratio is low and one cannot be sure this is really a specific signal, as well as for blood safety. Detection methods based on amplification are being implemented more and more frequently in diagnostic laboratories, and currently there is a WHO international standard available for the detection of HAV RNA; this standard contains genotype IA (2nd WHO International Standard for Hepatitis A Virus for Nucleic Acid Amplification Techniques, NIBSC code 00/562) (5). This should be very helpful for standardizing real-time assays for the detection in blood or blood products, food samples, as well as environmental samples. The best region for diagnostic testing is the 5′ UTR of the virus, as it is for other *Picornaviridae*.

The transmission of HAV by blood or blood products is rare but has been described, despite the fact that currently one can implement enough inactivation and filtration steps to eliminate this virus from blood products. Some European countries and the United States have started to test pooled plasma samples from blood donors, as has been done already for other blood-borne viruses. The currently available commercial molecular detection assays are not registered for blood screening purposes and have some limitations in the detection of the most common genotypes. The LightCycler HAV quantitation assay (Roche Diagnostics, Indianapolis, IN) is not registered for diagnostics, while the RealArt HAV assay (QIAGEN Diagnostics, Valencia, CA) seems to be less sensitive for the detection of genotype I. Adaptations to these commercial assays have been made to overcome sensitivity issues in detecting the different genotypes of HAV. It is expected that more commercial assays will become available in the near future (6–8). Also, an External Quality Assessment program has been set up by Quality Control for Molecular Diagnostics (QCMD) (Glasgow, United Kingdom) to assess the performance of laboratories (9). Currently, no FDA-approved molecular assays exist.

Epidemiology

While the detection of HAV is based on the 5′ UTR, typing of *Picornaviridae* is based on the sequencing of the VP1/2A junction. Sequence analysis is the method of choice and is getting easier every year. Currently six genotypes are described based on sequence homology in the complete VP1 protein gene. Genotypes I, II, and III can each be divided into subtypes A and B. They all can infect humans and correlate with geographic regions. The most prevalent genotype, IA, is present in North, Central, and South America, China, Japan, Thailand, and Europe, while genotype IB is found in the Mediterranean, South Africa, and Turkey. Genotype IIIA is prevalent in India, Nepal, and South Korea. Genotypes IIA, IIB, and IIIB are rarely found.

Molecular epidemiological investigation, including phylogenetic analysis, allows the linkage of HAV cases to one another as well as back to a common source in outbreaks. With the globalization of food and food components, it has been shown to be a useful means to identify infectious products, as has been illustrated by a case of acute liver failure and liver transplantation after the consumption of

TABLE 3 Algorithm and interpretation of serological and molecular tests for the detection of HAV

Sample type	Test and result	Interpretation
Serum/plasma	IgM anti-HAV negative; IgG anti-HAV negative	No indication for HAV infection. No protection against HAV.
Serum/plasma	IgM anti-HAV negative; **IgG anti-HAV positive**	Past HAV infection or vaccinated against HAV. Protected.
Serum/plasma	**IgM anti-HAV positive; IgG anti-HAV positive**	Indications for a recent or acute infection with HAV. Check with clinical parameters and epidemiological factors. If ratio of IgM is low, measurement of RNA in serum/plasma or stool supportive for diagnostics to determine whether there is an acute infection.
Plasma/stool	**HAV RNA positive**	Indication for an acute infection with HAV.

contaminated food (1). Furthermore, these epidemiological investigations are helpful to understand local epidemics that may occur when there is an introduction of a strain, e.g., by travelers, as well as for investigating the distribution of strains among specific susceptible populations, like men who have sex with men (2). Indeed, it has been shown that HAV strains can be transmitted within networks of people who have the same risk factor.

The continuous surveillance of HAV strains among the populations in different countries enables better anticipation of public health questions that may arise. Subsequently, intervention strategies, like vaccination of at-risk groups, can be implemented if these risk groups are not already part of other vaccination programs. Despite the fact that HAV infections can be prevented by vaccination, there is still a public health concern among some populations who have more recently been identified as being at risk (10).

HEPATITIS B VIRUS

Introduction

HBV is the major virus causing hepatitis worldwide. It is estimated that ~2 billion people have been in contact with the virus, as demonstrated by the detection of antibodies (anti-HBc) against the virus. The WHO estimates that ~240 million people are chronically infected, defined as having detectable HBsAg for a period of >6 months. Other findings suggest that the number must be higher and that >350 million persons are chronically infected. It is estimated that >780,000 persons die every year from complications of HBV infection. The virus is transmitted through contact with blood or other body fluids, for instance, during sexual activity, and is an important occupational risk factor for health care workers. However, a very good and safe vaccine has been available since the early 1980s.

The virus was discovered in the 1960s and 1970s when it was recognized that a virus must have been the cause of hepatitis in indigenous Australians. Once the connection with the so-called Australia antigen (discovered in 1966), now known as HBsAg, was established, studies using electron microscopy by Dane et al. (11) and Almeida and Waterson (12) in 1970 led to the visualization of the infectious virus (known as Dane particle) and the nucleocapsid. Later, the virus was better studied, the genome was analyzed, and the serological profiles were described in more detail in both acutely as well as chronically infected individuals. The connection between HBV and the development of hepatocellular carcinoma (HCC) followed soon thereafter (13).

HBV is the prototype human virus of the family *Hepadnaviridae* and belongs to the genus *Hepadnavirus*, which also contains the woodchuck hepatitis virus and the duck hepatitis virus. Primates can also be infected with HBV-like strains.

HBV has interesting biological characteristics. It has a partially double-stranded circular DNA genome ~3,200 bp in length. The virion particle contains a membrane. Replication occurs mostly within the hepatocytes, although extrahepatic sites are also known. After the virus enters the cell, a double-stranded covalently closed circular DNA is generated (called cccDNA). This cccDNA is the template for the host RNA polymerase II, and it generates an RNA molecule longer than the genome, known as pgRNA. Interestingly, the large HBV polymerase which is generated has essentially three functional domains: a terminal protein involved in priming; a reverse transcriptase (unique for hepadnaviruses since they are essentially DNA viruses); and an RNAse H domain, which degrades the pgRNA while the new partially double-stranded HBV DNA is formed. The reverse transcriptase activity of HBV polymerase is remarkable because it has been shown that some nucleotide inhibitors against the reverse transcriptase of HIV-1 could also inhibit the replication of HBV. Another remarkable feature of the HBV genome is its compact size, resulting in the fact that most of the nucleotides encode two proteins and thus the genes of HBV have overlapping coding sequences. The reverse transcriptase of HBV takes up ~75% of the genome and overlaps sequences for the surface protein HBsAg and the core protein known as HBcAg.

During viral replication, the surface glycoprotein HBsAg is produced in three forms, i.e., as preS1-HBsAg, preS2-HBsAg, and an excessive amount of HBsAg. This overproduction of HBsAg results in free protein in the bloodstream, and the HBsAg is present as large tubular as well as spherical aggregates without the presence of infectious DNA. Furthermore, HBeAg is produced and part of it is cleaved off to produce the core protein used within the virion. The HBeAg protein is released from infected hepatocytes and circulates freely in the bloodstream. This protein can be used as a marker of infectivity or replication of HBV, since its presence is accompanied by a high viral load. However, mutants are present in certain genotypes and populations that result in no production of HBeAg. In that case, HBV DNA viral load is high in the absence of HBeAg or anti-HBeAg. Aside from replication of HBV, the virus can also integrate into the host DNA as a nonreplicating particle (14, 15).

Clinical Parameters

Most primary infections with HBV do not result in detectable disease; this results in an asymptomatic seroconversion and is known as subclinical hepatitis.

In the case that there is damage to the liver, the patient initially presents clinically with acute hepatitis; this is observed in ~5% of perinatal infections and up to 30% of adult infections. These acute infections often have a preicteric phase during which the patient may have specific complaints such as loss of appetite, nausea, fever, and loss of tolerance to alcohol. After this, the liver damage is more severe and functions fail, such as the processing of pigments derived from hemoglobin in the blood and subsequent extraction of the products into the bile and feces. This results in clinical signs of jaundice caused by the excess of bile in circulation. These pigments are now filtered by the kidney, and the urine becomes darker. These acute infections often resolve within a few months (it can take up to 6 months).

During acute infections, HBsAg can be readily detected from about 4 weeks after the initial infection (Fig. 2A). HBV DNA can also be detected after 4 weeks using molecular techniques, and viral load can rise up to 1 billion to 5 billion IU per ml of serum or plasma. HBeAg, which is only produced during active replication of HBV, can be detected easily using immunological methods. As long as HBsAg is detectable, the patient is infectious. Resolution of the infection is accompanied by the appearance of antibodies against HBsAg or anti-HBsAg, the appearance of anti-HBeAg antibodies, and the decrease to low and subsequently undetectable levels of HBV DNA. During the course of an HBV infection, the first antibodies directed against HBV are antibodies against HBcAg. These antibodies appear within a few weeks after the appearance of HBsAg and they remain detectable a very long period and even lifelong. The appearance of IgM anti-HBcAg is detected at a very early stage of infection and may give information about whether the infection occurred recently. IgM anti-HBcAg titers rise

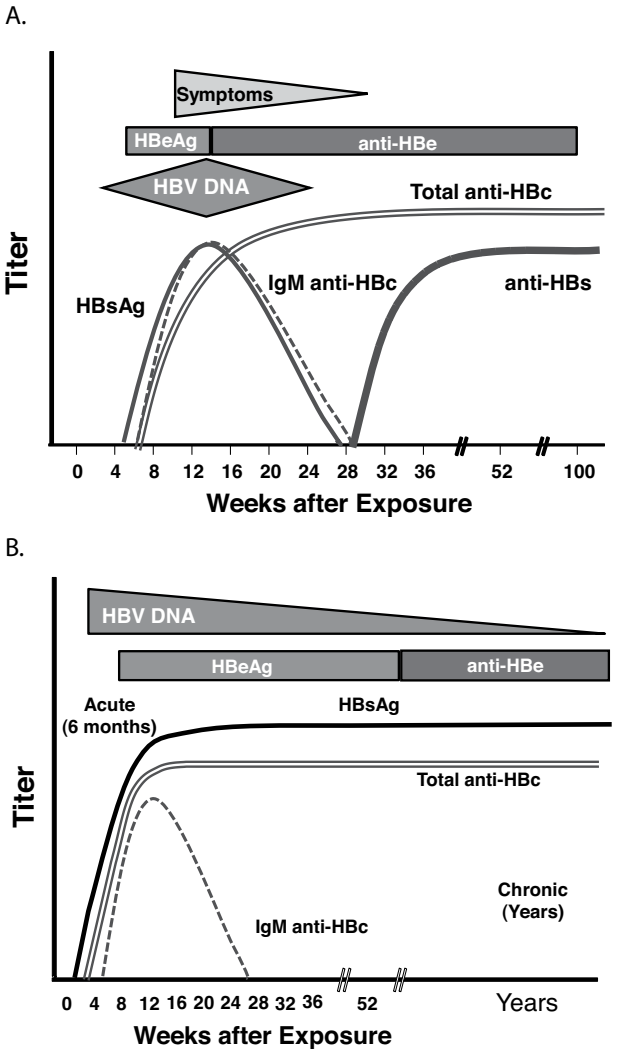

FIGURE 2 Virological profiles observed in patients infected with HBV. (A) Typical profiles in individuals with an acute HBV infection and subsequent resolution of the infection. HBV DNA is detected during a limited period of time and is ultimately undetectable using molecular techniques. Similarly, HBsAg is not detected anymore. The resolution of the infection and symptoms results in the presence anti-HBsAg antibodies, which is a marker for protection. (B) Profiles observed in individuals with a chronic HBV infection. In these cases, HBsAg and anti-HBc remain positive, while the patterns of HBeAg and anti-HBeAg may vary in time. The latter might be absent in the case of a precore mutation. HBV DNA is detectable at high levels during the whole period of the chronic infection.

rapidly in the acute phase of the infection but disappear in most patients after 3 to 6 months, although they may persist longer in some patients.

Since an excess of HBsAg is produced and also shed as noninfectious particles into the blood, the initial anti-HBsAg will form complexes and might give a negative value in the early stage of seroconversion. This anti-HBsAg has neutralizing activity against the virus and its levels rise when the infection is controlled by the immune system. Often, protective values of >1,000 IU/ml are reached.

A number of patients, especially those who acquired the infection at an early age, are not able to suppress the virus, which is recognizable by the continued production of HBsAg and no detectable anti-HBeAg antibodies. These patients continue to have replication of HBV in the liver and HBV DNA blood levels remain high. Chronicity of HBV infection is defined as having HBsAg present for a period of >6 months. Chronic infections also include partly suppressed infections, which can be distinguished by the presence of anti-HBe antibodies and usually low HBV DNA levels. During chronic infections there will be fluctuations of HBV DNA levels, notably when ALT levels are changing during so-called flares, while also IgM anti-HBc antibody can reoccur and fluctuate. These high levels of HBV replication result in a continuous infection of hepatocytes and ultimately may result in fibrosis and cirrhosis of the liver and in HCC. For a serological profile of a chronic HBV infection, see Fig. 2B. Persistent and chronic HBV infections may resolve spontaneously, but this is rare, occurring at a rate of ~1% per year.

The different HBV profiles are summarized in Table 4. Serology is the keystone in diagnostics, since it gives information on the presence or absence of the virus. Information on protection can be obtained by measuring anti-HBsAg levels. Anti-HBsAg is obtained after vaccination or after resolving a mostly acute HBV infection. In the latter case, anti-HBcAg is also detected. Anti-HBs levels of >10 IU/ml are considered protective. Following vaccination, levels of >1,000 IU/ml are not unusual. Serology is a relatively inexpensive diagnostic method, and serum or plasma is readily available. However, there may be more-complicated serological profiles in which the measurement of HBV DNA levels can be of assistance.

In the rare cases that only HBV DNA is measured and no other serological parameters are present, we describe this as an occult infection. The diagnosis of these infections remains a challenge, but they have been described in the absence of measurable HBsAg and/or anti-HBc (16–18). The measurement of HBsAg in the presence of naturally occurring mutants was shown in previous years to be a problem, but with the current commercial assays this has been resolved.

Cases in which only anti-HBc is detected need additional testing using sensitive molecular techniques, as these could be the result of low and undetectable levels of HBsAg or undetectable levels of anti-HBs, but also false-positive tests.

The loss of HBeAg followed by the appearance of anti-HBeAg signals seroconversion and suppression of the infection. HBV DNA levels decrease during HBeAg seroconversion, and levels of <20,000 IU/ml are indicative of this seroconversion. However, there are also known mutations in the HBV DNA, and particularly in the so-called precore protein, like the G1896A guanine-to-adenine substitution, which will result in the TAG stop codon and prevention of the production of HBeAg. The second known and prevalent dual mutation involves two substitutions at positions A1762T and G1674A. Both mutations result in high HBV DNA levels and no detection of HBeAg and anti-HBeAg in chronic HBV infections. They are more prevalent in HBV genotypes B, C, and D and less in HBV genotype A. There are data indicating that these mutations coexist together with the wild-type virus. With this profile it must be considered to include the measurement of HBV DNA, since many chronically infected patients do not have elevated ALT levels (13, 19, 20).

Molecular Methods: Measurement of HBV DNA

The measurement of HBV DNA is useful in cases in which patients are treated with antiviral therapy, and the viral load is indicative of the success as well as failure of

TABLE 4 Algorithm and interpretation of serological and molecular tests for the detection of HBV

Status, matrix is serum (usual)/plasma	HBsAg	Anti-HBsAg	IgM anti-HBc	Anti-HBc	HBeAg	Anti-HBeAg	HBV DNA
Susceptible to HBV	Negative	Negative	Negative	Negative	Negative	Negative	Negative

Anti-HBc only	Negative	Negative		**Positive**			
Occult HBV infection	Negative						**Positive**

treatment. The latter can be the case in those instances in which, for instance, resistance to antiviral drugs is observed with an increase in viral HBV DNA levels. Also, when no HBeAg as well as no anti-HBeAg is observed, the measurement of HBV DNA is useful to identify those cases in which precore mutations are present, resulting in no production of HBeAg.

During the past decade, several commercial assays for the quantitation of HBV DNA have been introduced, in most cases based on real-time amplification assays with a decreasing limit of detection with every new test and a large linear range, currently up to 100 million IU/ml and down to <10 IU/ml. To improve consistency of measurement between laboratories, the WHO established a standard preparation from a high-titer HBV DNA genotype A (code 97/746) sample with an assigned potency of 1 million IU/ml (1 IU/ml equals in this case ~5.4 genome equivalents). The proposal is that all results should be reported in IU per milliliter (20–23). These levels of replication described in IU per milliliter are important parameters to define and select patients who need treatment, also taking into account ALT levels, liver histology, and age. In the United States, the updated HBV algorithm for the management of chronic HBV infection even mentions specifically which assays need to be used routinely, both of which are real-time amplification assays (13). Important threshold levels are 2,000 and 20,000 IU/ml, which need to be identified accurately, since these levels are pivotal in identifying patients who require treatment and patients who could achieve HBeAg seroconversion.

Since measurement of HBV DNA is important in treatment strategies, it is also important in follow-up of patients who are receiving treatment with antivirals, whether it is to identify resistance variants, viral breakthrough, or success of treatment by looking at kinetic patterns (24–28). When treatment is started, serum HBV DNA levels should be monitored at week 12 to identify primary treatment failure, which is defined as a reduction of <1 log. Continued follow-up at week 24 is recommended to ensure virological suppression. Continued monitoring every 3 to 6 months is recommended to prove viral suppression or to identify viral breakthrough. Viral breakthrough is defined as an increase of HBV DNA levels by >1 log above nadir after achieving a virological response during treatment. A real viral rebound is defined as HBV DNA levels of >20,000 IU/ml or above the pretreatment level. Since HBV DNA levels are often measured in reference laboratories, strategies in which HBsAg is measured quantitatively can also be used as a rapid and cheaper way to predict HBeAg seroconversion or to measure the effect of antiviral treatment (29, 30).

HBV Sequencing: Epidemiology, Typing, and Mutation Detection

HBV was initially classified into several immunological serotypes, based on determinants in the so-called antigenic determinant (designated *a*), present in all serotypes, in combination with a second determinant that is present in two forms, i.e., *d-y* or *w-r*. This resulted in the serotypes *adw*, *adr*, *ayw*, and *ayr*. However, since there is only one serotype of HBV, this was initially used for epidemiological purposes. With the availability of sequencing technologies, HBV can now be analyzed according to sequence homology. There are currently eight genotypes described. Genotype A is present globally, while genotypes B and C are more prevalent in Asia, and genotype D more prevalent in southern Europe and Turkey; genotype E is present in Africa, genotype F in the Americas, genotype G in the United States and France, and genotype H in Central America. Moreover, several subgenotypes have been described. The relation between genotype and response to therapy is of greatest importance, but genotyping may also predict the occurrence of HBeAg mutations, resistance to antiviral drugs, the likelihood of achieving resolution of an infection, and the development of HCC. There are different potential responses to antiviral treatment among the HBV genotypes, and this is used for selecting the optimal strategy. Patients with genotype A, for instance, are better responders to pegylated interferon α-2b compared to genotypes B, C, and D (31). There are several options to determine the genotype, whether by Sanger sequencing of part of the genome or by performing a line probe assay (32, 33).

Currently, sequencing technologies are developing very quickly and becoming more easily accessible. Minor variants can be detected by using ultradeep pyrosequencing or next-generation deep-sequencing technologies. But they all have to be used as fit-for-purpose, and most of them are still for research use only. At this time, standard population sequencing techniques can be used to identify variants (if present above 20 to 25%), precore mutations, or HBV genotypes (13, 34, 35).

HEPATITIS C VIRUS

In the late 1970s, blood and blood products could be screened relatively easily for HAV and HBV, but a number of cases of blood transfusion-related hepatitis were still observed that tested negative for the two above-mentioned viruses. This infection was classified as non-A, non-B hepatitis until 1989, when the virus was discovered by Kuo and coworkers as the causative agent of this parenterally transmitted hepatitis (36). The positive-stranded RNA virus was

named hepatitis C virus. HCV is an important cause of liver disease, cirrhosis, and HCC worldwide. Humans are known to be the only natural reservoir of the virus.

HCV belongs to the genus *Hepacivirus* and is the only member of this group, within the family *Flaviviridae*. Other genera within the *Flaviviridae* are *Pestivirus* and *Flavivirus*. It is an enveloped, positive-sense RNA virus with a genome of 9.6 kb in length that encodes a single long ORF of ~3,000 amino acids, flanked by short UTRs at the 5′ and 3′ ends. The viral genome is translated directly into a polyprotein that is cleaved both post- and cotranslationally by viral and cellular proteases to generate 10 gene products. HCV particles are 40 to 80 nm in diameter and are pleomorphic, without apparent symmetry.

The amino-terminal part of the polyprotein encodes the structural proteins, i.e., the capsid-forming "core" protein and the envelope glycoproteins E1 and E2. The carboxy-terminal two-thirds of the polyprotein encodes the nonstructural proteins, i.e., p7 (an ion channel), NS2 (a transmembrane protein), NS3 (the protease and RNA helicase), NS4A and NS4B (cofactors), NS5A (a phosphoprotein), and NS5B (the viral RNA-dependent RNA polymerase).

The lack of suitable culture systems has hampered research into the interactions between host and virus. Therefore, essential details required for more advanced understanding of virus entry, replication, interaction with the immune system, and virus assembly are still unknown. A striking feature of infectious HCV particles is their association with lipoproteins. These are particles, produced in the liver, that serve to transport lipids between liver and tissues. The apolipoproteins are a group of molecules, present on the surface of lipoproteins, that act as chaperones directing the trafficking of lipids throughout the body. Serum-derived HCV particles have been found to associate with apolipoproteins A1 (apoA1), apoB-4B, apoB100, apoC-1, and apoE. This interaction suggests that HCV forms hybrid lipoviral particles, which facilitate virus entry into hepatocytes and possibly protect the virus from antibody neutralization (37). Moreover, the apoproteins may have a role in virus entry into the host cell. HCV has been shown to use the low-density lipoprotein receptor for attachment, and this receptor also interacts with apoE. However, other cell surface molecules are needed in the entry process, of which the precise mechanisms are still under debate. HCV shows distinct tropism for hepatocytes but also replicates in lymphoid cells, circulating plasmacytoid dendritic cells, and other cell types.

Pathogenesis

In primary infections, the virus usually becomes detectable in blood within 1 to 3 weeks and peaks a few weeks later; then the viral load in plasma gradually declines over the following months. Just before and shortly after seroconversion, the load of HCV in plasma can fluctuate extensively and drops to very low levels. In this phase, spontaneous clearance of primary infections has been observed and the infection becomes self-limiting. However, in the majority of patients, up to 85%, the infection becomes persistent. Modulations in HCV load and clearance of the virus (when it occurs) are believed to result from the host's immune response, which is slower than in most other systemic viral

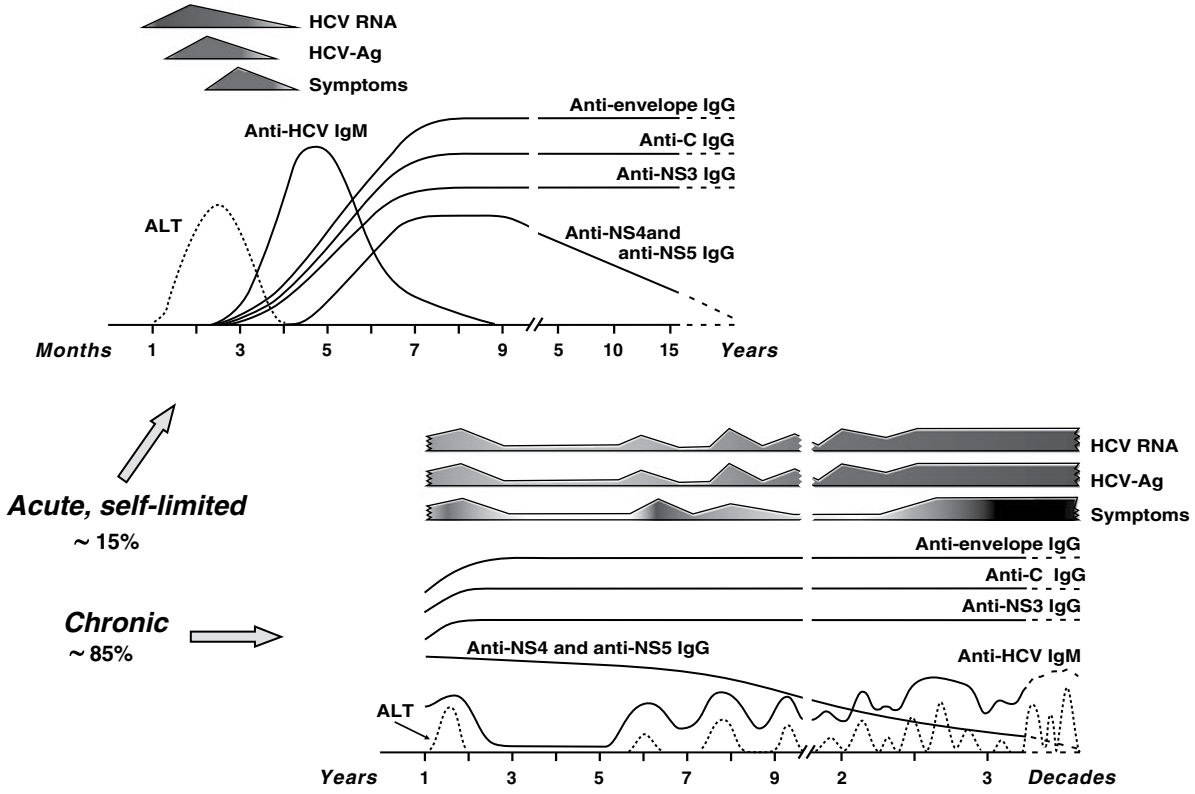

FIGURE 3 Virological profiles observed in patients infected with HCV: the course of an HCV infection and the immunological events that follow. Most patients become chronically infected, while a limited number are able to resolve the infection spontaneously. Many patients, whether acutely or chronically infected, do not know that they are infected or are having overt signals of the disease. They do, however, follow these patterns and those who are chronically infected will have clinical symptoms later in life.

infections. As a result, seroconversion may take as long as 9 months to a year. In most individuals, antibodies are nevertheless detectable within 2 months following infection. In Fig. 3, the typical immunological and virological profiles are presented both for the acute and self-limiting as well as for the chronically infected patient. Recently some host factors have been described that are associated with spontaneous clearance of acute infections. Individuals carrying a single nucleotide polymorphism of the interleukin-28B gene are more likely to clear the infection with and without treatment, and they are less likely to develop complications of chronic HCV infections (38). The C/C genotype, which is associated with a more favorable outcome, occurs to different degrees in different populations in the world. The C allele is the most prevalent in Asia, whereas in Africa the T allele is more prevalent. In Western Europe and North America, the C allele has an intermediate frequency. In addition to this polymorphism, a number of markers such as levels of particular cytokines and apolipoproteins have now been identified to be associated with spontaneous clearance of the infection (39, 40). Spontaneous clearance of HCV is rare in HIV-positive individuals, of whom it is estimated that 25% worldwide are coinfected with HCV.

In chronically infected individuals, up to 10^{10} to 10^{12} viral particles per day are produced and cleared. Levels of circulating HCV usually remain fairly constant over time, although they may fluctuate. HCV levels hardly ever fall below the detection levels of molecular assays. Spontaneous clearance of chronically established HCV infections has rarely been reported.

Acute infections are often mild or without clear symptoms, with ALT levels typically <1,000 IU/liter. Fulminant liver failure is seldom reported. Acute infections develop following an incubation period of 4 to 20 weeks and are frequently unnoticed. It is generally accepted that signs and symptoms of acute HCV infections are caused by the immune system, and the finding that symptomatic infections are more frequently associated with spontaneous clearance is in accordance with this.

Most individuals who have acquired the infection are not diagnosed due to the lack of symptoms, and may not become aware of the infection unless they are tested for other reasons. The long-term persistence of the virus nevertheless leads to damage to the liver, which progresses even without symptoms. In about a third of chronic infections, ALT levels remain normal for prolonged periods. Most patients start to show intermittently or persistently elevated levels of ALT and progressively deteriorated liver functions after 2 or 3 decades of infection, and up to 20% go on to develop cirrhosis. HCC can develop in 10% of cirrhotic livers. Male gender, old age at the time of infection, alcohol intake, elevated ALT levels, and coinfection with HBV and/or HIV-1 are all factors that negatively affect prognosis.

A significant proportion of patients acquire HCV in the absence of risk factors. Case control studies show that these cases, which are designated community acquired or sporadic, are associated with hospitalization, invasive medical procedures such as endoscopy, receiving injections in an outpatient setting, participating in contact sports, and beauty treatments (41, 42).

With no existing HCV vaccine and no demonstrated activity of postexposure prophylaxis in the form of immunoglobulins or drugs, the key to prevention of HCV lies in prevention of transmission. Needle-exchange programs for intravenous drug users have had mixed results, with some countries reporting a significant decrease in transmission and others no effect (43, 44). With a majority of HCV carriers being unaware of their HCV status, screening may well represent the way forward (45). Treatment options for chronic HCV infections have improved enormously in recent years and will continue to do so in the next few years, as new drugs become available in more countries. Treatment as prevention is already being considered in some settings (46). For now, unfortunately, the expense of the newly available regimens limits these prospects to high-income countries.

Diagnostics for HCV: Serology Combined with Molecular Testing

Anti-HCV screening is the first step in the diagnostic algorithm for HCV infection. Improvements in assay performance have been achieved in the past 2 decades, resulting in higher sensitivity and specificity of the tests currently in use. Due to delayed antibody formation in hepatitis C infection compared to other viral infections, the serological window period still is 4 to 6 weeks with the third-generation tests that are widely used. These third-generation assays can detect antibodies directed against the core gene as well against the nonstructural proteins NS3, NS4A, and NS5B. They are all enzyme immunoassays (EIAs) or chemiluminescence assays and have a sensitivity as well as specificity close to 100%. A negative screening test, however, does not exclude an acute hepatitis C infection, and testing blood for the presence of virus either by nucleic acid amplification techniques or by antigen testing is necessary for cases of suspected acute hepatitis C infection within the last 6 months. Also, for patients who are immunosuppressed, HCV RNA testing might be considered. However, under normal circumstances and without any risk factors, a negative result using HCV antibody testing with the third generation of serology testing implies no further investigation (47).

For patients at high risk of infection, who present with elevated ALT levels and high anti-HCV reactivity, supplemental anti-HCV testing can be skipped, since the correlation between a positive screening test and infection is nearly 100%. In all other cases a confirmatory test is essential. While some laboratories rely on a second immunological assay in these cases, other laboratories proceed to viremia testing, as recommended by the updated Centers for Disease Control and Prevention guidelines (48). For an algorithm for HCV detection, see Table 5.

If laboratories want to perform a serological confirmation, this usually involves immunoblotting, which allows dissection of antibodies directed to different viral determinants. Sera that react with products derived from at least two viral genes are considered positive, and those that are reactive with a single protein are indeterminate; reactivity to the carrier polypeptide fused to recombinant antigens shows that the positivity might be nonspecific. Indeterminate immunoblots may be indicative of false positivity, especially in low-risk individuals. Immunocompromised individuals with HCV infection nevertheless often show reactivity only to C and NS3 antigens, which may yield indeterminate results. Antibodies in response to NS4 and NS5 tend to be produced later during the infection, and these antibodies also wane earlier following spontaneous or posttreatment resolution of infection.

Testing for Viral Antigen

Immunoassays for HCV antigen detection and quantification have become available as an alternative to nucleic acid testing. Classical EIAs target the core antigen of HCV. The tests are highly specific and have a lower detection limit of 1,000 IU of HCV RNA per ml. They can be carried out in

TABLE 5 Algorithm and interpretation of serological and molecular tests for the detection of HCV

Sample type	Test and result	Interpretation
Serum/plasma	Total anti-HCV negative/ nonreactive	No HCV antibody detected. No indication for an HCV infection. If patient is immunosuppressed, HCV RNA testing can be considered. If exposed to possible HCV infection during the past 6 months, follow-up antibody testing or HCV RNA is recommended.
Serum/plasma	**Total anti-HCV positive;** HCV RNA negative	No indication for a current HCV infection. Repeat HCV RNA testing might be considered if exposure to HCV suspected within the past 6 months or clinical evidence of HCV disease, or if there are concerns with storage and handling of test specimen.
Serum/plasma	**Total anti-HCV positive; HCV RNA positive**	This is a current HCV infection and should be linked to care of the patient.

automated systems that give a result in 60 min. Therefore, they are faster but also less expensive than PCR assays. The assays have a role in the diagnosis of hepatitis C infection after anti-HCV antibodies have been detected. HCV core antigen tests nevertheless become positive a few days after the appearance of HCV RNA. These tests, which are available for testing on blood or saliva, have been evaluated for screening of high-risk individuals. In these settings, these rapid tests provide sensitivity and specificity comparable to that of the HCV EIAs, and provide a low-cost, easy-to-use assay alternative that can be used outside traditional laboratories (49).

Testing for Viral RNA

Methods of accurate quantification of HCV RNA levels are essential for the clinical management of patients with hepatitis C infection. Serum and plasma are routinely used, but recent research has shown good results using dried blood spots, which are easily transportable. Several automated, closed devices are available for nucleic acid extraction, detection, and quantitation while maintaining high sensitivity and specificity of tests. The benefits of these automated systems include minimal hands-on time and minimal potential for contamination of samples. The detection limits are as low as 12 to 50 IU/ml, and intra- and interassay variabilities are small. The available automated platforms have minor differences in detection of HCV RNA levels of different HCV genotypes. Underestimation of HCV RNA levels is most likely due to sequence polymorphisms in one of the primer or probe target regions. Quantification of HCV RNA is essential not only for making a decision to treat a patient but especially for monitoring the response to therapy.

In contrast with the relatively long serological window following infection, HCV RNA is usually detectable within just 1 week after infection. Viral RNA levels may reach 10^7 IU/ml, but commonly levels of 10^5 to 10^6 IU/ml are measured. Although there is some evidence that links plasma RNA levels to viral replication in the liver, the determination of HCV RNA is most relevant in response-guided treatment, where it is currently the standard procedure for measuring response to HCV treament. Quantitative HCV viral load testing is recommended at week 4 after the start of treatment and at 12 weeks after the therapy is completed. Antiviral therapy should not be interrupted or stopped if HCV RNA measurement has not yet been performed. If viral load has not been successfully reduced at week 4, the testing can be repeated at week 6 or week 8. Any increase in viral load is indicative of failure of treatment. Expressing the viral loads in IU has allowed comparison of results obtained by different methods, but quantitative differences between the different assay systems are such that in follow-up of patients the same method should be used throughout. Currently, levels of 12 IU/ml can be measured with high accuracy.

In a prospective study that followed a cohort of high-risk individuals for acute hepatitis C infections, it was shown that 28% had very low to undetectable HCV RNA levels at the time of the first serologically positive blood sample.

Detection of HCV: Epidemiology and Viral Genotype

Diversity among HCV isolates is minimal in the 5′ UTR and maximal in the E2 glycoprotein, where a stretch of 31 amino acids, the hypervariable region, has been proposed as a decoy for the immune system. Six major genotypes can be distinguished, designated 1 through 6. A genotype 7 has also been described (50). Each genotype can be divided into subtypes designated by lowercase letters. Intergenotype recombinants and more recently intragenotype recombinants have been reported (51, 52), of which so far only one, i.e., the 2k/1b intergenotype recombinant, has been transmitted (53). In addition to their epidemiological purposes, the subtypes have been shown to influence the response to certain therapeutic regimens.

About 3% of the world population is estimated to be infected, with prevalence rates ranging from <1% in some Western European countries to >10% in some African countries. The highest prevalence is found in Egypt, where 14.7% of the population is infected. Because the infection is asymptomatic in many individuals, the virus may continue to spread. The risk of transmission of HCV through blood transfusion is currently extremely low due to the use of molecular detection of HCV RNA in pooled blood donations. Intravenous drug use, tattooing, acupuncture, body piercing, and any other practice that involves contact with contaminated blood account for most of the new infections. Mother-to-child transmission, which is generally believed to be inefficient, still leads to infection of 1 in 20 children born from HCV-positive mothers, concurrent HIV infection being the most important predictor of HCV transmission in this group. Transmission to household contacts is rare, and there is no evidence for transmission through insect bites. Humans are the only known reservoir of HCV.

The prevalence of the genotypes depends largely on the population in which the screening was performed. Genotype 1 is most prevalent in Western Europe, North America, Central and South America, Australia, Indonesia, and Japan. Genotype 2 does not form the most prevalent genotype anywhere in the world, while genotype 3 infections are highly prevalent in the United Kingdom, Russia, India, and Brazil. Genotype 4 is prevalent almost exclusively in Egypt and surrounding countries; genotype 5 is found mostly in South Africa; and genotype 6 is so far found only in Southeast Asia, where this genotype is highly prevalent, and in Southeast Asian populations elsewhere in the world. The newly described genotype 7 was isolated from an individual from the Congo (50). Determining the viral genotype and subtype is essential for optimizing both treatment regimen and duration of treatment with current treatment protocols.

Until very recently the combination of ribavirin and pegylated alpha interferon formed the mainstay of treatment, with differences in dosing and duration depending on the genotype. Recently, new direct-acting antivirals have become available, which as a whole have improved the prospects of cure for all genotypes, but differences in response to different agents exist depending on the genotype. The new direct-acting antivirals are not universally available yet, because treatment of HCV infections with these agents is considered too expensive, even for many high-income countries. It is expected that direct-acting antivirals will continue to be introduced in Western countries but that their use will be restricted to some patient categories. Predicting the a priori chance that a patient will respond, and the subsequent adaptation of treatment and regimen to optimize treatment success, is expected to become the mainstay of HCV treatment. The need for reliable genotyping is therefore only becoming more obvious. Sequence analysis of the viral genome is the gold standard for any genotype determination, and in the case of HCV sequencing, the 5′-UTR region was historically chosen as the main target. Studies have shown more recently that analysis of the 5′ UTR unfortunately has its limitations for subtyping due to its high genetic conservation. Moreover, some genotype 1b subtypes and several genotype 6 subtypes have identical 5′-UTR sequences and are therefore indistinguishable by 5′-UTR analysis. For genotype and subtype sequencing, the core and NS5B regions are better targets, providing optimal genotype and subtype resolution. Methods such as reverse transcriptase PCR assays that amplify and detect portions of both 5′-UTR and NS5B regions have much better performance than methods that rely on amplification of 5′ UTR only. A frequently used commercial test exploits the ability of 5′-UTR amplicons to hybridize to type-specific probes immobilized on nitrocellulose strips (line probe assay). The line probe assay has a reasonable concordance with genotypes that have been identified by nucleotide sequencing; it misclassifies the subtypes of 10 to 40% of isolates, depending on genotype (54–56). At this time, all commercially available assays that aim to reduce hands-on time and are suitable for routine laboratories have significant shortcomings in accuracy (57).

Testing for Antiviral Resistance

Even before the introduction of the first direct-acting antiviral agents, reports showed the appearance of drug resistance mutations in regions targeted by antiviral agents. It has become clear that preexisting mutations are prevalent in treatment-naive patients and that this affects success rates of particular antiviral regimens (58). Early studies with the first protease inhibitors showed that the preexisting mutations were more common in treatment-naive patients with genotype 1a than with 1b (59). The major resistance mutation R155K, which is associated with treatment failure, required two nucleotide changes in subtype 1b strains and only one nucleotide change in subtype 1a strains (60). This resistance mutation confers resistance to all protease inhibitors currently on the market.

Following the introduction of protease inhibitors as the first direct-acting antiviral agents, the second class to become available were the polymerase inhibitors, of which sofosbuvir was the first available drug. This agent appears to possess a very high genetic barrier. The S282T mutation is most frequently seen, but it occurs in few patients with early relapses (61, 62).

The third class is the NS5A inhibitors, with daclatasvir and ledipasvir as the first representatives. Similarly to what was seen for protease inhibitors, resistance mutations are frequently seen in patients who have failed treatment, and preexisting drug resistance mutations are found in small percentages of treatment-naive patients.

The existence of preexisting mutations to certain direct-acting antiviral agents, together with the high prevalence of mutations in pretreated individuals and the high cost of modern hepatitis treatment options, is likely going to increase the demand for resistance testing. Some methods for targeted genotyping are now being explored, which could facilitate detection of resistance mutations more efficiently. Sequencing, however, remains the most commonly used method (63–65).

HEPATITIS DELTA VIRUS

HDV, initially called the delta agent, was described for the first time in 1977 in patients in Italy with a more severe form of HBV infection (66). It was found to resemble certain subviral agents of plants. Strictly it is not a virus since it requires the HBV surface protein HBsAg as its outer envelope protein, and is therefore called a subviral or satellite virus. There is no nucleotide homology between HBV and HDV. HDV has a single-stranded RNA genome structure of ~1,700 nucleotides and its infectious particles contain a ribonucleoprotein in a complex with ~70 copies of the delta antigen (HDV-Ag), which is the only protein encoded by its genome. This is the smallest circular RNA viral genome known in humans, and it forms an imperfect duplex by roughly 75% pairing of its nucleotides. Because of its small size, it is interesting to note that the replication of this genome is done by the host's RNA polymerase II and takes place in the nucleus of the cell. HDV replicates only in the liver, and no extrahepatic sites are known.

Pathogenesis

HDV infections can be more severe and may result in a more progressive liver disease, resulting in cirrhosis and liver failure, compared to HBV infections alone. An infection with HDV may be acquired at the same time as the HBV infection (coinfection) or may be acquired as a superinfection in a person already infected with HBV. The course of the infection is different in the two cases. With a coinfection, the number of HBsAg particles is low in the beginning, having an impact on the replication of HDV. This HDV infection therefore peaks at lower levels and has no influence on the replication of HBV itself. In superinfection, HBsAg is already abundantly present in the blood, and the replication of HDV is at full speed to begin with, in contrast with the

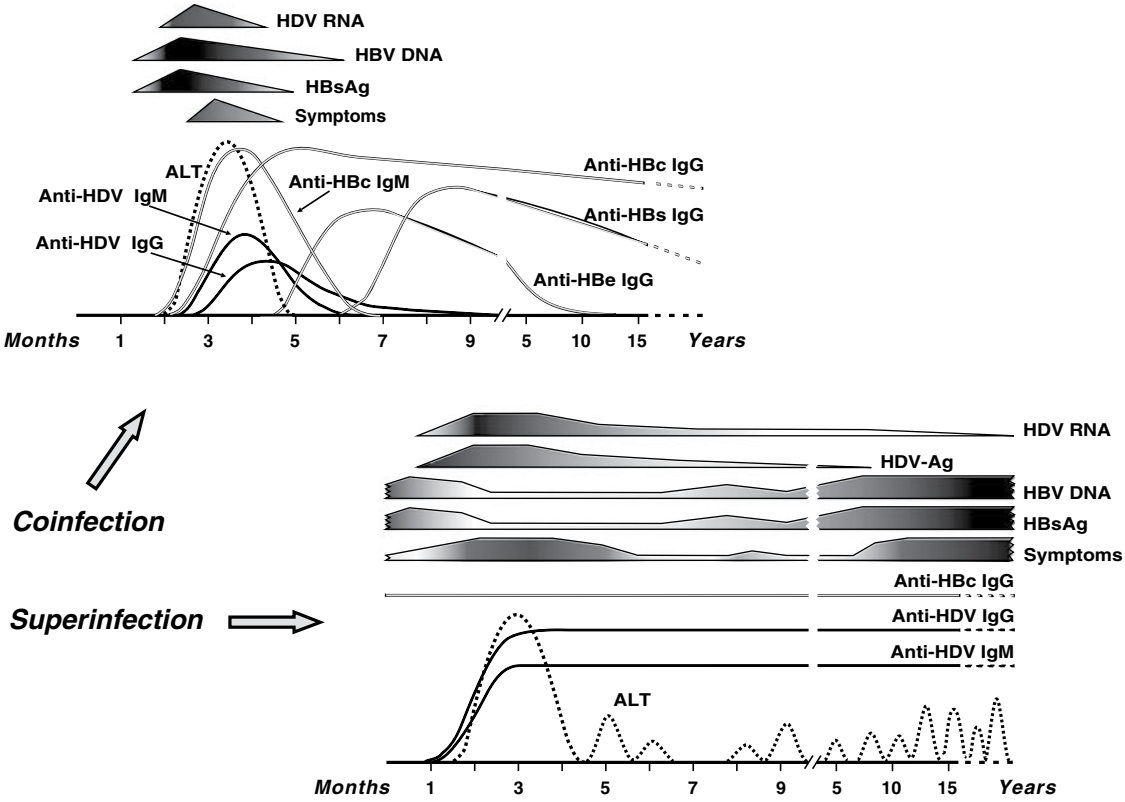

FIGURE 4 Virological profiles observed in patients infected with HDV. There are two routes of HDV infections. (Top) In the first one, HBV and HDV coinfect the same individual at the same time. Since the individual has not been infected previously with HBV, the replication of HBV and the production of HBsAg control the replication of HDV. As soon as the level of HBsAg is reduced due to the presence of anti-HBsAg, the replication of both HBV and HDV is dramatically reduced, and eventually both HBV DNA and HDV RNA are no longer detected in serum or plasma. Anti-HDV antibodies are present. (Bottom) In the case of a superinfection, HDV replication is enhanced from the beginning since an abundant amount of HBsAg is present in the liver. HDV RNA is detected by real-time amplification technologies as long as HBV replication and thus the production of HBsAg continue. In the case of this chronic infection with HDV, anti-HDV is also detected.

coinfection. It briefly causes a suppression of the replication of HBV. In the case of a superinfection with HDV, it may even worsen the HBV infection itself. For a typical course of these infections, see Fig. 4, in which the differences in profiles of coinfection and superinfection are described.

Diagnostics for HDV

Serology

Serological markers for the diagnosis of HDV are HDV-Ag and the anti-HDV antibody. Although IgM antibodies are detectable during the window phase of the infection, most diagnostics are based on the detection of total anti-HDV antibodies. The detection of IgM antibodies against HDV is only available in a limited number of reference laboratories. Total anti-HDV is indicative of an infection and may persist for several years even after the clearance of the infection. Patients with HBsAg-positive results from regions where HDV is endemic should be tested. HBV serological markers and HBV DNA levels can be of assistance in deciding whether treatment of the HBV infection is required. During an acute infection with HDV, HDV-Ag is detected in the early phase in serum or plasma but also disappears relatively quickly, making IgG anti-HDV in combination with HDV RNA the method of choice to establish the proper diagnosis. HDV-Ag can be detected in liver biopsy specimens using standard technologies (staining with anti-HDV-Ag peroxidase). The use of IgM antibodies as well as HDV-Ag is limited since its value can only be shown in the early phase of the acute super- or coinfection of HDV with HBV. During an acute coinfection with HBV, the IgM anti-HBcAg marker can be used. In conclusion, the detection of IgG anti-HDV is the most suitable test and can be viewed as a marker of exposure to the delta particle. For an algorithm of laboratory tests for HDV infection, see Table 6. The virological profiles are also summarized in Fig. 4. The first test to be performed has to show that indeed an HBV infection is also present by detecting HBsAg and anti-HBcAg, since HBsAg is needed for HDV replication.

Molecular Methods

The most efficient diagnostic parameter is the detection of HDV RNA as a result of viral replication. In the case of a coinfection of HDV with HBV, the resolution of HBV as determined by the presence of anti-HBsAg will also result in the resolution of HDV RNA. In the case of a superinfection with HDV when an HBV infection is already present chronically, HDV RNA is detected in most patients, if not

TABLE 6 Algorithm and interpretation of serological and molecular tests for the detection of HDV

Sample type	Test and result	Interpretation
Serum/plasma	IgM anti-HDV negative; total anti-HDV negative	No indication for an HDV infection. Determine HBV serological markers.
Serum/plasma	IgM anti-HDV negative; **total anti-HDV positive**	If HBsAg is negative and anti-HBsAg is positive, this is a past infection. HDV RNA will be negative. If HBsAg is positive and anti-HBsAg is negative, this is an acute HBV/HDV coinfection (early phase) or a chronic infection. Determine presence of IgM anti-HBc and HDV RNA.
Serum/plasma	**IgM anti-HDV positive; total anti-HDV positive**	Based on IgM anti-HDV positivity, this is most likely an acute HDV infection. Determine HDV RNA and HBV parameters (HBsAg, IgM anti-HBc). Total anti-HDV may be present for a long period of time and without clearance of HBV parameters.
Serum/plasma	**HDV RNA positive**	Indication for an active infection with HDV. Might be acute in early phase if IgM anti-HBcAg is positive.

all, continuously. The replication of HDV can be monitored by the detection of HDV RNA in serum or plasma, and with the availability of a WHO international standard, quantitative assays can be made more reliable, although no commercial assay is available at this moment. Currently, laboratory-developed tests based on real-time detection are available in laboratories with a special interest in diagnostics for hepatitis viruses. There are limited commercial assays available for the detection of HDV, but their performance and detection of the different HDV genotypes are not yet completely established (67–69).

Detection of HDV: Epidemiology

HDV was initially discovered in Italy and is more common in southern European countries (70). The particle has also been shown to be more endemic in certain parts of South America, in indigenous tribes living in the Amazon, and some parts of Asia. In North America and Western Europe, most of the infections are in intravenous drug users and their partners, and it coincides with the prevalence of HBV infections. It is estimated that in the United States, ~70,000 individuals are infected with HDV. These infections are all chronic. However, with increased vaccination against HBV in at-risk populations, the incidence of HDV infections is also decreasing in those countries. One has to be aware, however, that through migration of individuals from areas where HDV is endemic, the infection can still spread relatively easily and be maintained in specific populations like intravenous drug users, homosexuals, and practitioners of high-risk practices like tattooing or piercing, which are not often checked for their HBV vaccination status.

In the Asian-Pacific region, there is concern over an increase of HDV infections in Pakistan, Iran, and countries of Southeast Asia, where there is a higher prevalence of HBV and registration of HBV and HDV is absent. In Africa, too, the prevalence of HBV is high, and HDV is endemic in a number of countries, although this may not give a complete picture. HDV is known to be present in the Congo, Equatorial Guinea, Nigeria, and Cameroon. Phylogenetic data from Cameroon show that there are four different genotypes of HDV present, of which genotype 1 is the most prevalent (71–75).

HEPATITIS E VIRUS

HEV is an enterically transmitted hepatitis virus, similar to hepatitis A virus. It is a small (32 to 34 nm in diameter), nonenveloped, single-stranded, positive-sense RNA virus of ~7,200 bases that is capped and polyadenylated at the 5′ and 3′ termini and is organized in three ORFs. The first ORF codes for the nonstructural proteins and contains methyltransferase-, cysteine protease-, macrodomain-, RNA helicase-, and RNA-dependent RNA polymerase-encoding sequences. The second and third ORFs overlap and encode the structural proteins of the virus. ORF2 codes for the viral capsid protein and consists of three linear domains: the shell domain (S), a middle domain (M, also called P1), and a protruding domain (P, also called P2). The protein translated from ORF3 is a small phosphoprotein involved in virion morphogenesis and release.

The virus was discovered in the 1980s during a military campaign in Afghanistan among Soviet soldiers who had an unexplained hepatitis not caused by HAV. Its transmission route was discovered by a successful transmission to a human volunteer via the fecal-oral route with a stool sample from a non-A, non-B hepatitis patient. The logical next letter was E. Viral-like particles were seen by electron microscopy. HEV was already known to cause waterborne epidemics in developing countries, and it was also known that it coincided with a high fatality rate among pregnant women. There were also reports of outbreaks of jaundice caused by HEV in Europe with coincident fatalities among pregnant women, which is typically related to HEV genotype 1 (76).

HEV was initially classified in the family *Caliciviridae*, genus *Calicivirus*, based on the clinical symptoms and structural features. However, after subsequent studies, the virus is now a member of the family *Hepeviridae* and the genus *Orthohepevirus A* (formerly *Hepevirus*). Within this group of

Orthohepevirus A, there are four genotypes known (named 1 to 4) that can infect humans.

HEV genotypes 1 and 2 are strictly human viruses and mostly prevalent in areas of poor sanitation, causing endemic acute hepatitis in developing countries and resource-limited countries, resulting in occasional large waterborne outbreaks, and travel-related cases in developed countries. HEV genotype 1 is mainly present in Asia and Africa and genotype 2 in Mexico. Genotypes 3 and 4 have a zoonotic origin with a main reservoir in domestic pigs. Genotype 3 has a worldwide distribution, while genotype 4 is mostly found in Asia. These latter two genotypes, and in particular genotype 3, are drawing more and more interest as there is growing evidence of their zoonotic potential. Epidemics caused by genotypes 3 and 4 are rare. All four HEV genotypes belong to one serotype.

Pathogenesis

The clinical features of HEV infections range from asymptomatic infection to mild hepatitis to subacute liver failure. Following an incubation period of 15 to 60 (average, 40) days, patients may present with fever, nausea, jaundice, abdominal pain, vomiting, anorexia, malaise, and hepatomegaly. There are some differences in the clinical course between the developing and developed countries due to the different genotypes. In developing countries, hence mainly genotype 1 and 2 infections, most infected individuals present in their young adulthood with a mild self-limiting hepatitis. The fatality rate is low, but may still be up to 2% due to fulminant hepatitis. Exceptions are patients with underlying chronic liver disease. A unique feature of HEV infection is the high mortality rate, up to 25%, exclusively found among pregnant women in their third trimester and/or their unborn babies. The mechanisms of this fulminant hepatitis are still unknown. There have been no reports of such high mortality among pregnant women with infections of HEV genotype 3 or 4.

In developed countries, genotypes 3 and 4 are more prevalent. Symptomatically infected individuals are usually middle-aged and elderly males. Besides small clusters of cases due to a single food-related source, large outbreaks have not been documented. Most patients present, however, with a self-limiting hepatitis with elevated ALT levels up to 3,000 IU/liter. In contrast, HEV genotype 3 may cause a chronic infection that may lead to rapidly progressive cirrhosis in immunocompromised patients such as solid organ transplant recipients, individuals with HIV infection, or patients with a hematologic malignancy. This chronic infection, due to its often asymptomatic course, may be mistaken for drug-induced liver injury. Also, extrahepatic manifestations have been documented, including neurological syndromes, renal manifestations, pancreatitis, and hematologic disorders.

Transmission of HEV

HEV genotypes 1 and 2 are transmitted via contaminated water due to fecal shedding of HEV-infected individuals; transmission occurs from human to human through an environmental reservoir. In contrast, transmission of HEV genotypes 3 and 4 occurs mainly via an animal reservoir. HEV strains from domestic pigs, wild boar, deer, and rabbits have been identified as zoonotic causative agents for human infections. This is supported by phylogenetic studies showing that HEV strains circulating in pigs and humans are very closely related (77, 78). The main zoonotic transmission route is via consumption of undercooked meat of infected animals, yet persons with direct contact with infected animals are also at risk (79). Besides zoonotic transmission, waterborne infection and transfusion-transmitted HEV infection have been documented. Overall, clinicians should be aware of the fact that HEV diagnostics should be considered if elevated liver enzymes are detected, and that this should not be always travel related (80).

HEV RNA-positive blood products have been described repeatedly, and in almost all cases, HEV genotype 3 is involved, and to a much lesser extent genotype 4 (81–84). Only a limited number of transfusion-related transmissions have been reported, but there are more data suggesting that such transmissions may happen frequently. The incidence of HEV RNA-positive blood varies among countries, and rates of 1 in 1,000 blood donations have been reported (84). One should keep in mind that in most cases, blood and blood products are given to patients who already have an underlying condition that may cause immunodeficiency, such as hematological disease or transplantation. This may be one explanation why chronic HEV infections, which by definition are infections of >6 months, have been described in those immune-suppressed patients. The scale of the problem is still not known. A growing number of blood banks have begun to screen for HEV RNA by PCR to provide an indication of the problem of whether and how often viremic HEV-positive blood is drawn from a donor. There is growing evidence that HEV infections might be transmitted through blood transfusion, because HEV RNA can be detected in plasma pool samples (85, 86).

Diagnostics for HEV

Serology

As with other forms of hepatitis, HEV infection can be diagnosed either indirectly by using serology to detect anti-HEV antibodies in serum or directly by detecting the HEV genome in blood or stool. The serological profile is similar to that for infection with HAV, depicted in Fig. 1. After an incubation period of 2 to 6 weeks, antibodies can be detected. First, IgM antibodies appear as a marker of a recent infection; their levels may remain high for up to 8 weeks after an acute infection. IgG antibodies peak around week 4 and can remain high for >1 year (87). In immunocompetent individuals, these antibodies appear at the time of clinical onset of disease. There are several commercial EIAs based on ORF2/ORF3 peptides or recombinant antigens mainly from HEV genotypes 1 and 2, varying widely in sensitivity and specificity. Only one assay uses the combination of HEV genotype 1 and 3 antigens (88, 89). A WHO reference reagent for hepatitis E serum IgG (NIBSC code 95/584) can be used for evaluating the analytical sensitivity of anti-HEV IgG assays (90). Since many infections with HEV have occurred years before a serological assay is performed, one has to consider that the detection of antibodies may represent past infections. Moreover, some assays appear to have sensitivity problems for some genotypes, which may result in an underestimation of the seroprevalence in certain populations. Western blotting is still used in small-scale studies. There are assays available that use a specific pE2 peptide (amino acid residues 394 to 606), which is superior to alternative assays using shorter E2 peptides because of the stabilizing effect a 60-amino-acid extension has on the dimer formation of this antigen. This assay also uses a μ-chain capture strategy, which is known to improve both sensitivity as well as specificity of assays by combining the results of IgM and IgG assays (91). However, one has to keep in mind that not all IgM positive samples are also viremic for HEV. In those cases, HEV RNA has to be detected. For an algorithm of laboratory tests for HEV infection, see Table 7.

TABLE 7 Algorithm and interpretation of serological and molecular tests for the detection of HEV

Sample type	Test and result	Interpretation
Serum/plasma	IgM anti-HEV negative; IgG anti-HEV negative	No indication for an HEV infection.
Serum/plasma	IgM anti-HEV negative; **IgG anti-HEV positive**	Past HEV infection. If immunosuppressed, HEV RNA should be determined (like in transplant patients).
Serum/plasma	**IgM anti-HEV positive; IgG anti-HEV positive**	Indications for a recent or acute HEV infection. Check with clinical parameters and epidemiological factors. Measurement of RNA in serum/plasma or stool supportive for diagnostics to determine whether there is an acute infection.
Plasma/stool	**HEV RNA positive**	Indication for an acute infection with HEV. May be chronic in specific patient populations, like immunosuppressed patients (transplant).

Molecular Methods

In immunocompromised individuals, antibody production may be delayed or even absent, making detection of the HEV genome essential for diagnosing HEV infection. Most detection assays that are currently used are laboratory-developed tests, a phenomenon that is seen globally as the development of commercial assays is always behind the development needed in clinical practice. It has been shown that standardization is needed to enable a better comparison as well as to monitor the effect of antiviral treatment. A WHO international standard for nucleic acid testing of HEV genotype 3 is available (92), and a WHO genotype-specific reference panel will be made available in 2016. Also, an External Quality Assessment program is organized through the QCMD (9). However, one has to realize that laboratory-developed assays are currently used to screen blood and blood products, as no commercial assay is approved for screening these products for HEV RNA.

The existing commercial HEV viral load assays appear to have good sensitivity and specificity (93, 94). In immunocompetent patients, viremia peaks during the incubation period and during the first phase of disease. The window of HEV RNA detection may be rather short (3 to 6 weeks) in these patients; therefore, a negative HEV RNA result does not exclude a recent infection. On the other hand, in immunocompromised patients, HEV RNA testing is necessary to monitor for a chronic infection and to further characterize, using sequence analysis, the virus. If the HEV RNA remains detectable for 3 months, it is unlikely that the patient will spontaneously clear the infection without therapeutic intervention (95, 96). HEV RNA is less stable compared to HAV RNA, and therefore precautions have to be taken to ensure the integrity of the material, like storage at –80°C and rapid transportation of clinical materials to the diagnostic laboratory.

Treatment Options for HEV

HEV infections in developing countries can be prevented by good sanitary infrastructure and clean drinking water. As mentioned previously, most of these outbreaks of HEV are caused by genotype 1 or 2. Despite the clinical and epidemiological differences among the four different genotypes, cross-neutralization occurs, indicating that they belong to a single serotype (97). HEV infection is preventable by vaccination. Two recombinant genotype 1 HEV vaccines have been developed and have been shown to be safe and immunogenic in clinical trials. Immunizations resulted in cross-protection against different HEV genotypes (98, 99). All the trials were carried out in China and showed that the vaccines are well tolerated. These vaccines are very promising, although there are no data yet on their efficacy against emerging strains of HEV—including the animal strains with zoonotic potential—or in prevention of the infections seen in high-risk groups, specifically those caused by genotype 3.

For HEV infections in developed countries, a better understanding of the route of transmission and the relation to the zoonotic origin is needed to effectively prevent transmission. Discussion is ongoing on the exact routes of transmission, although eating of uncooked meat is certainly one such route, and contaminated water has also been seen as a source. The use of blood or blood products has been implicated for people in high-risk groups, although the virus might be inactivated during preparation of blood products as it is less stable than, for instance, HAV.

The first step in the treatment of chronic HEV infection in solid organ transplant recipients is to reduce the dose of immunosuppressive medications. This may result in viral clearance in nearly one-third of patients (100). For antiviral treatment of HIV-infected patients, patients with hematologic conditions, solid organ transplant recipients, or patients with severe acute infection, the first line of treatment is oral ribavirin. In addition, pegylated interferon α-2b has also been described as a potentially effective treatment of HEV infection (101). Recently several cell culture systems have been developed for HEV genotypes 3 and 4, making it possible to further analyze the basic biology of HEV (102, 103).

FINAL CONCEPT: THE DIAGNOSTICS OF HEPATITIS CAUSED BY THE PRIMARY FIVE HEPATITIS VIRUSES

In normal circumstances, the determination of the cause of viral hepatitis of unknown origin is not focused on a single determinant, but a combined testing scheme is used. For this purpose, low-cost serological screening methods could be used. Follow-up of viral infections after diagnosis is rather specific for each pathogen. When liver function tests are severely abnormal, or when specific risk factors in a patient

are identified such as travel history, vaccination status, and alcohol and drug use, more specific tests are appropriate.

In the case of fulminant hepatitis, serology for HAV and HBV is recommended, as IgM directed against HAV is generally present in the acute phase, and in the case of acute HBV infection, HBsAg is detectable. Serology for HCV usually does not contribute in this context, as HCV is an extremely rare cause of fulminant hepatitis and acute infections are not diagnosed by serological testing. HCV RNA testing could be considered when other infections have been excluded. In some countries, HEV serology is appropriate in patients presenting with fulminant hepatitis, depending on local epidemiology of the circulating genotypes. If needed, PCR against HAV and HEV can be carried out in those cases where it is not clear.

In cases where chronic hepatitis is suspected, it is obvious to start with detection of IgG antibodies against anti-HBc, anti-HCV, anti-HAV, anti-HEV, and HBsAg. If HBsAg is positive, reflex testing should be performed to determine HBeAg and anti-HBe. In cases where antibodies are positive against HBV and HCV, viral load is needed to determine the need for treatment. IgG anti-HEV in the immunocompromised is frequently absent even in chronic infections. The detection of IgM has to be complemented by an HEV PCR in these patients, and HEV PCR may even have to be considered without any serological markers compatible with HEV infection.

An important point is that new and acute infections of HAV, HBV, HCV, and in some countries even HEV must be reported to public health authorities. This should be done in countries where the prevalence of these viruses is low as well as in high-prevalence areas. Due to the high infectivity of primary hepatitis viruses, reporting is a first step in controlling continuous transmission.

Viral Agents of Gastroenteritis

GABRIEL I. PARRA AND KIM Y. GREEN

66

The healthy human enteric tract is populated by a complex community of microbiota in synergistic balance with its host. Infection with a pathogenic virus can cause intestinal damage, inflammation, and diarrhea that alter the gut environment. The ability to diagnose pathogenic viruses rapidly and accurately is important in providing appropriate patient care and in controlling virus spread.

Diagnostic virology is riding the wave of a technologic revolution. The increasing ability to assay small amounts of nucleic acid and protein in a clinical sample offers tremendous opportunity to identify viruses that were previously below the threshold of detection. However, this technology also presents new challenges in sorting through massive data sets and establishing etiologic significance. Multipathogen detection panels for gastrointestinal viruses will cast a wider net that will help establish the true incidence of viruses that have never been fully surveyed. However, they may also increase the number of diagnosed mixed infections, again demanding the ability to distinguish between symptomatic and asymptomatic infection and establishing the true etiologic agent of a diarrheal illness.

The purpose of this chapter is to review current techniques that are available for the specific detection and genotyping of major viral enteric pathogens associated with gastroenteritis, focusing on the rotaviruses, noroviruses, sapoviruses, astroviruses, and adenoviruses. Key features of these viruses and other enteric viral pathogens detected in stool are summarized in Table 1. Although the field of diagnostic virology is advancing rapidly, with multipathogen formats gaining widespread use, the techniques described here for individual viral pathogens will continue to provide important information on the epidemiology, natural history, and evolution of these viruses.

ROTAVIRUSES

Overview

Rotaviruses are a major cause of acute gastroenteritis in humans and animals. They have a double-stranded RNA genome divided into 11 segments that encode the viral proteins: 6 structural proteins (VP1 to VP4, VP6, and VP7) and at least 5 nonstructural proteins (NSP1 to NSP5) (Fig. 1A) (1). The rotavirus segmented genome is enclosed within a triple-layered protein icosahedral capsid, in which the inner capsid is formed by the VP2, the intermediate capsid by the VP6, and the outer capsid by the VP7 and VP4 (Fig. 1A). Based on differences within the VP6 protein, rotaviruses can be divided into nine groups (A to I) (2), with group A rotavirus (RVA) the most prevalent (>99% of the isolates) in humans (1).

Antigenic and genetic differences within the two outermost proteins, VP4 and VP7, have been used to classify RVA by a dual nomenclature system into P and G types, respectively. Currently, 37 P types and 27 G types have been described in different animal species (3, 4). Surveillance of RVA in humans has shown that five strains (G1P[8], G2P[4], G3P[8], G4P[8], and G9P[8]) are the most common (Fig. 1B), but temporal and geographic changes in strain prevalence as well as the emergence of strains bearing unusual G types (e.g., G8, G10, or G12) have been observed (1, 5). Based on full-genome sequencing and differences within each of the 11 segments, a comprehensive classification system has been established for RVA. This system recognizes the genomic characteristics of RVA from different species and defines the presence of three major genomic constellations, with two prevalent in humans (WA-like and DS1-like) and one in animals (AU1-like) (6).

Two RVA vaccines, Rotarix (monovalent G1P[8]) and Rotateq (pentavalent G1 to G4 and P[8]), are currently licensed for use in children. Both vaccines are highly effective against severe rotavirus gastroenteritis in high- and middle-income countries, which has reduced the public health burden of RVA (7). Interestingly, vaccination of children has been associated with a reduction in disease prevalence in older children and adults (8). Vaccination in low-income countries has been less effective (reviewed in reference 9).

Detection and Characterization

Nucleic Acid-Based

Early detection methods relied on direct visualization of RVA virions in stool by electron microscopy, as the virus (70 nm in diameter) is often abundant and exhibits a distinct morphology. The migration of rotavirus double-stranded RNA genome segments by PAGE (known as electropherotyping) became a popular technique during the 1980s and early 1990s. Depending on the mobility of segment 11, two electropherotypes have been described for RVA (i.e., long or short). In humans, strains with "short" electropherotypes

doi:10.1128/9781555818722.ch66

TABLE 1 Common viral agents of gastroenteritis identified in stool[a]

Virus	Classification	Nucleic acid	Characteristic epidemiologic features
Rotavirus	*Reoviridae*	Segmented, double-stranded RNA	Pediatric diarrhea
Norovirus	*Caliciviridae*	Nonsegmented, single-stranded RNA	Sporadic diarrhea and outbreaks in all age groups
Sapovirus	*Caliciviridae*	Nonsegmented, single-stranded RNA	Pediatric diarrhea
Astrovirus	*Astroviridae*	Nonsegmented, single-stranded RNA	Pediatric diarrhea
Adenovirus	*Adenoviridae*	Nonsegmented, double-stranded DNA	Pediatric diarrhea
Bocavirus	*Parvoviridae*	Nonsegmented, single-stranded DNA	Pediatric diarrhea (human bocavirus-2, -3, and -4)
Aichivirus A	*Picornaviridae*	Nonsegmented, single-stranded RNA	Sporadic diarrhea in all age groups

[a]Common features of these viruses are as follows. (i) They are nonenveloped, icosahedral particles; (ii) infectious virions are shed in stool; (iii) viruses have a global distribution with multiple genotypes or serotypes; and (iv) severe cases occur most often in young individuals and immunocompromised patients. Currently, vaccines are available only for the rotaviruses.

usually correspond to G2P[4] or G9P[6] strains, and those with "long" electropherotypes to G1P[8], G3P[8], G4P[8], or G9P[8] strains (1, 5).

The most widely used current technique for the detection and characterization of RVA double-stranded RNA is a multiplex reverse transcription-PCR (RT-PCR) that targets either the VP4 or the VP7 gene. Briefly, the strategy utilizes an anchoring cross-reactive primer and a pool of genotype-specific primers in the PCR reaction. Each genotype-specific primer yields an amplicon of defined length, so that the genotype can be assigned following sizing of the products by electrophoresis (Fig. 2). Two RT-PCR strategies have been reported for identification of the most common G types in humans (10, 11) and one for the most common P types (12). RT-PCR methods for detection of G and P types characteristically found in RVA strains infecting animals are also available (13) and have the potential to be multiplexed with human RVA typing assays. A modified scheme developed by Das et al. (11) for G typing is illustrated in Fig. 2. Although these multiplex RT-PCR assays are widely used, it is recommended that the results be validated by sequencing or an alternative strategy such as hybridization. Intragenotypic diversification could lead to mutations in the primer-binding sites, which might result in negative results or the misidentification of the genotype (14, 15). The state-of-the-art method for the complete genetic characterization of RVA strains is full-genome (or nearly full) sequencing analysis (6, 16).

Quantitative real-time RT-PCR (RT-qPCR) assays have been developed for rotaviruses that enhance the sensitivity of detection and that also allow the quantification of virus genome (17, 18). The use of RT-qPCR is advantageous in the analysis of environmental or food samples containing small amounts of virus. However, its higher cost often limits its general use because cheaper assays (antigen-based or multiplex RT-PCR) work well to detect the high levels of rotaviruses often present in patient stool. Recently, Bennett et al. have reported a correlation between low threshold cycle values and more severe infections when testing for the presence of rotavirus RNA in stool samples (17). This type of test could prove useful as a quantitative readout in vaccine efficacy studies that score disease severity.

Antigen-Based

Multiple tests are commercially available for the detection of rotavirus antigen in stool samples. Most are based on the use of antibodies directed to the VP6 (inner capsid protein), which is highly conserved among rotavirus strains from the same group (19). Most kits provide results within 2 h, and some strip-based kits provide detection of rotaviruses within the first 10 min. The method used for the interpretation of results can vary from visual inspection to spectrophotometric reading of the wells. The antigen-based methods present higher sensitivity than the molecular methods (like RT-PCR or PAGE); however, they are limited by the specificity of the antibodies, which in some cases may fail to detect certain strains.

NOROVIRUSES

Overview

Noroviruses are a major cause of acute gastroenteritis in humans and have gained increasing importance after the successful introduction of rotavirus vaccines in different countries worldwide (20, 21). Currently, noroviruses are the major cause of hospitalizations and emergency visits due to acute gastroenteritis in the United States (20), and it is estimated that they are responsible for up to 200,000 deaths per year, predominantly in children <5 years of age in developing countries (22). These viruses are known to cause outbreaks in semi-enclosed settings such as child care facilities, schools, universities, nursing homes, family events, and cruise ships. Norovirus outbreaks often occur during the coolest months of the year, and the illness has been called "stomach flu" and "winter vomiting disease" (23).

Noroviruses possess a single-stranded, positive-sense RNA genome organized into three open reading frames (ORFs) that are flanked by 5′- and 3′-end nontranslated regions (NTRs). ORF1 encodes the nonstructural proteins required for replication, including the RNA-dependent RNA polymerase (RdRp); ORF2 encodes the major capsid protein (VP1); and ORF3 encodes a minor capsid protein (VP2) (Fig. 3A) (23). The current norovirus classification scheme is based on differences in the genes encoding RdRp (polymerase or P genotype) and the VP1 (capsid or C genotype). Currently, at least 7 genogroups (GI to GVII) and >30 genotypes have been defined (24). Noroviruses in GI, GII, and GIV infect humans, and GII.4 strains are the most prevalent worldwide (Fig. 3B) (25). Because noroviruses can undergo recombination near the ORF1/ORF2 junction during coinfection, recombinant strains with different P and C genotypes are not unusual (26). The interchange of P and C genotypes occurs almost

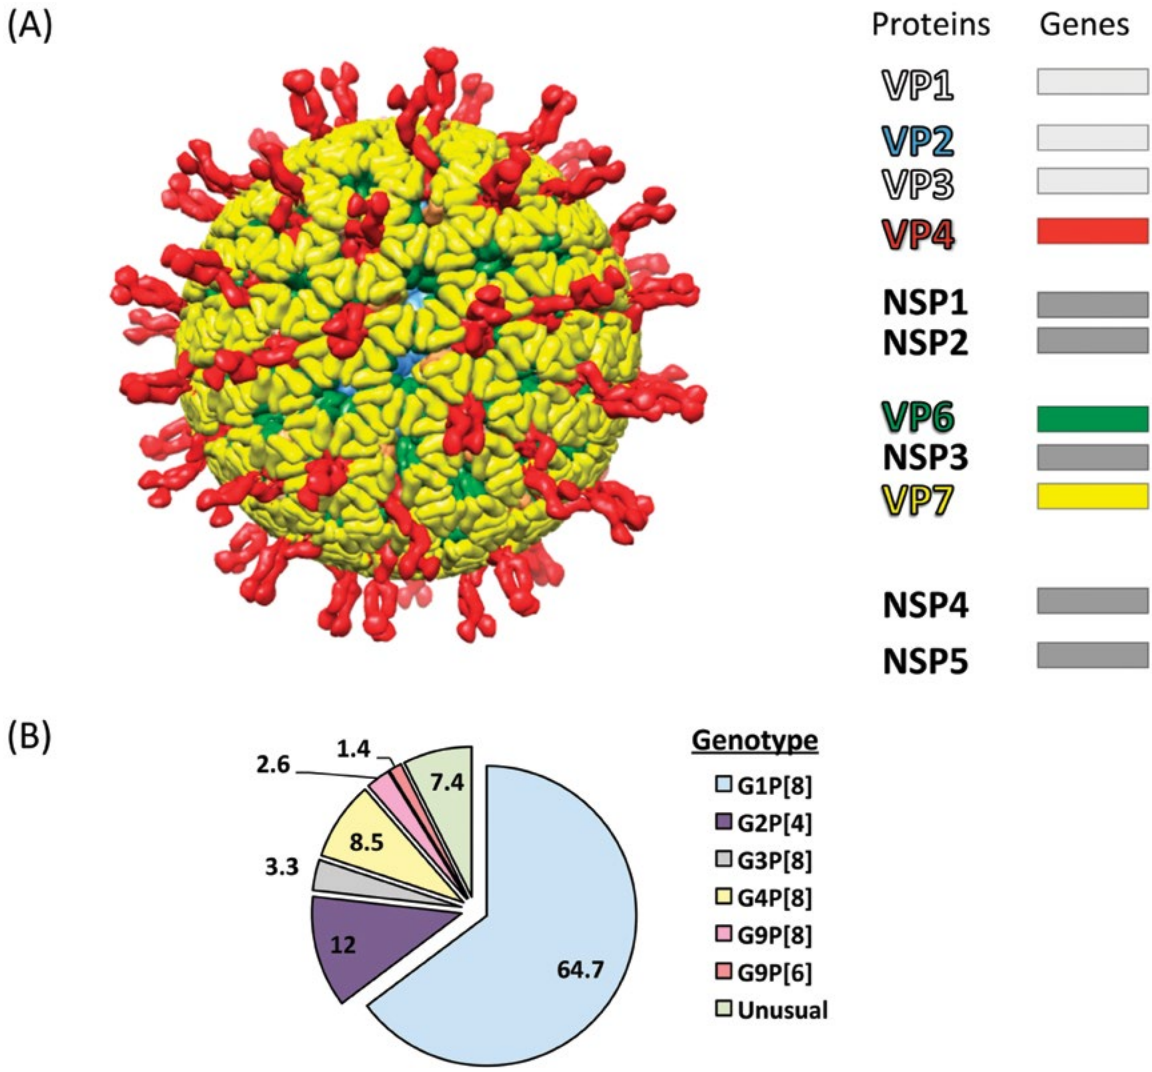

FIGURE 1 Rotavirus genome and genotype distribution. (A) Representation of rotavirus virion, proteins, and double-stranded RNA gene segments. Proteins are color coded, and genes used for typing are highlighted with corresponding colors. The rotavirus virion was modeled using crystal coordinates from VP2, VP6, VP7, and VP4 proteins (PDBs: 3IYU and 3N09) and visualized in Chimera. (B) Global incidence of the most predominant rotavirus strains in humans according to genotype. Numbers represent the percentage of total strains included (n = 16,474). (Adapted from reference 5.)

exclusively between strains within the same genogroup (i.e., intragenogroup recombinants).

The absence of a robust *in vitro* cell culture system or small animal disease model to study human noroviruses has been a roadblock in the field. The major capsid protein VP1 self-assembles into virus-like particles (VLPs) in several *in vitro* expression systems, and VLPs have been employed in the study of virus structure, antigenic diversity, diagnostics development, and virus-cell interactions. Furthermore, VLPs are currently under investigation as a promising vaccine candidate (27, 28).

Detection and Characterization

Nucleic Acid-Based

The detection of viral RNA in stool is currently the most widely used diagnostic method for the noroviruses (reviewed in reference 29), and commercial kits for RT-PCR are available. The two most common RT-PCR-based techniques require the initial isolation of highly purified viral RNA from stool specimens that is free of PCR inhibitors. In the first technique, RNA is subjected to RT-PCR with primers targeted to conserved regions of the genome (Fig. 3A) and the amplicon is directly sequenced (30–32). Sequences can be interrogated against an extensive norovirus database with the Norovirus Genotyping Tool (http://www.rivm.nl/mpf/norovirus/typingtool), and the P and/or C genotype assigned. Furthermore, sequence analysis provides the ability to track the emergence of new norovirus variants and recombinants. In the second technique, viral RNA is analyzed by RT-qPCR for virus detection and, if desired, quantification of genome copies. This method is sensitive and fast and provides the identity of genogroup (but not genotype, which requires sequence analysis of genomic RNA).

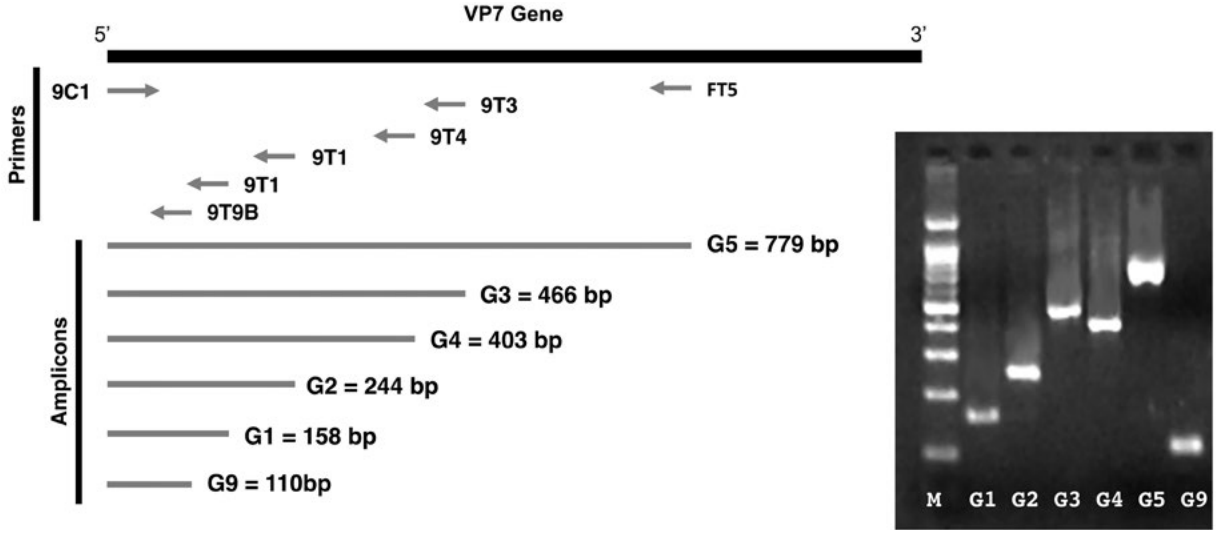

FIGURE 2 Representation of the RT-PCR genotyping strategy for human rotaviruses based on amplicon sizing. Genotype-specific primers annealing at different regions of the VP7 gene produce different-sized amplicons, which allows the genotype identification after electrophoresis of the PCR products. The molecular size marker (100-bp ladder) is shown in the first lane. (Primers were designed using reference strains and adapted from references 11 and 13.)

Antigen-Based

Although noroviruses are antigenically diverse, many strains within GI or GII share cross-reactive epitopes that have proven useful in the development of antigen-based diagnostic assays (33). Over the last decade, a number of commercial diagnostic immunoassays have become available that are generally based on an antigen capture step with cross-reactive antibodies (29). These assays can prove useful when rapid diagnosis is especially beneficial, such as during an outbreak investigation when the implementation of infection control measures is needed to limit virus spread.

SAPOVIRUSES

Overview

The association of sapoviruses with pediatric diarrhea was recognized long before their better-known calicivirus relatives the noroviruses. The sapoviruses (30 to 38 nm in diameter) were described initially as "classical caliciviruses" because of their distinct virion morphology that was similar to that of prototype animal caliciviruses such as feline calicivirus. The molecular characterization of the sapovirus viral genome showed that it was phylogenetically distinct from that of norovirus. Furthermore, the first ORF of sapovirus encodes a long, nonstructural, polyprotein-capsid protein fusion that is proteolytically processed to release the individual proteins, including the major capsid protein VP1. The second ORF encodes the putative minor capsid protein VP2 (34). Like noroviruses, the classification of sapoviruses is based on genetic differences within the RdRp and the major capsid protein VP1 genes (reviewed in reference 34). There are presently five major capsid-based genogroups (GI to GV), with human sapoviruses belonging to GI, GII, GIV, and GV. The GI and GII groups are further divided into genotypes, with GI.2 reported as predominant for a number of years (35). The dominance of a particular sapovirus genogroup varies according to region and year, and increased global tracking will be needed to fully establish the molecular epidemiology. Both intergenogroup and intragenogroup recombinant sapovirus strains have been described (36, 37), with the junction between the RdRp and VP1 genes as a major breakpoint for recombination.

Detection and Characterization

Nucleic Acid-Based

The detection of viral RNA in stool is the most widely used diagnostic method for sapoviruses. A number of primer pairs have been described for sapovirus RT-PCR assays that recognize the RdRp, the capsid, or the overlapping genomic region between the two genes, and these are reviewed by Oka et al. (34). Genotype identification requires sequence analysis of the full-length VP1 gene and comparison with sapovirus reference strains (34). A number of RT-qPCR assays have been developed to detect sapovirus RNA in stool, with some of these offered by commercial companies as part of a multipathogen array (38, 39).

Antigen-Based

Immunoassays have been developed for the detection of human sapoviruses in stool samples based on antibodies raised against VLPs (40, 41), but these are not yet commercially available.

ASTROVIRUSES

Overview

Soon after the discovery of rotaviruses and noroviruses, two groups independently reported the presence of small viruses (~28 nm in diameter) in fecal samples from children with acute gastroenteritis (42, 43). These viruses received the name "astrovirus" for their star-like (*astron* = "star" in Greek) appearance under the electron microscope, and early detection methods relied on this unique morphology for detection. Although initially described in humans, a

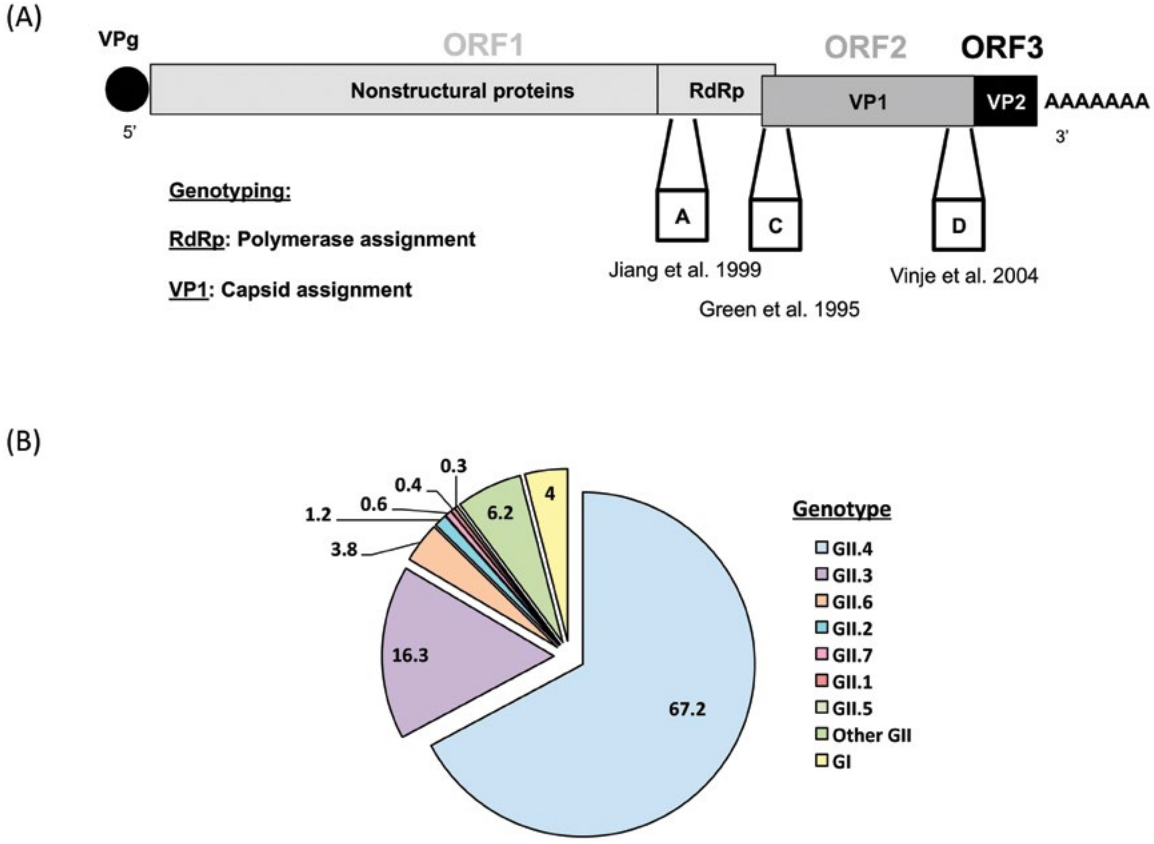

FIGURE 3 Norovirus genome and capsid genotype distribution. (A) Schematic representation of the norovirus positive-sense, single-stranded RNA genome (~7.5 to 7.6 kb) showing three of the major target regions for norovirus identification and characterization (regions A, C, and D) (30–32). The ORFs; the virus protein, genome-linked (VPg); and the poly(A) tail are indicated. (B) Prevalence of norovirus capsid genotypes in humans. Numbers represent the percentage of total number of strains tested (n = 2,968). (Adapted from reference 25.)

wide variety of astroviruses have been reported in different mammals (including pigs, cattle, sheep, minks, dogs, cats, bats, mice, and sea mammals) and birds (including chickens, ducks, pigeons, and turkeys) (44, 45). Astroviruses are an important cause of gastroenteritis in children and animals, but they have been also associated with neurological disease in immunocompromised patients or mammals, and fatal hepatitis in ducklings (44, 46–50).

Astroviruses are nonenveloped viruses with a single-stranded, positive-sense RNA genome that varies in length from 6.2 to 7.8 kb. The genome contains three overlapping ORFs and a 5′- and 3′-end NTR. ORF1a encodes multiple proteins required for replication, including a helicase, protease, and genome-linked viral protein (VPg). ORF1b encodes the RdRp, and ORF2 the proteins that form the viral capsid (44, 45). The proteolytic cleavage of the primary translation product (VP90) is required for maturation of the virion, which comprises VP34 (the highly conserved N-terminal region of ORF2) and VP27/29 and VP25/26 (both the variable C-terminal region of ORF2) (45).

Astroviruses can be cultured in LLC-MK2 (monkey kidney) cells and Caco-2 (human colorectal adenocarcinoma) cells (45). Based on their reactivity with type-specific rabbit antisera and neutralization assays, human astroviruses (HAstVs) have been classified into eight serotypes (HAstV-1 through HAstV-8) (45). The genetic characterization of the capsid gene (ORF2) of these viruses confirmed the presence of eight genotypes that correlated with the serotype designation (45). Epidemiological studies have shown that HAstV-1 is the most prevalent type in children with diarrhea, but outbreaks with different genotypes have been reported in various settings (45). Recently, two HAstV strains that were phylogenetically distinct from all other genotypes were detected by next-generation sequencing methods in stools from children with diarrhea in Australia (HAstV-MLB) and Virginia (HAstV-VA) (51, 52).

Detection and Characterization

Nucleic Acid-Based

Conventional RT-PCR is the method chosen by most research groups for screening and characterization of astroviruses. There are multiple primer pairs designed to detect HAstVs in stool samples (reviewed in reference 53). Most diagnostic primers target the conserved genomic regions encoding nonstructural proteins (ORF1a or ORF1b), while genotyping primers target the ORF2 region. The capsid genotyping primers flank a region of genomic variability near the 3′ end of ORF2 that is most commonly analyzed for typing (45, 53–55). Matsui et al. (55) developed a hemi-nested RT-PCR that in a first step amplifies the entire ORF2 with primers that anneal to the conserved 5′ and 3′ ends.

The resulting amplicon is then used as a template in a second PCR step with eight genotype-specific primers that allow typing based on size of the amplicon (a strategy similar to the one developed for rotavirus genotyping). This PCR strategy has been shown to be orders of magnitude ($\geq 10^5$) more sensitive than enzyme immunoassay (54). Sequence analysis of ORF2 amplicons provides definitive identification and can be used to monitor viral evolution.

There are several different RT-qPCR assays developed for astroviruses, with many of them part of multipathogen screening systems. The advantage of the RT-qPCR is that in some cases results can be obtained in <2 h. Several companies offer standardized RT-qPCR assays for astrovirus or multivirus screening in stool samples (38, 39).

Antigen-Based

Antigen-based detection kits for astroviruses offer the advantage of providing results within 1 or 2 h. Most of the tests use a combination of hyperimmune antisera as capture antibody and a panel of monoclonal antibodies that specifically detect the capsid protein of each of eight HAstV serotypes. The enzyme immunoassay tests for astroviruses have demonstrated high sensitivity and specificity (>90%) for the most common astroviruses circulating in humans (56, 57), although they do not detect the newly discovered HAstV-MLB and HAstV-VA viruses.

ADENOVIRUSES

Overview

Adenoviruses were first detected in individuals with respiratory disease, and their name derives from their initial isolation from human adenoids (nasopharyngeal tonsil) (58, 59). Adenoviruses can cause a variety of symptoms including respiratory distress, conjunctivitis, gastroenteritis, renal failure, and, to a lesser extent, neurological diseases.

Adenoviruses are medium-sized (90 to 100 nm in diameter), nonenveloped viruses with an icosahedral capsid that contains a long (34- to >37-kbp), double-stranded DNA genome. The genome is covalently linked at both ends to a 55-kDa protein that is required for the initiation of viral replication. Upon interaction with the cellular receptor, human adenovirus enters the cell by endocytosis and the genome is translocated to the nucleus to start replication. The "early" genes are mostly involved in viral DNA replication, while the "late" genes mediate viral assembly (59, 60).

Adenoviruses possess a complex capsid that is composed of multiple proteins, with three of them (hexon, penton, and fiber) containing the major antigen determinants (Fig. 4A). The most abundant protein in the virion is the hexon (240 trimers), and therefore most of the neutralizing antibodies are directed against the loops (outermost region) of this protein (Fig. 4A). Neutralizing epitopes are also present

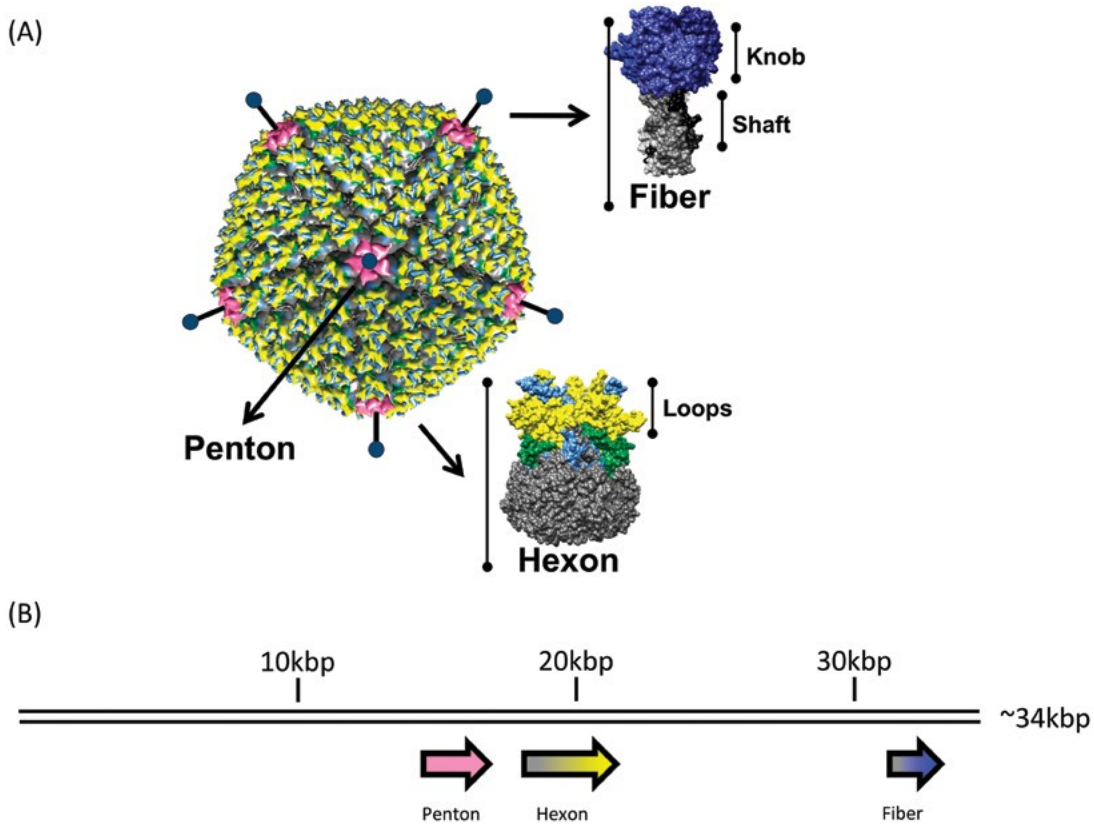

FIGURE 4 Adenovirus proteins and genome. (A) Capsid of adenovirus showing the three major external proteins: penton (pink), hexon (light gray), and fiber (shaft domain: gray; knob domain: navy blue). The three external loops of the hexon are indicated by yellow, green, and light blue. The model was visualized using Chimera and the structural coordinates from adenovirus type 5 (PDB: 3IYN) and adenovirus type 2 (PDB: 1QIU). (B) Schematic representation of the adenovirus double-stranded DNA genome (34 to 37 kbp) showing the position of the penton, hexon, and fiber genes used for molecular characterization.

in the penton and fiber proteins (61). The fiber protein is divided into two structural domains, the shaft and the knob, with the latter involved in interactions with the cellular receptor. The classification of adenoviruses is based on the biological and antigenic characteristics of these three proteins (59).

Based on genomic analyses, serological differences, and pathology, human adenoviruses can be divided into seven species (A to G) and >50 serotypes/genotypes (59, 60). Although different species of adenoviruses can be found in stool samples, species F (types 40 and 41) and G (type 52) have been directly associated with gastroenteritis in humans (59). In general, the incidence of enteric adenovirus in sporadic cases of diarrhea in children and adults is low (~5%), but adenovirus requires special attention in immunocompromised individuals, who can develop severe complications during infection (60).

Detection and Characterization

Nucleic Acid-Based

Because serotyping was expensive and time-consuming and required type-specific sera, the analyses of the DNA fragment patterns obtained by restriction enzymatic fragmentation of the whole genome became widely used in the 1990s. This technique was replaced by the amplification and sequencing of the genes encoding the hexon, penton, or fiber (Fig. 4B), which allowed the faster detection and characterization of clinical isolates (60). A qPCR that uses primers that anneal in a conserved region of the hexon gene proved to detect >50 different adenovirus prototype strains in different samples (62). Detection of adenovirus is also included in multiplex assays for screening stool samples (38, 39).

Cell Culture- and Antigen-Based

Isolation and propagation of clinical adenoviruses can be achieved in different continuous cell lines, including but not limited to HEp-2, HeLa, KB, and HEK 293. Upon infection, cells round, swell, and form grape-like clusters, which is the characteristic cytopathic effect. Adenoviruses were initially characterized and classified into serotypes by cross-neutralization or hemagglutination inhibition assays. Serum neutralization and hemagglutination inhibition serotyping assays correlate well for adenovirus strains that share hexon, penton, and fiber specificity. However, because hemagglutination specificity is conferred by the fiber protein, such correlation may not be seen in recombinant strains that bear a unique fiber protein (59, 60).

The hexon protein is the most abundant in the virion and is the major target for immunoassays developed to detect adenoviruses in stool. Although the tests are faster and require less equipment and training, they present lower sensitivity as compared to the nucleic acid-based tests (57).

SUMMARY

Multiplex nucleic acid-based tests are rapidly gaining widespread use in diagnostic laboratories. These multipathogen formats provide positive identification of the pathogen and may eventually provide in-depth information on the identity of the virus genotype. Next-generation sequencing and genome assembly is another emerging technology that is becoming more cost-effective and that will allow the ability to track viral evolution at the nucleotide level. Point-of-care diagnostics that are rapid and inexpensive and based on the detection of viral antigens in stool will undoubtedly continue as a popular and practical choice as these assays improve in specificity and sensitivity. The comparison of acute (or preinfection) and convalescent immune responses following infection will remain instructive in establishing the etiology of viral gastroenteritis when paired samples are available. This chapter reviewed key aspects of several viral diarrheal pathogens that are important in the development of diagnostic assays and in virus characterization. Basic information on virus structure and diversity, coupled with the clinical features and epidemiology of a pathogen, will also continue to be important parameters in the establishment of the etiology of viral gastroenteritis.

This writing of this review was funded by the Division of Intramural Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health and Human Services.

Arboviruses

ROBERT S. LANCIOTTI AND JOHN T. ROEHRIG

67

The arthropod-borne viruses (arboviruses) represent a diverse amalgam of more than 500 animal viruses that are grouped together because of their ability to replicate in both vertebrates and arthropods. While more than 150 arboviruses are known to cause human illness or infection, the list of the most medically important viruses is considerably shorter (Table 1) (1–3). Because of the vast number of agents that potentially should be considered in a differential diagnosis, the use of epidemiologic, ecologic, and clinical data to guide the choice and interpretation of clinical laboratory diagnostic tests is essential. Most arboviruses are transmitted seasonally in specific geographic locations or ecological habitats. The patient's history of travel, activities, and potential exposures to arthropods or habitats associated with arbovirus transmission provides vital data for selection of appropriate antigens and relevant diagnostic approaches. Knowledge of the patient's immunizations against yellow fever (YF), Japanese encephalitis (JE), or tick-borne encephalitis (TBE) viruses is also important for the proper interpretation of serological results. Although the laboratory diagnosis of arboviral infections still relies chiefly on serology, other approaches that directly detect viral antigen or genomic material and not antibodies are now routine.

METHODS

Antibody Detection

IgM ELISA

Assays that detect virus-elicited immunoglobulin M (IgM) are useful because they detect antibodies produced within days of a primary viral infection. IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) is the preferred approach to IgM detection because it is simple, sensitive, and applicable to serum and cerebrospinal fluid (CSF) samples. False-positive reactions due to rheumatoid factor also are minimized (4, 5). While most ELISAs are based on a 96-well microplate format, assays have been developed and adapted to microsphere-based systems (6, 7). These new systems require very small volumes of test specimens and permit antigen multiplexing, resulting in a considerable savings of time and money (8, 9).

IgM from serum or CSF is first captured onto the solid phase with μ-chain-specific antispecies antibody. IgM antibodies of all reactivities are thus concentrated, but during an acute infection, IgM antibodies directed at the etiologic agent are the principal circulating species. Virus antigen is next added, and if virus-specific IgM is present, viral antigen is bound to the plate. A variety of antigen sources such as virus-infected mouse brain, lysed cells, cell culture supernatant, or recombinant antigen can be employed. The bound antigen can be detected by a variety of means; however, the most practical approach is to use an enzyme-labeled antiviral monoclonal antibody (MAb). Since the reactivity of the patient's IgM with the test antigen in part defines the specificity of the assay, broadly reactive labeled antibodies can be used as detectors for most of the medically important arboviruses, e.g., monoclonal antibodies reactive against flavivirus group (6B6C-1), alphavirus group (2A2C-3), and California serogroup (10G5.4) (Table 2) (10).

Approximately 75% of patients with flavivirus encephalitis (e.g., JE or St. Louis encephalitis [SLE]) have detectable IgM in serum or CSF in the first 4 days of illness, and nearly 100% of samples are reactive by 7 days. Similar levels of sensitivity have been reported for patients with LaCrosse (LAC) encephalitis or alphavirus encephalitis and in patients with dengue (DEN) or YF. For patients with central nervous system (CNS) infections, greater sensitivity and specificity are obtained by also testing CSF.

The specificity of the MAC-ELISA is similar to that of the complement fixation (CF) test, and heterologous antibodies to related viruses may interfere with interpretation, particularly in patients with previous related infections. To improve diagnostic specificity, ratios of absorbances to related viruses can be calculated, yielding indices that are better discriminators than the individual absorbances alone. For example, antibodies to DEN and JE viruses cross-react in hemagglutination inhibition (HI) tests and ELISAs, but patients with the respective infections can be identified by calculating ratios of ELISA absorbances to the two viruses. Similarly, ratios of absorbances in IgM and IgG capture tests have a high predictive value in discriminating recent from previous infections with these viruses (11).

Although levels of IgM antibodies generally decline after 2 to 4 weeks and are absent after 90 to 120 days, IgM persists for a year or more after infection in some patients. This phenomenon has been reported for patients with JE, SLE, West Nile (WN) encephalitis, Murray Valley encephalitis (MVE), LAC encephalitis, and Sindbis and Ross River (RR) virus polyarthropathy, and it is common in patients

doi:10.1128/9781555818722.ch67

TABLE 1 Characteristics of selected medically important arbovirus disease

Disease	Viral agent	Arthropod vector or source	Clinical syndrome(s)	Geographic distribution	Risk factor(s)	Case-fatality ratio (%)
EEE	Alphavirus	Mosquito	CNS infection	Eastern United States, Central and South America	Advanced age	30
JE	Flavivirus	Mosquito	CNS infection	Asian rice-growing areas	Exposure to rural areas	15–30
LAC encephalitis	Bunyavirus	Mosquito	CNS infection	East-central United States (children)	Males > females; agricultural occupations	<1
Rocio encephalitis	Flavivirus	Mosquito	CNS infection	Sao Paulo state, Brazil	Males > females; agricultural occupations	5
SLE	Flavivirus	Mosquito	CNS infection	North, Central, and South America	Advanced age	7
TBE	Flavivirus	Tick	CNS infection	Europe, Asia	Forest exposure	1–10
Powassan encephalitis	Flavivirus	Tick, mosquito	CNS infection	Canada, United States, Russia, China	Forest exposure	10
WEE	Alphavirus	Mosquito	CNS infection	Western United States, South America, Canada, Mexico	Males > females; extremes of age	5
CTF	Coltivirus	Tick	Febrile grippe	Rocky Mountain states, South Dakota, California, western Canada	Exposure to areas >5,000 ft (ca. 1,500 m) in elevation	<1
DEN	Flavivirus	Mosquito	Febrile grippe and rash; hemorrhagic fever	Tropical locations worldwide	Urban, peridomestic exposure	5
WN fever	Flavivirus	Mosquito	Febrile grippe and rash; encephalitis	United States, Africa, Europe, Asia	Advanced age	<1
Oropouche fever	Bunyavirus	Midge	Febrile grippe	Central and South America	Agricultural occupation	<1
Phlebotomus fever	Phlebovirus	Phlebotomine fly	Febrile grippe	Europe, Africa, Asia	Peridomestic exposure	<1
Chikungunya	Alphavirus	Mosquito	Febrile polyarthropathy and rash; rarely hemorrhagic fever	Africa, Asia	Urban, peridomestic exposure	<1
Mayaro fever	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Central, South America	Males > females; forest exposure	<1
RR arthropathy	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Australia, Pacific	Females > males	<1
Sindbis virus fever	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Africa, Europe, Asia	Woodland exposure	<1
Crimean-Congo hemorrhagic fever	Nairovirus	Tick, infected blood	Hemorrhagic fever	Africa, Europe, Asia	Animal husbandry; agricultural and medical occupations	10–50
Rift Valley fever	Phlebovirus	Mosquito, infected blood	Febrile grippe; hemorrhagic fever	Africa, Middle East	Animal husbandry; butchering	<1
YF	Flavivirus	Mosquito	Febrile grippe; hemorrhagic fever	South America, West and Central Africa	Forest or rural exposure	15

TABLE 2 Selected arbovirus monoclonal antibodies for serologic and antigen detection assays[a]

Antibody[b]	Prepared against:	Reactivity	Use
6B6C-1	SLE virus (MSI-7)	Flavivirus group	As HRP[c] conjugate in antigen capture and IgM capture ELISAs
4G2	DEN virus 2 (New Guinea C)	Flavivirus group	Viral identification by IF or ELISA; ELISA capture antibody
6B4A-10	JE virus (Nakayama)	JE-SLE-WN-MVE complex	Capture antibody in antigen capture ELISA
JE314H52	JE virus (Nakayama)	JE virus specific	Viral identification by IF or ELISA
6B5A-2	SLE virus (MSI-7)	SLE virus specific	Viral identification by IF and neutralization
4A4C-4	SLE virus (MSI-7)	SLE virus specific	Capture antibody in antigen capture ELISA
4B6C-2	MVE virus (original)	MVE virus specific	Viral identification by IF or ELISA
D2-1F-3	DEN virus 1 (Hawaii)	DEN virus 1 specific	Viral identification by IF or ELISA
3H5-1-21	DEN virus 2 (New Guinea C)	DEN virus 2 specific	Viral identification by IF or ELISA
D6-8A1-12	DEN virus 3 (H87)	DEN virus 3 specific	Viral identification by IF or ELISA
1H10-6-7	DEN virus 4 (H-241)	DEN virus 4 specific	Viral identification by IF or ELISA
5E-3	YF virus (17D)	YF virus specific	Capture antibody in antigen capture ELISA
117	YF virus (Asibi)	YF wild-type virus specific	Viral identification by IF
864	YF virus (17D)	YF vaccine virus specific	Identification of vaccine strains by IF
4D9	TBE virus	Tick-borne flavivirus complex	Viral identification by IF or ELISA
H5.46	WN virus	WN virus specific	Viral identification by IF or ELISA
2A2C-3	WEE virus (McMillan)	Alphavirus group	As HRP conjugate in antigen and IgM capture ELISAs
2A3D-5	WEE virus (McMillan)	WEE complex	Capture antibody for WEE and HJ antigen capture ELISA
2B1C-6	WEE virus (McMillan)	WEE virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1B5C-3	EEE virus (NJ 60)	EEE North American virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1C1J-4	EEE virus (BeAn 5122)	EEE South American virus specific	Viral identification by IF or ELISA
1B1C-4	EEE virus (BeAn 5122)	EEE complex specific	Viral identification by IF or ELISA
2D4-1	Highlands J virus (B230)	Highlands J virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1A2B-10	VEE virus (E2 peptide)	VEE complex	Viral identification by IF or ELISA
5B4D-6	VEE virus (TC-83)	TC-83 (vaccine) specific	Viral identification by IF or ELISA
1A3A-5	VEE virus (IC)	Epizootic VEE virus	Viral identification by IF or ELISA
1A1B-9	VEE virus (IE)	Enzootic VEE virus	Viral identification by IF or ELISA
807-18	LAC virus (original)	LAC virus specific	Viral identification by HI, neutralization, or ELISA
10G5.4	LAC virus (original)	California serogroup reactive	Viral identification by ELISA

[a]Adapted from reference 35.
[b]Antibodies and/or conjugates are available from the Centers for Disease Control and Prevention.
[c]HRP, horseradish peroxidase.

with YF or after YF vaccination. This observation is of diagnostic importance, because in areas where the diseases are endemic, IgM from infection during a previous transmission season could be mistaken as evidence of recent infection. For this reason, demonstration of IgM in a single serum sample alone does not necessarily indicate a recent infection. Virus-specific IgM in CSF has been detected 50 to 180 days after onset of acute JE, indicating continuing intrathecal production of antibody and the possibility of persistent CNS infection. However, these appear to be unusual cases, and in most circumstances, detection of arbovirus-specific IgM in CSF is a reliable indication of recent infection.

A practical problem in implementing the MAC-ELISA is the unavailability of human positive-control sera containing IgM for all the antigens of interest. Although reactive human sera for many of the common arbovirus infections are available from the Centers for Disease Control and Prevention and other laboratories, human positive-control sera for less prevalent infections are unavailable. To solve this problem, chimeric murine/human IgM and IgG MAbs (cMAbs) have been developed for both alphaviruses and flaviviruses (12–14). These cMAbs are based on the broad flavivirus- and alphavirus-reactive MAbs, 6B6C-1 and 1A4B-6, respectively, Due to the presence of a human Fc region in these cMAbs, they react like human antibodies in ELISA and other binding assays, e.g., indirect immunofluorescence assay.

Reference laboratories can also provide testing panels of serum for quality control of test performance. Unlike the

HI, CF, and neutralization tests described below, in which mouse immune fluids can be used as controls, the MAC-ELISA incorporates a species-specific capture antibody and requires reactive human samples. MAC-ELISAs for agents of arbovirus encephalitis are offered by commercial reference laboratories, and a kit for TBE diagnosis is available in Europe. Commercial MAC-ELISAs for human WN and dengue infections that have U.S. Food and Drug Administration (FDA) approval are also available. Commercial dot blot kits for DEN and JE are available in Asia, but their sensitivity and specificity require further characterization.

The original source of flaviviral antigen (virus-infected mouse brain) used in ELISA protocols has been replaced for some flaviviruses with virus-like particles (VLPs) also known as recombinant soluble particles (15). These antigens are either transiently or stably secreted from animal cells (e.g., primate COS-1 cells) that have been transformed with a plasmid containing the flaviviral prM and envelope (E) glycoproteins. The prM and E proteins self-assemble into particles with a structure similar, but not identical, to virus without the nucleocapsid. The viral antigenic properties are retained in the VLP, so they are satisfactory substitutes for virus in binding assays, since the major antibody responses are against these viral surface proteins. Some VLPs have been modified to remove major flavivirus cross-reactive E protein epitopes, thus improving virus specificity (16).

IgG ELISA

IgG ELISA has replaced the HI test for the diagnosis of most infections because the procedure is less cumbersome and titration curves for the two procedures are similar. Various indirect procedures to measure the levels of IgG antibodies to arboviruses differ chiefly in the procedures for antigen preparation and methods for their attachment to the solid phase. Conventional mouse brain antigens extracted with sucrose and acetone generally do not have adequate potency as antigens unless they are first captured and concentrated onto the solid phase with antibody (mouse monoclonal or polyclonal ascitic fluid) (10). Dot ELISAs, in which antigens are adsorbed to nitrocellulose or other membranes, also have been used successfully. The sensitivities of IgG ELISAs generally are similar to or greater than those of HI tests, and their specificities correspondingly are equal or lower.

IF Test

The procedures for arbovirus diagnosis generally use virus-infected Vero or other cells fixed onto slides in monovalent or polyvalent preparations. Commercially available spot slides with SLE, western equine encephalitis (WEE), eastern equine encephalitis (EEE), and LAC virus-infected cells make it possible to screen a serum sample simultaneously against several arbovirus agents of encephalitis in the United States. A similar polyvalent slide is available to screen patients with suspected viral hemorrhagic fever for antibodies against Crimean-Congo and Rift Valley fever (RVF) viruses, two strains of Ebola virus, and Lassa and Marburg viruses in a single CRE_2LM (derived from the names of the viruses) slide. Virus-specific IgM and IgG antibodies in CSF also can be measured by immunofluorescence (IF), although the titers generally are lower than in serum. With all indirect tests for IgM, the confounding effects of IgM rheumatoid factors should be controlled.

Indirect IF, HI, and neutralization tests have similar sensitivities, but IF is less sensitive than ELISA. The indirect IF test for antibodies to most arboviruses is as specific as or less specific than the HI test. Indirect IF cannot be relied upon to distinguish infections among the flaviviruses, among the alphaviruses, or among viruses in bunyavirus serogroups. However, the broad reactivity of IF can be exploited in screening tests and in epidemiologic studies.

HI and CF Tests

Classical serodiagnosis of arbovirus infections relied on the HI and CF tests. These technically demanding assays rely on the availability of goose or other erythrocytes and have largely been abandoned in favor of the more readily standardizable IgM and IgG ELISAs except in the largest diagnostic reference laboratories (17). The major advantage of both the HI and the CF test is that species-specific positive-control reagents are not necessary. Consequently, more readily available, experimentally derived antiviral antibodies from mice, rabbits, or goats can be used in these tests.

HI antibodies are long-lived, and for this reason HI has often been used as a screening test, especially in serosurveys. After infection, HI antibodies rise within the first week, peak by the third week, and decline to low levels that may persist for years or decades. HI antibodies arising from a primary infection are relatively specific; however, with second and repeated flavivirus infections (superinfection), such as with DEN, YF, or JE virus, the antibody response broadens and heterologous reactions preclude differentiation of the most recent infection from previous infections. Patients with repeated exposures to flaviviruses routinely develop heterologous antibodies to agents to which they have never been exposed. Often, these heterologous reactions have titers that are equal to or higher than those of the presumed homologous reaction. More specific assays, described below, are required to differentiate these cross-reactions.

The CF test provides a level of specificity intermediate between those of HI and neutralization tests (17). CF antibody levels usually are late to rise, and in some patients they are not detectable until 6 weeks after infection. In up to one-third of proven SLE patients, no CF antibodies can be detected. Because of its insensitivity, the CF test should not be used alone as a diagnostic procedure. The test remains useful for viruses that do not hemagglutinate, such as Colorado tick fever (CTF) virus. The kinetics of the rise and fall (half-life of 2 years) of CF antibody levels can be exploited to identify infections that have occurred relatively recently, in the period after which IgM antibodies have disappeared. The test also is relatively specific in differentiating natural from vaccine-induced immunity to YF virus. Immunized patients generally do not produce detectable CF antibodies to YF virus unless they have had previous flavivirus infections.

Neutralization Test

The serum neutralization test is the most virus-specific test for serologic diagnosis and is used to confirm other serologic testing results (17). The serum dilution-plaque reduction neutralization test performed in cell culture is the standard method; however, animal, especially mouse, protection tests follow the same principle. A detailed description of the plaque-reduction neutralization test for DEN viruses has been published (18). Dilutions of heat-inactivated serum are added to equal volumes of a viral preparation known to contain a predetermined viral input dose from previous infectivity titrations. The resulting mixtures of serum, beginning at a 1:10 final dilution, and virus (100 plaques for 35-mm-diameter wells and 25 plaques for 16-mm-diameter wells) are incubated either overnight at 4°C or for 1 h at 37°C for viral neutralization to proceed. The resulting mixtures are used to inoculate confluent cell monolayers and are overlaid with a nutrient semisolid or solid medium (methylcellulose, agarose, gum

tragacanth, or agar can be used); after a suitable interval (e.g., 2 to 7 days, depending on the virus), when plaques have formed, a vital stain is added to differentiate infected nonviable cells, which appear as unstained plaques, from the uninfected stained monolayer. Neutral red in agar or as a liquid solution is conventionally used, but when removable semisolid overlays are used, a permanent record of the test can be made by fixing the monolayer and staining it with amido black or crystal violet.

Numerous variations of the procedure have been described, including (i) the use of DEAE-dextran or other cationic polymers to reduce electrostatic charges on agar that interfere with virus–cell interactions, and (ii) the addition of complement or normal human or animal serum to serum–virus mixtures to increase the sensitivity of neutralization.

The last serum dilution that significantly reduces the input dose of virus is the end point (80 to 90% reduction of the plaque count in the virus control). End points in animal protection assays are calculated by the Reed-Muench or Karber method, and six animals per serum dilution should be the minimum number used.

Neutralizing-antibody levels generally rise within days of the onset of illness, peak in the second week, and decline slowly to moderate or low levels, where they persist for years and often a lifetime. The sensitivity of the test is high, usually equal to that of HI or IF tests, but, most importantly, no other approach is as virus specific.

An alternative approach to measuring the neutralizing power of a serum is the constant serum-varying virus dilution test, resulting in a log neutralization index. This procedure has fallen into disuse because it is somewhat less specific than the serum dilution method and large quantities of serum are needed.

One of the most significant improvements in the plaque reduction neutralization test for pathogenic or poorly growing viruses has been the creation of chimeric viruses using recombinant DNA technology and full-length infectious cDNA clones of viruses (19). This technique has been applied most to flaviviruses. Chimeric flaviviruses that encode the nucleocapsid and nonstructural proteins of one virus (e.g., YF virus) and the prM E protein of a second flavivirus (e.g., WN virus) yield a chimeric, usually attenuated virus that maintains the growth parameters of YF virus and the serological reactivity of WN virus. This approach permits construction of chimeric viruses that have similar growth characteristics, but with differing serological attributes. By preparing chimeric viruses for all four DEN virus serotypes, the improved chimeric virus growth characteristics have resulted in a more robust and reproducible DEN virus plaque reduction neutralization test.

Antigen Detection

Certain arboviruses produce a viremia of sufficient magnitude and duration that the viruses can be isolated from blood during the acute phase of illness, e.g., 0 to 5 days after onset. Epidemiologically, this is significant because during the period of viremia, the viruses may be transmitted from person to person by biting vectors. Examples of these viruses include the agents of YF, DEN, chikungunya, sandfly, RR, and Oropouche fevers. The viremia in CTF is unique because it can extend for weeks or months and infection has been transmitted by transfusion. Recently, several commercial assays have been developed for the detection of soluble NS1 DEN antigen (20).

While Venezuelan equine encephalitis (VEE) virus can be recovered from the throat of one-fourth of patients, person-to-person spread has not been conclusively proven. SLE virus and certain hantaviruses can be detected in urine (see below). Many encephalitogenic arboviruses can be recovered from CSF obtained during the acute phase of illness, and, rarely, SLE, JE, WEE, and EEE viruses have been recovered from blood. The virus of TBE commonly contaminates milk of infected sheep, cows, and goats, but its occurrence in human milk has not been reported.

Antigen Capture ELISA

Antigen capture ELISA has been used to directly detect antigens of YF, DEN, sandfly fever, Rift Valley fever, Sindbis, and chikungunya viruses directly in blood. In some cases, viral antigens complexed with antibody must first be dissociated by use of a reducing agent, e.g., dithiothreitol. Generally, an overnight incubation of antigen maximizes sensitivity, which approaches 10^3 PFU/0.1 ml. The sensitivity of antigen capture ELISA for YF virus is similar to that of viral isolation from cell cultures, mosquitoes, or mice and is accomplished 3 to 7 days more quickly.

Antigen capture ELISA also has proved useful in epidemiologic surveillance of arbovirus infection rates in vector mosquitoes. A single infected mosquito in a pool can be detected rapidly and cheaply by the direct detection of antigen, allowing greater flexibility and time to implement emergency vector-control measures. This approach has been applied to SLE, WN, EEE, and LAC viruses (21). The SLE and EEE virus tests have been converted to a commercial dipstick format. Other arbovirus antigens have been detected directly in sandflies and ticks.

Immunohistochemical Staining

Certain arbovirus infections can be rapidly diagnosed by direct detection of virus-infected cells by IF or other histochemical techniques. The various causes of potentially fatal viral hemorrhagic fever, including DEN virus, cannot be reliably differentiated on a clinical basis, and immunohistochemical examination of liver tissues is a means by which a specific diagnosis can be reached. When liver biopsy specimens from patients with suspected YF are available, ordinary histopathological examination should be supplemented with more specific immunohistochemical techniques such as indirect IF. Similarly, IF and immunoperoxidase staining of brain biopsy or autopsy specimens have been helpful in differentiating arbovirus infections such as WEE, EEE, and LAC virus infections from other causes of encephalitis.

In disseminated infections such as YF and DEN, viral antigen has been demonstrated in various sites, including myocardium and kidney (YF) and bone marrow, spleen, lymph nodes, and dermal mononuclear cells (DEN) (22).

The CTF virus is unusual because it infects erythrocyte precursors, and infected erythrocytes can be detected in peripheral blood for the life of the infected cells. Examination of peripheral blood smears by IF is the most rapid approach to diagnosis and is more sensitive than serology. For patients with RR virus polyarthropathy, IF viral antigen has been found in monocytes and macrophages of synovial exudates, and it has been possible to rapidly identify infected patients by examining fluid from inflamed joints. Peripheral blood mononuclear cells are a principal replicative site for DEN virus and other flaviviruses. DEN and JE virus-infected mononuclear cells have been detected in peripheral blood by IF, and JE virus-infected cells have been found in CSF, making a specific diagnosis possible within hours of a diagnostic lumbar puncture. SLE virus-infected cells have been detected by IF in urinary sediment of some patients, and free viral particles were visualized by electron microscopy; however, virus was not recovered from urine. Patients with

suspected viruria had urinary incontinence and other symptoms possibly associated with myelitis.

IF is the simplest approach to identifying viral isolates recovered from clinical samples. The source of the isolate, the rapidity and characteristics of viral growth in cell culture, and mortality patterns and average survival time in mice may provide clues to its identity; e.g., alphaviruses kill suckling mice and produce plaques in cell culture within 1 to 5 days. The basic approach to viral identification is to prepare spot slides with an infected cell culture suspension. After being dried, the slides are fixed in acetone and stained by the indirect method with a series of mouse ascitic grouping fluids containing antibodies to various groups of arboviruses (National Institutes of Health grouping fluids) or broadly cross-reactive monoclonal antibodies (Table 2). A positive reaction to a single grouping fluid is followed by further IF and neutralization tests with monospecific ascitic fluids or monoclonal antibodies until the virus is identified (23–27). Inoculated cell cultures that do not show cytopathic effects still should be tested by the aforementioned method because arboviruses may not be lytic in every cell line. Alternatively, frozen brain sections of intracerebrally inoculated suckling mice or squashes of intrathoracically inoculated mosquitoes can be stained by the same procedure. Morphologic characteristics of the isolate should be confirmed by electron microscopy, but definitive antigenic classification requires the production of a homologous antibody (immune mouse ascitic fluid) and cross-serologic tests, especially cross-neutralization tests, with antigenically related agents.

In situ ELISA combines the sensitivity of cell culture systems for viral isolation with the rapidity of ELISA to identify the amplified isolates. Virus in clinical specimens is amplified briefly by growth in cell culture in 96-well panels; after fixation, the resulting amplified cell-associated antigens are detected directly by ELISA in the same vessel. Infected cell cultures can be identified within 24 to 72 h after inoculation, depending on the titer of the inoculum and viral growth characteristics. The approach is especially useful for mass screening, such as for inhibitory effects of candidate antiviral drugs and for viruses that do not produce cytopathic effects. If a long-working-distance objective is available, the monolayer also can be examined microscopically for infected foci.

Detection of Viral Genomic Sequences

In Situ Hybridization

In situ hybridization has been used to identify genomic sequences of LAC virus and other bunyaviruses, SIN virus, and DEN virus in mosquitoes; bluetongue virus in sandflies; and DEN and YF virus genomic sequences in formalin-fixed, paraffin-embedded liver tissue (28).

The principal advantage of *in situ* hybridization over immunohistochemical detection of viral proteins is the greater stability of viral RNA than of viral protein antigens in fixed, embedded specimens. Paraffin-embedded liver samples that had been stored at ambient temperatures for 23 years still had detectable viral RNA when viral antigens were undetectable by immunohistochemical stains. Non-isotopelabeled probes, such as biotin, have been used for the detection of DEN virus in human tissues.

Nucleic Acid Amplification Tests (NAAT) for the Detection of Arboviruses

A variety of nucleic acid amplification platforms have been successfully utilized for the detection of arboviruses, including standard reverse transcriptase PCR (RT-PCR) (with agarose gel analysis), real-time RT-PCR using fluorescent probes, nucleic acid sequence-based amplification (NASBA), and reverse transcription loop-mediated isothermal amplification (RT-LAMP). More recently, next-generation sequencing technologies have been described for the sequence-based identification of arboviruses (29). Because no prior sequence information is needed to employ this approach, it is anticipated that next-generation sequencing will be used more in the future both for virus identification as well as virus discovery. Several of these technologies will be described below; however, important issues common to each approach will be presented first. In general, the sensitivity of any of the NAATs in identifying arboviruses has been shown to be equal to or greater than that of the most sensitive viral isolation procedures (either in cultured cells or in neonatal mice) while providing equal specificity in identifying specific viruses. The dynamics of *in vivo* viral replication and tissue tropisms must be carefully considered so that the utility of a NAAT to a particular arbovirus can be properly applied and interpreted. For example, the encephalitic flaviviruses (i.e., WN, SLE, and JE viruses) demonstrate a short viremia which is often low or absent at the time of clinical presentation of CNS symptoms. With these viruses, the detection of virus in serum by NAAT (or any method) is typically unproductive and a negative result is not informative. Detection of virus in CSF obtained from meningitis or encephalitis patients is often better. In one study of WN encephalitis patients, virus was detected by a real-time RT-PCR in 14% of acute-phase serum specimens and 57% of CSF specimens (30). In contrast, the DEN viruses often achieve a much higher viremia of longer duration which can be detected by virus isolation or NAAT methods; as a result, NAATs are a good choice for detecting and serotyping the DEN viruses. In general, the alphaviruses demonstrate replication kinetics similar to those of the flaviviruses and are not commonly detected in acute-phase serum and/or CSF specimens, although detection is generally greater than with the flaviviruses. In contrast, NAATs have been highly successful in detecting arboviruses from tissues obtained from fatal human cases when the appropriate tissue target is known and assayed (i.e., brain tissue for WN virus, LAC or EEE virus cases, liver tissue from YF cases, etc.).

The use of NAATs for the detection of arboviruses in surveillance protocols is highly successful, in particular the testing of field-collected mosquitoes. In this application, NAATs have often demonstrated superior sensitivity compared to virus isolation or antigen detection assays. With the addition of automation, these NAAT approaches have been used to test hundreds of mosquito specimens in a single day (31). NAATs have also been successfully utilized in environmental surveillance by detecting arboviruses from tissues obtained from field-collected vertebrate hosts. Detection of WN virus in field-collected dead birds and detection of EEE virus from fatal equine cases are typical applications of this technology.

RNA Extraction and Purification

Most arboviruses have a single-stranded RNA genome, and as a result the sensitivity and specificity of all amplification strategies depend upon the efficient extraction and purification of the target RNA template. In the past, RNA extraction protocols were developed primarily in-house and suffered from inconsistency due to RNA degradation during purification; however, a variety of highly efficient RNA extraction and purification protocols which allow for more rapid, consistent, and high-volume sample processing are

now commercially available. Most of these utilize a chaotropic lysis buffer for efficient solubilization and stabilization of RNA from a variety of sources, followed by binding to silica, subsequent washing, and then elution in a low-salt solution. This approach also has been automated, and hundreds of samples can be processed within a single day (31). The use of a chaotropic lysis buffer has also enabled the efficient extraction of intact RNA from a variety of sources, including serum or plasma, whole blood, CSF, tissues, and homogenized ticks or mosquitoes. The last are particularly useful for environmental surveillance of arboviruses.

Testing Algorithms and Interpretation

Sound testing algorithms for NAATs are necessary to ensure that results have a high degree of confidence. The most desirable testing algorithm is one in which the amplification assays are complemented by another virus detection assay, such as an alternate NAAT, virus isolation, antigen capture ELISA, or direct IF assay. At a minimum, NAAT-positive results should be confirmed by retesting using the same technology with an additional primer set. NAAT assays must also incorporate the appropriate controls to ensure against false-positive or false-negative results. At a minimum, clinical samples should be tested in duplicate. Positive controls included in each assay should contain various levels of target RNA (high, medium, low, etc.) to evaluate the sensitivity of each test in comparison with previous tests. An internal positive control also can be very useful when specimens that may contain inhibitors of RT-PCR (i.e., blood, mosquito lysates, etc.) are tested. In all amplification-based technologies, it is essential that proper laboratory procedures be followed that prevent cross-contamination of nascent samples with amplified DNA (amplicon) from previous tests, resulting in the generation of false-positive results. In general, there should be complete physical separation of pre- and post-amplification laboratory space and equipment. Of particular importance is the use of several no-template (negative) controls spaced randomly throughout the assay to monitor for amplicon contamination.

RT-PCR

Standard RT-PCR-based assays (compared to the real-time assays described below) to detect arbovirus genomic sequences have been developed for a number of agents (32). These assays use either virus-specific primers or consensus primers that are designed to amplify genetically related viruses. These "first-generation" assays typically involve RT-PCR amplification followed by agarose gel electrophoresis with DNA visualization by staining with ethidium bromide to characterize the amplified DNA by molecular weight. Obtaining a DNA fragment of the predicted size is considered by some to be diagnostic. However, note that in some instances nonspecific amplification can generate DNA products with mobility on agarose gels similar or identical to that of the predicted fragment, which would lead to a false-positive interpretation of results. Greater specificity can be achieved by using sequence-specific approaches for detecting and confirming the identity of the amplified DNA, including hybridization with virus-specific probes (e.g., Southern blot, dot blot, or microtiter plate hybridization), PCR amplification with additional primers internal to the original primers (nested or seminested PCR), restriction endonuclease digestion of the DNA product, or nucleic acid sequence analysis. When consensus primers are utilized, a sequence-specific detection method such as one of those described above must be employed to specifically identify the resulting DNA, since by the design of the assay all related viruses would all be amplified. Consensus RT-PCR assays have been described for alphaviruses, flaviviruses, and the California and Bunyamwera serogroup bunyaviruses (33–36). Virus-specific assays include assays for the DEN viruses; the YF, JE, WEE, EEE, SLE, MVE, Powassan, TBE, and WN viruses; the California serogroup viruses; and the RR and Ockelbo and CTF viruses.

Real-Time 5′-Exonuclease Fluorogenic Assays

Real time RT-PCR assays combine RT-PCR amplification with fluorescently labeled virus-specific probes able to detect amplified DNA during the amplification reaction. These assays offer numerous advantages over standard RT-PCR, namely, increased sensitivity and specificity, quantitation of initial target RNA, high throughput, and rapid turnaround of results. The increased specificity of the TaqMan assay compared to that of standard RT-PCR is due to the use of the virus-specific internal probe during the amplification. The hybridization of this probe to the target sequence is detectable by the increase in fluorescence in real time. This sequence-specific detection obviates the need for any post-amplification characterization of the amplified DNA. As a result, amplified DNA is not manipulated in the laboratory as occurs with standard RT-PCR, thus greatly reducing the likelihood of amplicon contamination. Real-time fluorogenic assays also offer the advantage of the ability to detect multiple targets at the same time in the same amplification reaction (multiplexing). This can be accomplished by using multiple oligonucleotide probes (up to four in some instruments), each labeled with fluorescent reporter dyes with discrete emission spectra. Several TaqMan assays for the detection of arboviruses have been described, including assays for WN, SLE, CHIK, TBE, DEN, EEE, WEE, and LAC viruses (37–40).

NASBA

Another amplification technology which has successfully been used for the detection and identification of arboviruses is NASBA. This approach shows some similarities to RT-PCR at the initial stages. However, there are several significant differences; namely, the reaction is isothermic (41°C); the enzymes utilized are RT, RNase H, and T7 RNA polymerase; and the final amplification product is single-stranded RNA. Amplified RNA can be detected in a sequence-specific manner either by utilizing an electrochemiluminescence probe detection format or by using a fluorescently labeled molecular beacon probe in real time. These approaches have been successfully employed for the detection of a number of arboviruses, including WN, SLE, EEE, WEE, LAC, and DEN viruses (37, 41, 42).

RT-LAMP

A number of reports describing the detection of arboviruses by reverse-transcriptase loop mediated amplification have recently been described in the literature (43). The amplification is based upon strand-displacement DNA polymerization utilizing six target-specific oligonucleotide primers. After reverse transcription, isothermal DNA amplification proceeds using a DNA polymerase with high displacement activity (Bst DNA polymerase). The LAMP strategy generates double-stranded DNA stem-loop molecules of varying stem lengths based upon primer design, specifically the incorporation of complimentary target sequences into the 5′ region of some of the primers. The final DNA products can

be visualized as a DNA "ladder" on an agarose gel. Alternatively, amplification can be detected in real time by measuring the turbidity (using a photometer/turbidimeter) of the reaction mixture, which increases with the amount of DNA synthesized due to the accumulation of magnesium pyrophosphate. The specificity in LAMP is due to the binding of the six oligonucleotide primers; therefore, specific identification of the amplified DNA is not considered necessary, and the final detection can be accomplished by turbidity. LAMP reagent kits and detection equipment are available commercially, and the overall reaction costs are similar to those for real-time PCR reactions. LAMP assays have been described for the detection of WNV, RVFV, CHIK, JE, YF, CCHF, TBE, and DEN (44–50).

SELECTION AND SEQUENCE OF TESTS

The laboratory diagnosis of an arbovirus infection presents a unique set of problems because of the large number of arbovirus agents that must be considered in a differential diagnosis. The approach is simplified by first considering the viruses according to the clinical illness they produce, e.g., viruses that produce principally CNS infection, hemorrhagic fever, polyarthritis, or nonspecific febrile illnesses with or without a rash (Table 1). The geographic distribution of certain arboviruses may be restricted to certain countries or regions, and the choice of antigens to be included in a diagnostic battery can be reduced further by including only those that are relevant to the patient's history of travel and exposure. If the patient gives a history of exposure to a specific vector, the choice of antigens can be narrowed further; e.g., if the patient reports an attached tick or tick exposure, antigens of tick-borne viruses should be emphasized.

When brain or liver specimens are available from patients with encephalitis or hemorrhagic fever, respectively, the tissues should be submitted for viral isolation and detection of viral genome or antigens. The tissue should be divided, and portions should be fixed in buffered formalin for histochemical staining and frozen in liquid N_2 on dry ice or in a mechanical freezer at −70°C for viral isolation or molecular detection. If sufficient quantities are available, tissues in 10% (wt/vol) suspensions should be used to inoculate cell cultures and to intracerebrally inoculate suckling mice for viral isolation. While areas of the cerebral cortex have served as good sources of virus and antigen for many arboviruses, recent experience with WN virus suggested that more virus and antigen can be obtained from the brain stem and spinal cord. This observation is supported by the flaccid paralysis demonstrated by WN virus-infected patients.

Although a probable diagnosis sometimes can be made serologically from a single serum specimen, paired sera should always be used when possible. In patients with a CNS infection, an accompanying CSF sample should be requested routinely. The MAC-ELISA is more sensitive when CSF samples are tested, and IgM can often be demonstrated in CSF slightly earlier than in acute-phase serum. MAC-ELISA is now the serologic test of first choice in the laboratory diagnosis of arbovirus infections because of its sensitivity and the possibility that a presumptive diagnosis can be made in an early stage of infection.

The conventional sequence of serologic testing, which is still a valid and sensitive approach, is to test paired sera to quantify a change in antibody titer. Often, an elevated titer in an acute-phase serum sample is sufficient information upon which to make a presumptive diagnosis. If heterologous reactions are present, the sera are tested subsequently by neutralization to better elucidate the cause of infection.

INTERPRETATION OF RESULTS

Serologic test results should be interpreted in the context of the clinical and epidemiologic features of the case. Heterologous antibodies from previous infections or from immunizations (namely, to YF) may interfere with the correct interpretation of a result, especially if serum specimens are tested by a single screening assay. For example, anti-SLE virus antibody may be present in people who previously were infected with DEN virus during travel or residence in tropical countries of South or Central America or Asia. Unless changes in antibody titer or specific IgM antibody levels are demonstrable or more specific tests are done, it may be difficult to differentiate these reactions. Epidemiologically and clinically, 4-fold changes in serum antibody titer or the presence of virus-specific IgM in CSF confirms a recent infection.

Until the introduction of WN virus into the United States, the incidence of arbovirus infections had been low and the diseases occurred in certain geographic locations or episodically. Seroprevalence remains low, except in areas where WN virus outbreaks have been documented or where LAC virus is transmitted in an endemic pattern. Therefore, the discovery of specific arbovirus antibodies in a single serum specimen of an ill patient is likely to be associated with a recent infection. The recent introduction of WN virus into the United States has also complicated the serodiagnosis of SLE virus infections in regions where these viruses may cocirculate. Seroprevalence to EEE virus is the lowest among all the domestic arboviruses, and the positive predictive value of a single seroreactive serum sample for other arboviruses depends on the clinical and epidemiological circumstances of the case. For example, the majority of SLE virus infections are asymptomatic or result in mild symptoms of headache and fever. The probability of SLE in seroreactive patients without frank signs of CNS infection normally is low, but in an epidemic, seroreactions in patients with less distinctive symptoms, such as acute fever and headache, may have a high predictive value.

The interpretation of ELISA results is not standardized, and the significance of raw absorbance values has been determined by methods established in individual laboratories. Thorough evaluations of the operating characteristics of arbovirus ELISAs have been hampered by the large number of agents for which assays must be established and the scarcity of positive human specimens for rare infections. A frequently used standard for a positive absorbance value is 3 standard errors above the mean absorbance of a sample of known negative sera. An alternative approach is to calculate the ratio of the sample absorbances with test (positive) and control (negative) antibodies (positive-to-negative ratio). With the diagnosis of RR and JE virus infections, a binding index, in which the sample absorbance is expressed in units in relation to the absorbance of a known positive sample, has also been used.

The isolation and identification of an arbovirus or its antigen or viral genomic sequences in a clinical sample generally are specific evidence of a recent infection. With few exceptions, arboviruses cause acute self-limited infections without persistence or latency. Certain flavivirus infections, however, cause subacute or persistent CNS infection. A progressive degenerative infection of the brain stem and cervical spinal cord leading to paralysis and atrophy of the shoulder girdle and upper arm after infection with viruses of the tick-borne flavivirus complex has been described, and in a small proportion of patients with JE, clearance from the CNS is delayed for several months after the onset of acute illness. Experimental infection of monkeys with WN virus, another flavivirus, also results in persistent CNS infection.

IgM antibodies to YF virus remain detectable in a large proportion of patients for years or decades following infection or immunization, leading to the suspicion that this flavivirus persists in some individuals. Infections with certain viruses of the *Bunyaviridae* family also are followed by persistent silent infections in animals, of which the clearest examples are the lifelong infections of rodents with Hantaan, Seoul, and Prospect Hill viruses and other hantaviruses. There is no evidence, however, of persistent bunyavirus infections in humans.

CONCLUSIONS

Arbovirus infections in the wealthy countries of the world are usually rare events. As a result, funding for research on arboviruses had fallen dramatically, resulting in only small advances and improvements in the diagnosis of arboviral infections. Two events which have shifted these priorities have occurred in recent years. One is the renewed emphasis on preparedness for bioterrorist events. Three of these arboviruses (VEE, EEE, and WEE viruses) have been classified as possible biological threats. This designation has renewed interest in rapid and sensitive diagnosis of alphaviruses. The second event was the introduction of WN virus into the Western Hemisphere for the first time, reminding us of the ease with which new and emerging infections can travel great distances. As mentioned above, the introduction of a second mosquito-borne flaviviral encephalitis virus into the United States resets the diagnostic algorithms. It will be imperative for the diagnostic virologist to keep close watch for new, faster, and more sensitive diagnostic methods, which will undoubtedly result from this new level of recognition of this group of viral pathogens.

Diagnosis of Hantavirus Infections

WILLIAM MARCIEL DE SOUZA AND LUIZ TADEU MORAES FIGUEIREDO

68

Hantavirus is a genus in the family *Bunyaviridae* that includes small mammal-borne viruses. These viruses are causative of severe human diseases such as hemorrhagic fever with renal syndrome (HFRS) in Asia and Europe and cardiopulmonary syndrome (HCPS) in the Americas. Hantaviruses are 80- to 120-nm enveloped RNA viruses. Their negative-sense single-stranded genome has approximately 12,000 nucleotides and is divided into three fragments named S (small), M (medium), and L (large) (1). The S fragment encodes the nucleoprotein (N), the M segment encodes the envelope glycoproteins (Gn and Gc), and the viral RNA (vRNA)-dependent RNA polymerase (RdRp), the largest viral protein (250 to 280 kDa), is codified by the L segment. The viral RNA segments are circular, include base-paired inverted complementary sequences at the 3′ and 5′ ends, and wrap up by the N protein (1). An open reading frame encoding NSs can be found in American hantavirus and in the vole-borne Puumala and Tula viruses, all evolutionarily related (2, 3).

Hantaviruses are emergent zoonotic pathogens harbored by rodents and other small mammals (shrews, moles, and bats). Small mammals infected by hantavirus can be observed in the subtropics and tropics worldwide and transmit these pathogens to humans by inhalation of aerosols containing particles of their feces, urine, or other excreta (4, 5). The virus remains infectious in the environment for several weeks depending on humidity, temperature, and association with protective proteins (6). Risk factors for hantavirus infection include involvement in rural and forest-related activities, cohabitation with domestic and peridomestic rodents, exposure to potentially infected dust, and field military training (4). Additionally, in Argentina and Chile, human-to-human transmission of Andes hantavirus was reported (7–9). Different trends of hantavirus case numbers have been observed; whereas in China about 10,000 HFRS cases occur every year, even after implementation of a vaccination program, the number of cases in the Americas is much lower, about 500 HCPS cases per year (1, 10).

Hantaviruses produce acute febrile diseases, HFRS and HCPS. More severe than HFRS, HCPS produces 35 to 50% case fatalities. The pathogenesis of these hantavirus diseases includes capillary leakage of intravascular fluid into interstitium tissues that leads to respiratory and renal failure and shock (1). In fact, a comparative analysis of hantavirus diseases has revealed that HFRS and HCPS are mostly didactic names. Considering that most American HCPS patients also have renal failure and many HFRS European or Asiatic patients also have respiratory failure, it has been recently proposed to use the term hantavirus fever worldwide (11).

We present here laboratory diagnostic techniques used for diagnosis of hantavirus infections (summarized in Table 1).

LABORATORY DIAGNOSIS

Most hantavirus diseases (HCPS and HFRS) are rapidly progressive and often confused with other severe diseases, such as bacterial sepsis with respiratory failure, pneumocystosis, and leptospirosis. Blood biochemistry findings that may be helpful for clinical diagnosis of HCPS are low albumin levels in serum (<3.5 g/dl), thrombocytopenia (<130,000 platelets/μl), leukocytosis, and increased creatinine levels in serum (12, 13). However, specific and rapid laboratory assays should be used to confirm the clinical suspicion of a hantavirus disease. Laboratorial techniques confirm hantavirus infection based on (i) the presence of hantavirus-specific IgM or more than 2-fold rising titers of IgG in paired sera, (ii) the detection of hantavirus RNA by RT-PCR, and (iii) the detection of hantavirus antigens in tissues by immunohistochemistry. Other classical techniques such as hantavirus isolation in cell culture and neutralization assay are not routine procedures in laboratory diagnosis because they are laborious and time-consuming and can be performed only in laboratories of biosafety level 3 (BSL-3) by trained personnel (1). To develop fast, easy, reliable, and specific assays for diagnoses of hantavirus that infect humans and could be used in the laboratory routine is a major task for the next decade. We show below procedures used in each hantavirus diagnostic method.

SPECIMENS FOR DIAGNOSIS

Clinical specimens required for serological testing should be blood drawn into a silicone-coated tube containing no additive. For ideal diagnostic purposes, the sample should be collected at or immediately after hospital admission. A second specimen should be collected 2 or 3 weeks later, in the convalescent phase of the disease. Blood collected from the heart in autopsy should also be collected in tubes as mentioned above. Blood samples should be centrifuged, and the serum should be aliquoted and stored at 4°C when it is

doi:10.1128/9781555818722.ch68

TABLE 1 Laboratory methods used for hantavirus diagnosis[a]

Methods	Advantages	Disadvantages	Future perspectives
Virological			
Hantavirus isolation in cell culture	Allows studies on viral ultrastructure, replication, and genomics and infection of experimental models	Laborious and time-consuming Can only be performed by trained personnel in BSL-3 laboratories Far from being always successful	New cell cultures and techniques to enhance hantavirus isolation
Detection of hantavirus antigens (immunohistochemistry) by immunofluorescent test and enzyme immunoassay	Allows diagnosis on infected tissues of organs (lungs, heart, salivary glands, etc.)	Allows mostly diagnosis postmortem Requires laborious preparations	Improve the technique to process *in vivo* blood or organ tissues
Molecular			
Conventional RT-PCR	Fast, sensitive, and specific technique using primers selected for matching high-homology regions of the genome Allows diagnosis of hantavirus infection in the viremic phase Allows sequencing of amplicon nucleotides of the viral genome	Does not allow diagnosis of hantavirus infection after the viremic phase More expensive than serologic methods	Future improvements are likely
Real-time RT-PCR	Allows faster results than those from conventional RT-PCR Higher levels of sensitivity and specificity than conventional RT-PCR Lower risk of contamination than conventional RT-PCR Informs on the specific virus causing the infection and the viral load	More expensive than conventional RT-PCR Requires further procedure to obtain amplicon for nucleotide sequencing	Increase the specificity of the test using multiple targets
Hantavirus detection DNA microarray	Fast, sensitive, and specific Allows simultaneous detection of tens to thousands of virus genes	Still too expensive and complex for routine use	Increase in targets Reduction of costs Simplification of data analysis
Serological			
Indirect immunofluorescence assay	Allows detection of IgG and IgM antibodies to hantavirus	Low sensitivity Result of the test depends on a subjective analysis of microscopy	Increase the use of this technique with distinct and simultaneous fluorescent targets for research on viral replication and pathogenesis of hantavirus infections
Indirect IgG and IgM ELISAs and IgM capture ELISAs	Can be used in the acute viremic phase of the disease Sensitive Low cost and easy to perform Provides cross-reacting results among hantaviruses	Cross-reacting results among hantaviruses create difficulties in identifying the hantavirus species	Improvement of antigens that allow hantavirus-specific antibody detection
Neutralization test	The most specific of serological tests	Laborious, time-consuming, and expensive	New approaches to facilitate reading of results of the test
Immunoblotting	More sensitive and specific than ELISA Allows detection of antibody response to distinct viral antigens	Expensive and time-consuming	Improvement of the technique for hantavirus-specific antibody detection
Immunochromatographic test for diagnosis of hantavirus disease	Rapid test (15–30 min) detects IgM and IgG antibodies in patient sera Easy to perform Low cost	Cross-reacting results among hantaviruses create difficulties in identifying the hantavirus species	Improvement of antigens allowing increase in sensitivity and hantavirus-specific antibody detection

[a]Table adapted from Kruger et al., 2014 (5).

to be processed within 24 h or frozen at −70°C for later use. Shipped samples should be either frozen or stored with an ice pack. These samples are not considered as having "etiologic agents" for purposes of shipment even if a hantavirus has been previously diagnosed in the donor patient.

SEROLOGICAL TESTS

Immunofluorescence Assays

Immunofluorescence assays (IFA) have been widely used for hantavirus diagnosis. Advantages of IFA include low cost, simplicity, and a possibility of quantitative detection of either IgM or IgG. After the discovery of Hantaan virus, IFA was the first method used for diagnosis of HFRS in Europe and Asia (outbreaks in China or Korea) (1, 14).

The indirect type of IFA has been used to detect antibodies to hantavirus. For the assay, Vero-E6 cells in culture, which are normally susceptible to the hantavirus, are infected, collected, and fixed on glass microscope slides. Dilutions of the test serum are added to the slide, which is incubated and washed to remove the excess. In sequence, specific antibody-antigen complexes are detected by adding an anti-human IgG or IgM antibody conjugated to fluorescein isothiocyanate. This fluorescent dye is used because the human eye is more sensitive to the green portion of the spectrum; the background autofluorescence of clinical specimens is commonly red, highlighting the green fluorescence. The nonspecific background caused by the fluorescent dye can be blocked by Evans blue or dark stain. Finally, the slides are washed, dried, and examined under UV light in a fluorescence microscope. The results of immunofluorescence assays are subjective and usually require evaluation by an experienced technician. This is because the number of positive-fluorescing cells and the quality and intensity of the fluorescence must be carefully compared with those of uninfected cells. The direct-type IFA using positive sera has been used to detect infected cells and thus confirm the isolation of hantavirus or to look for the virus in human and animal tissues.

Major disadvantages of immunofluorescent assays for diagnosis of hantavirus are that (i) the preparation of hantavirus antigens for serologic testing is usually difficult because cell culture infections result in low virus yield, (ii) handling of hantavirus for concentration and purification procedures can be performed only in BSL-3 facilities, (iii) nonspecific binding of antibodies occurs, (iv) the procedure requires a darkroom and a fluorescence microscope, and (v) it may be difficult to read and interpret the test results. Currently, an approach used for IFA is a multiparametric IFA-based detection of hantavirus IgG and IgM available commercially by Euroimmun (Luebeck, Germany). This assay is performed with serum samples diluted 1:100 added into biochips containing either cells infected with Puumala virus (PUUV), Saaremaa virus (SAAV), Dobrava-Belgrade virus (DOBV), Hantaan virus (HTNV), or Seoul virus (SEOV) or uninfected cells. The cells are fixed by acetone and sterilized by gamma irradiation. These commercial assays do not depend on propagation of hantavirus in cell culture and can be used in any laboratory able to perform IFA-based diagnostics (15). Another test commercially available is a PUUV-IFA (Progen, Heidelberg, Germany), which requires only a positive reaction in sera diluted 1:32.

Neutralization Assays

Neutralization assays (NTs) are the most specific among all serologic tests, and that is why these assays are included in the four criteria of the International Committee on Taxonomy of Viruses (ICTV) to delineate new species of hantavirus. NTs can detect the ability of a serum to neutralize the infectivity and replication of the virus in cell culture. Also, NT is important to differentiate species of hantavirus in serological tests. This is necessary because in serological assays for hantavirus, cross-reaction between species is common. However, usually, high titers of neutralizing antibodies are found only against the hantavirus that is infecting the patient (16).

In the NT node focus reduction neutralization test (FRNT), a defined quantity of viable virus is mixed to test serum. Thus, heat-inactivated serum specimens (56°C for 30 minutes) are diluted 2-fold (1:10 to 1:160) in minimum essential medium (MEM), and 250 μl of each serum dilution is added to a mixture of the same volume containing a constant amount of virus (e.g., 100 PFU). Also, it is important to test negative sera as controls of the assay. Following the incubation to allow neutralizing antibodies to bind with the virus, the mixture is inoculated into Vero E6 cultured cells that are further incubated for 6 to 14 days, in order to present a visible focus of virus-induced cell death. At this moment, the cell monolayer is stained with naphthalene black, and the focus of dead cells is visualized and counted under microscope. The neutralizing antibody titer is defined as the reciprocal dilution of the serum able to reduce more than 5-fold the number of foci (microplaques) in comparison with the virus titer without serum (17, 18). Another NT is based on the cytopathic effect (CPE) produced by the hantavirus infecting Vero E6 cells. The test is performed as described above and after incubation, in order for the infected cells to present CPE (18).

The major disadvantages of NTs for routine diagnosis of hantavirus are that these in-house tests (i) are cumbersome, (ii) are expensive, (iii) are time-consuming, (iv) and require BSL-3 facilities for handling hantavirus and that (v) hantavirus infection in cell culture usually produces little or minimal CPE and development of plaques in the monolayer.

Alternatively, the FRNT for hantaviruses can be read using a chemiluminescent substrate. This assay is based on the conversion of a substrate into a luminescent product by peroxidase-antibody conjugates; the emitted light of infected cell foci can easily be recorded by autoradiography or video imaging, providing a hard copy for documentation. The main advantage of this method compared to conventional immunochemical staining is higher detection sensitivity due to the magnification effect of luminescence, which produces a boost in focal image and intensity. This technique enables reduction of the incubation period for the virus-infected cells and also reduces the amount of antibody necessary for antigen detection in foci (19). Another alternative method for NT of hantavirus is the replication reduction neutralization test (RRNT), which uses a quantitative reverse transcriptase (qRT)-PCR-based system. This assay is performed as previously described, but after an incubation of 2 weeks, virus titers are determined by qRT-PCR (20). Last, there is a recently published NT using recombinant pseudotyped lentivirus bearing the envelope glycoproteins of hantavirus (21).

Immunoblotting

Immunoblotting is basically used to detect antibodies to specific hantavirus proteins previously separated and immobilized after electrophoresis. In Western blotting, whole-virus lysates containing inactivated and disrupted viral proteins are separated by electrophoresis according to their molecular weight or relative mobility as they migrate

through a polyacrylamide gel in the presence of sodium dodecyl sulfate. The resolved protein bands are transferred to a nitrocellulose membrane that is cut into strips that are used in reaction with serum specimens. Hantavirus-specific antibodies bind to the viral proteins separated, and this produces bands in the nitrocellulose paper. The bands are directly visualized by using an enzyme-labeled anti-human antibody followed by a chromogenic substrate. The test results are determined by comparison of the nitrocellulose strip with those containing positive and negative controls (22). Western blotting produces a lower background and has a higher specificity than does IFA.

To minimize the use of infected cell culture in Western blotting, recombinant proteins of hantavirus have been used as antigens to detect IgM and IgG specific antibodies in human and small mammal sera. The sera of infected patients or animals commonly show antibodies to recombinant nucleocapsid protein of hantavirus, and that is why it is commonly used in diagnosis by Western blotting. The major disadvantages of this technique for routine diagnosis of hantavirus are that it (i) is labor-intensive, (ii) is expensive, (iii) is time-consuming, and (iv) requires BSL-3 facilities for handling of hantavirus.

Enzyme-Linked Immunosorbent Assays

Indirect enzyme-linked immunosorbent assays (ELISAs) IgM-ELISA, IgG-ELISA, and IgM capture ELISA are the most frequently used serological tests for diagnosis of hantavirus infections. ELISAs are capable of detecting hantavirus-specific IgM antibodies in human acute infections (HCPS and HFRS), since these antibodies are detectable starting on the first days of disease. The detection of IgG by ELISA is used in epidemiological surveys worldwide. ELISAs can use, as hantavirus antigens, infected cell lysates or viral proteins purified or produced by recombinant molecular techniques. The Nucleocapsid protein (N), which is the most immunogenic viral protein, is commonly used as the antigen in these tests. Recombinant N proteins have been produced in *Escherichia coli* or baculovirus (23, 24).

For the indirect ELISA, 96-well polystyrene plates are coated with hantavirus antigens and incubated at 4°C for 16 hours. These plates can be held for up to 7 days. The plate wells are washed with phosphate-buffered saline (PBS), blocked with milk or gelatin, and incubated at room temperature. The wells are washed with pure PBS or with PBS containing Tween-20. Following this, PBS-diluted serum samples to be tested are added to the wells. After another incubation, an anti-IgM or anti-IgG antibody conjugated with an enzyme, such as peroxidase, is added. The plates are incubated, the wells are washed with PBS, and a substrate, either 3,3′,5,5′-tetramethylbenzidine (TMB) or 2,2′-azinobis(3-ethylbenzthiazolinesulfonic acid) (ABTS) peroxide, is added to the wells. The optical density (OD) of the color generated in the reaction can be read visually or in the spectrophotometer. The capture-IgM ELISA is similar to the indirect IgM-ELISA, except that the wells of the plate are first coated with an anti-human IgM mu chain antibody and the plates are incubated overnight. At this point, plates may be prepared weekly and stored. The proper assay begins by adding the hantavirus antigen into the rows of wells A through D. A negative cell extract is added to rows E through H. Following this, the serum for test diluted is added. After incubation and washing, an enzyme (such as horseradish peroxidase) conjugated to an anti-human IgM is added to the wells. Finally, after incubation and washing, a substrate (ABTS) is added and the color reaction is read visually and/or spectrophotometrically. The washing steps of the plate wells are used to remove unspecific IgG and unwanted immune complexes, thus reducing background and improving the accuracy of the test. IgM capture assays are considered more sensitive and specific than those of indirect IgM-ELISA formats.

ELISAs are fast (4 to 6 hours) and sensitive, are simple to perform, allow titration of IgM or IgG, and do not require a BSL-3 laboratory, viral isolation in culture cells, or use of a darkroom or fluorescence microscope. The specificity of the assay depends on the virus antigen used. The rapid capture IgM-ELISA developed by the U.S. Army Medical Research Institute of Infectious Diseases and the Centers for Disease Control and Prevention is effective for diagnosis of HFRS and HCPS (1). In addition, other ELISAs have been developed for many species of hantavirus worldwide.

Other enzyme immunoassays (EIA) for detection of IgM or IgG to hantavirus are available commercially. The Reagena EIA (Finland) is able to detect IgM and IgG antibodies to PUUV, DOBV, and HTNV in human serum. The IgM antibodies for PUUV are captured in the microtiter plate and are detected by a horseradish peroxidase coupled to recombinant PUUV N protein. Finally, the color is developed by TMB substrate. The test requires 2.5 hours. The Hantavirus IgG Dx Select ELISA (Focus Diagnostics, Cypress, CA, USA) is supposed to detect all known European hantaviruses and is used for initial screening of sera. This assay has high specificity and sensitivity and is a suitable solution for routine testing in a reference laboratory.

Immunochromatographic Test

Highly sensitive and fast serodiagnostic tests for hantavirus include those using immunochromatography and stain revelation with protein A-labeled colloidal gold. This technique using representative antigens of different hantaviruses is an effective tool for screening the infection in humans (25).

Currently, three commercial immunochromatographic assays are used for hantavirus diagnosis. The recomLine Bunyavirus IgG/IgM test kit (Mikrogen, Neuried, Germany) evaluates serum samples diluted 1:100, incubated on test strips with six lines containing nucleocapsid proteins from HTNV and PUUV or a recombinant N terminus of the nucleocapsid antigen of PUUV, HTNV, DOBV, and SEOV and a control band for IgG or IgM. The rapid immunoblot strip assay (RIBA) (Novartis Vaccines and Diagnostics, Cambridge, MA, USA) employs combinations of recombinant N and/or G1 antigens from at least six different hantavirus serotypes, including HTNV, PUUV, SEOV, DOBV, Sin Nombre virus, and Andes virus. In Europe, there is also the POC PUUMALA test (Reagena Ltda, Finland), which uses a lateral-flow membrane-based assay technology, in which baculovirus-expressed highly purified PUUV N antigen is immobilized in a nitrocellulose membrane (23). The test result is visualized by using gold-conjugated rabbit anti-human IgM antibodies. These methods provide highly accurate results and allow the detection of infection so that treatment can be administered and death avoided. However, Western blot assays commonly have a limited use as a supplemental assay to confirm results obtained by other serologic tests.

Interpretation of Results of Serologic Tests

In patients having hantavirus fever, the appearance of IgM antibodies is detected until 3 days after the onset of symptoms. IgG antibodies to hantavirus are usually detected later than IgM. Therefore, specific IgM antibodies are used to diagnose hantavirus fever.

In order to improve control measures in serologic assays detecting IgM to hantavirus, tests of positive samples, besides the test with negative antigen control, should be performed

in duplicate, and their results should also be compared to the results observed with positive and negative controls. Positive results should be determined by subtracting of the OD value of a serum diluted 1:100 or more in the well containing the hantavirus antigen from the OD of the same serum under the same conditions, tested to the negative antigen. The result of this difference must be greater than 0.1. A good-quality test should have low fluctuation of OD values among replicates of positive and negative controls.

Besides the detection of specific IgM antibodies in serum, the conversion of IgG-negative serum obtained in the acute phase of disease into IgG-positive in serum obtained at the convalescent phase can be diagnostic of recent infection by hantavirus. Likewise, 4-fold or greater rises in IgG antibody titers in the serum obtained at the convalescent phase may support the diagnosis of recent infection. Unchanged titers of specific antibodies in paired sera indicate an old hantavirus infection or a vaccine. Negative tests in paired sera may exclude infection by hantavirus. However, the results of serologic tests for detection of hantavirus-specific antibodies must be interpreted with caution. A lack or delay in production of IgM or IgG antibodies in the serum may occur, giving false-negative results in the acute phase of hantavirus disease. IgM antibodies also may persist for extended periods after primary infection, giving false-positive results in infections by other pathogens. Significant rises in IgG antibodies do not always occur as a result of recurrent infections or exogenous reinfection. There is no "gold standard" to which any serological assay can be compared. Therefore, many caveats related to the serologic diagnosis of hantavirus infections indicate that the direct methods of detecting viral antigens or nucleic acids are more reliable.

MOLECULAR METHODS

Rapid diagnosis is essential for management of patients with severe diseases caused by hantavirus, such as HCPS, which produce respiratory failure, shock, and high case fatality rates. Thus, fast and highly sensitive diagnostic tests have been developed based on detection of the virus genome. This genome can be rapidly detected in clinical samples, such as blood, serum, or organ fragments, by reverse transcription (RT)-PCR. Hantavirus genome detection can be allowed starting on the first day of onset of symptoms. Detection of the hantavirus genome has been reported in patients before the first day of symptoms. However, the low levels of viral RNA present in human and rodent tissue samples can sometimes require the nested-RT-PCR or, alternatively, the real-time RT-PCR amplifying regions of high homology in the hantavirus genome. A large number of potential variants of RT-PCRs are available, including those involving different primer combinations. A representative procedure for these methods is described below.

Reverse Transcription-PCR

RT-PCR is a molecular method commonly used worldwide for diagnosis of hantavirus infections. This technique allows detection of the virus RNA in serum, in blood clots, in nucleated blood cells, and in lung tissues. However, RT-PCR is very prone to cross-contamination and meticulous care must be taken to avoid this contamination. For RT-PCR, it is essential to use specific primer sets for hantavirus. The small (S) genomic segment is a common place for selection of suitable primers for routine diagnostic work. However, for increasing the specificity and the sensitivity of the RT-PCR, it is recommended to perform an additional assay using primers for the M segment of the hantavirus genome (1, 26).

For the extraction of RNA from serum or plasma, there are commonly used commercial kits or TRIzol. A positive-control RNA, a negative-control RNA, and negative-control water are required for the interpretation of RT-PCR results. Hantaviruses are RNA viruses; they require a previous reaction of reverse transcription to make the cDNA, which in sequence is added into a mixture for PCR containing a heat-stable Taq-DNA polymerase, an excess of deoxynucleoside triphosphates, and forward and reverse oligonucleotide primers that flank the DNA sequence of interest. The PCR process is then performed during repeated cycles of heating and cooling of the reaction mixture, when the double-stranded target DNA (dsDNA) is heat denatured and cooled, enabling forward and reverse primers to anneal to complementary sequences on each target in the DNA strand. The primers are extended by the DNA polymerase and create double-stranded copies of the target DNA, which can act as templates for new DNA amplifications. In some cases, when the concentration of RNA of hantavirus is low or when a virus-specific detection is required, a second-turn PCR using internal primers to those of the first round (nested PCR) enables a more sensitive new amplification that could also be more specific, depending on the primers. The PCR products amplified from the hantavirus genome are visualized under UV light, in an agarose gel previously subjected to electrophoresis (26–28).

Currently, the number of commercial assays for hantavirus diagnosis is limited, and this leads to an extensive use of "in-house" protocols of RT-PCR. Subjective result interpretation, high cost, and laborious performance are limitations of the PCR technique. Additionally, in the nested PCR, manipulations of all reagents should be carried out exclusively with plugged pipette tips. Great caution must be taken to separate pre-PCR from post-PCR steps, including the use of separate pipettes and pipette tips and different bench or hood spaces.

Real-Time RT-PCR

The advent of real-time PCR represents a remarkable leap in DNA amplification technology. Therefore, numerous real-time PCR protocols have been described worldwide (29–33). Briefly, real-time PCR is achieved through the use of fluorescent detection technology. Fluorescent molecules are added to the reaction mixture and interact with the PCR product to produce an increase in fluorescent signal while DNA amplification occurs. This fluorescent signal is measured during each thermal cycle and monitored in real time.

There are two main types of fluorescent technologies used in real-time PCR. One uses DNA intercalating dyes, such as SYBR green, which bind nonspecifically into dsDNA; upon intercalation into dsDNA, SYBR green emits a fluorescent signal, which can be observed by a fluorescent reader. Thus, the SYBR green technology is a very simple and quick method for real-time monitoring of the cDNA amplification of hantavirus by PCR. The main disadvantage of SYBR green is its binding into any dsDNA, including nonspecific PCR products, such as primer dimer, and it requires an additional analysis of the melting curve for assay specificity (32–34). The other real-time PCR fluorescent technology is the TaqMan system that uses reporter fluorescent dye covalently coupled specifically into probes. The probe is degraded when it is found by Taq polymerase, and it hybridizes into a strand of the amplimer. In sequence, an endonuclease breaks the probe into shorter fragments, thus liberating the reporter fluor. The sequence detection system continuously interrogates each tube by using light

and simultaneously monitors the intensity of light in the wavelength emitted as fluor response (29–31).

Thus, real time RT-PCR provides numerous advantages over conventional RT-PCR. From a practical perspective, real-time PCR removes the need for a separate detection step, which significantly reduces test time. Also, the system is closed, reducing the potential for carryover contamination. Additionally, this technology allows the establishment of a parallel standard curve using a template molecule of known concentration and thus the determination of the quantity of the viral RNA in a sample (qRT-PCR). However, the equipment for the test is still expensive, and the real-time RT-PCR method for diagnosis of hantavirus has not been widely used in diagnostic laboratories.

Interpretation of RT-PCR Results

The RNA of hantavirus is present in samples from viremic symptomatic patients at the acute phase of infection. However, in later phases of illness, viral RNA becomes increasingly less abundant until it is undetectable, usually within 7 to 12 days after hospitalization. Using serum samples as the RNA source, nested PCR can detect viral genetic material in about 70% of acute-phase samples. Because RT-PCR assays are positive only in the acute phase of hantavirus infection, RT-PCR and qRT-PCR should be performed together with other diagnostic tests, such as IgM-ELISA. RT-PCR assays are fundamental for molecular epidemiology, including identification of emergent hantavirus genotypes in a region, and also for studies of pathogenesis.

NEW PLATFORMS FOR DIAGNOSIS

Microarray

A hantavirus-specific microarray was developed to detect amplicons from independent-sequence PCR amplifications. Nordström et al. developed a diagnostic DNA microarray specific for detection of PUUV, Prospect Hill virus, SNV, DOBV, SEOV, and HTNV. The array contains RNA fragments of S and M segments of 12 hantaviruses. The assay is performed with purified PCR products, and the amplicons from viral sequences contain nucleotides Cy3-dCTP or Cy5-dCTP (Amersham Biosciences). These amplicons are then annealed to a microarray chip, which is read by the GSI Lumonics Scanarray 4000 confocal laser scanner (GSI Lumonics, Billerica, MA). The slide produces TIFF images, which are quantified using ImaGene 4.0 (Biodiscovery, Inc., Marina del Rey, CA), identified (CloneTracker 1.3; Biodiscovery, Inc.), and analyzed (Microsoft Excel 2000; Microsoft Corp.) (35). The microarray possesses a large number of specific primers that can be used for detection of a panel of hantaviruses based on their diversity. However, this assay (i) is cumbersome, (ii) is highly expensive, (iii) requires laborious analysis, and (iv) has a high risk of contamination. Thus, the microarray is still an experimental method, which currently is not attractive and competitive for the clinical routine laboratory.

Flow Cytometry

Flow cytometry can be used for detection and titration of hantavirus. This technique was developed using an anti-N monoclonal antibody for detection of viral nucleocapsid protein (N). The flow cytometry method was used in cells infected with Andes virus. The viral titer was calculated based on the percentage of cells tagged for the nucleocapsid protein of hantavirus, and the results of flow cytometry were corroborated by viral titers obtained in the focus assay. This new assay for hantavirus is highly sensitive and a suitable tool to detect and quantify the virus in human samples. It also can be a fast quantitative method, applicable to studies on antiviral drugs (36). Although providing the advantage of circumventing the use of BSL-3 laboratories, flow cytometry requires expensive cytometers and labeled monoclonal antibodies.

Luminex

The Luminex system can be utilized for detection of many pathogens. When used for diagnosis, nucleic acid or protein probes of the pathogen are usually conjugated to distinct bead types and a mixture of these beads is used in an array for detection and differentiation, based on the products that are bead linked. Recently, it was established that a multiplexed Luminex-based immunoassay simultaneously detected the IgG antibodies produced in hemorrhagic fever, including those produced by Hantaan virus, Seoul virus, Puumala virus, Andes virus, Sin Nombre virus, Crimean-Congo hemorrhagic fever virus, Rift Valley fever virus, Severe fever with thrombocytopenia syndrome virus, bunyavirus, and dengue virus. This assay uses recombinant N proteins of each hantavirus linked into microspheres that are analyzed by lasers in the Luminex, allowing identification of the specific bead and also any IgG binding into the bead. The evaluation of this new method with clinical serum samples showed 98.04% diagnostic sensitivity for HFRS and a specificity ranging from 66.67 to 100% (37). The Luminex x MAP technology is rapid and sensitive and detects multiple pathogens. It is a high-throughput method but is still too expensive for use in clinical routine laboratories.

Rabies Virus

D. CRAIG HOOPER

69

Rabies virus (RABV) and RABV-related lyssaviruses are the causative agents of zoonotic viral encephalitis, with a case/fatality ratio approaching 1:1. These viruses are endemic in a number of terrestrial mammals and bat species throughout much of the world. Lyssaviruses (family *Rhabdovirus*, order *Mononegavirales*, of which RABV is the type species) are characteristically bullet-shaped particles averaging 75 by 180 nm with a single-stranded, negative-sense RNA genome encoding five proteins. In genome order, these proteins are nucleoprotein (N), which tightly encapsulates the genome; phosphoprotein (P), which was formerly referred to as the nonstructural (NS) protein; matrix (M) protein; glycoprotein (G), the primary target of neutralizing antibodies, which is found spread over the surface of the virus; and polymerase (L), the RNA-dependent RNA polymerase. Genetically and antigenically more diverse in glycoprotein than in nucleoprotein, the different lyssavirus variants are each associated with a particular host species. The major reservoir of RABV in Asia is the dog, historically and currently the cause of most human rabies cases; wildlife, including foxes, coyotes, skunks, raccoons, and bats, carry RABV or RABV-related viruses in diverse geographic regions. Effective vaccines and postexposure prophylaxis (PEP) regimens consisting of active and passive vaccination have been available for some time, and where animal reservoirs of the virus have been controlled by vaccination and PEP is readily available, human rabies is no longer the well-known disease of antiquity. However, in Asia, where dog rabies persists, human rabies is not uncommon, with cases estimated to occur at a rate of over 50,000 a year. Elsewhere, human rabies is sporadic, generally resulting from the bite of an infected dog while a traveler is in a region where rabies is endemic or from an interaction with an infected animal when the possibility of virus transmission is not recognized. As RABV can infect all mammals, the virus may be transmitted between a reservoir species and humans by intermediate species that are not normally associated with rabies, such as cats. However, the more common cause of unrecognized infection is through contact with an infected bat. In such cases, the bite or scratch responsible for the infection may be so minor as to go unnoticed.

HUMAN RABIES AND ITS PREVENTION

Historical evidence that the highest rabies mortality results from the bite of an infected animal on the head and face (1, 2) suggests that the lethality of RABV infection is related to the distance between the inoculation site and central nervous system (CNS). Generally, the initial signs of disease appear 2 to 6 weeks after exposure, but there have been occasional cases that developed a number of years after exposure (3, 4). Clinical rabies becomes apparent initially in nonspecific symptoms, which may include general malaise, chills, fever, headache, photophobia, anorexia, sore throat, cough, and musculoskeletal pain. In the case of a bite, there is often a prodromal period generally lasting from 2 to 10 days, with itching, burning, numbness, or paresthesia around the site. An acute neurologic phase in which patients manifest signs of neurological dysfunction, such as anxiety, agitation, paralysis, or episodes of delirium, follows. Various proportions of patients exhibit the classical pathognomonic sign of rabies, hydrophobia. Disease progression is variable but usually proceeds through coma to death from respiratory arrest by approximately 30 to 60 days after infection. The prolonged incubation period between infection and the development of the first clinical signs of rabies in humans led Louis Pasteur to speculate that the virus required time to spread from the inoculation site to the brain and that vaccination during this period might be protective (5). His proof of this principle is the foundation for PEP, which continues to be widely used where RABV exposure is suspected (6). Rabies PEP is highly effective in preventing the development of clinical rabies if administered in the first days after exposure but is ineffective once clinical signs of rabies appear, and the infection most often has a lethal outcome (7, 8). However, a number of individuals treated by the Milwaukee protocol, an experimental intervention that includes supportive care along with administration of neuroprotective and antiviral agents, have survived confirmed rabies (9, 10). Moreover, immune mechanisms capable of clearing RABV from CNS tissues have been described in animal models (11–14).

Human rabies is minimized by control of reservoirs of the virus, for example by vaccinating dogs, and by promptly providing PEP to individuals who may have been exposed. Recognition of potential exposure is the most important criterion for successful PEP, which entails the passive administration of RABV-neutralizing antibodies (VNA) and immunization with a potent vaccine. In the case of contact through broken skin or mucosal surfaces with the saliva of a suspect animal, as would occur with a bite, the decision to

doi:10.1128/9781555818722.ch69

administer PEP can be based on testing of the animal, if it is available. For a domestic animal that should have been vaccinated against rabies, confirmation of adequate VNA titers by serology is warranted. For wildlife, if the animal can be caught, the general approach is to have its neural tissues tested for RABV by immunohistochemistry or molecular techniques. Delaying the administration of PEP while tests are being conducted or the animal is observed for the development of clinical rabies is not advised. If the animal cannot be captured and the species is known to carry rabies in the area, PEP is recommended. Modern PEP is safe and effective, generally with minimal side effects, and should be commenced within the first several days of a possible exposure.

Bats present a unique problem with respect to human rabies, as the RABV and RABV-related lyssavirus reservoirs in these animals are difficult to eliminate through vaccination and the event transferring the virus between bat and human is often not recognized as the potential cause of an infection. Human deaths from bat RABV variants have been reported in North America and Europe and from the RABV-related Australian bat lyssavirus in Australia. In some cases where there was no history of possible exposure, "cryptic" rabies cases were initially classified as encephalitis of unknown origin and correctly identified as rabies only in the terminal stages of the disease or postmortem. As an infected individual presents a risk of infection to others, this can greatly expand the numbers of people who might be exposed to the virus and must receive PEP.

Because of the lack of specificity of the clinical signs of rabies, diagnosis of the disease requires immunohistochemical or molecular analysis of infected tissues. The failure to test for rabies when tissues from subjects who die of unexplained encephalitis are used for transplantation can have lethal consequences for recipients. Cornea, kidney, kidney/pancreas, liver, lung, and a segment of iliac artery are among the tissues known to have transmitted RABV to recipients (15–18). In one case, rabies was not suspected in the donor until the disease manifested in a recipient over a year later (18). RABVs originating in dogs, bats, and raccoons have all been implicated in the transmission of rabies by transplantation (15–18). Analysis of the donors' brain tissues for RABV by immunohistochemistry or molecular approaches would likely have prevented these deaths.

Due to the importance of rabies surveillance, a number of national and international agencies maintain recommendations for assessing RABV infection and immunity as well as guidelines for what to do in the case of a possible exposure. These are available on the Internet from the World Health Organization (WHO) at http://www.who.int/rabies/ and the United States Centers for Disease Control and Prevention (CDC) at http://www.cdc.gov/rabies/.

LABORATORY DIAGNOSIS

Immunohistochemistry and Immunofluorescence

Historically, the diagnosis of rabies was most often validated postmortem by histological examination of brain tissue for the intraneuronal cytoplasmic inclusions of RABV nucleocapsid particles (RNP) called Negri bodies. The presence of infectious virions may be confirmed by injecting suspect material into suckling mouse brain and looking for Negri bodies when the animal succumbs several days later. However, Negri bodies are not always present in RABV-infected brain tissue or may be confused with other viral inclusion bodies. Thus, more-specific immunohistochemical and immunofluorescence techniques have supplanted simple histology in testing of tissue specimens for evidence of RABV. The greater sensitivity of these approaches also allows RABV antigens to be detected in antemortem samples, including neural tissue biopsy specimens, skin biopsy specimens, saliva, and corneal impressions from individuals with rabies.

Since nucleoprotein antigens are more conserved among different RABV isolates than glycoprotein antigens, nucleoprotein-specific antibodies are normally used to detect RABV in histological specimens. The most widely employed methods for the general diagnosis of RABV infection utilize monoclonal anti-nucleoprotein-specific antibodies. A variety of different antibody-based tests have been developed to provide specificity and improve the sensitivity of RABV antigen detection in specimens. The method of choice for the detection of RABV infection in postmortem samples from either animals or humans is the direct fluorescent-antibody (dFA) test, which utilizes fluorescein isothiocyanate-conjugated RABV nucleoprotein-specific antibodies to detect viral antigen. The dFA test is more sensitive and specific than histochemical visualization of Negri bodies in CNS tissues, allowing a specific diagnosis to be made earlier in the infection, provided that appropriate samples are available. This methodology can detect RABV antigen in a variety of samples, including fixed and frozen material of varied quality. A positive dFA test on brain tissue sections, impressions, or smears (brain stem and cerebellum are preferred) is the minimum standard for the diagnosis of RABV infection in the United States (19, 20).

The fluorescein-conjugated N-specific monoclonal antibodies capable of detecting all known RABV variants that are used for dFA tests are commercially available. Such antibodies can also detect Australian bat lyssavirus as well (21). Preparation of samples from field specimens and clinical isolates for dFA analysis has been extensively detailed elsewhere (22), and a detailed protocol for the postmortem diagnosis of rabies in animals by the dFA test that includes sample preparation and the test procedure as well as a list of reagent suppliers can be found on the CDC website http://www.cdc.gov/rabies/.

The requirement for a fluorescence microscope for the dFA test and related technologies can be problematic in certain regions and in the field. Consequently, immunohistochemistry (IHC) techniques that can be performed with a light microscope have been developed (23). Through the use of enzyme-labeled, RABV-specific antibodies and substrate, IHC is as specific as the dFA test and may be preferable for fixed tissue specimens.

ELISA-Based Tests for Detection of RABV Antigen

The need to test tissue samples for RABV infection in the field where sophisticated technology is unavailable has led to the development of several enzyme-linked immunosorbent assay (ELISA)-based methods that enable the detection of RABV antigens by direct visual examination. The rapid rabies enzyme immunodiagnosis (RREID) assay and its many variants are essentially ELISAs in which RABV antigens are detected by a substrate reaction, the product of which, under optimal conditions, is readily visible. In RREID, plates coated with anti-N antibodies are used to trap RNP from specimen preparations, which is then detected using additional enzyme-conjugated anti-N antibodies and conventional ELISA. The sensitivity of the technique can be improved by the use of biotinylated N-specific antibodies for detection and peroxidase-streptavidin (24). Both the sensitivity and the specificity of these approaches are generally considered to be somewhat lower than those of

the dFA test with appropriately prepared samples. However, sample quality may be less critical than for the dFA test and the assay may be structured such that positive results can be visualized without microscopy (24, 25). Moreover, ELISA-based assays are more readily amenable to the quantitation of antigen content than is dFA analysis (26).

Detection of Rabies Viral RNA by RT-PCR

While dFA is the current standard for the analysis of both post- and antemortem samples from animals and humans suspected of having rabies, molecular technologies are increasingly used to confirm and assess RABV infection. Reverse transcription-PCR (RT-PCR) for RABV genomic RNA or mRNA can rapidly confirm a diagnosis from a relatively small amount of an infected sample, which has important implications for patient management, particularly with respect to transplantation and PEP of a patient's contacts. A number of different procedures for RT-PCR detection and characterization of RABV RNA using a variety of oligonucleotide primers and probes specific for conserved or strain-specific sequences have been developed (27–34). In addition, certain well-established RT-PCR-based technologies, such as real-time quantitative RT-PCR (QRT-PCR), are useful for the analysis of poor-quality specimens and archived material.

RT-PCR for RABV RNAs has been shown to sensitively detect evidence of infection in tissues from experimentally infected animals as well as in human autopsy material, including fresh, snap-frozen, formalin-fixed, and paraffin-embedded material (see, e.g., references 28, 29, 32, and 33). RNA purified from these specimens by conventional technology, or *in situ*, can be subjected to RT-PCR or nested RT-PCR if greater sensitivity and specificity is required. Through the use of the appropriate primer or primer/probe combinations, RT-PCR-based techniques can be used to screen for RABV infection as well as identify RABV strains associated with a particular reservoir species (see below). In addition, individual viral isolates can be identified by sequencing RT-PCR products (27).

For general screening for RABV infection, as is the case for antibody-based techniques, RT-PCR approaches commonly test samples for the presence of the more conserved nucleoprotein gene. For conventional RT-PCR, primers derived from the nucleoprotein gene sequence, such as a sense primer near the initial methionine codon of N and an antisense primer close to the initial methionine residue of the NS protein (Table 1), are appropriate for amplifying RABV RNA from a range of street virus isolates (22). This pair of primers will amplify a fragment of 1.4 kb. For increased sensitivity and specificity, nested PCR can be performed on this product (34). The lack of a product should not be considered confirmation that there is no infection. The quality of the RNA should be assessed by examining the expression of a cell housekeeping gene, such as those for β-actin, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), and ribosomal L13a, etc., as RNA degradation is not uncommon, particularly in field specimens. In this case, an RT-PCR reaction targeting a smaller RNA fragment may have greater success. For example, primers RabNfor and RabNbatl.l (Table 1) amplify a fragment of about 200 nucleotides of RNA from a large variety of RABV strains, including a silver-haired bat RABV (35). PCR amplification of viral mRNA can also be performed but is usually limited to research specimens, as opposed to field specimens.

QRT-PCR is well suited for the analysis of samples for RABV genome RNA or mRNA. This technology is based upon the replication of only a relatively short stretch of RNA (120 to 150 nucleotides) and therefore has utility for a wide variety of samples of varying quality, including archived paraffin tissue sections. As is the case for other

TABLE 1 Primer and probe sets for PCR for rabies N protein mRNA[a]

Test and direction of primer (name)	Primer or probe sequence	Virus strain(s)

Reverse	5′-GTGCCTACCCTAATTGCTGAA-3′	
NA (probe)	5′-FAM-CCGAACTTCAGATTCCTAGCTGGAACC-BHQ-3′	−/+++

[a]Primers and probes for QRT-PCR were designed from the N mRNA sequences of a CVS (NCBI accession no. AF406696) and SHBRV-18 (NCBI accession no. AY705373). FAM, carboxyfluorescein; BHQ, Black Hole Quencher; NA, not applicable; nt, nucleotides. +++ indicates a strong reaction and – indicates none, such that +++/– means that CVS is detected but not SHBRV and –/+++ means that CVS is not detected but SHBRV is. QRT-PCR was performed with a Bio-Rad iCycler on samples of mouse brain infected with CVS-24, CVS-N2C, CVS-F3, and a silver-haired bat rabies virus (SHBRV) isolate obtained from a human rabies case.

technologies, the choice of primers and probes for QRT-PCR (Table 2) is of paramount importance because of the extensive variability between RABV strains. The product may be detected nonspecifically using SYBR Green or with a sequence-specific probe, with the latter offering greater specificity and sensitivity. As is the case for conventional RT-PCR, the quality of the sample and the success of RNA extraction are assessed by examining the levels of expression of a housekeeping gene. Using the level of expression of a housekeeping gene as a measure of the quantity of the sample, QRT-PCR readily provides information about the extent of infection. To accurately assess the amount of RABV in a sample (genomic RNA) or extent of replication (mRNA) and provide a positive control for the reaction, synthetic DNA templates are advantageous. Using these, the absolute number of copies of RABV genomic RNA or mRNA in a sample can be determined and normalized to the quality of tissue studied.

RABV Characterization with Monoclonal Antibodies

A wide variety of monoclonal antibodies that can be used to antigenically phenotype different RABV isolates have been produced by a wide variety of laboratories (42–47). Since RABV glycoprotein has greater antigenic variability than nucleoprotein, glycoprotein-specific monoclonal antibodies have greater utility for the identification of diverse RABV and RABV-related lyssaviruses (48). While the dFA test, IHC, and other antibody-based technologies can be used to phenotype RABV, panels of antibodies for this purpose are not readily available, and more detailed characterization of isolates is generally performed using molecular approaches.

Molecular Characterization of RABV

Since each animal and bat species carries unique RABV strains, molecular analysis can determine the origin of an infecting virus, which is important in understanding the etiology of a human infection such that appropriate risk management strategies can be implemented. Conventional and real-time quantitative RT-PCR analyses using strain-specific primers or primer/probe combinations are now extensively used for this purpose. A number of these and their specificities have been reviewed elsewhere (34). Through analysis of areas of the genome that are highly variable, such as the pseudogene found between the G and L cistrons (32), individual RABV isolates may be identified. Sequencing the RT-PCR product of primers surrounding a region of interest is useful for this purpose.

PREPARATION OF RABV

Isolation

Wild-type (street) RABVs are highly neuronotropic and have limited potential to replicate in most common cell lines. Consequently, isolates of wild-type RABVs have historically been prepared by injecting the homogenate of an infected tissue sample or infected saliva into the brains of 1- to 3-day-old suckling mice, waiting over the next few days for neurological signs to manifest, and testing the tissues for the presence of virus by the dFA test or by titration as described below. However, many RABV variants, including all wild-type virus isolates tested so far, also replicate in cultures of neuroblastoma cells, such as mouse NA Cl300 cells (NB41A3, ATCC CCL-147). The dFA test is also the

[a]HEX, hexachlorofluorescein; TAMRA, 6-carboxytetramethylrhodamine.

method of choice to confirm that cultured cells are infected. General methodologies for the isolation of RABV by mouse inoculation and in cell culture can be found elsewhere (22).

Production

For preparation of virus for VNA assays or of antigen for serology or more-detailed analysis, RABV may be produced *in vitro*. Wild-type and certain animal-passaged RABVs generally exist as quasispecies, and their culture in different cell types can cause the ratios of the different RABV variants to vary widely (49). Consequently, when stocks of wild-type RABVs must be expanded with minimal selection pressure, the method of choice is to infect suckling mice intracranially and to prepare virus from these tissues several days later.

Due to their antigenic cross-reactivity with most RABVs and related viruses and their capacity to infect and replicate in cell lines, fixed laboratory strains of RABV, such as challenge virus standard (CVS) strain 11 (CVS-11) and Evelyn-Rokitnicki-Abelseth, are normally used for these purposes. Unlike wild-type RABVs, these laboratory strains readily infect and can replicate to high titer in BHK cells (BHK-21[C-13]; ATCC CCL-10) and BSR cells, an interferon-incompetent clone of BHK cells which are widely used for virus production in laboratories. The WI-38 human diploid lung fibroblast cell line or Vero cells, an African green monkey kidney epithelial cell line, are generally used to produce virus for human vaccines using the Pitman-Moore or Pasteur RABV strains. Other cell lines, such as mouse NA cells, are more permissive for the growth of diverse RABV isolates but more fastidious and do not readily support high-titer virus production.

For small-batch production of RABVs, confluent cultures of BHK or BSR cells are infected with seed RABVs at 37°C in Dulbecco's modified Eagle's medium-bovine serum albumin and then cultured at 34°C. Since many of these viruses have limited pathogenicity for the cells, virus-containing supernatants can often be collected twice at 3- to 4-day intervals. The supernatant is concentrated, for example by tangential-flow filtration, and the virus purified by centrifugation in a sucrose gradient, followed by centrifugation at 24,000 rpm for 1 h at 5°C. The virus is then resuspended in Tris-saline buffer and stored at −80°C. Virus stability can be greatly enhanced by including low concentrations of bovine serum albumin in the buffer.

Titration of RABV: The Fluorescent-Focus Assay

RABVs in general and wild-type RABVs in particular have limited cytotoxicity *in vivo* and *in vitro* (50, 51). Due to the nonlytic nature of the virus, conventional plaque assays are not possible and titration of the virus in cell culture is routinely performed by visualizing foci of infected cells with fluorescein-conjugated rabies antigen-specific antibodies. For example, in brief, 10-fold dilutions of sample containing virus are made in medium (e.g., 10 μl to 90 μl), and 90 μl is added to 30 μl of BHK or NA cells in suspension (approximately 2.5×10^6 cells per ml). The mixtures are transferred to the wells of flat-bottom 96-well microtiter plates and incubated for 24 to 48 h at 34°C, washed once with phosphate-buffered saline, and fixed with ice-cold 80% acetone for 20 to 30 min. The acetone is then removed, the plates are dried, and the cell monolayers are stained with fluorescein-labeled anti-RABV antibodies. Nucleoprotein-specific antibodies are preferred for virus detection because wild-type RABV strains tend to express relatively low levels of glycoprotein (52), and as noted above, the antigenic structure of nucleoprotein is more conserved than that of glycoprotein. The results of the assay, with each initially infecting virion being represented by a fluorescent focus of cells into which the virus has spread, are read with a fluorescence microscope. The RABV titer is then reported in focus-forming units (FFU).

SEROLOGIC ASSESSMENT OF RABV IMMUNITY

Titration of Rabies VNA by Fluorescent-Focus Reduction Assays

RABV-neutralizing antibodies are the principal effectors of RABV immunity, and serum VNA levels are universally used to assess the level of protective immunity in individuals vaccinated either due to an occupational risk of exposure or due to contact with a suspect animal. Determination of a domestic animal's RABV immune status is also appropriate if it has been involved in an event consistent with exposure. RABVs do not lyse but bud from infected cells; therefore, a fluorescent-focus assay, measuring FFU, rather than a plaque assay, is used for quantifying virus levels and the reduction in FFU is generally used to titer serum levels of rabies VNA. While there are many variations and adaptations of this fluorescent-antibody virus neutralization (FAVN) technique in practice, the basic principle is the same. Generally, a known titer of fixed, tissue culture-adapted virus (Table 3) is incubated with dilutions of sera and then added to cultures of a susceptible cell line (e.g., BHK, BSR, or NA cells) prior to measurement of FFU, visualized using fluorescein-conjugated antibodies to RABVs and a fluorescence microscope (53). RABV N-specific antibodies are normally used due to the more highly conserved antigen structure of N. With these reagents, the capacity of sera to neutralize essentially any RABV strain can be assessed. A widely used RABV neutralization assay is the rapid fluorescent-focus inhibition test (RFFIT). A representative microculture RFFIT protocol is as follows. Test sera (inactivated at 56°C for 30 min) or antibody preparations are serially diluted (e.g., 3-fold, starting at a 1:5 dilution) in medium to give a final volume of 30 μl and added to an equal volume of RABV, prediluted to contain sufficient virus to infect 50 to 70% of 30 μl of a 2.5×10^6/ml suspension or a monolayer of BHK, BSR, or NA cells (e.g., 5 to 10 FFU per cell). Virus plus cells in media alone is used as an infection control, and reference sera are used to establish potency in international units (IU). The mixtures are incubated in the wells of a microtiter plate at 37°C for 60 min and then added to 30 μl of a 1×10^6 to 2×10^6 BHK, BSR, or NA cell suspension for overnight culture at 37°C in 96-well flat-bottom microtiter plates. Following incubation, the plates are washed once with phosphate-buffered saline and then fixed and stained as described for the fluorescent-focus assay described above. The numbers of infected cells are read using a fluorescence microscope. The virus-neutralizing antibody titer is defined as the highest antibody dilution causing a 50% reduction in infected cells. A standard antirabies serum (e.g., the WHO reference serum) with a virus-neutralizing titer of at least 2 IU per ml should be included in each test so that the assays can be standardized.

To take into account variables in the assay, such as the percent infection obtained in the control and the reference serum titer, the RFFIT results may be calculated as follows:

1. Determine the average percentage of infected cells in the control wells (C; virus plus cells without serum).
2. Determine the dilution of the reference serum that causes 50% of the number of control infected cells (C/2) in wells containing infected cells plus reference

TABLE 3 Selected laboratory (fixed) strains of rabies virus

Virus designation	Origin
CVS	Thought to be derived from the original Pasteur rabies virus isolate passaged in rabbit brain and then in mouse brain; several variants exist in different laboratories (e.g., CVS-11, passaged in cell culture, and CVS-24, passaged in mouse brain)
Evelyn-Rokitnicki-Abelseth	Derived from Street Alabama Dufferin by passage in mouse brain
Flury (low and high passage numbers in eggs)	Isolated from a human with rabies by mouse brain inoculation and then passaged in chick brain and a chicken embryo
Kelev	Isolated from a rabid dog by mouse brain inoculation and then passaged in a chicken embryo
Louis Pasteur	Isolated from a rabid cow infected by a dog bite; passaged in rabbit brain and then cultured in primary hamster kidney cells
Pitman-Moore	Thought to be derived from a rabbit brain-passaged isolate from the original Pasteur virus, adapted to cell culture
Street Alabama Dufferin	Isolated from a rabid dog by mouse brain inoculation and then passaged in a chicken embryo and cultured in cells

serum dilutions. Determine the percentage of infection in wells containing the next-higher dilution of serum (A) as well as the percentage of infection in wells containing the next-higher concentration of serum (B). The 50% dilution point of the reference serum is calculated as follows: the dilution of serum giving $A - \{[(C/2 - B)/(A - B)] \times$ (the dilution of serum giving B – the dilution of serum giving A)$\}$. This number represents the dilution of reference serum that contains 2 IU (S).

3. Calculate the 50% dilution point in the test serum using the same formula and substituting the test values of A and B and their respective dilutions (the result of this calculation is T).
4. The titer of the test serum can now be expressed in international units by the following relationship: the titer of test serum (IU) $= 2 \times S \times (1/T)$.

The FAVN test, based on the fluorescence principle used in the RFFIT but with an endpoint titer determined by the absence of fluorescence, has also been described (54). No significant differences in specificity or sensitivity between the RFFIT and FAVN test were detected in comprehensive comparisons (55, 56), and the assessment of fluorescence in both assays has been automated (55), which is highly advantageous in the screening of large numbers of serum samples.

For humans vaccinated against rabies, WHO guidelines recommend that effectiveness of immunization, as well as the persistence of immunity, be assessed by virus neutralization at 6-month intervals and that a booster vaccination be administered if the neutralizing titer drops below 0.5 IU/ml (20; (http://www.who.int/rabies/vaccines/other_rabies_biolog_product/en/).

Analysis of RABV-Specific Antibody by ELISA

ELISA can be used for the general assessment of RABV-specific antibody titers. While the majority of antibodies are generally specific for the virus glycoprotein, substantial amounts of antibodies to the nucleoprotein and other components may be present. The majority of antibodies specific for RABV nucleoprotein and other viral proteins fail to neutralize the virus yet are readily detectable by ELISA. Thus, ELISA with virus as the capture reagent should not be taken as a surrogate for neutralization assays. On the other hand, glycoprotein-specific antibody titers determined by ELISA with glycoprotein-coated plates generally parallel virus-neutralizing antibody titers. Since RABV nucleoprotein is highly antigenically conserved and a significant segment of the humoral response to RABV is directed against the nucleoprotein, detection of these antibodies by ELISA may have particular utility where the virus that elicited the antibody is unknown or antigenically distinct from those available in the laboratory. A situation in which ELISA for RABV-specific antibodies may also be more advantageous than a neutralization test is for the screening of serum and CSF from individuals with encephalitis of unknown origin. Late in the disease process, individuals infected with RABVs often produce some RABV-specific antibodies. ELISA can sensitively detect these antibodies regardless of whether they are neutralizing, with increasing titers of RABV-specific antibodies in consecutive serum samples or the appearance of such antibodies in CSF being indicative of an active infection. ELISA is more suited than neutralization tests for automated screening. Moreover, ELISA can be used to profile the RABV-specific antibody isotypes produced, which provides valuable insight into the nature of the immune response responsible for their generation. For example, conventional killed RABV vaccines predominantly elicit Th2 antibodies (IgG2 and IgG4 in humans, IgG1 in mice), while infection elicits Th1 antibodies (IgG1 and IgG3 in humans, IgG2a in mice).

ELISA for RABV-specific antibody is straightforward. ELISA plates can readily be coated with purified inactivated (β-propiolactone or UV) virus, isolated virus RNP (for nucleoprotein-specific antibodies), or isolated or recombinant-expressed glycoprotein and nucleoprotein. Plates can also be sensitized with rabies antigen-specific antibodies to trap antigens from crude preparations containing the virus (e.g., infected suckling mouse brain) as long as cross-reactivity between the different trapping, primary, and secondary antibodies is avoided. After incubation with serum, bound antibodies can be detected and their isotypes characterized by conventional methods using secondary peroxidase- or alkaline phosphatase-conjugated antibodies. Commercial ELISA kits for the detection of RABV-specific antibodies are available.

QUALITY CONTROL AND INTERPRETATION

Natural RABV infection can be difficult to diagnose, the gold standard being the immunofluorescent detection of viral nucleoprotein in patient samples, such as neural tissue biopsy specimens, skin biopsy specimens, saliva, and corneal impressions. Detection of viral mRNA in these specimens is also useful for diagnosis and can provide additional information about the origin of the virus strain. Infection with wild-type RABVs, which spread with minimal glycoprotein production, may progress through the nervous system without producing substantial immunostimulatory antigen, depending upon the initial site of virus entry and the amount of viral antigen present in the initial inoculum. Thus, serum antibodies, which begin to appear 6 to 8 days after optimal immunization and generally peak at about 3 to 4 weeks, may not be detected until near the end stage of rabies in humans if at all. Rabies serology is therefore more useful in confirming that immunization has been successful than in diagnosis. The assessment of RABV-specific neutralizing antibody titers by fluorescent-focus inhibition tests like the RFFIT requires technical expertise. With variability in the quality of the cell culture and the percentages of cells infected by the assay virus in the absence of antibody and with changes in the appearance of the fluorescent signal when different assay viruses are used, individual assays give results which can be difficult to interpret and must be equilibrated using antibody standards. Observation of the correct staining pattern is important for both the dFA test and RFFIT. As nucleoprotein-specific antibodies are generally used, the staining pattern should be punctate intracellular, reflecting the detection of the RNP aggregates of Negri bodies, as opposed to a surface stain. NA cells infected with CVS-11, the positive control in an RFFIT, are shown in Fig. 1. ELISA-based technologies are relatively straightforward technically but cannot discriminate between neutralizing and non-neutralizing antibodies. Thus, while it is generally accepted that the level of glycoprotein-specific antibodies parallels the neutralization capacity of sera, ELISA cannot directly be used to assess protective immunity. However, quantitation by ELISA of RABV N produced by cells cultured with RABV in the presence and absence of antiserum can be used to provide an estimate of antibody neutralizing activity. Nevertheless, these and similar assays in which virus replication is assessed by RT-PCR have not been generally accepted. For both antibody and molecular analysis of RABV infection and immunity, antigenic and sequence disparities between different RABVs must always be taken into account. False negatives can occur where the antigenic cross-reactivity or sequence homology between assays and field viruses differ substantially. The use of nucleoprotein-specific antibodies and targeting highly conserved sequences for molecular analysis should always be the starting points for dealing with an unknown infection. Should RABV be identified as a possibility, strategies and reagents to more completely characterize the origin of the virus are readily available.

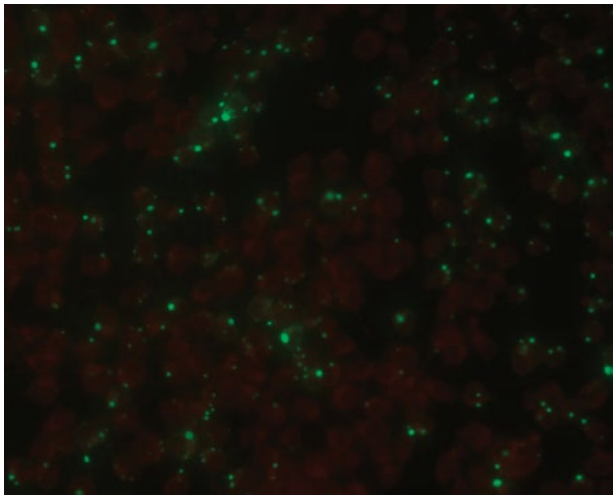

FIGURE 1 Mouse NA cells infected with CVS-11. Cells were infected and stained as described for an RFFIT in the text.

CONSIDERATIONS FOR WORKING WITH RABV

The U.S. Department of Health and Human Services, Public Health Service, CDC, and National Institutes of Health recommend biosafety level 2 practices and facilities for all activities with materials infected or potentially infected with RABV. Immunization is recommended for individuals whose occupations or other activities may predispose them to exposure to RABV. It is noteworthy in this regard that antigenic cross-reactivity between RABV G and human immunodeficiency virus type 1 (HIV-1) gp120 has been described, and sera from rabies-immune individuals have occasionally cross-reacted with HIV-1 gp120 in ELISAs (57).

Human T-Cell Lymphotropic Virus Types 1 and 2

BREANNA CARUSO, RAYA MASSOUD, AND STEVEN JACOBSON

70

INTRODUCTION

Discovery and General Characteristics

Human T-cell lymphotropic virus type 1 (HTLV-1) was the first pathogenic human retrovirus to be discovered. It was isolated in 1979 from the peripheral blood lymphocytes of a patient with adult T-cell leukemia/lymphoma (ATLL) (1). Following years of research to find a retroviral agent involved in ATLL, Yoshida and Yamamato isolated a retrovirus from an ATLL patient in 1986 that they named adult T-cell leukemia virus. Soon, the similarities between HTLV-1 and adult T-cell leukemia virus were confirmed, and the name HTLV-1 was chosen. Shortly thereafter, the closely related virus HTLV-2 was isolated from the splenic cells of an individual with hairy cell T-cell leukemia (2).

HTLV-1 and -2 belong to the *Deltaretrovirus* genus of the *Retroviridae* family and share approximately 70% nucleotide sequence homology. This genus also includes HTLV-3 and -4, simian T-cell lymphotropic virus types 1, 2, and 3, and bovine leukemia virus, all of which are characterized by an extra genomic region, pX, between the envelope gene (*env*) and the 3′ long terminal repeat (3′ LTR). pX encodes regulatory and accessory proteins that are implicated in pathogenesis. Both viruses also produce negative-strand transcripts: HBZ for HTLV-1 and APH-2 for HTLV-2.

Free virions of HTLV-1 and -2 are poorly infectious. Their transmission requires the transfer of live infected cells followed by the formation of specialized cell-to-cell contacts called virological synapses, which favor the infection of new cells (3). Despite a wide range of target cells *in vitro*, *in vivo* HTLV-1 primarily infects $CD4^+$ T cells, and HTLV-2 primarily infects $CD8^+$ T cells (4). Additionally, there is evidence that dendritic cells, B cells, and monocytes can be infected in individuals with HTLV-1 and -2 (5). HTLV-1 and -2 replicate mainly through clonal expansion of the infected cells; therefore, they both predominantly utilize the cellular DNA polymerase rather than the viral reverse transcriptase, which is less reliable, to duplicate their genomes. As a result, HTLV-1 and -2 are genetically stable, unlike other retroviruses.

Epidemiology and Geographic Distribution

It is estimated that 20 million people worldwide are infected with HTLV-1 (6). HTLV-1 is not ubiquitous but instead is found in clusters in areas where it is highly endemic, which include southwestern Japan (where the virus was first isolated from patients with ATLL), the Caribbean islands, equatorial Africa, and foci in South America (Colombia, French Guyana, and Brazil), the Middle East (the Mashad region in Iran), and Melanesia. In North America and Australia, the highest prevalence is among the indigenous populations. In Europe, the highest prevalence is in Romania.

Variations in the LTR region of HTLV-1 led to the discovery of four major subtypes of HTLV-1 (A, B, C, and D) based upon geographic origins. The cosmopolitan subtype A is the most widespread and is endemic in Japan, the Caribbean, Central and South America, North and West Africa, and parts of the Middle East. The other three subtypes are endemic to the areas specified by their names: Central African subtype B, Melanesian subtype C, and Central African/Pygmies subtype D. There have also been reports of other rare subtypes (E, F, and G) found only in Central Africa (7). Interestingly, these rare subtypes tend to cluster in areas where simian isolates have also been found, suggesting a possible simian-to-human transmission. Moreover, an African origin of HTLV-1 has been suggested, as Africa is the only continent where all the HTLV-1 subtypes and their simian counterparts have been found. Phylogenetic studies estimate that the virus originated in Africa about 27,000 years ago (8).

Currently, the prevalence of HTLV-2 infection remains unknown. HTLV-2 is endemic among Amerindian populations and intravenous drug users (IDUs) in the United States, Europe, South America, and Asia. There are four known subtypes of HTLV-2 (A, B, C, and D), with specific geographic distributions. Subtypes A and B are found throughout the Americas and in Europe. In the Americas, subtype A is found mostly in IDU populations, and subtype B is found predominantly in Amerindian populations. In Europe, subtype B is more common in IDUs in Italy and Spain, but subtype A is more common in IDUs in Ireland and Sweden. Subtype C is found exclusively in the indigenous populations of the Amazon region of Brazil, and subtype D is found in the indigenous populations of Central Africa. The discoveries of HTLV-2D and simian T-cell lymphotropic virus type 2 support an African origin for HTLV-2 as well (7).

Transmission

Transmission of HTLV-1 and -2 requires the transfer of live infected T cells via one of the following three routes:

doi:10.1128/9781555818722.ch70

mother to child, intravenous exposure to infected cells, and sexual contact.

For HTLV-1, mother-to-child transmission, mainly through breastfeeding, is the major mode of infection in areas of endemicity, with an infection rate as high as 35% when breastfeeding is prolonged beyond 6 months (9). Fewer than 5% of mother-to-child transmissions occur *in utero* or at birth (10). Intravenous exposure to infected cells also transmits HTLV-1 very efficiently, with reported seroconversion rates of 40 to 60% following transfusion of HTLV-1-contaminated blood products. Another currently more prevalent mode of parenteral transmission is through sharing of contaminated needles and syringes (11). Transmission through sexual contact appears to be more efficient from male to female because of infected T cells present in semen, though transmission in the reverse direction also occurs (12). HTLV-2 is transmitted similarly to HTLV-1, but much less is known about the specific modes and efficiency of transmission of this virus.

Pathogenesis

The majority of HTLV-1-infected subjects remain lifetime asymptomatic carriers of the virus; however, rarely, HTLV-1 can lead to serious neoplastic and inflammatory conditions. The outcome of the infection is influenced by several factors, including the route of transmission, genetic background, and age.

The two major HTLV-1-related conditions are ATLL and HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP) (13). Other associations include uveitis, infective dermatitis, and polymyositis (13).

ATLL is a lymphoproliferative malignancy of T cells that was first described in Japan in 1977 (14). It occurs in up to 5% of HTLV-1-infected subjects, is more common in males, and typically occurs 20 to 30 years after infection, which explains the higher risk for subjects infected via vertical transmission (15). ATLL can be divided into four types: smoldering, chronic, lymphoma, and acute. Clinical characteristics and laboratory features include subacute or chronic leukemia with a rapidly progressive terminal course, frequent leukemic cells with indented lobulated nuclei, skin involvement, lymphadenopathy, hepatosplenomegaly, and a high frequency of hypercalcemia (16).

In 1985, Gessain and colleagues suggested an association between HTLV-1 seropositivity and a myelopathy endemic to the tropics known as tropical spastic paraparesis (TSP) (17). Independently, a group in Japan recognized HTLV-1 infection and its association with a similar disorder that they called HTLV-1-associated myelopathy (HAM) (18). An international consensus conference sponsored by the World Health Organization in 1988 determined that these two syndromes were the same. The combined name HAM/TSP was selected, and diagnostic criteria for the disease were established (19). HAM/TSP is a chronic and progressive myelopathy that primarily affects the spinal cord. Patients typically present with weakness of the lower extremities, back pain, bladder dysfunction, constipation, sexual dysfunction, and sensory disturbances, including paresthesias of the lower extremities. HAM/TSP occurs more frequently in females than in males and is associated with transmission from sexual intercourse or blood transfusion.

Unlike the case for HTLV-1, the role of HTLV-2 in disease remains poorly understood. Some studies have suggested that HTLV-2 can be associated with a disorder similar to HAM/TSP, and others have suggested a relationship with other neurological disorders (20–22). Establishing a clear association of HTLV-2 with disease has been difficult to assess because of confounding factors, such as intravenous drug use or concomitant HIV-1 infection. Therefore, the clinical significance of HTLV-2 infections is an area of ongoing study.

INDICATIONS FOR HTLV-1 AND -2 TESTING

Testing for HTLV-1 is indicated for patients with clinical conditions that can be related to HTLV-1, such as myelitis, uveitis, arthritis, or $CD4^+$ T-cell leukemia, and can inform prognostic and therapeutic choices. Testing is especially indicated for high-risk individuals, such as those from areas of endemicity or with possible exposure to HTLV-1 or -2. Importantly, HTLV-1/2 testing is offered to asymptomatic at-risk subjects, such as sexual partners of known infected people, to help formulate specific counseling advice.

In Japan, a country where HTLV-1 is endemic, there is a nationwide public health policy requiring the screening of all pregnant women during antenatal care. This is aimed at decreasing the risk of mother-to-child transmission and subsequent ATLL. Unfortunately, other areas of endemicity still lack such policies. Finally, given that HTLV-1 and -2 can be transmitted by blood transfusion and solid organ/tissue transplantation, testing for these agents has become routine in these settings.

Screening for HTLV is based on the detection of anti-HTLV antibodies, which develop 1 to 3 months after infection and persist for life. In a clinical setting, this is typically done by use of enzyme-linked immunosorbent assays (ELISAs), which are very sensitive but lack specificity for low-prevalence populations. Samples that are positive twice by ELISA are referred to as "repeat reactive." There is currently no FDA-licensed HTLV-confirmatory test, and confirmation is based on any of several available, more specific tests, including a second manufacturer's enzyme immunosorbent assay, Western blotting (WB), and a specific line immunoassay, which can differentiate between HTLV-1 and -2 by identifying specific viral proteins. PCR, a nucleic acid sequence-based amplification test, can also be used to diagnose the infection and quantify the proviral load (PVL).

LABORATORY ASSAYS FOR HTLV-1 AND -2 DETECTION

Particle Agglutination

Particle agglutination was the first commercially available assay for HTLV screening. This method traditionally tests for HTLV-1 infection, so it is most useful in areas where HTLV-2 is not endemic, such as Japan. The assay is based on the ability of antibodies to cross-link their target antigens. This cross-linking allows the formation of a lattice due to antibody interactions with multivalent antigens.

Particle agglutination utilizes a particulate form of the target antigen, such as whole bacterial cells, antigen-coated red blood cells, or an inert particle sensitized with the target antigen. The test for HTLV-1 uses gelatin particles sensitized with antigen for HTLV-1 purified from concentrated culture fluid of an HTLV-1-producing cell line. This strategy uses whole-virion antigens and enriched whole Env proteins, which yields a greater sensitivity to HTLV-1 infection (23). Sensitized gelatin particles are preferred over antigen-coated red blood cells because they do not show nonspecific agglutination (24). If the test is negative, the suspension will remain homogenous and opaque. If the test is positive, the suspension will become clear with visible aggregates. The test is graded based upon the pattern and size of agglutination, on a scale of 1+ to 4+. A score of 2+ or higher is considered positive for HTLV-1 antibody (25).

In order for visible clumping to occur, the proportion of antigen to antibody should allow sufficient lattice formation. In the case of excess antibody in the sample, cross-linking is not observed because each antigen molecule can bind to a single antibody, and thus no lattices are formed, yielding a false-negative result. On the other hand, if there is very little antibody, then there may be no visible agglutination because there are insufficient antibodies for cross-linking to occur. Therefore, it is advisable to run samples at multiple dilutions to avoid these concentration issues (25).

Enzyme-Linked Immunosorbent Assay

The first ELISA developed for the detection of HTLV-1 and -2 became available in the mid-1980s (26). ELISAs do not differentiate between HTLV-1 and -2 infections but are useful for initial screening because of their low cost and easy adaptation for large-scale use. The first assay used whole-virus lysates from HTLV-1-infected cells, relying upon cross-reactivity to detect HTLV-2 (26). As a result, there was a high rate of false-positive reactions and a poor sensitivity for detecting HTLV-2 infections (27). Second-generation ELISAs combined HTLV-1 lysates with synthetic HTLV-1 peptides and recombinant proteins. One of the biggest developments was the addition of a recombinant envelope protein, rgp21e, which increased the detection of HTLV-2 infections. Although these second-generation ELISAs performed better, they still required a confirmatory test to eliminate false-positive reactions (26, 28). The third generation of ELISAs that are now available make use of the "sandwich" format for the detection of antibody. There have been additional improvements in sensitivity and specificity through the use of both HTLV-1 and HTLV-2 lysates, artificial proteins, recombinant proteins, and synthetic peptides (27, 29, 30).

Microwells included in assay kits have been coated with HTLV antigens. The exact components differ by kit: some include purified viral lysates, recombinant proteins, and/or synthetic peptides. Each assay kit includes a second recombinant HTLV antigen that has been conjugated to horseradish peroxidase, the enzyme used as a color indicator for this assay. Samples that are negative for HTLV infection remain colorless, while positive samples contain a yellow product that is proportional to the amount of antibodies present in the specimen.

One difficulty with interpreting ELISA results has been determining the cutoff value for differentiating between negative and positive results. The third-generation ELISAs show much higher specificities than those of their predecessors, and the majority of HLTV-infected specimens show very strong signals, making these assays suitable for use for screening (27, 30). However, these assays still show some false-positive results (23). Some researchers believe that optimization of the cutoff value can eliminate many of the false-positive reactions that have been reported (23, 30). It is still necessary that repeat reactive samples be tested using a confirmatory assay to differentiate between HTLV-1 and -2 infections. More problematic than the false-positive results by ELISA are the false-negative results that have been reported. Studies have shown that anywhere from 1 to 7.5% of ELISA-negative samples are actually positive for HTLV-1 or -2 by PCR (26, 31). One possible explanation for these false-negative ELISA reactions is a mutation in the MTA1 envelope gene which causes a truncated protein that results in false-negative ELISA outcomes (32). This is a significant concern in areas where HTLV is endemic. The use of a dual-ELISA screening assay can help to eliminate false-positive results and catch false-negative ones, which is an appealing solution in areas where access to confirmatory assays is more difficult due to the higher costs associated with these tests (33, 34).

Western Blotting

In 1994 and 1995, a commercially available WB kit became available to confirm all ELISA-reactive HTLV samples (26). The current WB kit contains nitrocellulose strips that contain HTLV-1 and -2 proteins derived from native inactivated viral particles and genetically engineered proteins. The development of recombinant proteins has been important in clarifying the interpretation of WB patterns. The older WB kits contained a native form of gp46 which was not recognized by almost half of HTLV-1 infections and most HTLV-2 infections (30). In recent years, a new clone was developed that produces a more specific recombinant envelope protein, GD21 (rgp21), which permits the detection of antibodies to envelope proteins in all HTLV-1 and -2 infections. The addition of rgp46-I (MTA1), a unique recombinant HTLV-1 envelope protein, and rgp46-II (K55), a unique recombinant HTLV-2 envelope protein, has allowed for more accurate differentiation between HTLV-1 and -2 (30).

Samples are considered HTLV-1 positive when reactivity to two Env proteins (GD21 and MTA1) and two Gag proteins (p19 with or without p24) is present (Fig. 1). Samples are considered HTLV-2 positive when reactivity to two Env proteins (GD21 and K55) and two Gag proteins (p24 with or without p19) is present (Fig. 1) (26, 30). HTLV seropositivity can be confirmed if reactivity to GD21, p19, and p24 is present, but further investigation is needed to differentiate between HTLV-1 and -2 (30). All other banding patterns are indeterminate (some examples are shown in Fig. 1); however, follow-up is recommended if reactivity to GD21 is present, because this pattern may correspond to recent seroconversion (16, 35).

A major concern in interpreting WB results is the presence of indeterminate patterns. Studies have shown that a surprisingly large proportion of ELISA-positive sera display indeterminate WB profiles. This is especially true for sera from areas of endemicity in Melanesia (36), Africa (37, 38), Brazil (34), and tropical areas (39). Estimates for WB seroindeterminate status range from as high as 67% for patients from Zaire with neurologic disease (38) to 4.1% for HIV-positive patients from Brazil (40) and $<0.1\%$ for healthy blood donors from Argentina (41). However, the true incidence of indeterminate WB results may be higher than estimated, because ELISA-negative individuals could also have a seroindeterminate status (35, 38). The clinical significance of a seroindeterminate status is still unclear. Occasionally, HTLV-1 or -2 has been confirmed by PCR for those with a seroindeterminate status, indicating that at least some cases are due to early seroconversion or low antibody titers (16, 38, 42). Others have found an indeterminate status in those exposed to HTLV-infected blood products without seroconverting (35). Still others believe that it could be due to the presence of a viral variant, but studies using PCR have not supported this claim (43). This difficulty, combined with the high cost associated with running the assay, does not make WB a good first-line screening assay for large-scale use, especially in areas of endemicity; however, WB remains a useful secondary confirmation test (26, 44).

Line Immunoassay

Recently, a highly sensitive and specific line immunoassay was developed for the confirmation and differentiation of HTLV-1 and -2 infections. The assay uses a combination of recombinant antigens and synthetic peptides derived from

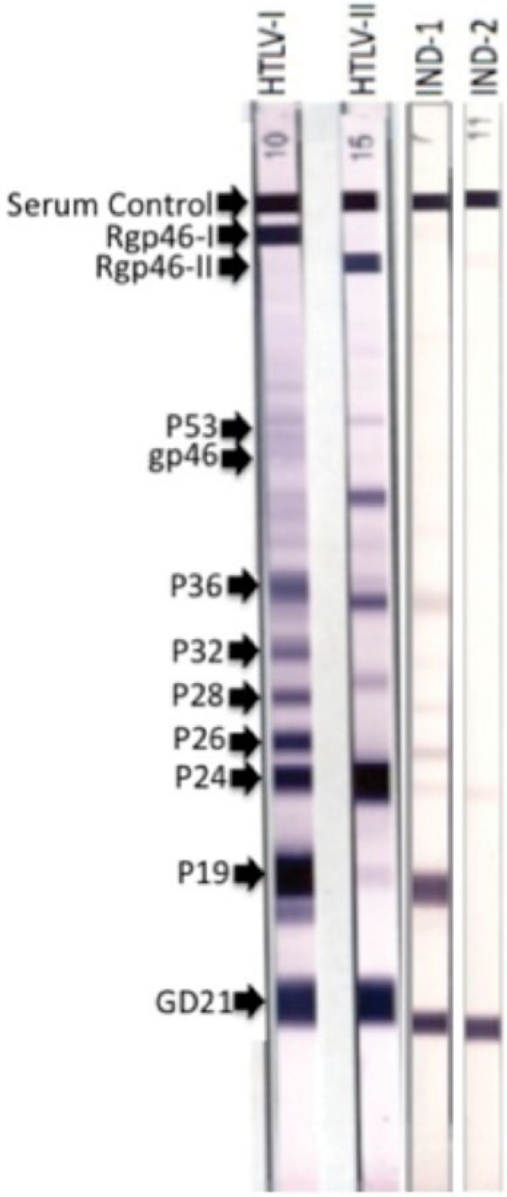

FIGURE 1 Representative examples of HTLV-1-positive and HTLV-2-positive WB patterns. WB patterns can also demonstrate indeterminate reactivity, and two examples of this are shown here (IND-1 and -2). This can complicate the interpretation of results.

HTLV-1 and -2 immunodominant protein sequences that are purified and fixed on a nylon membrane. It is designed to allow the detection of antibodies with a wide specificity to all known isolates of the HTLV strains, while also providing the ability to distinguish between HTLV-1 and -2. The manufacturers included antigens for Gag (p19 and p24) and Env (gp46 and gp21) that are common between HTLV-1 and -2, along with antigens that are type specific (Gag p19-1 and Env gp46-1 for HTLV-1 and Env gp46-2 for HTLV-2). The strips also contain four control lines: one negative-control line and three positive-control lines that include strong (3+), moderate (1+), and weak (cutoff) lines to allow for semiquantitative interpretation of results.

To evaluate the pattern on a strip, the color development of each line is compared to that on the control lines, and the intensity is scored. Results are considered positive if there is reactivity above the cutoff line with at least one envelope antigen (gp21 or gp46) and one Gag antigen (p19 or p24) or both envelope antigens. Positive results are classified as HTLV-1 if the sum of the gp46-1 and p19-1 band intensities is greater than the gp46-2 band intensity, HTLV-2 if the gp46-2 band intensity is greater than the gp46-1 band intensity or the sum of the gp46-1 and p19-1 band intensities, and nontypeable if the band intensities do not meet the criteria for HTLV-1 or -2. The results are considered indeterminate if gp21 is reactive or if any two bands are reactive without a detectable gp21 band.

Like WB, line immunoassays can have indeterminate results; however, research has suggested that line immunoassays produce a much smaller number of seroindeterminate results than the most current WB (45, 46). The line immunoassay is also more sensitive than WB for the verification of HTLV-2 infection (26). Because each strip contains three internal positive controls, comparing each band to the controls allows for more accurate differentiation between a band that is reactive and a band that is below the reactivity threshold. Researchers believe that this has helped to eliminate some false-positive and indeterminate results that are due to the subjectivity of scoring (45, 46). To help further reduce the subjectivity, companies have developed software that rates each band's intensity to create a report for each individual strip. The strips can be scanned and uploaded in batches for more efficient, high-throughput analyses. There are also options for automation available to facilitate large-scale use of this assay. Line immunoassays are cheaper than WB, making them a more economical option for use in screening donor populations. Several researchers have suggested making line immunoassays the standard confirmatory assay for HTLV-1 and -2, with WB becoming a secondary confirmation assay when needed (26, 45, 46).

Polymerase Chain Reaction

PCR is a DNA amplification technique that was developed in the 1980s for the detection and analysis of specific sequences of DNA (47). It has changed the field of viral diagnostics by allowing the sensitive detection and quantification of viral infections based on amplification of specific viral nucleic acid sequences. Several types of PCR are currently used for the detection of HTLV-1 or -2.

Nested PCR

Nested PCR increases the specificity of DNA amplification by reducing nonspecific amplification of DNA. In this technique, two sets of primers are used in two successive PCRs (48). In the first PCR, one set of primers is used to amplify the intended product but the reaction mixture may also contain nonspecific DNA products. Some of the product from the first PCR is added to a second PCR mixture that has a different set of PCR primers specific for the target sequence (49). The products are then analyzed on an agarose gel for the presence of a band at the predicted product size. Different PCR primers can be designed in order to differentiate between HTLV-1 and -2 infections (49).

Nested PCR is very sensitive because it utilizes two separate amplification reactions with two different primer sets. This makes it useful for situations where the HTLV status is in question, such as for samples that are seroindeterminate by WB. Faintly positive samples by WB are typically the most difficult to amplify by PCR because they generally have low antibody titers, which may be indicative of low viral loads. For this reason, several studies have suggested that

nested PCR be used for the analysis of seroindeterminate samples (30, 48, 49). On the downside, the sensitive nature of nested PCR makes it prone to contamination, which can complicate the interpretation of results.

Quantitative Real-Time PCR

Although several methods existed for detecting viruses, it was not until the advent of quantitative real-time PCR (qPCR) in the 1990s that scientists were able to quantify viral loads in HTLV-infected patients. Quantification of the HTLV-1 PVL has contributed to the understanding of HTLV-1 pathogenesis. In particular, it highlighted the association between an elevated PVL and the development of HTLV-1-related disease in infected subjects. Currently, a PVL of >1% is recognized as a risk factor for HAM/TSP and ATLL in infected subjects (50, 51). Additionally, the HTLV-1 PVL is an important biomarker in clinical trials for both HAM/TSP and ATLL (50, 52–54).

For qPCR, a single PCR mixture is prepared that contains primers complementary to a portion of the viral genome and a probe with a fluorescent reporter molecule attached. The most commonly examined genes for HTLV-1 detection are the *tax* and *pol* genes (Table 1). The most commonly examined genes for HTLV-2 detection are the *pol*, *tax*, and LTR genes (Table 1).

While the sample undergoes PCR, the qPCR instrument monitors and detects fluorescence to produce an amplification plot. All qPCR assays are characterized by the quantification cycle (C_q), which represents the number of cycles needed to reach a threshold fluorescence signal. To calculate the C_q, a threshold is set by a software-determined algorithm or manually by the user. However, the C_q can be affected by the efficiency of PCR amplification, the efficiency of hybridization of the fluorescent probe, and the sensitivity of detection. In order to determine the amplification efficiency, a standard curve is created by using HTLV-1- or -2-infected material. Different labs use different reference materials for their standard curves, including various infected cell lines or plasmids (Table 1) (54–56). Importantly, the use of a standard curve also allows for the quantification of HTLV-1 or -2. Typically, a lower C_q correlates with a larger amount of viral DNA and a higher C_q correlates with a smaller amount of viral DNA.

Due to the nature of detection, multiple target products can be analyzed in parallel by using different fluorophores. Therefore, it is common for a viral gene and a housekeeping gene to be examined for each sample. There are many different housekeeping genes that can be quantified, including albumin, β-actin, and β-globin. The housekeeping gene allows for normalization of the amount of virus detected in a sample to the amount of input DNA, which can then be translated into the PVL as a percentage of infected cells.

Like nested PCR, qPCR has been a useful tool for differentiating between HTLV-1 and -2 infections in seroindeterminate cases (29, 56–58). Moreover, qPCR has acceptable intra- and interassay reproducibility, making it a good method for quantifying PVL in patient samples (55, 56).

The major problem with qPCR, however, is the lack of standardization. Currently, different laboratories use different viral target genes and a variety of internal controls (Table 1). In addition, laboratories also use different reference materials for the creation of their standardized curves, which can affect the relative quantification of virus (Table 1). Taken together, these factors create known laboratory-to-laboratory variations in PVL quantification, limiting the relevance of this measure as a "gold standard" biomarker. In particular, this hinders the establishment of a threshold that differentiates asymptomatic carriers from those with disease, and it also complicates the use of PVL as a diagnostic criterion (46, 59, 60). In addition, the use of qPCR remains inconvenient for large-scale screening, impeding its implementation in blood banks as a confirmatory test (46).

TABLE 1 Viral target regions and reference materials for quantification of HTLV-1 and -2 by qPCR[a]

Virus	Target region	Viral reference material	Reference
HTLV-1	pX	MT2 cell line	51
	tax	Plasmid	63
	pol	Plasmid	54
	pX	TARL-2 cell line	64
	pol	MT2 cell line	29
	pX	TARL-2 cell line	56
	tax	MT2 cell line	55
HTLV-2	LTR	C3-44 cell line	65
	pol	Plasmid	29
	tax	Transfected cell line	66

[a]Several different viral target regions and viral reference materials are used for the quantification of HTLV-1 and -2 by qPCR. This lack of standardization makes comparison across laboratories challenging.

Droplet Digital PCR

Droplet digital PCR (ddPCR) was developed in 2011 and is considered the third generation of PCR, which allows for the direct absolute quantification of target genes. The reagents used in ddPCR are very similar to those used for qPCR; therefore, primer and probe sets specific for the detection of HTLV-1 or -2 can be designed to allow for differentiation of these viruses. Unlike qPCR, which amplifies mixtures in single wells in duplicate or triplicate, in ddPCR each PCR mixture is randomly partitioned into 20,000 nanoliter-sized droplets. PCR amplification of the template occurs in each droplet and is then analyzed for fluorescence in a flow cytometer, and the sample is designated either PCR positive or PCR negative based upon the level of fluorescence. As in qPCR, multiple genes can be analyzed simultaneously by using fluorophores that can be read on different channels of the flow cytometer. Because of the randomization of the sample partitioning and the large number of events queried, the data meet the criteria for analysis by Poisson statistics. The fraction of positive droplets is fitted to a Poisson distribution to directly determine the amount of template in the sample, most importantly without the need for a standard curve (61). The quantification of the HTLV-1 or -2 gene together with a housekeeping gene is sufficient to calculate the PVL.

Because of the statistical nature of the quantification, ddPCR has the ability to detect and quantify virus even in samples with very low viral copy numbers (61). Moreover, it is a highly precise and reproducible method of viral detection and quantification because it lacks the variability of relative quantification by qPCR (62). Because ddPCR is a novel technology, the ddPCR machinery is still expensive and the procedure is time-consuming, which limit the large-scale implementation and use of ddPCR as a confirmatory assay. However, it is a useful tool for monitoring patient PVL and for analyzing therapeutic interventions (62).

Diagnosis of Prion Diseases

RICHARD RUBENSTEIN, ROBERT B. PETERSEN,
AND THOMAS WISNIEWSKI

71

Prion diseases, or transmissible spongiform encephalopathies (TSEs), are a large group of transmissible, progressive, and invariably fatal neurodegenerative conditions that affect both animals and humans (1–5). Prion diseases are unique in that they can be inherited, occur sporadically, or can be acquired by infection (1, 3–5). As described below, the infectious agent in the prion disease is composed mainly or entirely of an abnormal conformation of a host-encoded glycoprotein called the cellular prion protein (PrP^{C}). The replication of prions involves the recruitment of the normally expressed prion protein (PrP^{C}) structure, which is largely alpha-helical, into a disease-specific conformation (PrP^{Sc}) that is rich in beta-sheets and that can adopt a fibrillar aggregated structure that is characteristic of many of the deposits found in the brains of TSE-affected species. In contrast to the protease-sensitive PrP^{C}, the beta-sheet conformation along with the aggregation properties of PrP^{Sc} makes this protein partially resistant to proteolytic digestion (6). Furthermore, this posttranslational modification of PrP^{C} into the abnormal, infection-associated isoform, PrP^{Sc}, is believed to be the principal molecular basis underlying prion diseases. Animal prion diseases include scrapie of sheep and goats, bovine spongiform encephalopathy (BSE) or mad cow disease, chronic wasting disease (CWD) of cervids (predominantly mule deer and elk), transmissible mink encephalopathy (TME), feline spongiform encephalopathy, exotic ungulate spongiform encephalopathy, and spongiform encephalopathy of nonhuman primates. Although some cases of sporadic atypical scrapie and BSE have also been reported, most animal prion diseases occur via the acquisition of infection from contaminated feed or via exposure to environmental contaminants. Scrapie and CWD are naturally sustaining epidemics. The human prion diseases can be sporadic, inherited, or acquired. Sporadic human prion diseases include Creutzfeldt-Jakob disease (sCJD), fatal insomnia, and variably protease-sensitive prionopathy (VPSPr) (3, 4). Genetic prion diseases are caused by inheritance of autosomal dominant mutations in the host *PRNP* gene, which encodes the normal cellular PrP^{C} and includes genetic CJD (gCJD), fatal familial insomnia (FFI), and Gerstmann-Sträussler-Scheinker syndrome (GSS) (3, 4). Acquired human prion diseases account for only 5% of cases of human prion disease. They include kuru, iatrogenic CJD (iCJD), and variant CJD (vCJD) (3, 4), which was transmitted to humans from affected cattle via meat consumption. The transmission of BSE to humans has resulted in more than 200 cases of vCJD and has raised serious public health concerns. All prion diseases have long incubation periods but are typically rapidly progressive once clinical symptoms begin. Currently, there are no effective treatments for prion diseases, although increased understanding of their pathogenesis has recently led to the promise of effective therapeutic interventions. Numerous therapeutic approaches are under development both for the prevention of prion disease prior to or shortly after exposure and for treatment of already symptomatic disease (2, 7–10).

ETIOLOGY OF PrP-RELATED DISEASES

Highly divergent hypotheses have been put forward regarding the makeup of the prions, including the existence of a nucleic acid-derived agent, the protein-only hypothesis, that they lack both proteins and nucleic acids, and that the prion is a polysaccharide. The most widely accepted hypothesis, first described by Griffith (11) and more explicitly detailed by Stanley Prusiner, is the protein-only hypothesis (1, 12). Prusiner introduced the term "prion" to indicate that scrapie is related to a proteinaceous infectious particle (i.e., PrP) (1, 13).

This prion hypothesis was initially greeted with great skepticism by the scientific community. Now it represents the current dogma, with Prusiner winning the 1997 Nobel Prize in Physiology and Medicine. This hypothesis suggests that prions contain no nucleic acid and are composed predominantly, if not entirely, of the conformationally modified prion protein PrP^{Sc}. PrP^{C} is found on the surface of many cells, in particular neurons. PrP^{Sc}, when introduced into normal healthy cells, causes the conversion of PrP^{C} into PrP^{Sc}, initiating a self-perpetuating vicious cycle (1, 12). PrP^{Sc} originates from an exogenous source in acquired prion diseases and, presumably, from a spontaneous somatic conformational change in sporadic disease. In recent years, it has become clear that the prion hypothesis is an epigenetic mechanism of transmitting information on protein conformation and can be applied to numerous other biological and pathological situations (14–19). If one defines a "prion" more broadly as a protein-based inheritance unit that confers a trait based on a posttranslational switch involving the acquisition of increased β-sheet structure, along with an increased propensity for aggregation, then a number

doi:10.1128/9781555818722.ch71

of yeast proteins can be viewed as prions, such as Ure2p, Sup35p, Rinq1p, and HETs (the respective prion forms are URE2, PSI+, PIN+, and Het-s) (16, 17). These yeast "prions" are not associated with disease but serve as an epigenetic mechanism for cellular responses to environmental stress (20, 21). It has also been demonstrated that long-term potentiation is regulated by a prion-like switch in *Aplysia*, involving the cytoplasmic polyadenylation element binding protein (CPEB) (18, 19). In addition, a "prion-like" spread of pathology has been invoked to explain the behavior of numerous proteins involved in a broad spectrum of neurodegenerative disorders, including amyloid β (Aβ), tau, TDP-43, FUS, α-synuclein, and huntingtin (which are associated with Alzheimer's disease [AD] [Aβ and tau] , frontotemporal dementia [tau, TDP-43, and FUS], Parkinson's disease [α-synuclein], and Huntington's disease) (12, 13). The specific targeting of the shared pathological prion-like conformation of these different neurodegenerative disease-associated proteins is currently being investigated as a novel therapeutic approach (22–25).

CELL BIOLOGY OF PRIONS

Function(s) of PrP^C

The human PrP gene (*PRNP*) is found on chromosome 20 and encodes a protein of 253 amino acids. PrP^C is a glycosylphosphatidylinositol-anchored cell surface glycoprotein with numerous suggested roles, although its exact cellular function(s) remains unknown. Expression of PrP^C is a prerequisite for prion replication and the development of pathology (26). The N-terminal region of PrP^C contains a segment of 5 repeats of an 8-amino-acid sequence (i.e., an octapeptide repeat region) that contains a high-affinity binding site for metal ions; hence, PrP^C may have a role in copper and manganese transport or metabolism (27). PrP^C has also been reported to facilitate uptake of zinc into neuronal cells at the synaptic cleft (28, 29). Metal imbalance has been reported as an early change during prion infections (30, 31). Chelation of both copper and manganese has been shown to prolong the incubation period of prion infection (32, 33). Immunological functions have also been suggested for PrP^C, such as involvement in T-cell development and macrophage phagocytosis (34). PrP^C and/or Shadoo (a PrP^C-like protein) have also been shown to be important for early mouse embryogenesis and trophoblastic development (35, 36). A surprising recently identified role for PrP^C is as a receptor for Aβ oligomers, in part mediating their toxicity (37–39). At least some of the function(s) of PrP^C is likely to be important because PrP^C is highly conserved among mammals and is found in all tetrapods and birds (5, 40, 41), although PrP^C knockout mice are viable (42).

PrP^C is found in most tissues of the body but is expressed at the highest levels in the central nervous system (CNS), especially in neurons. PrP^C is also expressed widely on cells of the immune system. PrP^C knockout mice, which were engineered to block expression of the PrP gene, show no obvious pathological phenotype (42). However, these mice have been shown to have abnormalities in synaptic physiology (43) and in circadian rhythms and sleep (44).

An amino acid polymorphism at codon 129 of *PRNP* is an important genetic risk modifier for human prion disease. Among Caucasian populations, about 51% of individuals are methionine-valine (MV) heterozygous, 38% are MM homozygous, and 11% are VV homozygous (45–47). MM homozygotes are significantly overrepresented among sCJD patients, as are, to a lesser extent, VV homozygotes. MV heterozygotes are relatively protected. For example, among 300 cases of reported sCJD cases from the United States and Europe, 71.6% were MM, 16.7% were VV, and only 11.7% were MV (46). Furthermore, all confirmed cases of vCJD have been MM homozygotes, with only one potential case of vCJD being an MV heterozygote (48).

The secondary structure of PrP^C was first elucidated by nuclear magnetic resonance (NMR) imaging using recombinant mouse PrP (49, 50). NMR was subsequently performed using recombinant hamster and human PrP as well (51–53). These studies showed that PrP^C is about 40% alpha-helix and about 3% beta-sheet. No high-resolution structural studies, such as NMR imaging, have been performed on PrP^{Sc} due to its insolubility and aggregation, which are properties that preclude the use of these techniques (54). However, less exact structural methods, such as circular dichroism and Fourier transform infrared spectroscopy, demonstrated that PrP^{Sc} contains about 45% beta-sheet and 30% alpha-helix (54–56). The high beta-sheet content correlates with PrP^{Sc} resistance to enzymatic digestion and infectivity.

Prion Strains and the Species Barrier

Many lines of evidence support the protein-only hypothesis of prion propagation. However, the protein-only hypothesis has had difficulty explaining the existence of several distinct isolates or strains of prions that can be stably passaged among inbred mice of the same genotype (1, 5, 57). The existence of strains suggests that PrP^{Sc} may adopt multiple distinct pathological conformations. Strains are defined by their incubation time, distribution of CNS involvement, and the pattern of proteolytic cleavage of PrP^{Sc} following proteinase K (PK) digestion (14, 58). For example, at least 14 significantly different scrapie strains have been isolated from natural sheep scrapie by passage into mice (57, 59). Each strain of prion has a characteristic range of infectivity. For example, strain 263K is pathogenic for hamsters but does not infect mice (60). This effect is called a species barrier and is related to PrP^{Sc} being an effective template for homologous PrP^C and a poor template for heterologous PrP^C; hence, mouse PrP^{Sc} can effectively convert mouse PrP^C but is a very poor template for human or hamster PrP^C. The species barrier is not absolute, as illustrated by the emergence of BSE.

Among the best-studied strain differences are the two strains of TME called hyper (HY) and drowsy (DY) (61, 62). The truncated DY PrP^{Sc} fragments (PrP27-30) migrate 1 to 2 kDa faster than similar preparations of HY because the sites of PK cleavage differ. The two strains also differ in the amount of beta-sheet content (61–64). Parchi et al. (47, 65, 66) defined two distinct types of sCJD based on the pattern of sodium dodecyl sulfate-polyacrylamide (SDS-PAGE) migration of the PrP27-30 fragment. Type 1 sCJD has a molecular mass of the deglycosylated PrP27-30 of about 21 kDa, while type 2 has a mobility of about 19 kDa. This allows the division of sCJD into six major phenotypic subtypes with distinctive clinicopathological features based on the genotype at the polymorphic codon 129 (M/M, M/V, or V/V genotype) in the prion protein gene, as well as the type 1 or 2 electrophoretic migration pattern. Collinge et al. (67, 68) reported two further types related to infectious CJD.

How Prion Agents Reach the CNS

Acquired prion diseases are naturally transmitted via peripheral routes, most commonly orally (69), but transcutaneous (70–73) or aerosol (74–77) transmission is also possible. Consequently, determining the route that prions employ to reach the CNS is an important issue. Aerosol transmission

has been identified to have a major role in CWD, which is the most infectious prionosis to date (74, 75, 77–79). Although the prion diseases are neurological conditions, critical events in their pathogenesis take place in restricted sites out of the nervous system, especially in peripheral lymphoid organs (80–83).

Lymphoid organs have long been known to be involved in the early stages of prion diseases (83–86). In particular, the spleen and lymph nodes were demonstrated to be the first sites of PrP^{Sc} replication after infection by peripheral routes, and they are also significantly involved following intracerebral challenge (87, 88). Their importance for neuroinvasion after peripheral inoculation was suggested by studies showing that splenectomy and other methods that reduce peripheral lymphoid structures delay clinical manifestations (85). Replication in the lymphoid organs is particularly important for specific prionoses, which are more "lymphotrophic"; these include scrapie, CWD, BSE, and vCJD (89–92). The lymphotrophic nature of vCJD allows the use of tonsil biopsy for its preclinical diagnosis and for analysis of appendices in nationwide prevalence screening studies (93–95). Following oral exposure, which is thought to be the most common route for acquired prionoses such as vCJD, BSE, and CWD, prions are able to resist exposure to digestive enzymes due to their protease resistance. Prions are able to cross the epithelial gut barrier and accumulate rapidly in Peyer's patches prior to colonization of the spleen (69). Susceptibility to prion infection following an oral challenge is correlated with the number of Peyer's patches present in the small intestine (96). At the epithelial level, three cell types can be involved in PrP^{Sc} entry in non-mutually exclusive pathways: enterocytes, dendritic cells (DCs), and microfold (M) cells (82, 83). Enterocytes express the 37-kDa/67-kDa laminin receptor (LRP/LR) on their apical brush border, which has been shown to bind PrP^{Sc} (96–98). It has also been shown that human enterocytes internalize BSE PrP^{Sc} via the LRP/LR receptor (99). M cells are unique epithelial cells that specialize in the transcytosis of particles. Coculture systems have been used to demonstrate that M cells are able to facilitate transcytosis of PrP^{Sc} (100) and that M cell depletion inhibits prion infection after oral challenge (101). DCs are known to patrol the gut-associated lymphoid tissue and are able to transcytose antigens for presentation to B and T cells. Depletion of $CD11c^+$ DCs was shown to inhibit PrP^{Sc} accumulation in the gut-associated lymphoid tissue and spleen, reducing susceptibility to prion infection after an oral challenge (102).

Once PrP^{Sc} gains entry and replicates in the secondary lymphoid organs, further spread to the CNS occurs via the autonomic nervous system (69, 103). Hence, following intraperitoneal or oral delivery of prions, onset of disease can be delayed by sympathectomy or can be accelerated by sympathetic hyperinnervation of lymphoreticular organs (104). Prions can also gain entry to the CNS via the circulation. The hematogenic spread of prions to the CNS is suggested by experiments that show BSE and CWD to be transmissible from sheep to sheep and deer to deer, respectively, by blood transfusion (105, 106). Three cases of vCJD infection associated with blood transfusion have also been identified (48). All received nonleucodepleted red blood cells and were homozygous for methionine at codon 129 of the *PRNP* gene, similar to all other vCJD cases (see discussion of vCJD below). The first patient developed vCJD in 2003, 6.5 years following transfusion from a donor who developed vCJD 3.5 years after donating blood. The second patient developed vCJD in 2006, 7.8 years after transfusion from a donor who was diagnosed with vCJD about 20 months after donation. One additional case received vCJD-contaminated red blood cells and died of causes unrelated to vCJD; however, at autopsy PrP^{Sc} was found in the spleen and cervical lymph nodes but not in the brain. Interestingly, this case was MV heterozygous at codon 129 (107). These cases raise the possibility of future human prion disease cases related to transmission through blood or blood products. Hematogenic neuroinvasion has been shown to be dependent on the presence of B lymphocytes (108). However, because expression of PrP^C by B cells is not required for neuroinvasion, some have suggested that their main function is to allow maintenance of follicular dendritic cells (109). A number of studies have implicated follicular dendritic cells as having a critical role in the replication of lymphotrophic strains of prions (85). Other studies have also implicated a distinct $CD11c^+$ dendritic cell population in prion neuroinvasion (110).

Establishing a better understanding of how PrP^{Sc} gains entry via the gut and ultimately into the CNS may lead to novel therapeutic approaches to prevent prion infection. A *Salmonella*-based vaccine applied orally to wild-type mice was observed to induce a specific anti-PrP mucosal immune response that can prevent prion infection after oral challenge in mice (111). More recently, a similar approach was shown to give partial protection to white-tailed deer immunized with a *Salmonella* vaccine strain expressing cervid PrP from oral challenge with CWD (112).

ANIMAL PRION DISEASES

The first of the animal diseases to be described was scrapie in the United Kingdom over 250 years ago (113). Referred to as scrapie based on the disheveled appearance of the affected sheep, at that time diagnosis relied solely on a physical description. Scrapie was subsequently found to affect goats as well. This illness, manifested by hyperexcitability, itching, and ataxia, leads to paralysis and death. It is called scrapie because of the tendency of affected animals to rub against the fences of their pens in order to stay upright, reflecting their cerebellar dysfunction. In the 1930s, scrapie was shown to be transmissible (114). The transmission of this disease was further demonstrated in 1943, when a population of Scottish sheep was accidentally inoculated against a common virus using a formalin extract of lymphoid tissue from an animal with scrapie. Accidental transmission of prions is a recurrent event in the history of these agents and is related to their unusual biophysical properties.

The observation that some strains of sheep were more susceptible to infection than others led to the hypothesis that scrapie may be inheritable as well (115). We now know that there are polymorphic sites in the protein underlying the disease, and genetic analysis of flocks is done to assess the risk of scrapie (http://www.aphis.usda.gov/animal_health/animal_diseases/scrapie/index2.shtml). At about the same time, TME, a disease in farmed mink, which presumably resulted from feeding scrapie-infected sheep to mink, arose (116), although recent speculation is that the source may actually have been an uncommon type of BSE (117).

The transmissible nature of the disease was used to create a bioassay in which brain homogenates from suspect animals were used to infect a test animal, of late typically transgenic mice (118). An important concept that arose from the transmission studies was, as mentioned above, that of the species barrier, i.e., the increased latency or inability to transmit disease between some species (119). One of the principal determinants of species barrier is the difference in the primary amino acid sequences of the PrP of the infected species and the PrP of the uninfected new host.

Of greater impact than any of the previously identified diseases was the identification of BSE as a prion disease (120). Primarily limited to the United Kingdom, a few cases traced to imported cattle from the United Kingdom were also identified in continental Europe. The suspected etiology was the ingestion of scrapie-contaminated feed, which may be linked to a change in rendering practices (121). Others have speculated that the origin of BSE may be linked to a mutation in an animal that initiated the epidemic. The origin of CWD in North America, while unknown, may also be linked to contaminated feed given to farmed deer and elk, which escaped to infect wild populations of cervids, although this is less certain (122). The spread of CWD throughout North America and to South Korea was facilitated by the transport of captive animals.

Unifying all of these diseases is its transmissibility, whether through vertical transmission from mother to offspring or by contaminants in the environment. Characterization of the pathogen indicated that it was resistant to those treatments that eliminate most infectious agents (UV inactivation, nucleases, heat, etc.) (123, 124), leading to the proposal that the prion agent may be composed solely of protein (13). Of note, while protease treatment reduced the titers of the agent, the partially protease-resistant PrP^{Sc} (also called PrP27-30 or PrP^{res}) could be detected in the CNS from infected animals (125) and has been subsequently used as a biomarker to identify infected animals (see below).

Diagnosis of Animal Prion Diseases

On the diagnostic front, the first neuropathological description of animal prion diseases characterized the vacuole-laden neurons found in scrapie-affected sheep (126). At that time, based on the transmissible nature of the diseases, they became known as TSEs. Another diagnostic feature was the presence of scrapie-associated fibrils (SAFs) in the detergent extract of brains from infected animals observed by negative-stain electron microscopy (127). However, it was the purification of the disease-linked PrP^{Sc} and the discovery that it was encoded by the PRNP gene that opened up a new age in prion disease diagnosis (125, 128, 129).

Purification of SAFs or PrP27-30, the PK-resistant core of the prion, permitted the development of PrP-specific antibodies (Abs) (130, 131). An early application to diagnosis that entailed performing PK treatment (a necessary step since PrP-specific Abs do not distinguish between PrP^{C} and PrP^{Sc}) prior to Western blotting was proposed (132). An alternative method using immunohistochemistry (IHC) was quickly adopted as the "gold standard" for diagnosis of TSEs (133) for its greater sensitivity. IHC staining used protease treatment or formic acid pretreatment of tissue to remove PrP^{C} before addition of Abs, while Western blotting required protease pretreatment. These tests were largely confined to academic laboratories and regulatory agencies monitoring scrapie. Table 1 lists the animal diseases and the clinical and pathological symptoms used to diagnose them as prion diseases. Final diagnosis depends on demonstrating PrP^{Sc} by Western blotting or IHC staining of fixed tissue.

The identification of vCJD in 1996 (134) and the link to BSE dramatically affected the demand for sensitive diagnostic tests for prion diseases to screen cattle. The diagnostic needs were 2-fold. First, there was a need for epidemiologic screening, and second, there was a need for a test to ensure food safety. While the nature of the infectious agent was still under debate, the utility of diagnosis based on the presence of PrP^{res} in brain was quickly accepted. Up to this point, animal bioassays using mice or hamsters were viewed as the definitive test. However, the long latency between intracerebral inoculation and infection, a minimum of 90 days in hamsters and >120 days in mice, and the cost of these studies made them impractical for screening samples from the abattoir. The

TABLE 1 Animal prion diseases

Species	Disease	Route	Clinical symptoms	Pathology	Genetics
Sheep, goats	Scrapie	Environmental contamination; vertical transmission	Ataxia, tremors, behavioral changes, pruritus	Spongiosis, astrogliosis, PrP^{Sc} deposition in CNS, tonsil, spleen, lymph nodes, nictating membrane (third eyelid), muscle, placenta, distal ileum, proximal colon	Polymorphisms at codons 136, 154, and 171 affecting susceptibility
Mink	Transmissible mink encephalopathy	Contaminated feed (MBM)[a]	Behavior, neglected grooming, ataxia, compulsive biting	Spongiosis in CNS as well as astrogliosis	
Cattle	Bovine spongiform encephalopathy	Contaminated feed (MBM)	Gait abnormalities, tremors, aggressiveness, hyperreactivity	Spongiosis, PrP^{Sc} deposition in CNS, spinal cord, retina, dorsal root and thoracic ganglia, and trigeminal ganglion	
Deer, elk, moose	Chronic wasting disease	Environmental contamination; contaminated feed (MBM)	Ataxia, tremor, teeth grinding, polyuria, polydipsia	Spongiosis in thalamus, hypothalamus, midbrain, pons, medulla oblongata, olfactory bulb, and cortex. PrP^{Sc} and infectivity found in virtually all tissues and fluids	Polymorphisms at codons 96, 132, and 225 affecting susceptibility
Domestic cats, large cats and exotic ungulates	Spongiform encephalopathy	Probably BSE-contaminated feed (MBM)	Behavioral changes, ataxia, loss of coordination, aggressiveness	Spongiosis in neuropil of brain and spinal cord. Plaques in CNS, PNS, retina, lymphoreticular system, kidney, and adrenal gland	

[a]MBM, meat and bone meal.

European Food Safety Agency (EFSA) approved 3 postmortem diagnostic screening tests for cattle from 1999 to 2001 (Table 2). These approved tests depended on the difference in protease sensitivity between PrP^{C} and PrP^{Sc} to remove the normal prion protein in the sample. Although there have been claims of PrP^{Sc}-specific monoclonal antibodies (MAbs), the difference in affinity was not sufficient for use in assays with samples that had not been treated with protease, given the great excess of PrP^{C} in the samples (135, 136).

The major time factor in testing was delivery of samples from the abattoir to the testing facility. Turnaround time was typically >24 hours and, depending on the site of the abattoir, could range to >3 days. While point-of-slaughter testing was never adopted, Prionics and Prion Developmental Laboratories developed capillary flow test devices that could have been used in that application (see below). For all of these tests, sample isolation and preparation were a significant issue. Unlike conventional infectious agents that are detected in body fluids, the highest titer, and hence greatest sensitivity, is obtained from solid CNS tissue. A key determinant of assay sensitivity in the postmortem tests was identification of the tissue region containing the highest amount of PrP^{Sc}. For BSE testing, a precisely defined section of the brain stem, the obex, was sampled, homogenized, treated with protease, and then analyzed (https://www.gov.uk/government/statistics/cattle-tse-surveillance-statistics). To facilitate higher throughput for sample processing, homogenization of tissue samples used devices such as the ribolyzer to produce homogenates from multiple samples simultaneously. The ribolyzer incorporates ceramic beads in a microcentrifuge tube and a modified centrifuge that shakes while it rotates to produce the homogenate. The Prionics Western blot used SDS gels to separate proteins before transfer to membrane for probing with MAb 6H4. One potential advantage of this system is the ability to create "glycoform" profiles; the PrP contains two nonobligatory N-linked glycosylation sites that potentially yield information about specific strains (137). Subsequently, the glycoform profile has also been used to distinguish natural scrapie from potentially BSE-infected ruminants (138). The two enzyme-linked immunosorbent assay (ELISA)-based tests prepared the sample in the same way as did Prionics except that they used a sandwich assay comprised of two Abs to detect the residual PrP^{Sc}. The Enfer test differed from the CEA/BioRad in that the second Ab used in the Enfer assay was fluorescently labeled.

In further rounds, the EFSA validated additional rapid postmortem BSE tests as well as rapid TSE tests for ovine and caprine animals (see the report entitled "Scientific Opinion on the Evaluation of new TSE rapid test submitted in the framework of the Commission Call for expression of interest 2007/S204-247339 2012" from the EFSA [http://www.efsa.europa.eu/en/efsajournal/pub/2660] and references therein). With the exception of the Prionics PrioStrip, the tests approved were largely variants on the ELISA platform. The PrioStrip is a chromatographic assay that employs a capture Ab in the well of a 96-well plate and a dipstick containing two immobilized Abs, one of which is PrP specific and the second an IgG control to demonstrate the integrity of the test strip. While not as sensitive as the ELISAs, the robust nature of this testing modality could have allowed on-site testing, although this was never done. As originally, all of these tests were dependent on protease treatment to remove the PrP^{C} from the sample.

TABLE 2 Postmortem diagnostic tests[a]

Company	Assay	Time (h)	Sensitivity (dilution)
Prionics	Western blot	6–7 (total)	~1:100
CEA/BioRad	ELISA	5	~1:1,000
Enfer	ELISA	3 (after sample preparation)	~1:100

[a]Data from http://eurlex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2001:147:0001:0040:EN:PDF.

An alternative diagnostic modality is provided by the conformational difference between PrP^{C} and PrP^{Sc}. Caughey and colleagues demonstrated that PrP^{Sc} could serve as a seed for converting PrP^{C} to a protease-resistant form (139). The observation that PrP^{Sc} could seed conversion *in vitro* led to the development of the cyclic protein-refolding assays PMCA (protein misfolding cyclic amplification) and QuIC (quaking-induced conversion), which "amplify" the conformationally altered structure in a PrP^{C} substrate. In these assays, the test sample is added to PrP^{C}, generally bacterially produced recombinant protein, to determine whether there is a prion-associated seeding activity in the sample (140, 141). The major difference between the two techniques, and the variants thereof, is that PMCA uses Western blotting of amplified, protease-treated samples for detection and in its most recent iteration RT-QuIC is a real-time assay employing thioflavin T to assess the accumulation of amyloid in the sample (142). A further refinement to the RT-QuIC assay was an immunoprecipitation step to concentrate the seed before addition use (143). In addition to concentrating the seed, this step also removes inhibitory substances from the sample that prevents conversion, which has been a particular problem with blood samples. The sensitivity of PMCA has been enhanced by the adoption of a novel detection platform, surround optical fiber immunoassay (SOFIA), which has provided detection as low as 10 attograms (144). SOFIA is based on a sandwich ELISA and also uses Rhodamine Red-X coupled to streptavidin. Specially designed hardware that enables maximum light collection and very high sensitivity of the method at the same time makes SOFIA less accessible for widespread use. However, the significance of this is that improving sensitivity at the level of the detection equipment can reduce the number of cycles required for amplification, which in turn reduces the number of false positives. PMCA-SOFIA has been used to demonstrate prion-associated seeding activity in blood (145), urine (146), and semen (147). The major limitation of this assay is that the detection equipment is still in prototype form. For the first time, however, the conformation-based assays offer the possibility of antemortem testing for prion diseases (Table 3).

While they represent a significant improvement in sensitivity relative to Western blotting of samples or ELISAs, the conformation-based tests do have some limitations. First, test results take a minimum of 1 day and range up to as long as 16 days. Second, the tests have been difficult to reproduce when moved to new laboratories. In many cases, lab personnel needed to visit the lab of the assay developers to successfully achieve results similar to those published. One reason may be the importance of the PrP^{C} preparation (B. Caughey, personal communication). Another difficulty with these tests is, like PCR in the early stages of development, the generation of false positives due to the sensitivity of the tests and the tendency for PrP^{C} to spontaneously undergo conversion to an abnormal isoform *in vitro*. The difficulty in standardizing the sonication step in PMCA (148) and the inherent tendency of PrP^{C} to undergo spontaneous fibrillization in QuIC remain as outstanding problems.

Finally, another test based on conformation that depends on epitope masking in structural variants of a protein was

TABLE 3 Conformation based tests[a]

Test name	Time/sensitivity[b]	Samples	Detection method
Protein misfolding cyclic amplification (PMCA)	1–16 days/1 attogram	Brain, blood, CSF, urine, semen	Western blotting, SOFIA
Quaking-induced conversion (QuIC)	1–3 days/1 attogram	Brain, blood, CSF, nasal fluids	Western blotting, thioflavin T detection
Conformation-dependent immunoassay (CDI)	2.5–4 h/≤1 ng/ml	Brain, plasma	Fluorescence, europium-labeled Ab

[a]Data from references 267 and 271–287.
[b]Sensitivity depends on the strain/species tested.

developed by Safar and colleagues (149). In this assay, Abs are added to samples in a native state or following denaturation. An Ab that reacts with native PrP^{C} but not PrP^{Sc} would show different amounts of reaction with native or denatured samples. The difference in signal reflects the amount of PrP^{Sc} in the sample. Sensitivity can be enhanced by the selective precipitation of PrP^{Sc} using sodium phosphotungstate (150). In addition, recent studies have demonstrated that there are protease-sensitive forms of PrP^{Sc} that are associated with prion disease (151–153).

HUMAN PRION DISEASES

A unifying feature of all the human prionoses is their neuropathology. These illnesses tend to affect the gray matter of the CNS, producing neuronal loss, gliosis, and characteristic spongiform change (1, 3, 4). The latter is a vacuolation of the neuropil and, to a variable degree, of the neurons. In addition, plaques with the typical staining properties of amyloid (e.g., apple-green birefringence after Congo Red staining when viewed under polarized light) are observed in many of these conditions. In approximately 10% of patients with sCJD, amyloid is present in the cerebellum or in the cerebral hemispheres. All cases of GSS are associated with multicentric cerebellar plaques. These amyloid plaques are immunoreactive with Abs to PrP and are not immunoreactive with Abs to other amyloidogenic proteins, such as Aβ (which is deposited in AD).

Several different forms of human prion disease exist (Table 4). As described above, human prion diseases are classified into three groups: sporadic (~85 to 90%), genetic (~10 to 15%), and acquired (~1 to 3%) (3, 4).

Kuru

The first human prionosis to be described is called kuru (154, 155). This is an illness of the Fore people living in the highlands of New Guinea that is thought to be linked to ritualistic cannibalism. Presumably, this illness originated with the consumption of an initial tribe member that died of sCJD. Kuru was once a major cause of death among Fore people; however, the disease has virtually disappeared with the end of cannibalistic rituals in the 1950s. A peak annual mortality of more than 2% was recorded in some Fore villages (155, 156). Human prion diseases have no gender preponderance, with kuru being the exception. Women had a greater tendency than men to develop kuru because it was part of the ritual cannibalism for women to prepare and eat the brains (neural tissue has the highest titer of PrP^{res}); some Fore villages became largely devoid of young women at the peak of the epidemic. Exhibiting symptoms similar to those of scrapie, patients present clinically with difficulty walking, and they develop progressive signs of cerebellar dysfunction ("kuru" means shivering in the Fore language). Death occurs approximately 1 year following the onset of symptoms. Between July 1996 and June 2004, 11 new cases of kuru were documented, suggesting that the incubation period of human prion disease can last as long as 56 years (that being the length of time following the last known cannibalism-related exposure and the onset of clinically symptomatic kuru) (157). This is an important fact to consider when evaluating the potential risks to humans for new animal prion diseases such as CWD, which have an unclear zoonotic potential (2, 78, 112).

The neuropathology of kuru, in common with all prionoses to a variable extent, includes widespread spongiform change and astrocytosis, as well as neuronal loss affecting the cerebral hemispheres and cerebellum. More intraneuronal vacuolation is observed in kuru than in sCJD (see below). In about 70% of cases, amyloid plaques are found, with amyloid deposition being a common, but not invariable, accompaniment of the prionoses. Carlton Gajdusek's detailed description of this illness led the scrapie scientist W. J. Hadlow to suggest that kuru might be the human homologue of scrapie (158). This in turn inspired Gajdusek and his team to test whether kuru was also transmissible. In 1965, they first showed that kuru was transmissible to chimpanzees, after a long incubation (159), and Gajdusek was awarded the Nobel Prize in 1976 for this work.

Similar to what is seen in sCJD, MM or VV homozygosity at codon 129 is overrepresented in kuru. Interestingly, among Fore women over 50 years of age who survived the kuru epidemics of the 1950s, there is a marked overrepresentation of the resistant MV genotype at codon 129 (160,

TABLE 4 Human prion diseases

Disease	Mechanism
Kuru	Cannibalism
sCJD	Spontaneous PrP^{C}-to-PrP^{Sc} conversion or somatic mutation
iCJD	Infection from prion-containing material (e.g., dura mater, cornea, electrode, hormones)
gCJD	Mutations in the PRNP gene
vCJD	Infection from consumption of BSE-infected meat
GSS	Mutations in the PRNP gene
FFI	D178N mutation in the PRNP gene with M129 polymorphism
Sporadic fatal insomnia (or sCJD MM2 thalamic type)	Spontaneous PrP^{C}-to-PrP^{Sc} conversion or somatic mutation
VPSPr	Spontaneous PrP^{C}-to-PrP^{Sc} conversion or somatic mutation

161). A novel *PRNP* variant, G127V, was found exclusively among people living in the region where kuru was prevalent and was present in ~50% of otherwise susceptible women from regions of highest exposure, who were homozygous for methionine at codon 129. This polymorphism was not found in patients with kuru or unexposed population groups worldwide (156). This is an example of recent human genotype evolution resulting from the selection pressures of an infectious human prion disease.

Sporadic Creutzfeldt-Jakob Disease

By far, the most common human prion disease is sCJD, accounting for about 85% of all human prion diseases. sCJD is found throughout the world, with an incidence of about 1 to 1.5 cases per million population per year (3). The peak age of onset of sCJD is ~68 years, with a wide range of 12 to 98 years (162, 163). However, sCJD patients that are <30 years old are rarely presented (164). The median duration of disease is from 4 to 6 months, with death occurring within 1 year in 90% of cases and another 5% dying in the second year of disease (165). Jakob initially described CJD in 1921 (166); ironically, the case reported by Creutzfeldt a year earlier is probably unrelated to the disease that carries his name.

An issue that has not been fully resolved is how sCJD arises. This has been suggested to be the result of either a random somatic mutation in the *PRNP* gene or more commonly a spontaneous conformational conversion of PrP^{C} to PrP^{Sc} (167, 168). Aging is recognized to contribute to protein quality control failure in the CNS, and this may be a factor in sCJD being an age-related disease. In fact, a recent therapeutic avenue for prion disease, which has shown some promise in mouse models, is ameliorating an aberrant unfolded protein response (169, 170). An argument in favor of the spontaneous-conversion hypothesis is the uniform worldwide occurrence of sCJD with no convincing geographic clustering, with the exception being areas with an increased incidence of genetic forms of CJD (i.e., gCJD). However, some case-control studies suggest that at least a portion of "sporadic" CJD can in fact be related to surgical procedures much earlier in life (hence in fact representing acquired CJD, i.e., iCJD). In a comparison of 241 patients with sCJD from the Australian CJD registry to 784 controls, there was an association with past surgical treatments that increased with the number to a maximum of three procedures producing an odds ratio of 2.13 (171). In another case-control study, using Danish and Swedish registries of 167 CJD patients compared to 3,059 controls, a similar association was found with past surgical procedures (172). The authors conclude, "We provide evidence to indicate that surgery, acting with long incubation periods, has constituted a risk factor for sCJD." A more recent risk-based classification of surgical interventions found that past procedures involving the retina and optic nerve as well as peripheral nerves were particularly associated with an increased risk of CJD (173). As mentioned above, PrP^{Sc} is known to be highly resistant to inactivation. Even ashing of the agent at 600°C does not result in complete inactivation (174). PrP^{Sc} is also known to bind to metals with a very high affinity (27, 175), hence perhaps allowing for the low-level contamination of some surgical instruments. This may be related to the reported association of "sporadic" CJD to prior surgical procedures, in particular, those related to the nervous system, many years prior to clinical presentation, discussed above. This issue requires further investigation.

Clinically, sCJD is classically characterized by a rapidly progressive dementia associated with myoclonic jerks, as well as a variable constellation of pyramidal, extrapyramidal, and cerebellar signs. However, the clinical presentation can be quite variable and is in part a feature of the six molecular subtypes that are based on the *PRNP* codon 129 polymorphism (MM, MV, or VV) and the type 1 or type 2 banding pattern of PrP^{res} on SDS-PAGE (as introduced above) (49, 68, 176–178). The most common phenotypes are the MM1 and MV1 variants, which are combined because they are very similar clinically. Together they account for ~50% of all sCJD cases (47, 176–178). The onset of symptoms is at a mean age of 65 years, and the average clinical duration is 4 months. Clinical signs typically include rapid cognitive decline at onset in almost all cases, with ataxia in about 50% of cases, as well as myoclonus and visual abnormalities. Periodic sharp wave complexes (PSWCs) are seen on electroencephalograms (EEG) in >80% of cases, usually in the first 3 months of onset of symptoms (179). Diffusion-weighted (DW) magnetic resonance imaging (MRI) shows increased signal in the basal ganglia in ~70% of cases and involvement of ≥3 cerebral cortical areas in ~50% of cases (180). The neuropathology displays the classical features of spongiform change, consisting of small vacuoles (2 to 10 μm) throughout the cortical neutrophil, with the basal ganglia and thalamus also affected. Often, the hippocampus and the brainstem are spared. The cerebellum typically shows focal spongiform change in the molecular layer. IHC with anti-PrP Ab shows a pattern of synaptic type (178). The next most frequent type is VV2, also called the ataxic variant, consisting of ~15% of cases (47, 176–178). The mean age at onset is 60 years, and the mean duration is 6.5 months. Typically, patients exhibit ataxia with dementia quickly developing in the course of the disease. Prominent myoclonus is a feature in one-third of the patients. Most patients lack the PSWC on EEG. DW MRI sequences commonly show increased signal in the basal ganglia and thalamus, while cortical signal changes are typically limited to the limbic cortex. The spongiform change is of similar fine vacuoles as in the MM1/MV1 type, but in the cortex it is often laminar and involves mainly the deeper layers. Immunostaining with anti-PrP antibodies shows plaque-like reactive deposits; however, these are Congo red and thioflavin S negative (and therefore not amyloid). The third most common type is MV, type 2, comprising ~8% of cases. This type is also called the kuru plaque variant. The mean age and clinical course are 59 years and 18 months, respectively. Clinically, both ataxia and dementia are prominent at disease onset. The longer duration of disease can cause diagnostic confusion. It is not usual for these patients to survive >2 years. Typically, there are no PSWCs on EEG. The DW MRI sequences, like the VV2 type, show abnormal signal in the basal ganglia and thalamus. Specifically, the thalamic signal hyperintensity is most commonly seen in the pulvinar, sometimes displaying the "pulvinar sign" (181). Neuropathologically, a distinctive feature is kuru-like plaques in the cerebellum, which are round, dense PrP^{Sc} immunoreactive deposits that are Congo red positive and are also easily seen on hematoxylin and eosin stains. These are abundant in the molecular and granular layers of the cerebellum but are rare in other cerebral locations. Two distinct clinical phenotypes can occur among individuals who are MM type 2. The first phenotype, MM2-cortical or MM2C, affects ~1% of patients. The mean age at onset is 65 years, with an average duration of ~17 months. These patients present with cognitive deficits and myoclonus, but typical EEG findings and visual symptoms are typically absent. Ataxia is mild or absent, even late in the clinical course. DW MRI hyperintensity is typically seen involving the temporal lobes, while basal ganglia involvement is

absent or limited. Thalamic hyperintensity may be present. The neuropathological changes are distinct by the lack of cerebellar involvement and by the spongiform change typically consisting of larger and coarser vacuoles. PrP^{Sc} immunoreactivity is often found at the rim of these coarse vacuoles. The second clinical phenotype associated with the MM2 type is also referred to as the sporadic form of fatal insomnia or MM2 thalamic type. This variant affects <1% of sCJD patients and is clinically characterized by insomnia and psychomotor hyperactivity. Motor signs may include diplopia, dysarthria, dysphagia, pyramidal tract signs, and gait abnormalities. Myoclonus is a typical finding. Typically, there are no PSWCs on EEG and there are no signal abnormalities on DW MRI. However, evidence of hypometabolism and/or gliosis may be found by fluorodeoxyglucose positron emission tomography (FDG-PET) and MR spectroscopy, respectively. The neuropathological changes principally affect the thalamus and inferior olive, consisting of atrophy of these structures, neuronal loss, and gliosis. Spongiform change can be absent or limited to focal areas of the cerebral cortex. PrP^{Sc} immunoreactivity may be limited to the entorhinal cortex. The least common molecular phenotype of sCJD is VV1, type 1, also called "early onset sCJD," since the average age at onset is ~39 years, with a disease duration of ~15 months (47, 176). Clinically, there is a progressive dementia at onset, often with features of a frontotemporal dementia. PSWCs are typical absent on EEG. Neuropathologically, there is severe fine spongiform change affecting the cortex and striatum with relative sparing of the cerebellum. PrP immunostaining shows a fine punctuate pattern in the cerebral cortex.

Other classical sCJD clinical phenotypes have been recognized. The Heidenhain variant, seen in ~10% of sCJD patients, mostly with the MM1 molecular subtype, is characterized by visual symptoms at presentation, typically visual hallucinations, cortical visual deficits, and/or oculomotor apraxias (182, 183). The Brownell-Oppenheimer variant has ataxia as its major feature, with a typical lack of PSWCs on EEG and with striatal DW MRI hyperintensities (182, 184). This variant is associated mostly with the MV2 molecular subtype. In addition, there is a panencephalopathic form, which has significant involvement of the white matter, along with severe global atrophy and status spongiosus (185–187). This form has been reported primarily in Japan, and some have suggested that this type of sCJD is related to Wallerian degeneration in the white matter, which may occur in patients with a prolonged survival, found among cultures in which more extraordinary life extending measures are taken (3).

In 2008, a new type of sCJD was described, termed variable proteinase-sensitive proteinopathy (VPSPr) (151, 188). The defining feature of VPSPr is the Western blot profile of PrP^{Sc} after PK digestion containing a ladder-like banding pattern including at least 4 bands. Relatively few cases have been described in the literature so far (151, 188–193). Diagnostic criteria for VPSPr remain to be determined, and most cases are diagnosed postmortem. The disease affects all three codon 129 genotypes, with slightly increased susceptibility with expression of valine. Symptoms include aphasia, parkinsonism, cognitive dysfunction, and ataxia. The 14-3-3 protein in the cerebrospinal fluid (CSF) is typically negative, and most cases do not have cerebral DW MRI hyperintensities. Neuropathologically, there is widespread spongiform change consisting of relatively large vacuoles. Small amyloid plaques containing PrP^{Sc} are often present in the cerebellar molecular layer among the MM and MV subjects. In these subjects, the PrP^{Sc} immunoreactivity is of target-like rounded clusters of granules, while in MM subjects a more plaque-like pattern like the one seen in VV2 sCJD is found (178).

Diagnosis of sCJD

Neuroimaging

Currently, the single most accurate method for the diagnosis of sCJD is by MRI using DWI (diffusion-weighted imaging) and apparent diffusion coefficient sequences, with a reported sensitivity of 91 to 96% and a specificity of 92 to 94% (3, 177, 194, 195). The major patterns of DWI MRI hyperintensities are cortical and subcortical (68% of cases), mainly cortical (24%), and predominantly striatal, with or without thalamic involvement (5%) (196). MRI abnormalities are often seen very early in the disease course, but in some cases these will appear only after repeated studies (197). MRI criteria for the diagnosis of sCJD have been published (194).

EEG

The classical EEG pattern in sCJD is PSWCs consisting of sharp or triphasic waves that occur about once per second. This pattern occurs in about two-thirds of sCJD patients, usually after serial EEGs are performed (197). PSWCs, although helpful in making an sCJD diagnosis, can also be seen in other conditions, such as Lewy body dementia, toxic-metabolic states, anoxic encephalopathy, progressive multifocal leukoencephalopathy, AD, and autoimmune encephalitis (197, 198).

Surrogate Biomarkers

The ultimate goal of TSE diagnosis is an antemortem test that would be sensitive enough to detect prions in body fluids such as blood, CSF, or urine. The standard CSF analysis of cell count, protein, and glucose is typically normal in sCJD. For antemortem diagnosis of sCJD, different proteins have been employed in tests that reach high sensitivity and are often used to complement clinical neurological assessment. However, none of these tests is 100% specific for prion diseases, and so far their use in diagnostics has been limited to the advanced stages of disease. In current clinical practice, the two widely used markers are CSF 14-3-3 protein and total tau. The American Academy of Neurology recommends ordering a CSF 14-3-3 protein when CJD is suspected (199). The 14-3-3 proteins are a group of cytosolic proteins that are released into the CSF as a result of neuronal damage; hence, all conditions with acute neuronal damage exhibit elevated CSF 14-3-3, including autoimmune, viral, paraneoplastic, or Hashimoto's encephalitis or a recent stroke (178). Rapidly progressive AD or Lewy body dementia may also elevate 14-3-3 (200, 201). A systematic review indicated that the sensitivity of 14-3-3 was 92% and the specificity was 80%. Total tau is also used as a marker of neuronal damage. Using a cutoff of >1,150 pg/ml of total tau in CSF, the reported sensitivity and specificity are >90% (202, 203). Other markers for neuronal damage have also been explored, such as neuronal specific enolase (a glycolytic enzyme) and S-100β protein (a glial protein), but they do not offer any advantage over 14-3-3 or total tau (201). The use of existing biomarkers, such as PrP^{Sc}, and the development of new biomarkers and/or methods that would enable their detection during preclinical stages will be important in the future for antemortem diagnosis of prion diseases. PMCA has been reported to be an efficient method for the amplification of PrP^{Sc} in human tissues and body fluids and thus can increase the sensitivity of disease diagnosis (204, 205). To lower the detection limit even further,

SOFIA was used in conjunction with PMCA for detection of PrP^{Sc} in human CSF from CJD (206).

As described above for animal prion diseases, the human prion diseases can also be diagnosed using immunochemical assays (IHC, Western blotting). Because of the abundance of PrP^{Sc}, CNS tissue is the most common and reliable diagnostic material. These methods exploit the physicochemical differences between PrP^{C} and PrP^{Sc}, namely, the resistance of PrP^{Sc} to denaturation and proteolytic degradation. However, PK digestion has in recent years become somewhat controversial since studies have identified PK-sensitive PrP^{Sc} that may comprise as much as 80% of the PrP^{Sc} population (151). Further, it is still debated whether PrP^{TSE} is unequivocally associated with prion infectivity, as there are occasions in which PrP^{Sc} is either not associated with infectivity (207) or absent in infected hosts (208). Despite these limits, PrP^{Sc} remains the best available choice for confirming the diagnosis of prion diseases and for the identification of prion-associated infectivity in tissues and body fluids. Moreover, the profile that PrP^{Sc} generates in Western blotting, reflecting different pathological conformations, is of great help in making a correct molecular diagnosis of sCJD and for differentiating sporadic from variant CJD (209).

In addition to PMCA, QuIC (210) and then real-time QuIC (RT-QuIC) have been used for amplification of human PrP^{Sc} (142, 210, 211). The two disadvantages of RT-QuIC are the relatively poor performance in amplifying PrP^{Sc} from vCJD tissues (211) and the failure to reproduce the original PrP^{Sc} signature, thus impeding the molecular diagnosis of sCJD and the distinction between sCJD and vCJD.

Safar and colleagues (150) developed an ELISA-formatted, dissociation-enhanced time-resolved fluorescence detection system, known as the conformation-dependent immunoassay, based on specific antibody binding to epitopes that are accessible in PrP^{C} but that are unmasked only after denaturation of PrP^{Sc}. This method does not require PK treatment and is able to recognize different PrP^{Sc} conformations. The assay was able to discriminate PrP^{Sc} signatures in different molecular forms of sCJDs, iCJDs, and genetic TSEs (212) with a detection limit at a 10^{-5} dilution of PrP^{Sc} from vCJD brain used for spiking human normal plasma (213, 214).

Brain Biopsy

The only definitive diagnosis of sCJD is by brain biopsy. However, this procedure is currently done less often, given the availability of the diagnostic methods discussed above. Current neuropathological diagnostic criteria require positive PrP^{Sc} immunoreactivity and the presence of spongiform change (215).

Genetic Prion Diseases

The genetics, clinical presentation, and pathological features of genetic prion diseases divide them into four types: genetic CJD (gCJD), GSS, FFI, and the newly described prion disease associated with diarrhea and autonomic neuropathy (3, 12, 216–218). Genetic prion diseases are sometimes referred to as familial; however, this often is not accurate, as studies have shown that up to 60% of genetic prion disease cases have no positive family history (219). In these cases, previous generations' family members may have been misdiagnosed with other neurodegenerative diseases such as AD. Alternatively, there can be an age-dependent penetrance or there may be incomplete information on the family history.

More than 20 CJD-associated point and octapeptide repeat mutations of PRNP are known. gCJD has been linked to point mutations leading to amino acid substitutions or deletion/insertions in the number of octapeptide repeats (3, 220). The clinical features of gCJD are extremely variable, with inter- and intrafamily differences reported (234, 235). A number of gCJD-associated point mutations have been reported, including G131V, D178N (with V129), V180I, T183A, H187R, T188K, E196K, E200K, D202N, V203I, R208H, V210I, E211Q, Q212P, and M232R (216, 217). On average, gCJD is associated with an earlier age at onset (<55 years) and a much longer clinical course. However, onset may be as late as the 9th decade of life. The codon E200K mutation (which is the most common *PRNP* mutation worldwide) is unusual in that it has been described in several unaffected elderly individuals, suggesting that the penetrance of this mutation is incomplete (3, 221). The penetrance has been calculated to be ~1% at age 40 but is closer to 100% after the 9th decade of life (222, 223). CSF, EEG, and brain MRI markers are not as sensitive in gCJD as in sCJD (3, 217, 220).

GSS was initially described in a large kindred in 1936 and is a slowly progressive autosomal dominant disease (224). It was the first human prion disease in which a mutation in the PRNP gene was discovered (225). The disease is rare, with a prevalence in the range of 1 and 10 per 100 million (12). GSS is most often caused by the P102L mutation in the *PRNP* gene, but additional mutations at codons 105, 117, 131, 198, 202, 212, 217, and 218 and insert mutations can also cause the syndrome. Patients with this illness present with a slowly progressive limb and truncal ataxia, as well as dementia. Death occurs 2 to 12 years following presentation. The prominent involvement of the brainstem often leads to symptoms suggestive of olivopontocerebellar degeneration. The neuropathology of GSS is remarkable in that extensive and invariable amyloid deposition occurs, in addition to the typical spongiform change, gliosis, and neuronal loss. The amyloid deposits are large and often multicentric. On Western blots, the PrP^{Sc} of GSS typically shows a 7- to 8-kDa or an 11-kDa band, distinct from the type 1 or 2 banding patterns seen in sCJD (226, 227). These lower-molecular-mass bands are most prominent in areas of the brain with the most abundant amyloid deposits. Interestingly, in several kindreds of GSS, extensive neurofibrillary tangle (NFT) formation is found (in association with mutations Y145X, F198S, Q217R, and Y218N) (228–230). NFTs are an essential feature of AD but are also observed in other neurodegenerative conditions.

FFI is only associated with the D178N mutation with a methionine at codon 129 (231). Patients with FFI present with intractable insomnia, dysautonomia (i.e., hyperthermia, hypertension, tachycardia, tachypnea, hyperhydrosis), dementia, and motor paralysis. However, the phenotypic expression is quite variable even within the same family (217, 221, 222, 232). The age of onset is also variable, ranging from 18 to 60 years, but occurs most commonly between 40 and 50 years of age. Once symptoms begin, the disease course ranges from 6 months to 3 years. Because of the diversity of clinical presentations of this disorder, genotyping is very important for definitive diagnosis. FDG-PET can also be helpful in the diagnosis, as a selective hypometabolism can typically be seen within the thalamus (221, 222). Neuropathologically, marked atrophy of the anterior ventral and mediodorsal thalamic nuclei occurs because of neuronal loss and gliosis. Unlike other prionoses, spongiform change can be a minor feature or can be absent altogether.

Recently, a novel human prion disease associated with diarrhea and autonomic neuropathy has been described (218). This condition is linked to a Y163X truncation mutation in the PRNP gene. The syndrome begins clinically with a chronic diarrhea in the patient's 30s. Next, symptoms of a length-dependent axonal and mainly sensory peripheral neuropathy begin. Cognitive decline and seizures occur in patients in their 40s and 50s. There is systemic deposition of PrP amyloid systemically including peripheral nerves and the gut, corresponding to the clinical symptoms. Neuropathologically, there are extensive cortical PrP amyloid plaques, PrP-related cerebral amyloid angiopathy, and a tauopathy. Spongiform change appears to be more limited, mainly to superficial cortical areas. The PrP banding pattern after PK digestion is distinct, with a ladder of protease-resistant fragments ranging in masses from 10 kDa to >100 kDa (218). Typical MRI findings are not present in these patients. Elevated total tau and 14-3-3 levels were found in one patient with advanced disease (218).

Iatrogenic Creutzfeldt-Jakob Disease

iCJD was first described in 1974 in a patient who received a cadaveric corneal transplant from a patient who was subsequently diagnosed with CJD (233). More than 400 cases of iCJD have been reported worldwide related to use of cadaver-derived human pituitary hormones (growth hormones [hGH] and gonadotrophic hormones [hPGJ), dura mater grafts, corneal transplants, EEG electrodes, or neurosurgical instruments (234, 235). The greatest number of cases of iCJD are related to either hGH (226 cases, mainly in France) or dural grafts (228 cases, mainly in Japan) (234, 235). As noted with sCJD, susceptibility to infection is linked to the codon 129 polymorphism, with the majority of iCJD cases being MM homozygous (12, 184). Between the late 1950s and 1985, about 30,000 children were treated with hGH; it is estimated that about 1/100 may have developed iCJD. Presumably, this was due to contamination by a cadaveric pituitary infected with sCJD during the batch processing (which included 5,000 to 20,000 cadaveric pituitaries in a single batch). With the availability of recombinant hormones, this source of iCJD is no longer an issue. The initiation of separate processing of individual dura mater grafts since 1987 has also eliminated this source of iCJD. The clinical and pathological features of iCJD linked to hGH were more similar to those of kuru, with prominent cerebellar signs at the onset, with dementia only late in the course of disease (184, 236). The incubation period range was from 4.5 to over 25 years, with a mean of 12 years. The features of iCJD linked to dural grafts were more similar to those of sCJD, with the incubation period being 1.5 to 18 years with a mean of ~6 years (234, 235). iCJD cases have been greatly reduced in number by increased surveillance in recent years (235). However, one caveat noted in the discussion above ("Diagnosis of sCJD") is that some epidemiological evidence suggests that a portion of apparently sporadic CJD cases may be acquired, related to surgeries much earlier in life (171–173).

Variant Creutzfeldt-Jakob Disease

vCJD is a novel human prionosis linked to BSE or "mad cow disease" (48). BSE caused more than 180,000 cattle deaths, mainly in the United Kingdom (3, 48, 237). This disease is thought to be caused by meat and bone meal dietary supplements to cattle that were contaminated with scrapie-infected sheep or to cattle with BSE. Extensive evidence suggests that BSE caused a new type of CJD called vCJD (48, 238). The first cases of vCJD were reported in 1995, when CJD was found in 2 British teenagers (48, 239, 240). The incidence of BSE has greatly declined since 1992 (48). Up to November 2013, 225 cases (http://www.cjd.ed.ac.uk) were reported worldwide, with no new cases in the United Kingdom in 2012 or 2013. All cases of vCJD have been methionine homozygous at codon 129, with the possible exception of one vCJD case (48, 241). vCJD patients differ from sCJD patients in that they are typically younger, with a median age of ~27 years (range, 12 to 74 years) (48). The disease duration is longer, ~14.5 months, and prominent psychiatric symptoms are often the presenting feature of vCJD, often for >6 months before clear neurological symptoms develop. An EEG rarely shows classic PSWCs. The brain MRI typically shows the "pulvinar sign," whereby the pulvinar nucleus of the thalamus has hyperintense signal on DWI MRI. This MRI finding is present in >85% of vCJD cases on the first examination (242). The definitive diagnosis of vCJD is dependent on PrP^{Sc} identification on brain biopsy or autopsy. PrP^{Sc} can also be identified in the lymphorecticular system, such as the tonsil (48). Neuropathologically, vCJD shows abundant PrP^{Sc} deposition in multiple fibrillary plaques surround by a halo of spongiform vacuoles, called "florid plaques" (48). Although the number of vCJD patients is declining, as discussed above, three cases of vCJD infection associated with blood transfusion have also been reported (48). Furthermore, a recent survey of 32,441 appendix samples in the United Kingdom has indicated a vCJD subclinical infection rate of ~1:2,000 (95), largely consistent with four prior prevalence surveys (94, 243–245). This suggests that a substantial number of United Kingdom individuals might be carriers of vCJD. It is unclear if any of these subclinically infected individuals will ever develop clinical vCJD. However, this represents a substantial pool of patients for a possible secondary spread of prion infection. At present, no effective method for screening blood for vCJD contamination exists (246, 247), although such assays are under development (248, 249). Therefore, the risk of further cases of vCJD occurring due to blood transfusion remains a distinct possibility. This highlights the need to develop better diagnostic means for the specific identification of PrP^{Sc} or prion-associated seeding activity in biological fluids.

EMERGING RISKS OF FUTURE NOVEL PRION DISEASES

The divergent clinical and neuropathological features of the more recent additions to the list of human prion diseases, such as FFI, VPSPr, and the recently described prion disease associated with diarrhea and autonomic neuropathy, highlight the wide spectrum of diseases associated with PrP^{Sc} accumulation and suggest that there may be other human illnesses that have yet to be recognized as a prionosis. Furthermore, a significant area of concern for a further outbreak of human prion disease relates to CWD in North America. CWD appears to be the most infectious prionosis to date, affecting free-ranging and farmed ungulates (white-tailed deer, mule deer, elk, and moose) (78, 250–252). CWD was first described in 1967 and was recognized to be a prion disease in 1978 on the basis of brain histopathology (78, 250, 252–254). CWD has been detected in 19 states in the United States, two Canadian provinces, and South Korea (78, 252, 255). Up to 90% of captive cervids have been reported to be prion positive, while in the wild the prion infection prevalence has been reported to be as high as 50%. The cervid population in the United States is estimated to be ~33 million, a large at-risk population. Transmission of CWD is mainly horizontal via a mucosal/oral route (252, 256, 257). CWD has been shown to be transmissible to

nonhuman primates (squirrel monkeys) by two groups using intracerebral inoculation (258, 259). Significantly, a recent study also showed CWD to be orally transmissible to squirrel monkeys (259). Interestingly, the clinical symptoms of CWD infection in the CWD-infected monkeys resembled a wasting syndrome rather than more typical symptoms such as ataxia, leading to the speculation that if CWD was transmitted to humans and presented in a similar manner, the disease would not be identified as a prion disease without neuropathological evaluation (something that is done on a very small proportion of patient deaths) (259). CWD has also been shown to be transmissible to sheep, cattle, fallow deer, reindeer, and several North American rodents (prairie voles, mice, and ferrets), which can scavenge on CWD carcasses (260–265). These animals can enter the human food chain directly or indirectly by accidental inclusion in grain and forage. Large predators of cervids in the wild are, not surprisingly, preferentially killing incapacitated CWD-infected animals, raising the possibility of further cross-species spread (266). Thus far, studies using transgenic mice expressing human PrP^{C} have failed to show transmission of CWD, indicating that this presents a more significant species barrier than BSE to human transmission (267–269). On the other hand, two different strains of CWD have been identified to date, with the likelihood that there may be more (79, 270). The possibility that these other, future strains of CWD will have greater potential for human spread remains to be explored. Recent studies have also shown evidence for strain-dependent, peripheral infection in humanized transgenic mice challenged by cervid prions (Q. Kong, unpublished results). Hence, CWD presents a significant threat to human populations, again highlighting the need to develop assays that can specifically detect PrP^{Sc} infection in biological fluids. Recent technologies that include PMCA-SOFIA and RT-QuIC are showing great promise at fulfilling this critical need.

CONCLUSION

Prion diseases continue to present a diagnostic and therapeutic challenge to clinicians and researchers worldwide. There are many aspects of prion biology that remain unclear; we still do not know the precise physical nature of the infectious agent, the molecular and biochemical mechanisms underlying associated neurodegeneration, or the physiological function of PrP^{C}. Current diagnostic methods are based mainly on the physicochemical differences between PrP^{C} and PrP^{Sc}, which, to date, are the only reliable markers for TSEs. The tests differ mainly at the level of the detection methods. Although the diagnostic tools currently available for prion diseases are less sensitive than those available for other infectious diseases, continued technological advances are being made. In addition, the search for additional markers for the detection of TSEs is of utmost importance. Several approaches to detect additional surrogate markers have already been undertaken. Furthermore, assessment of therapeutic advances are dependent on disease diagnosis and biomarker monitoring. Interestingly, with increasing understanding of neurodegenerative processes, it appears that protein misfolding and subsequent propagation of rogue proteins are a generic phenomenon shared with diseases caused by tau, α-synucleins, and β-amyloid proteins. Consequently, effective antiprion agents may have wider implications. In the past decade, research on prion diseases has advanced our knowledge and understanding of basic prion biology, and this trend will trigger further advances in disease diagnosis and therapeutics.

HISTORICAL PERSPECTIVE

The human immunodeficiency virus (HIV) is the etiologic agent of AIDS. The clinical manifestations of AIDS were first recognized in 1981 (1). Search for the cause of this severe cellular immune dysfunction led to isolation of lymphadenopathy-associated virus in 1983 (2). The following year, additional researchers isolated cytopathic retroviruses from persons with AIDS, which they termed human T-lymphotrophic virus type III (3, 4). These viruses were soon confirmed to be identical, and in 1986 the International Committee on Taxonomy of Viruses named the virus causative of AIDS HIV (5). Genetic sequences of HIV have been identified retrospectively in human plasma specimens from as early as 1959 (6). It is estimated that approximately 75 million people worldwide have become infected with HIV. In the United States, the Centers for Disease Control and Prevention (CDC) estimates that 1.1 million persons are living with HIV.

HIV exists as two major viral species. Both are members of the genus *Lentivirus* within the family *Retroviridae*. HIV type 1 (HIV-1), identified first, is the more virulent of the two and responsible for the majority of AIDS cases worldwide. HIV-2, first isolated in 1986, has biological and morphologic properties similar to those of HIV-1 but differs from HIV-1 in some of its antigenic components (7). HIV-2 is less pathogenic and has a more limited geographic distribution than HIV-1. Both HIV-1 and HIV-2 are related to simian immunodeficiency viruses, which are found in 26 different species of African primates but do not cause disease in their native hosts (8). A schematic of virus structure is shown in Fig. 1. HIV-2 has a comparable structure, and the major proteins of diagnostic significance for each virus type are shown in Table 1.

Laboratory Markers of HIV Infection

Analyses of specimens from seroconversion panels have established the dynamics of HIV-1 viremia after infection and the sequential appearance of different laboratory markers. The approximate times at which different markers appear have been estimated from multiple sources and are outlined schematically in Fig. 2 (9–12).

Immediately after HIV infection, low levels of HIV-1 RNA might be present intermittently, but no viral markers are consistently detectable in plasma (13). Within approximately 5 to 28 days after infection (median, ~10 days), HIV-1 RNA becomes detectable by nucleic acid testing (NAT) in plasma, and quantities increase to very high levels (9, 10). Next, HIV-1 p24 antigen is expressed, and quantities rise to levels that can be detected by antigen/antibody combo immunoassays within 4 to 10 days after the initial detection of HIV-1 RNA (11, 12). However, p24 antigen detection is transient because, as antibodies begin to develop, they bind to the p24 antigen and form immune complexes that interfere with p24 assay detection unless the assay includes steps to disrupt the antigen-antibody complexes (14, 15). Next, immunoglobulin M (IgM)-class antibodies, which can be detected by antigen/antibody combo, and antibody immunoassays, which detect IgM, are expressed 3 to 5 days after p24 antigen is first detectable, 10 to 13 days after the appearance of viral RNA (10–12, 16). Finally, IgG-class antibodies emerge and persist throughout the course of HIV infection. Immunoassays designed to detect only IgG exhibit considerable variability in their sensitivities during early infection, becoming reactive 18 to 38 days or more after the initial detection of viral RNA (10, 12). The antigenic targets for the majority of the circulating antibodies directed against the virus are shown in Table 1.

The pattern of emergence of laboratory markers is highly consistent and allows classification of HIV infection into distinct laboratory stages. The phases are as follows. (i) The eclipse period is the interval after infection with HIV when no laboratory markers are consistently detectable. (ii) Acute HIV infection is the interval between the appearance of detectable HIV RNA and the first detection of antibodies. Its duration depends on the design of the antibody immunoassay used and the sensitivity of the immunoassay during seroconversion. (iii) The seroconversion window period is the interval between infection with HIV and the first detection of antibodies. Its duration depends on the design of the antibody immunoassay and the sensitivity of the immunoassay during seroconversion. (iv) Established HIV infection is the stage characterized by a fully developed IgG antibody response sufficient to meet the interpretive criteria for a positive Western blot or immunofluorescence assay (IFA) (17).

HIV Testing Algorithms

Accurate laboratory diagnosis of HIV infection relies on testing algorithms that maximize overall sensitivity and specificity by employing a sequence of tests in combination and applying decision rules for resolving discordant test results. Beginning in 1989, the diagnostic algorithm

doi:10.1128/9781555818722.ch72

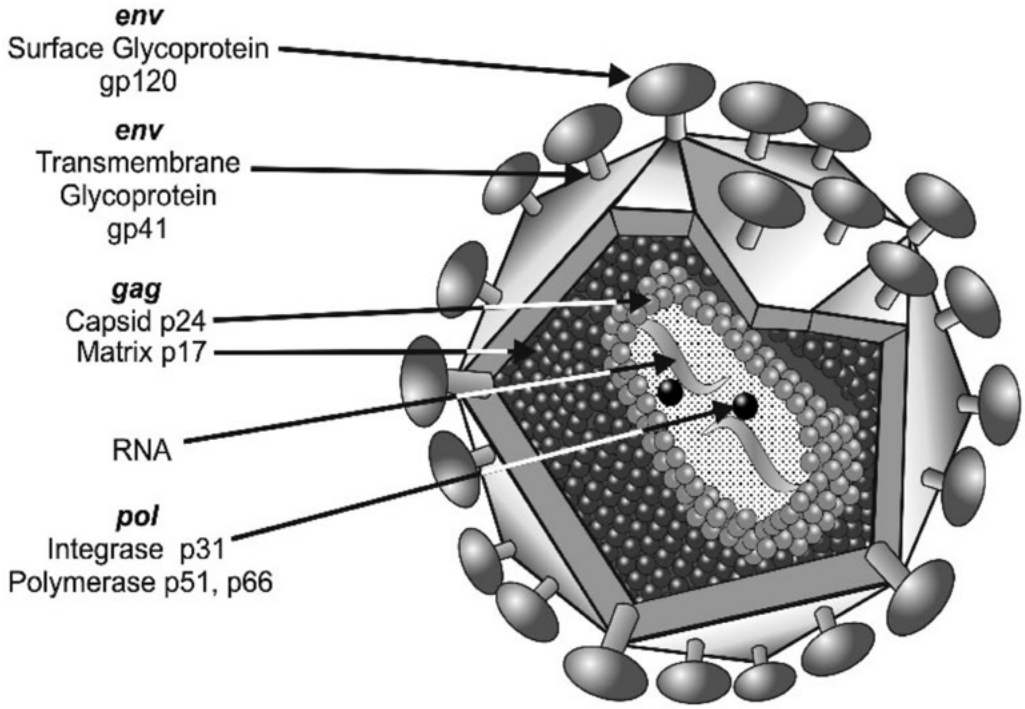

FIGURE 1 Structure of the HIV virion. The HIV genome consists of three major genes that encode the viral enzymatic and structural proteins: group-specific antigens or capsid proteins (Gag), polymerase, protease, and integrase enzymes (Pol), and envelope glycoproteins (Env). The nomenclature of viral proteins indicates either "gp" for glycoprotein or "p" for protein, followed by a number indicating its molecular weight in thousands. The major components of diagnostic utility for HIV-1 include envelope proteins (gp160, gp120, gp41), the *gag* core gene proteins (p55, p24, p17), and polymerase gene proteins (p66, p51, p31). HIV-2 proteins are similar but differ somewhat in the molecular weights of the three gene products (refer to Table 1).

for HIV testing in the United States, recommended by the CDC and the Association of Public Health Laboratories (APHL), began with screening using a sensitive HIV-1 antibody immunoassay. Specimens with repeatedly reactive initial immunoassays were then tested with a more specific HIV-1 antibody test, either the HIV-1 Western blot or the HIV-1 indirect IFA, to validate those results (18). In 1992, the CDC recommended specific testing for both HIV-1 and HIV-2 antibodies if demographic or behavioral information suggested that HIV-2 infection might be present, if there was clinical evidence or suspicion of HIV disease in the absence of a positive test for antibodies to HIV-1, and in cases in which the HIV-1 Western blot exhibited an unusual indeterminate pattern. At that time, the CDC also recommended that laboratories initiating testing with an HIV-1/HIV-2 antibody immunoassay conduct additional, more-specific tests to detect the presence of antibodies against HIV-2 if the HIV-1 Western blot was negative or indeterminate (19). In 2004, the CDC recommended confirmation of all reactive rapid HIV test results by either HIV-1 Western blotting or the HIV-1 IFA, irrespective of results of intermediate immunoassays that may have been conducted (20).

TABLE 1 Major HIV proteins of diagnostic significance

HIV gene and products	Viral protein in:	
	HIV-1	HIV-2
env		
Precursor	gp160	gp125

Reverse transcriptase	p51	p53
Endonuclease	p31	p31[a]
gag		
Precursor	p55	p56
Core	p24	p27
Matrix	p17	p16

[a]The molecular weight of p31 is 34,000.

Since those recommendations were issued, improved immunoassays, an HIV-1 NAT and differentiation immunoassays that distinguish HIV-1 from HIV-2 antibodies, received FDA approval for use in the diagnosis of HIV infections (43, 44). These developments resulted in the CDC and APHL issuing updated recommendations for laboratory HIV diagnostic testing in 2014. The updated algorithm employs an initial HIV-1/2 antibody/p24 antigen combination immunoassay followed by an antibody assay that differentiates HIV-1 from HIV-2 and, if necessary, a NAT to identify HIV RNA before antibodies develop. The currently recommended laboratory algorithm was designed to improve detection of acute/early HIV infection, improve diagnosis of HIV-2 (important for appropriate clinical management),

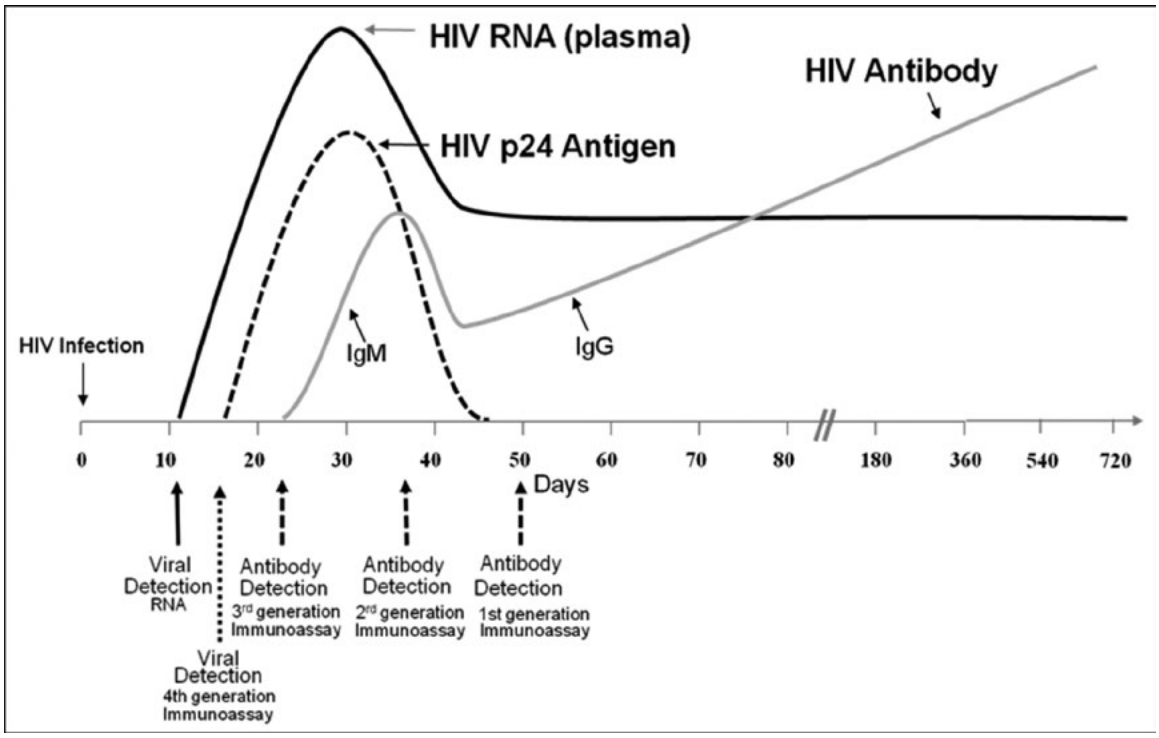

FIGURE 2 Time course of appearance of laboratory markers for HIV-1 infection. Units for vertical axis not given because the magnitude differs for RNA, p24 antigen, and antibody. Adapted data from reference 9 and updated with data from references 10–12.

decrease result turnaround time, allow more locations to conduct the first supplemental test, and not significantly increase the cost of HIV testing. A schematic diagram of the current laboratory algorithm recommended by the CDC and APHL is shown in Fig. 3, and the full set of guidelines (82) can be found at the following link: http://www.cdc.gov/hiv/pdf/hivtestingalgorithmrecommendation-final.pdf.

In addition to diagnostic assays, genotypic and phenotypic resistance assays guide the selection of antiretroviral regimens, and quantitative viral load assays that can detect fewer than 50 viral copies per ml are useful for prognosis and to monitor the response to therapy. These tests, while not strict diagnostic assays, are very important prognostic testing tools for monitoring and guiding the health care of HIV-infected individuals.

SEROLOGIC TESTS

As mentioned above, diagnosis of HIV infection has typically been accomplished via detection of HIV antibody using a sensitive initial immunoassay validated by a subsequent supplemental test. Because HIV infection typically persists for the lifetime of the individual and the initial infection may be minimally symptomatic, most patients who are identified by antibody detection are in the clinically latent or later phases of the illness. Immunoassays for HIV antibody are rapid and economical, but they suffer an important limitation because of the window period, i.e., the time between initial infection and the expression of detectable antibody. During the eclipse and window period, active viral replication and high levels of viremia occur. Different types of antibody immunoassays have different window periods, as indicated in Fig. 2, but all tests based on detection of antibody miss patients during early infection. Recognition that the risk of transmission from persons with acute infection is much higher than that from persons with established infection and indications of the clinical benefits from antiretroviral treatment during acute HIV infection have served as the impetus to adopt techniques that detect HIV earlier after initial infection (21–26). Antigen/antibody combination immunoassays and an HIV-1 NAT that allow earlier detection of HIV have received FDA approval and are now considered essential components in HIV diagnosis.

Laboratory Assays

HIV immunoassays based on different design principles are generally grouped into generations. Immunoassays for laboratory use consist of enzyme immunoassay (EIA) and chemiluminescence immunoassay (CIA) methods. Most of the commonly used assays incorporate specific antigens for the detection of HIV-1 group M and O and HIV-2. HIV antigens (and, in fourth-generation assays, anti-p24 antibodies) are adsorbed to a solid phase, usually plates, beads, or tubes, which bind HIV antibodies (or p24 antigen) in the specimens. Antibodies (and, with fourth-generation assays, p24 antigen) are conjugated to enzymes (alkaline phosphatase or horseradish peroxidase) or to acridinium esters. The indirect EIA format uses an enzyme-labeled antiglobulin conjugate (first- and second-generation assays); the antigen sandwich EIA and CIA formats used in third- and fourth-generation assays use a conjugate with enzyme-labeled HIV antigens (or anti-p24 monoclonal antibodies). With an EIA, the result is a color change, measured as optical density by a spectrophotometer, proportional to the amount of antibody (or antigen) in the specimen. CIA results are expressed in relative light units, also proportional to the amount of antibody (or antigen) in the specimen. Results are compared to internal control values; a result with a signal-to-cutoff ratio of >1.0

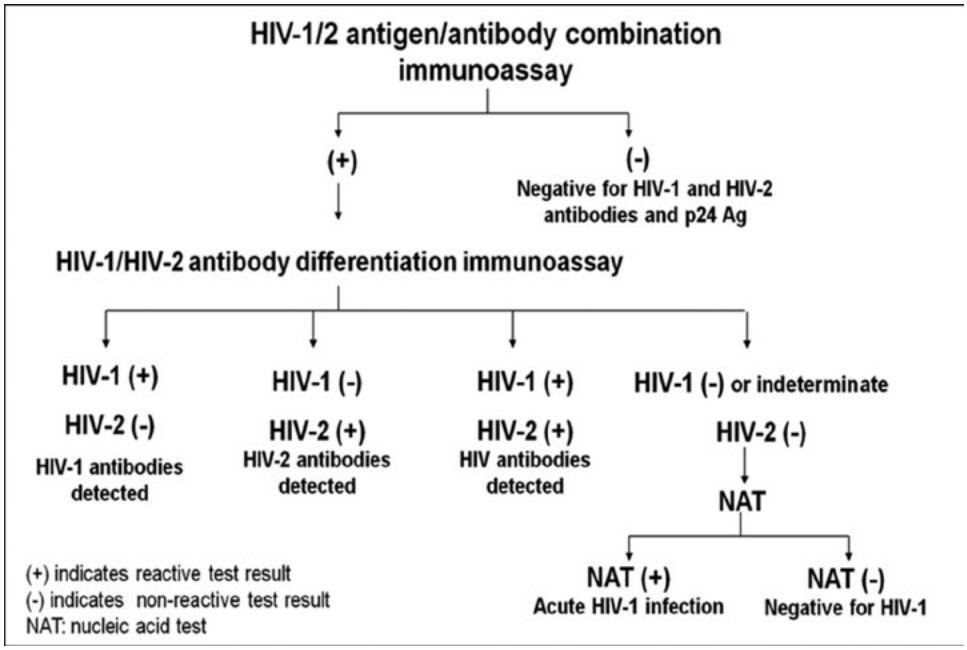

FIGURE 3 CDC and APHL recommended laboratory diagnostic HIV testing algorithm showing sequence of follow-up testing. Ag, antigen.

is considered to be reactive. Both EIAs and CIAs are suitable for automation. CIAs generally have a shorter processing time and wider dynamic range than EIAs. They have also been developed for random-access immunochemistry platforms with the potential to make laboratory-based HIV testing simpler and faster. In fact, some CIAs can produce results in a time frame similar to those of non-laboratory rapid tests and are a good alternative to rapid tests in situations where blood can be drawn and processed.

All third-generation antibody assays and the fourth-generation antigen/antibody assays report 100% sensitivity in their package inserts for specimens known to have HIV antibodies. For the fourth-generation antigen/antibody assays, the analytical sensitivity for p24 is reported to be between 5.2 and 18.39 pg/ml of p24. The specificity range reported for the third-generation assays is 99.58 to 99.92%. The specificities reported by the manufacturers for the antigen/antibody combo assays range from 99.72 to 99.87%. Analyses of specimens from seroconversion panels have established the approximate time of detection by the different generations of immunoassays. Estimates derived from several data sources are outlined schematically in Fig. 2 (9–12). Commercial assays currently available in the United States are summarized in Table 2.

Cautionary Remarks

The prevalences of HIV-1 group M subtypes and circulating recombinant forms (CRFs) vary geographically. All subtypes and most CRFs are found in sub-Saharan Africa. Subtype B is the predominant strain in the United States, Europe, Canada, and Australia. However, the prevalence of non-B subtypes in these countries is increasing. The most recent estimates for the United States indicate that non-B infections account for approximately 3 to 5% of HIV infections (27, 28). Current HIV immunoassays reliably detect the overwhelming majority of HIV-1 group M, B, and non-B subtype infections (11, 12). Group O infections remain rare in the United States. While HIV-1 group O infections can be missed by immunoassays that do not contain specific reagents for the detection of antibody to group O, most currently available assays now incorporate group O peptides (Table 2).

Immunoassays specific for the detection of HIV-1 antibodies can detect HIV-2 infections due to cross-reactivity to HIV-1 antigen present in the assay. However, levels of detection of HIV-2 infection by HIV-1-only immunoassays are highly varied: different assays detect 51 to 100% of HIV-2 infections (11). The ability of HIV-1/2 and HIV-2 assays to detect HIV-2 infections must be demonstrated for the assays to obtain approval by regulatory agencies, and most currently available FDA-approved HIV-1/2 assays incorporate gp36 antigen for reliable detection of HIV-2 (Table 2).

As with any assay capable of processing large numbers of test specimens at any one time, immunoassay methodology is subject to a number of technical drawbacks that should be considered. These range from procedural errors in the handling of samples, such as mislabeling of specimens, to deficiencies in the manual or automated performance of sample processing, such as well-to-well carryover during pipetting and the resultant contamination of neighboring wells. A false-positive result can also be caused by inadequate washing of the specimen or incorrect dilution of the sample or of any one of the assay reagents. Usually such false-positive reactions are corrected either by repeating the assay or by testing with another manufacturer's enzyme-linked immunosorbent assay kit. Apart from these purely technical considerations, the causes of false-positive immunoassay results may be both varied and obscure.

Rapid Immunoassays

The logistics of conventional laboratory HIV immunoassays require phlebotomy and, typically, a follow-up visit for test results after the specimen has been processed. This complicates HIV testing for many hard-to-reach populations for which phlebotomy is impractical; many persons may also fail to return for their test results. In addition, an immediate

TABLE 2 FDA-approved conventional laboratory HIV immunoassays

Test	Markers used for detection	Analyte(s) detected	Generation
Conventional EIAs			
Avioq HIV-1 Microelisa system	Viral lysate, native gp160	IgG antibodies	2nd

[a]This assay has the ability to differentiate between analyte reactivities.

HIV test result is medically desirable under certain circumstances when antiretroviral prophylaxis should be initiated promptly, for example, in assessment of the source patient after an occupational blood or body fluid exposure and for pregnant women in labor whose HIV status is unknown. To meet these needs, rapid HIV tests that are suitable for use at the point of care (POC) as well as in clinical laboratories have been developed.

Rapid HIV immunoassays are single-use devices that use either immunoconcentration (flowthrough) or immunochromatographic (lateral-flow) principles (29). Flowthrough assays require the sequential addition of specimen, conjugate reagent, and a clarifying buffer through a membrane. Lateral-flow assays contain all necessary reagents and are extremely simple to perform because they require the addition of only specimen or specimen and buffer. Rapid tests differ in their required specimen volumes (range, 3 μl to 50 μl for whole blood, serum, or plasma) and processing times (range, 1 to 20 min). Rapid tests that can use direct, unprocessed specimens (whole blood or oral fluid) have been classified as CLIA waived by FDA and are regulated differently under the Clinical Laboratory Improvement Amendments (CLIA) (83); they are especially well suited for testing outside traditional laboratory settings. There are currently nine rapid HIV antibody tests that are FDA approved in the United States and a multitude of other assays that are available outside the United States. Descriptions of the currently FDA-approved tests are shown in Table 3. Furthermore, one of these tests, OraQuick by OraSure Technologies, has been FDA approved for over-the-counter purchase and home use with oral fluid specimens (30, 31).

Cautionary Remarks

Disadvantages of rapid assays include their subjective interpretation, possible errors if the reader has vision problems, such as color blindness, and the potential for procedural errors when performed by less-skilled personnel (32, 33). Accurate specimen volumes must be dispensed and tests read within specified time limits, control lines must be observed, and instructions must be followed carefully. Rapid tests are useful primarily for small-volume testing. Accurate timing of steps can be adversely affected when multiple specimens are tested simultaneously. Nevertheless, rapid HIV tests have become valuable tools for clinical situations in which rapid results are essential and for outreach settings (34).

Published studies suggest that rapid HIV antibody immunoassays perform similarly to laboratory-based conventional immunoassays in identifying established HIV infection (35). For example, package inserts state that sensitivities range from 99.6 to 100% for all of the available rapid tests when used with blood specimens known to contain HIV antibodies. Specificities for antibody-only rapid tests range from 99.7 to 100% according to package inserts. However, most use colloidal gold bound to protein A for detection of IgG antibodies; the sensitivity of plasma seroconversion panels is similar to those of second-generation conventional immunoassays. Comparative studies of rapid tests performed on oral fluid, whole blood, and serum demonstrate that rapid tests identify fewer HIV infections than conventional laboratory immunoassays, and sensitivity with oral fluid specimens is lower than that with whole blood or serum in persons from populations with increased prevalences of early HIV infection (36, 37). One rapid HIV test that detects and distinguishes HIV antibodies and p24 antigen, the Alere Determine HIV Combo, has received FDA approval (Table 3). Its overall sensitivity is similar to those of third-generation assays; the sensitivity of the antigen component is lower than those of laboratory-based fourth-generation assays (37–39).

Alternative Specimens for Antibody Testing

Alternative specimens to blood, serum, or plasma for HIV antibody testing include oral fluid, urine, and dried blood spots (DBS). These may be useful in testing patients who are reluctant to undergo phlebotomy or who have poor vascular access, in mass-screening settings, in locations in

TABLE 3 FDA-approved rapid and POC HIV tests

Test	Manufacturer	Specimen types	CLIA category	Antigen(s) represented	Yr of FDA approval
OraQuick Advance rapid HIV-1/2 antibody test	OraSure Technologies, Inc.	Oral fluid, whole blood, plasma	Waived; moderate complexity	gp41, gp36	2002
Reveal G3 Rapid HIV-1 antibody test	MedMira, Inc.	Serum, plasma	Moderate complexity	gp41, gp120	2003

[b]This assay was FDA approved for supplemental testing only.

which phlebotomy is impossible, in infants, and for seroprevalence studies. It is essential to employ only specimen collection systems and testing methods designed and validated for the specific specimen type. Oral fluid is a complex mixture of secretions from several different sets of glands, as well as transudated plasma from the capillaries of the gum and mucosa. Glandular secretions of saliva contain primarily secretory IgA, which is not a reliable target for diagnostic testing. Most IgG in the oral cavity derives from the crevicular space between the gums and the teeth and not from salivary glands, or can be obtained by inducing an oral mucosal transudate. The OraSure specimen collection device is designed to collect oral mucosal transudate for conventional testing with an FDA-approved oral-fluid-based HIV-1 EIA and Western blot. Two rapid tests are FDA approved for use with oral fluid as well as whole blood and plasma specimens (Table 3). DBS, after appropriate elution, can be tested for HIV antibody, p24 antigen, and HIV RNA and produce results comparable to those from matched serum or plasma specimens when the reduced sample volumes contained in DBS are taken into consideration.

Cautionary Remarks

None of the newer immunoassays that allow detection of IgM antibodies and p24 are approved for use with DBS (Table 2). Data indicate that infection is detected later when oral fluid specimens are used than when blood specimens are used (36, 40).

DIRECT DETECTION

p24 Antigen Assays

In the early days of the AIDS epidemic, p24 antigen testing played an important role as a tool for the diagnosis, prognosis, and evaluation of antiretroviral activity and for monitoring of HIV-1-infected cultures. In 1996, the FDA approved the Coulter HIV-1 p24 antigen assay (Coulter Co., Miami, FL) for screening blood products. This test was used for screening blood and plasma donors in the United States for a few years until it was replaced with more-sensitive nucleic acid tests in 1999 (55). Currently, there are no FDA-approved, stand-alone p24 antigen tests, and the use of individual p24 antigen assays is very limited in the United States. However, standalone p24 assays are still utilized by laboratories in various other countries as part of their HIV testing algorithm.

NUCLEIC ACID TESTING

HIV RNA Qualitative Assays

Aptima HIV-1 RNA Qualitative Assay

Presently, the Aptima HIV-1 RNA qualitative assay is the only nucleic acid test (NAT) that is FDA approved for diagnosis of HIV-1. The assay is intended for detection of HIV-1 in serum and plasma, which has utility for the identification of acute and neonatal HIV-1 infection. The sample preparation, amplification, and amplicon detection steps occur in a single tube. During the sample preparation step, HIV-1 RNA is isolated from clinical specimens by hybridization to target-specific, oligonucleotide-bound magnetic microparticles. The target RNA is amplified via transcription-mediated amplification, followed by detection of the amplified material by a hybridization protection assay (HPA), which involves capture via a chemiluminescent labeled oligonucleotide complementary to the amplicon sequence. The assay is capable of detecting virus sequences within HIV-1 groups M, N, and O, with a limit of detection of 30 RNA copies/ml. The Aptima assay does not detect HIV-2.

NAT Platforms on the Horizon for HIV Testing

Point-of Care NATs

NAT is restricted primarily to centralized laboratories, since the platform characteristics preclude testing in developing countries or other resource-limited settings. Viral load platforms are costly and require extensive training and laboratory resources, including space for the dedicated equipment. Although the platforms are typically high-throughput platforms, the turnaround time is relatively high and test results cannot be provided during the same office visit. Sample collection, storage, and shipment present a challenge for most POC settings, especially since care must be taken in order to preserve the integrity of the RNA for viral load testing. Dried blood spots have improved sample collection in resource-limited settings, as they are easier to transport and are stable at room temperature; however, they still must be shipped to a centralized laboratory for testing. Implementation of viral load testing at the POC is critical in order to avoid loss to follow-up and clinical progression. Thus far, NAT at the POC is not feasible, though several rapid NAT technologies are in development or in the early stages of commercialization. To highlight a few promising technologies, the following rapid NAT platforms are available commercially for other pathogens and are currently in development or in early-phase distribution for HIV: Alere q HIV-1/2 Detect (Alere Technologies, Jena, Germany), Liat HIV (Roche Molecular Branchburg, NJ), GeneXpert (Cepheid, Sunnyvale, CA), and a simple amplification-based assay (SAMBA) (Cambridge, United Kingdom). Currently, none of the HIV tests are FDA approved or available for purchase in the United States, but several have received CE marks (Alere, Cepheid, and SAMBA).

Alere q HIV-1/2 Detect

The Alere q HIV-1/2 Detect is a fully automated, portable real-time PCR platform for quantitative detection of HIV-1 and HIV-2 in whole blood or plasma. The assay is intended for detection of early infant diagnosis and acute/early infection at the POC or in resource-limited settings (41). A total of 25 μl of blood from a finger stick, venous blood, or plasma is added directly to the preloaded test cartridge, and the cartridge is immediately placed in the analyzer. The analyzer has a touchscreen interface and integrated battery for use if electricity is not available. The total run time for detection of HIV-1 and HIV-2 results is approximately 1 h. Internal controls are incorporated into each test cartridge. The Alere q is optimized to detect group M (A to H), group N, group O, CRFs, and HIV-2 groups A and B.

Liat

Like the Alere q HIV-1/2 Detect, the Liat (lab-in-a-tube) HIV Quant VL assay is a fully automated platform that can be used with either whole blood or plasma (42, 43). The sample preparation, target amplification, and amplicon detection occur in a single disposable tube, which is encoded with a barcode. All of the assay reagents, along with an internal RNA control, are prepackaged in segments of the Liat tube, which are separated by peelable seals. The clinical sample is added directly to the Liat tube with a disposable pipette, the barcode on the tube is scanned by the Liat analyzer, and the tube is placed in the analyzer. The tube compartments are compressed by an actuator in the analyzer to expose the reagents needed for the next step in the process. Sample processing involves silica magnetic bead extraction, followed by multiplexed real-time reverse transcription-PCR (RT-PCR) amplification. The Liat analyzer has a display screen with a keypad that indicates test time remaining and final test result, which is achieved within 30 to 35 min. One of the drawbacks of the current Liat platform for POC use is that the testing cartridges require cold storage at 4°C. Both qualitative and quantitative assays are being finalized.

GeneXpert

The GeneXpert is a fully automated rapid real-time PCR platform. The sample processing, amplification, and fluorescence-based detection are all performed in a single-use, microfluidic cartridge, which is preloaded with all of the test reagents. The GeneXpert platform is currently available in 1-, 2-, 4-, 16-, 48-, or 80-module configurations to customize throughput. The modules are stackable to reduce space requirements. For HIV-1 detection, the GeneXpert platform supports a qualitative and quantitative version of the assay, the Xpert HIV-1 Qual and Xpert HIV-1 viral load assays, respectively. For the HIV-1 Qual assay, 100 μl of blood and 750 μl of sample reagent are added to the test cartridge, while the HIV-1 viral load assay requires 1 ml of plasma. After transfer of the clinical specimen to the cartridge, the cartridge is scanned and placed in the module to begin the run. The GeneXpert platform can also be used with dried blood spots. Unlike the Alere q and Liat analyzers, the GeneXpert modules do not contain a display screen but communicate with an external computer. The total test time is approximately 90 min for both the Xpert HIV-1 Qual and Xpert HIV-1 viral load assay. A new, even-more-simplified instrument for running Cepheid GeneXpert assays (Omni) is projected to be available in 2016 and will be capable of easy transport and battery-powered operation.

Simple Amplification-Based Assay

The SAMBA is available in two different formats: SAMBA I and II. SAMBA I is intended for semiautomated batch testing and can run four samples at a time or 24 to 48 samples a day (44, 45). SAMBA II is fully automated, and individual assay modules can be added to the system to customize throughput. The assay modules are controlled by a display module, which is linked via Bluetooth. Each display module can support up to 16 assay modules. The SAMBA platform supports the following tests: whole-blood qualitative, plasma semiquantitative, and whole-blood semiquantitative. The intended use for the whole-blood qualitative test is early infant and acute-infection diagnosis, while the plasma semiquantitative and whole-blood semiquantitative assays are for therapy monitoring. The display module contains an integrated barcode scanner, which is used to scan the barcode on the cartridge box to identify the specific test and to scan the sample identifier. Unlike with most other rapid NAT platforms, the SAMBA involves isothermal amplification of target sequences. Test results are obtained within 90 min by a lateral-flow-based visual readout. The disposable, preloaded cartridges are stable at room temperature and have been shown to maintain stability at room temperature or at 37°C for up to a year.

Cautionary Remarks

HIV NAT testing has utility in screening high-risk individuals suspected of having had recent exposures, since RNA is the first marker of infection that can be detected in plasma (9). However, it is known that RNA detection is not always reliable in persons with established infections. It has been shown that approximately 2 to 4% (46) of specimens from

patients with established HIV infections are not reactive/positive for HIV RNA (11, 47).

Supplemental Assays for HIV

Initial screening immunoassays for HIV are optimized to provide very high sensitivity, often at the expense of specificity. HIV diagnostic testing therefore relies on a sequence of tests used in combination to improve the accuracy of HIV laboratory diagnosis. Specimens that are nonreactive in the initial immunoassay are generally considered HIV negative. If the initial immunoassay result is reactive, it must be followed by one or more supplemental tests. Four assay methods are FDA approved as supplemental tests: HIV-1 Western blotting, indirect IFA, HIV-1/HIV-2 antibody differentiation assay, and qualitative HIV-1 RNA assay. The following Web link lists licensed and approved tests: http://www.fda.gov/BiologicsBloodVaccines/BloodBloodProducts/ApprovedProducts/LicensedProductsBLAs/BloodDonorScreening/InfectiousDisease/UCM080466. Both the Western blot and the IFA are highly specific, but because they rely on viral lysate antigens and anti-human IgG conjugates, they detect HIV-1 later during seroconversion than most currently available conventional initial immunoassays and thus may produce false-negative or indeterminate results (9, 10). In addition, because of cross-reactivity, the HIV-1 Western blot has been interpreted as positive for HIV-1 in 46 to 85% of specimens from persons infected with HIV-2 (48–50). An HIV-1/HIV-2 antibody differentiation assay was approved by the FDA in 2013 for use as a supplemental test and for differentiation of HIV-1 and HIV-2 antibodies. Because the differentiation assay uses an indirect EIA format with an anti-human IgG conjugate, it also detects HIV antibodies later during seroconversion than most currently available conventional initial immunoassays (51, 52).

Historically, the HIV-1 Western blot has been the gold standard for HIV diagnosis (18). The Western blot owes its specificity to separation and concentration of viral components. A viral lysate of HIV is applied in a gel under an electric field; the mixture of viral components is separated by their molecular weights into specific "bands." Each viral component becomes relatively pure as it is separated. Components are blotted separately onto a membrane which is cut into strips. The testing laboratory incubates the strips with patient serum, plasma, or dried blood spot eluates and then develops the reaction with an enzyme-labeled anti-human antibody. Antibodies to the following HIV-1-associated antigens can be detected: gp160, gp120, p66, p55, p51, gp41, p31, p24, p17, and p15. Additional viral bands may be described by some manufacturers, and the molecular weights of some antigens might vary slightly between assays produced by different manufacturers. Because Western blot antigens are prepared from HIV grown in cell culture, non-viral cellular proteins may be present on the nitrocellulose strip and lead to nonspecific reactions. The interpretation of HIV-1 Western blots predominantly follow CDC guidelines. A positive result requires detection of at least two of three antigens: p24, gp41, and gp120/gp160 (18). The absence of all bands is a negative result. The presence of HIV-associated bands not meeting the criteria for positivity or the presence of nonviral bands is interpreted as an indeterminate result. After a reactive initial HIV-1/HIV-2 immunoassay, additional negative or indeterminate HIV-1 Western blot testing specific for HIV-2 antibodies was recommended (19). Western blots that include HIV-2 antigens (e.g., gp36 or gp105) are available outside the United States, but none are FDA approved. Line immunoassays employ a principle similar to that of the Western blot, but recombinant or synthetic antigens are placed on the strip instead of viral lysate antigens from an electrophoretic gel. This approach has the advantage of using only viral antigens in the reaction mixture, eliminating the background from cross-reactivity with nonspecific cellular proteins. The manufacturer also has control over the quantity and type of antigens represented and can include HIV-2 and group O antigens to confirm these infections with a single assay (53). The INNO-LIA HIV I/II Score test (Innogenetics, Ghent, Belgium) is a line immunoassay widely available outside the United States.

The Fluorognost HIV-1 IFA (Sanochemia) has been used as both an initial screening test and a supplemental test for HIV-1 infection with serum, plasma, and dried blood spot eluates. HIV-infected and uninfected lymphocytes are fixed on a slide. The slide is incubated first with patient serum and then with a fluorescently labeled anti-human antibody (54). For interpretation, patterns of fluorescence in infected and uninfected cells are compared for each patient specimen; fluorescence on the infected lymphocytes that exceeds that from nonspecific antibody binding on the uninfected lymphocytes is interpreted as a positive result. Considerable skill is required, and indeterminate results can be produced for patients with autoantibodies and other conditions. In addition to being used as an independent supplemental test, IFA can be used to resolve indeterminate HIV-1 Western blots. An HIV-2-specific IFA has been described, but it is not FDA approved.

The Multispot HIV-1/HIV-2 rapid test (Bio-Rad Laboratories, Redmond, WA) is a flowthrough rapid EIA that differentiates HIV-1 and HIV-2 antibodies in a single-use cartridge. Microscopic particles are coated separately with a synthetic gp41 peptide and recombinant gp41 antigen for HIV-1 and a synthetic gp36 peptide for HIV-2. The microparticles are immobilized separately on the reaction membrane in three separate test spots. Antibodies against HIV-1 or HIV-2 in the test specimen bind to the antigens in the spots on the membrane. Alkaline phosphatase-labeled goat anti-human IgG is added to the cartridge and binds to the antibody/antigen complexes immobilized in the spots. When development reagent is added to the cartridge, a purple color develops at the spots in proportion to the amount of antibodies present. The membrane is examined visually for the presence of purple color on the test spots. Reactivity at both gp41 spots is required to define a positive supplemental HIV-1 test result; reactivity at only one HIV-1 spot is interpreted as indeterminate. The sensitivity of the Multispot antibody differentiation assay for established HIV infection is comparable to that of the HIV-1 Western blot, but it produces fewer indeterminate results and accurately identifies HIV-2 antibodies, including those in specimens misclassified as HIV-1 by the HIV-1 Western blot (51, 52, 55, 56). Because of cross-reactivity, approximately 0.4% of reactive specimens remain dually reactive at the HIV-1 and HIV-2 spots after recommended dilution procedures (52). Although most dually reactive specimens represent HIV-1 infections with cross-reactivity to HIV-2 (57), one U.S. study of five dually reactive specimens found detectable HIV-2 RNA in the one specimen with strong HIV-2 reactivity, suggesting that strong reactivity at the HIV-2 spot indicated the need for further investigation with HIV-2 NAT (56).

Recently, another rapid assay designed for differentiation of HIV-1 and HIV-2 antibodies has been FDA approved as a supplemental test. This test, the Geenius HIV 1/2 supplemental assay (Bio-Rad Laboratories, Redmond, WA) is an

immunochromatographic test. The Geenius HIV 1/2 supplemental assay cassette contains antibody-binding protein A, which is conjugated to colloidal gold dye particles, and HIV-1 and HIV-2 antigens (gp36 HIV-2 envelope peptide, gp140 HIV-2 envelope peptides, p31 HIV-1 polymerase peptide, gp160 HIV-1 envelope recombinant protein, gp41 group M and O HIV-1 envelope peptides, and p24 HIV-1 core recombinant protein), which are bound to the membrane's solid phase. The sample is applied to the sample-plus-buffer well. After the sample and buffer have migrated onto the test strip, additional buffer is added to the buffer well. The buffer causes the specimens and reagents to flow laterally and facilitates the binding of antibodies to the antigens. In a reactive sample, the antibodies are captured by the antigens immobilized in the test area. The protein A-colloidal gold binds to the captured antibodies, causing development of pink/purple lines. When there are no HIV antibodies, there are no pink/purple lines in the test area. The sample continues to migrate through the membrane, and a pink/purple line develops in the control (C) area, which contains protein A. In the FDA-approved version, the results are read with a reader that incorporates a standardized algorithm to make a final determination of HIV-1 or HIV-2 reactivity (58, 59).

The Aptima HIV-1 qualitative assay is FDA approved for detection of HIV-1. HIV-1 RNA in the test specimen is hybridized to capture nucleotides homologous to highly conserved regions of HIV-1. The hybridized target is then captured onto magnetic microparticles and separated from plasma in a magnetic field. Target amplification occurs via a transcription-based nucleic acid amplification. Detection is achieved by chemiluminescence-labeled nucleic acid probes that hybridize specifically to the amplicon. The chemiluminescent signal, measured in a luminometer, is reported as relative light units. Analytical sensitivity is 30 copies/ml of HIV-1 RNA. The HIV-1 qualitative RNA assay can be used for the diagnosis of acute HIV-1 infection in serum or plasma from patients without antibodies to HIV-1 and as a supplemental test, with specimens repeatedly reactive for HIV antibodies.

Cautionary Notes

Some tests, such as Western blotting and the Geenius assay, are designed to be used only as supplemental assays. Use of either of these tests as screening assays may result in false-positive or false-negative results.

While HIV-1 RNA levels are generally very high in recently infected individuals, HIV-1 is undetectable in 2 to 4% of HIV-1 Western blot-positive specimens from infected persons (11, 46, 47, 59) and thus one of the reasons why NAT is currently not the second step in the lab diagnostic algorithm recommended for use in the United States. Quantitative HIV-1 and HIV-2 RNA and DNA NAT are also available but are not FDA approved for HIV diagnosis http://www.fda.gov/BiologicsBloodVaccines/BloodBloodProducts/ApprovedProducts/LicensedProductsBLAs/BloodDonorScreening/InfectiousDisease/UCM080.

Nucleic acid testing technology is subject to contamination due to the highly sensitive nature of the technique. Extreme care should be taken to separate pre- and postamplification specimens and reagents.

PROGNOSTIC HIV TESTING

Following HIV-1 diagnosis or presentation of clinical symptoms associated with infection, HIV RNA viral load assays are used as a clinical tool to monitor disease prognosis. Viral load assays measure HIV-1 RNA in plasma as a means of monitoring the response to antiretroviral therapy, adherence to treatment, or virological failure, which, in turn, aids clinicians in making decisions about treatment changes. Studies strongly indicate that HIV-1 RNA levels are predictive of transmission risk; therefore, viral load assays may be used to guide treatment-for-prevention interventions (60). In the United States, viral load testing is the standard for assessing care in patients (61, 62), and five commercial assays are FDA approved for the quantification of HIV-1 RNA in plasma; however, only three of these assays can still be obtained in the United States from the manufacturer: Abbott RealTime HIV-1, Roche COBAS AmpliPrep/COBAS TaqMan HIV-1 v2.0, and Roche Amplicor HIV-1 Monitor v1.5. None of the viral load platforms are intended for diagnosis, donor screening, or detection of HIV-2 (Table 4).

RealTime HIV-1

The RealTime HIV-1 assay is an RT-PCR-based, automated platform that quantitates HIV-1 RNA in human plasma. The automated m2000 system includes two components: the m2000sp for sample preparation and the m2000rt for real-time amplification and detection. Prior to sample processing, an internal control RNA sequence is added to the clinical specimen to ensure quality control of sample processing and amplification steps. Magnetic particles capture RNA in the sample, and bound nucleic acids are washed, eluted, and transferred to a 96-well plate. At this point, the assay plate is transferred to the m2000rt component for amplification of the target by real-time RT-PCR. Detection of the amplicon is mediated by a 5′ fluorochrome-labeled oligonucleotide probe that is complementary to the target sequence. In the absence of the target amplicon, the probe is bound to a shorter complementary sequence that contains a quencher molecule at the 3′ end. In the presence of target amplicon, the probe will preferentially bind the amplicon and dissociate from the quencher sequence, allowing fluorescence emission. Quantitation is based on a standard curve generated from two controls included in the assay kit.

There are several advantages to the RealTime HIV-1 assay. The test is designed to quantify all group M, N, and O viruses and CRFs, with a broad linear range of 40 to 10,000,000 RNA copies/ml. There is also a reduced risk for carryover amplicon contamination since the amplification and detection steps are carried out in a sealed 96-well optical plate.

COBAS AmpliPrep/COBAS TaqMan HIV-1

The COBAS AmpliPrep/COBAS TaqMan HIV-1 test version 2.0 is an automated platform based on real-time TaqMan technology for detection of HIV-1 in plasma. Automated sample processing is performed by the COBAS AmpliPrep instrument, and automated amplification/detection is carried out on the COBAS TaqMan analyzer or COBAS TaqMan 48 analyzer. Docking the COBAS TaqMan analyzer to the AmpliPrep instrument creates a fully automated system. Alternatively, the amplification tubes can be manually loaded into the COBAS TaqMan 48 analyzer. Sample processing involves a silica-based extraction method. The target RNA binds to silica-coated magnetic glass particles. An internal-control quantitation standard is added to the clinical sample along with the lysis buffer. After sample processing, the target RNA is added to the amplification mixture and transferred to the COBAS TaqMan analyzer or COBAS TaqMan 48 analyzer for amplification and detection, involving a fluorochrome-labeled oligonucleotide probe/quencher pair. Viral load is quantitated based on the threshold cycle of the QS standard, which is added at a

TABLE 4 Nucleic acid tests

Type of test	Test(s)	Manufacturer	Intended use	Amplification method	Detection range (no. of RNA copies/ml)[d]	Specificities
Qualitative RNA	Aptima HIV-1 RNA qualitative assay[a]	Gen-Probe, Inc., San Diego, CA	Diagnostic	Transcription-mediated amplification	30–ND	HIV-1 groups M, N, and O
Viral load	RealTime HIV-1[b]	Abbott Molecular, Des Plaines, IL	Patient monitoring, quantification	Real-time RT-PCR	40–10,000,000	HIV-1 groups M and O, CRFs
	COBAS AmpliPrep/ COBAS TaqMan HIV-1 version 2.0[b]	Roche Diagnostics, Indianapolis, IN	Patient monitoring, quantification	Real-time RT-PCR	20–10,000,000	HIV-1 groups M and O, CRFs
	Amplicor HIV-1 Monitor version 1.5	Roche Diagnostics, Indianapolis, IN	Diagnosis of HIV, qualitative	RT-PCR	400–750,000 (standard), 50–100,000 (ultrasensitive)	HIV-1 group M
Point of care	Alere q HIV-1/2 Detect[c]	Alere, Technologies, Jena, Germany	Proposed diagnostic use and patient monitoring	Real-time RT-PCR	ND	HIV-1 groups M, N, and O, CRFs, HIV-2 groups A and B
	Liat system[c]	Roche Molecular Diagnostics, Branchburg, NJ	Proposed diagnostic use and patient monitoring	Real-time RT-PCR	100–1,500,000	HIV-1 groups M and O, HIV-2
	GeneXpert (Xpert HIV-1 viral load and Xpert HIV-1 Qual)[c]	Cepheid, Sunnyvale, CA	Proposed diagnostic use and patient monitoring	Real-time RT-PCR	40–10,000,000 (Xpert HVI-1 viral load)	HIV-1 groups M, N, and O

[c]Not currently FDA approved.
[d]ND, not determined.

constant concentration to each sample. Like the RealTime HIV-1 assay, the COBAS AmpliPrep/COBAS TaqMan HIV-1 assay has the ability to quantify all group M, N, and O viruses, including CRFs4, with a broad detection range of 48 to 10,000,000 copies/ml.

Amplicor HIV-1 Monitor

The Amplicor HIV-1 Monitor can be performed with the standard or UltraSensitive specimen processing procedure, which quantitates HIV-1 RNA in plasma over a range of 400 to 750,000 copies/ml or 50 to 75,000 copies/ml, respectively. The standard procedure includes a sample lysis step, followed by RNA precipitation with alcohol, while the ultrasensitive procedure involves ultracentrifugation of the virus particles in the sample prior to lysis and precipitation of the nucleic acid. A known concentration of QS RNA is added to each specimen along with the lysis reagent for quality control. Amplification of HIV-1 RNA in the plasma is mediated by RT-PCR, followed by PCR of the cDNA. One of the advantages of the Amplicor assay is the use of dUTP in the deoxynucleoside triphosphate mix. The enzyme uracil-*N*-glycosylase is added in the master mix reagent, which catalyzes the cleavage of DNA containing dUTP. Any contaminating amplicon from prior amplification reactions is destroyed at the start of the reaction, but the target amplicon is not affected. Colorimetric detection of the target amplicon is mediated by a probe-bound microplate containing sequences complementary to the target and QS. RNA is quantitated relative to the QS, which is a noninfectious RNA molecule with the same sequence as the target. The probe-binding sequence on the microplate distinguishes the QS amplicon from the target amplicon. A disadvantage of the Amplicor HIV-1 Monitor is that the assay has a smaller dynamic range than the RealTime HIV-1 and COBAS AmpliPrep/COBAS TaqMan HIV-1 assays. The Amplicor assay is also optimized for the detection of group M subtypes only.

Cautionary Remarks

Biological variation of HIV-1 RNA levels among clinically stable patients has been estimated to be approximately 0.3

$\log_{10}$. The abilities of commercial assays to be reproduced range from 0.1 to 0.3 $\log_{10}$ depending on the region of the assay's dynamic range. Numerous studies comparing the performances of the conventional FDA-approved viral load assays show high correlations between assays in terms of net changes in plasma RNA levels after antiretroviral therapy (63–65). Early assays showed larger variations in absolute values between assays with the same sample, but current-generation assays have been standardized so that the differences in values between assays are narrowing. The two real-time RT-PCR assays show improved correlation and agreement between viral load values (66). Although there is improved overall agreement between the different viral load assays, it is still considered optimal for patient care to monitor viral load values over time with the same assay.

HIV-1 RNA load testing is sometimes requested to resolve equivocal serologic findings, to facilitate the diagnosis of HIV-1 infection during the acute phase of infection, or to diagnose disease in children. Viral load tests can be performed for these purposes with a physician's order, but they are not approved by the FDA for the diagnosis of HIV-1 infection and they should be validated within a laboratory prior to routine use for these purposes. False-positive results can be obtained because of contamination during specimen processing, carryover of amplified products, or selection of incorrect thresholds for defining positivity.

ANTIVIRAL SUSCEPTIBILIES

Drug Resistance Testing

Antiviral drug resistance testing is an essential element in the management of antiretroviral therapy. Testing is important for the selection of initial regimens because of the prevalence of transmitted drug resistance in therapy-naive patients and is a recommendation of the Department of Health and Human Services (HHS). The HHS recommendations are updated periodically and can be found in reference 62. Drug resistance testing is also important for the selection of alternative antiretroviral treatment for patients who are failing their current regimen due to the development of antiviral resistance.

The clinical utility of HIV resistance testing has been evaluated in a number of prospective randomized clinical trials (67–69). Patients whose antiretroviral treatment was based on the results of resistance testing had greater decreases in viral load than patients in whom the antiretroviral regimen was based on prior antiretroviral usage, and the use of resistance testing to guide treatment is cost-effective (70, 71). Two types of methods are available to assay for HIV resistance. Genotyping tests examine the population of viral genomes in the patient sample for the presence of mutations known to confer decreased susceptibility to antiretroviral drugs. Phenotypic assays measure viral replication of the patient's virus in the presence of antiretroviral drugs. In addition, HIV tropism assays have become important to evaluate susceptibility to HIV entry inhibitors that inhibit viruses using the CCR5 coreceptor for cell entry. Table 5 provides a list of the currently available commercial HIV-1 resistance and tropism assays.

Genotyping Assays

The initial steps of genotypic assays for antiviral drug resistance include extraction of viral RNA from plasma and RT-PCR to amplify viral RNA sequences which code for portions of the viral genome that are targeted by antiretroviral drugs. These sequences include genes in the *pol* region of the virus for reverse transcriptase, protease, and integrase, as well as envelope regions related to the entry inhibitors. The nucleotide sequence is determined and examined for the presence of known resistance mutations. This can be accomplished most commonly using automated sequencing technology. The nucleotide sequence of the gene(s) of interest is obtained and compared to the sequence of wild-type virus to identify resistance mutations. The process requires alignment and editing of the sequence, comparison to the wild-type sequence, and final interpretation to identify mutations associated with resistance to specific antiretroviral drugs. FDA-approved kits containing sequencing reagents and the software programs required for sequence alignment and interpretation are commercially available. The Trugene HIV-1 genotyping kit, the OpenGene DNA sequencing system (Siemens Healthcare Diagnostics), and the ViroSeq HIV-1 Genotyping System (Abbott Molecular) have been found to perform in equivalent manners (72), although the Trugene kit may be coming off the market. These tests detect mutations in the reverse transcriptase and protease genes but do not detect mutations associated with resistance to the integrase or CCR5 inhibitors. The databases used for interpretation of resistance mutations require regular updating, as the number of new antiretroviral drugs continues to expand (http://hivdb.stanford.edu/).

One limitation of genotypic assays is that they are able to detect only mutants comprising major fractions of the patient's virus; resistant variants must constitute at least 25 to 30% of the virus population (73). Although the clinical significance of resistance mutations present at low levels remains to be fully elucidated, there is evidence that minor mutations which are missed by standard genotyping assays can lead to failure of subsequent treatments (74). Because standard genotyping assays lack sensitivity for low-frequency drug resistance mutations, efforts are under way to increase sensitivity by various methods, including PCR-based assays (75) and single-genome analysis (76). These techniques are not FDA approved, and the single-genome sequencing approach is not yet a practical clinical tool because the process is expensive and labor-intensive. However, next-generation sequencing technologies offer the promise of decreasing the cost of sequencing, and evaluations of this approach for clinical laboratories are under way (77).

Phenotyping Assays

Phenotyping assays measure the ability of HIV-1 to grow in the presence of various concentrations of an antiretroviral agent. The amount of drug required to inhibit virus replication by 50% or by 90% is determined and given as a 50% or 90% inhibitory concentration (IC_{50} or IC_{90}). The IC_{50} or IC_{90} obtained with the patient sample is compared to that of a control wild-type virus, and the result is reported as a relative difference. Early phenotypic resistance assays were labor-intensive because they necessitated the isolation and culture of HIV from the patient's specimen. Currently, commercially available methods use HIV-1 RNA amplified from plasma and are based on recombinant DNA technology. These phenotypic assays are automated but remain labor-intensive and technically complex. One such commercial assay is available from Monogram Biosciences (South San Francisco, CA). The first step involves extraction of HIV-1 RNA from plasma. Reverse transcription and PCR amplification of the protease and reverse transcriptase genes follow. The amplified genes from the patient's specimen are then inserted into vectors, and recombinants are used in culture to examine resistance against a drug concentration gradient. The PhenoSense assay (Monogram Biosciences) uses an HIV-1 vector

TABLE 5 Assays for drug resistance and cell tropism determination

Test(s) (manufacturer)	Format	Description
Trugene HIV-1 genotyping kit and OpenGene DNA sequencing system (Siemens Healthcare Diagnostics, Tarrytown, NY)	Genotypic resistance	Detects mutations known to be associated with protease and reverse transcriptase drug resistance
ViroSeq HIV-1 Genotyping System (Abbott Molecular, Des Plaines, IL)	Genotypic resistance	Detects mutations known to be associated with protease and reverse transcriptase drug resistance
Integrase and envelope genotypes (various commercial labs)	Genotypic resistance	Sequence analysis of integrase or envelope genes to identify mutations associated with resistance to integrase inhibitors or the fusion in inhibitor enfuvirtide (Fuzeon)
PhenoSense HIV (reverse transcriptase and protease inhibitors) (Monogram Biosciences, South San Francisco, CA)	Phenotypic resistance	Measures decrease in virus replication in the presence of reverse transcriptase and protease inhibitors
PhenoSense for entry inhibitor susceptibility (Monogram Biosciences, South San Francisco, CA)	Phenotypic resistance	Measures decrease in virus replication in the presence of entry inhibitors
PhenoSense integrase (Monogram Biosciences, South San Francisco, CA)	Phenotypic resistance	Measures decrease in virus replication in the presence of integrase inhibitors
SensiTrop II HIV coreceptor tropism (Pathway Diagnostics, Malibu, CA)	Genotypic cell tropism	Virus gene sequences used to predict CCR5 cell tropism
Trofile coreceptor tropism (Monogram Biosciences, Inc., South San Francisco, CA)	Phenotypic cell tropism	Single-round virus replication assay which uses envelop sequences from patient viruses to determine the ability to replicate in cells with CCR5, CXCR4, or both coreceptors

with a luciferase reporter gene that replaces the viral envelope gene, allowing viral replication to be quantified by measuring luciferase activity. PhenoSense tests are also available to measure resistance to the entry inhibitor and integrase inhibitors. As with genotypic testing, the phenotypic assays can detect only mutant variants that comprise at least 25% of the viral population. The combination of genotyping and phenotyping tests may offer a benefit to patients by better resolving potentially conflicting test results.

Tropism Assays

A new CCR5 inhibitor, maraviroc, has brought about a need for a tropism assay, because the drug is effective only against virus that uses CCR5 as a coreceptor for entry. The drug is not active against CXCR4-tropic virus or dual-tropism or mixed-tropism virus. The tropism assay must be performed prior to initiating maraviroc or any other CCR5 inhibitor to determine whether the virus is CCR5 tropic. As with drug resistance assays, there are two general approaches in use, and two tropism assays are commercially available. The Trofile (Monogram Biosciences) uses the phenotypic approach, and the SensiTrop II HIV coreceptor tropism assay (Pathway Diagnostics, Malibu, CA) uses the genotypic approach. For the Trofile assay, the *env* gene from the patient is amplified and used to construct pseudoviruses. Coreceptor tropism is then determined by measuring the ability of the pseudoviral population to infect CD41/U87 cells that express either CXCR4 or CCR5. Depending on which cells they infect, the viruses are then designated CXCR4 tropic, CCR5 tropic, or tropic to both. The SensiTrop assay uses a heteroduplex tracking assay combined with sequence analysis to identify minor viral populations that may be CXCR4 tropic. Only patients that are solely CCR5 tropic are candidates for a CCR5 inhibitor. Resistance to maraviroc has been reported and results from the development of mutations that allow the virus to use CXCR4 coreceptors or mutations that lead to structural changes in the envelope that prevent the drug from being effective (78, 79). In addition to the commercially available tropism assays, research tools are being developed for the prediction of virus tropism, including prediction of affinity for CCR5 binding (80) and next-generation sequencing to predict viral quasi-species binding to CXCR4 (81).

QUALITY ASSURANCE PROGRAM

All laboratories that report results for clinical care must have a quality assurance program in place. This includes quality control and proficiency testing to ensure the accuracy of laboratory results. Such a program consists of written policies and procedures that the laboratory has implemented to ensure that its performance is acceptable to its clients and regulatory agencies. Information related to the Clinical Laboratory Improvement Act can be found at the Web link https://www.cms.gov/Regulations-and-Guidance/Legislation/CLIA/index.html?redirect=/clia/.

CONCLUSIONS

HIV diagnostic and prognostic assays have continued to evolve as information has been gained about virus replication, therapy, and the importance of timely diagnosis and monitoring. As a result of this evolution, new tests and algorithms that allow for earlier diagnosis of infection and improved patient monitoring are available.

The Primary Immunodeficiency Diseases

HOWARD M. LEDERMAN

73

Patients with primary immunodeficiency diseases most often are recognized because of their increased susceptibility to infection (chronic or recurrent infections without other explanation, infection with an organism of low virulence, or infection of unusual severity). However, these patients may also present with autoimmune or inflammatory disorders (e.g., hemolytic anemia, inflammatory bowel disease, vasculitis, or systemic lupus erythematosus) or as part of a syndrome complex (Table 1). Finally, in the future we will see an increasing number of people who are identified as having an immunodeficiency because of an abnormal newborn-screening test for T-cell receptor-excision circles (TRECs) or a mutation identified by genome sequencing.

SYMPTOMS OFTEN CAN GUIDE THE LABORATORY EVALUATION

The type of pathogen and the location of the infection may give valuable insight into the nature of the immunologic defect. For example, individuals with antibody deficiencies are unusually susceptible to encapsulated bacteria and enteroviruses, which cause infections along mucosal surfaces. Individuals with defects in cell-mediated immunity can have problems with almost any microorganism, including opportunistic pathogens. Individuals with complement deficiencies most often present with bacteremia, septic arthritis, and meningitis, caused by encapsulated bacteria. Phagocytic disorders are characterized by bacterial and fungal infections of the skin and abscesses in the reticuloendothelial system (lymph nodes, spleen, and liver). Defects in natural killer cell function cause life-threatening viral infections and hemophagocytic lymphohistiocytosis (HLH).

Autoimmune and inflammatory diseases are more commonly seen in particular primary immunodeficiency diseases, most notably common variable immunodeficiency, selective immunoglobulin A (IgA) deficiency, chronic mucocutaneous candidiasis, and deficiencies of early components of the classical complement pathway (C1 to C4).

When immunodeficiency is part of a constellation of signs and symptoms in a syndrome complex, the diagnosis of immunodeficiency may be made before there are any clinical manifestations of that deficiency. For instance, children with DiGeorge syndrome are most often first identified because of the neonatal presentation of congenital heart disease and/or hypocalcemic tetany. This should lead to T-lymphocyte evaluation prior to the onset of opportunistic infections. Similarly, a diagnosis of Wiskott-Aldrich syndrome can often be made in young boys with eczema and thrombocytopenia even prior to the onset of infections.

LABORATORY EVALUATION

Although immune system dysfunction can be suspected by the clinician after careful review of the history and physical exam, specific diagnoses are rarely evident without the use of the laboratory. However, the types of infections and other symptoms should help to focus the laboratory workup on specific compartments of the immune system (Table 2).

TABLE 1 Examples of immunodeficiency syndromes

Syndrome	Usual clinical presentation(s)	Immunologic abnormality
DiGeorge syndrome	Congenital heart disease, hypoparathyroidism, abnormal facies	Thymic hypoplasia
Wiskott-Aldrich syndrome	Thrombocytopenia, eczema	Variable B- and T-lymphocyte dysfunction
Ataxia-telangiectasia	Ataxia, telangiectasia	Variable B- and T-lymphocyte dysfunction
Ivemark syndrome	Congenital heart disease, bilateral three-lobed lungs	Asplenia
Polyendocrinopathy syndrome	Endocrine organ dysfunction	Chronic mucocutaneous candidiasis

doi:10.1128/9781555818722.ch73

TABLE 2 Patterns of illness associated with primary immunodeficiency

Disorder	Illnesses	
	Infection	Other
Antibody	Sinopulmonary (pyogenic bacteria) Gastrointestinal (enterovirus, giardiasis)	Autoimmune disease (autoantibodies, inflammatory bowel disease)
Cell-mediated immunity	Pneumonia (pyogenic bacteria, *Pneumocystis jiroveci*, and viruses) Gastrointestinal (viruses) Skin, mucous membranes (fungi)	
Complement	Sepsis and other blood-borne infections (streptococci, pneumococci, and neisseriae)	Autoimmune disease (systemic lupus erythematosus, glomerulonephritis)
Phagocytosis	Skin, reticuloendothelial system, abscesses (*Staphylococcus*, enteric bacteria, fungi, and mycobacteria)	
Natural killer cells	Herpes family and papilloma viruses	Hemophagocytic lymphohistiocytosis

Screening tests that should be performed for almost all patients include a complete blood count with differential, and quantitative measurement of serum immunoglobulins. Other tests should be guided by the clinical features of the patient (Table 3). Finally, whenever primary immunodeficiency is suspected, consideration must also be given to secondary causes of immunodeficiency, including infections (e.g., HIV and Epstein-Barr virus), therapy with anti-inflammatory or immunosuppressive medications (e.g., corticosteroids, rituximab), and other underlying illnesses (e.g., lymphoreticular neoplasms and protein-losing enteropathy). Details about the selection and performance of specific laboratory tests are discussed in the following chapters, organized by immunologic compartment: antibody, cell-mediated immunity (severe combined immunodeficiency), complement, phagocytes, and natural killer cells.

TABLE 3 Screening tests for primary immunodeficiency

Suspected abnormality	Diagnostic test(s)
Antibody	Quantitative immunoglobulins (IgG, IgA, and IgM) Antibody response to immunization
Cell-mediated immunity	Lymphocyte count T-lymphocyte enumeration (CD4 and CD8) HIV serology Delayed-type hypersensitivity tests
Complement	Total hemolytic complement
Phagocytosis	Neutrophil count Nitroblue tetrazolium dye test or equivalent
Natural killer (NK) cells	NK cell enumeration NK function, measurement of intracellular perforin

Severe Combined Immune Deficiency: Newborn Screening

JAMES W. VERBSKY AND JOHN M. ROUTES

74

PURPOSE AND BENEFIT OF NEWBORN SCREENING

The history of newborn screening (NBS) in the United States began in 1963, when Guthrie demonstrated that phenylketonuria (PKU) can be detected using dried blood spots (DBSs) on filter paper from newborns (1). Neonatal testing for PKU proved to be inexpensive, sensitive, specific, and amenable to high-throughput screening. The ability to screen neonates for other serious diseases increased dramatically, and in 1968, Wilson and Jungner published a landmark report that included guidelines for population-based health screening (Table 1) (2). This report tried to balance the desire for early detection and treatment of disease with the potential harms to patients, family, and society. The report defined principles for NBS programs and has undergone revisions to address concerns for both newborn screening and population-based screening programs in general (Table 1) (3–5).

SCID as a Model Disorder for NBS

Severe combined immunodeficiency (SCID) is a genetically heterogeneous group of disorders with a common phenotype characterized by profound deficiencies in cellular and humoral immunity (6–9). The vast majority of infants with SCID lack lymphoid tissue. However, this finding is frequently missed on routine physical examination, and most infants otherwise appear physically normal at birth. Subsequently, these infants develop failure to thrive, severe infections, and ultimately death, without intervention. Absent NBS, the median age of diagnosis of SCID is 6.6 months, with an average delay of 2 months from the onset of symptoms to diagnosis (10, 11). Viral and opportunistic infections acquired in the first few months of life can be persistent and fatal, even with aggressive treatment (9, 11, 12). Importantly, the current Centers for Disease Control and Prevention recommendation for vaccinations includes the live attenuated rotavirus vaccine at 2 months, which causes life-threatening rotavirus infection in children with undiagnosed SCID (13–16).

SCID is estimated to occur in 1 in 50,000 to 100,000 live births (17). More recent estimates based on preliminary data by NBS screening programs in the United States put the incidence closer to 1:40,000 to 1:60,000 (18–20). SCID is treated through immunologic reconstitution by hematopoietic stem cell transplantation (HSCT) (6) or, in certain cases, gene therapy (e.g., X-linked SCID, adenosine-deaminase [ADA] deficiency) (21, 22). ADA deficiency can also be treated with enzyme replacement (23). Children who receive HSCT early in life, before the development of severe infections, have improved survival and immune reconstitution (6, 10, 24). For example, at one center, infants who received HSCT before 3.5 months had a 95% survival rate, compared with a 76% survival rate for those who received HSCT later (6).

There are several characteristics that fulfill the criteria proposed by Wilson and Jungner and that make SCID an ideal disease for NBS (2). The incidence of the disease is high enough to warrant screening, there is a test amenable to population-based screening that detects SCID (i.e., the T-cell receptor excision circle [TREC] assay), and there is a definitive and potentially curative treatment for the disease. Finally, the cost associated with screening all infants and the treatment of the infants found to have SCID needs to be considered. This is a complex question and can be definitively answered only when NBS screening for SCID is widely used. However, there are studies that have modeled NBS for SCID, taking into account numerous factors, and indicate that it is cost effective if the screening test is sufficiently robust and relatively inexpensive (25).

BRIEF OVERVIEW OF TYPES OF SCREENING AND METHODOLOGY

Newborn screening refers to any testing done on all infants during the newborn period and includes both blood-based and other modalities. For example, NBS for hearing defects is performed in a number of states. Blood-based screening tests include sickle cell anemia, hypothyroidism, and cystic fibrosis. With the advent of tandem mass spectroscopy, the number of metabolic disorders screened at birth increased greatly. SCID is the first disease in which the NBS assay uses DNA-based technology.

Current NBS programs in the United States and elsewhere (Brazil, Canada) use the TREC assay to screen neonates for SCID. However, other methods of screening for SCID have been proposed, such as determining the absolute lymphocyte count from a complete blood count (CBC) or by flow cytometry (9, 26). These screening modalities have significant shortcomings, including the cost of a CBC and the need to obtain, transport, and analyze an additional blood sample. A normal absolute lymphocyte count will

doi:10.1128/9781555818722.ch74

TABLE 1 Criteria for newborn screening[a]

The incidence of the disease should be sufficiently high to warrant screening.
The disorder should not be readily identifiable by physical examination.
The disorder should cause serious medical complications.
There should be an accepted treatment for patients with recognized disease.
There must be a sensitive and specific screening test.
The screening test should be economically viable.
There should be a definitive confirmatory test.

[a]Adapted from reference 55.

result in a small but significant rate of false negatives in infants with SCID due to maternal engraftment of T cells, certain subtypes of SCID that have normal numbers of B and NK cells, or SCID due to hypomorphic mutations that result in expansion of a few clones of T cells (9, 27, 28).

Other modalities to detect SCID have been proposed, including assays to detect interleukin-7 (IL-7) or T cell-specific proteins in the peripheral blood. High IL-7 levels are associated with T-lymphopenic states, and one study demonstrated that 11 of 13 infants with SCID had high levels of IL-7 in the serum or extracts from DBSs (29). The use of the IL-7 assay to detect SCID has not been replicated to date. Other studies have evaluated serum levels of T cell-specific proteins, including CD3 or CD45 (30). These modalities have not been implemented as population-based screening tests, but have been proposed as ancillary or follow-up testing.

The TREC Assay

The TREC assay is currently the test used for neonatal screening for SCID and relies on the fact that all forms of SCID lead to a reduction in the number of naive T cells in the affected infant. The theoretical basis of the TREC assay is as follows. In order to exit the thymus, all T cells must express a functional T cell receptor (TCR). In the normal development of T cells, the variable (V), diverse (D), and joining (J) segments of the TCR genes undergo a process of DNA rearrangement that involves DNA breakage and repair. This rearrangement process brings distant segments of the TCR genes together (VDJ rearrangement). The by-products of this process are small, circular, nonreplicating pieces of DNA known as TRECs. The δRec-ψJα TREC is produced by approximately 70% of all T cells that express the α/β T cell receptor, which is the most common type of TCR produced by the thymus (31). By performing RT-qPCR using DNA extracted from the DBS, the TREC assay enumerates the copy number of the δRec-ψJα TREC (32). Since TRECs do not replicate, the number of TRECs per cell is diluted as T cells divide into memory T cells. Consequently, TRECs serve as a biomarker of naive T cells (33).

The ability of the TREC assay to serve as a biomarker for naive T cells is extremely important. In some cases of SCID or so-called "leaky" SCID, the specific mutation may result in a gene that encodes for a protein that has partial activity. Consequently, a small number of T cells may be generated in the thymus and then expand in the periphery of the affected infant and cause disease (e.g., Omenn's syndrome). In other cases, T cells from the mother may engraft in the infant. Infants with hypomorphic mutations in genes that cause SCID or Omenn's syndrome, or infants with maternally engrafted T cells, may not have profound T cell lymphopenia. However, the majority of T cells in these infants will have expanded by cellular division and are memory T cells (CD45RO+). TRECs do not replicate, and therefore the number of TRECs enumerated by the TREC assay will be abnormally low. Thus, regardless of the molecular cause, in all forms of SCID there is a profound reduction of naive T cells that will be detected by the TREC assay (28, 31, 34). It is important to acknowledge that the TREC assay will detect SCID as well as known and unknown causes of T cell lymphopenia (TCL).

NBS cards are sent to central labs in extremely variable environmental conditions, which may result in poor DNA template integrity. In addition, the DBS may contain substances that inhibit the PCR component of the TREC assay. For example, there are times when the blood is obtained through an intravenous line rather than the conventional heel stick (35). In either of these cases, the resulting TREC number may be falsely low. This important issue is addressed by performing RT-qPCR using the same DNA as the TREC assay on a housekeeping gene such as β-actin.

Optimization and Validation of the RT/PCR Reaction for TRECs

Successful implementation of NBS for SCID using the TREC assay requires careful optimization of the assay to ensure sensitivity and reproducibility. Optimizing the yield of DNA extracted from DBSs, as well as amplification efficiency of the RT-qPCR reaction, is essential. Once optimized, reproducibility of the assay should be determined on DNA isolated from DBSs. Finally, the sensitivity of the assay should be determined. This is ideally determined with blood spots with specific amounts of TRECs added, which can be accomplished with leukocyte-poor blood or blood from a known SCID patient. Attempts have been made to standardize the TREC assay with cell lines that express a single TREC per cell (36). Finally, a pilot study using large numbers of anonymized NBS cards should be performed to determine the range and variability of the assay (34).

Determination of TREC Cutoff Value and Sensitivity

As NBS for SCID moves forward in other states and countries, the number of TRECs considered abnormally low as determined by the TREC assay must be determined empirically. The different laboratories performing the TREC assay use different methodologies of DNA extraction and RT-qPCR. Even laboratories utilizing the very similar methodologies have reported different sensitivities in the TREC assay. Thus, before implementation for NBS, it is important that each laboratory establish its unique TREC cutoff values. In Wisconsin, the number of TRECs considered abnormally low was empirically determined based on a pilot study of 10,000 anonymized blood spots (34). In addition, the cutoff value for the TREC assay needs to be adjusted longitudinally, as small changes in any component of the assay may result in slightly enhanced or reduced assay efficiency.

During the first 5 years of screening for SCID in Wisconsin, 340,037 infants were screened; 0.03% of term births and 0.48% of preterm births (<37 weeks adjusted gestational age [AGA]) were abnormal on initial testing (Table 1) (20). The rate of inconclusive results due to a low β-actin level was 0.03% in term infants and 1.25% in preterm infants. Thus, the repeat testing rate of preterm infants (inconclusive and abnormal results) and full-term infants (inconclusive results) was 0.18%. In total, 110 infants were ultimately classified as abnormal after repeat screening of inconclusive results (20).

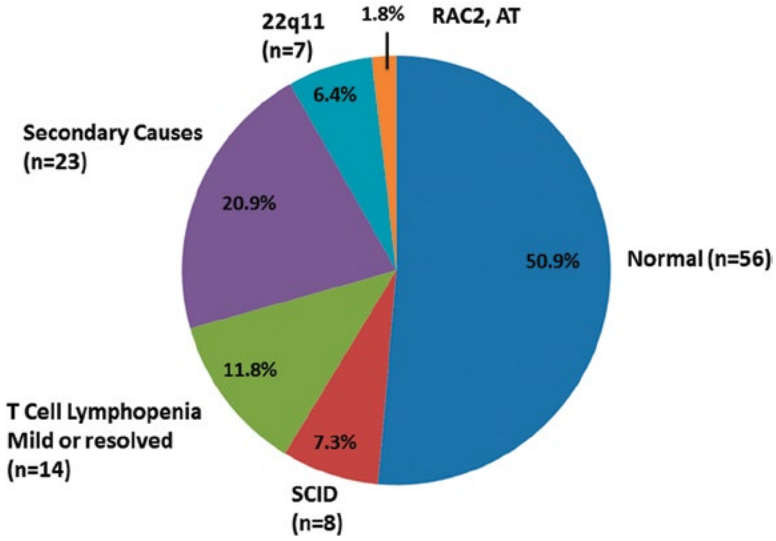

FIGURE 1 Final diagnoses of 110 infants with abnormal TREC screen for SCID. Secondary causes include metabolic disorders, chromosomal abnormalities, infections (e.g., necrotizing enterocolitis, sepsis). 22q11, 22q11 deletion syndrome; AT, ataxia telangiectasia.

Of these, 56 infants were ultimately found to be normal, resulting in a false-positive rate of 0.016% and a specificity of 99.98% (Fig. 1). Fifty-four infants were found to have TCL of varying degrees, giving a positive predictive value of the TREC assay predicting TCL of 49%.

FOLLOW-UP ALGORITHM AND RESULTS OF NBS FOR SCID

In Wisconsin, an algorithm was developed that established a standard operating protocol for the TREC assay, and this was in part based on the high false-positive rate of preterm infants (35). Briefly, full-term infants with a TREC level below the cutoff were first tested for DNA integrity by analyzing β-actin by RT-qPCR. If the β-actin level was normal with abnormally low TRECs, an abnormal report was issued, and the primary care provider was contacted for confirmatory testing by flow cytometry. If the β-actin result was low, an inconclusive report was issued, and the screening test was repeated with a new newborn screening card. For preterm infants with an abnormal or inconclusive TREC assay, the screening test was repeated either until it was normal or until the infant reached 37 weeks AGA, at which time the infant's results were reclassified as an abnormal. Lymphocyte subset analysis by flow cytometry was recommended on all full-term infants and all preterm infants with an AGA of 37 weeks with an abnormal TREC assay. Infants with an abnormal flow cytometry were then referred for evaluation by a clinical immunologist.

Each state that has implemented NBS for SCID has generated an algorithm for follow up of positive NBS results. In some states, DNA integrity is determined using a control gene (β-actin or RNase P) at the time of the initial TREC analysis using multiplex assays (37). In contrast, other states such as Wisconsin check DNA integrity only if the TREC assay is abnormal (19, 35). Determining DNA integrity at the time of TREC analysis is convenient, but it may increase the cost of the assay due to the need for extra primers and fluorescent probes. In Wisconsin, a repeat TREC assay is performed using DNA obtained from a different part of the DBS on all abnormal TREC assays. By repeating abnormal TREC assays and retesting infants until they reach an AGA of 37 weeks, the number of infants who have needed the much more costly lymphocyte subset analysis performed by flow cytometry has been reduced.

Findings in 5 Years of NBS in Wisconsin

Of infants with an abnormal TREC assay who were found to have TCL, 43% ($n = 23$) had secondary causes for their TCL such as anatomic abnormalities of the lymphatics, chromosomal abnormalities, multiple congenital anomalies, infections (necrotizing enterocolitis or sepsis), or a presumed metabolic disorder (Table 2). The remaining 30 infants had primary TCL, including 7 infants with 22q11.2 deletion syndrome, 14 infants with idiopathic mild TCL, 8 infants with SCID/severe TCL, 1 infant with ataxia telangiectasia, and 1 infant with a *RAC2* mutation. Of note, no known cases of SCID have been identified in infants screened in Wisconsin since the implementation of neonatal screening in 2008. For comparison, we show the results of 2 years of NBS for SCID of 993,724 infants in California (Table 3).

TABLE 2 Initial screening results and results of confirmatory flow cytometry[a]

Testing	Abnormal	Inconclusive
Initial testing (340,037 births)		
Preterm (30,664; 9%)	147 (0.48%)	382 (1.25%)
Term (309,373; 91%)	99 (0.03%)	90 (0.03%)
Second testing (110 abnormal)	54 (49%) (lymphopenic)	56

LIMITATIONS WITH SCID AND NON-SCID IDENTIFICATION THROUGH NBS PROGRAMS

Vunerable Populations (Amish, Athabascans, etc.)

It is clear that the TREC assay is effective at identifying SCID. However, all mass screening programs require screening of all infants to ensure that these rare patients are not missed. This becomes problematic with certain populations that may be unwilling to undergo NBS, such as the Amish, Mennonite, or Navajo Indian populations. Due to consanguinity, these populations exhibit much higher rates of SCID than the general population (38). In these situations, babies with SCID may be missed until they have SCID-defining illnesses. It is essential that outreach programs approach these communities to inform them of the NBS assays, what they detect, and how these disorders are treated, in hopes of alleviating any fears regarding the screening program.

Immune Deficiencies Not Detected

Although the TREC assay detects a variety of causes of SCID and TCL, several serious immune defects could be missed by the TREC assay. In bare lymphocyte syndrome, there is a defect in HLA class II expression resulting in loss of development of CD4 T cells. Since CD8 cells are still present, these patients likely will express approximately one-third the level of TRECs present in a normal infant, which could be above the cutoff value. In this regard, an infant screened for SCID who had bare lymphocyte syndrome was not detected (39, 40). In delayed ADA deficiency, the initial TREC value at birth can be normal but become negative later in life (41). In addition, there are serious SCID-like illnesses that do not result in a lack of T cells. Defects in ORA1, STIM1, or CD25 result in illness with a severe propensity to opportunistic and other infections, but these disorders can have relatively normal T cell counts (42–45). Thus, primary immunodeficiencies should still be considered in children presenting with SCID-defining disorders (e.g., failure to thrive, opportunistic or severe infections), even if NBS for SCID was normal.

Since the TREC assay detects any form of TCL, it is not uncommon to detect an infant with a T cell level that is low but not at levels typically seen in SCID (<200 T cells/mm^3); these disorders can be considered combined immunodeficiencies (CID). The decision of whether to perform HSCT on infants with CID can be difficult, particularly if a specific genetic mutation known to cause CID is not identified. This illustrates why it is of the utmost importance that infants with SCID or CID identified by the TREC assay should be referred to centers of excellence in the diagnosis and treatment of primary immunodeficiencies.

The more widespread implementation of the NBS using the TREC assay has resulted in some unexpected findings. One infant was identified with immunodeficiency due to a *de novo* mutation in the *RAC2* gene, the second reported case of this primary immunodeficiency (46). The previously described case of a *RAC2* mutation resulted in immunodeficiency secondary to dysfunction of neutrophils (47). However, immunological assessment of the infant identified by neonatal screening for TCL demonstrated both neutrophil and T cell abnormalities. In addition, two cases of Jacobsen syndrome have been detected, and reports have linked this chromosomal abnormality with the development of common variable immunodeficiency (20, 48–50). Finally, a case of DOCK8 deficiency has been detected by the TREC assay (51). These cases illustrate that the NBS using the TREC assay will identify infants with known and unknown cellular immunodeficiencies.

Finally, the TREC assay will not detect defects in B cell development, such as x-linked agammaglobulinemia. A RT-qPCR-based assay has been developed that detects excision circles that are generated during B cell receptor formation. Similar to T cell receptor development, B cell receptors are generated by the rearrangement of the light chains of the B cell receptor (i.e., kappa and lambda chains) and the heavy chain of the B cell receptor, resulting in the production of circular episomal pieces of DNA known as kappa receptor excision circles (KRECs). The KREC assay is able to detect all forms of inherited agammaglobulinemia characterized by an absence or near absence of naive B cells (52, 53). Since the KREC assay is performed in a similar manner to the TREC assay, a TREC/KREC multiplexed assay could be used to screen for defects in both T and B cell development. This multiplexed assay could be performed with a minimal increase in cost, as only an extra primer pair and probe need to be added to the RT-qPCR assay. Although congenital agammaglobulinemias do not inevitably result in death, when they are undiagnosed they are associated with significant morbidity and mortality (54). As definitive therapy that may lead to a normal or near-normal life expectancy exists for congenital agammaglobulinemias (i.e., intravenous or subcutaneous immunoglobulin replacement), it appears that these disorders may fulfill the abridged criteria for NBS proposed by Wilson and Jungner. However, the KREC assay has yet to be implemented on a statewide basis, and the issue of fulfilling the NBS criteria is still a matter of debate.

SUMMARY

The establishment and implementation of the TREC assay for SCID has proven highly effective in the detection of SCID as well as other primary immune deficiencies. Successful implementation of this program requires a validated,

sensitive assay and appropriate algorithms for follow up of abnormal results. Since this assay detects a variety of defects other than SCID, and evaluating these infants can be difficult, referral to a clinical immunologist with expertise in the evaluation and treatment of SCID and other primary immune deficiencies is recommended. The DNA-based TREC assay is amenable to multiplex analysis, which allows the addition of other tests such as the KREC assay for B cell defects with incremental increases in cost.

Combined Immunodeficiencies

CHRISTINE SEROOGY AND MELISSA ELDER

75

This chapter is dedicated to describing combined immunodeficiencies (CIDs) and useful diagnostic assays. Here, a CID is defined as a defect that affects the two most prominent arms of the adaptive immune system: T cells and B cells. The molecular defect may directly affect both cell types or just one cell type, specifically T lymphocytes, with indirect effects on B-cell function. CIDs are distinguished from severe combined immunodeficiencies (SCIDs) because T-cell numbers and function are higher than per established criteria for SCID and thus may not be detected on SCID newborn screening (NBS). Several CIDs are attributed to distinct genetic mutations in SCID-associated genes. In recent years, the field of immunology has witnessed increased reporting of unique CIDs affecting isolated families or small numbers of individuals. This increase is attributable to the advent of improved genetic testing, such as whole-exome sequencing. In Table 1, we provide a comprehensive list of CIDs, their immunophenotypes, and useful diagnostic tests. Common themes for CIDs include aberrant T-cell development, function, cytoskeletal regulation, and survival. These defects translate to clinical problems secondary to immune deficiency and, in many instances, immune dysregulation. This chapter does not include in-depth description of all CIDs but rather focuses on categorical descriptions and highlights more prevalent genetic abnormalities along with overviews of diagnostic assays for CID confirmation.

ABNORMALITIES OF THYMOPOIESIS

Defects in T-Cell Development

T-cell development occurs in the thymus over a period of 2 weeks in humans and via a complex series of gene rearrangements and productive T-cell signals mediated by interactions between thymic stromal cells, bone marrow-derived antigen-presenting cells, and developing thymocytes. These interactions provide signals to developing thymocytes to survive, proliferate, and egress from the thymus to the periphery. Profound defects in any of these pathways result in severely diminished T-cell development and a SCID immunophenotype. Defects that partially affect T-cell development result in CID.

MHC Class I and II Deficiencies

A number of genetic defects have been described for both major histocompatibility complex (MHC) class I and II deficiencies with an associated broad spectrum of clinical phenotypes, ranging from mild defects to severe and life-threatening (Table 1). Defects in MHC-I affect $CD8^+$ T-cell development without impairing $CD4^+$ T cells (1), while defects in MHC-II affect $CD4^+$ T-cell development and spare $CD8^+$ T cells (2). The most common cause of MHC-I deficiency is a homozygous inactivating mutation in one of the two subunits of the protein transporter associated with MHC-I endoplasmic reticulum processing (*TAP1* and *TAP2*). Severe clinical phenotypes of MHC-II deficiency or "bare lymphocyte syndrome" that would be classified as SCID are most often due to homozygous mutations in essential transcription factor genes, such as *CIITA*, required for MHC-II gene transcription. Interestingly, MHC-II deficiency is not detected on SCID NBS (3). Genetic mutations in *CD8A*, encoding the CD8α chain, have been described in one family and represent another example of a critical interaction between T-cell surface receptors and MHC molecules on thymic stromal cells during T-cell development (4).

Diagnostic Evaluation

MHC-I deficiency. Flow cytometry for lymphocyte subset enumeration demonstrates decreased peripheral blood $CD8^+$ T cells, and diagnosis is supported by unsuccessful serological HLA class I typing but normal molecular typing or observation of significantly diminished cell surface expression of MHC-I antigens by flow cytometry using a pan-anti-HLA class I antibody (such as clone W6/32). These patients are often from consanguineous families and have homozygous HLA genotyping. Rare causes of MHC-I deficiency, including transcription defects, may be characterized using Epstein-Barr virus (EBV)-transformed B-cell lines before and after incubation with proinflammatory cytokines.

MHC-II deficiency. Decreased $CD4^+$ T cells by flow cytometry and diminished *in vitro* T-cell responses to foreign antigens in proliferative assays or in mixed lymphocyte culture are seen. Hypogammaglobulinemia with inability to make specific antibody is typical despite normal B-cell numbers. Diagnosis is confirmed by absence of cell surface expression of MHC-II antigens on peripheral blood mononuclear cells (PBMCs) and EBV-transformed B-cell lines by flow cytometry or by serological HLA class II typing.

doi:10.1128/9781555818722.ch75

TABLE 1 CIDs, their immunophenotypes, and useful diagnostic tests

Combined immunodeficiency disease	Gene mutation(s)	Immunophenotype	Useful diagnostic tests	Reference(s)
Defects in T-cell development				
MHC-II deficiency	*CIITA* (*MHC2TA*), *RFX5*, *RFXAP*, *RFXANK*	Absent MHC-II expression, low $CD4^+$ T cells, diminished T-cell-antigen-specific function	Flow cytometry, T-cell function	2, 43
MHC-I deficiency	*TAP1*, *TAP2*, *TAPBP*	Diminished $CD8^+$ T cells	Flow cytometry	1
CD8α deficiency	*CD8A*	Absent CD8 T cells, increased $CD3^+CD4^-CD8^-$ $TCR\alpha\beta^+$ T cells	Flow cytometry	4
Cartilage hair hypoplasia	*RMRP*	T-cell lymphopenia	T-cell function, flow cytometry, TREC	5
Defects in DNA repair and recombination				
Rag1/2 hypomorphic mutations	*RAG1*, *RAG2*	$CD4^+$ T-cell lymphopenia, normal Vβ gene usage	Flow cytometry	8, 44–46, 72
Ataxia telangiectasia	*ATM*	T-cell lymphopenia, variable T- and B-cell dysfunction	Flow cytometry, T-cell function	12, 47
Omenn syndrome	*RAG1*, *RAG2*, *IL7RA*, *DCLRE1C*, *AK2*	Oligoclonal and activated T cells, poor T-cell function, hyper-IgE, hypereosinophilia	T-cell proliferation, spectratyping, TREC, flow cytometry	8–11, 21, 48
Defects in proximal T-cell activation				
ORAI-1 deficiency (CRAC channel defect)	*ORAI1*	Normal lymphocyte numbers, diminished T-cell function	T-cell calcium flux	49, 50
Stromal interaction molecule (STIM-1) deficiency	*STIM1*	Normal lymphocyte numbers, diminished T-cell function	T-cell calcium flux	50
CD3γ deficiency	*CD3G*	Mild T-cell lymphopenia, diminished T-cell function, diminished naive T cells	Flow cytometry, TREC, T-cell function	13, 51
TCRα deficiency	*TRAC*	Defective surface expression of TCRαβ, diminished T-cell function, intact humoral function	Flow cytometry, T-cell function	52
Hyper-IgM (CD40 ligand deficiency)	*CD40LG*	Hyper-IgM, hypogammaglobulinemia	Flow cytometry	16, 53
Defects in T-cell signal transduction pathways				
Lymphocyte-specific protein kinase (Lck) deficiency	*LCK*	$CD4^+$ T-cell lymphopenia, defective T-cell activation, low-level CD4 and CD8 surface expression	Flow cytometry, T-cell function, spectratyping	18, 54
ζ chain-associated protein of 70 kDa (ZAP-70) deficiency	*ZAP-70*	Absent CD8 T cells, defective TCR signaling, defective specific humoral antibody response	Flow cytometry, T-cell function	19
Uncoordinated 119 (Unc119) deficiency	*UNC119*	$CD4^+$ T-cell lymphopenia, defective T-cell activation, intact humoral function	Flow cytometry, T-cell function	17, 20

Defects in cytokine signaling pathways				
IL-21R deficiency	*IL21R*	Poor B-cell differentiation, diminished T-cell cytokine production, defective NK-cell function	Flow cytometry	55
Autosomal dominant hyper-IgE syndrome	*STAT3*	Impaired T-cell memory, impaired Th17 differentiation, impaired T-cell function	Memory-T-cell enumeration, Th17 differentiation, T-cell function	27, 28, 56, 57
JAK3 G2775(+3)C	*JAK3*	Lymphoproliferation, skewed TCR repertoire	Flow cytometry, Vβ gene usage	23
STAT5b deficiency	*STAT5B*	T-cell lymphopenia, diminished lymphocyte proliferation, decreased Treg-cell number	Treg-cell function and enumeration, T-cell function	26, 58
CD25 deficiency	*IL2RA*	Lymphoproliferation, increased T-cell activation markers, diminished antigen-specific T-cell responses	Flow cytometry, Treg-cell function and enumeration	24, 59, 60
Common γ chain, p.R222C	*IL2RG*	Normal T-, B-, and NK-cell numbers, normal T-cell function, normal immunoglobulins with diminished vaccine response	IL-2 response, vaccine antibody response	22, 61
Defects in T-cell survival				
Mammalian sterile 20-like protein (MST1) deficiency	*STK4*	Defective naive-T-cell survival, possible impaired thymic egress	Flow cytometry, TREC, T-cell function, apoptosis assay	6, 62, 63
Coronin-1A deficiency	*CORO1A*	Naive CD4 T-cell lymphopenia, EBV lymphoproliferation	Flow cytometry	7, 64
Purine nucleoside phosphorylase deficiency	*PNP*	T-cell lymphopenia	T-cell function, serum uric acid, flow cytometry	29
Defects in NF-κB activation				
Caspase recruitment domain family member 11 (CARD11) deficiency	*CARD11*	Mild lymphopenia (T and NK), blocked B-cell differentiation, defective T-cell activation	Flow cytometry, T-cell function	66, 67
Caspase-8 deficiency state (CEDS)	*CASP8*	Diminished $CD4^+$ T-cell numbers, diminished T- and NK-cell function	Flow cytometry, T-cell function, apoptosis assay	68, 69
X-linked anhidrotic ectodermal dysplasia with immunodeficiency (X-ED-ID)	*NEMO*	Hyper-IgA/IgM, normal T- and B-cell numbers, variable T-cell function, hypogammaglobulinemia with poor polysaccharide antibody responses, impaired production of cytokines	T-cell function, flow cytometry, immunoglobulins	30–32, 70, 71
Defects in cytoskeletal and migration pathways				
Wiskott-Aldrich syndrome	*WASP*	T-cell lymphopenia, defective TCR signaling, impaired immune synapse, impaired NK-cell function	Flow cytometry, T-cell functional studies	33, 73
WASp-interacting protein deficiency	*WIP*	Defective TCR signaling, impaired immune synapse, impaired NK-cell function	Flow cytometry, T-cell functional studies	74

(Continued on next page)

TABLE 1 CIDs, their immunophenotypes, and useful diagnostic tests *(Continued)*

Combined immunodeficiency disease	Gene mutation(s)	Immunophenotype	Useful diagnostic tests	Reference(s)
Warts, hypogammaglobulinemia, infections, myelokathexis syndrome (WHIM)	*CXCR4*	Lymphopenia, decreased naive T cells and memory B cells, hypogammaglobulinemia, impaired chemotaxis, impaired thymic output	Flow cytometry, TREC, immunoglobulins	75
Ras homology family member H (RHOH) deficiency	*RHOH*	Skewing toward effector memory T cells, impaired TCR signaling, diminished β7 integrin expression on circulating T cells	T-cell function, flow cytometry	76
Dedicator of cytokinesis 8 (DOCK8) deficiency	*DOCK8*	Hyper-IgE, T-cell lymphopenia, eosinophilia, impaired T-cell survival, impaired immune synapse, impaired NKT-cell survival	TREC, T-cell function, flow cytometry	34, 35, 65
Combined immunodeficiencies with narrow clinical phenotypes				
X-linked with magnesium defect Epstein-Barr virus infection and neoplasia (XMEN)	*MAGT1*	$CD4^+$ T-cell lymphopenia, defective T-cell activation	Flow cytometry, T-cell Mg^{2+} and Ca^{2+} flux	77, 78
CD27 deficiency	*CD27*	Absent memory B cells, hypogammaglobulinemia	Flow cytometry	79, 80
X-linked lymphoproliferative (XLP) disease	*SH2D1A*	Low numbers of NKT cells, hypogammaglobulinemia, impaired T-cell apoptosis	Apoptosis assay	36, 37, 41
X-linked inhibitor of apoptosis (XIAP) deficiency	*BIRC4*	Enhanced lymphocyte apoptosis, low numbers of invariant NKT cells, hypogammaglobulinemia	Flow cytometry, apoptosis assay	38–41

Cartilage Hair Hypoplasia

During thymopoiesis, in addition to critical interactions between MHC molecules and T-cell receptors (TCRs), T-cell proliferation is essential for T-cell development. Defects in cell activation or cell cycle progression can dramatically affect T-cell development. One T-cell proliferation defect shown to directly impact thymopoiesis results from mutations in the gene encoding the RNA component of the mitochondrial RNA-processing endoribonuclease (*RMRP*), which is the genetic basis of cartilage hair hypoplasia (5). RMRP is important for ribosomal assembling, telomere stability, and cell cycle control.

Diagnostic Evaluation

Although the immunologic and clinical phenotype of cartilage hair hypoplasia is broad, decreased T-cell numbers by flow cytometry, diminished thymic function by TCR excision circles (TREC) analysis, and reduced *in vitro* T-cell function are usually seen. Unlike MHC-I and MHC-II deficiencies, discussed above, severe *RMRP* mutations are detected by SCID NBS.

MST1 and *CORO1A* Mutations

Another mechanism that may affect T-cell development is impaired thymic egress of single-positive T cells. This abnormality has been described in several distinct CIDs, including hypomorphic mammalian sterile 20-like protein (*MST1*) mutations (6) and *CORO1A* mutations, encoding coronin-1A (7). Coronin-1A regulates actin cytoskeletal rearrangement and may be the mechanism for impaired egress of T cells from the thymus. MST1 is a kinase important for activating Rho family GTPases and as such impacts actin cytoskeleton. However, the underlying mechanisms for impaired thymic egress have not been fully delineated, and other functional defects have been described with these genetic mutations, such as decreased survival of naive T cells in apoptosis assays (6, 7). Homozygous *MST1* mutations are characterized by progressive $CD4^+$ T lymphopenia with few naive T cells in the peripheral blood. Patients with *CORO1A* mutations exhibit decreased T-cell but not B-cell or NK-cell numbers as well as poor T- and B-cell function.

Diagnostic Evaluation

TREC analysis as a measurement of thymic output, characterization of T-cell surface antigens by flow cytometry that differentiate naive ($CD45RA^+CCR7^+$) from memory ($CD45RO^+$) T cells produced in the periphery, and determination of TCRαβ and TCRγδ expression as well as TCR Vβ repertoire by TCR Vβ spectratyping provide information about thymic function. Expected abnormalities of thymic function and egress include T-cell lymphopenia, diminished frequency of naive T cells, increased memory and activated T cells, and possibly a restricted or skewed TCR Vβ repertoire. *In vitro* proliferative responses to TCR stimulation using anti-CD3 or phytohemagglutinin (PHA) are diminished. Apoptosis of MST1-deficient T cells is increased and survival decreased by annexin flow cytometry-based assays (6).

Defects in DNA Repair and Recombination

Omenn Syndrome

In addition to adequate cell activation and migration, T-cell development requires tightly regulated DNA cleavage and repair during thymopoiesis. Complete abrogation of nonredundant DNA repair gene activity results in SCID, while hypomorphic mutations in SCID-associated genes involved in these pathways are associated with CIDs. The best examples are hypomorphic mutations in the *RAG1* and *RAG2* genes. The classical presentation of hypomorphic *RAG1/2* mutations results in the CID termed Omenn syndrome (8). This is often described as a "leaky" SCID and is a disease that is universally fatal in the first 2 years of life without hematopoietic stem cell replacement. The classic features of Omenn syndrome include dermatitis, hepatomegaly, eosinophilia, elevated IgE, and expansion of oligoclonal T cells. Hypomorphic mutations in other SCID-associated genes have also been described in Omenn syndrome patients (*IL7RA* [9], *DCLRE1C* [10], and *AK2* [11]). The overarching paradigm in Omenn syndrome is a profound immune deficiency with immune dysregulation. More recently, hypomorphic *RAG1* and *RAG2* mutations have also been identified in older patients with CID and have been associated with a spectrum of clinical phenotypes distinct from Omenn syndrome (81).

Diagnostic Evaluation

Initial immunologic testing for DNA repair and recombination defects includes flow cytometry, TCR Vβ spectratyping, TREC analysis, and T-cell functional studies. Expected abnormalities include diminished T-cell numbers, restricted T-cell repertoire by TCR Vβ spectratyping, reduced thymopoiesis by TREC analysis, and diminished T-cell functionality (determined by *in vitro* mitogen responses and expression of lymphocyte activation markers by flow cytometry). Sequencing of known SCID genes would be required to confirm the underlying mutation(s).

Ataxia Telangiectasia

Ataxia telangiectasia (AT) is characterized by cerebellar ataxia, oculocutaneous telangiectasia, cellular radiosensitivity, and predisposition to malignancy and CID and is due to mutations in ataxia telangiectasia mutated (*ATM*), a phosphatidylinositol 3-like protein kinase critical for activation of the complex cellular response to double-strand DNA breaks and for cellular homeostasis. AT is characterized by progressive cerebellar degeneration in association with variable and progressive cellular and humoral immune dysfunction and predisposition to T- and B-cell malignancies. Most symptoms are the result of defective cellular responses to physiological and induced double-strand DNA breaks. AT patients are lymphopenic, with selective loss of $CD4^+$ T cells, T-cell dysfunction, and progressive hypogammaglobulinemia due to defects in the DNA damage and repair responses including phosphorylation of NF-κB essential modulator (NEMO) during NF-κB activation and multiple other signaling events involved in cell survival and cell death (12). The neurologic symptoms are the typical presenting symptom leading to a diagnosis of AT.

Diagnostic Evaluation

Initial immunologic screening includes lymphocyte subsets by flow cytometry, *in vitro* mitogen and antigen proliferative responses, immunoglobulin levels, and specific antibody production. As mentioned, the spectrum of immune defects and function is broad. In general, AT patients are expected to have decreased T-cell numbers, diminished B-cell function (in particular, polysaccharide antibody responses), and relatively intact T-cell function. SCID NBS has picked up infants with AT (82).

T-CELL ACTIVATION, SIGNAL TRANSDUCTION, AND SURVIVAL

Defects in Proximal T-Cell Activation

The TCR is a multisubunit complex consisting of a disulfide-linked αβ heterodimer noncovalently associated with the CD3 γ, δ, and ε chains and a ζζ homodimer (CD247). Defects in proximal T-cell activation include abnormal cell surface expression of TCR and CD3 subunits ε, γ, or δ (5, 13–15). Defective CD3 expression may present as SCID or CID depending on the affected subunit and mutation severity.

Patients with typical (complete) CD3δ deficiency have virtually no αβ or γδ T cells and present as SCID with absent T-cell function. The phenotype of CD3ε deficiency is dependent on the level of residual CD3ε expression. Absence of CD3ε causes $T^-B^+NK^+$ SCID, while partial CD3ε expression results in CID with decreased T-cell numbers and variably reduced mitogen responses *in vitro*. Mutations in CD3γ and ζζ usually result in defective, but not absent, T-cell numbers and function, although SCID has been reported.

Diagnostic Evaluation

A diagnosis of defective CD3 expression is usually suggested by moderately to severely decreased numbers of peripheral T cells that weakly express TCRαβ and CD3 by flow cytometry using a range of monoclonal antibodies (MAbs) to all subunits. Measurement of the mean fluorescence intensity of the TCR complex on the T-cell surface is critical to determining which subunit is affected. TCR Vβ usage is often restricted, with some skewing of percentages of TCRαβ versus TCRγδ cells. Most peripheral T cells are not recent thymic emigrants by TREC analysis or naive by flow cytometry. It is unknown if CD3γ or partial CD3ε mutations would be detected in SCID NBS. As with other forms of CID and SCID, gene sequencing is required to confirm mutations in a CD3 subunit.

Hyper-IgM Syndromes

Hyper-IgM (HIGM) syndromes are characterized by low serum IgG, IgA, and IgE with normal or elevated IgM as a result of failure to complete immunoglobulin class switch recombination due to defects in the CD40 ligand/CD40 signaling pathway. X-linked HIGM (X-HIGM) is due to CD40 ligand (CD154) deficiency, often with absent expression of CD40 ligand on $CD4^+$ T cells or failure of mutant CD40 ligand to bind CD40 on B cells and antigen-presenting cells (16). The inability to signal via CD40 interrupts activation of NEMO (nuclear factor κB essential modulator) and thus NF-κB, preventing immunoglobulin class switching, somatic hypermutation, and development of memory B cells. In addition, the interaction of CD40 ligand with CD40 is important for T-cell costimulation and cytokine responses involving gamma interferon (IFN-γ) and interleukin-12 (IL-12). Abnormal CD40 ligand signaling leads to impaired T-cell function with defects in T-cell priming and differentiation and increased susceptibility to opportunistic infections, particularly *Pneumocystis jirovecii* and *Cryptosporidium parvum*. As a result of chronic cryptosporidial infection of the biliary tract, boys with X-HIGM develop sclerosing cholangitis and tumors of the biliary tract, and liver autoimmunity and neutropenia are common.

The autosomal recessive (AR) forms (AR-HIGM) are caused by defects in CD40 or in downstream signaling molecules and are most often due to mutations in the *AICDA* gene, encoding activation-induced cytidine deaminase, but also may be due to mutations in *CD40*, *PMS2* (postmeiotic segregation increased 2), or *UNG* (uracil-*N*-glycosylase) (16). As expected, HIGM is also a frequent consequence of AT, NEMO deficiency, gain-of-function mutations in the IkBα subunit of the IκB kinase (IKK) complex, and Nijmegen breakage syndrome.

Diagnostic Evaluation

Initial screening includes lymphocyte subset enumeration for presence of B cells, measurement of serum immunoglobulins, and specific antibody titers. A rapid screening test for X-HIGM uses the knowledge that CD40 ligand is a T-cell activation surface marker easily detected by flow cytometry on PHA- or phorbol myristic acetate (PMA)-stimulated PBMCs using CD25 and CD69 expression to document T-cell activation (see below for more detailed protocol). Although deficient expression of CD40 ligand on activated $CD4^+$ T cells by flow cytometry is often seen in X-HIGM, genotyping may be required to confirm a *CD40L* mutation, especially in non-informative families. CD40 expression on PBMCs can also be determined by flow cytometry. In contrast to X-HIGM, AR-HIGM due to CD40 deficiency is characterized by absent CD40 expression on B cells and monocytes but normal expression of CD40 ligand on activated T cells. Genotyping is usually required to confirm diagnosis of AR-HIGM, particularly when CD40 expression is normal on B cells.

Defects in T-Cell Signal Transduction Pathways

The polymorphic TCRαβ chains are responsible for recognition of peptide bound to self-MHC molecule; these chains lack signaling capability. In contrast, the ζ and CD3 proteins are able to transduce extracellular antigen-binding events to intracellular signaling pathways through associations with cytoplasmic protein tyrosine kinases via conserved immunoreceptor tyrosine-based activation motifs (ITAMs) within their extensive cytoplasmic domains. Propagation of antigen-binding signals from the TCR to the nucleus is dependent on the recruitment and activation of two protein tyrosine kinases, lymphocyte-specific protein kinase (Lck) and ζ chain-associated protein of 70 kDa (ZAP-70), whose functions are critical for lymphocyte responses to antigens. Lck and ZAP-70 are also required for normal TCR signaling, CD4 versus CD8 selection in the thymus, and lymphocyte proliferation in the periphery.

Recruitment of Lck to the plasma membrane and its subsequent activation is dependent on activity of the signaling adapter protein Uncoordinated 119 (Unc119) (17). Roles of Unc119 include activation of the GTPase Rab11 to facilitate transport of Lck from perinuclear endosomes to the plasma membrane in resting T cells, and also as an SH3 ligand for Lck activation during early TCR signaling. Once activated, Lck mediates ITAM phosphorylation and recruitment of ZAP-70 to the TCR. Activation of first Lck and then ZAP-70 triggers phosphorylation of phospholipase Cγ1 via recruitment of numerous proteins to the signaling complex, referred to as the signalosome. The recruited downstream proteins include linker for activation of T cells (LAT) and SH2 domain-containing leukocyte protein of 76 kDa (SLP-76). Formation of these protein complexes at the plasma membrane is dependent on Unc119 function (17), and the resulting TCR-mediated signal amplification culminates in transcription of genes essential for T-cell activation and initiation of T-cell-specific responses.

Lck Deficiency

Lck is expressed at high levels in peripheral T cells and in thymocytes at all stages of maturation. Disruption of Lck in

humans usually presents with a selective CD4 lymphopenia and normal numbers of $CD3^+$ and $CD8^+$ T cells (18) and may be missed by SCID NBS. B-cell and NK-cell numbers are normal, but hypogammaglobulinemia and defective functional antibody responses are typical. The clinical presentation of selective CD4 lymphopenia due to Lck deficiency is variable and typical of CID, although SCID has been seen.

Diagnostic Evaluation

Despite CD4 lymphopenia, Lck-deficient T cells do proliferate, although not fully, to mitogens (phytohemagglutinin [PHA], concanavalin A [ConA], pokeweed mitogen [PWM]), anti-CD3, and IL-2 *in vitro*, and demonstrate normal alloantigen responses. Genotyping is required for diagnosis in most patients, but the underlying genetic defects resulting in decreased Lck function in a few sporadic cases of CD4 lymphopenia are unknown but may include patients with mutations in *UNC119* (uncoordinated 119 protein) or *MAGT1* (magnesium transporter 1) genes (see below and Table 1).

ZAP-70 Deficiency

ZAP-70 is expressed in all thymocyte subpopulations, peripheral T cells, NK cells, and also aberrantly in a subpopulation of human B-cell chronic lymphocytic leukemia. In contrast to ZAP-70-deficient mice, human ZAP-70 deficiency is characterized by the selective absence of $CD8^+$ T cells but with abundant nonfunctional $CD4^+$ T cells in the peripheral blood (19). B-cell numbers are normal, but serum immunoglobulins and specific antibody responses are defective due to lack of T-cell function in the majority of patients. The diagnosis of ZAP-70 deficiency is suggested by a clinical phenotype of SCID requiring hematopoietic stem cell transplantation but with normal numbers of $CD3^+$ and $CD4^+$ T cells and absent $CD8^+$ T cells in the peripheral blood. Therefore, ZAP-70 deficiency is missed by SCID NBS.

Diagnostic Evaluation

Diagnosis of ZAP-70 deficiency is suggested by lack of T-cell proliferation *in vitro* to mitogens and TCR stimuli (PHA, ConA, PWM, or anti-CD3) but normal proliferative responses to PMA plus ionomycin, agents that bypass proximal TCR signaling events by mimicking actions of the second messengers Ras, in the case of PMA, and $[Ca^{2+}]_i$ for ionomycin. Further studies to confirm a proximal TCR signaling defect include defective $[Ca^{2+}]_i$ mobilization by fluorimetry or flow cytometry and abnormal tyrosine phosphoprotein induction after anti-CD3 stimulation on immunoblots or by flow-based methods using phospho-site-specific antibodies (phosphoepitope flow cytometry; see below). IL-2 production is also absent in anti-CD3- or PHA-simulated, ZAP-70-deficient T cells but normal using PMA plus ionomycin. In most cases, Western blotting or intracellular flow cytometry using permeabilized PBMCs demonstrates lack of ZAP-70 protein. DNA sequencing is required to confirm two mutant *ZAP-70* alleles in patients with SCID characterized by a paucity of circulating $CD8^+$ T cells.

Unc119 Deficiency

Unc119 is essential for Lck activity, and its deficiency results in a rare form of idiopathic CD4 lymphopenia. The dominant-negative Unc119 mutation (G22V) interferes with both Lck recruitment to the plasma membrane and its activation, resulting in impaired immunologic synapse formation, defective T-cell activation and proliferation, and a CID phenotype on diagnostic testing (20). SCID is not seen, possibly due to a less critical role for Unc119 in Lck activation during thymocyte development.

Diagnostic Evaluation

Genotyping of the *UNC119* gene is reserved for the rare patients with reproducible CD4 lymphopenia, reduced T-cell proliferation to mitogens and antigens *in vitro*, and defective Lck activity but normal Lck gene sequencing.

Defects in Cytokine Signaling Pathways

Partial Common γ-Chain Defects

Mutations in the γ chain (γc) common to the receptors for IL-2, IL-4, IL-7, IL-9, and IL-15 are found in boys with X-linked recessive SCID (SCID-X1). The γc molecule is essential for the intracellular transmission of cytokine signals and is required for T-cell development. Absence of γc-containing cytokine receptor complexes usually results in SCID with early arrest of T- and NK-cell development and normal numbers of immature B cells exhibiting defective isotype switching. However, at least one hypomorphic γc mutation, R222C, only partially blocks T-cell development, resulting in a variant form of Omenn syndrome (21). In such patients, normal numbers and subset distribution of T, B, and NK cells as well as levels of serum immunoglobulins are observed, but specific antibody production is absent.

Diagnostic Evaluation

Unlike in SCID-X1 patients, normal expression of the γc chain of the IL-2 receptor (IL-2RG; CD132) by flow cytometry is seen and T-cell proliferation to PHA and anti-CD3 *in vitro* is normal. However, addition of exogenous IL-2 to mitogen-stimulated T cells *in vitro* does not increase proliferation further, as would be expected (22). Genotyping is required to confirm two hypomorphic R222C mutations.

Partial JAK3 Deficiency

Females, as well as some males with the typical SCID-X1 phenotype, do not have mutations in γc. Instead, these patients have autosomal recessive SCID due to mutations in the downstream cytoplasmic tyrosine kinase Janus kinase 3 (JAK3), whose activation is required for transduction of ligand-binding signals from γc-containing cytokine receptors. Like CID due to the R222C mutation in γc, the clinical spectrum of JAK3 deficiency may include CID rather than SCID if due to hypomorphic mutations, such as A96G or G2775(+3)C (23).

Diagnostic Evaluation

Affected patients exhibit CD4 T-cell lymphopenia and reduced mitogen proliferative responses *in vitro* that are variably increased with addition of exogenous IL-2 despite poor IL-2-dependent signal transducer and activator of transcription (STAT) 5 phosphorylation on immunoblots or by phosphoepitope flow cytometry (23). However, affected T cells do not upregulate Fas ligand in response to IL-2 by flow cytometry. Genotyping is needed to confirm a hypomorphic *JAK3* mutation.

CD25 Deficiency

The IL-2R is composed of three chains: α (IL-2Rα, CD25), β (IL-2Rβ, CD122), and γc (IL-2Rγ, CD132) (3), and only CD25 binds IL-2 exclusively. Due to its roles in IL-2-mediated effector-T-cell responses and regulation of $CD4^+CD25^+Foxp3^+$ T regulatory cell (Treg) responses in homeostasis, CD25 deficiency results in both chronic viral infections and severe autoimmunity (24), somewhat resembling the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, caused by mutations in the *FOXP3* gene (25). Patients with CD25 deficiency

tend to have normal numbers of $CD4^+$ T cells, unlike in IPEX, but elevated $CD8^+$ T cells, possibly from chronic viral infections, inverting their CD4/CD8 ratio.

Diagnostic Evaluation

Absence of CD25 expression on T-cell subpopulations and impaired IL-2 production can be demonstrated by cell surface and intracellular flow cytometry. *In vitro* proliferative responses to TCR stimuli are poor but can be partially rescued by exogenous IL-2, unlike specific viral and antigen responses, which are consistently absent. As expected, phosphorylation and activation of the transcription factor STAT5b is markedly reduced in the presence of IL-2 but is normal with other cytokines. Diagnostic tests to document CD25 deficiency include flow cytometry, phosphoepitope flow cytometry, soluble CD25 and cytokine production, and T-cell function including cytotoxicity and proliferation to mitogens and specific antigens *in vitro*.

STAT5b Deficiency

STAT5b is a critical downstream effector of JAK-mediated signal transduction, including for γc-containing cytokines, growth hormone, and erythropoietin, and is involved in the pathogenesis of a variety of human diseases. The phosphorylation of JAK3 and STAT5b is required for normal IL-2 signaling, and disruption of these events results in impaired development, immune homeostasis, and proliferation of most lymphocyte populations. Engagement of the high-affinity IL-2R on T cells results in activation of JAK3 with subsequent phosphorylation and activation of STAT5b. In the nucleus, phosphorylated STAT5b initiates transcription of multiple genes, including *FOXP3* and *CD25*, required for Treg development. As a result, the rare patients with STAT5b deficiency have chronic diarrhea, atopic dermatitis, recurrent herpesvirus infections, and autoimmunity and are very short due to growth hormone insensitivity (26). All patients have been from consanguineous families.

Diagnostic Evaluation

The immunophenotype may include SCID or CID with pan-lymphopenia, significantly decreased numbers of Treg cells by flow cytometry, and diminished Treg-cell suppressor function *in vitro*. Gene sequencing is required to confirm the diagnosis.

STAT3 Deficiency (Autosomal Dominant Hyper-IgE Syndrome)

In contrast to STAT5b, heterozygous mutations in *STAT3* cause the autosomal dominant form of hyper-IgE syndrome (AD-HIES), which is characterized by recurrent severe lung and skin infections with pneumatocele formation; staphylococcal abscesses; generalized eczema; mucocutaneous candidiasis; and abnormalities of bone, teeth, and connective tissue in association with markedly elevated serum IgE (27).

Diagnostic Evaluation

In addition to measurement of serum IgE, quantification of IL-17-producing $CD4^+$ T cells (Th17) by intracellular flow cytometry after mitogen stimulation has proven to be a useful diagnostic test for HIES (28, and see below). A severe reduction or absence of Th17 cells is characteristic of AD-HIES.

Defects in T-Cell Survival

PNP Deficiency

Purine nucleoside phosphorylase (PNP) deficiency is associated with both immune defects and neurological symptoms, including developmental delay and behavioral and motor problems (29). Immunologic features of PNP deficiency include lymphopenia, severely decreased T-cell numbers, poor *in vitro* T-cell function, and attrition of B cells over time. Despite significant decline in B-cell function, many patients develop autoimmune disease and are at increased risk for lymphoma or other malignancies.

Diagnostic Evaluation

Initial immunologic tests include flow cytometry for T- and B-cell enumeration and T-cell functional studies (e.g., *in vitro* mitogen proliferation). Absent PNP function results in an undetectable serum uric acid level, which can be used to screen for the disorder with measurement of erythrocyte or lymphocyte PNP activity for confirmation of the diagnosis.

Defects in NF-κB Activation

NEMO Deficiency (X-linked Anhidrotic Ectodermal Dysplasia with Immunodeficiency)

Anhidrotic ectodermal dysplasia with immunodeficiency (HED-ID or X-ED-ID) is caused by hypomorphic mutations in NEMO (IκKγ). NEMO functions as a regulatory subunit of the IκB kinase complex, which tightly controls activation of the NF-κB/Rel transcription factor pathways by promoting phosphorylation and degradation of cytosolic IκB. Null mutations in the NEMO gene *IKBG* cause incontinentia pigmenti in females and are lethal in males *in utero*. In contrast, hypomorphic mutations are associated with broad phenotypic variability, depending on the localization of the mutation and effect on NEMO function (30, 31). Affected males usually have ectodermal dysplasia and tooth abnormalities and may present with life-threatening pyogenic and mycobacterial infections and autoimmune disease, especially inflammatory colitis (30, 31).

Diagnostic Evaluation

Defective NF-κB/Rel activation in NEMO patients leads to a wide range of immune defects, including hypogammaglobulinemia with hyper-IgM due to failure to undergo CD40-mediated class switch recombination, defective CD40 ligand-mediated IL-12 and tumor necrosis factor alpha production, deficient NK cytotoxicity, and impaired polysaccharide antibody responses, particularly to *Pneumococcus*. Sequencing of the *IKBG* gene is required for diagnosis, particularly since phenotype of NEMO deficiency is dependent on location and severity of the underlying mutation. A similar phenotype can be seen with a hypermorphic (gain-of-function) mutation in the gene encoding the IkBα subunit of the IKK complex (32).

DEFECTS IN CYTOSKELETAL AND MIGRATION PATHWAYS

Optimal activation of immune cells requires a dynamic and intimate interaction between immune cells. This is best exemplified by the immunologic synapse. The immunologic synapse is a physical and dynamic engagement of immune cells typically with other immune cells brought together by receptor-ligand recognition, resulting in numerous outcomes, such as T-cell activation, differentiation, or death. A basic fundamental process underlying this critical engagement is proper actin cytoskeletal rearrangement. Defects in the actin cytoskeleton can have profound effects on immune function, including aberrant immunologic synapse formation, as well as diminished effector function. The characterization of immunologic synapse formation, chemotaxis, adhesion, and

cell migration remains research-use-only applications that have greatly enhanced the biologic knowledge of the role of the actin cytoskeleton in immune function and the essential proteins for key functions. Readily available functional immunologic testing for the CIDs with actin cytoskeletal defects includes functional tests of B and T cells, including proliferation assays and flow cytometric analysis for protein expression and immune phenotype.

Wiskott-Aldrich Syndrome

The most prevalent example of an actin cytoskeletal defect resulting in CID is Wiskott-Aldrich syndrome (WAS), caused by mutations in the gene encoding the Wiskott-Aldrich syndrome protein (*WASP*). WASp is an important regulator of the actin cytoskeleton, and loss of WASp activity results in impaired hematopoietic cell migration, impaired phagocytosis, and impaired immune cell synapse formation. The immunologic defects and clinical findings in WAS are broad, and *WASP* mutations causing the full spectrum of WAS simultaneously result in immune deficiency and autoimmunity.

Diagnostic Evaluation

Initial immunologic assays for immune defects that affect cytoskeletal and migration pathways include flow cytometry, T-cell function, immunoglobulin levels, specific antibody production, and TREC analysis. Platelet volume can be used to screen for WAS; unlike immune thrombocytopenia, in which platelet size is large, platelet volume is small in WAS. Genetic sequencing is done if rapid screening for detection of WASp in PBMCs by intracellular flow cytometry is abnormal (33).

DOCK8 Deficiency

Dedicator of cytokinesis 8 (DOCK8) loss-of-function mutations are a recently described CID that is often categorized as an autosomal recessive form of hyper-IgE syndrome (34). DOCK8 is a member of the DOCK180 family of guanine exchange factors important for activating Rho family GTPases. DOCK8 is important for actin cytoskeletal regulation and has been shown to interact with WASp. Similar to *WASP* mutations, *DOCK8* mutations impact immune function broadly. A full mechanistic understanding of the role of DOCK8 in immune function is still an area of active investigation. Other rarer mutations have been described that affect cytoskeletal and migration pathways (*RHOH*, *WIP*, *WHIM*, and *CORO1A*; see Table 1).

Diagnostic Evaluation

In addition to the initial immunologic screening tests listed above for WAS, serum IgE level is increased in DOCK8 deficiency, unlike in WAS. Interestingly, DOCK8-deficient patients have been detected by SCID NBS (35). This supports a nonredundant role for DOCK8 in naive-T-cell survival and T-cell egress from the thymus. Whereas WAS is generally not picked up by SCID NBS, retrospective TREC analysis revealed diminished values in a subset of WAS patients (83).

COMBINED IMMUNODEFICIENCIES WITH NARROW CLINICAL PHENOTYPES

X-Linked Lymphoproliferative Syndromes

X-linked lymphoproliferative syndrome (XLP) is characterized by overwhelming susceptibility to EBV infection, leading to life-threatening complications such as hemophagocytic lymphohistiocytosis (HLH), fulminant infectious mononucleosis, and B-cell lymphoma. Two different genetic defects cause XLP. Most cases of XLP (XLP type 1) are due to mutations in *SH2D1A*, the gene encoding the signaling lymphocyte activation molecule (SLAM)-associated protein (SAP) (36, 37). SAP is a cytoplasmic adapter protein critical to normal lymphocyte signal transduction, and its deficiency affects the development and effector functions of T-, NK-, and NKT-lymphocyte populations. Observed defects in humoral immunity, including dysgammaglobulinemia, are due in large part to lack of T-cell help, particularly failure of $CD4^+$ T cells to produce IL-10 required for generation of memory B cells and isotype class switching.

X-linked inhibitor of apoptosis (XIAP) is a member of the inhibitor of apoptosis family of proteins and is encoded by *XIAP/BIRC4*, which is mutated in XLP type 2 and the cause of X-linked familial HLH (38, 39). In XIAP deficiency, EBV-associated HLH is the most common presentation and dysgammaglobulinemia is seen less often (40). The development of HLH is related to overproduction of IL-18 and other proinflammatory cytokines by activated T cells and monocytes.

Diagnostic Evaluation

Initial immunologic testing includes enumeration of immune cell numbers and ascertainment of EBV levels and antibody response, as well as apoptosis assays. Flow cytometry and immunoblotting can be used to analyze intracellular expression of SAP and XIAP and support a diagnosis of XLP (40). However, genotyping is required to confirm mutations in either *SH2D1A* or *XIAP/BIRC4*, and clinically it is important to make this distinction since XLP type 1 is associated with malignancy and the clinical features are not overlapping.

DIAGNOSTIC ASSAYS

Flow Cytometry

The invention of flow cytometry and its entry into the clinical laboratory has revolutionized the field of immunology. The past 30-plus years in which flow cytometry has been available as a clinical laboratory tool have been witness to a growing list of quantitative and qualitative assays. With ongoing development of novel suitable antibodies, discovery of new immunologic disorders, and development of new platforms for cytometry such as mass cytometry, or CyTOF, the clinical diagnostic utility of flow cytometry will undoubtedly continue to expand.

Enumeration of Lymphocyte Cell Populations

Flow cytometry for immune cell quantification is a widely used and easily standardized diagnostic test for initial CID evaluation. Clinically useful cell surface and intracellular expression determination of various proteins can be achieved with appropriate controls and proper maintenance of a four-color flow cytometer. Essentially every initial diagnostic screen for CID includes quantification of T cells, B cells, and NK cells using various antibodies that recognize surface antigens.

1. Peripheral blood should be collected in sterile Vacutainer tube or syringe containing anticoagulant. Samples should be kept at ambient temperature without agitation until processing. Samples should be processed within 24 h of collection. In the clinical setting, fresh samples are typically used. If a sample is being shipped for flow cytometry analysis at another site, it is important for the submitting institution

to obtain a complete blood count prior to shipment. The flow cytometry analysis determines the frequency of the stained population. If the sample cannot be processed within 24 h of collection, many adaptive immune cells are amenable to flow cytometry analysis after recovery from viably frozen samples.

2. For convenience, whole blood with anticoagulant is stained and red blood cells are removed by osmotic lysis prior to sample acquisition on the flow cytometer when surface staining is performed in unmanipulated samples. Determine the number of staining conditions needed; wash 0.5 ml of blood per FACS staining tube needed with 5 ml of phosphate-buffered saline (PBS) containing heparin. Centrifuge at 400 × *g* for 10 min and aspirate carefully. Mix cell suspension well by flicking the tube and repeat the wash. Resuspend cells in 50 μl of fluorescence-activated cell sorter (FACS) staining buffer (e.g., PBS with bovine calf serum and azide)/staining tube. Add 10 μl of human IgG (12 mg/ml) to block nonspecific staining and incubate for 15 min at 4°C.

3. Add desired antibody cocktail. Manufacturers provide recommendations on the amount of antibody used to stain a sample, but it is critical that the operator determine the optimal antibody concentration in their laboratory since results can vary. This can be achieved by using a fixed number of cells and incubating with a range of concentrations that are above and below the manufacturer's recommended amount. This becomes particularly important for intracellular staining (see below). Mix tube by flicking and incubate at 4°C for 30 min in the dark.

4. Add 3.5 ml of FACS buffer and centrifuge.

5. Discard supernatant and resuspend in fixation/red blood cell lysis buffer (for example, 1× FACSLyse; BD Biosciences, San Jose, CA). Invert all tubes and centrifuge at 1,300 rpm for 10 min. Keep samples cold and protected from light. The samples can be run on flow cytometer between 30 min after fix to after an overnight incubation.

6. Run on flow cytometer with appropriate compensation tubes.

Interpretation

The frequency of the targeted populations can be determined using compatible software for analysis of acquired data. The absolute lymphocyte count from the submitting institution is used to determine the absolute values of the various lymphocytic cell subsets determined by the flow analysis. Age-adjusted normal ranges are available from the published literature (84). Determination of T-, B-, and NK-cell subsets is by a standard flow cytometry panel used to screen for CIDs. Inclusion of additional antibodies against various surface molecules can broaden the utility of flow cytometry surface staining. Depending on the staining panel used and commercially available antibody conjugates, acquisition beyond four-color flow cytometry may be necessary.

Thymic function and egress can be determined indirectly by quantification of CD45RA and CD45RO isoform distribution on peripheral blood lymphocytes with interpretation of the frequencies using age-related controls. This is commonly added to screening panels for CIDs and does not require flow cytometer upgrade. Determination of TCRαβ and -γδ expression and distribution can provide additional information on thymic function and is feasible with the flow cytometer platform. Additionally, interrogation of the T-cell memory compartment can be done by flow cytometry using a combination of antibodies for T-cell resting and activated surface receptors. Naive T cells are defined as $CD45RA^{+}CCR7^{+}$, central memory ($CD45RA^{-}CCR7^{+}$), effector memory ($CD45RA^{-}CCR7^{-}$), or effector memory RA (TEMRA; $CD45RA^{+}CCR7^{-}$) cells.

Intracellular Protein Expression and T-Cell Differentiation

Flow cytometry has been essential for expanding diagnostic testing aimed at determining T-cell differentiation and quantification of critical intracellular proteins (e.g., transcription factor Foxp3 or cytosolic WASp) and has proven to be a useful diagnostic tool. These more in-depth flow cytometry analyses require cellular manipulation and increased flow cytometer capability. Example protocols, outlined below, include intracellular staining for Th17 cells, which is a useful screening test for AD STAT3 HIES. Intracellular and extracellular staining for Treg quantification is discussed and serves as a useful screening test for IPEX and STAT5 or CD25 deficiency. Intracellular staining for WASp, SAP, or XIAP is used to screen for affected males with WAS or XLP and also to screen for carrier females.

Intracellular Cytokine Staining (IL-17)

1. Peripheral blood should be collected, stored, and processed as described above. One exception is that the anticoagulant used should be sodium heparin since EDTA can interfere with the activity of the stimulant. Whole blood with anticoagulant can be used for intracellular staining of unmanipulated cells or stimulated cells. However, PBMCs are used more routinely to decrease the volume of the sample to allow for more accuracy in cell numbers. PBMCs are isolated using a density gradient as described elsewhere. If the sample cannot be processed within 24 h of collection, many adaptive immune cells are amenable to flow cytometry analysis after recovery from viably frozen samples.

2. Plate 2×10^6 cells/well in appropriate culture media (e.g., RPMI-1640 plus 10% fetal calf serum, 100 μg/ml penicillin, 100 U/ml streptomycin, and 2 mM L-glutamine) with stimulant; options include 1 μg/ml *Staphylococcus* enterotoxin B or PMA (100 ng/ml) + ionomycin (1 μg/ml) and 2.5 μg/ml brefeldin A at 37°C for 5 h. Unstimulated wells should be included as an appropriate control.

3. Wash cells with FACS buffer. Add predetermined concentration of antibody cocktail for surface proteins (e.g., CD3, CD4, and CD45RO) and incubate for 30 min at 4°C.

4. Wash the cells once with 2 volumes of FACS buffer, followed by resuspension in 2% paraformaldehyde, and incubate for 20 min at room temperature.

5. Wash cells in 1× permeabilization (Perm) buffer (commercially available products for intracellular cytokine staining work consistently, such as from eBioscience, San Diego, CA), then resuspend in 100 μl of 1× Perm buffer containing blocking antibody (e.g. human IgG) and incubate at room temperature for 10 min.

6. Add predetermined amount of anti-IL-17A (e.g., clone N49-653) and anti-IFN-γ (e.g., clone B27) and incubate for 60 min at room temperature. Appropriate control tubes should include fluorescence minus one (FMO) and/or isotype controls for the intracellular protein. An FMO is a staining tube that contains all fluorescent antibodies in a panel except for one and controls for spread of fluorochromes into the channel of interest. These controls assist with gate setting in data analysis.

7. Wash twice with 1× Perm buffer, resuspend in FACS buffer, and proceed to flow cytometer.

Interpretation

In this assay, IL-17A cytokine production by memory Th17 cells is triggered in polyclonally activated PBMCs in the presence of brefeldin A to block endoplasmic reticulum release of secretory proteins, thus trapping cytokines

produced during activation inside the cells. Determination of the frequency of Th17 cells is used as a screening test in HIES. Th1 cells (IFN-γ) should not be affected in HIES patients.

Foxp3 Analysis

Whole blood or isolated PBMCs can be used. A PBMC protocol is presented below.

1. Peripheral blood should be collected, stored, and processed as described above for IL-17 staining. PBMCs should be resuspended in FACS buffer at a concentration of 1×10^7 cells/ml.
2. Place 1×10^6 cells/FACS staining tube and incubate for 15 min at 4°C. Appropriate control tubes must be included to account for background staining and assist with setting gates in data analysis, for example, isotype control for Foxp3 antibody.
3. Add surface staining antibody cocktail containing predetermined concentrations. A standard cocktail for Treg surface staining includes CD3, CD4, CD127, and CD25 antibodies. Incubate for 60 min at 4°C in the dark.
4. Add 2 ml of FACS buffer/tube. Spin at 1,300 rpm for 10 min at 4°C. Remove supernatant.
5. Add 1 ml of 1× fix/perm buffer to each tube (commercially available from BioLegend or eBioscience and should be compared by the investigator). Incubate for 30 min at room temperature in the dark.
6. Spin at 1,300 rpm for 10 min at 4°C and resuspend in 1 ml of 1× Perm buffer/tube. Repeat. Remove supernatant, leaving residual 50-100 μl/tube. Add 10 μl human IgG (12 mg/ml) to block, and incubate 10 min at 4°C in the dark.
7. Add predetermined anti-FoxP3 (e.g., clone 206D) or isotype control (e.g., clone MOPC21) to appropriate tube. Incubate for 60 min at room temperature in the dark.
8. Add 1 ml of 1× Perm buffer/tube. Spin at 1,300 rpm for 10 min at 4°C. Remove supernatant and repeat with FACS buffer.
9. Resuspend in 1% paraformaldehyde and store at 4°C in the dark until acquired on flow cytometer.

Interpretation

Tregs are defined as $CD4^+CD25^+CD127^{lo/-}Foxp3^+$. Both CD25 and Foxp3 can be upregulated on activated conventional T cells (CD25 routinely and Foxp3 transiently and at lower levels than bona fide Treg cells). This assay is a helpful screening test in inherited immunodeficiency/immune dysregulation states that are secondary to Treg abnormalities, such as STAT5b deficiency or CD25 deficiency. This approach determines Treg cell numbers but does not address functionality.

WASp, SAP, or XIAP Expression

Whole blood or PBMCs can be used. Below is an example protocol for PBMCs. This assay protocol follows the same principles as Foxp3 staining for Treg analysis.

1. Stain 1×10^6 cells/tube for surface markers with predetermined concentration of antibodies in FACS buffer for 30 min at 4°C in the dark.
2. Fix cells with 2% paraformaldehyde.
3. Resuspend cells in 1× Perm buffer; incubate for 15 min at 4°C in the dark. Wash once and resuspend in 1× Perm buffer.
4. Incubate with predetermined amount of antibody for protein of interest and include tubes for appropriate controls (isotype controls).
   a. Mouse anti-WASp MAb (e.g., clone 5A5)
   b. Monoclonal anti-SAP (e.g., clone EPR3168)
   c. Anti-XIAP (e.g., clone 48)

   Incubate 60 min at 4°C in the dark.
5. Wash with 1× Perm buffer. These antibodies are not available with directly conjugated fluorophore and thus require stain with appropriate fluorophore-conjugated secondary antibody for 30 min at 4°C in the dark.
6. Wash once with 1× Perm buffer, followed by FACS buffer, then resuspend in 1% paraformaldehyde and store at 4°C in the dark until acquired on flow cytometer.

Interpretation

WASp is expressed in many hematopoietic cells including platelets, neutrophils, monocytes, and lymphocytes. WASp protein expression in lymphocytes and monocytes can be determined after gating by a distribution pattern in the forward and side scatter. Protein positivity is compared to isotype control and with the results of a healthy control. If the sample was shipped, it is critical that a healthy shipping control be included with the test sample.

SAP can be detected in T and NK cells. Patients with SAP deficiency typically have severely diminished SAP expression detected by flow cytometry. XIAP is detectable in neutrophils, monocytes, and all lymphocyte subsets. Reported patients with XIAP mutations can have absent or decreased protein expression depending on the mutation. Female carriers display bimodal distribution of SAP and XIAP expression. Skewing toward XIAP-positive cells has been observed and suggests a selective survival advantage in XIAP-expressing cells and can complicate carrier testing by this methodology (41).

T-Cell Activation

1. Whole blood or PBMCs have been successfully used for this assay. Ideally, the anticoagulant should be sodium heparin.
2. Stimulate the cells with PMA 15 ng/ml + ionomycin 300 ng/ml (should determine optimal dose in your facility with dose-response curve) for 4 h in appropriate culture media at 37°C.
3. Wash in FACS staining buffer.
4. Stain with anti-CD3, anti-CD8, anti-CD154, and anti-CD69 antibodies and appropriate controls. Here is an example template.
   a. Tube 1: anti-CD3, anti-CD8, and isotype control (for anti-CD154)
   b. Tube 2: anti-CD3, anti-CD8, and anti-CD154 (e.g., clone TRAP-1)
   c. Tube 3: anti-CD3, anti-CD8, and anti-CD69

   Incubate for 20 min at room temperature in the dark.
5. Wash cells with FACS staining buffer.
6. Resuspend in 1% paraformaldehyde and store at 4°C in the dark until acquired on flow cytometer.

Interpretation

For screening of X-HIGM, peripheral blood T cells stimulated first with PMA and ionomycin are stained for T-cell surface markers such as CD69 and CD40 ligand (CD154). Cell surface markers of T-cell activation may be analyzed by flow cytometry to investigate adequate T-cell activation and the ability of T cells to upregulate critical costimulatory molecules. CD69, a member of the C-type lectin domain family, is a surface receptor upregulated within hours of T-cell

activation and can serve as a positive control or marker for adequate T-cell activation and is routinely used in screening for CIDs such as X-HIGM. Since CD69 and CD154 are not present on resting T cells and are activation markers with similar kinetics of expression, CD69 staining serves as a suitable positive control for adequate culture stimulation conditions. Additionally, since CD69 expression is dependent on activation of the Ras/mitogen-activated protein kinase pathway, absence of CD69 expression on activated T cells may suggest a proximal signal transduction defect. If CD154 is detected but the clinical suspicion is still high for HIGM, use of soluble biotinylated CD40:Fc can determine the functionality of the expressed protein; however, this reagent is more difficult to acquire.

Tyrosine Phosphorylation by Flow Cytometry (Phosphoepitope Analysis)

A number of suitable reagents are now available to stain for phosphorylation of essential signaling molecules by flow cytometry rather than more labor-intensive immunoblotting methods and can offer more information since single cells can be analyzed for multiple parameters (42).

1. PBMCs should be isolated as detailed elsewhere.
2. Stimulate PBMCs to induce the desired phosphorylation step. For example, to screen for signaling defects in the IL-2–IL-2R axis, PBMCs are incubated with 1,000 U of recombinant IL-2 and then stained intracellularly with a fluorophore-conjugated anti-phospho-STAT5 antibody (26). A proper control includes unstimulated cells.
3. Wash cells and stain with predetermined concentration of desired antibodies against surface receptors. Incubate for 30 min at 4°C in the dark. Wash with FACS buffer.
4. Fix cells with 2% paraformaldehyde for 30 min at room temperature in the dark. Wash cells with FACS buffer.
5. Permeabilize cells with ice-cold methanol and incubate at 4°C in the dark for 15 min. Wash with FACS buffer × 2.
6. Stain cells with predetermined concentration of antibodies that recognize intracellular protein of interest as well as antibodies specific for the phosphorylated form of the protein of interest in FACS buffer for 30 min at room temperature in the dark. Proper controls include an isotype control.
7. Acquire data on flow cytometer.

Interpretation

Analysis of tyrosine phosphoproteins is indicated if a defect in proximal antigen receptor signaling is suggested by defective lymphocyte proliferation or $[Ca^{2+}]_i$ mobilization with CD3 cross-linking. The development of these tools has resulted in more-rapid screening techniques for CIDs, decreased sample volume requirements, and increased sensitivity compared with immunoblot assays. STAT5b deficiency provides an excellent example for the use of phosphoepitope flow cytometry. In this CID, stimulation with IL-2 demonstrates diminished phospho-STAT5 based on frequency of positive cells determined with isotype control and compared to control cells. With flow cytometry the amount of protein per cell can be determined with various software analysis programs and is expressed at median fluorescence intensity. Ratios between phosphorylated and nonphosphorylated protein can be determined with the experimental approach. This is a rapid screening test, and positive results should be confirmed at the genetic level.

T-Cell Proliferation Assays

Lymphocyte proliferation response *in vitro* can be assessed by [^{3}H]thymidine incorporation and liquid scintillation or by flow cytometry using 5-ethynyl-2′-deoxyuridine. Alternatively, carboxyfluorescein succimidyl ester dilution can simultaneously determine cell proliferation and cell division number by flow cytometry (43). Typical T-cell stimulants include mitogens such as PHA, vaccine antigens (e.g., tetanus toxoid), PMA plus ionomycin, or antibodies that cross-link the TCR complex (i.e., anti-CD3 clone OKT3). The response to the stimulant can provide useful information on the extent of the T-cell dysfunction and provide guidance for additional studies. For example, T-cell proliferation to PMA plus ionomycin may be used to screen for proximal TCR signaling defects. Since PMA plus ionomycin bypasses the need for TCR expression or function, a significantly diminished response to PHA or CD3 cross-linking but normal PMA plus ionomycin response is suggestive of abnormalities in the TCR complex or in very early TCR signaling events.

Lymphocyte Proliferation

1. Suspend PBMCs in appropriate culture media (e.g., RPMI-1640 plus 10% fetal calf serum, 100 μg/ml penicillin, 100 U/ml streptomycin, and 2 mM L-glutamine) at a concentration of 1×10^6 cells/ml.
2. Incubate 1×10^4 cells in 200 μl at 37°C in flat-bottomed 96-well plates with 50 ng/ml anti-CD3 antibody (agonistic clone, e.g., UCHT1), 5 μg/ml PHA (Burroughs Wellcome, Research Triangle Park, NC), or 0.5 ng/ml PMA plus 1 μM ionomycin for 72 h.
3. Pulse wells with 0.96 μCi/well of [^{3}H]thymidine for 6 h, harvest, and count in a scintillation counter.

More-nuanced T-cell proliferation studies can be performed by adding cytokines to the culture alongside CD3 cross-linking. For example, the addition of IL-2 increases the proliferative response above CD3 stimulation alone. The absence of an increased proliferative response would be suggestive of a defect in the IL-2–IL-2R axis, such as STAT5b deficiency, CD25 deficiency, or JAK3/common γ-chain hypomorphic mutations. Another example is the addition of IL-7 or IL-15 to the culture media alongside CD3 cross-linking. The absence of additional proliferation with IL-7 suggests a defect in the IL-7–IL-7R axis or impaired differentiation or maintenance of T-cell memory, as seen in STAT3 deficiency.

Recall response to vaccine antigens can be determined by all of the methodologies listed above. The responding T-cell frequency is diminished and will require longer incubation times and ideally acquisition of high event counts for flow cytometry-based methods. Diminished recall response is seen in CIDs with global T-cell functional defects, as well as in CIDs with intact T-cell function with global stimulants, e.g., PHA, but impaired T-cell memory differentiation or maintenance.

Ca^{2+} Flux Assays

If T-cell proliferation is diminished with CD3 cross-linking, measurements of $[Ca^{2+}]_i$ mobilization may be indicated in order to localize a putative signaling defect, calcium channel dysfunction, or store-operated Ca^{2+} entry defect. $[Ca^{2+}]_i$ flux assays may be done either by fluorimetry or by flow cytometry. Fluorimetric methods require more cells but do not require concomitant cell staining with potentially stimulatory antibodies. The advantages of flow cytometry $[Ca^{2+}]_i$ flux assays include smaller cell number requirement, and they more easily allow for continuous monitoring of $[Ca^{2+}]_i$ flux alongside other immune markers. To test for proximal signaling defects, depletion of intracellular Ca^{2+} stores is monitored after cross-linking of surface TCR (with agonistic antibody such

as clone UCHT1) in cells loaded with a ratiometric Ca^{2+} indicator dye (e.g., Indo-1). In patients with defects in calcium channels or store-operated Ca^{2+} entry defects, after depletion of intracellular Ca^{2+} stores with activation, Ca^{2+} is added to the analysis tube and reentry is monitored (42).

Fluorimetric Assay

1. Suspend PBMCs at 2×10^7 cells/ml in complete RPMI and load with 3 μM Indo-1 acetomethoxy (AM) for 30 min at 37°C.

2. Wash cells in calcium-containing buffer (e.g., Hanks balanced salt solution plus 1% bovine serum albumin, 1 mM $CaCl_2$, and 0.5 mM $MgCl_2$), resuspend at 5×10^6 cells/ml in calcium-containing buffer, and keep on ice until use.

3. Warm 400 μl of cell suspension at 37°C for 2 min before analysis. Measure absorbance at an excitation wavelength of 355 nm and emission wavelengths of 400 nm and 500 nm using a fluorescence spectrophotometer. Maximal fluorescence is determined after cell lysis with 5 μl of 10% Triton X-100 detergent; minimal fluorescence is determined after addition of 50 μl of 1 M Tris base and 15 μl of 0.4 M EGTA.

4. Recordings are made before and after cells are stimulated by TCR cross-linking. For T-cell analysis, add 2 μl of biotinylated anti-CD3 antibody (agonistic antibody such as clone UCHT1) plus 5 μg/ml streptavidin, or a purified anti-CD3 antibody followed by IgM MAb to TCR to cross-link surface may be used instead. To ensure proper loading of Indo-1, add 1 μl of 1 mM ionomycin to nonresponding cell suspensions after 5 min.

Flow Cytometric Assay

1. Stain 2×10^7 PBMCs with a purified, azide-free anti-CD3 antibody for 30 min in the dark at room temperature, wash, and resuspend 2×10^6 cells in 1 ml calcium/magnesium-free RPMI or Hanks balanced salt solution.

2. Incubate PBMCs for 30 min at 37°C in 3 μM Indo-1 AM, wash, and resuspend in 1 ml calcium/magnesium-free RPMI.

3. Measure baseline fluorescence of gated $CD3^+$ for 1 to 2 min, followed by recordings for 10 min of fluorescence after addition of an anti-CD3 cross-linking antibody.

4. Change in calcium flux after stimulation is calculated as fluorescence intensity peak increase by subtracting fluorescence intensity value before stimulation from the value after stimulation.

Protein Tyrosine Phosphorylation by Immunoblotting

Analysis of tyrosine phosphoproteins is indicated if a defect in proximal antigen receptor signaling is suggested by defective lymphocyte proliferation or $[Ca^{2+}]_i$ mobilization to TCR stimulation.

1. Incubate 100 μl of 2×10^6 PBMCs or enriched for CD2 using magnetic bead selection (Dynal, Life Technologies) for 20 min on ice with 2 μl each of biotinylated anti-CD3 MAb plus biotinylated anti-CD4 MAb or PBS alone. Wash cells, resuspend in 100 μl PBS, and cross-link with 5 μg/ml avidin for 4 min at 37°C.

2. Lyse cells in 45 μl of NP-40 buffer (1% NP-40 plus 10 mM Tris [pH 7.6], 150 mM NaCl, 0.5 mM EDTA, 10 mM NaF, 1 mM phenylmethylsulfonyl fluoride, 1 μg/ml pepstatin A, 10 μg/ml leupeptin, 1 μg/ml aprotonin, and 1 mM Na_3VO_4) for 30 min at 4°C. Centrifuge cells at $12{,}000 \times g$ at 4°C for 10 min, collect supernatants, and mix with 15 μl of 4× sample buffer dye (2% SDS, 5% 2-mercaptoethanol, 250 mM Tris, 10% glycerol, and 1 mg/ml bromophenol blue [pH 6.8]). Boil at 90°C for 5 min prior to separation by SDS–12% PAGE under reducing conditions.

3. Electrophoretically transfer separated protein bands to Immobilon-P membranes (Millipore), block in blotting buffer (Tris-buffered saline plus 0.1% Tween) plus 3% bovine serum albumin, and incubate at room temperature for 1 h in blotting buffer with 4G10 (anti-phosphotyrosine MAb; Upstate Biotechnology, Millipore).

4. Wash filters three times in blotting buffer, and incubate with horseradish peroxidase-conjugated goat anti-mouse MAb (Southern Biotechnology Associates, Birmingham, AL) for 1 h at room temperature. Phosphoproteins are assayed using an enhanced chemiluminescence detection system (e.g., ECL; GE Healthcare, Piscataway, NJ).

Apoptosis

Apoptosis, or activation-induced cell death, is a normal consequence of T-cell activation and serves to maintain T-cell homeostasis. Defects in apoptosis are observed in several CIDs. The clinical consequences of impaired apoptosis include lymphoproliferation (e.g., SAP deficiency), impaired T-cell survival (e.g., MST1 deficiency), and possibly impaired $CD8^+$ T-cell effector responses (e.g., XIAP deficiency).

In vitro induction of apoptosis is routinely performed using T-cell restimulation. PHA T-cell blasts are first generated *in vitro*, followed by CD3 cross-linking that typically would induce apoptosis in a proportion of the blasting T cells. T cells are subsequently stained for annexin V (AV; surface phosphatidylserine is an early marker of apoptosis) and a marker for necrosis (typically propidium iodide [PI]). Survival is determined as the percentage of AV-PI-negative cells. It is essential to run healthy controls alongside the subject's cells. T-cell survival above or below healthy control is suggestive of an apoptosis defect. This activation-induced cell death is Fas (CD95) dependent, and CD95 cross-linking can be a suitable alternative to CD3.

Apoptosis assays are a useful screening tool for some CIDs, but correlation with clinical disease is not always apparent. Therefore, normal apoptosis results should not strongly influence decision making for confirmatory genetic testing or additional immunologic studies in cases with abnormal immunophenotyping and suggestive CID-associated clinical disease (40).

Antibody Deficiencies

KIMBERLY C. GILMOUR, ANITA CHANDRA, AND D.S. KUMARARATNE

76

DISORDERS CHARACTERIZED BY ANTIBODY DEFICIENCY

Antibody deficiency can be defined as a condition characterized by a reduction in serum immunoglobulin concentrations below the fifth centile for age. Antibody deficiency may affect all classes of immunoglobulins or may be confined to a single isotype.

WHO SHOULD BE INVESTIGATED FOR ANTIBODY DEFICIENCY: CLINICAL MANIFESTATIONS OF ANTIBODY DEFICIENCY

Key Concepts

1. Patients with antibody deficiency typically develop recurrent infection with encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* type B. The common sites affected are the upper and lower respiratory tracts and the middle ear. From these sites, infection can spread via the bloodstream to produce metastatic infections, for example meningitis or bone and joint infection.

2. Structural lung damage (bronchiectasis, pulmonary fibrosis) can be a consequence of recurrent respiratory tract infections in untreated or inadequately treated, antibody-deficient patients, and contributes to morbidity and mortality. Once respiratory tract damage is established, patients are prone to sinopulmonary sepsis caused by nontypeable *Haemophilus influenzae* strains and with other bacterial species like *Pseudomonas*. Granulomatous lesions may affect the lungs, giving rise to a sarcoid-like state with impaired gas transfer and secondary fibrosis, or they may affect other organs like the liver, spleen, kidneys, or lymph nodes.

3. Diarrhea and malabsorption may occur due to chronic infection with intestinal pathogens including *Giardia*, *Campylobacter*, *Salmonella*, or Norovirus, or as a consequence of bacterial overgrowth in the small intestine.

4. In general, the course of uncomplicated viral infection (chicken pox, measles, etc.) is not significantly different from that in normal individuals, except for the rare occurrence of enteroviral infections; ECHO viruses or Coxsakie viruses can cause meningoencephalitis or dermatomyositis-like conditions. Oral polio vaccine-associated poliomyelitis has also been rarely reported in patients with antibody deficiency.

5. Arthritis has been reported in about 20% of patients and may be septic, caused by *Haemophilus influenzae* type b, *S. pneumoniae*, or *Mycoplasma/ureoplasma*, or aseptic, resembling seronegative rheumatoid arthritis.

6. Fungal and intracellular bacterial infections are not a feature of antibody deficiency.

7. About one-fifth of patients with antibody deficiency due to common variable immunodeficiency (CVID) develop autoimmune disorders. These include autoimmune hematological disorders (hemolytic anemia, autoimmune thrombocytopenia, pernicious anemia), autoimmune endocrinopathies (e.g., thyroid disease) or neurological diseases such as Guillain Barre Syndrome, and, rarely, a lupus-like syndrome.

8. Infants with antibody deficiency may present with failure to thrive.

MAJOR CATEGORIES OF PRIMARY ANTIBODY DEFICIENCY

Antibody deficiency may occur on its own or as part of a syndrome of severe combined immunodeficiency or combined B- and T-cell immunodeficiency. The latter two conditions are outside the scope of this chapter. The main features of primary antibody deficiencies are summarized in Tables 1 and 2.

APPROACH TO EVALUATION OF PATIENTS WITH SUSPECTED ANTIBODY DEFICIENCY

Antibody deficiency should be considered in patients with the following problems:

1. Recurrent, severe, or persistent sinopulmonary infections
2. Invasive encapsulated bacterial infections
3. Chronic diarrhea, malabsorption, or occasionally inflammatory bowel disease
4. Infants with failure to thrive

Suspected antibody deficiency should be confirmed with:

1. Measurement of serum IgG, IgA and IgM (IgG subclasses), and comparison with age-specific normal ranges to determine if these levels are below the 5th centile.

doi:10.1128/9781555818722.ch76

TABLE 1 The main phenotypes of primary antibody deficiencies[a]

Phenotype	Main clinical features	Main B-cell biological features	Known affected proteins
Pan-agammaglobulinemia (absence of IgM, IgG, and IgA)	Bacterial infections with encapsulated organisms (mainly respiratory tract) and enteroviral infections	Absence of $CD19^+$ B cells	λ5, BLNK, BTK, Cμ, Igα, Igβ, and PI3Kα May have trisomy 7 or 8 or dyskeratosis congenita
Pan-agammaglobulinemia in association with thymoma	Bacterial and opportunistic infections; autoimmunity	Decreased number of pro-B cells	Unknown
Variable pan-hypogammaglobulinemia (CVID)	Bacterial infections (affecting respiratory tract and GI system), autoimmunity, lymphoproliferation, and systemic granulomata	Decreased frequency of $CD27^+$ memory B cells; defective plasma cells in tissues	CD19, CD20, CD21, CD27, CD81, DNMT3B, ZBTB24, ICOS, SAP, XIAP, TACI, BAFFR
CSR deficiencies: reduced or absent IgG and IgA with normal or low IgM	Bacterial and opportunistic infections	Decreased frequency of $CD27^+$ memory B cells	CD40 and CD40L
	Bacterial infections, autoimmunity and lymphadenopathies	Normal frequency of $CD27^+$ B cells	AID and UNG, PMS2, PI3Kδ, NEMO
Isotype or light chain deficiencies:			
Variable low Igs	May be asymptomatic		Mutation or chromosomal deletion at 14q32
All Igs have lambda light chain	Asymptomatic		Mutations in κ constant gene
Isolated IgG subclass deficiency	Usually asymptomatic; minority poor Ab response to specific antigen and recurrent viral/bacterial infections	Normal B-cell numbers	Unknown
IgA with IgG subclass deficiency	Recurrent bacterial infections		Unknown
Selective IgA deficiency	Majority asymptomatic; some have recurrent bacterial infections with poor Ab responses; may have allergies or autoimmune disease		Unknown
Specific antibody deficiency (normal Ig concentrations)	Bacterial infections after 2 years of age associated with defective polysaccharide-specific Ab production	Normal B-cell numbers	NF-κB pathway proteins (CARD11, HOIL1, IκBα, and NEMO), BTK, LRBA, and CD20

[a]Abbreviations: AID, activation-induced cytidine deaminase; BAFFR, BAFF receptor; BTK, Bruton's tyrosine kinase; BLNK, B-cell linker; Cμ, constant region μ; CD40L, CD40 ligand; CSR, class switch recombination; CVID, common variable immunodeficiency; ICOS, inducible T-cell c-stimulator; NF-κB, nuclear factor κB; PI3K, phosphoinositide 3-kinase; SAP, SLAM-associated protein; TACI, transmembrane activator and CAML interactor; UNG, uracil *N*-glycosylase; PMS2, postmeiotic segregation 2; LRBA, lipopolysaccharide beige-like anchor protein; Ab, antibody.

2. In those above 20 years of age, serum protein electrophoresis, and if required, immunofixation should be carried out for the exclusion of paraproteinemia.
3. Assess response to immunization with T-cell-dependent (tetanus toxoid, haemophilus B conjugate), and T-cell-independent (polyvalent pneumococcal polysaccharide) (if >2 years of age) vaccines. The use and interpretation of these vaccine responses or the diagnosis of antibody deficiency is described in Orange et al., 2012 (1).

Antibody Deficiency Associated with Absent B Cells

B-cell maturation beyond the pre-B-cell stage found in the bone marrow requires signals received through the pre-B-cell receptor complex. The pre-B-cell receptor is composed of the μ chains, surrogate light chains (heterodimers of λ constant region with V pre-β), and the signal-transducing components Igα and Igβ. The activities of the protein Bruton's tyrosine kinase (BTK) and B-cell linker protein (BLNK) are also essential for the transduction of signals received via the B-cell (and pre-B-cell) receptors. Therefore, it is not surprising that mutations in each of these elements cause early onset antibody deficiency associated with lack of circulating B cells.

Ninety percent of all such cases occur in boys due to mutation of the *BTK* gene (2), which maps to the X chromosome (Xp22). This condition is called X-linked agammaglobulinemia, which was the first immunodeficiency to be described in 1952 by Colonel Ogden Bruton. Mutations in the genes, including μ (3), λ5 (4), Igα (5), Igβ (6), and BLNK (7) cause rare autosomal recessive forms of early onset antibody deficiency with severe B lymphopenia.

Antibody Deficiency Due to Defect in Immunoglobulin Isotope Switching

During primary antibody responses, B cells initially produce IgM and later on in the response switch to the production of IgG, IgA, and IgE.

During the so-called immunoglobulin class-switching process, the heavy-chain constant region changes while antigen specificity is maintained. Immunoglobulin class switch takes place within germinal centers contained within B-cell follicles of the secondary lymphoid organs. Another process that occurs within germinal centers is somatic hypermutation, which results in the sequential accumulation of point mutations in the Ig variable-region gene. If the point mutation(s) result in increased binding affinity to the inducing antigen, the B-cell blasts (centrocytes) survive, proliferate, and eventually give rise to memory B cells and plasma cells that secrete high-affinity antibody (this process is called affinity maturation). Through these processes, memory B cells are generated within germinal centers.

Defects in genes encoding molecules required for the above processes, which operate within germinal centers, result in a form of antibody deficiency with elevated (or normal) IgM levels but lacking IgG, IgA, and IgE. These conditions are called hyper-IgM syndromes (HIGM). A key requirement for germinal center formation and function is the interaction of CD40 (belonging to the TNF-receptor superfamily) found on the surface of B cells with an "activation induced" CD40-ligand (CD40L) protein expressed on the surface of CD4 lymphocytes. Mutations in the *CD40L* (8) gene or the *CD40* (9) gene result in X-linked (relatively

common) and autosomal recessive (rare) HIGM, respectively. Patients with the CD40L deficiency suffer from recurrent bacterial infections typical of antibody deficiency. However, because CD40L function is required for optimal T-cell immunity, they also suffer from opportunistic infections characteristic of T-cell deficiency. About one-third of patients with CD40L deficiency develop *Pneumocystis pneumonia*. Infections with cryptosporidiosis, toxoplasmosis, and nontuberculous mycobacteria also occur in this condition. These opportunistic infections can be explained on the basis that the interaction of CD40L on activated T cells with CD40 expressed on the surface of macrophages and dendritic cells, which in turn undergo maturation and activation, is required for the optimum expression of antimicrobial immunity.

A high proportion of CD40L-deficient patients develop progressive liver damage (sclerosing cholangitis), probably the result of cryptosporidial infection of the bile ducts.

Defects in the RNA-editing enzymes, activation-induced cytidine deaminase (AID), and uracil-DNA glycosylase (UNG) result in two further types of hyper-IgM syndromes: defective class switching and affinity maturation. Mutations in the gene encoding the PMS2 component of the mismatch repair machinery cause a variable but significant defect in class-switch recombination.

Signaling through CD40, which belongs to the TNF-receptor superfamily, depends on the activation of the inhibitor of κ kinase complex, resulting in the induction of NF-κB. Hypomorphic mutations of the gamma subunit of the inhibitor of κ kinase complex, which is called NEMO (NF-κB essential modulator), impair NF-κB activation. Patients with mutations in NEMO develop a complex immunodeficiency, which includes features of the hyper-IgM syndrome.

An activating heterozygous mutation in PI3 kinase δ is responsible for about 10% of cases of hyper-IgM syndrome without one of the genetic defects described above, and is characterized by IgG2 subclass deficiency, normal or modestly elevated serum IgM levels, impaired specific antibody responses to bacterial capsular polysaccharides, and recurrent respiratory infection with progressive lung damage (10).

Common Variable Immune Deficiency

Most patients with primary antibody deficiency are collected under the heading "common variable immune deficiency," which is a condition characterized by low serum IgG and IgA and a variable decrease in IgM and the impaired production of specific antibodies following natural microbial exposure or immunization. The estimated prevalence of CVID is between 1 in 10,000 and 1 in 50,000. Clinically, CVID is dominated by the effects of antibody deficiency. About 20% of patients with CVID develop autoimmune disorders (arthritis, cytopenias, endocrinopathies). Some patients with CVID develop noncaseating sarcoidlike granulomata infiltrating various organs (lungs, liver, spleen, skin). The mechanisms underlying autoimmunity and granulomatous disease in CVID are unknown.

The immunological phenotype of CVID is heterogeneous with documented defects in B-cell survival, generation of B memory cells, and *in vitro* B- and T-cell activation. About 10% of cases of CVID are familial, with a predominance of autosomal dominant or autosomal recessive inheritance. CVID or selective IgA deficiency can affect different members of the same kindred. Recently, a number of gene defects have been identified in CVID patients, accounting for about 10 to 15% of the total patient pool.

The most common defect (in approximately 10% of CVID patients) is a mutation of the gene TACI (transmembrane activator and calcium modulator and cyclophilin ligand interacter). TACI, which belongs to the TNF-receptor superfamily, is a ligand for the cytokines BAFF (B-cell-activating factor of the TNF family) and APRIL (a proliferation-induced ligand), which induce immunoglobulin class-switch recombination.

Mice deficient in BAFF or its receptor have impaired B-cell development and antibody deficiency. TACI$^{-/-}$ mice have reduced serum IgA and IgM levels, reduced antibody responses to T-cell-independent antigens, and tend to develop autoimmunity and B lymphoproliferation. Mutations in TACI have been found in CVID patients and their relatives, with selective IgA deficiency, indicating variable penetrance of this gene defect. In the majority of currently documented patients, TACI mutations affect only one allele, indicating a dominant negative effect of the mutated gene. A possible explanation is that TACI, like other members of the TNF-receptor family, undergo ligand-independent preassociation and function as multimeric units. Thus, incorporation of a mutated TACI chain in this multimeric complex may disrupt ligand binding or signal-transducing capacity. Recent studies have found that family members of CVID patients possessing heterozygous TACI mutations may have completely normal serum immunoglobulin levels and "*in vitro*" B-cell function. This leads to the conclusion that the development of antibody deficiency in those carrying heterozygous TACI mutations may depend on modifier genes or environmental factors.

Inducible costimulating receptor (ICOS) is a costimulatory T-cell molecule that induces cytokines required for supporting class-switch recombination, Ig production, and terminal B-cell differentiation. ICOS$^{-/-}$ and ICOS ligand$^{-/-}$ mice exhibit defective germinal center formation and antibody production. Mutations in the ICOS gene account for about 1% of CVID patients.

A single CVID patient was identified as having a mutation on the gene encoding the BAFF receptor, a finding that could be predicted from observations in BAFF$^{-/-}$ mice.

CD19 deficiency has been described in two families with CVID. CD19 is a B-cell accessory molecule that is required for B-cell activation, proliferation, and hence B-cell development. CD19$^{-/-}$ mice exhibit hypogammaglobulinemia and poor antibody responses to protein antigens. Deficiency of CD20, CD21, CD27, CD81, DNMT3B, and ZBTB24 have also been reported in rare patients with antibody deficiency.

In the case of the large majority of patients with CVID, the underlying molecular defect is unknown.

IgA Deficiency

IgA deficiency is characterized by reduced (<0.07 g/liter) or absent serum IgA levels. IgA deficiency is the most common form of primary antibody deficiency and affects about 1 in 700 Caucasians. IgA deficiency is rare in some racial groups (Japanese, Africans). The majority of IgA-deficient individuals remain free of infection due to the ability of IgG and IgM to compensate for the lack of IgA. Long-term studies have shown that a small proportion of IgA-deficient patients develop recurrent sinopulmonary or gastrointestinal infections. Most infection-prone IgA-deficient patients have concomitant IgG2 subclass deficiency and a selective inability to produce antibodies against bacterial capsular polysaccharides. IgA deficiency is associated with an increased incidence of atopy, celiac disease, and a range of autoimmune diseases, including arthritis, "lupus-like" syndrome, autoimmune endocrinopathies, and autoimmune cytopenias.

IgA-deficient patients with serum levels below 0.07 g/liter are at the risk of developing anti-IgA antibodies after receiving blood products. Such individuals are at risk of developing anaphylaxis on receiving blood products.

IgA deficiency and CVID can affect different members of the same kindred. Rarely, IgA deficiency can precede the development of CVID. Therefore, in some instances, the molecular mechanisms underlying CVID and IgA deficiency may be identical. TACI deficiency can cause IgA deficiency in some family members while others develop CVID. However, the molecular basis of IgA deficiency in most cases is largely unknown.

Genetic analyses of kindred with CVID and IgA deficiency have highlighted the existence of susceptibility loci within the MHC region of chromosome 6. The strongest linkage lies within the DR/DQ within the MHC class II region.

IgG Subclass Deficiency

Serum IgG comprises four subclasses, called IgG1, IgG2, IgG3, and IgG4, reflecting the relative abundance of these isotypes in the serum. IgG subclass deficiency is diagnosed on finding a reduction in the serum concentration of IgG subclasses, of more than two standard deviations below the mean value for age, despite the total IgG level being normal. In practice, IgG subclass assays are difficult to standardize due to the lack of an internationally accepted reference preparation. Furthermore, genetic variations that influence serum IgG subclass levels exist among different ethnic groups. Hence, age- and population-related normal ranges are not always available.

Some individuals with IgG subclass deficiencies are asymptomatic. Others with IgG subclass deficiencies are prone to recurrent sinopulmonary infections. Such infection-prone patients exhibit reduced antibody responses to bacterial capsular polysaccharides. Defective antipolysaccharide antibody responses are most often seen in individuals with IgG2 subclass deficiency with or without concomitant IgA deficiency. The molecular mechanisms underlying IgG subclass deficiencies are unknown.

THE LABORATORY INVESTIGATION OF PRIMARY ANTIBODY DEFICIENCY

Figure 1 shows an algorithm for suggested laboratory investigations.

Methods

Flow Cytometry

Flow cytometry is a widely available technology that can be used to examine surface markers (extracellular staining) and intracellular proteins (intracellular staining). Extracellular fluorescent staining for lymphocyte markers (CD3, CD19, $CD56^{+}16$, CD4, CD8) is readily available.

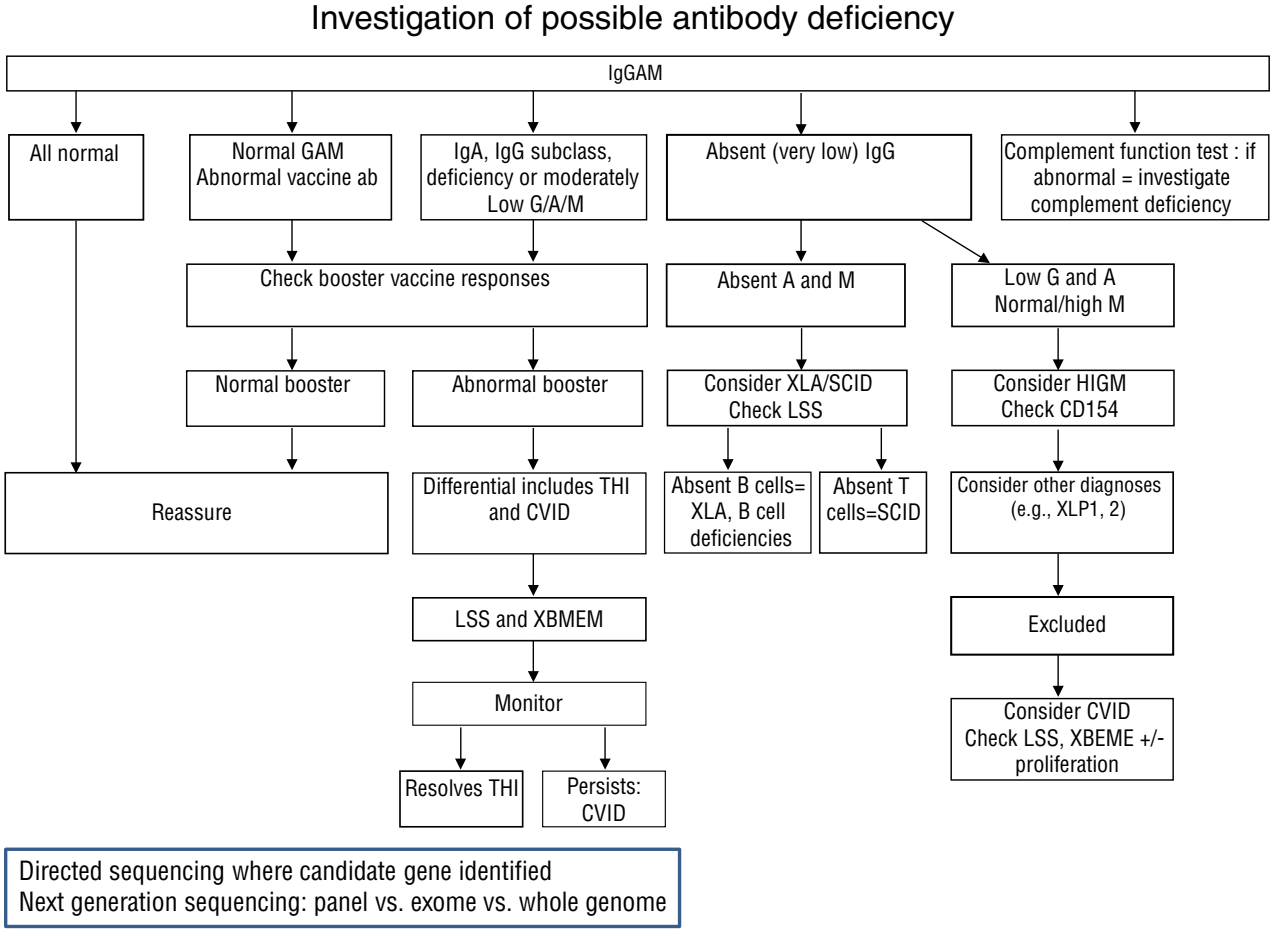

FIGURE 1 Investigation of possible antibody deficiency. This picture shows laboratory investigations in patients suspected of antibody deficiency.

Extended B-Cell Immunophenotyping

Extended B-cell immunophenotyping enables the measurement of different subtypes of B cells, which aids in the classification of CVID as patients with few switched memory B cells may have defects in genes such as ICOS and CD40L, those with increased transitional B cells tend to have lymphadenopathy, and the presence of elevated CD21low B cells correlates with splenomegaly (11).

Materials and Reagents

5-ml FACS tubes (VWR, catalog no. 734-0442)
CD27 (V500) (Becton Dickinson, catalog no. 561222)
CD38 (PerCp Cy5.5) (Becton Dickinson, catalog no. 551400)
IgM (Alexa 647) (Stratech Scientific, catalog no. 309-605-095)
CD19 (Pe-Cy7) (Becton Dickinson, catalog no. 341113)
IgD (FITC) (Life Technologies, catalog no. H15501)
CD21 (PE) (Becton Dickinson, catalog no. 555422)
FACS Lyse (Becton Dickinson, catalog no. 349202)
Cell Wash (Becton Dickinson, catalog no. 349524)
Cell Fix (Becton Dickinson, catalog no. 340181)
300 μl of EDTA blood from the patient – should be stained within 72 hours of collection

Procedure

1. Label tube with patient identifiers.
2. Add 300 μl of whole blood to a FACS tube. Mark the volume on the side of the tube.
3. Add 3 ml of Cell Wash and mix.
4. Spin for 45 seconds in the bench-top centrifuge at 1,000 rpm (relative centrifugal force of 800).
5. Using a Pasteur pipette, remove the supernatant, leaving the packed cells.
6. Add 3 ml of Cell Wash and resuspend the cell pellet.
7. Spin for 45 seconds in the centrifuge.
8. Using a Pasteur pipette, remove the supernatant, leaving the packed cells.
9. Add 3 ml of Cell Wash and resuspend the cell pellet.
10. Spin for 45 seconds in the centrifuge.
11. Using a Pasteur pipette, remove the supernatant, leaving the packed cells.
12. Resuspend using cell wash to the marked line on the tube.
13. Add 2 μl of antibodies (predilute IgM 1/100) to the bottom of a new tube.
14. Add 100 μl of washed blood to the bottom of the tube.
15. Mix all of the tubes well and incubate at room temperature in the dark for 10 minutes.
16. Add 1 ml of FACS Lyse to all of the tubes, mix well, and incubate at room temperature in the dark for 10 minutes.
17. At the end of the incubation, wash with the centrifuge: centrifuge on high for 45 s, and tip the supernatant off and blot the tubes on tissue. Mix all of the tubes to resuspend, and add 1 ml of Cell Wash. Centrifuge on high for 45 s, tip the supernatant off, and blot the tubes on tissue.
18. Resuspend in 500 μl Cell Wash or 500 μl Cell Fix.
19. Acquire on the day of staining using a flow cytometer that can detect 8 or more colors.
20. Analyze by gating on lymphocytes and then $CD19^+$ cells and then the different B-cell populations (see Fig. 2).

Adult normal ranges are the following: naive B cells, 43 to 82%; non-switched memory B cells, 7 to 32%; class switched memory B cells, 6.5 to 29%; $CD21^{Low}$ $CD38^{Low}$ B cells, 09 to 7.6%; transitional B cells, 0.6 to 3.5%; and plasmablasts, 0.4 to 3.6% (11). It is important to remember that memory B cells increase with age in children, and the younger the child, the more naive B cells he or she will have (12).

CD40L (CD154) Expression for Diagnosis of X-linked Hyper IgM Syndrome (HIGM)

Absence of CD154 expression is indicative of X-linked hyper-IgM syndrome (13). Whole blood is incubated with phorbol myristate acetate (PMA) and phytohemagglutinin (PHA) to stimulate the lymphocytes. Monoclonal antibodies conjugated with fluorochromes are then added, the red blood cells are lysed, and the results are acquired and analyzed by flow cytometry.

Materials and Reagents

FACS capped Tubes (VWR, catalog no. 734-0443)
5-ml FACS tubes (VWR, catalog no. 734-0442)
CD25 PE (Becton Dickinson, catalog no. 36793)
CD154 FITC (Ancell, catalog no. 353040)
CD45 PerCP (Becton Dickinson, catalog no. 347464)
CD4 APC (Becton Dickinson, catalog no. 58505)
FACS Lyse (Becton Dickinson, catalog no. 349202)
Cell Wash (Becton Dickinson, catalog no. 349524)
Cell Fix (Becton Dickinson, catalog no. 340181)
Culture media (RPMI + 10% FCS)
PHA (working solution, 320 μg/ml) (Bio-Stat Diagnostics, catalog no. HA17)
PMA (working solution, 5 μg/ml) (Sigma, catalog no. P8139)
1 ml lithium heparinized patient blood
1 ml lithium heparinized control blood (blood from any healthy adult)

Samples should be stimulated on the day the blood is taken and must be stained the day after stimulation, but the whole blood may be left at room temperature and set up to two days later as long as it has been diluted 50:50 in culture medium and kept at room temperature. These results are not as clear as samples set up on the day of receipt, and so this should be avoided if possible.

Procedure

1. Two FACS capped tubes per sample are required. In a tissue culture cabinet while following aseptic techniques, label tube one "Unstim" plus patient or control details. Label tube two "Stim" plus patient or control details.
2. Add 0.5 ml of culture medium and 0.5 ml of patient or control whole blood to each tube.
3. Add 18.5 μl of PHA working solution (final 6 μg/ml) and 4 μl of PMA working solution (final 20 ng/ml) to the "Stim" tubes. Mix gently.
4. Secure the caps loosely and incubate overnight at 37°C in CO_2.
5. Label two FACS tubes with the patient's initials and antibody combination plus 'S' for stimulated or 'U' for unstimulated. Do the same for the control. Stain both 'Stim' and 'Unstim' tubes, using CD154-FITC, CD25-PE, CD4-APC, and CD45-Percp.
6. Add 5 μl of antibody to the bottom of each tube, except for CD154.
