Library of Congress Cataloging-in-Publication Data

Names: Detrick, Barbara, editor. | Schmitz, John L. (John Leo), editor. | Hamilton, Robert G., editor.
Title: Manual of molecular and clinical laboratory immunology / edited by Barbara Detrick, John L. Schmitz, and Robert G. Hamilton.
Description: 8th edition. | Washington, DC : ASM Press, [2016] | ?2016
Identifiers: LCCN 2016012270 (print) | LCCN 2016014573 (ebook) | ISBN 9781555818715 | ISBN 9781555818722 ()
Subjects: LCSH: Immunodiagnosis—Handbooks, manuals, etc. | Immunology—Handbooks, manuals, etc. | Molecular immunology—Handbooks, manuals, etc.
Classification: LCC RB46.5 .M36 2016 (print) | LCC RB46.5 (ebook) | DDC 616.07/9—dc23
LC record available at http://lccn.loc.gov/2016012270

doi:10.1128/9781555818722

Johns Hopkins University, Department of Pathology, Rutland Ave., Baltimore, MD 21205

HEBA DEGHEIDY
FDA, Center for Biologics Evaluation and Research, WO52/72 RM 3209, 10903 New Hampshire Ave., Silver Spring, MD 20993

ALESSANDRA DELLAVANCE
Fleury Laboratories, Research and Development Department, Avenida Valdomiro de Lima 508, São Paulo, SP 04344-070, Brazil

BARBARA DETRICK
Immunology Laboratory, Department of Pathology, Johns Hopkins University, School of Medicine, 600 N. Wolfe St., Baltimore, MD 21287

JOSEPH A. DiGIUSEPPE
Hematopathology and Special Hematology Laboratory, Department of Pathology & Laboratory Medicine, Hartford Hospital, 80 Seymour St., Hartford, CT 06102

STEVEN D. DOUGLAS
The Children's Hospital of Philadelphia, University of Pennsylvania, Suite 1208 Abramson Research Building, 34th & Civic Center Blvd., Philadelphia, PA 19104

ELIZABETH R. DUFFY
Boston University School of Medicine, Pathology and Laboratory Medicine, 670 Albany St., Boston, MA 02118

JAMIE DUKE
The Children's Hospital of Philadelphia, 3401 Civic Center Blvd., Philadelphia, PA 19104

BRUCE E. DUNN
Medical College of Wisconsin, 8701 Watertown Plank Road, Milwaukee, WI 53226

GEORGE S. EISENBARTH
[Deceased]

MELISSA ELDER
University of Florida, Pediatrics, 1600 S.W. Archer Road, Gainesville, FL 32610

DEBORAH FERRIOLA
The Children's Hospital of Philadelphia, 3401 Civic Center Blvd., Philadelphia, PA 19104

LUIZ TADEU MORAES FIGUEREIDO
Virology Research Center, School of Medicine of Ribeirao Preto of University of Sao Paulo, Ribeirao Preto, São Paulo, Brazil

DAVID M. FLEISCHER
Children's Hospital Colorado, Pediatrics, Aurora, CO 80045

MARTIN FLEISHER
Memorial Sloan Kettering Cancer Center, 1275 York Ave., New York, NY 10065

THOMAS A. FLEISHER
Department of Laboratory Medicine, Clinical Center, National Institutes of Health, Bldg. 10 Rm. 2C306, 10 Center Drive, Bethesda, MD 20814

JUAN FLORES-MONTERO
Centro de Investigación del Cáncer (Instituto de Biología Molecular y Celular del Cáncer, CSIC-USAL), Instituto Biosanitario de Salamanca (IBSAL), Servicio General de Citometría (NUCLEUS-Universidad de Salamanca), Salamanca, 37007, Spain

PAULO LUIZ CARVALHO FRANCESCANTONIO
Pontifícia Universidade Católica de Goiás, School of Medical, Pharmaceutical and Biomedical Sciences, Avenida Universitária 1440, Setor Universitário, Goiânia, GO, 74.605-010, Brazil

MARVIN J. FRITZLER
University of Calgary, Cumming School of Medicine, Calgary, Alberta T2N 4N1, Canada

DENNIS GALANAKIS
State University of New York, Stony Brook, NY 11794

M. ERIC GERSHWIN
Division of Rheumatology/Allergy and Clinical Immunology, Genome and Biomedical Sciences Facility Suite 6510, School of Medicine, University of California at Davis, Davis, CA 95616

EMANUELA M. GHIA
UCSD, Moores Cancer Center, 3855 Health Science Drive, M/C 0820, La Jolla, CA 92093

PATRICIA C. GICLAS
National Jewish Health, Diagnostic Complement Laboratory, 1400 N. Jackson St., Denver, CO 80206

KIMBERLY C. GILMOUR
Immunology, Camelia Botnar Laboratories, Great Ormond Street Hospital for Children NHS Foundation Trust, London WC1N 3JH, United Kingdom

ELIZABETH A. GODBEY
Department of Pathology, Columbia University Medical Center, New York, NY 10032

PETER D. GOREVIC
Division of Rheumatology, The Mount Sinai Medical Center, Annenberg Building; Room 21-056, Box 1244, New York, NY 10029

KIM Y. GREEN
Caliciviruses Section, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, 9000 Rockville Pike, Building 50, Room 6318, Bethesda, MD 20892

PAMELA A. GUERRERIO
Food Allergy Research Unit, Laboratory of Allergic Diseases, National Institute of Allergy and Infectious Diseases, 4 Memorial Dr., Building 4, Room 228B, MSC0430, Bethesda, MD 20892

ROBERT G. HAMILTON
Johns Hopkins University School of Medicine, Dermatology, Allergy and Clinical Immunology Reference Library, 5501 Hopkins Bayview Circle, Baltimore, MD 21224

SHUHONG HAN
University of Florida, Division of Rheumatology & Clinical Immunology, PO Box 100221, Gainesville, FL 32610-0221

J. G. HANLY
Dalhousie University and Nova Scotia Health Authority (Central Zone), Departments of Medicine and Pathology, Nova Scotia Rehabilitation Center, 1341 Summer St., Halifax, NS B3H 4K4, Canada

RONALD J. HARBECK
National Jewish Health, 1400 Jackson Street, Denver, CO 80206

NEIL HARRIS
University of Florida, Department of Pathology, 1600 SW Archer Rd, Gainesville, FL 32610

CHOLI HARTONO
Weill Cornell Medical College, Nephrology, 505 E. 70th St., Helmsley 2nd Floor, New York, NY 10021

HARRY R. HILL
University of Utah, Department of Pathology, Pediatrics and Medicine, 50 N. Medical Drive, Room 5B-114, Salt Lake City, UT 84132

MICHITO HIRAKATA
Medical Education Center, Graduate Medical Education Center, Keio University School of Medicine, Tokyo, Japan

RICHARD L. HODINKA
University of South Carolina School of Medicine Greenville and Greenville Health System, Room 210, Health Science Administration Building, 701 Grove Rd., Greenville, SC 2960

KRISTIN A. HOGQUIST
Center for Immunology, University of Minnesota, 2-186 MBB, 2101 6th St. SE, Minneapolis, MN 55455

STEVEN M. HOLLAND
National Institutes of Health, LCID, CRC B3-4141, MSC 1684, Bethesda, MD 20892

JOHN J. HOOKS
National Institutes of Health, Immunology & Virology Section, NEI, Bldg. 10 Rm. 10N248, 10 Center Drive, Bethesda, MD 20814

D. CRAIG HOOPER
Thomas Jefferson University, Jefferson Center for Neurovirology, 1020 Locust St, Philadelphia, PA 19107

AMY P. HSU
National Institutes of Health, Laboratory of Clinical Infectious Disease, National Institute of Allergy and Infectious Diseases, Bldg. 10 CRC Rm B3-4233, 10 Center Drive, Bethesda, MD 20892

RICHARD L. HUMPHREY
Johns Hopkins Hospital, Pathology, 600 North Wolfe St., Baltimore, MD 21287

ANDREA ILLINGWORTH
Dahl Chase Diagnostic Services, 417 State St., Suite 540, Bangor, ME 04401

SABINA A. ISLAM
Center for Immunology and Inflammatory Diseases, Division of Rheumatology, Allergy and Immunology, Massachusetts General Hospital, Boston, MA 02114

ANNETTE M. JACKSON
Immunogenetics Laboratory, Johns Hopkins University School of Medicine, 2041 E. Monument Street, Baltimore, MD 21205

STEVEN JACOBSON
National Institute of Neurological Disorders and Stroke, National Institutes of Health, 9000 Rockville Pike, Rockville, MD 20892

ELAINE S. JAFFE
Laboratory of Pathology, Center for Cancer Research, National Institutes of Health, 10 Center Dr./Rm. 3S235, MSC-1500, Bethesda, MD 20892

JEFFREY A. JOHNSON
Division of HIV/AIDS Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30329

JERRY A. KATZMANN
Mayo Clinic and Mayo Foundation, Laboratory Medicine and Pathology, 200 First St. SW, Rochester, MN 55905

MICHAEL KEENEY
Hematology/Flow Cytometry, London Health Sciences Centre, Victoria Hospital, 800 Commissioners Road E, London, Ontario, N6A5W9 Canada

DAVID F. KEREN
University of Michigan, 5228 Medical Science I, 1301 Catherine, Ann Arbor, MI 48109

THOMAS S. KICKLER
Johns Hopkins University School of Medicine, 1800 Orleans Street, Sheikh Zayed B2-120Q, Baltimore, MD 21287

KAREN E. KING
Johns Hopkins Hospital, Transfusion Medicine, 1800 Orleans St., Baltimore, MD 21287

THOMAS J. KIPPS
UCSD, Moores Cancer Center, 3855 Health Science Drive, M/C 0820, La Jolla, CA 92093

AMY D. KLION
National Institutes of Health, Laboratory of Parasitic Diseases, NIAID, Bldg. 4, Rm. B1-28, Bethesda, MD 20892

VIJAYA KNIGHT
National Jewish Health, National Jewish Health Advanced Diagnostic Laboratories, Division of Pathology, Department of Medicine, 1400 Jackson St., Denver, CO 80206

DOUGLAS B. KUHNS
Clinical Services Program, P.O. Box B, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD 21702

D.S. KUMARARATNE
Department of Clinical Biochemistry and Immunology, Box 109, Addenbrooke's Hospital, Hills Road, Cambridge CB2 0QQ, United Kingdom

MARK KUNKEL
The Children's Hospital of Philadelphia, 3401 Civic Center Blvd., Philadelphia, PA 19104

MASATAKA KUWANA
Department of Allergy and Rheumatology, Nippon Medical School, 1-1-5 Sendagi, Bunkyo-ku, Tokyo 113-8602, Japan

ROBERT S. LANCIOTTI
Arbovirus Diseases Branch, Centers for Disease Control & Prevention, 3150 Rampart Road (CSU Foothills Campus), Fort Collins, CO 80521

MARIE LOUISE LANDRY
Yale University, Laboratory Medicine and Internal Medicine, P.O. Box 208035, New Haven, CT 06520

TERRI LEBO
National Jewish Health, Advanced Diagnostic Laboratories, 1400 Jackson St., Denver, CO 80206

HOWARD M. LEDERMAN
Pediatric Allergy & Immunology, Johns Hopkins Hospital - CMSC 1102, 600 N Wolfe St, Baltimore, MD 21287-3923

DIANE S. LELAND
Department of Pathology and Laboratory Medicine, Indiana University School of Medicine, IU Health Pathology Laboratory Building, Room 6027F, 350 W 11th St, Indianapolis, IN 46202

PATRICK S. C. LEUNG
Division of Rheumatology/Allergy and Clinical Immunology, Genome and Biomedical Sciences Facility Suite 6510, School of Medicine, University of California at Davis, Davis, CA 95616

ARNOLD I. LEVINSON
Perelman School of Medicine, University of Pennsylvania School of Medicine, Room 316 Blockley Hall, 423 Guardian Drive, Philadelphia, PA 19104

YI LI
University of Florida, Division of Rheumatology & Clinical Immunology, PO Box 100221, Gainesville, FL 32610-0221

CURT LIND
The Children's Hospital of Philadelphia, 3401 Civic Center Blvd., Philadelphia, PA 19104

MARK D. LINDSLEY
Mycotic Diseases Branch, Centers for Disease Control and Prevention, 1600 Clifton Road, Mailstop G-11, Atlanta, GA 30333

ROBERT P. LISAK
Wayne State University Medical Center, Neurology, 4201 St. Antoine St., Detroit, MI 48201

CHRISTINE M. LITWIN
Department of Pathology and Laboratory Medicine, Medical University of South Carolina, 171 Ashley Ave., Charleston, SC 29425

SHELDON E. LITWIN
Department of Medicine, Medical University of South Carolina, 114 Doughty St., Charleston, SC 29425

DONNA P. LUCAS
Johns Hopkins University, Immunogenetics Laboratory, 2041 E. Monument St., Baltimore, MD 21205

ANDREW D. LUSTER
Center for Immunology and Inflammatory Diseases, Division of Rheumatology, Allergy and Immunology, Massachusetts General Hospital, Boston, MA 02114

HOLDEN T. MAECKER
Stanford University, Institute for Immunity, Transplantation, & Infection, Stanford University Medical School, 299 Campus Drive, Stanford, CA 94305

CHERYL L. MAIER
Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA 30322

MICHAEL P. MANNS
Department of Gastroenterology and Hepatology, Zentrum Innere Medizin, Medizinische Hochschule Hannover, Hannover, Germany

REBECCA MARSH
Division of Bone Marrow Transplantation and Immune Deficiency, Cincinnati Children's Hospital Medical Center, 3333 Burnet Ave., Cincinnati, OH 45229

JOHN MASSINI
University of Florida, Division of Rheumatology & Clinical Immunology, PO Box 100221, Gainesville, FL 32610-0221

RAYA MASSOUD
National Institute of Neurological Disorders and Stroke, National Institutes of Health, 9000 Rockville Pike, Rockville, MD 20892

J. PHILIP McCOY, JR.
National Institutes of Health, NHLBI, 10 Center Drive, Bethesda, MD 20892

BENJAMIN D. MEDOFF
Center for Immunology and Inflammatory Diseases, Pulmonary and Critical Care Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114

DIANA METES
University of Pittsburgh Medical Center, Thomas E Starzl Transplantation Institute, BST E1549, 200 Lothrop St., Pittsburgh, PA 15213

DIMITRI MONOS
The Children's Hospital of Philadelphia, 3401 Civic Center Blvd., Philadelphia, PA 19104

MARTINA MURPHY
University of Florida, Hematology/Oncology, 1600 SW Archer Rd., Gainesville, FL 32610

THANGAMANI MUTHUKUMAR
Weill Cornell Medical College, Division of Nephrology & Hypertension, 525 E. 68th St., Box 3, New York, NY 10065

MOON H. NAHM
University of Alabama at Birmingham, 845 19th St. S, BBRB 614, Birmingham, AL 35294

STANLEY J. NAIDES
Immunology, Quest Diagnostics Nichols Institute, 33608 Ortega Highway, San Juan Capistrano, CA 92675

HUBERT G. M. NIESTERS
University Medical Centre Groningen, Department of Medical Microbiology, Division of Clinical Virology, Hanzeplein 1, Groningen, The Netherlands

TIMOTHY B. NIEWOLD
Mayo Clinic, Department of Immunology and Division of Rheumatology, 200 1st Street SW, Rochester, MN 55905

DOUGLAS F. NIXON
Dept. of Microbiology, Immunology and Tropical Medicine, School of Medicine & Health Sciences, The George Washington University, Ross Hall 736, 2300 Eye Street, NW, Washington, D.C. 20037

ROBERT NUSSENBLATT
Laboratory of Immunology, National Eye Institute, National Institutes of Health, Bldg. 10 Rm 10N109, 10 Center Drive, Bethesda, MD 20814

THOMAS B. NUTMAN
Laboratory of Parasitic Diseases, National Institute for Allergy and Infectious Diseases, National Institutes of Health, 4 Center Drive, Room B1 03, Bethesda, MD 20892

MAURICE R. G. O'GORMAN
Keck School of Medicine, University of Southern California, and the Children's Hospital of Los Angeles, Pathology and Pediatrics, 4650 Sunset Blvd #43, Los Angeles, CA 90027

ALBERTO ORFAO
Centro de Investigación del Cáncer (Instituto de Biología Molecular y Celular del Cáncer, CSIC-USAL), Instituto Biosanitario de Salamanca (IBSAL), Servicio General de Citometría (NUCLEUS-Universidad de Salamanca), Salamanca, 37007, Spain

S. MICHELE OWEN
National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30329

GABRIEL I. PARRA
Caliciviruses Section, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, 9000 Rockville Pike, Building 50, Room 6316, Bethesda, MD 20892

R. STOKES PEEBLES, JR.
Vanderbilt University, Medicine, T-1218 MCN, Vanderbilt University Medical Center, Nashville, TN 37232

JOSÉ JUAN PÉREZ
Departmento de Hematología, Hospital Universitario de Salamanca, Instituto Biosanitario de Salamanca (IBSAL); Centro de Investigación del Cáncer (Instituto de Biología Molecular y Celular del Cáncer, CSIC-USAL), Salamanca, 37007, Spain

ROBERT B. PETERSEN
Case Western Reserve University, Department of Pathology, 5-126 Wolstein Building, 2103 Cornell Road, Cleveland, OH 44106

SUHAS H. PHADNIS
Medical College of Wisconsin, Pathology, 9200 W. Wisconsin Ave., Milwaukee, WI 53005

FANNY POJERO
Centro de Investigación del Cáncer (Instituto de Biología Molecular y Celular del Cáncer, CSIC-USAL), Instituto Biosanitario de Salamanca (IBSAL), Servicio General de Citometría (NUCLEUS-Universidad de Salamanca), Salamanca, 37007, Spain

YVONNE POSEY
Beaumont Hospital – Royal Oak, Clinical Pathology, 3601 W. 13 Mile Road, Royal Oak, MI 48073

DEBRA LONG PRIEL
Clinical Services Program, P.O. Box B, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD 21702

CALMAN PRUSSIN
Laboratory of Allergic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Building 10, Room 11N238, Bethesda, MD 20892-1881

NOEMÍ PUIG
Departmento de Hematología, Hospital Universitario de Salamanca, Instituto Biosanitario de Salamanca (IBSAL); Centro de Investigación del Cáncer (Instituto de Biología Molecular y Celular del Cáncer, CSIC-USAL), Salamanca, 37007, Spain

RONALD L. RABIN
Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, 10903 New Hampshire Avenue, Silver Spring, MD 20993

MARK RAFFELD
Laboratory of Pathology, Center for Cancer Research, National Institutes of Health, 10 Center Dr./Rm. 3S235, MSC-1500, Bethesda, MD 20892

ALEX J. RAI
Department of Pathology, Columbia University Medical Center, New York, NY 10032

RAJA RAJALINGAM
University of California at San Francisco, Immunogenetics and Transplantation Laboratory, Department of Surgery, 45 Castro St., Main Hospital Level B, CPMC Davis Campus, San Francisco, CA 94114

AMY RASLEY
Host-Pathogen Laboratory Group, Lawrence Livermore National Laboratory, Livermore, CA 94550

LAURA Z. RASSENTI
UCSD, Moores Cancer Center, 3855 Health Science Drive, M/C 0820, La Jolla, CA 92093

ELAINE F. REED
UCLA, Pathology, Rehab 1520, 1000 Veteran Avenue, Immunogenetics Center, Los Angeles, CA 90095

WESTLEY H. REEVES
University of Florida, Division of Rheumatology & Clinical Immunology, PO Box 100221, Gainesville, FL 32610-0221

NANCY L. REINSMOEN
HLA and Immunogenetics Laboratory, Comprehensive Transplant Center, Cedars-Sinai Health Systems, HLA and Immunogenetics Lab-SSB 197, 8723 Alden Drive, Los Angeles, CA 90048

RYAN F. RELICH
Department of Pathology and Laboratory Medicine, Indiana University School of Medicine, IU Health Pathology Laboratory Building, Room 6027E, 350 W 11th St, Indianapolis, IN 46202

DANIEL G. REMICK
Boston University School of Medicine, 670 Albany St., Boston, MA 02118

LYNNSEY RENN
Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, 10903 New Hampshire Avenue, Silver Spring, MD 20993

ADRIANA RICCIUTI
Johns Hopkins University, Department of Pathology, Rutland Ave., Baltimore, MD 21205

ANNELIES RIEZEBOS-BRILMAN
University Medical Centre Groningen, Department of Medical Microbiology, Division of Clinical Virology, Hanzeplein 1, Groningen, The Netherlands

KIMBERLY RISMA
Division of Allergy/Immunology, Cincinnati Children's Hospital Medical Center, 3333 Burnet Ave., Cincinnati, OH 45229

E. RENE RODRIGUEZ
Department of Pathology, 9500 Euclid Ave., Cleveland, OH 44022

JOHN T. ROEHRIG
Centers for Disease Control and Prevention, Atlanta, GA (Retired)

NOEL R. ROSE
Johns Hopkins University, Department of Pathology, SOM, 720 Rutland Avenue, Baltimore, MD 21205

JOHN M. ROUTES
Department of Pediatrics and Department of Microbiology and Molecular Genetics, Medical College of Wisconsin, Milwaukee, WI 53226

RICHARD RUBENSTEIN

Acknowledgment of Previous Contributors
The *Manual of Molecular and Clinical Laboratory Immunology* is by its nature a continuously revised work which refines and extends the contributions of previous editions. Since its first edition in 1976, many eminent scientists have contributed to this important reference work. The American Society for Microbiology and its Publications Board gratefully acknowledge the contributions of all of these generous authors over the life of this *Manual*.

Foreword: How It Began

In 1971, I was working at the University of Oxford's Sir William Dunn School of Pathology in the laboratory of James Gowans, the investigator who first definitively showed that the lymphocyte was the source of specific adaptive immunity. I was busily cannulating the thoracic ducts of rats in order to harvest T lymphocytes when I was informed that a transatlantic telephone call was coming in. My first reaction was fear of bad news. Rather, it was a phone call from Earle Spaulding. I knew Earle as the chairman of microbiology at Temple and active in the Eastern Pennsylvania branch of the American Society for Microbiology (ASM). He explained that he was calling as a member of the editorial group of the *Manual of Clinical Microbiology* (MCM), at that time in its first edition. His particular concern was the chapter on immunology, which devoted 100 pages to various serologic tests for infectious organisms with no mention of noninfectious diseases. Earle felt strongly that the field of immunologic diagnosis was growing exponentially and deserved a separate, companion manual. The MCM editorial board agreed, providing I was willing to accept the position of Editor-in-Chief.

I was delighted to receive the invitation. I had recently chaired a "blue ribbon" committee of the American Association of Immunologists (AAI) on the future of clinical immunology. We concluded that there was no space for a new patient-centered clinical specialty, but great need for improved, expanded laboratory support. A comprehensive manual would serve as a great stimulus to the whole field of laboratory-based clinical immunology. I accepted the offer with two qualifications. First, I needed a co-editor, particularly someone well versed at a practical level in immunology related to infectious diseases. Second, I asked that such a manual be cosponsored by the AAI. Both qualifications were agreed to by the ASM Publications Board.

The person I had in mind as co-Editor-in-Chief was Herman Friedman. I knew Herman from contacts arising from our joint interest in allergy research. I knew he understood the practice of laboratory immunology and was one of the few immunologists who actually researched the immunology of infection. Herman readily agreed to partner with me on the *Manual*, and so began a close collaboration that continued for three subsequent editions of the *Manual*, ended only by his untimely death. The AAI also accepted an offer of collaboration and appointed a liaison committee to work with us.

We were off and running, but we had no idea of how to proceed. There had never been a manual describing the entire laboratory practice of immunology. Part of our mission was to include the many applications of immunology devoted to detection and analysis of a wide variety of diseases, not only those induced by microorganisms. Should we approach the subjects disease by disease or method by method? We finally decided to compromise by beginning the book with invited chapters on the common methods used in the immunology laboratory, then continuing with sections covering their application to the main categories of disease. We included a final section on laboratory administration and quality control.

Having developed particular sections, we then sought the most experienced and highly qualified individuals to serve as section editors. Because of the cross-cutting matrix arrangement, there was major concern that some topics would be dealt with twice or even three times. We therefore decided to organize a "stakeholders meeting," at which all of the section editors met at ASM in Washington, DC, with proposed outlines of their sections. Going through each one systematically, we identified topics where overlap occurred and ensured that everything important was included once, but not more. We also made a fundamental decision that the book would be complete and free-standing. The methods would be described in sufficient detail that the laboratory worker could actually prepare the materials, perform the tests, and interpret the results without consulting other references. It should be understood that, at that time, most laboratory reagents

were prepared within the laboratory and were generally not available as commercial kits. This format required that we keep descriptions terse and the reference lists short.

When the first edition of the *Manual of Clinical Immunology* was published in 1976, we felt it warranted some type of celebration. Herman suggested that we should organize a meeting to mark the birth of the book and to bring together the leaders in clinical laboratory immunology, including our authors and section editors. Eventually, this led to the formation of the Association of Medical Laboratory Immunologists and the American Board of Medical Laboratory Immunology.

The *Manual* continues to be published at regular intervals to the present, as the editorial lineup has evolved. Barbara Detrick and Robert G. Hamilton joined me as Editors for the Sixth Edition, and Dr. Detrick has continued to lead the *Manual* for the Seventh and the present Eighth Edition. I hope the series will go on for many years. Although the *Manual*'s name has changed and the format is altered, the overall aim is still to improve the care of patients with infectious malignant inflammatory and immune-mediated disorders. With the ready availability of validated kits, the job of the clinical laboratory immunologist has shifted toward working with clinical colleagues on the significance and interpretation of laboratory tests.

I'm proud to have been involved in the genesis of this *Manual*. It would not have been possible without the continued support of ASM, the cooperation of AAI, the persistence of succeeding volume and section editors, the contributions of hundreds of practicing clinical laboratory immunologists, and the foresight of a few visionary microbiologists of the 1970 era who realized that immunology had become a discipline and specialty of its own. It never would have happened if Herman Friedman had not joined with me in accepting the challenge. I hope that he will long be remembered for his numerous contributions to immunology.

NOEL R. ROSE, MD, Ph.D.

Preface

For over 40 years, the *Manual of Clinical Laboratory Immunology* has been the leading reference source, both in the United States and abroad, to advance the field of laboratory immunology, to foster the best contemporary and most cutting-edge methodologies, and to translate basic immunologic principles into appropriate laboratory tests.

Since the publication of the 7th edition of this *Manual*, remarkable progress has been made in the field of immunology, and these notable advancements have been reflected in the clinical immunology arena as well. The scope of clinical immunology is exceptionally broad and encompasses nearly every medical specialty, including such areas as transplantation, rheumatology, oncology, infectious disease, allergy, hematology, and neurology, to name a few. Because of its strategic position in the hospital setting, it is critical that the clinical immunology laboratory should have a guide to follow with regard to accurate and appropriate laboratory procedures. As the field of clinical immunology continues to expand, we look to the laboratory director as a key person to gather the new basic information and integrate it into useful clinical procedures as well as to serve as a pivotal contact for communication with the various disciplines. In addition to keeping abreast with the most updated testing systems, the goal for this *Manual* is that it must not only serve the needs of today's clinical immunology laboratory but also look to the future, where even more dramatic progress in diagnosis and treatment can be anticipated.

In an effort to capture the new dimensions in this field and to reflect the continuous evolution of clinical immunology, significant changes have been introduced into the 8th edition of the *Manual of Molecular and Clinical Laboratory Immunology*. Several sections of the *Manual* have been notably updated to reflect the latest laboratory approaches in molecular assays as well as the shift to automated testing, kit-based diagnostics, and new technical tools: themes that are carried throughout the book. New chapters have been introduced to highlight these changes. For example, section D, Flow Cytometry, describes the latest applications of these techniques, such as polychromatic flow cytometry and mass cytometry; section F reviews fresh information on the clinical applications of cytokines and chemokines; the infectious disease sections H, I, and J include the newest strategies used in infectious disease diagnosis and treatment, including the HIV and syphilis algorithms; section K, Immunodeficiency Diseases, presents the recent newborn screening programs for severe combined immune deficiency; and section P, Transplantation Immunology, outlines the usefulness of next-generation sequencing in the human leukocyte antigen (HLA) laboratory.

Once again, this *Manual* is offered not just in print but also electronically as either an EPUB file or a PDF. This special feature will allow a larger audience to review and use the *Manual*.

As we produce the 8th edition of this *Manual*, it is appropriate to celebrate its success. Noel Rose, the *Manual*'s first Editor-in-Chief, has provided a foreword reflecting on how the field has changed over the past 5 decades.

Since the publication of this *Manual* is a joint effort of many dedicated individuals, I wish to acknowledge the outstanding commitment and invaluable support of our volume editors, section editors, and chapter authors, all of whom, as internationally renowned experts in their areas, have contributed their extraordinary experience, energy, and time to the success of this edition. Also, I would like to extend my appreciation to the ASM editorial staff, in particular Ellie Tupper, Senior Production Editor, and Christine Charlip, Director, ASM Press, who have provided their valuable experience and support to complete this edition.

BARBARA DETRICK, Ph.D.
Editor in Chief

Author and Editor Conflicts of Interest

Cem Akin (coauthor on chapter 85) has consultancy agreements with Novartis and Patara Pharma and receives research funding from Dyax.

Barbara Detrick (Editor in Chief, coauthor on chapter 106) serves as a consultant to Siemens Healthcare Diagnostics, Inc., Abbott Laboratories, and INOVA Diagnostics, Inc.

Deborah Ferriola (coauthor on chapter 113) receives royalties from Omixon. Omixon has licensed the protocol we developed for HLA typing by NGS from the Children's Hospital of Philadelphia and makes it available as a commercial product named "Holotype HLA." Omixon is mentioned in this chapter as a company that provides software analysis tools for the genotyping of HLAs using NGS data. It is not mentioned as a company that commercializes HLA typing products/kits, because at the time of writing Omixon had not developed this activity.

Marvin J. Fritzler (coauthor on chapter 88) has been a consultant to or received research gifts in kind from Inova Diagnostics Inc., Euroimmun GmbH, Mikrogen GmbH, Dr. Fooke Laboratorien GmbH, ImmunoConcepts, GSK Canada, Amgen, Roche, and Pfizer. He is the Director of Mitogen Advanced Diagnostics Laboratory.

Andrea Illingworth (coauthor on chapter 18) has received unrestricted Educational Grant funding and speaker honoraria from Alexion Pharmaceuticals.

Michael Keeney (coauthor on chapters 18 and 19) is a consultant for Beckman Coulter, Canada, and Alexion Pharma, Canada. He has received unrestricted Educational Grant funding and speaker honoraria from Alexion Pharmaceuticals.

Masataka Kuwana (chapter 91) holds a patent on an anti-RNA polymerase III antibody measuring kit.

Curt Lind (coauthor on chapter 113) receives royalties from a licensing agreement between Omixon Biocomputing and the Children's Hospital of Philadelphia and is an employee of Thermo Fisher Scientific, Transplant Diagnostics.

Robert P. Lisak (coauthor on chapter 99) is on an advisory board for Syntimmune.

Dimitri Monos (coauthor on chapter 113) receives royalties from Omixon. Omixon has licensed the protocol we developed for HLA typing by NGS from the Children's Hospital of Philadelphia and makes it available as a commercial product named "Holotype HLA." Omixon is mentioned in this chapter as a company that provides software analysis tools for the genotyping of HLAs using NGS data. It is not mentioned as a company that commercializes HLA typing products/kits, because at the time of writing Omixon had not developed this activity.

Stanley J. Naides (chapter 62) is a full-time employee of Quest Diagnostics Nichols Institute and receives a salary, stock, and stock options from Quest Diagnostics.

Timothy Niewold (coauthor on chapter 38) has received research grants from Janssen Inc. and EMD Serono Inc.

Maurice R. G. O'Gorman (chapter 20) is a BD Biosciences consultant and contractee.

Paul Sikorski (coauthor on chapter 114) is an employee of One Lambda, Inc., a Thermo Fisher Scientific brand.

Marek Smieja (coauthor on chapter 63) has done small studies with Copan and GenMark.

Melissa R. Snyder (chapter 103) participates on the Strategic Advisory Committee with INOVA Diagnostics.

Kathleen E. Sullivan (section editor) is a Baxter grant recipient and an Immune Deficiency Foundation consultant.

D. Robert Sutherland (coauthor on chapters 18 and 19) has received speaker fees and consulting fees from Alexion Pharmaceuticals.

Yi-Wei Tang (coauthor on chapter 57) has received research funds from Roche Molecular Dignostics and the Luminex Corporation.

Brent Wood (coauthor on chapter 22) has received research funding and honoraria for Advisory Board participation from Seattle Genetics and Amgen and honoraria from Abbvie for Advisory Board participation.

Andrea A. Zachary (coauthor on chapter 114) is a consultant for BiologicTx and Genentech and is a Scientific Advisory Board member for Immucor.

General Methods *section A*

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: THOMAS A. FLEISHER

Introduction

THOMAS A. FLEISHER

1

The "-omics" revolution has begun. Since the publication of the previous edition of *Manual of Molecular and Clinical Laboratory Immunology*, there have been major technological advances that are facilitating the application of genomics, proteomics, and microbiomics to better understand human health and disease. These disciplines are truly complementary, as genomics is directly linked to proteomics, and these new technologies are providing an improved understanding of the functional consequences related to alterations in the genome that lead to changes in the protein products of genes. The major advancements in next-generation sequencing have made characterization of the human microbiome a reality. Major efforts in microbiomics currently are focused on evaluation of the human bacterial community in health and disease. These three disciplines find common ground in the field of immunology, in which the genome provides the triggering instructions for protein products that are critically important for immune function and host defense. Alterations in the genetic code are now known to contribute to an ever-growing list of defects in immune function that result in susceptibility to microbial disease. In addition, altered immune function leading to inflammatory disease will be further clarified with these powerful new tools. Early lessons in the study of the human microbiota have revealed that commensal bacteria interact directly with the immune system to aid and model immunity. They also provide advantage to the host in settings of health and contribute to pathogenesis in circumstances of disease. The future of clinical immunology at a diagnostic and therapeutic level increasingly will rely on these techniques and further advances that will evolve more and more rapidly.

The laboratory methods available to evaluate proteins and the nucleotide code form the substance of chapters 2 and 3. Chapter 4 by Abraham and Barnidge focuses on specific protein quantitation using current qualitative and quantitative methods as well as the applications of mass spectrometry to generate a more accurate reflection of the constituent protein components in a sample. The promise of new biomarkers that may aid in diagnostic and/or therapeutic monitoring has yet to be realized, but advances in proteomics technology suggest that these applications should become a reality in the near future. The field of genomics has exploded with readily available next-generation sequencing techniques that have clarified genetic causes for a number of newly characterized immune disorders. This trend will continue: currently based primarily on genomic applications focused on exome sequencing, but within the very near future the approach will move to whole-genome sequencing. The technology for next-generation sequencing continues to be refined, and there is every reason to believe that faster, less expensive, and more accurate whole-genome sequencing will result. Chapter 2 by Hsu provides an overview of the standard Sanger-based sequencing, with clinical examples to help exemplify successful application of this method. This chapter also provides an overview of next-generation sequencing and reviews clinical applications of this methodology. More-extensive discussions of next-generation sequencing applied in health and disease can be found in reviews by Gonzaga-Jaurequi et al. (1) and Manolio et al. (2). A newer component of the technological revolution in biologic systems is focused on evaluating the microbial constituents—the microbiome—that are the commensal "partners" of every living host. Chapter 3 by Bushman provides a clear overview of the basic principles that have propelled the field of microbiomics and how this is likely to provide insight into understanding human health and disease. A recent review focusing on the microbiome of the human gastrointestinal tract provides additional insights into this important and emerging field (3).

The combination of genomics, proteomics, and microbiomics, three complementary disciplines, has substantial impact on the field of clinical immunology. Discovery of new genes provides insight that is further clarified by studying the protein products of these genes both at a basic characterization and a functional level. The developments in the field of microbiomics are revealing that the environment of each individual makes significant contributions to the immunologic system and that perturbations among our microbial "partners" can significantly influence human health and disease. Familiarity with these developing areas is necessary as they move more and more into mainstream laboratory testing linked to patient diagnosis and care.

Molecular Methods for Diagnosis of Genetic Diseases Involving the Immune System

AMY P. HSU

2

Disorders of the immune system affect a significant number of individuals, with prevalence estimates (per 100,000) determined by registries ranging from 5.6 in Australia (1) to 4.979 in France, 2.6 in The Netherlands, and down to 1.377 in Germany (2). Accurate diagnosis of immune system disorders may allow early intervention prior to extensive illness for severe disease, or more specific treatment in the case of later-diagnosed or milder disease. This chapter explores some of the current molecular methodologies for detecting disorders of the immune system and highlights specific pitfalls that may hinder accurate diagnosis.

SAMPLES

Study of the immune system is aided by the accessibility of an appropriate sample. A single 8-cc tube of blood may be lysed to extract DNA and/or RNA from all the blood cells together. Alternatively, whole blood may be processed to separate peripheral blood mononuclear cells (PBMCs) from granulocytes, followed by DNA or RNA isolation from a subset of cells. If obtaining a blood sample is not possible, then small amounts of DNA may be isolated from buccal swabs, tissue biopsy samples, saliva, or cell lines such as fibroblasts or Epstein-Barr virus-transformed B-cell lines. A secondary sample may be utilized if the patient has already undergone hematopoietic stem cell transplant, in which case a non-hematopoietic-cell sample is required. Buccal swab samples are easily obtained, are room temperature stable, and may be shipped to a testing lab. DNA from a buccal sample is often used for diagnosing family members of an affected individual. Care must be taken, however, if a patient has already received a bone marrow transplant because the cells obtained from a buccal sample may contain a large percentage of neutrophils and thus produce a false-negative result. DNA extraction involves lysing of the nucleated cells either mechanically or with a detergent-based lysis solution, removal of lipids and proteins, followed by DNA purification through alcohol precipitation or column capture. RNA isolation is similar, although care must be taken to avoid RNA degradation by RNases. There are numerous off-the-shelf kits available for small-scale DNA and RNA isolation, as well as instruments for medium- to large-scale isolation.

PCR

One of the fundamental techniques in molecular genetics is the use of PCR. This technique allows the specific amplification of a segment of DNA defined by the forward and reverse primer pair used in the reaction. The double-stranded DNA template is denatured, and oligonucleotide primers in the 20- to 35-bp range anneal to the template at the location complementary to the sequence of the primer. A polymerase enzyme is then used to add individual deoxynucleotides to the 3′ end of the primer to continue copying the template molecule. After a specified time, the temperature rises to denature the template-copy strand, and both then become available for primer binding. The cycle then repeats itself, resulting in an exponential amplification of the target region.

Sanger sequencing has been the gold standard for genetic diagnosis in recent decades. The technique is similar to standard PCR; however, only one primer is used, either forward or reverse, and included in the PCR mix is a percentage of fluorescently labeled dideoxynucleotides (ddNTPs). When the polymerase incorporates a ddNTP, the extension ceases, resulting in a fragment labeled with a fluorochrome dependent on the identity of the final nucleotide. This is repeated through multiple cycles. The resulting product is cleaned to remove unincorporated, labeled ddNTPs and then electrophoresed through a polymer-filled capillary to separate the fragments based on size. The resulting chromatogram is actually a display of time on the *x* axis versus intensity on the *y* axis, with the color of the peak being the third dimension. Because smaller fragments migrate through the polymer faster, they are detected first and longer fragments are seen later (Fig. 1).

Peak heights from one base to the next are not necessarily even; there is some variability within the local sequence, and certain base combinations result in higher or lower peaks. In general, however, the shorter fragments seen at the beginning of the sequence readout have higher signal strengths and well-defined peaks (Fig. 1A), while larger, later fragments have shorter, broader peaks and less resolution in homopolymer runs, seen in the three red peaks in the middle panel. Good-quality sequence should have well-defined peaks with little to no baseline noise compared with the lower tracing in Fig. 1A, in which the baseline is high

doi:10.1128/9781555818722.ch2

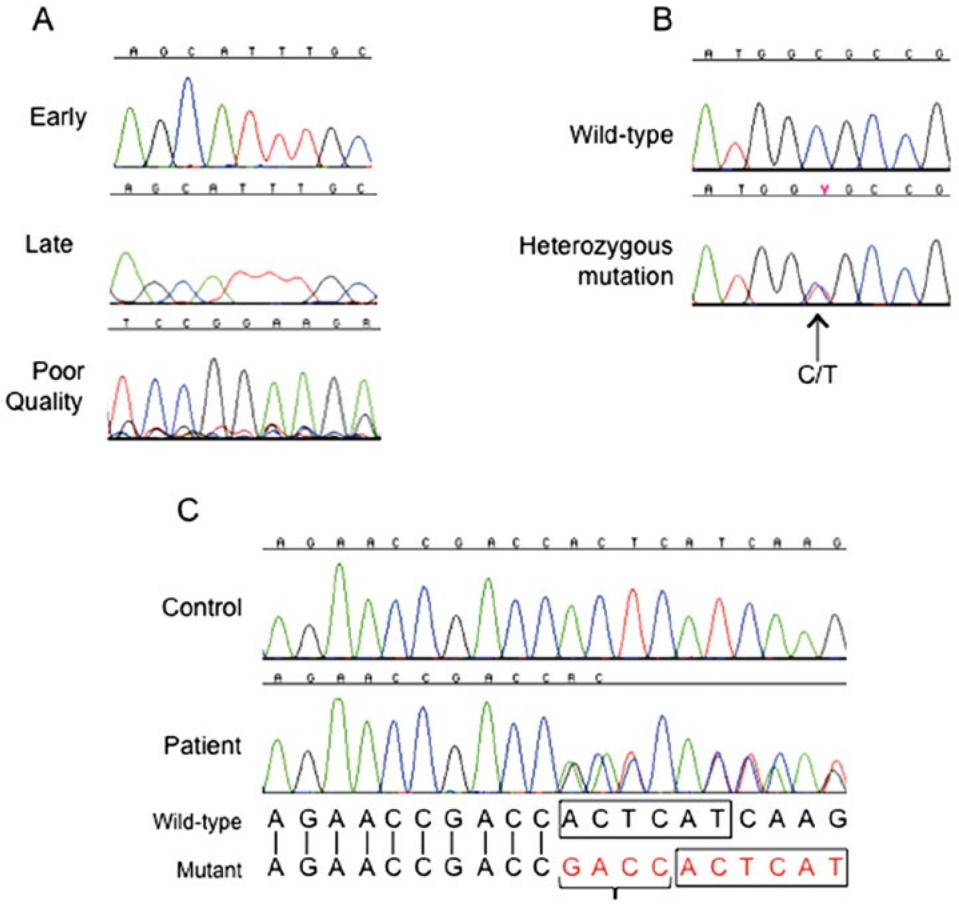

FIGURE 1 Sanger sequence chromatograms. (A) Normal sequence displaying a single base call at each location. The top row demonstrates sequence from early in the chromatogram, ~150 bp into the sequence, while the middle row is the same location but near the end of the chromatogram, at ~750 bp. The bottom chromatogram shows readable sequence but significant nonspecific baseline noise, making interpretation less than ideal. (B) An example of wild-type sequence compared to a heterozygous mixed base. The wild-type blue (C) peak has decreased in height, and the red (T) allele overlays the same location. (C) An example of wild-type sequence (top tracing) compared to 4-bp duplication (bottom tracing). The bases listed below the tracing demonstrate how to determine the variation causing the heterozygous peaks. Bases in black are wild type, while bases in red signify the mutant allele. Boxed bases correspond between wild type and mutant, allowing identification of the inserted bases indicated by a bracket.

with apparent nonspecific sequence. Poor sequence quality renders interpretation difficult.

SANGER SEQUENCE ANALYSIS

The product of a Sanger sequence reaction is a series of fragments of varying size with the final base labeled with an identifying fluorochrome. Each fragment is the product of one allele, while the resulting chromatogram is the sum of the fragments. Patients heterozygous for a single nucleotide polymorphism (SNP), a variant occurring in the general population that is usually not pathogenic, or a point mutation, a change from one nucleotide to another that is pathogenic and often specific to a patient or related individuals, have a chromatogram showing individual peaks with one site containing two peaks of roughly equal height. When compared with a chromatogram from an individual who is homozygous at the variant site, the peaks have decreased amplitude, because the signal is being split between two nucleotides in the heterozygous patient versus two copies of the same nucleotide in the homozygous patient. Figure 1B shows the control sequence on top, while the lower sequence has a decreased blue peak corresponding to the wild-type C allele and the presence of a red T peak as well at the same location. This is a mutation in the coding region of *GATA2* at cDNA 1081 that results in an amino acid change. It is named according to the Human Genome Variation Society nomenclature (3) as c.1081C>T. It indicates a change at base 1081 of the cDNA using the initiating ATG as base 1, and that the wild-type or major allele has cytosine while the mutation or minor allele has thymidine at that site. The protein nomenclature, p.R361C (preceded with a "p"), shows that the wild-type arginine at amino acid position 361 has been replaced with a cysteine.

In addition to single nucleotide changes, Sanger sequencing also detects small insertions or deletions. These may range from one to hundreds of nucleotides, but they must be wholly contained within the PCR product used as a sequence

template to be detected. In the case of Fig. 1C, two sequences align, with the left-hand portion being identical between the control and patient chromatograms. The tracings change from clean, individual peaks to double peaks in the patient. This has a very different appearance from the tracing in Fig. 1A with poor sequence quality. In this case, the peaks are still well defined, with no additional baseline. To determine the mutation resulting in the double sequence, it is helpful to write the bases on two lines, using the top line for the wild-type sequence seen in the top tracing and the mutant bases underneath seen in red. When the two sequences are compared, it becomes apparent that they differ by the insertion of the bracketed red bases, GACC, which is a duplication of the four preceding bases. After the duplication, the sequence matches the wild type, as shown by the boxed bases that are the same between wild type and mutant. Occasionally when the mutant allele is written out, it is determined to be a complex mutation containing both an insertion and deletion.

NEXT-GENERATION SEQUENCING

While Sanger sequencing is still the gold standard for molecular genetic diagnostics, decreasing cost and increased throughput are driving the use of next-generation sequencing (NGS). A further impetus for the use of NGS is the identification of disease genes in rare diseases in which only a few individuals are diagnosed with mutations in the gene. With targeted gene sequencing, the patient's phenotype or infection is used to suggest candidate genes to evaluate for mutations. For narrow, well-defined phenotypes such as infection with a mycobacteria species, this approach has identified ~80 to 90% of patient disease genes (S. M. Holland, personal communication), while in large-scale newborn screening, targeted sequencing has identified specific genetic lesions for T-B+ SCID in ~85% of patients (J. M. Puck, personal communication). In other cases with unusual presentations, pursuing Sanger sequencing of candidate genes can become expensive and time-consuming and still not identify a causative genetic lesion. Many laboratories are moving to NGS platforms as research tests, with suspected mutations confirmed by Sanger sequencing.

There are currently three main benchtop platforms available: the Illumina MiSeq, the Ion Torrent PGM, and the Roche 454 GS Junior. Each instrument is capable of generating sufficient data to perform exome sequencing or targeted resequencing of a defined panel of multiple genes, ranging from tens to a few hundred. All of the platforms have a workflow that includes fragmentation of the input sample, size selection, cleanup, and adapter ligation. The MiSeq then undergoes a cluster generation and sequencing on the instrument, while the 454 GS Junior and PGM have an emulsion PCR, bead recovery, and enrichment prior to sequencing. The library preparation allows for amplified input of numerous target regions compared with the single amplified fragment for Sanger sequencing. Coupled with the high-volume capture of the three instruments, it is easy to see the appeal for clinical usage. As of September 2013, the capital costs of the instruments ranged between $65,000 and $125,000, with the cost increased for a laboratory interested in higher throughput needing ancillary instrumentation such as robotics to take advantage of the capacity of the machines (4). Each instrument has its own advantages. Which platform is optimal for any given laboratory is based on the currently available configurations and the goals of the laboratory. Capacity will continue to increase at an astonishing rate, making comparisons virtually obsolete by the time they are published; however, recently reported performances for the three main platforms (5) are shown in Table 1. The broad conclusions drawn at the time of the analysis are that the MiSeq has the highest throughput and the lowest substitution error rate, at 0.1 per 100 bases; the 454 GS Junior has the longest reads; and the Ion Torrent is the fastest, with the highest reads per run, although it is less accurate when calling homopolymers of any length, with accuracy declining as the homopolymer stretch increases.

Data obtained from NGS need to undergo stringent analysis to obtain variant calls. There are numerous software packages available online or as part of genomics software suites (reviewed in reference 6 and elsewhere). While the choice of software is individual, all follow the same basic pipeline. For this discussion, the publicly available Genome Analysis Toolkit (GATK) pipeline is used as a model (7, 8). Because the reads are much shorter (100 to 500 bp) than those obtained by Sanger sequencing (800 to 1,000 bp) and the read outputs are pooled so they come from mixed locations, the reads must be mapped to a framework. In the case of patient samples, this would be the current human genome reference sequence. Each read aligns to a region, resulting in a pileup of fragments per region—this provides the read depth or coverage of a given target sequence. Once the data are mapped, the alignment is converted to the standard Sequence Alignment/Map (SAM) format (9), containing chromosome, start and stop bases of the alignment, strand, mismatch information, and probability scores. The SAM format can be converted to a compressed, indexed binary format called BAM, allowing for fine-tuning of the alignment. The mapped reads are filtered to remove duplicate reads, preventing overrepresentation of a variant or wild type due to repeat sequencing of one clone from the library preparation. Next, insertions and deletions (indels), which may align differently depending on the size of the indel and the strand sequenced, can be made consistent across all the reads in a region through the use of a realignment tool. This allows more confident detection of small indel variations. Lastly, just as individual peak heights vary in Sanger

TABLE 1 Comparison of three major NGS platforms

Platform	Price comparison					Run comparison			
	Cost per run	Minimum predicted throughput (Mb)	Run time (h)	Cost/Mb	Mb per h	Total bases	Mean read length (bases)	Indel error frequency (per 100 bases)	Assembled contig alignment to reference
454 GS Junior	$1,100	35	8	$31.00	4.4	71 Mb	522	0.38	3.72% unmapped
Ion Torrent PGM (316 chip)	$ 425	100	3	$ 4.25	33.3	300 Mb	122	1.5	4.6% unmapped
MiSeq	$ 750	1,500	27	$ 0.50	55.5	1.6 Gb	141	<0.001	3.95% unmapped

sequencing due to nucleotide neighbors, there is a similar variation in sequencing by synthesis. The quality scores of the alignment need to be recalibrated using base quality score recalibration to more accurately reflect the probability of mismatch to the reference. These scores are used in downstream variant calling that may identify a disease-causing mutation. At this point, the data are a BAM file that can be utilized for variant calling.

The goal of sequencing is to identify regions differing from the reference sequence. In Sanger sequencing, this is a visual process in which a peak is altered in height or fluorochrome detected, as seen in Fig. 1, and the investigator can decide if the variation is real or an artifact of the sequence reaction. In a similar manner, the BAM file needs to be analyzed to determine appropriate variants and sensitive enough not to miss calls, but specific enough to weed out most artifacts. There are several online tools available for variant detection, with new methods being published frequently (reviewed in reference 10). Here we use GATK's HaplotypeCaller as an example. The BAM file is analyzed for local regions of possible variation, and those regions undergo a *de novo* alignment to fine-tune the site. The local realignment can determine both single nucleotide variations as well as indels. The output of a variant detection script is a VCF file that provides a list of all changes identified and verified in the data set. As should be apparent at this point, unlike Sanger sequencing, the labor-intensive portion of generating NGS is not the bench science but the computational and bioinformatics demand of data analysis. As pointed out by McCourt et al. (11), moving forward, molecular diagnostic laboratories will have a basic requirement for molecular diagnostic bioinformaticians.

RT-PCR

Some mutations result in alteration of the primary RNA transcript, leading to errors in splicing, polyadenylation, or mRNA stability. Not all of these variants are detected by genomic sequence of the coding exons. In cases in which a patient's phenotype strongly suggests a specific gene, analysis of the RNA transcript may provide an answer. There is an extra step, however, in processing the patient sample. Because genomic DNA is double stranded, the use of two primers, one forward and one reverse, leads to exponential amplification of the target region. RNA, on the other hand, is single stranded and must first be made double stranded by reverse transcriptase PCR (RT-PCR). This is performed from total RNA using an oligo(dT) primer that will bind to the poly(A) tail of the mRNA. This process results in double-stranded mRNA, with random hexamer primers that will bind to any RNA molecule with the appropriate complementary hexamer or with a gene-specific primer that will bind only to a specific target. Once the RNA has been converted to double-stranded cDNA, amplification of a transcript of interest proceeds as in genomic DNA.

One measure of RNA is message abundance. This has been examined by the use of Northern blots, which entails running the RNA on an agarose gel to separate it by size. It is then transferred to a membrane support and probed with a complementary probe and detection label (either by radioactivity or a biotin-streptavidin reaction). The blot is then exposed to X-ray film or a capture screen, respectively. Densitometry may be used to obtain a relative quantitation of a specific transcript compared to a housekeeping gene, if the blot is stripped and reprobed, or compared to a healthy individual's control on the same blot. The initial gel or blot image can also provide information regarding the size of the transcript or the presence of multiple splice forms.

qPCR

An alternative method for measuring RNA transcripts is the use of quantitative RT-PCR (qPCR), in which the cDNA is amplified with a set of primers and the production of product is measured in "real time" via a scanning detector. This can be accomplished with the use of an intercalating dye such as SYBR green that will bind to double-stranded product and produce a fluorescent emission that accumulates over successive cycles. Alternatively, a fluorescent reporter probe can be used that binds between the two amplification primers. The reporter probe contains both a reporter and quencher molecule, which prevents fluorescence while the two are in close proximity. As extension from the amplification primer occurs, the exonuclease activity of the polymerase causes degradation of the probe separating the quencher from the reporter, allowing emission that is detected during scanning. As with SYBR green, as subsequent cycles of PCR occur, the intensity of the signal from the released fluorophore increases. The output of a qPCR assay is a logarithmic plot of fluorescence intensity versus cycle number (Fig. 2). Analysis of a qPCR assay is performed by quantifying each well to determine at which cycle the fluorescence exceeds a threshold value (C_T). Quantifying input copy number may be performed through the use of a standard curve with a titrated sample of known concentration and plotting of the experimental concentration (C_T) on the standard curve. Alternatively, a relative quantitation may be obtained by comparing the C_T of the target gene to a reference gene, usually a housekeeping gene. The difference in threshold cycles between target and reference transcripts provides a measure termed the ΔC_T. The difference in the ΔC_T between the experimental (treated or disease) and reference (untreated or healthy control) samples provides the $\Delta\Delta C_T$. Because PCR provides exponential amplification, the final calculation for quantification of input becomes $2^{-\Delta\Delta C_T}$. The derivation of this formula is well covered by Livak and Schmittgen (12).

TRECs

T-cell excision circles (TRECs) are formed during T-cell receptor V(D)J recombination and are biomarkers for newly produced naive T cells (13). Once this residual, circular DNA fragment is produced in an immature thymic T cell, it is not replicated during cell division. This dilutes the TREC concentration as naive T cells migrate to the periphery and expand in response to antigen. While relative quantitation is useful for looking at expression levels of target transcripts, genomic qPCR was adopted to quantitate total TRECs from newborn babies (14). It has become the gold-standard method for performing this analysis (15). Low or absent TRECs are a phenotypic indicator of poor or declining thymic output and usually severe T-cell lymphopenia, a marker of SCID or other severe defects in T-cell development. Many states are now screening for the presence of TRECs using dried blood spots obtained from all infants in the United States at birth. Reports from Wisconsin (16, 17) and California (18) have documented genetic diagnosis of infants who were initially discovered during newborn screening for TRECs, allowing medical intervention prior to the onset of illness.

ARRAYS

Microarray-based comparative genomic hybridization was initially utilized to screen for variations within cancer samples. It has been adapted by clinical laboratories, however, to screen for variations in DNA copy number, both deletions

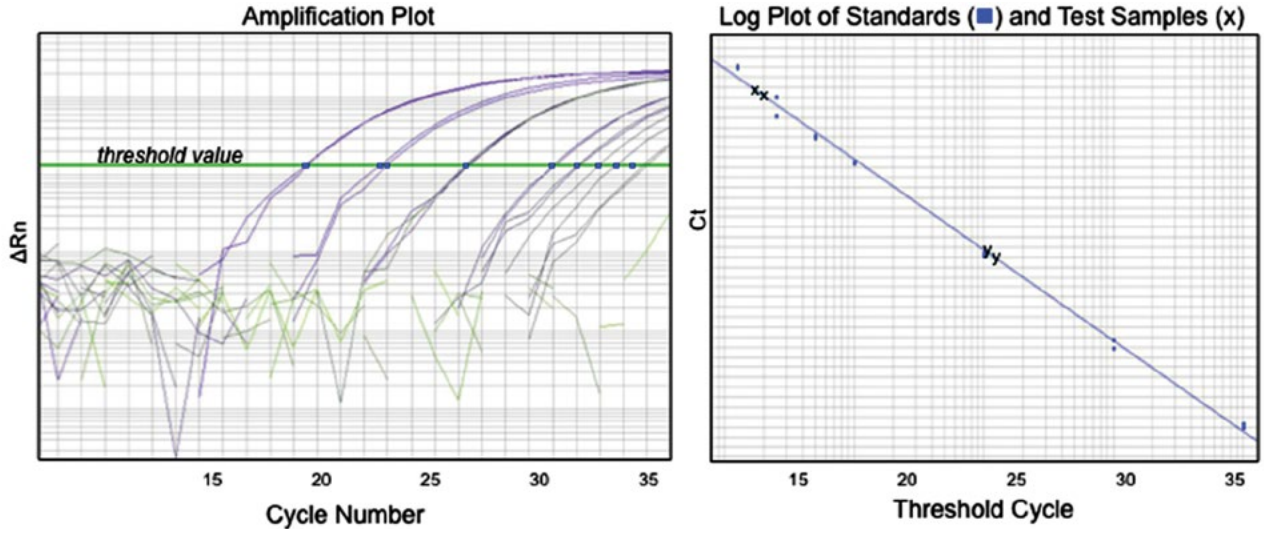

FIGURE 2 Real-time qPCR plot. (Left) Amplification plot of duplicate dilutions of a known standard TREC plasmid. The *x* axis is PCR cycle number; the *y* axis is ΔRn, which is Rn (the ratio of the reporter signal normalized to a constant fluorescent signal) minus the value of Rn at baseline; the green line is threshold value. Threshold cycle (C_T) is defined as the cycle number at which the amplification plot crosses the designated ΔRn threshold (blue dots). (Right) Logarithmic plot of the same standards as well as two duplicate unknown samples, *x* and *y*, for which the C_T value, and therefore copy number or concentration, can be derived by comparison with the standard curve. (Figure courtesy of Jennifer M. Puck.)

and insertions of 200 to 500 bp or larger. High-resolution comparative genomic hybridization, first described by Urban et al. (19), uses oligonucleotide probes spanning targeted genomic regions and spotted to a glass slide. DNA samples from a control and patient are fluorescently labeled, each with a different dye, and the resulting labeled DNA is hybridized to the array. After hybridization, the slide is scanned and the fluorescence intensity of each dye signal is calculated for each oligonucleotide probe on the slide. In regions where each sample hybridizes equally, the ratio of the signal between the two samples will be 1 because each has the same number of copies of the target region. If the patient sample contains a deletion on one chromosome, then the signal from that sample will be 0.5 times the signal of the control. Likewise, if there is a duplication of a region, the signal will be increased. As the probes are tiled across the target region, the ratios are plotted on a log 2 scale, so equivalent ratios will be plotted on the zero axis. If multiple consecutive probes have an aberrant signal, either high or low, then the analysis software will highlight the region as an insertion or deletion, respectively, as shown in Fig. 3. Similar to DNA arrays, which look for genomic variation, microarrays may be used with total RNA from a specific tissue to examine differences in RNA transcript levels between two tissue types or healthy versus diseased tissues. Mapping increased or decreased RNA transcripts may aid in defining pathways involved in disease pathogenesis.

ANALYSIS OF VARIATIONS

Regardless of whether a variant is identified by Sanger sequencing or NGS, once a change is recognized, then the consequence of the variant on the transcript or protein needs to be evaluated to determine if the change may be disease related. Single base changes can be mapped to the consensus coding sequence to determine if an amino acid codon is changed. SNPs resulting in an altered codon for the same amino acid as the consensus are referred to as

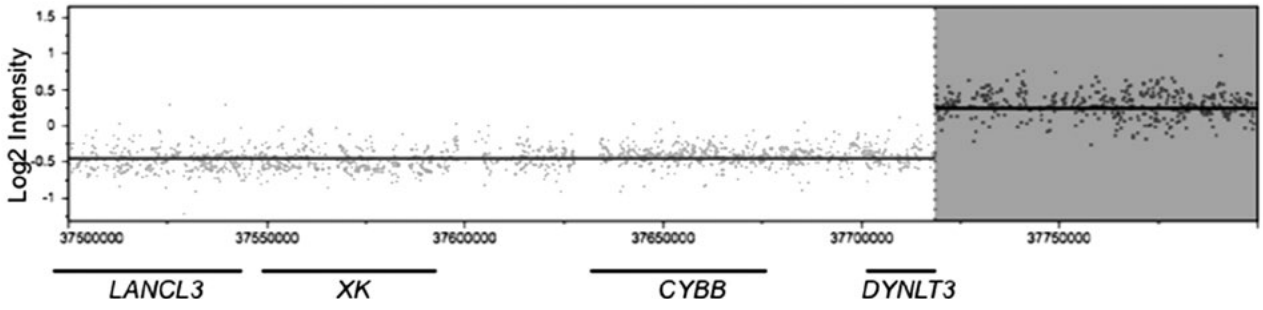

FIGURE 3 High-resolution comparative genomic hybridization array spanning 375,000 bases of the region surrounding *CYBB* on the X chromosome. Plots are log 2 of the intensity of the patient sample compared to all samples run on the array. Panel A demonstrates one female patient with a large deletion encompassing *LANCL3*, *XK*, *CYBB*, and *DYNLT3* as evidenced by the contiguous −0.5 intensity signal, which then resolves to 0, indicating the presence of two alleles.

"synonymous," while those causing amino acid substitutions are "nonsynonymous" SNPs. If a SNP is disease causing, then a nonsynonymous SNP is termed a "missense mutation," while a base change that results in a termination codon is referred to as a "nonsense mutation." At a given nucleotide, patients may be homozygous, meaning their two alleles have the same nucleotide at the site; or heterozygous, meaning they have two different bases at the site, indicating the presence of two identifiable alleles. A third possibility is that they may be hemizygous, meaning they have only one copy at that location. This is most often seen in the case of X or Y chromosome genes in males, although a deletion of one allele also results in hemizygosity. Sanger sequence chromatograms from homozygous and hemizygous individuals are indistinguishable, so care must be taken especially when reporting X chromosome genetic variations.

Identified variants need to be examined for suggested deleterious effects in light of the phenotype of the patient and possible inheritance patterns. Missense changes may be analyzed by examining the sequence homology within a protein family as well as across species, predicted structure-based alterations, mRNA and protein features, as well as conservation of the region identified by multiple alignments and phylogenetics. Historically, this was performed by aligning protein sequences across species or within the protein family to estimate conservation of the specific amino acid. Examining amino acid properties of the substituted amino acid versus the wild type could strengthen the prediction. Currently, there are numerous bioinformatics analysis programs available online to predict whether a change is deleterious. Several of these programs are listed in Table 2. The left-hand section of the table lists analyses that may be performed on single changes, while the two columns farthest to the right highlight two programs, wANNOVAR (20) and dbNSFP (21), for higher-throughput data such as NGS. The table shows which analyses the programs include. The second group is especially helpful for filtering the large number of variations identified with NGS.

Nonsense mutations, those resulting in a premature termination codon, can have different effects depending on the location within the transcript. Late stop codons, occurring in the last exon or near the end of the penultimate exon, usually result in a stable mRNA transcript, which may be translated into a truncated protein. The shortened protein may cause disease in a dominant-negative fashion by interfering with partner chains. This has been seen in autoimmune lymphoproliferative syndrome, in which the shortened FAS protein is capable of assembling into the stable trimer receptor. However, it is lacking the intracellular death domain critical for downstream signaling. The presence of one mutant allele results in only one in eight receptors being fully wild type. This is insufficient to transduce the apoptosis signal (22, 23). Transcripts containing a premature termination codon, such that splicing occurs more than 50 to 55 bp after the mutation, usually result in nonsense-mediated decay, a mechanism by which the cell degrades erroneous mRNA molecules (24; reviewed in reference 25). Loss of transcript or protein product from one allele may be seen in autosomal recessive diseases, in which case a mutation should be seen on the second allele as well. Alternatively, in tightly regulated genes, loss of one allele may result in haploinsufficiency, in which half the level of protein product is not sufficient. Haploinsufficiency in immune disorders has been reported in autoimmune lymphoproliferative syndrome due to insufficient FAS protein on the cell surface (26), as well as in GATA2 deficiency leading to MonoMAC syndrome (27).

In addition to changes within the coding sequence, many mutations occur at consensus splice sites immediately flanking the coding exons. Traditionally, splicing has been thought of in terms of the three core splicing signals: 5′ splice sites (5′ss), 3′ splice sites (3′ss), and the intronic branch point near the 3′ end of the intron. Figure 4 shows the conserved motifs associated with intron removal. Most easily identified are those changes altering the invariant GT or AT splice sites immediately flanking the exon. However, the entire motif may be critical to appropriate spliceosome formation. Wang and Burge (28) and Ward and Cooper (29) provide reviews of the motifs for recognition of splice sites and exon identity as well as components of the spliceosome. For example, a mutation at the first or last base of an exon, even if predicted to be synonymous, often leads to loss of correct splicing of that exon, as do mutations at the +5 site of an intron. For introns with short polypyrimidine tracts, a mutation that changes one of the pyrimidines to a purine may result in exon skipping, as seen in DOCK8 (dedicator of cytokinesis 8) deficiency (30). In addition to the three core splicing signals, there is an increased recognition of splicing regulatory elements (SREs) that occur in both exons and introns. SREs are composed of elements that enhance or inhibit splicing and are named by their location and effect on the transcript; exonic splicing enhancers (ESEs), exonic splicing silencers (ESSs), intronic splicing enhancers (ISEs), and intronic splicing silencers (ISSs) all act by recruiting factors to increase or decrease exon recognition and spliceosome recruitment. Many mutations predicted to result in missense or nonsense substitutions are being shown to affect SRE sequences and alter proper splicing of the exon (31). The third section of Table 2 indicates current websites available to screen for splicing mutations.

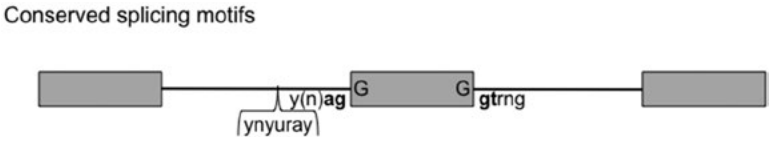

FIGURE 4 Conserved splicing motifs. Gray boxes indicate exons; solid lines are introns. 3′ss begins with the branch point located between 15 and 40 bases 5′ to the exon, noted in brackets, with the loose motif of YNYURAY. Y represents pyrimidines (C or T); N is any base; U is uracil, the RNA equivalent of T, R is A or G. Following the branch point sequence is the polypyrimidine tract, Y(n), where n ranges from 5 to 20 bases of mostly pyrimidines, followed by the 5′ss invariant AG (bold) as the last two bases. The first base of the exon is usually a G. At the end of the exon, the final base is again usually a G, followed by the invariant GT (bold) at the start of the intron. The 5′ss motif is GTRNG.

DIAGNOSIS

Bioinformatics tools may be utilized to screen variants identified by sequence. However, on some level, the effect of the change needs to be demonstrated and correlated with the patient's phenotype. If a male infant presents with SCID, lacking T cells and NK cells but having adequate numbers of B cells, then the most likely diagnosis would be X-linked SCID and *IL2RG* would be the first gene sequenced. A mutation identified within the coding region that is predicted to be deleterious would fit the phenotype of the patient and correlate with other, previously identified mutations. There are some special cases that need to be considered and will be demonstrated by specific case studies below.

A young male patient presenting with granulomas and conical teeth, often seen with NF-κB essential modulator (NEMO) deficiency, was sequenced for *IKBKG*. Genomic sequencing revealed an apparent heterozygous change in exon 5, c.597G>A, which did not alter the encoded amino acid. Given the phenotype of the patient, which was strongly suggestive of an *IKBKG* mutation, intracellular NEMO protein was examined by flow cytometry. While the healthy control had a fluorescence index (FI) of 30.6, the patient had an FI of only 12.6, demonstrating reduced levels of intracellular NEMO protein. Full-length *IKBKG* cDNA was generated by RT-PCR, revealing a smaller fragment in the patient than in the control sample. Sequencing of the PCR product revealed a 153-bp in-frame deletion corresponding to exon 5 containing the c.597G>A change (Fig. 5). The 153-bp deletion is expected to result in a stable mRNA that should be translated into a protein missing 51 amino acids. Using the Human Splicing Finder website (32), the original c.597G>A mutation was predicted to cause both the loss of an exonic splicing enhancer and the creation of an hnRNP A1 silencer motif. The exonic binding of a silencer in place of a splicing enhancer has been recognized to mediate silencing of exon sequencing (33). Mutations such as this, in which the protein is present but not fully functional, are termed "hypomorphic."

A second patient with infections related to NEMO deficiency, *Haemophilus influenza* pericarditis in childhood and disseminated *Mycobacterium avium* as an adult, was screened by genomic PCR. The patient was reported to be

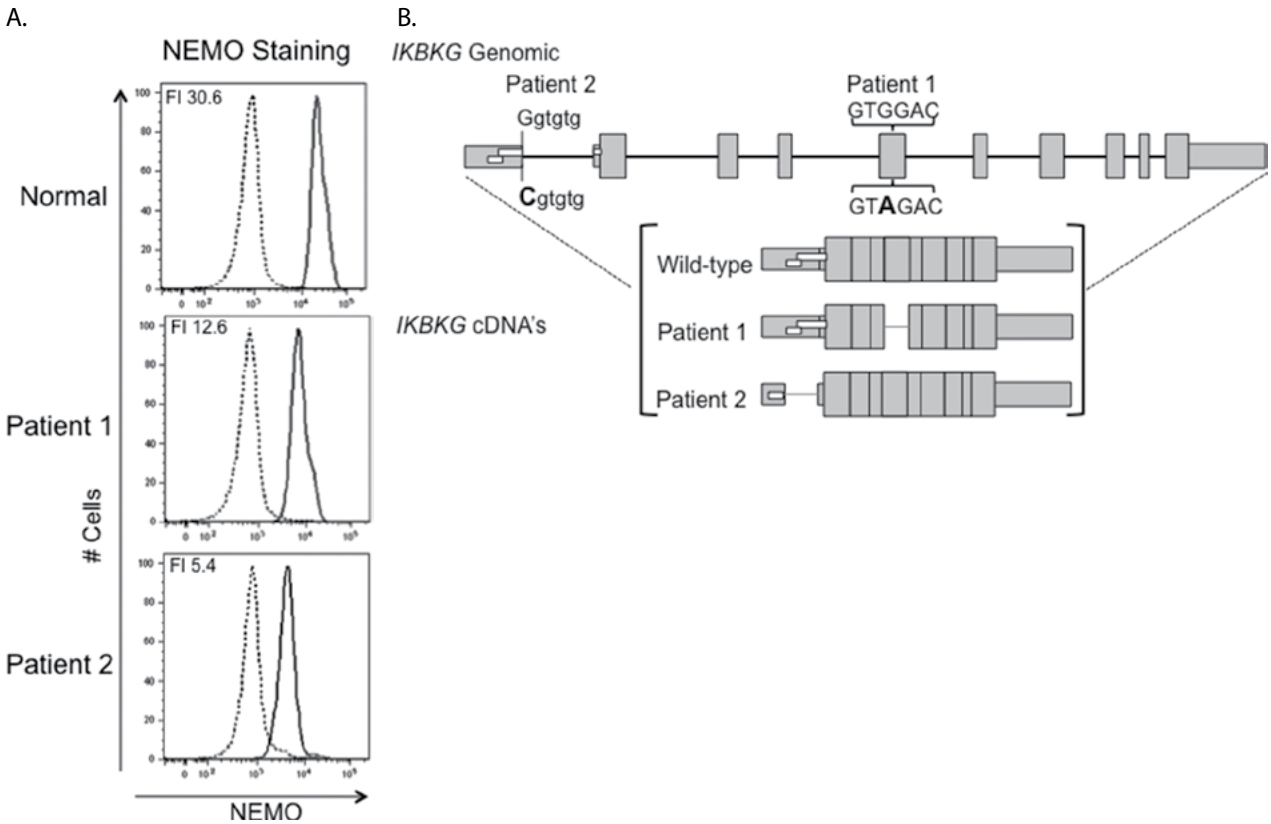

FIGURE 5 Analysis of NEMO variants. (A) Intracellular flow cytometry for NEMO protein. The dotted line is isotype control; the solid line is specific NEMO staining. The top panel is the normal control, showing an FI of 30.6. The middle panel is patient 1, with all cells showing specific staining but with a reduced intensity and an FI of 12.6. The bottom histogram is patient 2, again demonstrating that all cells contain NEMO protein, but less than both the control and patient 1, with an FI of 5.4. (B) The top panel shows the genomic organization of *IKBKG*, the gene encoding NEMO. Gray boxes are exons, narrow boxes are untranslated, and small white box insets are uORFs. Locations of patient genomic mutations are noted, with wild-type sequence above the genomic structure, mutant motif below, and the single base mutation in bold. The lower panel depicts the structure of the cDNA, showing aberrant splicing. Patient 1 has a 153-bp deletion of exon 5, noted by the thin line in the middle of the cDNA. Patient 2 has a deletion of a portion of the 5′ untranslated region, including one of the two uORFs.

wild type for the coding exons of *IKBKG*. Again, due to the phenotype of the patient, intracellular NEMO staining was performed, which demonstrated reduced, but not absent, NEMO protein levels. The patient had an FI of 5.4, compared with the 30.6 seen in the healthy control. Full-length cDNA was generated by RT-PCR, and Sanger sequencing revealed a 110-bp deletion at the 3′ end of the noncoding exon 1. Genomic sequencing of the exon revealed a G>C mutation at the last base of the exon. This caused a loss of the 5′ss of intron 1 and usage of an alternative, cryptic 5′ss contained within exon 1, resulting in the deletion seen in the cDNA. Contained within the untranslated exon are two upstream open reading frames (uORFs). Disruption of uORFs has been shown to alter uORF-mediated control of protein expression (34), suggesting that the deletion in the 5′ untranslated region seen in this patient leads to his decreased intracellular protein level and that his disease is caused by insufficient levels of NEMO protein.

A third male patient with possible NEMO deficiency was screened for mutations in the X-linked gene *IKBKG*. Genomic DNA was isolated, and PCR amplification of the 10 *IKBKG* exons was performed. Sanger sequencing demonstrated a single nucleotide change, c.761C>T, causing the substitution of glutamine for arginine at amino acid position 254, p.R254Q. This mutation has been seen previously in an unrelated family and is predicted to be deleterious by PolyPhen2 (unpublished data). Due to the genomic structure of the *IKBKG* locus, which is flanked by an inverted pseudogene of *IKBKG* exons 4 to 10, the genomic mutation appeared to be heterozygous. The sequencing was repeated using RT-PCR performed on RNA isolated from PBMCs. The primers were designed to amplify the full coding sequence of *IKBKG*. When the resulting PCR product was sequenced, only wild-type bases were seen throughout the coding region. This demonstrated that the mutation had occurred in the pseudogene and not in the transcript-producing *IKBKG* locus. Changes in the coding region that appear silent, mutations in the untranslated exons, and the presence of a pseudogene demonstrate the importance of performing cDNA analysis for *IKBKG* mutation screening.

There are some mutations that may be predicted to be benign. However, given the location within the protein or the clinical phenotype of the patient, they may warrant further analysis. A patient presented with an IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked)-like phenotype but without an identified mutation in *FOXP3*. Because there were other patients in this cohort with identified *STAT1* mutations, all exons of *STAT1* were sequenced and a single base change was seen that resulted in an amino acid substitution within the coiled-coil domain of STAT1, p.V266I. All of the algorithms from Table 1 predicted the amino acid change to be benign or neutral; however, there is a known mutation at the adjacent amino acid, A267V, causing an autosomal dominant gain-of-function mutation associated with disseminated coccidioidomycosis (35). Signal transduction studies performed using cells from the patient with V266I demonstrated that, similar to other mutations in the coiled-coil domain, this patient had increased and prolonged phosphorylation of STAT1 in response to cytokine stimuli (36).

Another class of mutations that may be initially dismissed by *in silico* analysis involves variations detected within a gene with autosomal recessive inheritance. To present with a disease phenotype, the patient requires two mutant alleles. Often the parents will be healthy because they have one normal allele and one mutant allele. Deleterious variations therefore may be seen at low frequency in the general population. With the explosion of whole-exome sequencing, every variation may now be deposited into the NCBI curated database, dbSNP, and be assigned an "rs" identifier number. Additionally, there is an active effort by NCBI to extract variants from the literature and enter them, which may result in errors due to mutations later being retracted or corrected. Currently, many mutant alleles are present in dbSNP, albeit with a low or absent population frequency, and automated analysis of NGS variants returns dbSNP identifiers. Assuming that presence in the "healthy" population excludes an allele from being pathogenic, this may result in a disease-causing mutation being filtered out. Large-scale data analysis is a balance between sensitivity and specificity, and care must be taken if a variant is identified in a logical candidate gene to not dismiss it based solely on *in silico* predictions.

Sometimes patients are seen with mild phenotypes reminiscent of a recognized disease. In this case, sequencing of the target gene should be performed and examined carefully. There are numerous cases in the literature in which a mutation is identified in an affected individual and screening of the family members reveals one parent as being a mosaic for the mutation, having a small percentage of cells with the mutation and the remaining cells being wild type. This has been reported in hyper-IgE syndrome due to mutations in *STAT3* in two unrelated families. In each case, the mutation seen in the children was identified in PBMCs from the father but at low levels (37). In this case, the mutation was identified by Sanger sequencing and the mutant peak, while heterozygous in the children, appeared as a minor peak in the father (Fig. 6A). Had the father been sequenced in isolation, the mutation may have been overlooked as nonspecific background. This is even though the wild-type peak is diminished in comparison with the normal control, as seen by the decreased height of the wild-type G (black) peak when compared with the C (blue) peak preceding it. The change in peak height is one sign that a portion of the sequence is derived from an altered nucleotide sequence rather than background nonspecific sequence.

A similar case is seen in a male patient with a presentation of leaky SCID, with reduced numbers of T cells and NK cells but normal numbers of B cells. Mutation of *IL2RG* is the most common genetic defect in SCID. Screening revealed two peaks at c.260T>C, which caused the substitution of proline for leucine at amino acid 87 (p.L87P). This mutation is predicted to be deleterious, and the patient's mother is heterozygous for it, indicating germ line inheritance. Closer examination of the sequence tracing, however, reveals a small wild-type peak in the patient (Fig. 6B). Because he has only one X chromosome, this change is suggestive of a reversion mutation—a change occurring in somatic cells that results in correction or modification of the mutation. In this case, it returned to the wild-type nucleotide. The most common single nucleotide change seen in the human genome is a C>T substitution that occurs in the context of a CG dinucleotide. In this patient, the mutation created a CG dinucleotide that subsequently underwent a C>T reversion event in a lymphocyte precursor. This reversion allowed for the development of T cells and the leaky phenotype observed (unpublished data). Both the mosaic and reversion patients demonstrate the importance of considering patient phenotype and family inheritance whenever possible. Given errors in amplification by PCR enzymes and natural occurrences of somatic variations, the low-level presence of the mosaic mutations and wild-type reversion may be filtered out in exome sequence data.

The phenotype of the patient, those characteristics or infections that bring him to seek medical attention, is a key

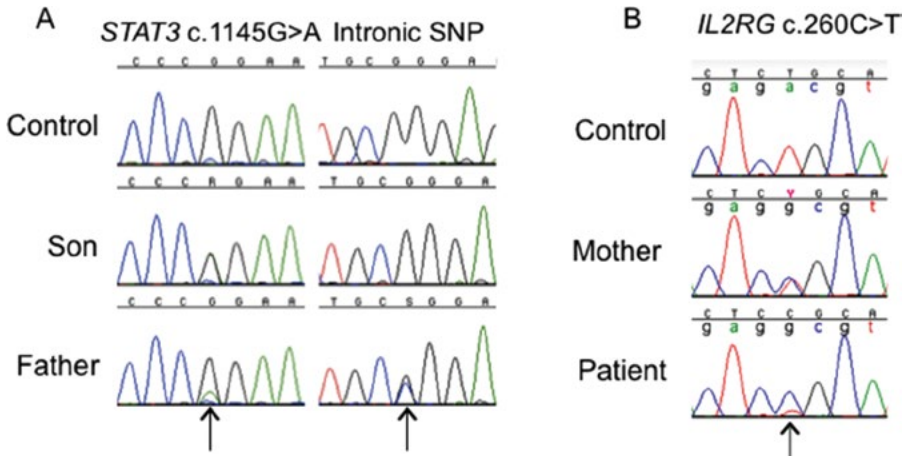

FIGURE 6 (A) Sanger sequence chromatograms from a patient demonstrating mosaicism for a *STAT3* mutant allele. The left column shows coding sequence; the right column, the intronic SNP 132 bp 3′ to the mutation but contained within the same PCR product. The top row is from a healthy control, demonstrating the wild-type G at c.1145 and homozygous G at the intronic SNP. The middle row is from the affected son, with heterozygous peaks at the site of the mutation, c.1145G>A, and homozygous G at the SNP. The bottom row is from the father, showing a reduced peak height of the wild-type G allele (black) compared with the healthy control and the presence of a small green peak corresponding to the mutant allele (arrow) but at less than heterozygous levels. This is in contrast to his intronic SNP, which demonstrates heterozygosity (arrow). (B) Sequence tracings of the X-linked *IL2RG* gene. The top tracing is from a healthy control, showing only wild-type sequence. The middle tracing is from the patient's mother, who is heterozygous for the c.260C>T mutation, showing the reduced T peak (red) and the presence of the mutant C peak (blue). The bottom tracing, from a male patient with the inherited mutant C allele from his mother, shows a small, wild-type T peak (red) underneath (arrow).

factor when evaluating genes for mutations. The patient's clinical presentation often suggests a need for specific, targeted gene or pathway evaluation using Sanger sequencing or whole-exome sequencing to discover variants. However, there are patients with a disease phenotype in whom no mutation can be identified, even when all exons and coding and noncoding regions are sequenced. In this case, if the phenotype of the patient matches a recognized disease gene, then screening for variations in cDNA may be helpful. Three unrelated patients presented with infections characteristic of chronic granulomatous disease (CGD). By the standard dihydrorhodamine flow cytometric assay for CGD, all three patients had reduced activity. This was reflected by an abnormal neutrophil oxidative burst. Sequencing of *CYBB*, the most frequently mutated gene causing CGD, failed to reveal a causal variation. RNA was isolated from patients' neutrophils, and full-length cDNA was generated by RT-PCR. Sequencing of the PCR product revealed an insertion in the cDNA between exons 3 and 4 in one patient, between exons 5 and 6 in a second, and between exons 6 and 7 in the third. Sequencing of the genome between the two exons in each case revealed that the inserts were derived from intronic sequences and were cryptic exons included due to a point mutation that created a strong 5′ss. As seen in Fig. 7, the cryptic exons in the first two patients resulted in a frameshift, which would indicate a loss of mRNA stability and subsequent protein production. The third patient had an insertion of 120 bp that was not predicted to disrupt mRNA stability and resulted in a 40-amino-acid in-frame insertion (unpublished data). Two additional patients with similar mutations have been reported by Noack et al. (38) and Rump et al. (39). None of these mutations would be identified by standard Sanger or whole-exome sequencing because the deep

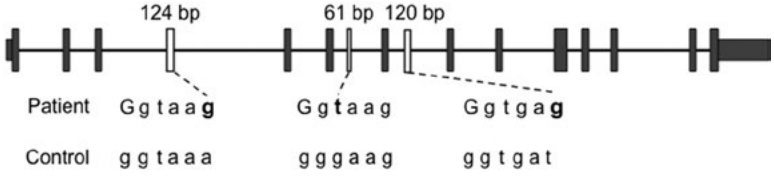

FIGURE 7 *CYBB* genomic structure showing exons (black boxes) and introns (black line). Below is intronic sequence from three patients, demonstrating the intronic point mutation (bold) in each that creates a cryptic 5′ss allowing for inclusion of a cryptic exon (white boxes). Wild-type sequence for each site is shown below the patients' mutant sequences. The insertion of the cryptic exon results in a frameshift for the first two patients, while the third, with an insertion of 120 bp, is predicted to have a 40-amino-acid insertion.

introns would not be screened again. This emphasizes the need for cDNA analysis.

One final example comes from a group of patients with MonoMAC syndrome (40), which is an autosomal dominant disease caused by mutations in the hematopoietic stem cell transcription factor GATA2. Missense mutations have been identified in the C-terminal region of the protein encoding the highly conserved second zinc finger involved in binding to the GATA motif on DNA. Additional mutations result in the loss of mRNA transcript from one allele, which is caused by a frameshift insertion or deletion mutation or premature stop codons. This indicates that a reduced level of GATA2 transcript or protein is sufficient to cause disease. Among patients with phenotypic MonoMAC syndrome, there were several without identified mutations after all exons and flanking splice sites had been sequenced. Similar to the patients without identified *CYBB* mutations, full-length *GATA2* cDNA screening was performed. In two patients, although they displayed heterozygosity by genomic sequence for known SNPs found within the exons, cDNA sequence demonstrated the presence of one predominant allele (Fig. 8A). Further work needs to be performed to elucidate the genetic lesion leading to loss of expression of the allele in these patients. Haploinsufficiency of *GATA2*

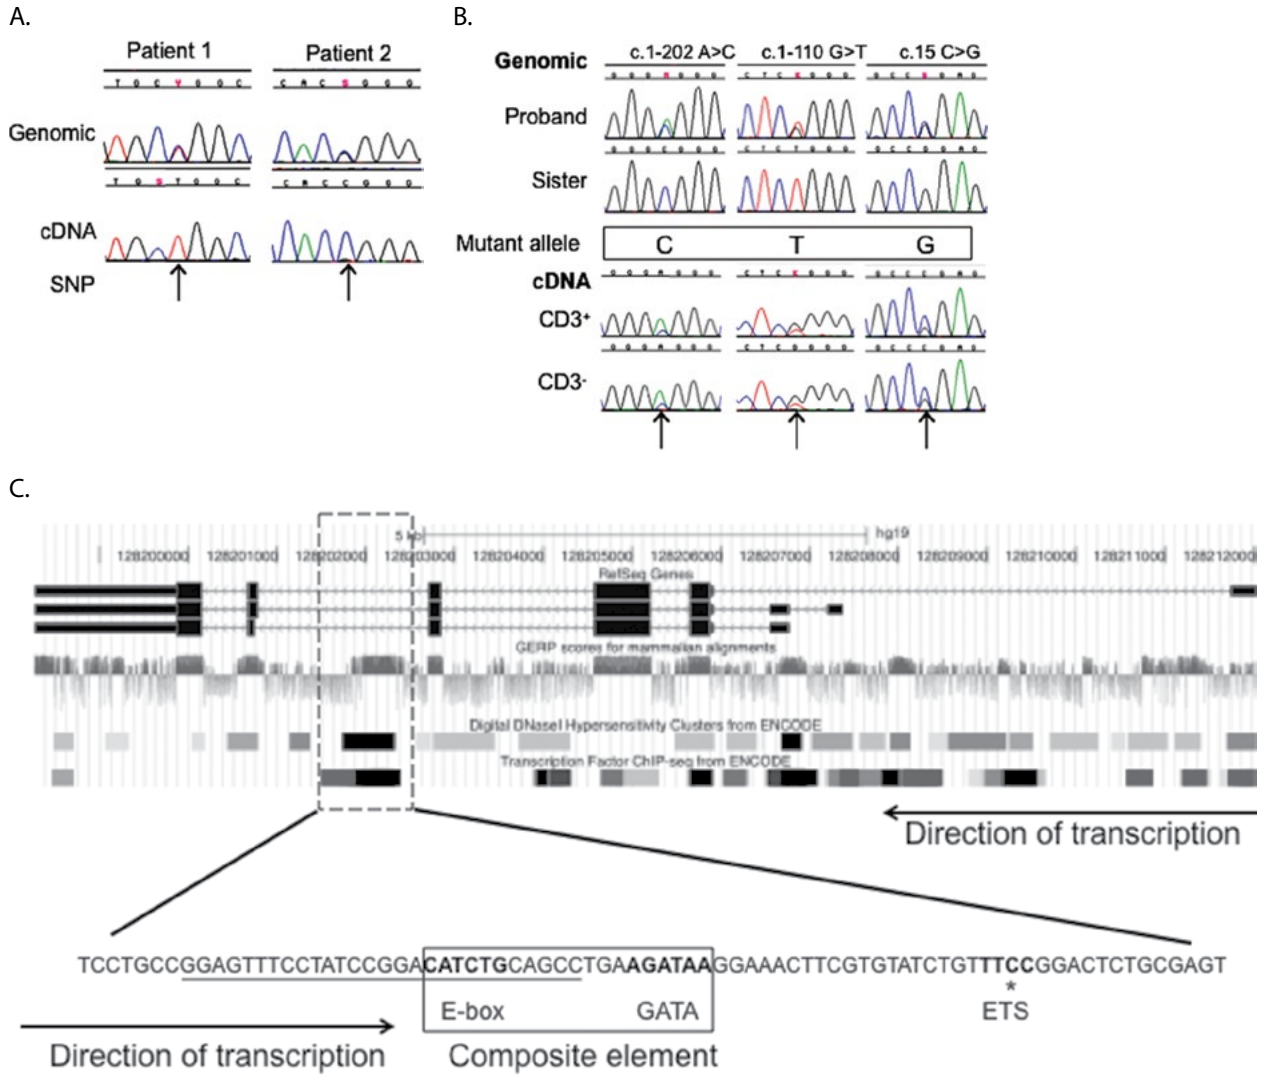

FIGURE 8 Reduced *GATA2* allelic expression in MonoMAC syndrome. (A) The top row shows genomic sequence from two patients demonstrating heterozygosity for a SNP within the cDNA transcript of *GATA2*. The bottom row shows cDNA sequence from full-length RT-PCR. In patient 1, only the T allele is present (arrow), indicating loss of the transcript containing the C allele, while patient 2's sequence contains the C allele with only a small peak of the G allele (arrow). These sequences demonstrate uniallelic expression leading to haploinsufficiency of *GATA2*. (B) At the top is genomic sequence from two affected sisters; the proband is heterozygous for three known SNPs found within the cDNA, while her sister is homozygous, allowing determination of the shared mutant allele haplotype (boxed bases). At the bottom is *GATA2* cDNA sequence from the proband's $CD3^+$ and $CD3^-$ PBMCs, revealing decreased levels of the mutant allele as represented by peak height (arrows). (C) *GATA2* genomic locus showing three reported isoform structures. The dashed box indicates a conserved intron 5 region with a high GERP score, DNase I hypersensitivity, and strong transcription factor binding. Zoom of bases highlights the E-box/GATA composite element (boxed); the 28-base deletion seen in the first patient (underlined sequence); and the ETS motif with a C>T mutation seen in five patients (asterisk), including the sisters shown in panel B.

has been demonstrated in patients with mutations causing mRNA instability. This suggests that the molecular basis of the disease in these two patients is likely a loss of expression of one *GATA2* allele. In another group of MonoMAC patients, reduced but not absent expression from one allele was recognized by cDNA analysis. Figure 8B shows genomic sequence from one patient and her sister, both affected with MonoMAC. The proband is heterozygous for three known SNPs found within the cDNA, while her sister is homozygous for the same SNPs. This allows determination of the mutant allele haplotype, as both sisters must have inherited the mutation. Subsequent screening of *GATA2* cDNA in the proband shows decreased peak height of the mutant allele compared with the heterozygous peaks seen in the genomic sequence. Examination of the genomic structure of *GATA2* from the UCSC Genome Browser reveals a region within intron 5 notable for high levels of conservation, DNase I sensitivity, and evidence of multiple transcription factor binding (Fig. 8C). Located with this is a composite element recognized as critical for *GATA2* expression (41). Screening of the conserved intronic region revealed a 28-base deletion encompassing a portion of the composite element in one patient, while a single point mutation at the nearby ETS transcription factor family motif was identified in the other patients. Functional constructs demonstrated reduced expression caused by each mutation (27, 42) and correlated with the reduced allelic expression seen in the patients. The data from these patients demonstrate another class of mutations, those resulting in reduced expression in a protein in which haploinsufficiency may cause disease. This condition is recognized primarily by screening for uniallelic expression by cDNA.

Figure 9 provides a framework for analysis of patients with immune disorders. First, the clinical phenotype needs to be defined. Clinical presentation including age, gender, TREC levels in infants, and medical history provides certain clues. The infection history of the patient also can suggest a target gene or pathway. Lastly, clinical laboratory assays such as lymphocyte phenotyping and functional flow cytometric assays can further refine a working diagnosis. If there is a specific pathway or gene suggested based on clinical presentation, then targeted Sanger sequencing of that gene may identify a genetic lesion. In the absence of a limited candidate gene list, then NGS via a medium-scale, targeted approach, such as using a panel of genes screened by Ion Torrent, or a large-scale whole-exome analysis may be performed. After bioinformatics processing of the data, a filtered list of candidate variations is obtained, which then

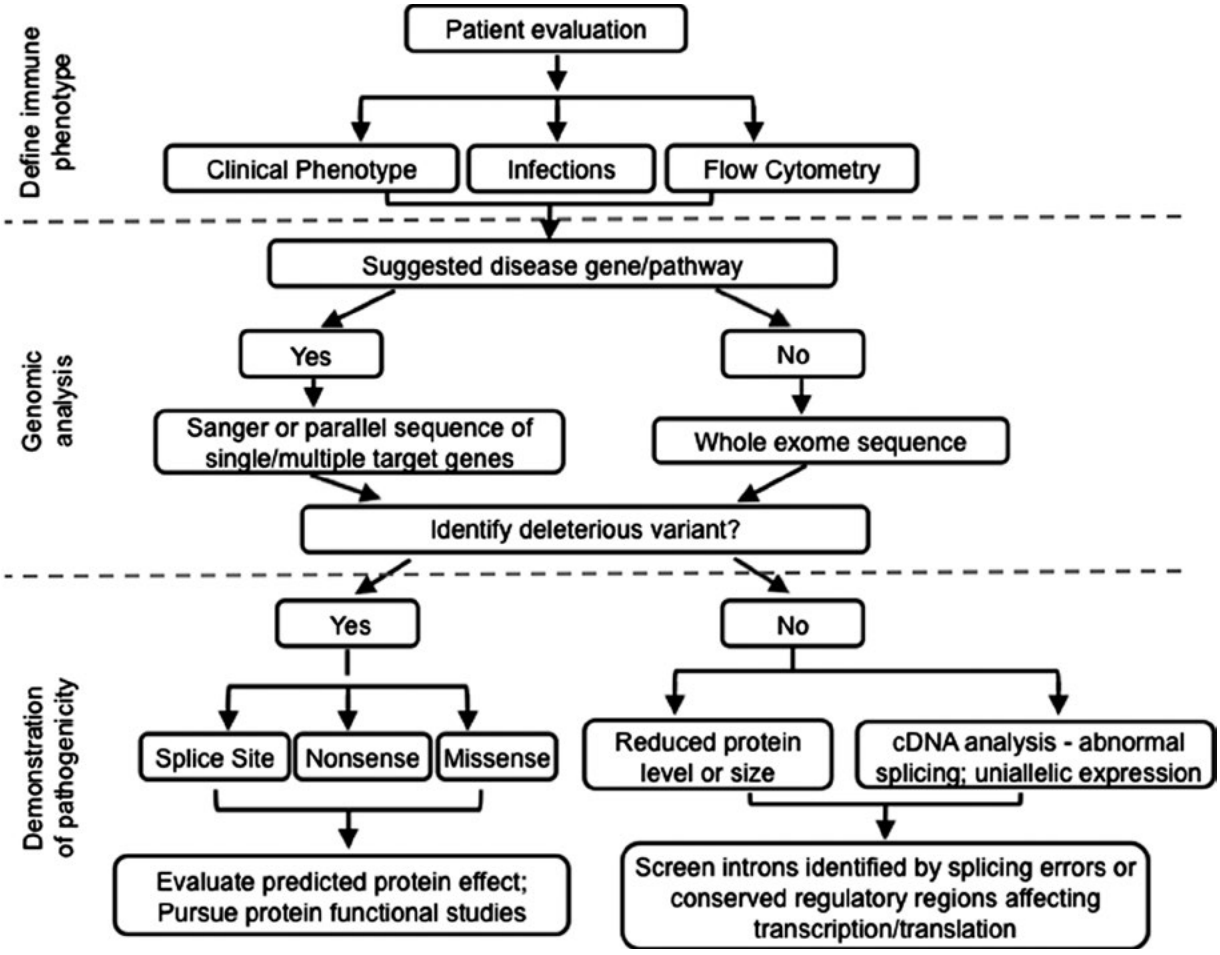

FIGURE 9 Framework for molecular and genetic diagnosis in immunocompromised patients, beginning with defining of patient phenotype, proceeding to performing genomic analysis, and concluding with inferred or demonstrated pathogenicity of mutation.

are examined to see if they are consistent with regard to the patient's phenotype. Variations resulting in loss of canonical splice sites or nonsense or missense changes should be evaluated for the predicted protein effect and confirmed with functional studies of the protein. In the case in which a deleterious variant is not identified, if a target gene is suspected, then screening for altered protein size or levels or aberrant cDNA caused by splicing defects or uniallelic expression may be useful. Recognition of the possibility of mutations in the untranslated exons and conserved regions within and flanking the gene is also important for defining genetic lesions. While methods to detect variations will continue to improve in both sensitivity and throughput, understanding how to analyze variations and their potential effect on transcript and protein will continue to be necessary to diagnose genetic lesions involved in defects of the immune system.

The Human Microbiome and Clinical Immunology

FREDERIC D. BUSHMAN

3

Humans, in many respects, are not single organisms, but more like coral reefs, complex assemblages of myriad diverse creatures. The human microbiota, the bugs living in association with humans, contains more cells than comprise the human body itself (1). Like the fish on a reef, the microbes interact with each other, sometimes competing and sometimes collaborating, to form a complex and resilient food web. Some of the population promote the growth and development of the reef, while others consume the reef material, turning the hard corals to sand.

This chapter reviews the nature of the human microbiome, with emphasis on methods for microbiome research and the pitfalls that have ruined many studies in the field. However, despite the challenges, the output from the field has been spectacular (2–7), and the technology emerging from microbiome research holds tremendous promise for translation to clinical applications. A few of the possible future directions are described at the end of the chapter.

WHAT IS METAGENOMIC ANALYSIS?

Microorganisms often live in mixed communities, and it is clear that the global composition and function of mixed communities can be relevant to human health. For example, actions of human microbial communities have been implicated in all the major causes of human mortality (1), including heart disease (8, 9), cancer (10), and diabetes (11). Loss of normal control of the microbiome in immunodeficient states is associated with pathogenesis of opportunistic infections, and the tools of metagenomic analysis can report the composition and nature of those communities in unprecedented detail.

Complicating analysis of the human microbiome, only a small minority of all the microbes on earth have been subjected to culture in the laboratory, so traditional culture-based methods are often not suitable for studies of mixed microbial communities. A new approach is made possible by the remarkable new "deep sequencing" methods, which allow determination of millions or even billions of bases of DNA sequence in a single instrument run.

Bacterial genomes range in size from ~500 kb to many megabases, and the genomes of fungi are larger still (12). Thus, sequencing all the genomes in a mixed community, which may contain hundreds of types of microbes, is still a daunting task. Furthermore, in a typical biomedical study, the goal is often to compare a set of healthy control samples to a set of samples from a disease state. For example, one might compare stool samples from a cohort of healthy children to samples from a cohort of immunocompromised children. It is typically not feasible to complete the sequences of all microbes in each sample, but it is possible to collect a deep sequence sample of each community. Sequences can then be aligned to databases and the types of microbes present inferred from database annotation. If total DNA is analyzed, then the gene types present (e.g., genes for adenine biosynthetic enzymes and virulence factors) can be assessed as well. One can then compare results for the collection of healthy control samples to the immunocompromised subject samples and identify differences associated with disease. Such an analysis, based on large-scale but incomplete characterization of mixed communities by sequencing, has come to be called "metagenomics."

METHODS FOR METAGENOMICS RESEARCH

In this section, we review the DNA isolation, library preparation, and sequencing approaches used in metagenomic studies. The overall lesson is that details of the analytical approach used are driven quite strongly by the exact question posed—relatively small differences in the goals of the study can mean dramatic differences in the metagenomic methods needed for analysis. Several examples of types of questions and approaches to their investigation are presented toward the end of this chapter.

Nucleic Acid Purification

First, a set of samples must be acquired and nucleic acid purified for sequencing. Many nucleic acid purification kits are available from commercial suppliers, and many can be used successfully (13). A key control for any study is to run DNA-free water samples through the purification procedure side by side with the samples of interest. Some commercial kits contain substantial quantities of contaminating 16S DNA, which can be ruinous if the starting amount of nucleic acid is low in the samples of interest. Commercial kits are also available that yield both DNA and RNA from the same sample, allowing assay of both.

Methods for lysis are worked out to allow capture of many organisms in a sample, but the methods represent a compromise between convenience and complete sampling. Some

doi:10.1128/9781555818722.ch3

Gram-positive bacteria and fungi have tough cell walls and are known to be harder to lyse than typical bacteria. Spores are tougher still, and any study for which data on spores are important requires targeted evaluation of methods for lysis. Unfortunately, it is possible that harsh lysis methods may degrade nucleic acid from the first-to-lyse organisms before the toughest are cracked open.

Stepping back, a general lesson is that it is important to carefully formulate the question under study, and if possible to check the performance of the methods chosen in addressing the question posed.

DNA Sequencing

The development of the astounding new DNA-sequencing methods has made possible the explosion of work on the human microbiome. For example, using the new Illumina HiSeq technology, one can acquire hundreds of billions of bases of sequence information in a single instrument run. The availability of such vast amounts of sequence data allows characterization of mixed microbial communities in unprecedented detail.

The automation of the Sanger sequencing chemistry was a breakthrough in its day, driving the completion of the first drafts of human genome sequence in 2001. These instruments could generate 384 reads of ~500 bases each, or ~200 kb of sequence per run, under favorable circumstances.

The first of the massively parallel deep sequencing methods to be commercialized was the Roche 454 pyrosequencing method (14). This allowed collection of ~500,000 sequence reads of ~350 bases per instrument run, or close to 200 million bases. All of these next-generation sequencing methods have higher error rates than the original Sanger sequencing method. The Roche 454 platform is particularly error prone at homopolymer sequences, so that the numbers of bases in the homopolymer runs are commonly miscounted.

While impressive, the newer Solexa/Illumina method is, at this writing, the most widely used and produces the most data per instrument run (15). The HiSeq instruments can generate >250 billion bases of sequence information in a single run in the form of paired 250-base reads. The ABI SOLiD system also delivers amounts of sequence in this range.

Additional companies are also developing still more remarkable technologies. Pacific Biosciences has marketed a third-generation instrument capable of generating long reads on single molecules (16) (in the jargon, the "first generation" was instruments automating Sanger sequencing and the "second generation" the Roche 454, Illumina, and ABI SOLiD technologies). Ion Torrent has marketed an inexpensive instrument that yields reads in the 350-base range at relatively low cost. Both Roche 454 and Illumina have also marketed benchtop machines—the 454 Junior and Illumina MiSeq—that can yield sequence samples of about one-tenth the output of the larger instruments at reduced cost and increased convenience.

DNA Barcoding

Often it is not desirable to collect billions of bases of sequence information on a single sample, but rather it is more cost-effective and efficient to collect much less data per sample over many more samples. A popular approach to this is to engineer DNA barcodes into synthetic DNA primers used in preparation of sequencing libraries, and use separate primer sets to amplify each sample in a set. The amplification products can then be pooled together after library preparation, sequenced together, and separated out computationally after the run based on the barcode information in each sequence read (17, 18). Multiple strategies can be used to mark primers in this fashion. Barcode systems are now available for most of the major sequencing platforms.

Tag Sequencing

Several approaches are commonly used to acquire deep sequence data on microbiome populations. In one popular implementation, PCR is used to amplify conserved sequences present in bacteria or fungi, and then the collections of sequence tags are used to characterize a sample. The bacterial 16S rRNA gene contains highly conserved regions, which can be used as binding sites for PCR primers (19–22). An advantage to the use of 16S data is that well-curated databases are available containing 16S sequences together with phylogenetic annotation, and sophisticated pipelines are in place (QIIME, mothur) that can take in such data and output finished analysis (23, 24). For fungi, 18S rRNA can be used similarly as a tag, as well as the internal transcribed spacer region (25, 26).

A variety of methods have been worked out for comparing sets of communities with one another. Given a set of samples from, for example, healthy controls and immunocompromised subjects, one might want to ask whether there are general trends in the data that distinguish one from the other. Several methods have been developed for calculating pairwise distances between communities, so that all pairs can be calculated to form a matrix of distances between communities. Such matrices can then be used for statistical analysis of possible patterns in the data. For example, one can ask whether the mean distance between all pairs of samples of the same group is smaller than the mean distance for pairs of samples between groups. If yes, this is evidence for separate clustering, and allows simple statistical evaluation. The UniFrac method is one popular tool for generating distances in a phylogenetic framework (27–29) and is implemented in the QIIME pipeline (23). An example is shown in Fig. 1, illustrating the difference in microbial communities at different human body sites analyzed by UniFrac.

Shotgun Sequencing

Tag sequencing yields information on the organisms represented in a microbial population but does not report on the full complement of genes present. Bacteria of even the same species can vary by up to 30% of their genes (30), so naming a strain using tag sequence data provides only part of the picture. Thus, shotgun sequencing of total DNA followed by alignment to databases adds information not just on the organisms present but on the types of genes present in the community as well. The methods for analyzing shotgun metagenomic data are less well worked out than for tag sequencing data (31), and the data volumes can be very large, presenting challenges in data transfer and management that are not as severe with tag sequencing. However, methods are improving with each passing year. For example, MEGAN allows collection of aligned sequences to yield taxonomic attribution (32), MetaPhlAn uses a sequence tag approach over shotgun reads to annotate bacteria in an efficient fashion (33), and multiple databases allow assignment of genes detected to functional classes or pathways (34, 35).

Thus, although methods development is ongoing, methods for metagenomic research are in place and available to address many questions of interest in clinical immunology.

ARTIFACTS IN MICROBIOME RESEARCH

Essentially all the steps described for microbiome analysis above are imperfect. Carrying out a successful microbiome study involves understanding the limitations of the methods

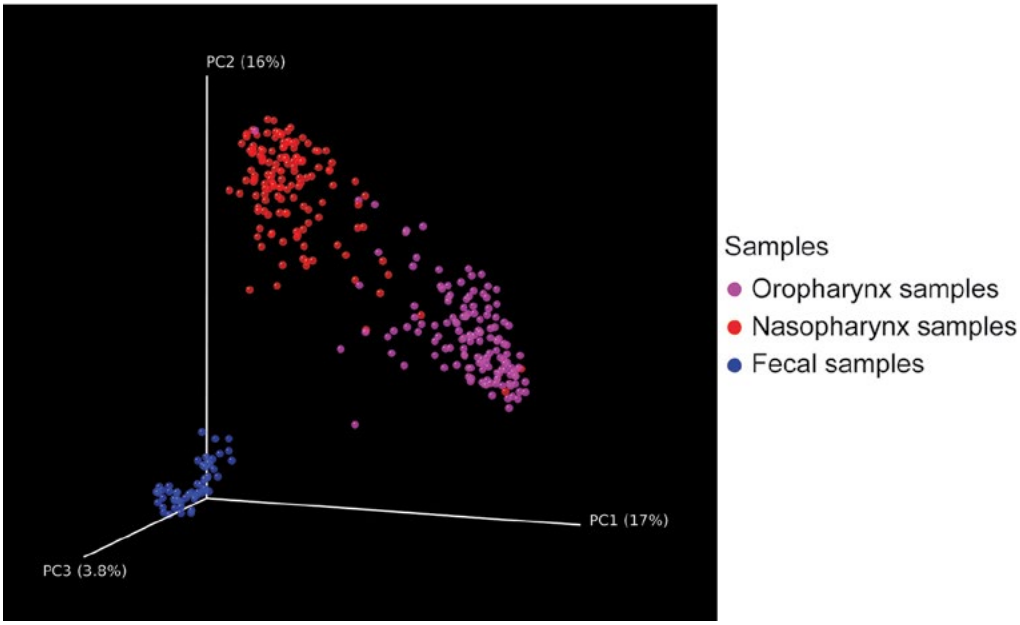

FIGURE 1 Clustering of bacterial communities by body site analyzed using UniFrac. Each dot represents one human microbiome sample, characterized by deep sequencing of 16S tags from the V1V2 region of the gene. Each sample was characterized using a few thousand sequence reads. PC indicates principal coordinates.

used and aligning the question posed with the strengths of methods and not the weaknesses. Some relevant reports have been published (4, 36, 37).

Biases in Sequence Tag Analysis

All of the 16S tag systems used to analyze bacteria are biased in the bacterial types they recover (4, 38, 39). This is unavoidable because the highly conserved sites in the 16S rRNA gene are not perfectly conserved, just well conserved, so that primers anneal to some target sequences better than others. Careful comparisons over defined communities can yield startlingly different results with different primer sets when relative abundance is queried, though differences are less when data are scored for presence and absence of relatively high-level taxonomic groups.

How much this matters depends entirely on the question posed. If the goal is to identify exactly the types and proportions of bacteria in a complex mixture, these biases are significant concerns. Tag sequence data provide an overview of much of the community, but further experimentation is needed to characterize abundance convincingly (e.g., quantitative PCR). However, if the goal is to compare two groups of samples—perhaps fecal samples from immunocompromised children to healthy controls—then the sequence sample returned in a typical 16S tag study may be fine for documenting a difference in communities such as separate clustering. As with any measurement in experimental science, it is always best to verify an important conclusion using multiple forms of measurement. For example, if a single bacterium is judged to be functionally important in distinguishing sample sets, then quantitative PCR could be used to verify the difference between groups.

Tag systems for analyzing microeukaryotes such as fungi present an even more extreme case. For such studies, researchers need to expect from the start that they are only looking at the slice of the fungal community accessible with the primers used. Careful studies are starting to appear comparing the fungi queried using different primer sets that provide a starting point for experimental design (25, 26).

Challenges with Low-Biomass Samples

Much of the work on the human microbiome has focused on the lower gastrointestinal tract, where bacteria are present in the range of 10^{11} per g of intestinal contents (1). Given such gigantic amounts of bacteria, one doesn't usually worry about other sources of bacterial DNA in a gut sample. However, the situation is much different for many other sample types. Bronchoalveolar lavage, skin scrapings, blood plasma, and multiple other sample types typically contain low levels of bacteria, so that admixture of environmental DNA from dust or contamination in commercial reagents can be a substantial fraction of the total.

Thus, it is absolutely critical to surround low-biomass samples with controls to assess the types and proportions of contaminating sequences. Never carry out such an experiment without working up DNA-free water through the full DNA purification procedure. Blank PCR reactions are another must. More-sophisticated controls include instrument washes and matched tissues from germ-free animals. Control samples are put through the DNA purification procedure side by side with the samples of interest and then sequenced with dedicated barcodes in the final deep sequencing run. A handful of reads can sometimes be obtained even from PCR reactions that appear blank after analysis by gel electrophoresis and staining with ethidium bromide, so it is important to sequence everything. In addition, it is valuable to use quantitative PCR to quantify the total number of 16S-complementary sequences per unit volume. Estimates of total 16S gene copies can then be compared between samples of interest and contamination controls to check whether the experimental samples indeed contain sequence counts above background.

These issues are particularly pronounced in studies of the fungal microbiome. Here the absolute amounts of fungal DNA in samples are commonly low, and environmental organisms are abundant. Achieving credibility for any study of the fungal microbiome requires reporting extensive contamination controls and a careful discussion of how these controls were incorporated in the interpretation. One approach to dissecting the contributions of different sources is the Bayesian SourceTracker software (40).

A further challenge comes in comparisons among samples with different starting numbers of 16S copies. Suppose that two sets of samples contain indistinguishable bacterial communities, but one set has a lower biomass. Now add the same number of contaminating environmental 16S DNA copies to each. The contaminating DNA comprises a larger proportion in the samples with fewer starting 16S DNA copies. A sensitive measure comparing communities can then falsely call the two sample sets as different when in reality they differed only in the amount of starting material.

Papers making extreme claims but lacking sufficient control of the above artifacts are common in the literature.

Cage Effects in Studies of Mouse Models

Another underappreciated artifact in microbiome studies using mouse models is the strength of cage effects. Mice are copraphagic, so all the mice in a cage quickly come to share a common set of gut microorganisms. Mice of the same treatment group or genotype in different cages can differ just because of cohousing. The effects can be so strong as to dominate over what would otherwise seem to be extreme treatments.

However, this is a solvable problem. The solution is to design the experiment so as to allow the cage effect to be treated explicitly as a variable in the final statistical analysis of the experiment. For two treatment groups, one can set up multiple cages for each group. It is okay to have relatively few mice per cage, but the number of cages needs to be sizeable. Then in the statistical analysis of sequence data, one can ask whether the microbial communities differ between groups given the measured effect of the cage variable.

Another approach involves longitudinal analysis, such as a drug treatment study, in which each mouse can serve as its own control. Thus the changes can be tabulated and compared between treatment groups. Such an analysis presupposes that differences in the starting communities due to cage effects do not influence the subsequent response to the treatment.

Cage effects are extremely strong for fungal populations. In one recent study (41), fungal populations were monitored longitudinally during an antibiotic intervention. Episodic increases in specific types of fungi were seen in all groups, including the untreated controls, and these waves of colonization differed between cages. Fungal colonization of mice has recently been reported to influence inflammatory bowel disease models (42), which are known to show different results in different mouse facilities, raising the possibility that fungal colonization and cage effects may represent an underappreciated confounding variable.

METAGENOMIC ANALYSIS OF VIRUSES

A number of compelling studies have examined the viruses of the human microbiome (43–51)—however, their analysis requires careful design. For example, it may be of interest to query shotgun sequence samples from total stool DNA to identify the virome present, but this presents major challenges. For one, genomes of all metazoans harbor integrated sequences from endogenous retroviruses and retrotransposons that are clearly related to exogenous retroviruses (12), obstructing clear assessment of this viral group. Additional gene families are known to be common between viruses and bacterial sequences, so that alignment of total shotgun sequence data to databases of viruses often falsely pulls out matches.

If feasible, one approach to studying viruses is to first purify viral particles—if samples are clean enough, one can be confident that each sequence analyzed likely came from a virus. A disadvantage of this approach is that any purification method likely recovers some viruses better than others, and some not at all, so only a portion of the viral population is queried.

This method is well suited for analysis of bacterial viruses. Global populations of bacterial viruses are thought to be gigantic—up to 10^7 particles per ml in rich seawater (43). These viruses are thus necessarily poorly represented in sequence databases, and so simply aligning newly acquired sequence to a database does a poor job in identifying bacterial viruses. In sequence surveys of highly purified natural viral communities, most of the reads look like nothing you have ever seen before, consistent with this picture.

As for bacteria and fungi, the method used is dictated by the question posed. For example, for hunting for new types of viruses in immunocompromised subjects, one can take database hits as candidates for validation by quantitative PCR and other methods. As long as downstream validation is part of the experimental plan, then metagenomic data can be simply treated as hypothesis generating, obviating many of the concerns above.

METAGENOMIC ANALYSIS TO INVESTIGATE DISEASE STATES

Despite the above challenges, the microbiome field has yielded much striking data, some of which bears on problems in clinical immunology. The Human Microbiome Project has completed draft sequences of thousands of bacteria, providing a rich resource for analysis of new sequences by alignment (52). Studies of immunocompromised states such as lung transplant (53, 54) or lentiviral infection (5) have shown characteristic changes in microbial community composition. These are likely to lead directly to improved methods for diagnosis of microbial colonization in immunocompromised patients. As the methods for sequence acquisition become less expensive, focus turns to collection of appropriate samples for analysis and development of analytical tools for interpreting data. Many groups are presently developing tools to allow molecular diagnostics based on deep sequencing data.

Another area of interest centers on understanding patterns in healthy and dysbiotic communities based on microbiome sequence data. One pattern characteristic of immunocompromised states is higher variance in composition. You could say that this parallels the famous Bumpus study of sparrow mortality in 1898 (http://fieldmuseum.org/explore/hermon-bumpus-and-house-sparrows), which may be the first application of multivariate mathematics to a problem in ecology. Bumpus studied sparrows that were knocked down by a violent storm. Some survived and others died. Bumpus took many anatomical measurements of each bird and asked how the birds that died differed from those that survived. Bumpus did find a pattern, but there was no single trait associated with mortality. Instead, the

birds that died tended to diverge more from the average "perfect" bird than did the survivors, but each fatality diverged in its own way. That is, the fatal cases were distinguished by higher variance, not by any single feature. A similar pattern is seen for microbial communities in immunocompromised subjects.

One example is provided by studies of lung transplant recipients. In bronchoalveolar lavage samples, the variance was higher for samples from lung transplant recipients than from healthy subjects. The lung transplant subjects also showed lower richness, which is the total number of species detected in the sample (53). All of this is consistent with outgrowth of specific organisms in each immunocompromised subject, but different organisms in each case. The drop in richness can be understood as a single microbial lineage proliferating and "shouldering out" other community members. Consistent with this picture, the total amount of 16S DNA was higher in lung transplant recipients than in healthy controls by PCR, and individual recipients showed outgrowths of *Pseudomonas*, *Staphylococcus*, *Achromobacter*, and other known species of concern. In one case, an organism not previously considered a lung resident, *Snethia*, was found to be predominant. This organism would not normally be tracked in transplant recipients, presenting an example of how the new sequencing methods can provide information that is unavailable with other commonly used diagnostic methods. Similar patterns of high variance are seen in metagenomic analysis of stool samples from pediatric subjects with primary immunodeficiencies (unpublished data).

The human microbiome has been implicated in multiple further aspects of human health and disease. Studies from Gordon and coworkers have emphasized that obesity can be associated with distinctive patterns of gut microbial colonization (5, 55–60). Strikingly, the obese phenotype in humans can be transferred to gnotobiotic (germ-free) mice by inoculation from obese but not lean individuals, suggesting that the gut microbiome plays a causal role in the obese phenotype. Going the other way, a recent study suggested that long-term diet dictates the composition of the gut microbiome (7), providing a potential mechanism connecting diet and the many health outcomes linked to dietary choices.

Another striking series of studies have recently linked metabolic products of the gut microbiome to heart disease (8, 9, 61). Hazen and coworkers began by analyzing metabolites associated with adverse cardiac outcome in a large cohort of subjects. Comparison of discovery and validation cohorts revealed phosphatidylcholine, choline, and trimethylamine oxide as metabolites linked to adverse outcome. Further studies added carnitine and trimethylamine to the pathway. Very extensive follow-up studies outlined a pathway involving the gut microbiome as a key step. Foods such as eggs and meat are rich sources of phosphatidylcholine and carnitine. The compounds are broken down to yield trimethylamine in a step dependent on the gut microbiome. Trimethylamine is then metabolized by liver oxidases to yield trimethylamine oxide, which is directly proatherogenic. The microbial genes for production of trimethylamine have recently been identified by Craciun and Balskus (62), opening up the possibility of modulating this pathway to minimize heart disease.

In summary, the new technology and new insights of microbiome research are tremendously potent, but with increased sensitivity comes new types of artifacts that are not to be underestimated. Nevertheless, microbiome analysis is becoming an important contributor to diagnostics and research in clinical immunology and many other fields.

Protein Analysis in the Clinical Immunology Laboratory

ROSHINI SARAH ABRAHAM AND DAVID R. BARNIDGE

4

THE ROLE OF PROTEIN ANALYSIS IN DIAGNOSTIC IMMUNOLOGY

The diagnostic immunology laboratory relies heavily on protein measurements, especially with the explosion of clinically relevant biomarker analysis. Of particular import are the tremendous advances that have been made in the technology for protein detection, and while not all of it has gained traction in the clinical immunology laboratory, this remains an area of huge growth. However, regulatory processes have not kept up with the burgeoning research in the area of protein analysis, and new diagnostic tests for protein analytes are approved for clinical testing at a glacial pace. Nonetheless, it is critical for the clinical immunologist to understand these advances and determine how they can best be utilized in the clinical laboratory. Besides keeping pace with the rapidly changing technology, the age-old fundamental principles of analytical validation of new tests, protein based or not, are still applicable. This chapter covers the basic principles of protein testing in the clinical laboratory and provides special emphasis on the role of mass spectrometry (MS) in diagnostic protein analysis.

PREANALYTICAL ISSUES IN PROTEIN ANALYSIS

Preanalytical parameters determine the validity of any diagnostic test result; therefore, the importance of considering preanalytical issues in clinical test development and validation cannot be overemphasized. The components of the preanalytical phase include both generic elements and those specific for protein analysis. Generic preanalytical measures include relevant test selection with appropriate analytical sensitivity and specificity to detect the biomarker (protein) of choice and the probability it will aid in diagnosing the disease or clinical condition (clinical sensitivity/specificity). Other factors to consider include preparation of patient and sample collection and handling (1). Each of these has to be individually assessed and validated so that the analysis is performed under predetermined conditions that will contribute to a reliable test result and interpretation.

Sources of Protein for Diagnostic Analysis

Diagnostically relevant proteins can be studied from a variety of sources, and sample collection depends on the protein of interest, which defines the optimal method for analysis. Most proteins measured in the immunology laboratory are soluble and present in serum or plasma, urine, or body fluids including ascites, cerebrospinal fluid (CSF), and peritoneal and bronchial fluid. However, other important sources of nonsoluble proteins include cells present either in fluid matrices (blood, urine, CSF, or other body fluids) or tissue matrices, obtained primarily from biopsy samples (2). Further, proteins can be studied *in vivo*, either for diagnostic or therapeutic purposes, either in the context of cells or soluble protein, using magnetic resonance and other imaging modalities that assess labeled proteins (3, 4). A notable example of *in vivo* protein analysis for determining diagnosis and monitoring response to treatment is the use of ^{123}I-labeled serum amyloid P component in systemic amyloidosis (5). Also, the use of labeled bisphosphonate bone tracers has been shown to be specific and sensitive in identifying transthyretin amyloid protein deposits in the heart (6).

Sample Collection and Its Impact on Protein Analysis

Many factors influence the measurement of proteins. These can be subdivided into four major categories: (i) physiological processes, (ii) collection processes, (iii) sample processing, and (iv) therapeutic intervention (2).

TYPES OF PROTEIN ANALYSIS

Diagnostic evaluation of proteins is dependent not only on the source and collection factors but also on how the result is used for interpretation or correlation with clinical and other findings. Therefore, protein analyses can be categorized into qualitative, semiquantitative, and quantitative measurements. Qualitative analyses are used largely in contexts in which the presence or absence of the protein of interest is sufficient for diagnostic utility, and there are typically large differences between positive and negative responses. Most qualitative protein tests use visual assessment to determine if the protein biomarker is present or absent. Other qualitative measurements include contexts of structural alteration of proteins necessitating some form of physical separation using chromatography, electrophoresis, or MS. The most common examples of this approach include monoclonal protein analysis by serum or urine standard electrophoresis

doi:10.1128/9781555818722.ch4

followed by immunofixation electrophoresis or assessment of α_1-antitrypsin variants by isoelectric focusing, which overcomes the imprecision of electrophoresis by determining protein migration based on its charge (isoelectric point) in a pH gradient (7).

Protein analyses can also be semiquantitative, whereby the absolute amount of the analyte in the sample is not provided but the relative proportion of the analyte of interest to other proteins in the mixture can be obtained. A common example of semiquantitative protein measurement is in the use of point-of-care dipsticks that measure urine protein. Newer dipsticks are available that can report albumin-to-creatinine or total protein-to-creatinine ratios, and though the analytical sensitivity is reasonable, there is significant variability in the specificity of these dipstick reagents. Therefore, the most definitive test for detecting proteinuria is the quantitative measurement of urine protein. Similarly, most diagnostic measurements of clinically relevant proteins require quantitative evaluation and comparison with age- and gender-matched reference values derived from healthy controls. Further, confounding factors in interpretation of many diagnostically relevant proteins include diurnal, seasonal, and exercise-related variability, and these elements have to be incorporated into clinical interpretation of results, besides being relevant in formulating reference values.

METHODS OF PROTEIN ANALYSIS

The above-discussed types of protein measurements can utilize a variety of methodologies, depending on whether it is relevant to quantify the amount of protein or the functional activity of the protein. Similarly, qualitative assays can use different methods for determining the presence or absence of protein or normal versus abnormal function without quantifying the magnitude of functional activity.

Methods for detecting protein function range from binding assays to enzyme activity assays measured by flow cytometry, immunoassays, or MS. Examples include NADPH oxidase activity as assessed by dihydrorhodamine flow cytometry (8–10) and C1 esterase inhibitor function as determined by an enzyme immunoassay using a labeled, activated target protein. This target protein facilitates complex formation between the "test" protein (enzyme inhibitor) and the target protein (enzyme substrate). Examples of these different methods are discussed below.

Immunoassays

There are many immunoassay formats used in the clinical immunology laboratory for the measurement of proteins or peptides. Most immunoassays offer quantitative analysis of proteins, although the degree of accuracy of quantitation may vary depending on the specific method. Immunoassays can be divided into those that use heterogeneous or homogeneous formats, with the former having either antibody or antigen immobilized on a solid substrate and a separate step and the latter having antigen-antibody complex formation taking place in the solution phase with no separation of bound and free ligand. Immunoassays were described extensively in the previous edition of this book (2); therefore, only a synopsis of key methodologies is provided herein.

RID

Radial immunodiffusion (RID) is a relatively old method that has been replaced in most laboratories. It is based on the classic precipitin reaction, in which antigen and antibodies react to form precipitates in liquid or semifluid gel media (11). Under conditions of antibody excess, the quantity of the precipitate is directly related to the quantity of antigen in the test sample. The major limitations include the duration of time required; the relative imprecision of the assay, with coefficients of variation often >10%; the relative insensitivity; and dependence on antigen quantity and structure.

Nephelometry

RID has been supplanted by nephelometry in most laboratories as the method of choice for measuring most proteins in body fluids, including immunoglobulins and intact or free light and heavy chains (12–14). Nephelometry is a method that relies on light scattering by soluble immune complexes in solution. The amount of light scatter produced by soluble immune complexes is directly proportional to the concentration of antigen. In contrast to the standard precipitin reaction, which requires that the concentrations of antigen and antibody be at equivalence, nephelometry often performs best with excess antibody. The two main types of nephelometric reactions include endpoint (fixed time) and rate (kinetic) nephelometry, which measure light scatter after equilibration of the antigen-antibody reaction and the peak rate of immune complex generation, respectively (12–14). The primary disadvantages of nephelometry include increased costs for instruments and reagents, although these can be offset by replacing manual methods with automation; variability in reagent antisera, especially to structurally altered proteins; and interfering substances that can alter light-scattering properties.

Electrophoresis

The migration of proteins on agarose electrophoresis is used most commonly for identification of monoclonal proteins in patients with monoclonal gammopathies (13, 15). In the serum protein electrophoresis depicted in Fig. 1, the stained protein bands representing albumin and α_1-, α_2-, and β-globulins can be easily visualized. While the most abundant protein bands, such as albumin, are clearly visualized with definition, immunoglobulins migrating in the γ region are often broad and diffuse. This lack of resolution in the γ region is due to the presence of many electrophoretically heterogeneous immunoglobulins that migrate in the same region. Serum protein electrophoresis can be used to qualitatively or semiquantitatively identify, by visual and densitometric analysis, the presence of monoclonal immunoglobulins, hypogammaglobulinemia, nephrotic syndrome, and polyclonal hypergammaglobulinemia. Serum electrophoresis is not a particularly sensitive method for the detection of hypogammaglobulinemia, and there should be additional confirmation with quantitation of immunoglobulins by nephelometry. Monoclonal proteins should be further assessed by immunofixation electrophoresis. Densitometric analysis of stained proteins after total serum electrophoresis is an acceptable method for following the response to therapy of diseases characterized by monoclonal proteins after an initial diagnosis.

Most proteins display a net charge in an electrical field, which allows for their electrophoretic separation. The size and shape of a protein molecule, the ionic strength of the buffer, the frictional resistance of the supporting medium, the applied current, the temperature of the reaction, and the duration of the applied current all influence the migration of proteins in a typical electrophoresis reaction (13, 16). As many as 12 discrete regions may be visualized with higher-resolution protein electrophoresis using agarose and controlled voltage and temperatures (Fig. 1).

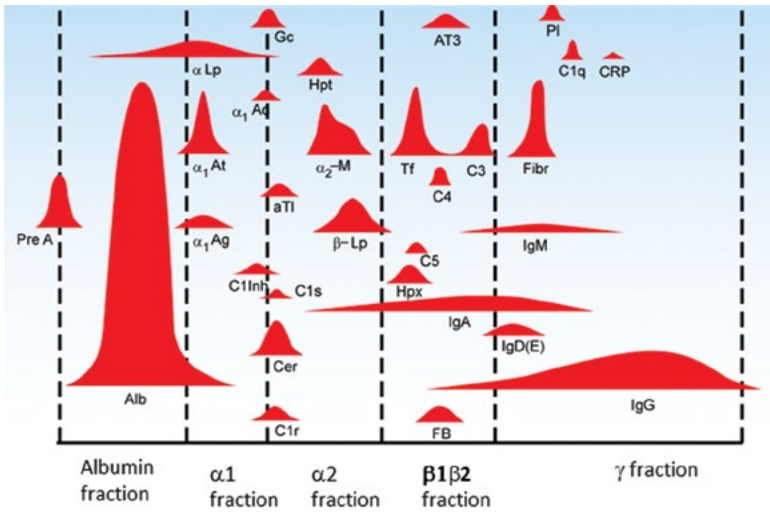

FIGURE 1 Agarose gel electrophoresis separation of plasma proteins based on their electrophoretic mobility. α1Ac, α1-antichymotrypsin; α1Ag, α1-acid glycoprotein; Alb, albumin, α1At, α1-antitrypsin; AT3, antithrombin III; C1Inh, C1 esterase inhibitor; Cer, ceruloplasmin; CRP, C-reactive protein; FB, factor B; Fibr, fibrinogen; Gc, Gc-globulin (vitamin D-binding protein); Hpt, haptoglobin; Hpx, hemopexin; α-Lp, α-lipoprotein; β-Lp, β-lipoprotein; α2-M, α1-macroglobulin; Pl, plasminogen; Pre A, prealbumin; Tf, transferrin. Reproduced from reference 11 with permission from Elsevier Ltd.

Besides serum analysis, other body fluids are evaluated in the clinical laboratory by electrophoresis. Urine samples are routinely tested in patients with serum monoclonal proteins to identify the monoclonal protein components, particularly light chains, and CSF can be tested for oligoclonal immunoglobulins that may be present in neurological disorders such as multiple sclerosis.

IFE

Immunofixation electrophoresis (IFE) is the most common method used for establishing the presence and isotype of a monoclonal immunoglobulin protein in serum and urine (13, 17). The use of a marker dye facilitates visual analysis of the monoclonal protein, and the location of the immunoprecipitate depends on the electrophoretic mobility of the specific monoclonal protein. Most clinical laboratories use IFE after screening samples by serum electrophoresis and/or quantitative immunoglobulin measurements. Although serum is the most common sample type, urine or CSF may also be examined to detect and/or characterize monoclonal proteins or their fragments. IFE has several advantages, including a shorter time to obtain results, increased sensitivity, better resolution, and greater ease of interpretation. However, the IFE method is not without its disadvantages, which include the enhanced quality, increased quantity, and greater cost of the antisera required. Optimal resolution necessitates that the exact amount of antisera be determined for each sample to avoid either excess dilution or excess antibody. In addition, because of the increased sensitivity of IFE, smaller bands are more frequently identified, which can confound the clinical interpretation.

ELISA

The enzyme-linked immunosorbent assay (ELISA) is probably the most widely used immunoassay (13, 18), and it is available in either competitive or noncompetitive formats. In the competitive format, unlabeled antigens compete with labeled antigens for limited antibody-binding sites. If the amount of unlabeled antigen increases, the amount of labeled antigen bound to antibody decreases, resulting in a decrease in detection signal if antibody-bound antigen is the readout or, conversely, increase in detection signal if labeled free antigen is the readout. In the noncompetitive format, antigens bind to an excess of labeled antibody, forming a complex, which increases with increase in antigen in the sample. ELISA is a highly sensitive method capable of measuring proteins in nanogram or picogram amounts, without the use of radioactive tags. While ELISA methods may be used to detect specific antibodies qualitatively or to make semiquantitative measurements of specific antibodies by use of a standard curve calibrated in arbitrary units, there are limitations on the accuracy and precision of semiquantitative tests performed by ELISA. Accurate and true quantitative applications of the basic ELISA method are less common.

More recently, detection of single protein molecules by ELISA has been reported using a novel modification of the standard ELISA technique (19). This method involves the use of a capture antibody immobilized to a matrix of thousands of microspheres. This assay format results in the measurement of individual target molecules, in contrast to the measurement of a collective signal generated in a conventional ELISA, and can be used to quantify low-abundance proteins. However, there are other bead-based, multiplex assays that have greater utility in the clinical laboratory, which are discussed in further detail in this chapter. Other protein detection methods include agglutination and immunofluorescence; these have been used for identification of pathogenic antibodies typically associated with autoimmune diseases.

Multiplex Methods for Protein Detection and Quantitation

The demand for simultaneous, quantitative measurement of several proteins of diagnostic interest has been growing, leading to a focus on multiplex technology (20–23). While

the benefits of multiplex methodology are apparent, analytical concerns include artifacts in quantitation due to matrix effects. Also, cross-reactivity between the capture and detecting reagents, which often are antibodies, can confound quantitation and data interpretation (24).

Among multiplex methods, protein arrays and bead-based technologies are most widely used at present, with rapidly evolving advances in both their chemistries and formats. There are five types of protein arrays most commonly used. These include planar glass or silicon chips; flow cytometric bead arrays; multiplex, microplate immunoassays; and nitrocellulose and three-dimensional microarrays (25); each has its advantages and disadvantages and specific applications. There are also antibody arrays available for protein analysis, which utilize either direct labeling, single-capture, or dual-antibody formats (Fig. 2) (25, 26). Alternatively, antigen or peptide capture arrays can be used with single readout antibodies (Fig. 3). The substrates for both of these microarrays and the signal readout are numerous. They include microplates, gels, slides, suspension arrays with colorimetry, fluorescence, radioactivity, chemiluminescence, enzyme-linked, nanoparticle, light scattering, and other signal-generation and -amplification procedures.

To improve the sensitivity (limit of detection) of these microarrays to detect extremely low concentrations of proteins, a robust signal-enhancement method called rolling circles amplification is used (27). This modification allows the limit of detection of a protein array assay to be increased into the picomolar and subpicomolar ranges, which represents a significant advance in the detection of proteins in biological samples. Studies with standard ELISA methods reveal comparable sensitivity between the two techniques. Alternatively, sensitivity can be enhanced by using bright fluorochromes for antibody detection, as well as optimizing surface chemistry and engineering antibodies to increase valency, or using intermediate detection agents that have multiple binding sites, such as streptavidin, or nanocrystals, such as quantum dots (Qdots) (27, 28). Multiplex methods for autoantibody detection are of particular relevance in the field of autoimmune diseases.

Considerations during selection and validation of a multiplex assay in the laboratory include evaluation of detection reagent and analyte cross-reactivity, stability of reagents, precision across different lots of multiplex kits, multianalyte interactions, the ability to achieve both the dynamic range and relevant sensitivity and specificity, and the impact of diverse matrices and biological states on the accuracy of the final result. The pros and cons of each array approach have to be carefully considered before selecting the appropriate format relevant to the goal of protein quantitation in a specific diagnostic context and the analytes being measured (Table 1). Multiplex cytokine analysis offers a good example of the benefits and disadvantages of multianalyte analysis. The most common biological sample for cytokine analysis is plasma or serum, although conceivably any body fluid matrix could be used. Multiplex cytokine assay formats include planar protein arrays or suspension arrays. Several cytokines can be simultaneously detected and quantified using either

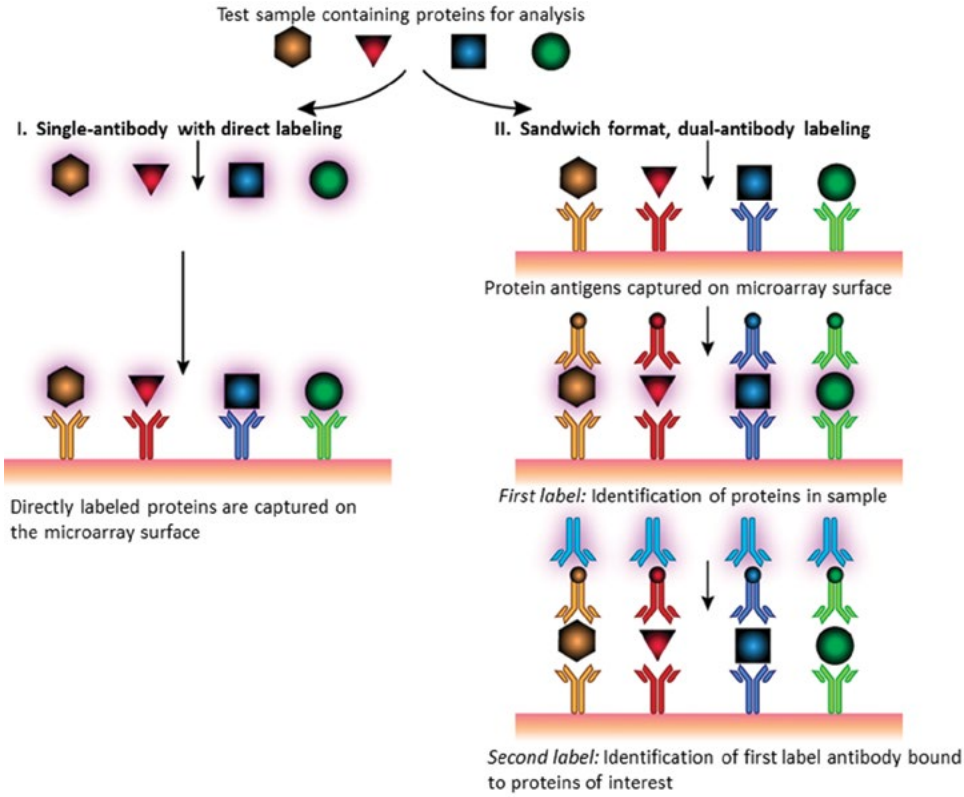

FIGURE 2 Representation of experimental formats for antibody microarrays. (I) Direct labeling of proteins and detection using a single antibody captured on the microarray. (II) Indirect assessment using a two-antibody system. The capture and the first detection antibody are matched, and the detector antibody is measured using a labeled second (readout) antibody.

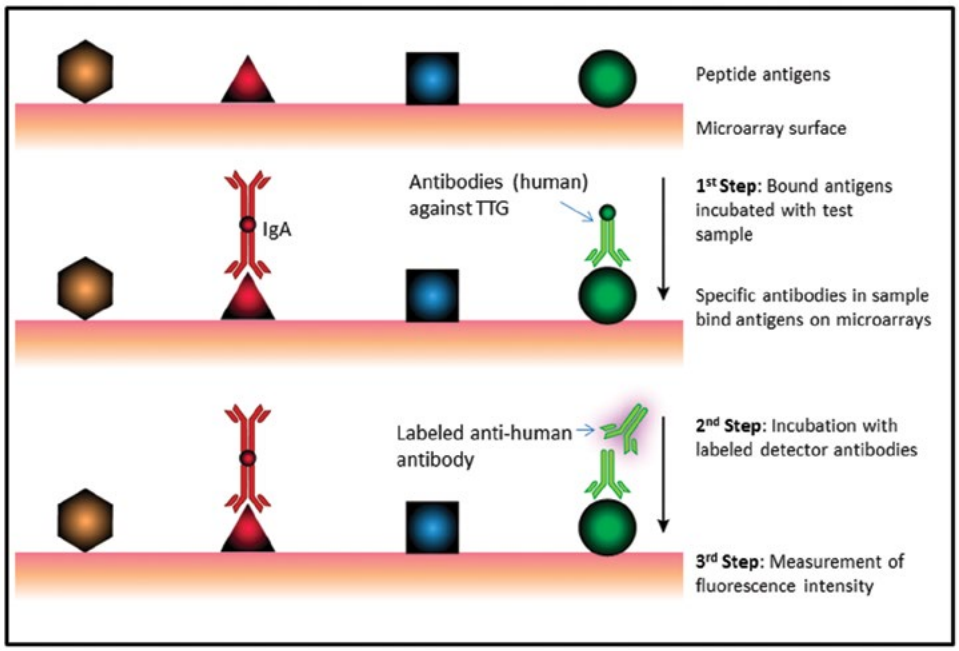

FIGURE 3 Representation of antigen microarray. Antigens are "caught" on the microarray through many different processes, which can be generalized as "printing." Antibodies against specific antigen are detected using a labeled second detector antibody. TTG, tissue transglutaminase.

the flow cytometry approach—Cytometric Bead Array (Becton Dickinson, San Jose, CA)—or the specialized instrument approach—the Luminex xMAP technology.

The accuracy of multiplex cytokine analysis methods has been compared to standard ELISA methods. Although overall correlations are relatively good, there is loss of such correlation for quantitative data (24). A study comparing three commercial multiplex cytokine assays revealed variability between kits from different manufacturers for various analytical parameters, such as accuracy, quantitation in different matrices, recovery, and reproducibility. This indicates that the introduction of a multiplex cytokine assay necessitates careful optimization and validation (29, 30). Besides various multiplex reagent kits, there are instrumentations that offer multiplex technology besides the flow cytometric and Luminex instruments described above. They include the Meso Scale Discovery, which uses a microplate format with electrochemiluminescence detection using labeled tags that emit light on electrochemical stimulation, and the Pierce Endogen SearchLight platform, which utilizes ELISA technology in a similar 96-well format. A study comparing multiplex cytokine analysis using these two platforms (31) revealed that while solid-phase multiplex assays can perform consistently within a platform, optimization and validation experiments should include recombinant cytokine spike recovery, linearity based on dilution analysis, stability

TABLE 1 Advantages and disadvantages of different protein arrays[a]

Types of protein arrays	Positive features	Negative features
Peptide (antigen capture)	Multiplex capability for several hundred analytes Requires a single detection antibody	Primarily useful for autoantibody detection and microbial serological diagnosis Extent of quantitation is variable Sensitivity is variable Specificity is variable
Single capture antibody	Multiplex capability for several hundred analytes Requires a single antibody for antigen capture	Sensitivity is low Specificity is low Analysis is semiquantitative and not absolute
Dual antibodies (capture and readout)	Absolute quantitation Sensitivity is high Specificity is high	Requires separate antibodies for antigen capture and detection Limited number of analytes that can be multiplexed in a single assay format

[a]Adapted from reference 25.

TABLE 2 Factors to consider in selecting multiplex assay platforms

Factor	Relative importance
Antibody cross-reactivity (other detecting reagents)	High
Accuracy of calibration curve	High
Source of antibodies used for capture and detection	High
Sample source (serum, plasma, body fluid)	High
Alternate assay reagents and effect on:	
Spike recovery	High
Accuracy	Low
Analytical measuring range	High
Nonspecific binding due to heterophile antibodies	Variable, depending on clinical context and sample
Consistency of detection of analyte	High

of samples, inter- and intraobserver variability, and consistent measurement of analytes of interest. In the clinical laboratory, the decision to choose an appropriate platform for multiplex cytokine analysis must take into account the various factors that contribute to variability in analyte measurement (Table 2).

The multiplex bead-based assays have a distinct advantage over ELISA in that they use direct fluorescent detection of the analyte, in contrast to an enzyme-mediated colorimetric detection; this provides greater sensitivity. Also, the capture reagents are prepared by covalent coupling of antibodies or antigens to beads, in contrast to passive adherence by adsorption in the ELISA method, which results in greater density of capture molecules and firmer adherence. Therefore, multiplex bead assays have become popular in the diagnostic setting, though they have not completely supplanted ELISA-based methods.

Cytokines are not the only analytes that can be measured by multiplex analysis. The function of anti-vaccine antibodies can be assessed using fluorescent flow cytometric beads conjugated with antigen. An example is the multiplex opsonophagocytic assay (OPA) that is used to detect functional antibody responses to capsular polysaccharides of *Streptococcus pneumoniae* (32) (Fig. 4 and 5). While most antibody detection formats offer multiplex quantitation of IgG antibodies to the 23 serotypes of the pneumococcal polysaccharides, functional antibody assessment using flow cytometry cannot be practically achieved for 23 serotypes due to the limitations related to time and complexity of analysis. Therefore, a clinical OPA can assess at the most six serotypes in a multiplex combination on a three-laser flow cytometer, which necessitates careful selection of serotypes for analysis, primarily based on their immunogenicity and their incorporation in either the protein conjugate or polysaccharide pneumococcal vaccine.

Flow Cytometry and Mass Cytometry for Protein Detection

This section is not meant to be a comprehensive treatise on the subject of flow cytometry but specifically discusses its use in relation to protein detection. Flow cytometry has been used in the clinical laboratory for a variety of applications, including diagnostic immunology for identifying cell

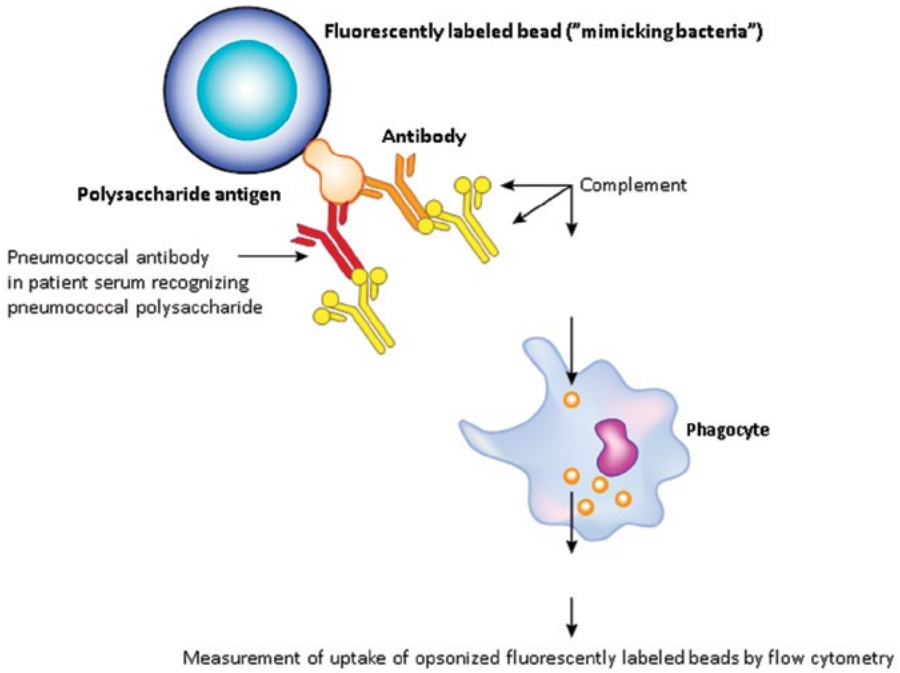

FIGURE 4 OPA for detection of functional antipneumococcal antibodies in serum after vaccination. The use of fluorescently labeled pneumococcal polysaccharide-coated beads permits flow cytometric assessment of the opsonic capability of antipneumococcal antibodies in serum, in the presence of exogenous complement, by measuring phagocytic uptake using a differentiated granulocyte cell line.

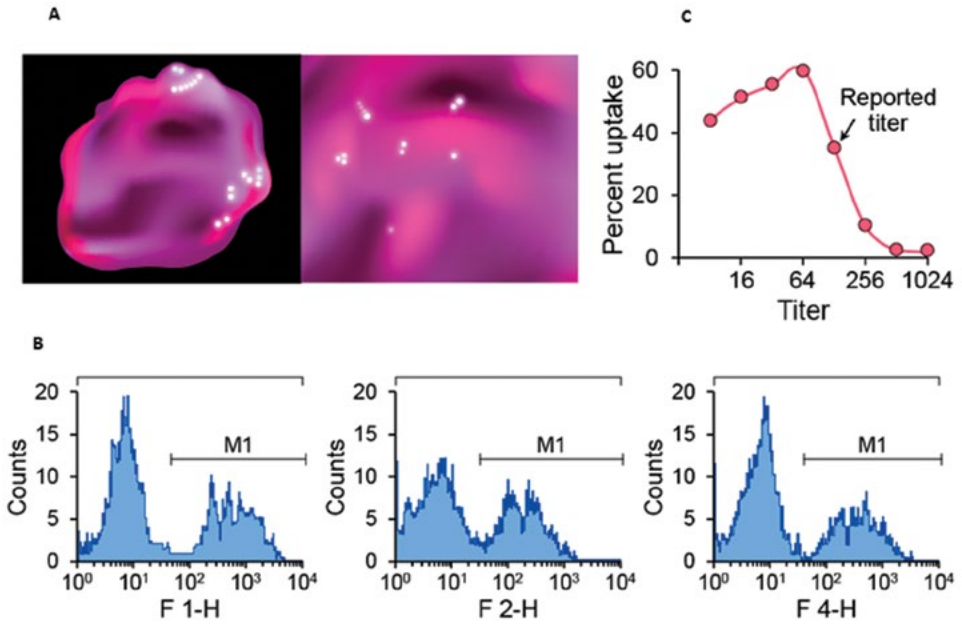

FIGURE 5 (A) Fluorescent microscopy showing differentiated granulocyte cell line with phagocytosed (opsonized) fluorescent beads coated with pneumococcal polysaccharide. (B) Flow cytometric analysis of fluorescent signal from phagocytosed beads. Each bead is coated with a unique polysaccharide, and a multiplex mixture of beads is used to measure functional antibodies produced for each specific pneumococcal serotype. (C) The reciprocal dilution that demonstrates 50% maximal uptake of labeled beads is calculated as the phagocytic titer.

populations of interest for both malignant and nonmalignant conditions. However, flow cytometry can also be used to look at the expression of particular cell surface receptors (proteins and glycoproteins) that are either constitutive or induced by cell activation. CD64, for instance, is expressed on monocytes. It is constitutive but also induced at high levels on neutrophils as a result of infection (Fig. 6A). Flow cytometry can also be used to perform intracellular protein analysis, including identification of proteins for a diagnostic purpose (present or absent). Illustrative examples are Bruton's tyrosine kinase (Btk) for the diagnosis of X-linked agammaglobulinemia (XLA) (Fig. 6B); functional alteration of proteins, including phosphorylation (Fig. 6C) (33); and cytokine production on cellular activation (see chapter 28). The distinct advantage of using flow cytometry for these applications is the ability to correlate the protein of interest with its cellular counterpart or association with specific function or expression under specific conditions. These relationships cannot be achieved in a comprehensive manner by static *in vitro* protein analysis. Flow cytometry has also been used to study protein-protein interactions *in situ* in live or intact cells using the fluorescence resonance energy transfer technique (34). While these approaches may sound somewhat futuristic in the clinical laboratory, phosphoprotein analysis and *ex vivo* measurement of cytokine-producing T cells is already part of the diagnostic armamentarium of specialized reference laboratories.

Similar to multiplex immunoassays, multiplex protein analysis by flow cytometry has made major advances. Fluorescence-based cytometry can quantify ~18 proteins at a rate of >10,000 cells/s. However, this can be exponentially increased using the new technology of mass cytometry, which combines flow cytometry and MS and can measure >36 proteins at a rate of 1,000 cells/s. This advanced methodology allows analysis of up to 45 simultaneous parameters without the use of fluorescent agents or interference from spectral overlap (35). Mass cytometry uses stable, nonradioactive isotopes of rare earth elements (lanthanides) as reporters. Mass cytometry is a modification of inductively coupled plasma MS for single-cell analysis. Similar to flow cytometry, cells are stained with antibodies labeled with metal isotopes. Cells can be stained with DNA intercalators, which provide information on DNA content and cell viability. In the specialized mass cytometer instrument, the stained cells are nebulized into single-cell droplets, and the charged atomic ions are subsequently introduced into the mass spectrometer. While there are distinct advantages of the mass cytometry technique, there are certain disadvantages compared with standard fluorescent polychromatic flow cytometry. The primary limitation is that the new method does not allow for cell sorting of viable cells for additional analysis. Also, the standard light-based measurements of forward and size scatter analysis for cell size and complexity, as well as assessment of cell proliferation (see chapter 28) and Ca^{2+} flux, among other analyses, cannot yet be studied by mass cytometry since metal-reporter equivalents are not available. Also, the sensitivity of lanthanide-labeled antibodies is lower than that of most fluorescent labels due to the chelating polymer used, and this could pose difficulty for analysis of cellular targets with low signal-to-noise ratios. Furthermore, the throughput of most commercial flow cytometers is much higher than that of the mass cytometer, which is limited to ~1,000 cells/s. At present, the best use of the mass cytometer is for the analysis of intracellular regulatory molecules (cytokines and phosphoproteins) for which autofluorescence can pose a confounder or in contexts of numerous simultaneous measurements (35). Complex immunophenotyping and rare-event analysis, on the other hand, may currently be best suited

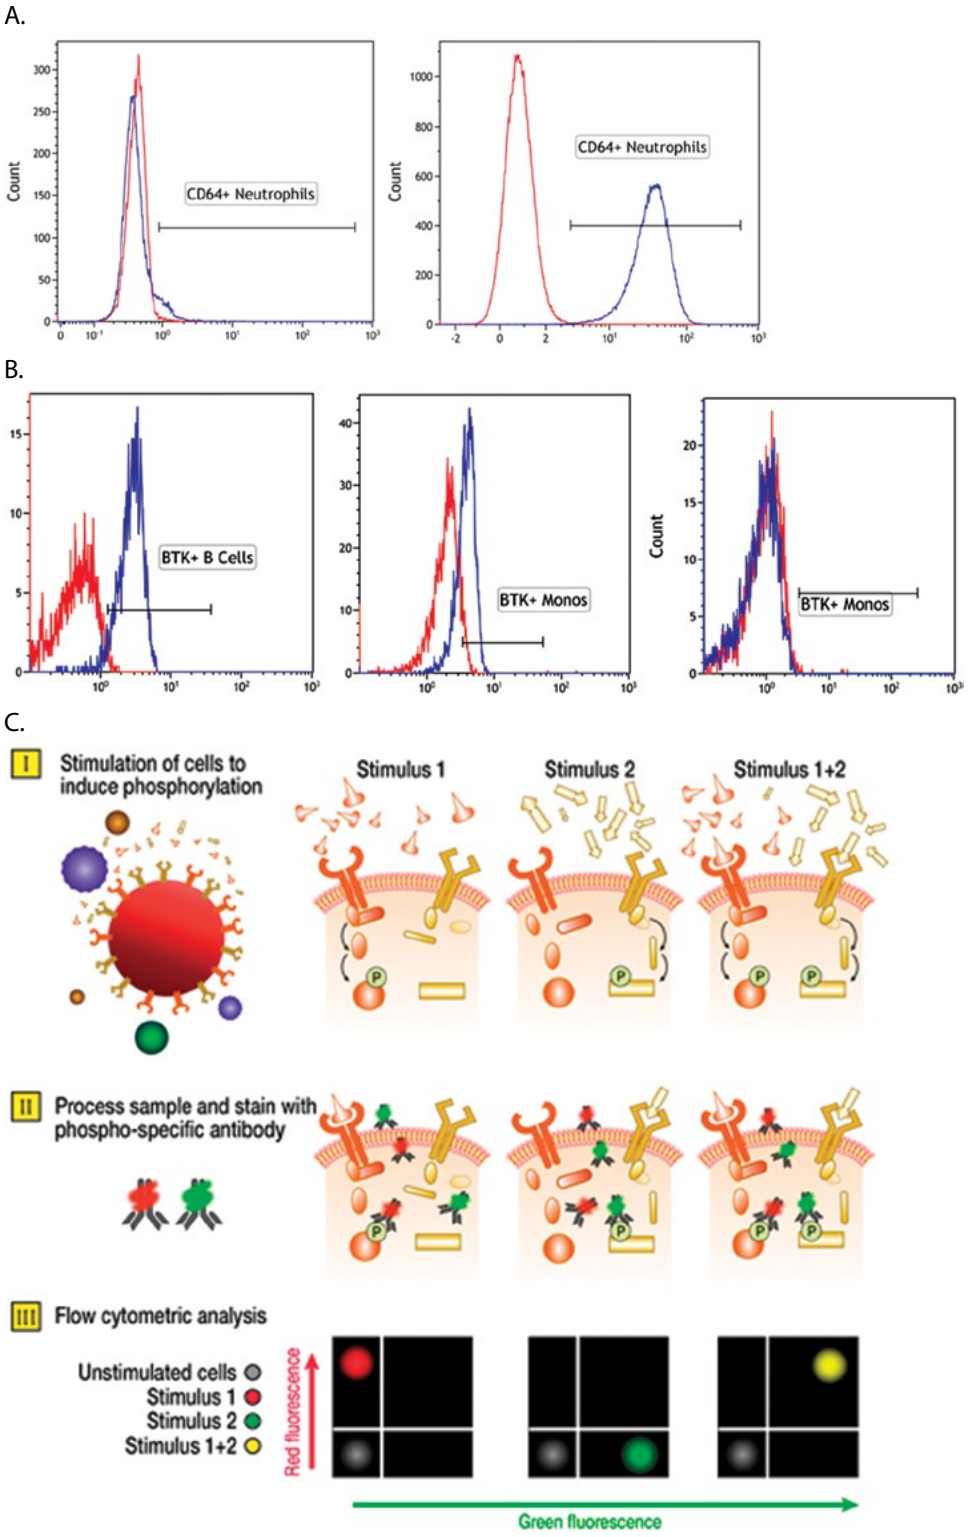

FIGURE 6 (A) Flow cytometric expression of CD64 on "resting" neutrophils (left panel), which is essentially absent because it is not a constitutive marker in this cellular subset. CD64 expression on neutrophils from a patient with bacterial sepsis (blue peak, right panel), as it is a marker expressed on neutrophil activation specifically in the context of infectious stimuli. (B) Flow cytometric analysis of an intracellular protein, Btk, in B cells from a healthy donor (left panel) and in monocytes (Monos) from a healthy donor (middle panel), and the absence of Btk protein in monocytes from a patient with XLA (right panel). Red peak, isotype control; blue peak, specific anti-human Btk antibody. (C) Flow cytometric analysis of modification (e.g., phosphorylation) of intracellular cell signaling proteins. Alterations in function of cell signaling pathways can be assessed after cell stimulation and activation. The assay format can be singleplex (stimulus 1 or stimulus 2 only) or multiplex (stimulus 1 and stimulus 2 in combination), assessing different cell signaling proteins simultaneously (i.e., single experiment). Panel C reproduced from reference 11 with permission from Elsevier Ltd.

for flow cytometry. However, since there is rapid evolution of instrumentation, reagents, and analytical software, these boundaries may blur with time and permit use of each technology interchangeably or for highly specific applications in the clinical laboratory.

QA AND QC ISSUES IN PROTEIN ANALYSIS

Every clinical laboratory must have a robust quality assurance (QA) and quality control (QC) program to ensure that diagnostic testing meets regulatory standards and is optimized for use in patient care. The QA program ensures that appropriate checks are present for the routine analytical process of testing but also for the elements related to analytical and clinical validation prior to introduction of a new test. These include preanalytical issues such as sample stability, anticoagulant, and interfering substances; analytical components including accuracy and precision, reportable range, and reference values; and postanalytical parameters of test reporting, interpretation, and test utilization. For appropriate use of clinical laboratory tests, there must be guidelines that define the clinical utility, strengths, and limitations of the assay. Additionally, implementation of a new test has to take into account appropriate training of lab personnel; documents detailing instrument evaluation and maintenance for robust performance; and strategies for handling poor-quality results, improperly handled specimens, and inaccurate data entry or reporting of test results. In the case of protein analysis, instrumentation and reagents are a critical aspect of test maintenance and performance in the laboratory. Therefore, protocols have to be developed to monitor both instruments and reagents, including regular instrument validation and lot-to-lot comparison of reagents, using predefined acceptance criteria for clinical use of a new lot of a reagent. Certain methodologies also can pose unique QA challenges, particularly multiplex assays (36). These have to be considered in detail before selecting the assay as well as in developing QA parameters for monitoring assay performance. QA programs also involve the use of QC materials, which can include calibrators, standards, and other well-characterized QC reagents available through national or international agencies. Different levels of QC assessment have to be performed for both instruments and assays. QC reagents for assays should include those that assess the analytical measuring range, e.g., low, medium, and high controls. The types of QCs used may vary depending on whether the assay is qualitative or quantitative. For the former, it may be sufficient to have materials that include those with negative and positive results, while for quantitative assays, a more graded QC assessment may be required, with measurement of the high and low end of the range, and possibly an intermediate level.

Another part of a clinical QA system is regular performance of proficiency testing (PT), which evaluates the entire process within the laboratory. This includes sample assessment for stability, interfering materials, analytical measurements, and postanalytical data reporting and interpretation. For some protein analytes, there are standardized PT materials available through regulatory agencies or professional societies (e.g., College of American Pathologists) in which multiple laboratories participate. For other more esoteric protein-based assays, especially those using flow cytometry or MS, standardized PT materials are not available. In these cases, laboratories must develop their own alternative assessment of proficiency (AAP), which is performed similarly to PT, at least twice a year, by the clinical lab staff. The AAP process can include split samples within the laboratory, shared samples between laboratories at different sites, or chart review for protein tests that are used as screening or diagnostic tests for a single clinical condition. In all cases, whether regular PT or AAP is performed, there must be appropriate documentation of PT and test results.

PROTEIN ANALYSIS: PROTEOMICS USING MS

Ionization Techniques

Mass spectrometers can now be found in many laboratories actively providing molecular mass data for proteins and peptides from a wide variety of biological matrices. Every mass spectrometer consists of three parts: an ion source, an analyzer, and a detector, all of which are linked to a vacuum system. Ions created in the source are separated in the analyzer region and then detected. The two most widely used ion sources for MS-based proteomics are electrospray ionization (ESI) (37) and matrix-assisted laser desorption ionization (MALDI) (38). These two ionization techniques have played a key role in the acceptance of mass spectrometers as practical protein chemistry lab tools. ESI and MALDI create intact molecular ions from high-molecular-mass proteins without destroying the polypeptide chain and are therefore referred to as "soft" ionization techniques. Once in the gas phase, protein ions can then be separated by their mass-to-charge ratio (m/z) in the analyzer region.

ESI

The ESI process transfers ions in solution to ions in the gas phase at atmospheric pressure. ESI sources continuously create ions as proteins and peptides arrive at the source through a solution running from a syringe pump or a liquid chromatograph to an electrically conductive capillary held at a high electric potential (3,000 to 6,000 V). A spray is created as the solution reaches the exit of the capillary (often referred to as a Taylor cone) due to the electrostatic field between the end of the capillary and the entrance to the mass spectrometer. The ions in the solution are transferred to the gas phase as spray droplets burst due to charge repulsion and are further reduced in size due to heated gas that evaporates the solvent surrounding the ions. When the ESI emitter is positively charged, proteins and peptides are positively charged via protonation, while a negatively charged ESI emitter results in negatively charged, deprotonated proteins and peptides. The mechanism of ESI creates multiple ions from the same protein, each with a different number of charges and therefore a different m/z value (39). For a molecule such as an immunoglobulin light chain with a molecular mass of 23,000 Da, a series of charges ranging from +10 to +25 is observed. Because of this, ESI spectra can be complex due to the fact that a single protein has multiple peaks. The molecular mass is determined after the multiply charged peaks are converted from the mass-to-charge (m/z) domain to the uncharged molecular mass (Da) domain, through the aid of a computer program (40). Figure 7 shows an ESI mass spectrum acquired on a quadrupole time-of-flight mass spectrometer (Q-TOF) showing the κ light chain of the therapeutic monoclonal antibody adalimumab after reduction with dithiothreitol. The mass spectrum at the top of the figure shows all the multiply charged ions from the monoclonal light chain of adalimumab, while the bottom figure shows a single peak after the multiply charged ions were converted to molecular mass. The average molecular mass observed was 23,412.19 Da, which matches closely with the known average molecular mass of 23,412.13 Da. The spectrum in Fig. 7 was acquired

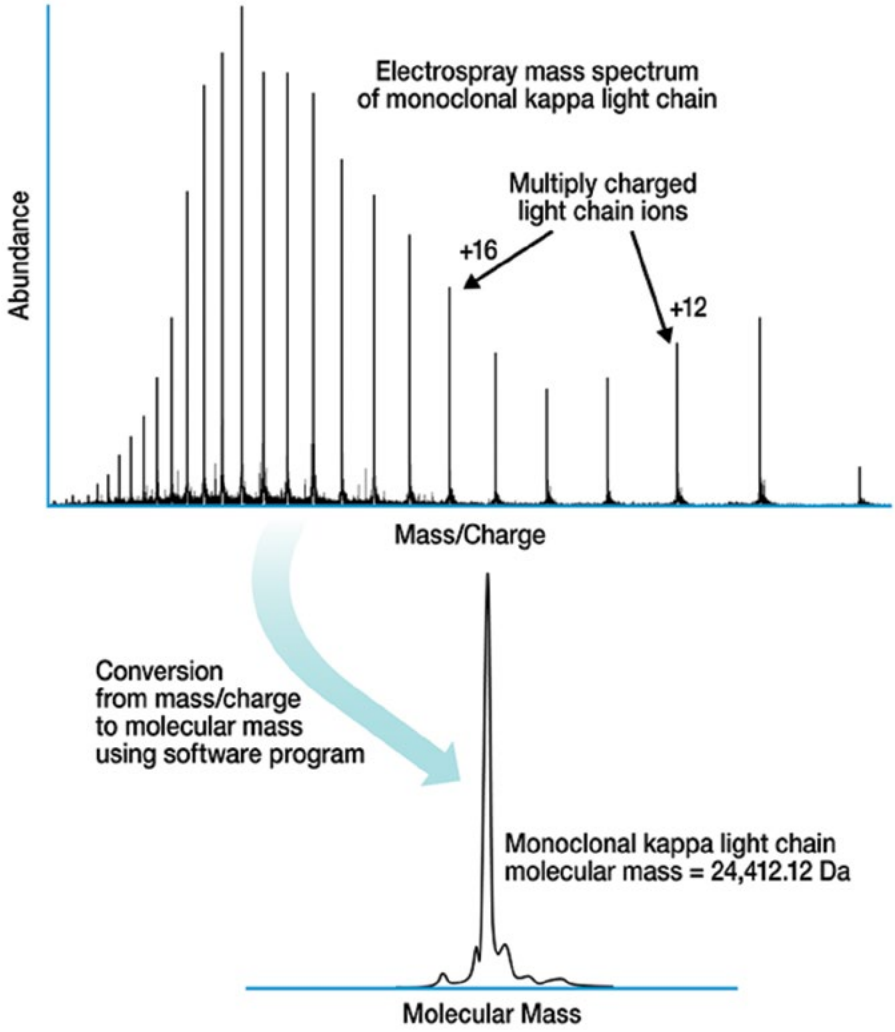

FIGURE 7 Mass spectrum of a monoclonal immunoglobulin light chain protein showing the multiply charged ions produced by ESI (top). Each peak represents the same light chain protein with a different number of protons attached, which changes each ion's mass/charge ratio (m/z). The molecular mass of the light chain is determined by converting each peak to the uncharged state through an algorithm performed by a computer program (bottom).

at a liquid chromatography (LC) flow rate of 25 μl/min with a 2-μl injection, but ESI can be performed at many different flow rates ranging from nanoliters per minute up to a milliliter per minute. Injection volumes for a sample can range from a few microliters to a few hundred microliters.

MALDI

MALDI, on the other hand, produces ions that have much lower charge states compared with ESI. For example, the predominant ions created for an immunoglobulin light chain are typically +1 and +2. MALDI typically creates ions under vacuum instead of atmospheric pressure using a saturated solution of an organic acid mixed with the analyte solution and then dried to form a crystalline matrix. The plate containing the dried spots is transferred into a vacuum via an airlock system. Then a laser is fired at the matrix to form ions. The organic acid matrix absorbs the light energy from the laser and rapidly heats, creating a plume where protons from the matrix are transferred to the analyte in positive-ion mode (41). Figure 8 shows a MALDI mass spectrum from the same sample shown in Fig. 7 of adalimumab monoclonal light chains after reduction with dithiothreitol collected on a TOF mass spectrometer. The difference in the number of charge states produced for the light chain of adalimumab by ESI versus MALDI is easy to see when the two spectra are compared. Because MALDI uses a laser to produce ions, it can be focused on a particular spot to produce an ion image from a tissue sample. MALDI MS imaging is a relatively new technique that is becoming more prevalent in clinical pathology laboratories (42). There are also new ionization techniques that combine dried samples and ESI, such as desorption ESI, that are gaining ground as tools for monitoring tissue samples in real time (43). Together, ESI and MALDI make up the vast majority of ion sources on instruments that analyze proteins and peptides for clinical assays.

Mass Analyzers

The triple-quadrupole mass spectrometer is the most common mass spectrometer encountered in clinical laboratories due to its ruggedness and reliability. The instruments

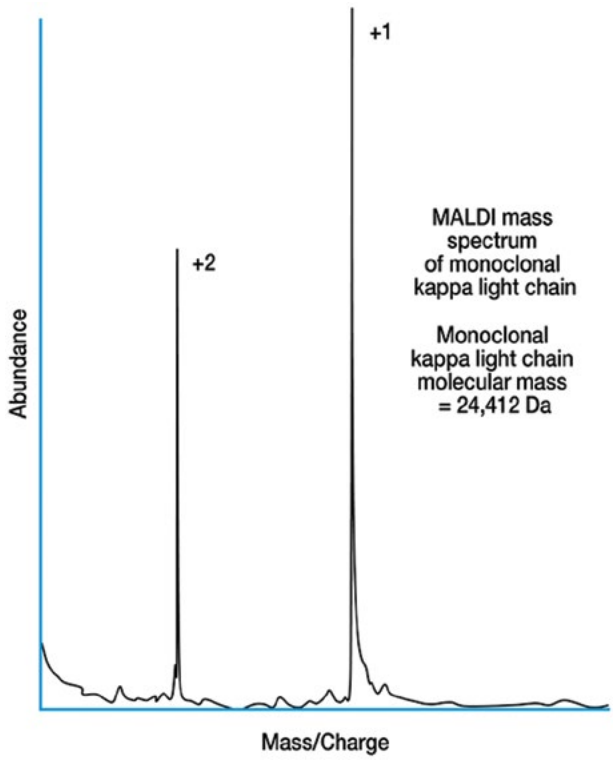

FIGURE 8 Mass spectrum of the same monoclonal immunoglobulin light chain protein shown in Fig. 7 ionized using MALDI. The spectrum clearly shows the prevalence of the +1 and +2 charge states as compared with the highly charged ions created by ESI. The molecular mass of the light chain with the +1 charge state is determined by subtracting the mass of a proton.

typically run at a resolution of 1,000 with mass measurement accuracy of ~40 ppm. The geometry of a quadrupole instrument is just as its name implies; it is made up of a set of four identical parallel rods (~20 cm in length and 1 cm in diameter). Rods that are opposite each other have the same polarity and the same DC voltage. An additional radio-frequency AC voltage is applied to all rods. As the polarity and the voltages are changed on the rod pairs, the electrical field oscillates and ions with the correct m/z remain stable and are transmitted through the quadrupole (44). Quadrupole instruments can be operated in scanning mode, which allows ions with different m/z to be transmitted through the detector, or they can be set to transmit only ions with a specific m/z. Triple-quadrupole mass spectrometers are used in the clinical laboratory due to the high level of sensitivity and specificity obtained using three different quadrupole analyzers in tandem. Ions entering a triple-quadrupole instrument first encounter a single quadrupole (Q1), followed by a collision cell (this is not a true quadrupole but is often referred to as Q2), followed by another single quadrupole (Q3). The first quadrupole is typically set to transmit a specific m/z, which is transferred to the collision cell, where neutral gas molecules (usually nitrogen) collide with the ions to form fragment ions. The fragment ions produced can be scanned in the third quadrupole, or the third quadrupole can be set to transmit a specific m/z that is unique to a fragment ion for the analyte. This series of events is called tandem MS, or MS/MS. When the first quadrupole is set to transmit a specific m/z to be fragmented in the collision cell and the third quadrupole is set to transmit a specific fragment ion m/z, the experiment is called selected reaction monitoring, or SRM (also referred to as multiple reaction monitoring, or MRM). This type of experiment is the mainstay of quantitative MS performed in clinical laboratories. Figure 9 shows a graphical representation of the SRM process.

Quadrupole ion trap mass spectrometers are another commonly used mass spectrometer in clinical laboratories. An ion trap is designed as either a three-dimensional ion trap where the ions oscillate in a circular fashion or a two-dimensional linear ion trap where the ions move back and forth. Both geometries use the same principles of modifying DC polarity and radio-frequency AC voltages to keep ions in a quadrupole trap. Instead of being transmitted down a linear path as in a triple-quadrupole mass spectrometer (45), ions are injected into the ion trap, excited, and then allowed to oscillate in the trap before being ejected and detected. The resolution of a quadrupole ion trap can be upwards of 4,000 with a mass measurement accuracy of ~40 ppm. The benefit of quadrupole ion traps is their scanning speed, which can be orders of magnitude faster than a quadrupole instrument. They are often used for structural analysis of peptides because they have the capacity to do MS/MS/MS. A specific peptide ion can be trapped and then fragmented multiple times all in the same experiment and at scanning rates much faster than with a triple-quadrupole instrument. Quadrupole ion traps also have the added benefit of being able to use different dissociation techniques to fragment ions, such as electron transfer dissociation (46).

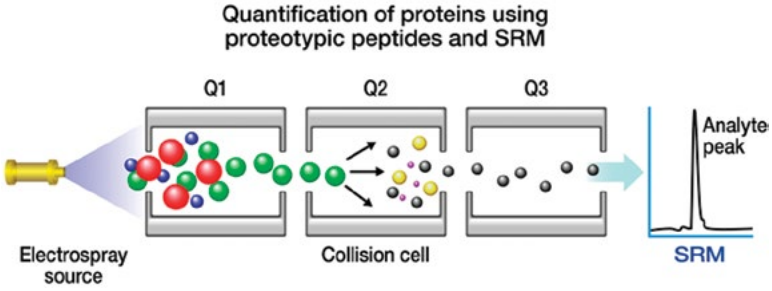

FIGURE 9 A graphical representation of the transmission through a triple-quadrupole mass spectrometer for a specific proteotypic peptide ion quantified using SRM. The intact peptide ion is created by ESI and is represented by the green balls. The peptide ion is selected in Q1 and fragmented in the collision cell (Q2), and then a proteotypic peptide-specific fragment ion is transmitted through Q3 on to the detector.

Such new methods can generate fragment ions containing posttranslational modifications that are not observed using other fragmentation techniques. One issue with ion traps is the space-charging effect, which can limit the linear dynamic range of the instrument and is not observed in triple-quadrupole mass spectrometers. Instrument manufacturers have employed techniques such as automatic gain control to limit the number of ions entering the trap, allowing new instruments to better manage space charging.

TOF mass spectrometers can also be found in the clinical laboratory and are well suited for measuring the molecular mass of large proteins (47). TOF instruments consist of a flight tube in which the *m/z* of an ion is determined by the time it takes to travel a set distance between a start position and the detector. This is called the flight time, and it is dependent on the ion's mass and the voltage on the pulser that forces the ions into the flight tube (48). There are two common types of TOF instruments, linear and reflectron. Linear TOF instruments measure the time it takes an ion to travel between two set points in a linear flight path from the ion source to the detector. A reflectron instrument contains a flight tube that includes a series of lenses that slow the ions and then force them to reverse direction on to the detector. The ions travel farther in a reflectron instrument and are more focused compared with a linear instrument, resulting in better resolution. There are differences in the resolution and mass measurement accuracy of ESI-TOF versus MALDI-TOF instruments due to the kinetic energy of the ions after they are created. In an ESI-TOF instrument, the ions enter the TOF region at a 90° angle, creating the orthogonal-TOF geometry. The steady stream of ions from the ESI source is pulsed into the flight tube in a tight beam, making their mass measurement highly accurate. MALDI-TOF instruments have the ions enter the flight tube after the laser pulse when the ions are dispersed throughout the ablated matrix plume. To compensate for the ion dispersion, delayed extraction is used to make a tighter ion beam before the ion packet is accelerated through the flight tube to the detector. Advances in the speed and data transfer rates of the electronics used in TOF instruments have made them faster and more reliable, enabling resolution of upwards of 30,000 with a mass measurement accuracy of 2 ppm for most high-end ESI-TOF instruments.

The newest generation of mass spectrometer is the Orbitrap, based on a new design developed by Makarov (49). The Orbitrap measures an ion's *m/z* by collecting the image current produced while the ions oscillate around an electrode assembly. The mass of each ion is found by converting the image current to *m/z* using the Fourier transform. The instrument is capable of attaining resolution of 240,000 with a mass measurement accuracy of <1 ppm. The high resolution is a function of the high precision and accuracy with which the frequency of the ions orbiting in the cell can be measured via the image current. The Orbitrap itself is <10 cm in length and is kept at very low pressure. The ions are injected into the Orbitrap (Fig. 10) using a C-trap that focuses the ions to a point within the cell where they begin their orbit around the center electrode. Orbitrap instruments were first introduced in research laboratories, but they are becoming more popular in clinical laboratories with the advent of new instruments that combine the robust attributes of quadrupole instruments with the Orbitrap.

Orbitrap and TOF mass spectrometers are often coupled with quadrupole mass spectrometers, resulting in a hybrid instrument. The reason for combining the two instruments stems from the fact that a quadrupole can function as an ion guide, in which all ions within a certain *m/z* range can be transmitted, or as an ion selector, in which only ions with a specific *m/z* are transmitted. The first generation of Orbitraps was hybrid instruments with a linear ion trap (LIT) in front of the Orbitrap, while the second generation combined a single quadrupole with the Orbitrap. Instruments with a LIT most often generate ion fragments in the LIT, while instruments with a quadrupole have a separate collision cell called a higher-energy collisional dissociation cell for generating fragment ions for structural analysis. In Q-TOF instruments, a quadrupole is coupled with a collision cell in the same manner as in a triple-quadrupole instrument and the third quadrupole is replaced by a TOF analyzer. Both Orbitrap and TOF hybrid instruments offer superior scanning speed, resolution, and mass measurement accuracy

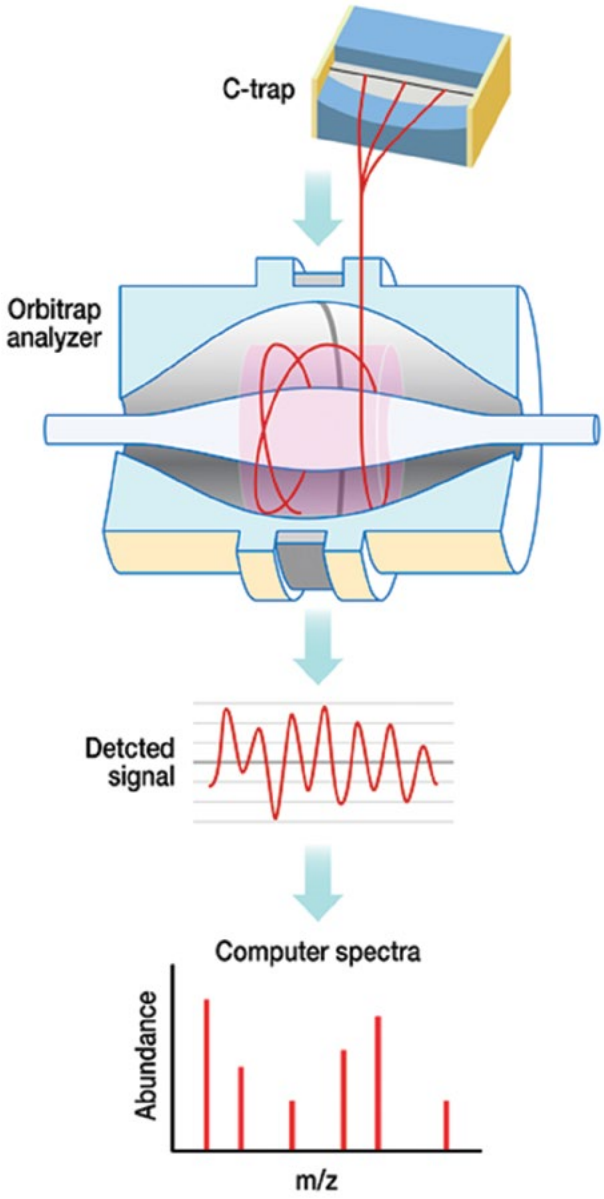

FIGURE 10 Diagram of an Orbitrap analyzer showing how ions are injected into the Orbitrap via the C-trap and then allowed to orbit the isolated electrodes. The induction current made by the ions is detected and then converted to *m/z* using the Fourier transform.

compared with triple-quadrupole and quadrupole ion trap mass spectrometers. While triple-quadrupole instruments with ESI sources have been the primary instrument for performing absolute quantification in the clinical laboratory, Orbitrap and Q-TOF mass spectrometers with ESI sources are being used more often for both qualitative and quantitative analysis. These hybrid instruments have a promising future in the clinical laboratory as they have the ability to provide high resolution and excellent mass measurement accuracy to address specific clinical questions related to unknown compounds and interferences.

LC Coupled with MS

High-performance LC has been used in clinical laboratories for decades, typically coupled with optical detectors such as UV-visible spectrophotometers. Because ESI is a flowing liquid-based ionization technique, it is perfectly suited to be coupled with LC (50). Manufacturers of mass spectrometers used in clinical laboratories now provide ESI sources that are robust and can easily handle running large volumes of samples using standard-flow LC methods. These ESI sources can be directly coupled to an LC with flow rates ranging from 10 to 1,000 μl/min and incorporate high temperature (up to 600°C) and heated gas to remove excess solvent to optimize the number of ions that enter the mass spectrometer (51). High-volume clinical laboratories often use multiplexed LC systems in which up to four columns running the same method take turns eluting into the ESI source in a "leapfrog" approach (52). These multiplexed systems may also incorporate two-dimensional LC, or LC/LC, in which columns are set in tandem to further purify the sample in a completely automated fashion. Between standard-flow and nanoflow LC systems are the micro LC systems that run at 10 to 50 μl/min. A micro LC uses less solvent and less sample and can be easily connected to a standard ESI source. Micro LC systems are not currently multiplexed, and the number of LC columns commercially available is limited compared with high-flow systems. In practice, one-dimensional LC is still the most commonly used LC setup in the clinical laboratory setting. Regardless of the LC flow rate, the majority of peptide and protein LC separations are done using reverse-phase LC columns with water and acetonitrile, or methanol, gradients containing formic acid for ion pairing when coupled with ESI (53).

Using MS to Analyze Peptides and Proteins

Mass spectrometers have played a central role in the identification, structural characterization, and quantification of proteins and peptides in research laboratories for decades. Since the early 1980s, MS has been used to quantify endogenous peptides of clinical importance, with many of the first studies focusing on neuropeptides (54, 55). Currently, clinical laboratories are beginning to use mass spectrometers for quantifying endogenous peptides such as insulin-like growth factor 1 and insulin (56–58), as well as endogenous peptide biomarkers (59). However, the majority of work is done using peptides obtained by digesting the sample with an enzyme before using MS.

MS/MS Analysis of Tryptic Peptides To Identify Proteins

Mass spectrometers routinely identify and quantify peptides from the proteolysis of protein mixtures. This is accomplished by what is often referred to as "bottom-up proteomics" (60). The term gets its name from the fact that an enzyme with known cleavage specificity, such as trypsin, is first used to digest proteins into peptides. The tryptic peptides are then analyzed by LC-MS/MS to obtain amino acid sequence information. The mass of the peptide combined with the amino acid sequence found by MS/MS is used to reconstruct each protein in the sample from the bottom up. The first bottom-up experiments in the early 1990s used the accurate mass of the tryptic peptide without the use of MS/MS amino acid sequence. The tryptic peptide masses observed were compared to the masses of the tryptic peptides expected from the protein database (61). This approach led to a high level of uncertainty due to large numbers of peptides with nearly the same intact mass but different amino acid sequences. Many of the first bottom-up experiments relied on SDS-PAGE to separate proteins followed by cutting out of the stained bands followed by in-gel digestion (61). Tryptic peptides were extracted from the gel and subjected to MS/MS to obtain peptide sequence information to compare to a protein database. The selection of the tryptic peptides to be sequenced by MS/MS was done manually at first, as was the protein database searching (62, 63).

By the turn of the millennium, advancements in automated peptide MS/MS acquisition combined with automated protein database search engines enabled Yates and coworkers to coin the term "shotgun proteomics." This refers to the broad swath of protein identifications that could be generated in one LC-MS/MS experiment (63, 64). At present, there are any number of mass spectrometers coupled with commercially available protein database search engines that can provide tens of thousands of MS/MS spectra, and thousands of protein identifications, from a single analysis, all performed in a matter of hours (65). A diagram of the shotgun proteomics process is shown in Fig. 11. While the majority of shotgun proteomics has been performed in a research setting, some clinical laboratories have adopted the approach to identify proteins present in biopsy samples, in which specific regions of the tissue are removed using laser capture dissection and then analyzed using shotgun proteomics (66, 67). The laser capture dissection-shotgun proteomics approach is essentially equivalent to immunohistochemistry using thousands of protein-specific antibodies. However, the mass spectrometer is a nonbiased detector, and it provides information on all the proteins present in the sample via tryptic peptide sequences. This results in more-sensitive and -specific results.

MS/MS Analysis of Proteolytic Peptides To Quantify Proteins Using SRM

Currently, the majority of MS-based clinical laboratory assays that quantify peptides quantify a protein-specific peptide created by digesting a sample with a protease. This approach was first described by Barr and coworkers (68) and has since been widely adopted by clinical laboratories to quantify a wide range of proteins (69–73). The peptide representing the protein to be quantified is commonly referred to as a proteotypic peptide (74). A proteotypic peptide represents the stoichiometric equivalent of the intact protein in the sample. This approach works when the sample is complex, such as serum, and the intact protein is present at a low concentration because the response by ESI is higher for peptides than for proteins.

The best proteotypic peptide to use for quantification can be found empirically by digesting a pure form of the protein if it is available. If purified protein is not available, then the best proteotypic peptides can be identified *in silico* using computer software (75). The software uses the known sequence of the protein and the enzyme that will be used to generate a list of the proteotypic peptides along with suggested collision energies. In addition, databases are being

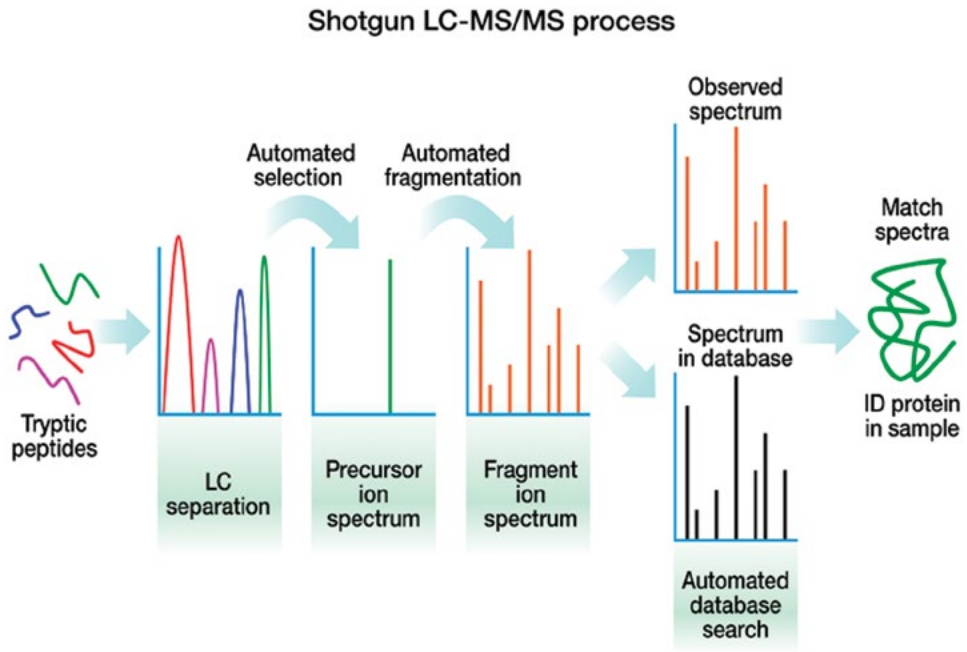

FIGURE 11 Stepwise depiction of a shotgun LC-MS/MS experiment. The figure shows how a tryptic peptide mixture is first separated by LC, ionized, and then scanned in the mass spectrometer. Tryptic peptides with sufficient signal are automatically selected for fragmentation, and the observed MS/MS data are automatically compared to a protein database. A list is provided of the best matches to tryptic peptides derived from proteins in the database.

created that give the proteotypic peptides that have been successful using publicly available data. There are numerous examples of assays being developed to quantify upwards of 50 proteins in serum and urine (76) using SRM on a triple-quadrupole mass spectrometer with an ESI source and a high-flow LC.

Research groups continue to push the number of proteins that can be quantified in a digest of plasma, serum, and urine by means of relative quantification. However, absolute quantification is the norm in clinical laboratories, which typically involves the use of a traceable protein standard. The ideal standard for protein quantification by SRM is a ^{13}C and ^{15}N stable isotope-labeled protein with the same amino acid sequence as the native protein. Stable isotope-labeled standards have the same solution chemistry as the native protein but have a different mass due to the added neutrons in the carbon and nitrogen nuclei. This allows the mass spectrometer to distinguish them from the native protein. Limited studies have been done using stable isotope-labeled protein standards because the proteins are made using recombinant expression systems (*Escherichia coli*, mammalian cell culture, etc.) and are not always easy to produce. Stable isotope-labeling reagents may also be cost-prohibitive. Examples of clinical studies using a stable isotope-labeled recombinant standard protein include the absolute quantification of urinary albumin (73), serum parathyroid hormone (72), and C-reactive protein (77). Alternatively, a stable isotope-labeled synthetic peptide with the same amino acid sequence as the proteotypic peptide can be produced at a reduced cost and can serve as an internal standard to monitor retention time and fragment ion ratios. Quantification is most often done using a standard curve and QC samples made using purified protein diluted in a similar matrix that is digested in the same way as the samples. Stable isotope-labeled peptide is added at the same concentration in every sample to serve as an internal standard. Peak areas from selected fragment ions are then used to calculate the concentration in unknown samples in the same manner as other LC-MS/MS assays quantifying small molecules.

MS/MS of Intact Proteins: Top-Down MS

The bottom-up LC-MS/MS approach to protein identification and quantification has a proven track record. However, there is the argument that information that could prove useful in clinical diagnostics is lost by cleaving the intact protein into peptides. Researchers continue to create new ways to identify proteins by LC-MS/MS without digesting them first. This approach is referred to as "top-down proteomics" and involves the fragmentation of intact proteins followed by piecing together the fragments in the same manner as protein database searching in shotgun proteomics (78, 79). There are a number of technical challenges that are faced when trying to identify a protein using fragment ions produced from the intact protein. The majority of top-down experiments use ESI to generate protein ions to be analyzed in the mass spectrometer. Because ESI generates multiple charge states for the intact protein, it also creates fragment ions with multiple charge states. Most tryptic peptides have +2, +3, or +4 charge states with fragment ions that primarily have a +1 charge state. In the case of proteins, there may be upwards of 20 different charge states for the same protein, and when a specific charge state is fragmented, it can generate hundreds of multiply charged fragment ions. Most top-down proteomics is done on instruments that have high resolution (>30,000) and high mass measurement accuracy (<2 ppm). This aids in the interpretation of the fragment ions using software specifically designed to identify a protein from the multiply charged intact protein ions and the large collection of multiply charged fragment ions (80). Another

challenge when doing top-down analysis of proteins is separating the proteins prior to ESI. LC is the method of choice; however, additional separation techniques such as preparative electrophoresis, in which proteins are first separated by their pI, have been reported (81). Clinical applications of top-down protein analysis include determining the mutation sites in transthyretin and hemoglobin from dried blood spots (82, 83). Top-down analysis is also being done on immunoglobulin light chains from patients with multiple myeloma, whereby the isotype of the light chain is determined by the singly charged fragment ions that originate from the constant region of the κ or λ light chain (84). Figure 12 shows an example of the top-down fragment ion spectrum acquired for a κ light chain. Although advances are being made in top-down protein analysis due to advances in high-resolution mass spectrometers with high mass measurement accuracy, the technique has yet to be used routinely in a clinical laboratory setting.

Intact Proteins—Phenotyping Proteins Using MS

MS has been used in the clinical laboratory to identify phenotypic changes in proteins by observing the shift in the molecular mass of the protein compared to the normal wild-type molecular mass. One of the first examples reported right after the discovery of ESI was the detection of mutations in hemoglobin (85). Since that time, many clinical groups have described using LC-ESI-MS to identify mutations in hemoglobin, and the assay is routinely performed in clinical labs because hemoglobin can be obtained easily in high concentrations from red blood cells (86). Another high-abundance protein that has been monitored for mutations using MS is transthyretin, as certain mutations are known to be associated with amyloid deposition (87). An online immunoaffinity-LC-ESI-MS assay was developed to purify transthyretin from serum to obtain an accurate molecular mass for transthyretin. Another protein phenotype assay developed for the clinical laboratory is an online

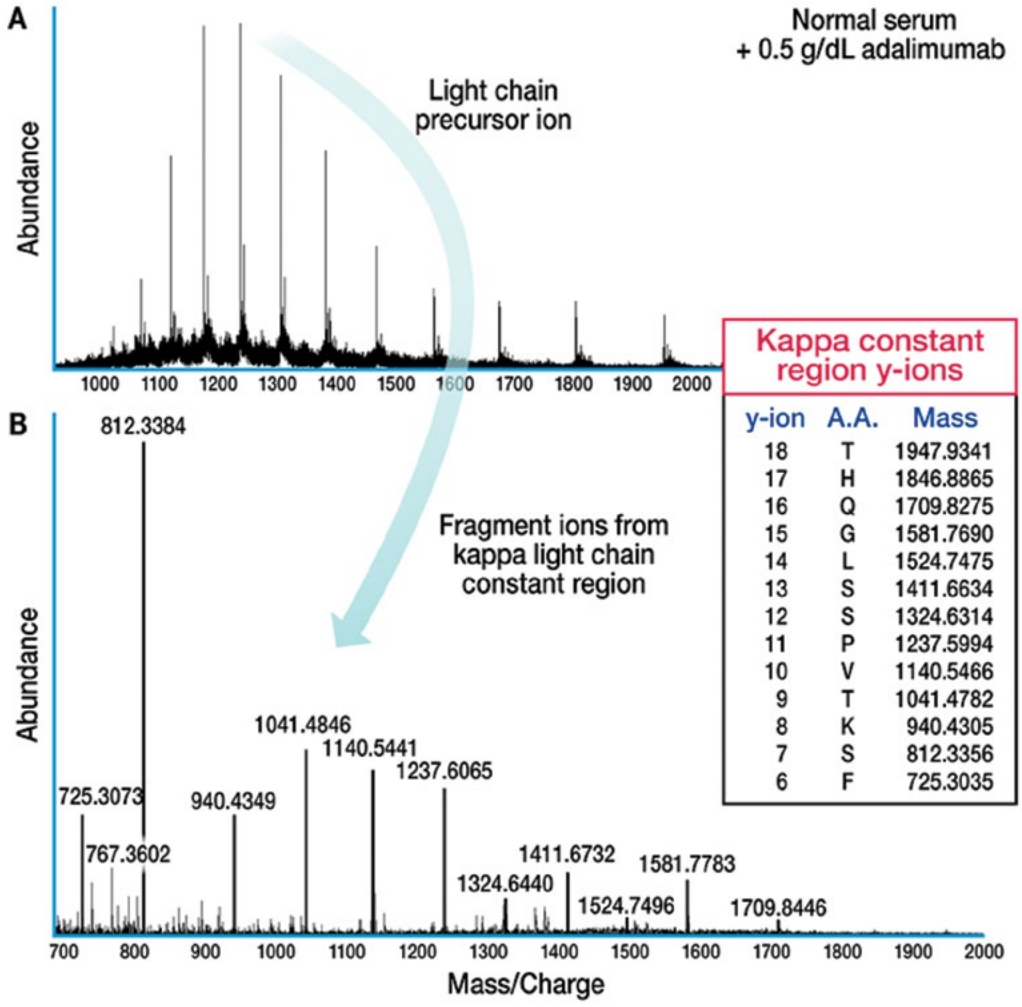

FIGURE 12 Top-down MS of adalimumab spiked into normal serum. The ion at m/z = 1,233 in the top spectrum matches the +19 charge state ion from the κ light chain of adalimumab and was selected for top-down MS. The arrow points to the fragment ion mass spectrum shown below. The labeled fragment ions match the expected masses for fragment ions from the C-terminal portion of the κ light chain, which contains the constant region. The calculated y ion masses for the κ light chain constant region-specific amino acid sequence are shown in the table.

immunoaffinity-LC-ESI-MS test for evaluating carbohydrate on transferrin (88). All of these examples use the mass spectrometer to provide an accurate molecular mass of the patient sample compared to a normal wild type. If the molecular mass of the patient sample does not match the normal sample, it indicates that a mutation is present. In the case of transferrin, a mass shift matching a change in carbohydrate structure indicates an alteration in metabolism.

Clinical Samples Analyzed by MS

The higher the concentration of the protein or peptide in a sample, the less sample preparation is needed prior to analysis. It is not surprising that proteins such as hemoglobin require minimal sample preparation due to the high concentration of the protein in red blood cells. When evaluating the preparation needed for proteins, one must also consider molecular mass and posttranslational modifications. As a general rule, the higher the mass, the less response, due to a number of physical factors in the ionization process whether using ESI or MALDI. If a protein has a mix of possible posttranslational modifications, this reduces the response for any one species. The three-dimensional structure of the protein also alters the ionization efficiency, and denaturation may be needed to obtain the best signal (89). If a protein or peptide needs to be purified prior to analysis, there are a number of methods that are often used to prepare clinical samples. One of the fastest and most inexpensive ways to isolate proteins is to use saturated ammonium sulfate to bring proteins out of solution. The pellet containing the sample can then be resolubilized, desalted, and then analyzed directly for intact proteins or digested for analysis of proteotypic peptides. The reverse holds true for small proteins and peptides, for which the supernatant from an ammonium sulfate protein precipitation can be analyzed instead of the pellet. Other methods of precipitating large proteins can also be used, such as adding organic solvent to create a protein pellet. There is also the option of using molecular weight cutoff filters to separate proteins and peptides. Various sizes are available and work due to centripetal force, preferentially forcing analytes of a specific size through a filter. Alternatively, solid-phase extraction can be used to capture peptides or proteins to remove low-molecular-weight compounds or to partition analytes with certain hydrophobicity, basicity, or acidity attributes.

Immunopurification can also be used to purify a protein or peptide prior to analysis using MS. When an immunocapture method is used, reagents used to remove the protein or peptide from the antibody need to be cleared from the sample before ionization. One of the more successful uses of immunocapture for clinical proteomics is stable isotope standards and capture by antipeptide antibodies (SISCAPA) (90). This method is based on capturing proteotypic peptides using antibodies raised against a specific proteotypic peptide. The technique dramatically lowers the level of detection for low-abundance proteins (91) and can be automated for high-throughput clinical laboratories. Ideally, a purification method should end with the final step having the analyte in a solvent matrix that will allow for the best separation when using LC-ESI-MS (92) or efficient ionization when doing MALDI MS (93). As a general rule, volatile buffers

TABLE 3 Key concepts in clinical MS

Test type	Common instrument format	Examples and references
Peptide quantitation	Standard-flow LC system coupled to an ESI source on a triple-quadrupole mass spectrometer. The LC system can be multiplexed for high throughput. Sample quantification is done by using a standard curve using a purified peptide standard.	Insulin-like growth factor and human growth hormone (97); see also reference 59
Protein quantification using a proteotypic peptide	Standard-flow LC system coupled to an ESI source on a triple-quadrupole mass spectrometer. The LC system can be multiplexed for high throughput. Sample quantification is done by using a standard curve using a protein standard. The sample is digested and a protein-specific proteotypic peptide is monitored by SRM. A stable isotope-labeled peptide or stable isotope-labeled intact protein may be used for quantification. Multiple proteins can be quantified at the same time. Proteotypic peptides can be enriched using immunoaffinity (SISCAPA).	Zinc-α_2 glycoprotein and prostate-specific antigen (70, 71); see also reference 98
Protein phenotyping—intact	Standard-flow LC system coupled to an ESI source coupled to a quadrupole, Q-TOF, or TOF mass spectrometer. MALDI can also be used. Protein can be immunopurified offline or online. The mutation is identified via a mass shift observed in the intact protein molecular mass.	References 87, 88, and 99
Protein phenotyping—mutation-specific peptides	Standard-flow LC system coupled to an ESI source coupled to a triple quadrupole, Q-TOF, or TOF mass spectrometer. MALDI can also be used. The LC system can be multiplexed for high throughput. The sample is digested and a mutation-specific peptide is monitored by SRM. Phenotype is determined using stable isotope-labeled peptides and mutation-positive samples.	References 85, 86, and 100
Proteomic profiling of tissue-derived samples	Nanoflow LC system coupled to an ESI source coupled to an Orbitrap mass spectrometer. The sample is extracted from a slide containing the tissue using laser capture dissection. The sample is digested and shotgun proteomics is performed with protein database searching. Phenotype is determined by the protein identifications from the database search.	References 67, 101, and 102

such as ammonium acetate and ammonium bicarbonate at concentrations of <50 mM are acceptable. Inorganic salts and acids can interfere with LC separation and ionization and should be avoided. Ionic detergents such as SDS are also problematic and should be removed or exchanged with a nonionic detergent. Two-dimensional LC systems can also be used to reduce matrix effects from the sample buffer by trapping proteins and peptides on a trap column, where they are held while the matrix is flushed to waste before eluting the sample onto the analytical column (94).

LC-ESI-MS assays, as with any other clinical assay, have their level of quantification based on the analyte concentration that is clinically relevant. In general, proteins or peptides at or above 1 μM in concentration are relatively easy to quantify by LC-ESI-MS. For SRM methods, much of the work is still trial and error. A digest is done on the sample and the expected proteotypic peptides are monitored. If a response is observed, then the specificities of the transitions are examined. The most effective way to determine specificity is to have a stable isotope-labeled peptide synthesized with the same amino acid sequence as the proteotypic peptide. If the LC retention time and fragment ion ratios of the stable isotope-labeled peptide match the native peptide, then specificity is established. This process becomes difficult to manage as the number of proteotypic peptides increases; however, it is becoming easier to manage due to advances in software and tryptic peptide databases that provide information on the proteotypic peptides that have already been observed by others to give the lowest level of detection (75, 95, 96). See Table 3 for a summary of the key concepts in clinical MS.

Immunoglobulin Methods

section B

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: DAVID F. KEREN

Introduction

DAVID F. KEREN

5

The section on immunoglobulin methods covers the basic genetic background for immunoglobulin production, measurement of immunoglobulins, identification of monoclonal protein products by serum protein electrophoresis and immunofixation, and detection of oligoclonal bands in cerebrospinal fluid. In addition, this section covers the characterization of cryoglobulins and cryofibrinogens and an overall strategy for using all the techniques in this section to detect, stratify risks of progression of, and monitor patients with monoclonal gammopathies.

Since the 7th edition of the *Manual of Molecular and Clinical Laboratory Immunology* (2006), there have been significant advances in the design and implementation of analytical tools to study immunoglobulins and interpret their results in a clinical context. The background for the molecular basis of immunoglobulin complexity and antigen specificity has evolved rapidly. Kipps, Ghia, and Rassenti (chapter 6) present a cogent discussion of the immunoglobulin heavy-chain and light-chain complexes together with a detailed explanation of the lack of uniform expression of each functional immunoglobulin heavy-chain variable gene. This is accompanied by a comprehensive overview of the molecular basis for immunoglobulin gene rearrangement and its relationship to the heterogeneity of the humoral immune response. This is illustrated using a detailed figure of the light- and heavy-chain gene complexes. They also describe how the detection of immunoglobulin gene rearrangements using PCR can aid in detecting clonal populations of B cells and how these highly sensitive methods may be deployed to investigate minimal residual disease.

Warren (chapter 7) reviews how IgG, IgA, IgM, immunoglobulin subclasses, serum free light chains, and even IgD and IgE are measured by nephelometric or immunoturbidimetric assay systems. Former gel diffusion and Laurell rocket techniques have fallen out of use. He makes note of their problem with the antigen excess effect and occasional nonlinearity in the serum free-light-chain test (1, 2). He highlights the recently FDA-approved heavy/light-chain assays. Using a nephelometric method similar to that used in quantifying serum free light chains, one may now separately measure IgG-kappa (IgGκ) from IgG-lambda (IgGλ), IgAκ from IgAλ, and IgMκ from IgMλ (3, 4).

This analysis may be especially useful in following the beta-region M proteins that are cloaked by transferrin and C3 bands.

Serum and urine protein electrophoreses are still the principal assays for the detection of monoclonal gammopathies and other immunoglobulin-based clinical abnormalities. In chapter 8, Keren and Humphrey review both the technical details and the clinical applications of serum and urine protein electrophoresis. Because of the expanded use of capillary electrophoresis since the previous edition, the chapter discusses both the classic gel and newer capillary electrophoresis patterns along with problems and pitfalls that may lead to false-positive or false-negative serum and urine findings. In addition, the chapter provides useful details for specimen processing, quality control, and quality assurance (5). The chapter illustrates the ability of capillary electrophoresis to detect polyclonal increases in IgG4 as part of IgG4-related systemic disease (6).

In cases where monoclonal gammopathies are detected or suspected, Sykes and Posey (chapter 9) present a thorough review of their characterization in serum and urine by immunofixation and immunosubtraction. Their presentation provides useful examples of both immunosubtraction (immunotyping) patterns, when capillary electrophoresis is used for the characterization, and immunofixation patterns, when gel techniques are employed. In addition, their chapter presents illustrative examples of isoelectric focusing with immunofixation in the evaluation of cerebrospinal fluid for the presence of oligoclonal bands.

Gorevic and Galanakis (chapter 10) discuss the state-of-the-art methodology in the detection and measurement of cryoglobulins. They also provide a thorough review of cryofibrinogenemia and pyroglobulins. This comprehensive chapter provides recent information on the importance of hepatitis C virus in both type II and type III cryoglobulins (7). Many practical suggestions are made about the importance of proper handling in the identification and characterization of these temperature-sensitive specimens (8). The section on cryofibrinogens has an up-to-date discussion of the effect of heparin and citrate anticoagulation on cryofibrinogen detection. Lastly, the authors discuss the peculiar phenomenon of pyroglobulins, which lack the clinical manifestations of cryoglobulins but can present confounding laboratory findings in heat-based assays such as those used to inactivate complement.

To coordinate the use of the above-mentioned techniques in the context of current clinical guidelines, Katzmann and Keren (chapter 11) first provide a handy

doi:10.1128/9781555818722.ch5

categorization of plasma cell proliferative disorders. This is followed by a diagnostic testing strategy that uses an efficient electrophoretic and nephelometric assay analysis. They recommend a basic diagnostic screening panel consisting of serum protein electrophoresis, immunofixation, and serum free-light-chain testing. However, the chapter provides caveats and illustrations of special cases to prevent missing low tumor burden conditions such as light-chain-type amyloidosis and light-chain deposition disease. They show how these measurements are useful in stratifying the risk of progression, in survival estimates, and in monitoring of monoclonal gammopathies. The authors discuss the use of immunosubtraction and the new heavy/light assays to monitor IgA and IgM monoclonal gammopathies that may be obscured by comigrating beta-region proteins.

IMMUNOGLOBULIN MOLECULES

Introduction

Immunoglobulins are a heterogeneous group of glycoproteins produced by B lymphocytes and plasma cells. A single person can synthesize 10 million to 100 million different immunoglobulin molecules, each having distinct antigen-binding specificities. This great diversity in the so-called humoral immune system allows us to generate antibodies specific for a variety of substances, including synthetic molecules not naturally present in our environment. Despite the diversity in the specificities of antibody molecules, the binding of an antibody to an antigen initiates a limited series of biologically important effector functions, such as complement activation and/or adherence of the immune complex to receptors on leukocytes (1). Resolution of the immunoglobulin structure has revealed how these molecules can have such great diversity in antigen-binding activities while maintaining conserved effector functions, such as complement activation.

Basic Immunoglobulin Structure

The basic unit of the immunoglobulin molecule is composed of two identical heavy chains and two identical light chains. These four polypeptides are held together by disulfide bonds and noncovalent interactions (2–5). The amino-terminal domains (110 to 120 amino acids) of the heavy and light chains are designated the variable regions, because their primary structures vary markedly among different immunoglobulin molecules (6). The carboxy-terminal domains, however, are referred to as constant regions, because their primary structures are the same among immunoglobulins of the same class or subclass. The amino acids in the light- and heavy-chain variable regions interact to form an antigen-binding site (2, 7). Each four-chain immunoglobulin basic unit has two identical binding sites. Stability for the immunoglobulin molecule is provided by the constant-region domains of the heavy and light chains. The specific effector functions of the different immunoglobulin classes are mediated by the heavy-chain constant regions (Table 1) (8).

There are two classes of immunoglobulin light chains, the κ and λ light chains, which differ in the amino acid sequences of the constant-region domains. The ratio of κ to λ chains in adult plasma is 2:1. The light-chain constant region's main purpose may be to allow for proper assembly and release of an intact immunoglobulin molecule. Soon after synthesis, the antibody light-chain constant region associates with the nascent immunoglobulin heavy chain, releasing the latter from the immunoglobulin-binding protein. In the absence of antibody light chain, the immunoglobulin-binding protein binds the first constant-region domain of the newly synthesized heavy chain, thereby retaining the heavy-chain polypeptide in the cell's endoplasmic reticulum (9).

Heavy-Chain Isotypes

Five major classes of immunoglobulin molecules—immunoglobulin G (IgG), IgA, IgM, IgD, and IgE—correspond to the five classes of heavy-chain isotypes (γ, α, μ, δ, and ε). The immunoglobulin molecule of each isotype can contain either a κ or a λ light chain but not both. The physical properties of each of these classes of immunoglobulin molecules are summarized in Table 1.

IgG

IgG is the most abundant of immunoglobulins found in adult plasma, accounting for approximately 80% of the total immunoglobulin. IgG is the predominant antibody produced during a secondary immune response. IgG molecules can penetrate extravascular spaces and cross the placental barrier to provide immunity to the fetus. These molecules have a four-chain 150-kDa immunoglobulin structure with a hinge region that can be attacked by proteolytic enzymes such as papain and pepsin, allowing for separation of the antigen-binding fragment(s), Fab or F(ab)2, from the crystallizable or constant fragment (Fc) of the antibody molecule. Receptors for the Fc (FcR) allow effector cells to recognize target cells coated with a specific antibody (10).

There are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4. Each subclass has a particular heavy-chain constant region and has different effector functions (8). The most abundant class is IgG1, which accounts for approximately 65% of the total IgG in the plasma. Of the IgG subclasses, IgG1 binds best to FcRI (CD64) and FcRII (CD32), with affinities (K_d) of 10^{-8} M and 5×10^{-7} M, respectively. IgG1 and IgG3 bind equally well to FcRIII (CD16), with a K_d of 2×10^{-6} M. FcRIII is the FcR expressed by natural killer cells (NK cells, or K cells) that mediate antibody-dependent cell-mediated cytotoxicity. Proteins of the IgG4 or IgG2 subclass bind poorly to FcRI (CD64) or FcRII (CD32) and do not bind to FcRIII (CD16) at all. The average half-life

doi:10.1128/9781555818722.ch6

TABLE 1 Physical properties of human immunoglobulins

Heavy-chain class (isotype)	Heavy-chain subclasses	No. of heavy-chain domains	Secretory form(s)	Molecular mass (Da)	Antigen-binding valency	Concn (mg/ml) in serum	% of total immunoglobulins
IgG (γ)	γ1, γ2, γ3, γ4	4	Monomer	150,000	2	8–16	80
IgA (α)	α1, α2	4	Monomer, dimer	160,000 (monomer)	2 (monomer)	1.4–4.0	13
				400,000 (secretory protein)	4 (secretory protein)		
IgM (μ)		5	Pentamer	900,000	10	0.5–2.0	6
IgD (δ)		4	Monomer	180,000	2	0–0.4	1
IgE (ε)		5	Monomer	190,000	2	17–450 ng/ml	0.002

of circulating IgG molecules is about 21 days. The response to a given antigen can result in a skewed IgG subclass response, and this is frequently a source of investigation as to correlates of protection or for the design of vaccines. Specific subclasses can be associated with individual disease processes. For example, in patients with pemphigus vulgaris, a mucocutaneous blistering disease, IgG4 antibodies to desmoglein 3 are pathogenic (11, 12).

IgA

The IgA molecules constitute 13% of the total plasma immunoglobulins. There are two major classes of IgA molecules, designated IgA1 and IgA2, with IgA1 being the more abundant (85% of total IgA in plasma). The half-life of IgA molecules is about 6 days.

IgA antibodies are synthesized during a secondary immune response and contribute to mucosal immunity (13–15). IgA antibodies are the primary antibodies in saliva, tears, breast milk, and the fluids of the gastrointestinal, respiratory, and urinary tracts (16). These secreted immunoglobulins consist of an IgA dimer bound to the joining (J)-chain polypeptide and a secretory protein with a molecular mass of 70 to 80 kDa. The J chain is required for proper hepatic transport of IgA (17). The secretory component is actually part of an FcR for dimeric IgA that is synthesized not by B cells but rather by epithelial cells of organs such as the intestine. This protein facilitates the transport of the IgA protein across the epithelial cell and may protect the secreted IgA molecule from proteolytic digestion by enzymes in the intestinal lumen. Since these molecules do not cross the placenta barrier and do not easily bind to cell surfaces, their main role may be to prevent foreign substances from binding to mucosal surfaces and entering the blood. Finally, it has been proposed that secretory IgA might also act as a potentiator of the immune response in intestinal tissue by means of uptake of antigen to dendritic cells (18).

IgM

The IgM immunoglobulins comprise about 6% of the immunoglobulins in adult plasma. These molecules have very high molecular weights (thus, they are called macroglobulins), and they are formed by the linking of five identical immunoglobulin units by disulfide bonds and a J chain. IgM is the predominant class found during a primary immune response. The IgM molecules do not cross the placenta and do not enter into extravascular spaces; however, they fix complement more efficiently than the monomeric IgG molecules. The half-life of IgM molecules in plasma is approximately 6 days. In addition, monomeric IgM is the main component of an antigen receptor expressed on B cells (B-cell receptor). The IgM monomer represents the ligand-binding part of the receptor. The component that is responsible for signal transduction consists of two glycoproteins, CD79a and CD79b. The cytoplasmic domains of CD79a and CD79b contain tyrosine motifs responsible for transduction of signal from the receptor (19).

IgD

The IgD molecules constitute only 1% of the plasma immunoglobulins, and they are expressed on B cells with IgM. These immunoglobulins do not cross the placenta and do not easily penetrate extravascular spaces. However, IgD molecules are found in relatively high concentrations in umbilical cord blood. IgD molecules are thought to function as B-cell membrane receptors for antigens and may help in the recruitment of B cells for specific antigen-driven responses (20). Similar to IgM, membrane-bound IgD is associated with CD79a and Cd79b for signaling. IgD is expressed on the membranes of B cells when they leave the marrow and populate secondary lymphoid organs. Most IgD-positive B cells also coexpress IgM, and both participate in B-cell receptor signaling through CD79a and CD79b. It has been proposed that membrane-bound IgD regulates B-cell fate at specific developmental stages through changes in activation status (21). B-cell stimulation and activation can result from the binding of specific bacterial proteins to the constant region of IgD. For example, circulating IgD can react with IgD-binding protein of *Moraxella catarrhalis*, independently of the variable regions of the antibody (22).

IgE

IgE has been called a reaginic antibody to denote its association with immediate hypersensitivity. IgE antibodies constitute a very small percentage of the total plasma immunoglobulins (0.002%). Although four human IgE isoforms can be produced by alternative splicing of the epsilon primary transcript (23), the isoforms appear to have similar functions. Plasma IgE levels may increase (5 to 20 times the baseline) in parasitic infections and children with atopic diseases. The Fc portion of the IgE molecule can bind with high affinity to receptors on the surfaces of basophils and mast cells. The cross-linking of IgE antibody by an allergen can induce the release of vasoactive amines, proteases, lipid-derived inflammatory mediators, and cytokines, such as tumor necrosis factor alpha, gamma interferon, or interleukins 1, 3, 4, 5, and 6. Studies indicate that the microenvironment of mucosal tissues in allergic disease favors class switching to IgE (24). Anti-IgE antibodies have been developed as therapy for allergy and asthma (25).

IMMUNOGLOBULIN GENE COMPLEXES

Immunoglobulin Heavy-Chain Gene Complex

Immunoglobulin Heavy-Chain Constant-Region Exons

The heavy-chain gene complex is located at band q32 on the long arm of chromosome 14 (26). This complex is composed of 38 to 46 functional heavy-chain variable-region genes (IGHV genes), over 80 nonfunctional IGHV pseudogenes, 23 functional diversity (IGHD) segments, 6 functional IGHJ minigenes, and exons encoding the constant regions for each of the immunoglobulin heavy-chain isotypes (27–29). The order (5′→3′) of the genes encoding each of the immunoglobulin heavy-chain isotypes is C_μ (M), C_δ (D), $C_\gamma 3$ (G3), $C_\gamma 1$ (G1), $C_\varepsilon 1$ (EP1, a nonfunctional pseudogene), $C_\alpha 1$ (A1), C_γ (GP, an open reading frame lacking the switch region), $C_\gamma 2$ (G2), $C_\gamma 4$ (G4), C_ε (E), and $C_\alpha 2$ (A2) (Fig. 1). The genes encoding the heavy-chain constant regions and each associated intronic switch region are as depicted in Fig. 1. These genes are labeled, and pseudogenes are also indicated in the figure.

Immunoglobulin Heavy-Chain Variable-Region Genes

The IGHV gene segments map within a region of approximately 1,100 kb that is telomeric to the IGHJ and constant-region genes (Fig. 1). Each IGHV gene can be assigned to one of seven IGHV gene subgroups. Each subgroup comprises IGHV genes, which share more than 80% nucleic acid sequence homology. Genes of the IGHV1, IGHV5, and IGHV7 subgroups have similarities in the primary structure, suggesting a common ancestral origin in evolution, whereas the IGHV2, IGHV4, and IGHV6 families share similarities that allow them to be classified into a different clan (30, 31). The IGHV3 genes constitute their own discrete clan.

The IGHV genes of each subgroup, except IGHV6, are interspersed throughout the immunoglobulin heavy-chain locus. By convention, the loci encoding each of the various IGHV genes are assigned a number corresponding to the IGHV gene subgroup followed by a hyphen and then the rank order distance from the heavy-chain D segments on chromosome 14 (Fig. 1). The immunoglobulin IGHV6 subgroup has only one functional IGHV gene. Since this is the first IGHV gene telomeric to the D segments, this gene is called IGHV6-1 (Fig. 1). There are an additional 50 loci that have been identified as functional IGHV genes (32) (Fig. 1). The largest subgroup is IGHV3, with 25 functional genes. The next largest are the IGHV1 and IGHV4 subgroups, each with 11 functional genes. The IGHV2, IGHV5, and IGHV7 subgroups each have one to four functional genes. Interspersed among the functional IGHV genes are several nonfunctional pseudogenes (Fig. 1).

The extent of identified genetic polymorphism varies between the different IGHV gene loci. Some immunoglobulin IGHV gene loci, e.g., IGHV6-1, IGHV5-51, or IGHV4-34, are highly conserved (33, 34). Indeed, the single-copy immunoglobulin IGHV6 gene, IGHV6-1, is conserved even among higher primates (35). Other loci have been used to identify genetic polymorphic variations. These allelic variations are of two different types. The first type of genetic polymorphism is the classic form, in which there are two or more alleles at a single locus, each differing from one another in one or more nucleotide bases. For example, IGHV3-30*18 (1.9III) and IGHV3-30*1 (hv3005) differ from each other at several nucleotide bases and share only 98.8% overall homology (98.3% coding sequence homology) but are alleles of locus IGHV3-30. The second type of allelic variation results from duplications, insertions, and/or deletions of whole segments of IGHV genes within the immunoglobulin heavy-chain gene complex. Duplication of an IGHV gene(s) results in some haplotypes having identical IGHV genes belonging to distinct loci, each possibly differing from their respective alleles by one or more nucleotide base substitutions. For example, there may be an insertion in and about the locus for IGHV3-30, in part consisting of another copy of this gene. As a result, alleles of IGHV3-30, e.g., IGHV3-30*18 (1.9III) and IGHV3-30*1 (hv3005), also may be alleles of locus IGHV3-30.5 in haplotypes containing this insertion. On the other hand, some haplotypes are missing gene loci altogether. For example, allele frequencies for IGHV3-30*1 (hv3005) and IGHV3-30*18 (1.9III) in the Caucasian population are 0.19 and 0.72, respectively (36). An additional haplotype(s) with an allele frequency of 0.08 lacks either IGHV3-30*18 (1.9III) or IGHV3-30*1 (hv3005) and thus apparently is a blank haplotype for this locus. Genetic disequilibrium also is noted for certain groups of IGHV genes on a given haplotype. For example, IGHV3-30-3*01 (56p1 or 3d216) is an insertion or deletion element that has been observed only with haplotypes carrying one or two copies of IGHV3-30*18 (1.9III).

The relative expression level of each functional IGHV gene is not uniform. Certain IGHV genes, e.g., IGHV3-23, IGHV4-34, or IGHV1-69, are overexpressed relative to their physical representation among other IGHV genes (36, 37). Each of nine IGHV3 genes (IGHV3-23, IGHV3-30, IGHV3-7, IGHV3-33, IGHV3-21, IGHV3-48, IGHV3-11, IGHV3-15, and IGHV3-30-3) accounts for 5 to 19% of the IGHV3 gene rearrangements, whereas the remaining functional IGHV3 genes contribute to less than 4% of the rearrangements. Some of the IGHV genes that encode a disproportionate share of the immunoglobulin expressed by normal adults also are polymorphic. For example, three deletion/insertion polymorphisms (Del I to Del III) with deletion allele frequencies ranging from 0.1 to 0.3 were identified. Del I is a polymorphism affecting three IGHV genes (IGHV1-8, IGH3-9, and IGHV2-10), of which two are functional. Greater than 10% of individuals in the human population may not have these gene segments in their genome, and ~44% may have only one copy of these gene segments (38). In Del II, a 50-kb insertion containing five IGHV genes (IGHV3-30-5, IGHV4-30-4, IGHV3-30-3, IGHV4-30-2, and IGHV4-30-1) was identified; this insertion has been observed in 45% of Caucasoids (39). Del III spans ~21 to 53 kb, involving four contiguous genes, among which only the functional gene IGHV4-39 has an identified null allele (40, 41). In addition, some persons have a deletion of the IGHV gene IGHV4-31, which otherwise may encode a significant proportion of the heavy-chain repertoire (36). The International Immunogenetics database (http://www.imgt.org/) provides an Internet listing of IGHV gene maps and alleles (42).

Immunoglobulin Light-Chain Gene Complexes

κ Light-Chain Complex

The κ light-chain gene complex is contained within band p11.2 on the short arm of chromosome 2 (Fig. 2). This gene complex consists of approximately 34 to 38 (4 genes may be functional or pseudogenes depending on the alleles) functional kappa light-chain variable-region genes (IGKV genes), 5 functional IGKJ genes, and 1 constant-region gene (Fig. 2) (43, 44).

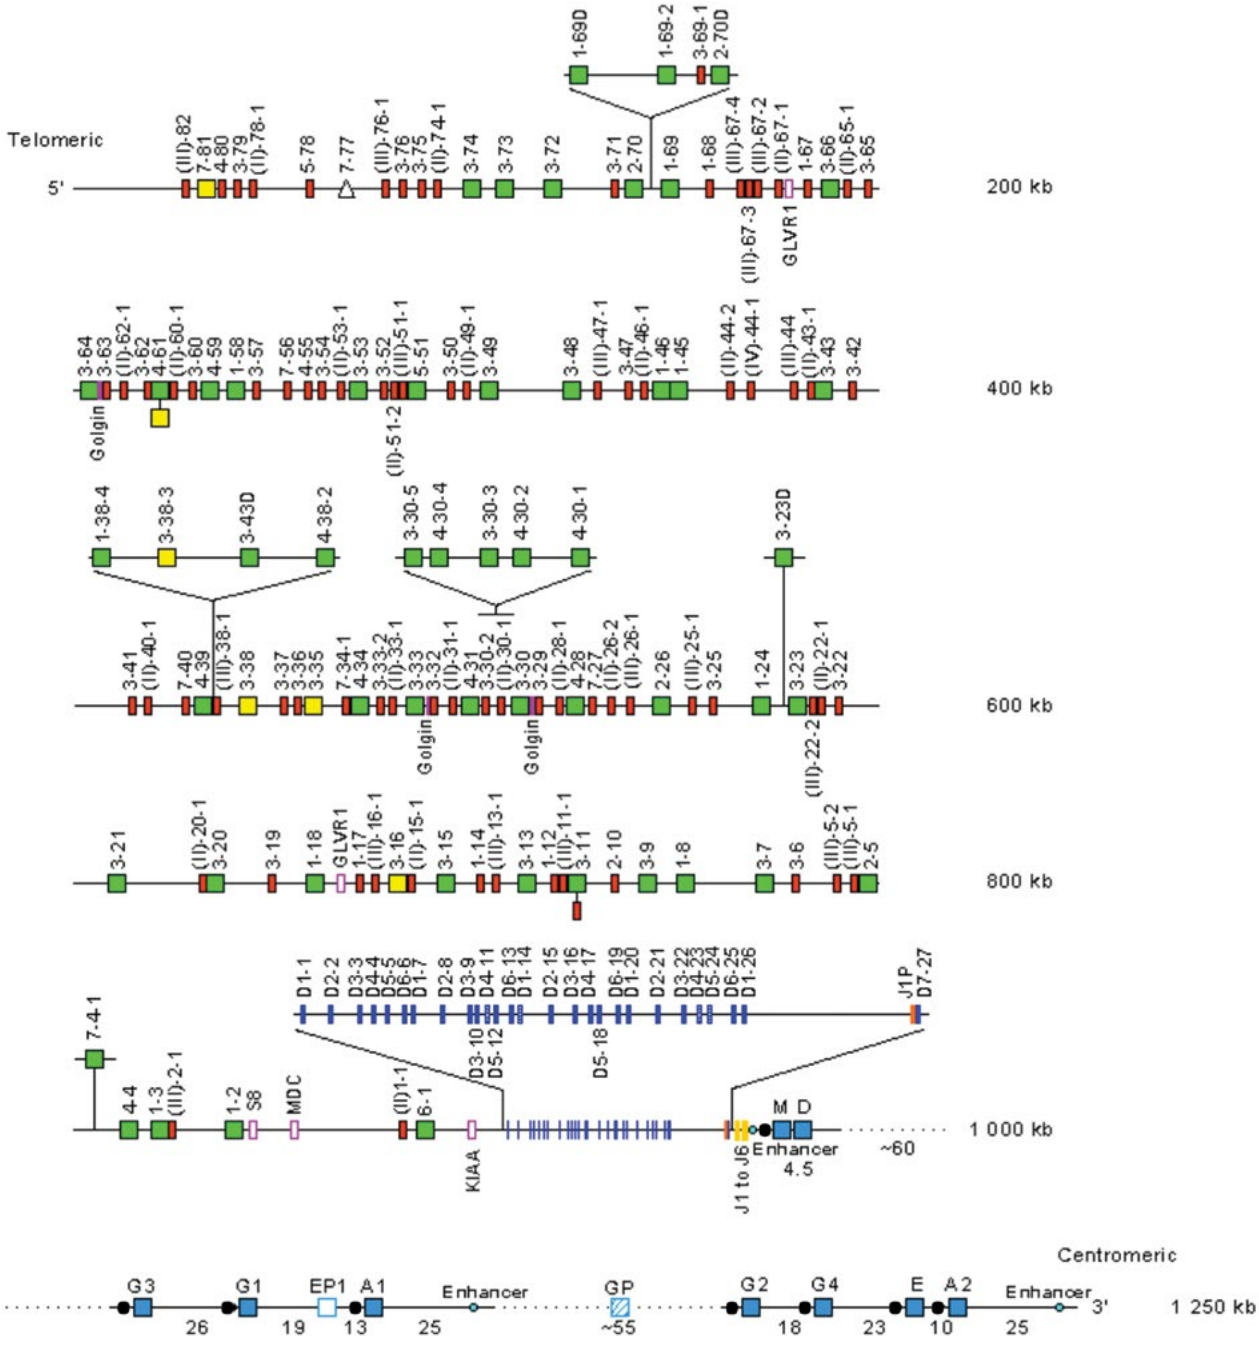

FIGURE 1 Immunoglobulin heavy-chain gene complex. The heavy-chain genes encoding the constant regions are represented by blue boxes. Switch regions are represented by a filled circle upstream of the IGHC genes. Enhancers are represented by light blue circles. Each IGHV, IGHD, and IGHJ gene is labeled on the right of each symbol. Functional IGHV, IGHD, and IGHJ genes are represented by green boxes, blue lines, and yellow lines, respectively. IGHV, IGJH, and IGHC pseudogenes are represented by red boxes, orange boxes, and blue open boxes, respectively. IGHV and IGHC open reading frames are represented by yellow boxes and blue dashed boxes, respectively. Unrelated pseudogenes are represented by purple open boxes. Colors are according to the international ImMunoGeneTics information system (IMGT) color menu for genes. Reproduced with the kind authorization of Marie-Paule Lefranc (IMGT [http://www.imgt.org]).

The IGKV genes in the κ light-chain gene complex are found in two regions: an IGKC-proximal region, designated the *p* region, and an IGKC-distal region, designated the d region. Each region spans approximately 500 kb. Approximately 800 kb separates the two regions (Fig. 2). The p region contains 40 IGKV gene segments, while the *d* region contains 36 gene segments (Fig. 2). The d region apparently arose through duplication of a large portion of the *p* region. Consequently, there are 33 pairs of IGKV genes that share 95 to 100% nucleic acid sequence homology,

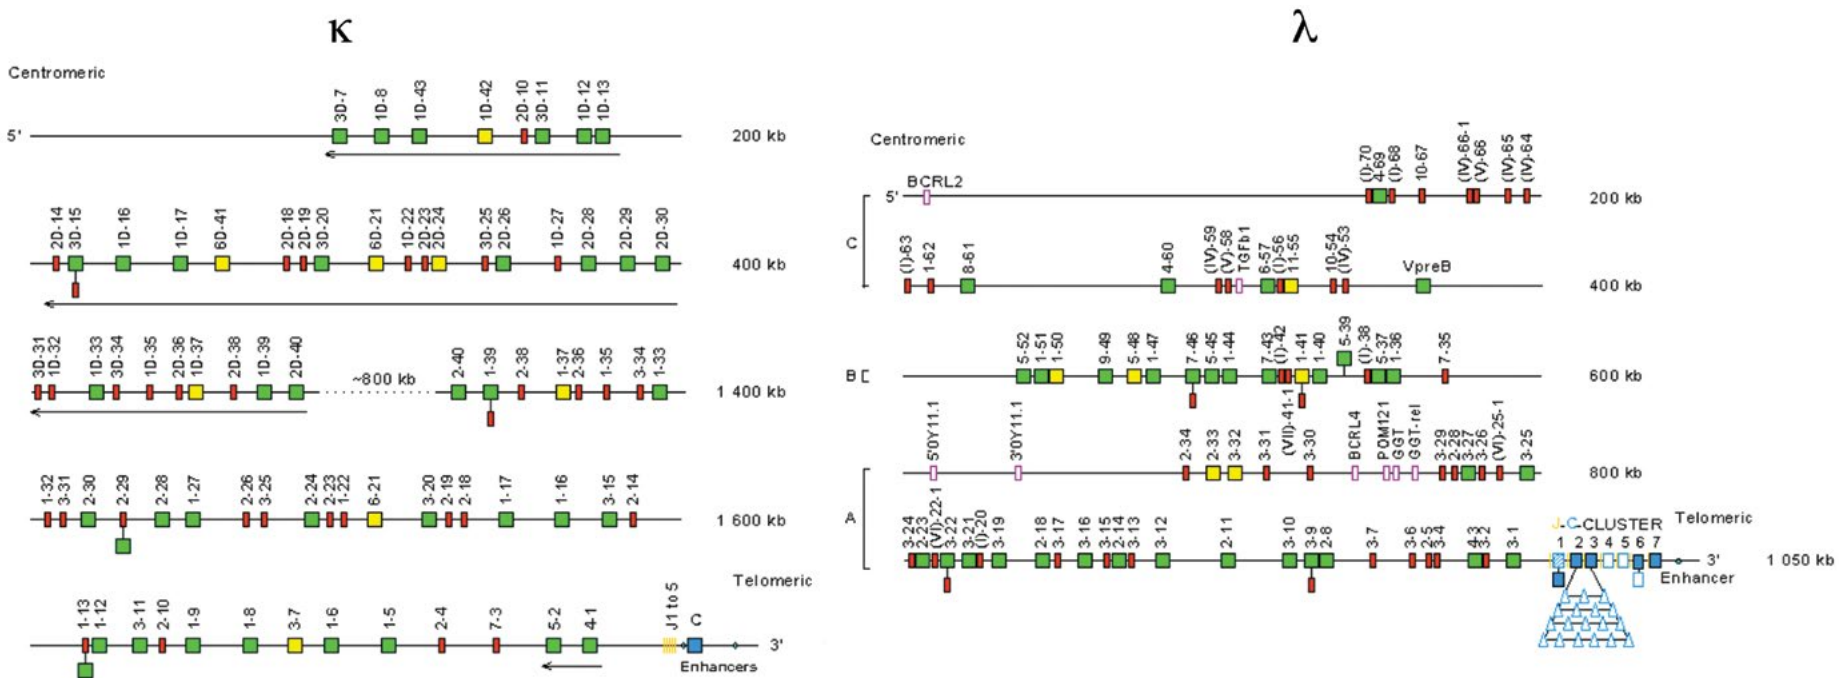

FIGURE 2 Immunoglobulin light-chain gene complexes. (Left) κ light-chain gene complex on chromosome 2p11-12. The blue box represents the functional IGLC gene. The IGKJ gene segments are indicated by yellow lines labeled "J1 to 5." The κ light-chain enhancers are represented by light blue circles. IGKV functional genes, pseudogenes, and open reading frame are indicated by green, red, and yellow boxes, respectively. The IGKV genes of the *p* region are designated by a number for the subgroup, followed by a hyphen and a number for the localization from 3′ to 5′ in the locus. The IGKV genes of the *d* region are designated by the same numbers as the corresponding genes in the *p* region, with the letter D added. Arrows show the IGKV genes whose orientation is opposite to that of the IGKJ gene segments. (Right) λ light-chain gene complex on chromosome 22q11.2. The blue boxes represent functional IGLJ and IGLC gene segments, whereas blue open boxes represent IGLJ and IGLC pseudogenes. IGLV functional genes, pseudogenes, and open reading frame are indicated by green, red, and yellow boxes, respectively. IGLV pseudogenes that could not be assigned to subgroups with functional genes are represented by red boxes and designated by a roman number in parentheses, corresponding to the clans, followed by a dash and a number for the localization from 3′ to 5′ in the locus. The IGLV genes are organized into three clusters, designated A, B, and C, which are indicated to the left of each cluster. Unrelated pseudogenes are represented by purple open boxes. The λ light-chain enhancer is represented by a light blue circle. Colors are according to the IMGT color menu for genes. Reproduced with the kind authorization of Marie-Paule Lefranc (IMGT, the international ImMunoGeneTics information system [http://www.imgt.org]).

accounting for 66 of the 76 IGKV genes in the κ light-chain complex (45, 46).

The IGKV genes in the κ light-chain gene complex can be categorized into three main subgroups (1 to 3) and several smaller subgroups (4, 5, 6, and 7), based on nucleotide sequence homology (47, 48). The largest subgroup is IGKV1, with 20 functional genes (Fig. 2). The next largest subgroups are IGKV2, with 10 functional genes, and IGKV3, with 7 functional genes. There are three open reading frame genes in the IGKV6 subgroup and one functional gene in each of the IGKV4 and IGKV5 subgroups. The IGKV7 subgroup has only one nonfunctional pseudogene.

Similar to the IGHV locus, there are several prominent alleles identified in the IGKV gene locus. The IGKV genes coding for segments IGKV1-13 (L4) and IGKV3D-15 (L16) each have several alleles, some having stop codons (49, 50). Moreover, the IGKV2D-29 (A2) gene also is polymorphic, with some alleles having defective promoters that preclude their expression into protein. Inheritance of defective IGKV2D-29 (A2) alleles has been associated with an increased risk for serious infection with type b *Haemophilus influenzae*, suggesting that the polymorphic variations in the germ line repertoire can influence the susceptibility to infectious disease (51).

As with the immunoglobulin IGHV genes, the expression of IGKV genes is not uniform. Eleven of the approximately 34 to 38 known functional IGKV genes encode most of the κ light-chain variable regions expressed in the normal adult repertoire (49). Moreover, of the 44 genes that are potentially functional, only 28 commonly encode κ light-chain variable regions (Fig. 2) (49, 50). This raises the possibility that some of the potentially functional IGKV genes have defects that preclude their ability to undergo light-chain gene rearrangement or to be expressed into protein. Alternatively, these genes may have an extremely low expression frequency.

λ Light-Chain Gene Complex

The λ light-chain gene complex is located at band q11.2 on the long arm of chromosome 22. These λ constant-region genes are telomeric to the λ variable-region genes (IGLV). Originally, the isotypes that they encoded were designated Mcg^+, Ke^- Oz^-, Ke^- Oz^+, and Ke^+ Oz^-, depending on their reactivity with Mcg, Kern, and Oz antisera that were raised against λ Bence Jones proteins of patients with multiple myeloma (52). These isotypes are now designated IGLC1, IGLC2, IGLC3, and IGLC7, respectively. In total, there are 7 to 11 IGLC genes telomeric to the IGLV genes, depending on the haplotype (53). Each IGLC gene is associated with its own IGLJ segment. The most prevalent haplotype contains four functional IGLC genes (IGLC1, IGLC2, IGLC3, and IGLC7, encoding the Mcg, Ke^- Oz^-, Ke^- Oz^+, and Ke^+ Oz^- isotypes, respectively) and three pseudogenes (IGLC4, IGLC5, and IGLC6) (Fig. 2) (54, 55).

There are approximately 29 to 33 functional IGLV genes and over 40 nonfunctional IGLV pseudogenes that are arranged into 10 subgroups (56–58). Each subgroup comprises IGLV genes sharing more than 75% nucleotide sequence homology (57, 59) (Fig. 2). Like that of the κ light-chain locus, the sequence organization suggests that large DNA duplications contributed to the generation of the germ line repertoire of IGLV gene segments (56). The IGLV genes are clustered into three large DNA segments located within 860 kb of the IGLJ and IGLC genes (56, 58, 60). The cluster most proximal to the IGLJ-IGLC exons, designated cluster A, comprises 16 functional IGLV genes, mostly belonging to the IGLV2 and IGLV3 gene subgroups, designated IGLV3-1 (3r, DPL23) through IGLV3-27 (V2-19) in Fig. 2. The next cluster, cluster B, contains 12 functional IGLV genes of the IGLV1, IGLV5, IGLV7, and IGLV9 gene subgroups, designated IGLV1-36 (1a, DPL1) through IGLV5-52 (5b). The third cluster, cluster C, contains five functional IGLV genes of the IGLV4, IGLV6, IGLV8, IGLV10, and IGLV11 gene subgroups, designated VpreB through IGLV4-69 (4b) (Fig. 2). As with the other immunoglobulin complexes, there are multiple nonfunctional pseudogenes interspersed between these functional IGLV genes in all three clusters.

As noted for the relative expression of individual IGHV and IGKV genes, the expression of individual IGLV genes appears to be nonrandom. IGLV genes of the IGLV1 and IGLV3 subgroups are used most frequently. These subgroups respectively encode approximately 44 or 40% of the λ light-chain immunoglobulins in normal adult sera (61). This proportionate representation apparently is not observed in B-cell plasmacytic disorders. Although the IGLV2 subgroup was identified on 3% of the λ light-chain immunoglobulins in normal adult sera, it accounted for 40% of the λ Bence Jones proteins and 60% of the λ macroglobulins from patients with Waldenström macroglobulinemia in one survey (61).

IMMUNOGLOBULIN GENE REARRANGEMENT

Immunoglobulin Gene Rearrangement and Expression in Ontogeny

As B cells develop, they generally first rearrange their immunoglobulin heavy-chain genes (62). One or more IGHD segments rearrange to become juxtaposed with a single IGHJ element. This generates an IGHD-IGHJ complex that then may rearrange with any one of approximately 38 to 46 functional IGHV genes.

Subsequently, gene rearrangements occur within the light-chain complexes. One of the 40 functional IGKV genes rearranges with any one of five IGKJ segments. Should these gene rearrangements fail to generate a functional IGKV-IGKJ exon, the Kde generally rearranges to a site in or immediately downstream of the IGKV-IGKJ exon, thus deleting the κ light-chain constant-region exon (63). Many of the IGKV genes in the *p* region are in the opposite orientation of the IGKJ segments, thus requiring that the V exons in this region undergo inversion during immunoglobulin gene rearrangement. The processes of *Ig* gene locus contraction and looping during V(D)J recombination are essential for creating a diverse antibody repertoire. Recently, a 650-bp sequence corresponding to DNase I hypersensitive sites HS1 and HS2 within the mouse IGKV-IGKJ intervening region was described. This sequence binds CCCTC-binding factor and specifies locus contraction and long-range IGKV gene usage. Its deletion results in a 7-fold increase in proximal IGKV gene usage along with an ~50% reduction in overall locus contraction (64). Subsequent to a failed κ light-chain gene rearrangement, one of the functional IGLV genes can rearrange with any one of the four or five functional IGLJ-IGLC exons to generate a gene that can encode a λ light chain (55).

The term progenitor B cells (or pro-B cells) is reserved for precursor B cells that have only rearranged IGHD and IGHJ elements, whereas precursor B cells that have completed immunoglobulin heavy-chain gene rearrangement and have a functional V_H-D-J_H complex are referred to as pre-B cells. The immunoglobulin light-chain loci of both pro-B cells and pre-B cells are generally in the germ line configuration.

Nevertheless, a small amount of immunoglobulin μ chain in association with "surrogate" light chains is expressed by pre-B cells. The surrogate light chain is made up of two noncovalently associated proteins called lambda-5 (λ_5) and VpreB, which together form a molecule having structural homology with conventional light chains (65). Thus, in the surrogate light chain, λ_5 replaces a light-chain constant region and VpreB the variable part although bearing an extra N-terminal protein sequence. Both are located on chromosome 22: the λ_5 gene is telomeric to the true light-chain locus, and the VpreB gene is located within the cluster of IGLV genes defined by breakpoints of chromosomal translocations found in a few leukemias and lymphomas (66). During the early stages of B-cell development, VpreB and λ_5 are covalently associated with the μ heavy chains to form a primitive immunoglobulin receptor referred to as pre-B-cell receptor (pre-BCR). Pre-B cells may be expressed on the surface membrane of such a receptor together with CD79a and CD79b (67). Monoclonal antibodies that recognize λ_5 or VpreB specifically bind to pre-B cells and can react with B-lineage acute lymphocytic leukemias (68).

Expression of the surrogate light chains plays a critical role in normal B-cell development. This is underscored by studies on transgenic mice that lack functional λ_5 genes (69). In these mice, B-cell development in the marrow is blocked at the pre-B-cell stage, thereby markedly reducing the numbers of functional mature B lymphocytes in the blood and lymphoid tissues (70). Similarly, humans that have inactivating mutations in the λ_5 genes on both alleles of chromosome 22 have agammaglobulinemia and markedly reduced numbers of B cells (71). When immunoglobulin μ chains form a complex with the "surrogate" λ light chains, the complementarity-determining region 3 (CDR3) of the "surrogate" λ light chain covers the CDR3 of the heavy chain in the pre-B-cell receptor, allowing the pre-B cell to avoid antigen-specific selection (72).

Even though the cell has two different sets of each of the immunoglobulin gene complexes that initially undergo seemingly independent immunoglobulin gene rearrangements, under normal conditions, immunoglobulin expression by each B lymphocyte or plasma cell is limited to only one immunoglobulin heavy-chain allele and one light-chain allele through a process called allelic exclusion. Allelic exclusion generally is observed in most B-cell tumors; however, rare cases of B-cell leukemia may lack allelic exclusion and express both immunoglobulin alleles (73).

Genetic Basis for Immunoglobulin Gene Rearrangement

Recombination signal sequences (RSSs) flanking each germ line V gene, D element, and J segment serve as the recognition site for the V(D)J recombinase and direct the site of DNA recombination. The RSSs consist of two conserved sequence elements of different lengths, one of 7 bp (the heptamer; consensus, 5′ CACAGTG 3′) and one of 9 bp (the A/T-rich nonamer; consensus, 5′ ACAAAAACC 3′), separated by either 12 bp or 23 bp of nominally conserved intervening DNA (12-RSS or 23-RSS, respectively) (74). V(D)J recombination is directed between distinct gene segments whose flanking RSSs contain different-length spacers (62, 75, 76). This is referred to as the 12/23 joining rule (77). Because all segments of a particular type (e.g., segments of IGKV genes) are flanked by one type of signal sequence and all the segments to which they should be joined (e.g., IGKJ segments) are flanked by the opposite type of signal sequence, the 12/23 rule ensures that the joining will be restricted to events that could be biologically productive. Although each spacer varies in sequence, the length of each spacer is conserved and corresponds to one or two turns of the DNA double helix. Each spacer serves to bring the heptamer and nonamer sequences to the same side of the DNA helix, where they both can be bound by a protein complex that catalyzes recombination.

This process of somatic DNA recombination is initiated when the recombination activating gene (RAG) endonuclease introduces DNA double-strand breaks (DSBs) at the border of two recombining gene segments and their flanking RSSs (78–80). DNA cleavage by RAG leads to four broken DNA ends that are repaired and joined through a process called nonhomologous DNA end joining (NHEJ) to form coding and signal joints (81, 82). Occasionally these DSBs can be repaired aberrantly, leading to the formation of chromosomal lesions such as translocations, deletions, or inversions (83, 84). If the breakpoints of these chromosomal lesions lie near potential oncogenes or tumor suppressor genes, they can lead to cellular transformation and lymphoid tumors. The mechanism of DNA rearrangement is similar for the heavy- and light-chain loci. However, only one joining event is needed to generate a light-chain gene, whereas two are needed to generate a complete heavy-chain gene. The most common mode of rearrangement involves the looping out and deletion of the DNA between two gene segments on the same chromosome; this occurs when the coding sequences of the two gene segments are in the same orientation in the DNA (85). The 12- and 23-mer-spaced RSSs are brought together by interactions between proteins that specifically recognize the length of the spacer between the heptamer and nonamer signals, thus accounting for the 12/23 joining rule (75, 76). The two DNA molecules then are broken and rejoined in a different configuration (86). By joining precisely in a head-to-head configuration, the ends of the heptamer sequences form a signal joint in a circular piece of extrachromosomal DNA that then is lost from the genome when the cell divides. However, the DNA that lies between the two gene segments is retained in an inverted orientation when a second mode of recombination occurs between two gene segments with opposite transcriptional orientations. Although this mode of recombination is less common, such rearrangements account for about one-half of all IGKV-to-IGKJ joins, as the transcriptional orientation of one-half of the human IGKV gene segments is opposite to that of the IGKJ gene segments.

RAG-1 and *RAG-2* are coexpressed normally only in developing lymphocytes that are undergoing receptor gene rearrangement. During B-cell development, the appearance of cytoplasmic immunoglobulin μ chains defines the pre-B cell. Pre-B cells, whose immunoglobulin μ chains can associate with the "surrogate" λ light chains, begin to express a pre-B-cell receptor. Its appearance turns off RAG1 and RAG2, preventing further immunoglobulin heavy-chain rearrangement (allelic exclusion). This is followed by four to six cycles of cell division (87). Late pre-B daughter cells reactivate RAG1 and RAG2 and begin to undergo light-chain rearrangement. Mice with either of these genes knocked out cannot undergo immunoglobulin or T-cell receptor gene rearrangements and consequently fail to produce mature B or T lymphocytes (88). A form of combined immune deficiency called Omenn syndrome in humans results from mutations that impair, but do not completely abolish, the function of *RAG-1* or *RAG-2* (89). It is interesting that patients with Omenn syndrome harbor point mutations in the RAG1 RING domain (see below) that reduces the efficiency of V(D)J recombination (90, 91).

After the RAG-1/RAG-2 endonuclease recognition of either the 12-mer-spaced or the 23-mer-spaced RSS, such

endonuclease introduces DSBs and remains bound to the DNA. The presence of mutations affecting the ability of the RAG proteins to bind and to maintain the broken ends in a stable postcleavage complex can lead to misrepair of the DSBs, thereby enhancing the risk for oncogenic chromosomal aberrations (92, 93). Involved in the processing and juxtaposition of these DSBs are several proteins, including the high-mobility-group proteins 1 and 2 (HMG1 and HMG2). HMG1 and HMG2 play an important role in the assembly of nucleoprotein complexes involved in DNA repair and transcription because they are widely expressed, abundant nuclear proteins that bind and bend DNA without sequence specificity (94). HMG1, facilitating the bending of the DNA, allows the components of one DSB-RAG complex to bind and to cleave the DNA at a different RSS, therefore, in accordance with the 12/23 joining rule, bringing together two disparate RSSs (75, 76).

The RAG complex introduces DSBs immediately adjacent to immune receptor gene segments, resulting in blunt phosphorylated signal ends and covalently sealed hairpinned coding termini that are joined by NHEJ (80). Coding and signal ends are joined at very different rates, rapid for coding ends while slower for signal ends (95). This is likely explained by the fact that the RAG complex remains tightly associated with signal ends after cleavage in a postcleavage complex, whereas coding ends are released from this postcleavage complex and need to be brought together again for repair (96). Seven NHEJ components are required for VDJ recombination: Artemis, Ku70, Ku80, DNA-dependent protein kinase (DNA-PK), XRCC4, XLF, and DNA ligase IV (Lig4) (97). Although all seven are required for efficient coding end joining, the dependence of signal end joining on these NHEJ factors is less absolute. The serine-threonine protein kinase (DNA-PK) is activated by DNA DSBs and is essential for the normal repair of DNA breaks induced by ionizing radiation, chemical agents, or VDJ recombination (98–100). DNA-PK-deficient mice can make only trivial amounts of immunoglobulin or T-cell receptors and are called severe combined immunodeficiency mice (101). Artemis-deficient mice have a "leaky" severe combined immunodeficiency phenotype and develop some T and B cells in later life (100). Artemis is not required for signal end joining but instead plays a specific role in opening the sealed hairpinned termini of cleaved coding ends (102). The dependence of signal end joining on DNA-PK is variable. Artemis's endonuclease activity requires physical interaction with DNA-PK as well as DNA-PK's enzymatic activity. Because Artemis is dispensable for signal end joining, it is reasonable to assume that signal end joining also might progress normally in the absence of DNA-PK (102). Indeed, signal end joining proceeds fairly efficiently in developing murine lymphocytes (10 to 50% of wild-type levels) and in some murine cell lines and one human cell line deficient in DNA-PK (103, 104). However, DNA-PK deficiency in other species (hamster, horse, dog) results in a more severe reduction in signal end joining (30- to 1,000-fold reduced) (105–107). Interestingly, mice deficient in Ku not only are deficient in T and B cells but also have small stature and other nonimmunologic defects, suggesting that the Ku proteins also play important roles in normal development (108, 109). Mice defects resulting from mutations in either Ku, XRCC4, Lig4, Artemis, or DNA-PK genes predispose to lymphoma (110, 111). The initial recognition and recruitment of repair proteins to DSBs is heavily dependent on phosphorylation events (e.g., kinase activity and autophosphorylation of DNA-PK), but the downstream repair events appear to be more dependent on E3-ubiquitin ligases (112).

Junctional diversity is generated in the sequences of the rearranged gene segments during the recombination process. Each coding joint originating from the hairpinned termini of gene segments is cleaved at random sites by an endonuclease. An overhanging flap is generated by the cleavage of a hairpin away from its apex and, if incorporated into the joint, results in the addition of palindromic nucleotides that contribute to junctional diversity. Further modifications on the opened hairpin ends by nucleases can remove a self-complementary overhang or cut further into the original coding sequence. In addition, the terminal deoxynucleotidyl transferase, a lymphocyte-specific enzyme, can add non-template-encoded nucleotides (113). Finally, nucleolytic activities that remove potential coding end nucleotides prior to the final ligation of the DNA breaks into one intact recombination joint can provide additional junctional diversity (86).

Lineage, stage, order, and feedback regulation of V(D)J recombination are mediated epigenetically by modulating the accessibility of particular loci or regions of loci to RAG (114). Numerous epigenetic accessibility markers, such as the histone H3 lysine 4 trimethylation, are enriched around IGHJ in early pro-B cells in association with germ line transcription (115). In addition, ubiquitination events can regulate recombination of immunoglobulin gene segments. The zinc finger region A of RAG1 includes an N-terminal RING domain that acts as an E3-ubiquitin ligase, which can ubiquitinate a panel of targets for various downstream events (77, 116–121) and can interact with other E2 enzymes to ubiquitinate substrates involved in V(D)J recombination, such as histone 3 (116, 117). Ubiquitination of RAG2 allows for rapid degradation of the protein upon entering S phase, thereby halting any potential off-target activities of RAG and limiting its capacity to induce V(D)J recombination during inappropriate phases of the cell cycle. DNA breaks during S phase are potentially harmful for cells, as such breaks can lead to deleterious translocations when misrepaired by homologous recombination. It is therefore crucial to limit V(D)J recombination activity within G_1 phase; this restriction appears to be controlled by RAG2 degradation (122–124).

Heavy-Chain Class Switching

A single B lymphocyte, during differentiation, can synthesize heavy chains with the same variable region coupled to different constant regions (125). As pre-B cells develop into mature B cells in early development, intact IgM monomers are inserted into the plasma membrane, followed by IgD molecules with the same antigen-binding specificity. The IgM and IgD constant-region genes generally are transcribed together. Alternative splicing permits simultaneous coproduction of IgM and IgD from a single species of RNA.

Later during development, these variable domains can associate with other isotypes (IgG, IgA, or IgE) through a controlled process called class switch recombination (CSR). CSR requires active transcription of the downstream constant-region exons encoding the switched immunoglobulin isotype. Such active transcription generally is triggered by stimulation of the B cell with antigen, mitogens, and/or ligation of CD40 via the ligand for CD40 (CD154), which is expressed by activated T cells. Patients with X-linked or autosomal recessive inheritance of mutations in CD154 or CD40, respectively, can have an immune deficiency syndrome (hyper-IgM syndrome type I), which is characterized by normal to high levels of IgM and extremely low levels of other immunoglobulin isotypes in serum (126, 127). Antigen-reactive T lymphocytes also provide interleukins that can influence whether the B cells continue to

express IgM or switch their immunoglobulin heavy-chain isotype to IgG, IgA, or IgE (125, 128).

Immunoglobulin CSR occurs in or near the switch region upstream of the gene and any one of the switch regions of the other heavy-chain isotype genes. Switch regions in Fig. 1 are represented by filled circles upstream of the IGHC genes. The μ switch region (Sμ) consists of approximately 150 repeats of the sequence $(GAGCT)_n(GGGGGT)$, where n is generally three but can be as many as seven. Other switch regions (S_γ, S_α, and S_ε) consist of similar sequences that contain repeats of the GAGCT and GGGGGT sequences. DNA recombination between S_μ and S_γ, S_α, or S_ε accompanied by the deletion of intervening DNA segments results in the apposition of the previously rearranged variable-region gene next to the new constant-region gene, thus switching the heavy-chain class. While VDJ recombination occurs mostly in the G_0 and/or G_1 stage of the cell cycle, CSR seems to require DNA replication (129).

Unlike VDJ recombination, CSR requires expression of activation-induced deaminase (AID), an enzyme expressed in activated B cells that also is required for somatic hypermutation (see "Generation of Antibody Diversity" below) (130–132). Inherited defects in AID can result in an immune deficiency syndrome called hyper-IgM syndrome type II, which is characterized by relatively high levels of IgM and negligible levels of other immunoglobulin isotypes in serum (133). Specific inactivation of the C-terminal AID domain, encoded by exon 5 (E5), allows very efficient deamination of the AID target regions but greatly impacts the efficiency and quality of subsequent DNA repair. Specifically eliminating E5 not only precludes CSR but also causes an atypical, enzymatic-activity-dependent, dominant-negative effect on CSR. This explains the autosomal dominant inheritance of AID variants with truncated E5 in patients with hyper-IgM syndrome type II and establishes that AID, through the E5 domain, provides a link between DNA damage and repair during CSR (134). The sites where CSR takes place in B cells activated in response to an antigen are germinal centers of the lymph nodes and spleen where AID is expressed (135).

Uracil-DNA glycosylase (UNG) is an enzyme that removes the uracils (dU) generated from the deamination of cytosines (dC) by AID. Inherited defects in this enzyme underlie an autosomal recessive form of the hyper-IgM immune deficiency syndrome, which is similar to that of patients with inherited defects in AID (6, 136). Apurinic/apyrimidinic endonuclease cleaves the abasic sites generated by UNG; the staggered nicks in the DNA are closely positioned and may result in DNA DSBs (137). Such DNA DSBs are end processed, repaired, and joined by mechanisms and proteins similar to those involved in NHEJ used for VDJ recombination. Since CSR occurs in the intron between the variable-region exon and the exon encoding the first constant-region domain, no mutations in the regions encoding the variable or constant regions of the newly generated immunoglobulin heavy chain are generated by this process (138).

GENERATION OF ANTIBODY DIVERSITY

The diversity among immunoglobulin variable regions can be generated by several mechanisms: (i) the germ line presence of multiple V, J, and D gene segments; (ii) the DNA segments randomly joining to produce a complete variable-region exon; (iii) uncorrected errors made during the recombination process; (iv) the heavy- and light-chain polypeptides pairing to produce a complete immunoglobulin monomer capable of binding an antigen; and (v) somatic mutations in the rearranged DNA segments themselves (62). The last of these occurs through a process called somatic hypermutation (SHM). This process occurs in antigen-activated B cells and cannot be triggered merely by mitogen-induced B-cell activation.

The SHM process primarily introduces single nucleotide exchanges into the rearranged immunoglobulin variable region, at a rate of 10^{-3} per base pair per generation. However, during discrete stages of B-cell differentiation and in particular during the secondary immune response to an antigen, expressed immunoglobulin variable genes can incur new mutations at rates as high as 10^{-3} base changes per base pair per generation over several cell divisions (139). Mutations generated by SHM are clustered in the region spanning from 300 bp 5′ of the rearranged variable-region exon to approximately 1 kb 3′ of the rearranged minigene J segment, frequently around hot spots defined by the primary DNA sequence, such as the sequence RGYW (R, purine [A or G]; Y, pyrimidine [C or T]; W, A or T) and its complement. Such sequences are hot spots for mutation that are conserved among species (140, 141).

SHM is dependent on the expression and activity of AID through a process that has some similarity to CSR (142). AID is responsible for initiating mutations at RGYW motifs. Mutations spread as a consequence of downstream events orchestrated by the mismatch repair and base excision repair pathways (143–147). In addition to having the hyper-IgM immune deficiency syndrome type II, patients with inherited defects in AID have B cells that lack the capacity to undergo SHM (131). As with CSR, SHM requires active transcription of the genes undergoing mutation. In the region encompassing the rearranged variable-region gene, AID most likely deaminates the dC, converting the dC into dU, which is converted into T after DNA replication, giving rise to CG-to-T or -A transitions. Alternatively, UNG may remove the dU, resulting in staggered nick cleavage of the DNA. Such abasic sites are subsequently cleaved by apurinic/apyrimidinic endonuclease. Low-fidelity DNA synthesis may repair these staggered nicks, resulting in frequent mutations. A complex called the mutasome, formed by DNA-cleaving enzymes and DNA repair enzymes (e.g., mismatch repair enzymes, base excision repair enzymes, proteins involved in NHEJ, etc.), also apparently binds the target DNA to reduce its tendency to incur complete DNA DSBs. Through this process, mostly transitional mutations are introduced at high frequencies into the expressed immunoglobulin V genes as well as other transcriptionally active genes within hot spots, which serve as substrates for AID, UNG, and the mutasome (140, 143, 148). Subsequently, "affinity maturation" of the antibodies expressed during the immune response to antigen takes place by selection of the B cell and its daughter cells that express mutated V genes encoding an immunoglobulin variable region with improved fitness for binding antigen (149). Such selection enhances the frequency of nonconservative base substitutions in the DNA sequences encoding the complementarity-determining regions that serve as the contact sites for antigen binding (150).

Immunoglobulin enhancers may account in part for the preferential somatic hypermutation of immunoglobulin genes. Combinations of immunoglobulin enhancers target somatic mutation to immunoglobulin genes by recruiting AID and/or by making the immunoglobulin genes better substrates for mutation (151). In addition, posttranslation AID ubiquitination has an important regulatory role during CSR and SHM (152, 153). Unlike RAG2, AID protein stability is not associated with phases of the cell cycle but rather with subcellular localization. In mouse B cells, nuclear AID is subjected to rapid turnover upon polyubiquitination (152).

DETECTION OF IMMUNOGLOBULIN GENE REARRANGEMENTS

Analysis for immunoglobulin gene rearrangements can detect clonal immunoglobulin gene rearrangements. Immunoglobulin gene rearrangement irreversibly alters the genomic DNA of the developing B cell and its descendant daughter cells. Because of the many possible distinct immunoglobulin gene rearrangements possible, a B cell's particular type of immunoglobulin gene rearrangement can serve as a clonal marker.

PCR Assays

Sensitive methods for detecting immunoglobulin gene rearrangements, such as PCR, can be used to examine for residual cells of a malignant B-cell clone following antitumor therapy. PCR, using sense strand oligonucleotide primers corresponding to an immunoglobulin V gene subgroup (Table 2) together with antisense strand oligonucleotide primers corresponding to the relevant J-region or constant-region exon, can amplify the rearranged V gene in genomic DNA or cDNA, respectively.

Because these gene segments are separated by large stretches of intervening DNA in germ line DNA, a PCR assay with genomic DNA and primers specific for a V gene subgroup and the J gene segment(s) will fail to amplify any immunoglobulin genes unless the genes have first undergone rearrangement. However, after immunoglobulin gene rearrangement, the variable-region gene leader sequence primers and J primers anneal to sites that are separated by fewer than 400 bp, making PCR straightforward (154). On the other hand, a PCR assay on genomic DNA with primers specific for a V gene subgroup and a constant-region exon does not amplify rearranged immunoglobulin genes because the distance between the J segment and the immunoglobulin constant-region exon is too large. Such primer pairs are better suited for amplifying cDNA derived from the immunoglobulin transcripts from which the intron separating the J region and the constant-region exon are deleted through RNA processing and splicing.

Genomic DNA is the most commonly used for PCR in clinical laboratories, as this does not require synthesis of cDNA from isolated RNA. However, care must be taken when using genomic DNA for PCR, which can amplify both the productively rearranged immunoglobulin gene and its unproductively rearranged allele. The use of downstream primers located in the constant region (isotype-specific primers) allows definition of the isotype and may be advantageous in the case of mutated sequences, since it is not targeted by the somatic hypermutation process (155).

Resolution of the junctional sequences in the rearranged immunoglobulin genes expressed by a tumor can provide a specific tumor marker. This marker can be used to examine for any tumor-derived immunoglobulin gene fragments amplified by PCR performed on genomic DNA of lymphoid tissue. Such methods are highly sensitive, allowing for detection of minimal residual disease of small numbers of lymphoid tumor cells that otherwise cause no detectable pathologic or immunophenotypic trace of residual disease after therapy.

Immunoglobulin Quantification and Viscosity Measurement

JEFFREY S. WARREN

7

Quantification of intact serum immunoglobulins has proven useful in the evaluation of patients with suspected immunodeficiency disorders, lymphocyte and plasma cell neoplastic diseases, allergic conditions, and some chronic inflammatory and autoimmune disorders. Since the advent of quantitative immunoglobulin assays nearly 50 years ago (1), increasingly robust analytical methods have been developed. The armamentarium of intact immunoglobulin assays was first substantively expanded by the development of immunoglobulin light-chain measurements in which the light chains are bound to heavy chains (intact immunoglobulins). The last decade has seen the development of both free (unbound) immunoglobulin light-chain assays and heavy/light-chain (HLC) or junctional epitope assays, the latter of which allows for individual measurements of IgGκ, IgGλ, IgAκ, IgAλ, IgMκ, and IgMλ (2, 3). Despite these advances in immunoglobulin and light-chain quantification methods, there remain technical complexities that can influence accuracy and, in turn, proper clinical application. Equally important, even with robust assays, is the need for thorough understanding of the clinical indications for, and limitations to, immunoglobulin and related measurements.

Viscosity is the internal friction of a fluid, caused by intermolecular attraction, leading to resistance of the fluid to flow (4). Viscosity measurements can be very complex (4). By extension, rigorous whole-blood, plasma, and serum measurements are also very complex. Fortunately, clinically useful measurements of viscosity are relatively straightforward. A variety of clinical conditions can affect the viscosity of blood (5). While abnormalities of the formed elements of blood (e.g., polycythemia, some hemoglobinopathies, and extreme leukocytosis) can result in clinically significant hyperviscosity, overwhelmingly the most common causes are either immunoglobulin concentration or abnormal immunoglobulin structure. There are several analytical methods for measurement of whole-blood, plasma, and serum viscosity. It is important to understand the uses and limitations of these measurements and how each is reported.

This chapter is divided into three sections. The first provides a brief review of immunoglobulin structure, important because of its direct relevance to quantitative immunoglobulin and related measurements. The second provides an overview of assay methods and highlights issues related to quality control, test validation, and quality assurance, as well as a brief discussion of the clinical application of immunoglobulin and related measurements. Developments since the 7th edition of this *Manual* include the advent of free-light-chain assays and heavy/light-chain or junctional epitope assays. The third section addresses fundamental technical aspects of clinically useful viscosity measurement and important interpretive considerations.

IMMUNOGLOBULIN STRUCTURE

Knowledge of immunoglobulin structure is important for understanding measurements of intact immunoglobulins and free light chains as well as in clinical viscometry. Basic antibody function (i.e., antigen binding) was recognized years before the elucidation of immunoglobulin structure (6). Early studies of antibody binding to highly purified carbohydrate antigens led to the deduction that antibody was composed of protein (6). The development of clinical electrophoresis led to the recognition that antibody migrated largely within the so-called gamma region of serum proteins, hence the names "gamma globulin" and "immunoglobulin" (Fig. 1) (7). In 1952, Colonel Ogden Bruton, a pediatrician, used serum protein electrophoresis (SPEP) to evaluate a boy suffering from recurrent bacterial infections (8). Recognition that the gamma fraction of protein was absent, coupled with the boy's favorable response to injections of gamma globulin from healthy donors, supported the conclusion that this serum fraction was important in host defense and led to the clinical definition of a specific immunodeficiency syndrome (Bruton's agammaglobulinemia). Recognition of *m*onoclonal immunoglobulin (also known as M-protein or "paraprotein") as the structurally uniform product of a clonal proliferation of neoplastic B lymphocytes or plasma cells was important in the recognition and understanding of such diseases as multiple myeloma and Waldenström's macroglobulinemia.

In contrast to serum alpha and beta globulins, which are composites of structurally homogeneous proteins (e.g., alpha-1 antiproteinase, transferrin, and complement protein 3), polyclonal immunoglobulins are structurally heterogeneous (9). This structural heterogeneity is accounted for at several levels. There are five major immunoglobulin classes (isotypes), each determined by heavy-chain type (see below) and each different in structure and function (Table 1). Subclasses within immunoglobulin G (IgG), IgA, and IgM (Table 2) also contribute to immunoglobulin heterogeneity, as do allotypic variations within both heavy- and light-chain

doi:10.1128/9781555818722.ch7

isotypes. Immunoglobulins are also subject to posttranslational modification. Overwhelmingly, however, the great heterogeneity of structure reflects the vast array of different amino acid sequences within the variable and hypervariable regions of immunoglobulin molecules. One of the pivotal scientific advances in the history of immunology was the elucidation of the molecular mechanisms responsible for the generation of antibody (immunoglobulin) diversity (chapter 6) (10). It is important to remember these different levels as contributors to the structural heterogeneity of immunoglobulins because they warrant consideration in both the quantification of polyclonal immunoglobulins by class (e.g., total IgG or IgM) and in the quantification of monoclonal immunoglobulins (e.g., in patients with multiple myeloma). The general structure of an intact immunoglobulin molecule includes two heavy chains (gamma, alpha, mu, delta, or epsilon), two light chains (kappa or lambda), and several bridging disulfide bonds (Fig. 2). Within each heavy and light chain are N-terminal variable and hypervariable (antigen-binding) domains and C-terminal constant domains. Antibody structure is best understood in the context of the genetic and molecular bases of structural and functional diversity (chapter 6).

Pioneering studies of antibody structure, carried out in the 1950s and 1960s, provided important insight into antibody function and resulted in the immunoglobulin subunit nomenclature still in use. In 1958, Porter (11) digested rabbit gamma globulin with the enzyme papain. Separation of the digestion products revealed two identical *a*ntigen-*b*inding *f*ragments (Fab) and one fragment that could be crystallized (Fc). Fab fragments had sedimentation coefficients of 3.5 S (Svedberg units). That the Fc fragment could be crystallized provided evidence that it was biochemically homogeneous. Digestion of purified antibody with pepsin yielded a different set of fragments. The largest, with a sedimentation coefficient of 5 S, had an antigen-binding valence of 2, hence its designation, $F(ab')_2$. Reduction of the disulfide bonds that hold an $F(ab')_2$ fragment intact resulted in the formation of two fragments that each resembled (but were not identical to) papain-generated Fab. In 1961, Edelman and Poulik reported that chemical reduction (of disulfide bonds in intact immunoglobulin molecules) leads to the formation of two "heavy" chains and two "light" chains (12).

As noted above, the structurally variable (and hypervariable) Fab domains of immunoglobulin molecules are responsible for antigen binding. In contrast, the Fc domain determines the biological function of a given immunoglobulin molecule. As summarized in Table 1, the biological functions of immunoglobulins are diverse, including such characteristics as complement fixation (e.g., IgG and IgM), placental transfer (IgG), and high-affinity cytophilic binding to mast cells (IgE) (13). IgM generally circulates as a pentamer that consists of five covalently linked IgM monomers with an antigen-binding valence of 10. Serum IgA occurs as a monomer that weighs nearly 160 Da with a valence of 2. In secretions, IgA commonly occurs as a multimer, usually a dimer.

Light chains (kappa and lambda) each possess an N-terminal 110-amino-acid variable (V) region and a C-terminal 107- to 110-amino-acid constant (C) domain. By analogy, heavy chains (gamma, alpha, mu, epsilon, and

TABLE 2 Characteristics of IgG subclasses

Property	IgG1	IgG2	IgG3	IgG4
Concn in serum (g/liter)	1.8–7.8	1.0–4.6	0.3–1.4	0.08–1.8
Half-life (days)	14–23	14–23	7–8	14–23
Complement fixation	Strong	Weak	Strong	None
Phagocyte binding (via Fc receptors)	Yes	No	Yes	No
Associated with allergies	No	No	No	Yes

TABLE 1 Characteristics of immunoglobulins[a]

Nomenclature	IgG	IgA	IgM	IgD	IgE
Heavy-chain class	Gamma	Alpha	Mu	Delta	Epsilon
Heavy-chain subclasses	1, 2, 3, 4	1, 2	1, 2		
Light-chain types	Kappa and lambda	Kappa and lambda	Kappa and lambda	Kappa and lambda	Kappa and lambda
Physical characteristics					
Molecular mass (Da)	143,000–160,000	159,000–447,000	900,000	177,000–185,000	187,000–200,000
Sedimentation coefficient (Svedberg units)	6.7–7.0	7.5–9.0	18–19	6.9–7.0	7.9–8.0
Functional characteristics

Placental transfer	+	−	−	−	−
Reaginic activity	±	−	−	−	++

[a] ±, borderline; +, present; ++, strong activity; −, no activity.

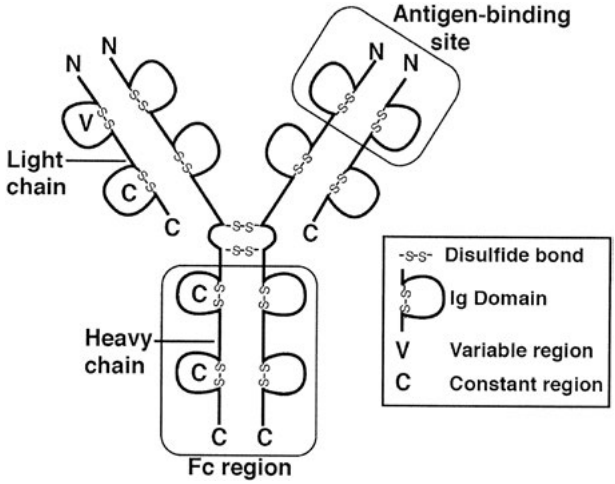

FIGURE 2 Schematic of an intact immunoglobulin G molecule. Antigen binding occurs between light and heavy chains in the N-terminal variable-hypervariable binding regions. IgG possesses an antigen-binding valence of 2. Monomeric immunoglobulin molecules, whether the heavy chains are gamma, alpha, mu, delta, or epsilon, possess the same general structure. Individual immunoglobulin molecules include either kappa *or* lambda light chains, *not both*.

delta) each possess a 110-amino-acid N-terminal variable region and, depending on the particular class, three or four 110-amino-acid constant-region domains. Individual variable- or constant-region domains are folded into globular motifs called "Ig domains." Ig domains are held in conformation by disulfide bonds (Fig. 2). Structurally apposed light- and heavy-chain variable regions form an antigen-binding domain. It is useful to think of the antigen-binding (Fab) region of an immunoglobulin molecule as a hand that grasps a uniquely shaped doorknob (antigen). Finally, as alluded to above, the genetic and molecular bases for immunoglobulin structure, antibody diversity, and immunoglobulin assembly and secretion have been studied intensively (chapter 6) (10, 13). Kappa light chains are encoded by chromosomal band 2p11, lambda light chains are encoded by 22q11, and the heavy chain is encoded by the loci on chromosome 14. A highly regulated series of DNA recombination, nucleic acid splicing, and subunit assembly steps is required to generate intact immunoglobulin molecules (10, 13). Immunoglobulins are produced only by B lymphocytes and plasma cells.

IMMUNOGLOBULIN CLASSES

IgG is the predominant class of serum immunoglobulins. More than 60% of circulating IgG is IgG1, with IgG2, IgG3, and IgG4, in that order, present in decreasing concentrations (Table 2) (13, 14). Except for IgG3, which has a serum half-life of 1 week, the IgG subclasses have half-lives of 2 to 3 weeks. IgG antibodies comprise the most important effector class of molecules in a secondary or anamnestic humoral immune response. Among large populations of B lymphocytes that express different cell surface IgG molecules, high-affinity antigen binding provides a selective advantage for subsequent clonal expansion (13). As a result, as a humoral immune response "matures" over time, increasing proportions of IgG antibodies exhibit higher degrees of antigen-binding affinity (affinity maturation). This is in part why repetitive exposures to a given antigen result in increasingly effective humoral immunity.

IgA is the most important immunoglobulin in the mucosal host defense system. Mucosal IgA exists chiefly as paired monomeric subunits linked by J ("joining") chains to form dimers (13). A 60-kDa peptide called the "secretory piece" is necessary for IgA to be secreted by various types of epithelial cells that line mucosal surfaces. IgA, like all immunoglobulins, is produced by B lymphocytes and plasma cells. Mucosal IgA is actively transported across mucosal epithelial layers (from the abluminal to the luminal surface). As noted in Table 1, IgA exists as IgA1 and IgA2 subclasses, the former present in higher concentration in serum and each having a half-life of 4 to 5 days.

Serum IgM circulates chiefly in the form of pentamers. Monomeric subunits include two mu heavy chains, which in turn each possess one more constant-region domain than most gamma heavy-chain species. As a result, pentameric IgM has a molecular mass of approximately 900 kDa (J chain plus 5 times nearly 180 kDa). IgM is the initial immunoglobulin class expressed on B cells during lymphocyte development and is the predominant immunoglobulin class in a primary humoral response (13).

IgD circulates in very low concentrations. Like IgM, B cell surface IgD is expressed early in lymphocyte development (13). Monomeric IgD consists of two heavy chains (each weighs approximately 60 kDa) and two identical kappa or lambda light chains. The biological role of serum IgD is not well understood, and clinical measurement of IgD has no value except for the rare patient with an IgD-secreting neoplasm (e.g., multiple myeloma) or the equally rare patient with a familial hyper-IgD fever syndrome.

The clinical utility of IgE measurements is discussed in greater detail in section M, which describes allergic diseases. Serum IgE molecules circulate as monomers that consist of two epsilon chains (each approximately 70 kDa) and two identical kappa or lambda light chains (14). Like mu heavy chains, epsilon heavy chains contain an additional constant-region domain. While IgE is normally present in low concentrations, elevated polyclonal IgE immunoglobulin is seen in a wide variety of allergic and autoimmune diseases. Antigen-specific IgE measurements are widely used in the evaluation and management of patients with specific atopic disorders (14). For instance, one may quantitatively measure IgE antipollen or IgE antipeanut antigen. These measurements require very sensitive analytical immunoassay systems that rely on detection of specific binding of IgE immunoglobulin molecules to their defined cognate antigens. Cytophilic IgE binds to mast cells and basophils via very-high-affinity Fcε receptors. Activation of such cells via divalent IgE-specific antigen binding results in the rapid release of vasoactive and chemotactic mediators that can cause localized swelling and/or a generalized, sometimes life-threatening reaction (anaphylaxis) (15). Measurement of total IgE and antigen-specific IgE antibodies is discussed in section M.

MEASUREMENT OF IMMUNOGLOBULINS

Currently, quantification of intact IgG, IgA, and IgM is almost exclusively performed by automated rate nephelometric or immunoturbidimetric assay systems (16). Application of nephelometry and immunoturbidimetry to immunoglobulin measurement represents a trend away from more labor-intensive, less sensitive, and slower manual methods such as radial immunodiffusion (RID) and the Laurell rocket technique (17, 18). Likewise, most serum-bound kappa and lambda light-chain measurements and total IgE measurements are also carried out using automated nephelometric

or immunoturbidimetric assay systems (16). More than 20% of clinical laboratories that participated in the 2004 College of American Pathologists (CAP) proficiency testing survey program used a RID method for IgG subclass measurements, and nearly all laboratories that measured total IgD employed a RID assay (17, 18). Currently, nearly all laboratories (that participate in the CAP proficiency testing program) utilize nephelometric or immunoturbidimetric assays (16). The exception is for total IgE, which is measured by nonisotopic immunoassay.

Nephelometric assays are based on rate reactions in which antigen, in this case an immunoglobulin such as IgG, is injected into a reaction chamber with an antigen-specific antibody (19). As antigen-antibody complexes form in suspension, they form a precipitin "cloud." ("Nephos" is derived from the Greek word for cloud.) Antigen-antibody complexes are detected with an intense light source. As immune complexes form, increasing numbers of photons are deflected at 30° to 90° angles. They are then quantified with a photomultiplier tube located on the inner side surface of the reaction chamber. As the antigen-antibody precipitin "cloud" grows in size and density, more photons are deflected and a greater signal is recorded. The rise in the number of light signal events (photons) as a function of time (in milliseconds) is determined by the concentrations of antigen and antibody. Modern rate nephelometers are sophisticated instruments that employ parallel duplicate assay chambers, thus ensuring precision; they exhibit high throughput and are programmed to run through a series of dilutions of antigen or antibody, thus allowing for the "finding of" a near-optimal precipitin-forming rate reaction. While rate nephelometers are robust, wildly aberrant results can occur as the result of extreme antigen excess (the high-dose "hook" effect) (20). This problem may be particularly pronounced when measuring an unusually high concentration of an analyte (outside the expected dynamic range of the assay) otherwise expected to have a relatively low concentration. Such antigen excess can escape detection via antigen excess checks (a series of repeated measurements with more-dilute antigen or antibody solutions). When measuring IgG subclasses, it is a useful quality check to sum the concentrations of all four subclasses to ascertain that their additive total approximates the separately measured total IgG concentration. Immunoturbidimetric assays are formatted similarly, but rather than relying upon the quantitation of deflected light, they rely on the interruption of light transmission (180°) through the suspension of immune complexes being formed by antigen and reagent antibody (21).

Nephelometric and immunoturbidimetric test systems have had a large economic impact on clinical laboratories because they are automated, can be used to measure many different analytes with a single platform, and allow rapid and high-volume throughput. As a result, employment of these methods yields a lower cost per test in laboratories that process significant volumes.

RID assays entail addition of reagent antibody to warm (50°C) agar while it is in the liquid state (1, 22). Liquefied antibody-containing agar is poured into a shallow, flat plastic dish or plate and allowed to cool to room temperature. The resulting semisolid agar has the consistency of cold Jell-O. Cylindrical vertical wells are then cut into the solidified agar. Standard dilutions of known concentrations of antigen, in this case, immunoglobulin such as a specific IgG subclass, are placed into multiple wells. Serum samples that contain patient IgG to be measured are placed in other wells. As the antigen (IgG subclass) diffuses in all directions from each well, a visible antigen-antibody precipitin line forms where antigen and antibody achieve equivalence. The concentration of the unknown analyte, in this case the serum IgG subclass, can be calculated by comparing the diameter of the precipitin ring to those precipitin rings of the standard curve generated by the serially diluted known concentrations of antigen added to different wells. Higher concentrations of antigen must diffuse further to reach concentrations low enough to form antigen-antibody complexes at equivalence. Typically, a 5 $\log_{10}$ dilution standard curve is employed (1, 22). The diameters measured from precipitin rings formed by patient samples can be interpolated from the set of standard curve diameters. RID offers the advantages that it is simple and requires very little equipment. The major disadvantages are that RID assays are manual, take 16 to 48 hours to run because of the diffusion time required, and often employ very expensive reagents. Technical artifacts attributable to lipids, monomeric IgM or IgA, or cross-reacting antibodies to animal proteins can lead to inaccurate results. When reagent antibody is monoclonal, as in many IgG subclass assays, the per-test cost can be extraordinarily high. One decade ago, when more than 20% of laboratories that participated in the CAP proficiency testing program used RID assays for IgG subclass measurement (17, 18), a single set of RID plates (enough to test nine patients) cost $400 (J. Warren, unpublished observation)! Inherent in RID immunoglobulin assays are higher coefficients of variation than those observed for nephelometric and immunoturbidimetric methods (greater than 10% versus less than or equal to 8%) (16–18). Because of high relative expense and long analytical times, the use of RID assays in clinical laboratories has decreased dramatically during the past 2 decades (16).

The Laurell rocket technique is very similar to RID, except that the diffusion phase of the assay is accelerated from hours to minutes by the application of an electrical field (23). While the endpoint is still the formation of a precipitin line (antigen-antibody complexes at equivalence in agar), the geometry is changed from a circle to that of a rocket-shaped arc, hence the designation "rocket." With the Laurell technique, the height of the precipitin rocket is proportional to the antigen concentration. As in the RID technique, a standard curve is constructed by running a series of different known concentrations of a standard antigen preparation. Again, immunoglobulin concentrations in patient samples are calculated based on interpolation from the standard curve. While Laurell rocket electrophoresis is faster than RID, the remaining shortcomings still hold, and use in clinical laboratories is very uncommon (16). Both RID and Laurell rocket assay systems may be most appropriate for very-low-volume laboratories, where a nephelometer may be too expensive.

MEASUREMENT OF FREE LIGHT CHAINS

In the past decade, an analytical approach to quantification of free (dissociated from heavy chain) immunoglobulin light chains in serum and/or urine has been developed, and the assay has been tested in a variety of clinical settings. Mature B lymphocytes and plasma cells typically produce approximately 40% excess of free light chains (13). Thus, early after the emergence of a single (disordered or neoplastic) clone, the "signal-to-noise" ratio of monoclonal light chains to "background" polyclonal light chains is low—making monoclonal populations difficult to detect. Identification of free monoclonal light chains in the sera of patients with multiple myeloma, other B cell disorders, and light-chain (amyloid light-chain [AL])-type amyloidosis is also limited, especially early in the course of the disease, because these proteins, by virtue of their low molecular mass (22 to 25

kDa), are filtered by glomeruli and subsequently reabsorbed by proximal renal tubular epithelial cells. Accordingly, SPEP may reveal no apparent abnormality. The diagnostic yield is increased by also testing urine for such Bence Jones proteins (monoclonal urinary free light chains). Again, low concentrations of Bence Jones protein may not be seen early in disease because proximal tubular reabsorption of such clonal proteins is relatively efficient until the quantities of protein increase and exceed the reabsorptive capacity of the tubular epithelium or until tubular damage (acquired Fanconi syndrome) occurs and there is increased excretion of Bence Jones protein. The advent of the nephelometric serum free-light-chain (sFLC) assay has increased the ability to detect monoclonal proteins (43) (see below).

In 2001, Bradwell et al. developed a sensitive immunoassay for the quantification of free immunoglobulin light chains in both urine and serum (2). Affinity-purified antibodies that react specifically with epitopes accessible only on *free* light chains (Fig. 3), but unable to reach the same epitopes sequestered in bound light chains, are linked to the surface of latex particles. These antibody-coated particles form aggregates when incubated with free light chains. Employment of such particles in automated nephelometric or immunoturbidimetric analyzers has resulted in a robust test system. Because free kappa and lambda (polyclonal) light chains are normally also present in serum and urine (and measured), the clinically useful assay for detection of monoclonality necessitates calculation of the ratio of free kappa to free lambda light chain. The occurrence of a significant clonal increase in either free kappa or free lambda light chains distorts this ratio. Thus, a very high or a very low ratio of kappa to lambda free light chains is reflective of a kappa monoclonal or lambda monoclonal process, respectively. Individual sFLC measurements, kappa *or* lambda, reflect the total circulating respective free-light-chain concentration.

Clinical studies since the widespread deployment of sFLC assays have led to a better understanding of when and how to utilize this test. Much of what has been learned was distilled into a set of practice guidelines published by the International Myeloma Working Group in 2009 (see below) and has since been reiterated, refined, and extended in more-recent studies (24–26).

The addition of sensitive and specific free-light-chain assays to the armamentarium of laboratory tests available for the diagnosis and management of patients suspected to have multiple myeloma, Waldenström's macroglobulinemia, B cell leukemias and lymphomas, and AL-type amyloidosis is an exciting prospect. As in other nephelometric and immunoturbidimetric immunoglobulin assays, sFLC measurements are prone to the high-dose "hook" effect (19, 20). This is of particular concern in measurements of serum free light chains in patients with B lymphocyte and plasma cell neoplasms because of the extreme variation in concentrations that can be seen in a single patient over time. There are several analytical limitations to sFLC assays. These include lot-to-lot variability and the fact that some sFLCs do not dilute in a linear fashion (27). It will be important for additional clinical studies to address the specific potential applications and limitations of these assays. Particular attention will need to be paid to comparisons between free-light-chain assays and *optimally* used "traditional" assays. For example, it will be appropriate to compare diagnostic sensitivities and specificities of free-chain-assays to those of serum *and* urine immunofixation assays, not merely serum *or* urine immunofixation assays. In addition, it will be important to assess the impact of sensitive free-light-chain assays on clinical outcomes in patients. Serum and urine free-light-chain assays are Food and Drug Administration cleared for use in the diagnosis and monitoring of patients with B cell and plasma cell neoplasms and collagen vascular diseases such as systemic lupus erythematosus (25).

Many important utilization and cost-effectiveness questions remain to be answered for these expensive tests. For instance, what are appropriate testing frequencies in the context of various disease processes and therapies? How should sFLC assays be utilized in the context of other laboratory testing? Any studies of cost-effectiveness of sFLC testing versus "traditional approaches" (SPEP, 24-hour Bence Jones protein quantification, etc.) should take into account not only the cost of "traditional" testing but also inconvenience (e.g., 24-hour urine collection) and technical limitations (e.g., quantification of urine Bence Jones protein and M-protein quantification by SPEP). Clearly, assessments of optimal utilization and cost-effectiveness encompass a broad set of questions and consideration of many factors.

JUNCTIONAL EPITOPE (HEAVY/LIGHT-CHAIN) ASSAYS

In 2009, Bradwell et al. described the development of an assay based on reagent antisera that specifically recognize and bind to unique epitopes displayed at the junction between

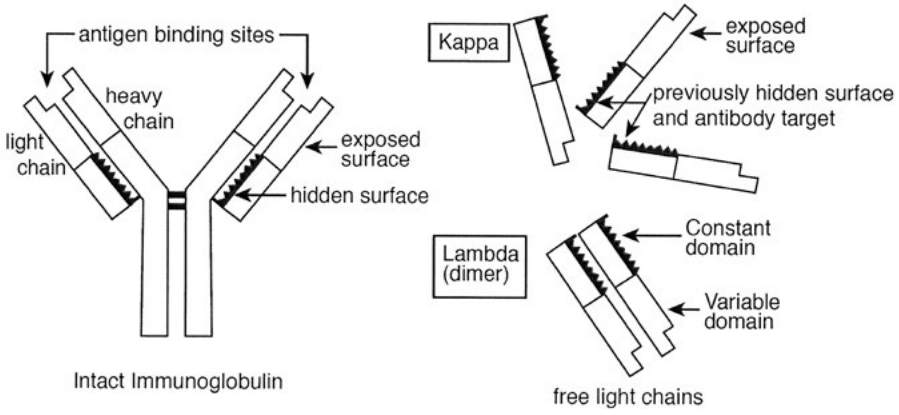

FIGURE 3 The serum free-light-chain (sFLC) assay is based on purified polyclonal antibodies that specifically bind epitopes that are accessible on free light chains but hidden (and inaccessible) in intact immunoglobulin molecules.

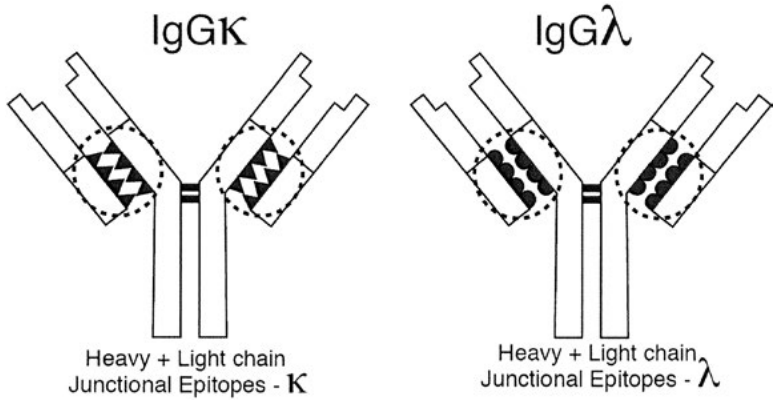

FIGURE 4 The heavy-light chain (HLC) assay, a junctional epitope assay, is based on purified polyclonal antibodies that specifically bind unique epitopes that occur where heavy and light chains are structurally apposed. Antibodies specifically bind IgGκ, IgGλ, IgAκ, IgAλ, IgMκ, and IgMλ (six reagents).

the heavy- and light-chain constant regions of IgGκ, IgGλ, IgAκ, IgAλ, IgMκ, and IgMλ molecules (six reagents), hence the name "junctional epitope" or so-called "*h*eavy/*l*ight" chain (HLC) assays (Fig. 4) (3). The quantitation of immunoglobulins by isotype-specific light chain type (e.g., IgGκ and IgGλ) may provide diagnostically useful information related to clonal proliferation, and HLC-pair ratios (e.g., IgGκ/IgGλ) coupled with individual heavy/light chain measurements (e.g., IgGκ *and* IgGλ) may be useful in disease monitoring (28). As noted with sFLC assays, demonstration of cost-effectiveness and impact on clinical outcomes in patients will be important considerations.

CLINICAL ASPECTS OF IMMUNOGLOBULIN MEASUREMENT

Serum immunoglobulin concentrations vary widely between children and adults (13, 29). Immunoglobulin G concentrations in a newborn are nearly equal to those observed in adults as a result of transplacental passage from the mother. (Maternal IgA and IgM do not pass into the fetal circulation.) Immunoglobulin G concentrations then decline to a nadir at approximately 6 months of age. After this nadir in the IgG concentration, it rises progressively until adult concentrations are reached during early adolescence. It is important to apply age-specific reference ranges when one interprets quantitative immunoglobulin measurements in prepubertal children. Likewise, it is important to recognize that there is some individual-to-individual variation in this pattern.

Many congenital and acquired immunodeficiency disorders are characterized by hypogammaglobulinemia (29). Depending upon the underlying etiology and accompanying abnormalities, humoral immunodeficiency syndromes are often accompanied by specific clinical manifestations. In general, patients with humoral immunoglobulin deficiencies are at risk for a variety of infections, including some caused by high-grade encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, etc. (29). A detailed discussion of humoral immunodeficiency syndromes is beyond the scope of this chapter, but many such disorders have been elucidated and are currently best classified based on identification of specific molecular defects. For example, children suspected of suffering from Bruton's (X-linked) agammaglobulinemia or a severe combined immunodeficiency and adults suffering from suspected common variable immunodeficiency all exhibit markedly subnormal concentrations of IgG, IgA, and IgM in serum. The most common congenital humoral immunodeficiency disorder is selective IgA deficiency, which ranges, depending on the ethnicity of the population, from 1 in 400 to 1 in 700 adults (29). Many patients with selective IgA deficiency are asymptomatic, but some suffer from recurrent mucosal infections and/or autoimmune phenomena. A subset of selective IgA deficiency patients exhibit concomitant IgG subclass deficiency. Aggressive treatment of patients with various neoplastic and autoimmune diseases has resulted in many individuals with acquired humoral immunodeficiencies. Like patients with congenital humoral immunodeficiency disorders, these individuals are at risk of high-grade bacterial and other infections. Likewise, multiple myeloma is frequently accompanied by both the presence of a monoclonal immunoglobulin spike (M-protein) and the suppression of polyclonal "background" gamma globulin (see below).

A vast array of chronic inflammatory and infectious diseases are accompanied by polyclonal increases in immunoglobulin concentration. In these settings, there is usually little to no value in specific quantitative measurements of IgG, IgA, or IgM. Serum protein electrophoresis, accompanied by densitometric measurement of the total gamma globulin concentration, usually suffices as a "first-tier" means to assess the humoral immune system.

A substantial majority of patients with multiple myeloma and essentially all patients with Waldenström's macroglobulinemia have monoclonal increases in immunoglobulins in serum, urine, or both (30). Serum protein electrophoresis and both serum and urine immunofixation electrophoresis (IFE) remain key assays used in the diagnosis and monitoring of disease progression/response to therapy in patients with multiple myeloma and related plasma cell/B lymphocyte proliferative diseases (30). Increasingly, clinical laboratories have shifted from agarose gel to capillary zone electrophoresis as the primary method for SPEP (31). Secreted monoclonal immunoglobulins (M-proteins) or immunoglobulin components (e.g., free light chains) are *de facto* tumor markers. Major limitations of SPEP and IFE in the evaluation of patients with myeloma and other plasma cell disorders have been lack of analytical sensitivity in oligosecretory lesions and the unwieldiness of 24-hour urine collections. "Traditional" SPEP and IFE studies are particularly insensitive in the evaluation of patients with AL amyloidosis (32).

Studies conducted since the development of the quantitative kappa and lambda sFLC assays have led to the creation of expert guidelines for the clinical applications of these tests (24). The combination of the sFLC assays, SPEP, and serum IFE is a highly sensitive screen for myeloma and related plasma/B cell proliferative diseases and, except in the case of suspected AL amyloidosis, negates the need for 24-hour urine studies (32–38). (Tissue biopsy is still required for definitive diagnosis of all of these entities.) Baseline sFLC measurements offer prognostic value in essentially all plasma cell disorders (including monoclonal gammopathy of undetermined significance [MGUS]) (39–42). The sFLC assay provides utility in quantitative monitoring of patients with "oligosecretory" plasma cell diseases including oligosecretory myeloma, nonsecretory myeloma (when there is an abnormal sFLC kappa or lambda concentration), and light-chain (AL) amyloidosis. (Elevations of sFLC are not observed in all patients with nonsecretory myeloma.) Several studies support the use of absolute sFLC measurements (i.e., free kappa and/or free lambda) in monitoring with AL amyloidosis, oligosecretory myeloma, nonsecretory myeloma (applicable cases), and solitary plasmacytoma (24). Currently, as emphasized by the 2009 International Myeloma Working Group guidelines, the data do not justify the use of serial sFLC measurements *rather than* serial measurements of *otherwise measurable* M-proteins by SPEP, serum IFE, and/or quantitative 24-hour urine Bence Jones protein quantification studies in patients with multiple myeloma (24).

Katzmann and Rajkumar recently summarized a series of studies that addressed the clinical utility of junctional epitope-HLC assays (28). First, Bradwell et al. (44) and Ludwig et al. (45) provided data that suggest that the diagnostic sensitivity of HLC-pair ratios (e.g., IgGκ/IgGλ) in multiple myeloma is similar to that of SPEP plus serum IFE. These investigators also observed that highly abnormal HLC-pair ratios were prognostic (44, 45). Finally, Katzmann et al. (46) used the junctional epitope assay to reveal that heavy/light-chain-pair suppression (e.g., suppression of IgGλ in patients with IgGκ MGUS) is an independent predictor of disease progression (MGUS to multiple myeloma). The last observation may refine risk assessment for MGUS patients beyond that available by simple estimation of serum M-protein concentration (30).

VISCOSITY MEASUREMENT

Viscosity is the intrinsic resistance of a fluid to flow. Abnormalities of the formed elements of blood (e.g., increased red blood cell mass, decreased red blood cell deformability, and changes in numbers and/or properties of white blood cells) and abnormalities of plasma proteins (e.g., increased immunoglobulin concentration) can cause hyperviscosity. While emerging technologies such as laser Doppler velocimetry and mass-detecting sensors can be used in clinical viscometry (47), most laboratories continue to employ either Ostwald, Wells-Brookfield, or falling-drop viscometers.

Ostwald viscometers are based on the relationship between fluid viscosity and the rate of flow through a fixed wall narrow-bore tube. The greater the viscosity of either anticoagulated whole blood, plasma, or serum, the lower the rate of flow. Typically, the flow rate of the sample of interest is compared to a standard (e.g., water). The Wells-Brookfield viscometer employs a stationary plate (sample cup) and a cone (needle) that is rotated within the cup by a motor run at a constant speed under standard temperature conditions (37°C). The fluid sample of interest is placed into the cup in which the cone rotates. (The fluid spreads between the apposed sample cup/plate and the rotating needle/cone.) The greater the viscosity of the fluid, the greater the torque generated. In turn, the torque is measured with a torque meter and translated into "viscosity." Falling-drop viscometry exploits the fact that particulates fall more slowly through a viscous fluid than through a less viscous fluid.

The viscosity of biological samples is typically reported in SI (International System of Units) unit centipoise (cP); normal plasma viscosity is approximately 1.35 to 1.85 cP. (Water exhibits a viscosity of 1.0 cP at 37°C). Whole-blood viscosity can also be expressed as "equivalent hematocrit of whole-blood viscosity," which is the viscosity equivalent to that exhibited by anticoagulated whole blood at the given hematocrit. Clinical interpretation of "equivalent hematocrit" requires an actual hematocrit measurement for comparison. For example, a patient with hyperviscosity due to a high concentration of a monoclonal paraprotein might exhibit a hematocrit equivalent of 55% and an actual hematocrit of 40%. In this case, the "excess" viscosity is attributable to the paraprotein. Conversely, a patient with polycythemia and hyperviscosity might exhibit a hematocrit equivalent of whole-blood viscosity of 55% and an actual hematocrit of 55%. In this case, the elevated viscosity is wholly attributable to the increase in red blood cell mass. Tables or figures that display the mathematical relationship between hematocrit and viscosity of whole blood are useful in clinical practice (4), particularly given the nonlinear relationship between hematocrit and whole-blood viscosity (see below).

CLINICAL ASPECTS OF VISCOSITY MEASUREMENT

The most common cause of hyperviscosity is the presence of a paraprotein. More than 80% of cases of hyperviscosity are due to an IgM paraprotein associated with Waldenström's macroglobulinemia. IgM molecules possess a high molecular mass (pentamers are approximately 900 kDa) as well as a shape that increases their intrinsic viscosity. IgA paraproteins, less commonly IgG paraproteins, and rarely, very high concentrations of polymerized or aggregated monoclonal light chains can also result in hyperviscosity (5). Increases in red blood cell mass (e.g., polycythemia), reduced deformability of red blood cells (e.g., hemoglobinopathies), and very high white blood cell counts (e.g., chronic lymphocytic leukemia) can also increase whole-blood viscosity. It is important to recognize that the arithmetic relationship between hematocrit and whole-blood viscosity is nonlinear (5). There is a steep upward inflection in viscosity near a hematocrit of 60%. As a result, a patient may be asymptomatic with a hematocrit of 55% and dramatically affected at 60%. As alluded to above, hyperviscosity attributable to a paraprotein increases both whole-blood *and* plasma (or serum) viscosity, while abnormalities of formed elements affect whole-blood viscosity *but not* plasma (or serum) viscosity.

Symptoms and signs of hyperviscosity are primarily rheologic but quite varied. They include fatigue, blurred vision, headache, tinnitus, decreased hearing, vertigo, paresthesias, segmental dilation of retinal veins, retinal hemorrhage, mucosal bleeding, nystagmus, ataxia, somnolence, stupor, and coma (5). Individual patients exhibit different thresholds and findings, but symptoms and signs of hyperviscosity "typically" occur when whole-blood viscosity exceeds 4 cP (2 to 3 times the normal level). For example, an individual with advanced atherosclerosis involving the cerebral vasculature might exhibit neurologic symptoms and signs of hyperviscosity with a plasma viscosity of 3 cP, while an otherwise healthy person (with patent and distensible vessels) might not become

symptomatic until plasma viscosity reaches 6 cP. Serum protein electrophoresis, IFE, a complete blood count with differential, and review of a peripheral blood smear nearly always elucidate the underlying cause of hyperviscosity. In the great majority of cases of clinically significant hyperviscosity, the underlying etiology has previously been established (e.g., Waldenström's macroglobulinemia and multiple myeloma).

Clinical Indications and Applications of Serum and Urine Protein Electrophoresis

DAVID F. KEREN AND RICHARD L. HUMPHREY

8

Protein electrophoresis is performed on serum (SPEP) and urine (UPEP) to detect and quantify monoclonal gammopathies (M proteins). In effect, serum and urine protein electrophoresis provides an immunochemical biopsy of the humoral immune system. However, other clinically relevant information is also available from examination of the proteins demonstrated from these studies. This chapter reviews basic principles of electrophoresis, the types of apparatus that are available, quality control and quality assurance procedures, costs, and illustrative patterns with recommended interpretations.

BACKGROUND ON PROTEIN STRUCTURE

Electrophoresis of serum and urine in the clinical laboratory takes advantage of the fact that each major protein has its own unique structure. Proteins are composed of amino acids, each of which contains a basic amino group ($-NH_2$), an acidic group ($-COOH$), and a portion that is specific to each amino acid, referred to as an R group (Fig. 1). The R groups may be acidic or basic, and they vary in size from a single hydrogen atom, to linear or branched hydrocarbon chains, or to a complex double ring structure. The complex structure and charge characteristics of these amino acids and the unique amino acid sequence of each protein determine the position that the protein migrates to on electrophoresis (1).

The primary structure of a protein results when amino acids connect to one another by linking the amino group of one amino acid to the carboxyl group of the next. During construction of this covalent peptide bond, a water molecule is released (Fig. 2). The resulting linear chain of amino acids is a polypeptide containing a free amino group at one end (N terminus) and a free carboxyl group at the other end (C terminus). Assembly takes place on the ribosome reading mRNA transcribed from DNA. The amino acid composition and linear structure of each protein are therefore determined by the information encoded in the individual's DNA.

As the polypeptide chain of amino acids takes form, a simple secondary structure is created by folding along one dimension and is held together primarily by hydrogen bonds. These may take the shape of random coils, an α helix, or a β-pleated sheet. A three-dimensional tertiary structure forms as a result of several types of attachment: hydrogen bonds, disulfide bonds, van der Waals forces, and hydrophobic bonds. In more complex molecules such as immunoglobulins, a quaternary structure forms when several polypeptide chains link together. For instance, consider the immunoglobulin M (IgM) molecule. Though classified as a single protein, it consists of 10 identical heavy chains, 10 identical light chains, and 1 joining chain. These protein chains combine to create a molecular mass of about 900 kDa. Finally, many proteins are glycosylated with carbohydrate groups that are covalently attached. These carbohydrate groups stabilize the protein's conformation (2). Following synthesis of the protein, post-translational modifications which convey heterogeneity to the protein may occur. These include phosphorylation, N-terminal acylation, side chain acylation, sulfation of tyrosine, C-terminal α-amidation of glycine, and γ-carboxylation of glutamic acid (1)

The charge on the protein molecule and, consequently, its migration on serum and urine protein electrophoresis are determined both by its constituent amino acids and by the pH of the buffer used for the electrophoresis. Each protein may be defined by its isoelectric point (pI), the pH at which its positive and negative charges are equal and hence migration does not occur in an electric field. At pH 8.6, which is used for agarose gel electrophoresis, the algebraic sum of the protein's positive and negative charges determines its migration through the gel. This allows the laboratory to separate the major serum proteins into unique bands and fractions that can be used to identify a wide variety of clinical conditions (Fig. 3).

PRINCIPLES OF PROTEIN ELECTROPHORESIS

The first studies on serum protein electrophoresis were performed entirely in a fluid-based system devised by Arne Tiselius, winner of the 1948 Nobel Prize in Chemistry. He called his method moving boundary electrophoresis (3, 4). In that regard, it is similar to the most recently available technique of capillary electrophoresis. In his system, Tiselius layered a mixture of proteins in the form of serum on a buffer in a U-shaped tube with electrodes at each end of the U. The migration of the proteins through the electrical field was detected by a sensitive Schlieren band optical system. With this technique, the major serum protein fractions of albumin and α, β, and gamma globulins were defined.

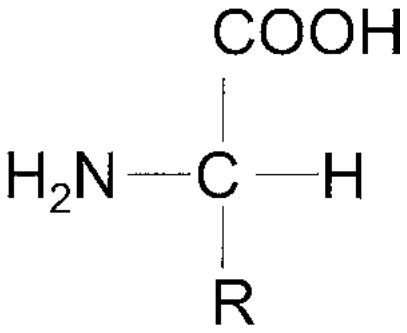

FIGURE 1 General structure of an amino acid. The R group determines the specific amino acid.

Zone Electrophoresis

In the late 1930s, filter paper was deployed as the first solid support medium to improve separation and allow direct visualization of the major protein fractions. The filter paper was placed between two reservoirs of buffer with electrodes at each end. The protein solution was carefully applied to the filter paper, and after electrophoresis, the major bands were visualized by use of a protein dye. However, the use of this support medium introduced new variables such as the texture of the medium, which provided resistance to protein migration, as well as charge effects due to endosmotic flow (5). The resistance would vary according to the filter paper brand and lot. Endosmotic flow changes reflected the fact that the support medium itself contained a net negative charge that could not migrate. As a consequence, the positive buffer ions would flow toward the cathode. The result was that weakly anionic proteins were pulled cathodally from the application point. The use of cellulose acetate and agarose began in the 1950s, and by the 1970s, they had vastly improved the resolution of protein electrophoresis. These clear support media allowed rapid electrophoresis, crisp separation of major protein fractions, and densitometric scanning to quantify the protein fractions (6).

The simplicity of separation in a fluid-based system has been revisited in the past decade with the development of capillary electrophoresis. In this procedure, instead of

a large, glass U-shaped tube, thin fused silica capillaries, about 25 μm in diameter, are the vessels through which the proteins pass. The narrow silica capillaries create a huge negatively charged surface area that results in a strong endosmotic flow toward the cathode. At strong alkaline pH (10.0), the proteins are pulled by the endosmotic flow past a UV detector which uses a 200- or 215-nm wavelength. It permits recording of the amount of each protein fraction on an electropherogram as a densitometric scan, and it is able to convert the values to a virtual gel image (Fig. 3) (7–13).

Unfortunately, while detection of peptide bond absorbance at 200 to 215 nm is efficient, it also detects other substances that absorb at those UV wavelengths. So far, the most frequent causes of false-positive deflections in the electropherogram have been radiocontrast dyes and, occasionally, antibiotics (8, 14–17). Radiocontrast dyes and some antibiotics can produce suspicious bands anywhere from the transthyretin (prealbumin) area through the γ region (Table 1).

One key feature in the evolution in electrophoresis systems has been the improvement in resolution. With the development of clear cellulose acetate gels in the 1950s, densitometric scans could distinguish five major protein fractions, with the bands in each fraction being relatively diffuse. Improvements have included an enclosed system that prevents evaporation of buffer. This helps to keep the ionic concentration of the buffer constant. Additional improvements have involved the addition of calcium lactate to buffer, the use of thin gels, and the use of cooling devices to control heat production. These improvements, applied to zone electrophoresis and capillary electrophoresis, have enhanced their ability to identify M proteins that are present in low concentrations and protein genetic variants, such as α_1 antitrypsin, that were difficult or impossible to visualize with previous techniques (Fig. 4).

TABLE 1 Location of radiocontrast and antibiotic spikes on capillary electrophoresis[a]

[a]Table from reference 1.

Guidelines for the diagnosis of monoclonal gammopathies recommend the use of electrophoretic systems that provide a crisp separation of the β_1 from β_2 region, and which are able to recognize M proteins as low as 0.05 g/dl in the γ region (18, 19). In the β region, measurement of M proteins is complicated by the presence of transferrin and C3. However, by taking advantage of so-called immunosubtraction techniques (see chapter 9) on capillary electrophoresis, one can determine the amount of the β region that is occupied by the M protein (see below).

With currently available semiautomated gel systems, the samples are placed in a well connected to special paper that wicks the sample to its sharp edge, which is applied directly to the surface of the gel. This application process can be interfered with by the presence of particulate matter in some urine samples or the precipitation of immunoglobulins in the serum of patients with cryoglobulinemia (8, 20). To prevent such problems, it is recommended to centrifuge the urine and ensure that the paper moistens all the way to the sharp edge. In addition, it is advisable to always compare the total protein value with the color intensity observed in the gel. This will aid in preventing false-negative results. Laboratories should establish their own reference ranges when adopting these techniques. While the different methods provide similar numbers, significant differences have been reported (Table 2) (16, 21).

QUALITY CONTROL AND QUALITY ASSURANCE

Specimen Requirements for Serum

For serum testing, the blood sample should be drawn into a Vacutainer tube without anticoagulant. After clotting, the serum is separated and stored at 4°C for up to 72 h. Although serum can be used after 72 h, C3 will deteriorate. Loss of C3 integrity will change the quantity of protein in the β_2 region of the electrophoresis. If the sample is to be held longer than 72 h before electrophoresis, freezing the sample at −20°C preserves the C3 for future analysis.

Proper sample collection is important because interferences can create special problems for interpretation. Hemolysis will provide a broadly migrating band in the α_2-β region, reflecting the presence of hemoglobin haptoglobin complexes. This may obscure or even mimic an M protein in this region. Lipemic samples may not disperse effectively

α_2	0.41–0.69	0.39–0.64
β	0.65–1.00	0.55–0.87
γ	0.49–1.21	0.53–1.32

[a]Data modified from those of Bossuyt et al. (16).

into a gel. Centrifugation followed by use of the clear layer below the lipid (the infranatant) may provide an adequate result if a better sample cannot be obtained.

Specimen Requirements for Urine

An early morning void collected into a container without preservative is adequate for screening for the presence of monoclonal free light chains (MFLC, or Bence Jones protein) (21). The urine should be stored at 4°C until electrophoresis. Prior to electrophoresis, the sample should be concentrated to optimize the detection of MFLC. The amount of concentrating necessary depends on the protein concentration of the urine. Usually, a 100-fold concentration is sufficient for urine samples with relatively small amounts of protein. One approach is to place the urine samples into a commercial ultrafiltration concentrating device and allow them to concentrate for a set period of time. One of our laboratories uses a concentration period of 4 h. Samples with small amounts of protein will concentrate more rapidly, up to 100 times, whereas urine specimens with high protein concentrations will concentrate to a lesser degree. If the patient is known to have an M protein in the serum and/or an MFLC in the urine, a 24-h urine sample should be collected in a container without preservative. Collection of the sample is key to obtaining accurate and reproducible information about the M protein. The first morning of the collection, the patient should be instructed to note the time when the collection is begun and to empty his or her bladder prior to the start. The next day, at the same time, finish the collection by including the final bit of urine in the 24-h collection. While this may seem excessively compulsive, if the first sample is included, it may be including urine which has been in the bladder for as long as 8 h (effectively making this a 32-h collection). The container should be refrigerated at 4°C between collections to minimize deterioration of proteins and growth of microorganisms. The 24-h collection is needed to quantify the amount of MFLC in the estimation of tumor burden and the response to therapy.

Internal Controls

Each protein electrophoresis analysis should have a control sample run on each gel. The percentage of the protein in each fraction should be recorded and compared day to day. Even with urine protein electrophoresis, serum controls are recommended because normal urine contains only trivial amounts of protein and would not serve as an adequate estimation of the migration of proteins on the gel. The controls should be evaluated for migration position of the major bands and for the amount of protein in each region. One convenient way to do this is by using a Levey-Jennings chart (Fig. 5). For systems such as capillary electrophoresis, which may have as many as 8 capillaries, each capillary should have such samples performed daily because the separation characteristics will differ slightly from one capillary to the next.

PROTEINS IDENTIFIED IN SERUM PROTEIN ELECTROPHORESIS

Using agarose or acetate electrophoresis, serum proteins were classified as the five major regions identified by electrophoresis: albumin, α_1, α_2, β, and γ. However, we now can recognize several specific major proteins by electrophoresis (Fig. 3). A tiny transthyretin (formerly named prealbumin) band may be seen on systems with superior resolution (Fig. 3). It is a 55-kDa protein that is used mainly to assess the nutritional status of patients with protein calorie malnutrition. The normal concentration in serum (20 to 40 mg/dl) is too small to be reliably evaluated by serum protein electrophoresis; therefore, measurements are usually performed by nephelometry. Rare genetic abnormalities of transthyretin are the most common cause of hereditary senile systemic amyloidosis and familial amyloidotic polyneuropathy (22).

Albumin is the main serum protein. It is a 69-kDa protein that is responsible for the osmotic effect of serum proteins and serves as a transport protein for a wide variety of molecules. An innocuous variant, bisalbuminemia, is occasionally seen. Analbuminemia is a rare condition where patients do surprisingly well. Occasionally, the latter patients require diuretics to control mild edema and some have had elevated cholesterol levels.

α_1 lipoprotein (high-density lipoprotein) is better evaluated by specific biochemical methods, but it may be seen on serum protein electrophoresis. On gel-based techniques, it usually accounts for the faint, diffusely staining broad band between the α_1 antitrypsin band and albumin. By capillary electrophoresis, it may migrate in the albumin or the α_1 region depending on the system used.

α_1 acid glycoprotein is a heavily glycosylated acute-phase reactant protein that migrates just anodal to α_1 antitrypsin. With its usual concentration of 50 to 150 mg/dl and heavy glycosylation, it is either barely visible or not seen on normal samples. However, with acute-phase reactions, it is seen on the anodal side of α_1 antitrypsin. Because the glycosylation interferes with protein staining, it is not seen well on gel-based methods. However, capillary electrophoresis methods show it as an anodal shoulder to the α_1 antitrypsin band. It may be especially prominent in patients with an acute-phase reaction.

α_1 antitrypsin is a 52-kDa protein that is a member of the serine protease inhibitors (serpins). It functions to inhibit a wide variety of proteases, including trypsin, and increases during an acute-phase reaction. This important protease inhibitor (PI) is usually present as PIMM, the normal homozygous type. However, there are several genetic variants. The Z and S variants are secreted in decreased amounts and are ineffective in inhibiting proteases. These variants in their homozygous form predispose the patient to emphysema and cirrhosis. The α_1 region must be carefully scrutinized to be certain that the α_1 antitrypsin band is present with

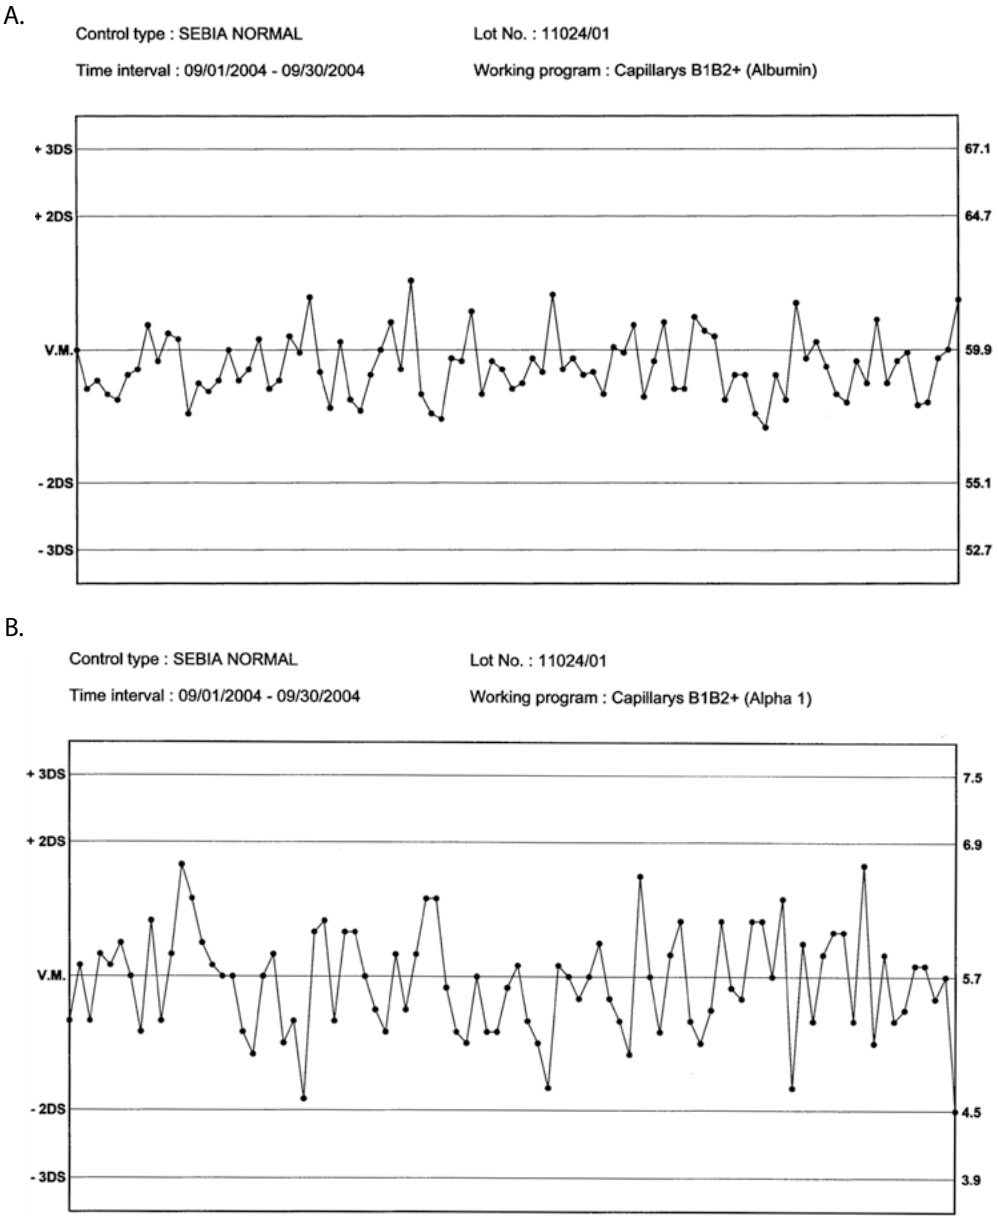

FIGURE 5 (A) This Levey-Jennings chart monitors the daily variation of albumin in the normal control sample performed on capillary zone electrophoresis for 3 months. No control sample is beyond 2SD (2 standard deviations) and no trend of high or low values is evident, indicating consistent precision. (B) This Levey-Jennings chart monitors the daily variation of the α_1 fraction in the normal control sample performed on capillary zone electrophoresis for 3 months. Wider swings of the daily value are present in the α_1 fraction than in albumin (panel A) due to the smaller percentage of proteins present in this fraction. Nonetheless, no sample is beyond 2SD and no trend of high or low values is evident on either chart, indicating consistent precision. V.M., median value.

appropriate migration. When heterozygotes are present, two discrete bands are seen (Fig. 4). When there is a homozygous PIZZ deficiency, the capillary electrophoresis electropherogram will show a flat α_1 region with the α_1 antitrypsin band missing. However, there is an underlying protein, orosomucoid (also known as α_1 acid glycoprotein), that may be present in sufficient amount to account for an α_1 fraction measurement in the lower end of the normal range (Fig. 6). In contrast, when a serum with a homozygous PIZZ deficiency is viewed on an agarose gel, the pattern indicates a virtual absence of protein staining in the α_1 region (Fig. 6). The disparity between these two techniques reflects the ability of capillary electrophoresis to measure orosomucoid more accurately than densitometry by agarose gels. This is because orosomucoid is a heavily glycosylated molecule that does not stain well with protein dyes and consequently is not seen on agarose gel electrophoresis. Since capillary electrophoresis uses peptide bond absorbance for detection, it is measured more accurately on capillary electrophoresis.

α_2 macroglobulin is a huge 720-kDa molecule that is a member of the thiol ester plasma proteins and functions as a protease inhibitor. Despite this, it is not an acute-phase

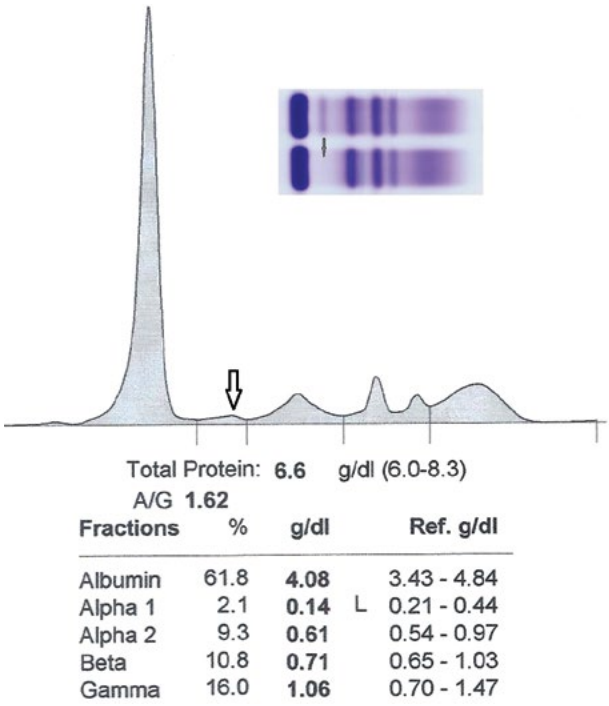

FIGURE 6 The capillary zone electropherogram pattern has a relatively flat α_1 fraction with a markedly blunted α_1 antitrypsin peak (arrow). This indicates the lack of the α_1 antitrypsin band which is consistent with the quantitative decrease of that fraction. However, the protein that remains in the α_1 fraction is orosomucoid (α_1 acid glycoprotein). This protein is measured by capillary zone electrophoresis, but not usually stained by protein dye on gel electrophoresis. Insert above shows two serum samples performed on gel electrophoresis. The top pattern shows a normal serum with a prominent α_1 antitrypsin band while the bottom pattern has a clear α_1 region because the α_1 antitrypsin band is not seen and the orosomucoid does not stain well with the protein dye. Ref., reference; T.P., total protein; A/G ratio, albumin-to-globulin ratio; L, low value.

protein. It is elevated in patients with nephrotic syndrome primarily due to its large size. Serum levels are moderately higher in cord blood.

Haptoglobin is the other major α_2 region protein. It binds free hemoglobin and exists in various forms. The 1-1 genotype, with a mass of 86 kDa, migrates slightly anodal to α_2 macroglobulin. The 2-1 genotype, with a mass of 86 to 300 kDa, completely overlaps α_2 macroglobulin, and the 2-2 genotype, with a mass of 170 to 900 kDa, is located slightly cathodal to α_2 macroglobulin. Because it binds free hemoglobin, haptoglobin is decreased in hemolysis but increases during an acute-phase reaction.

Transferrin, the major β_1 region molecule, is a 76.5-kDa protein that transports non-heme ferric iron. During acute-phase reactions, this protein decreases in concentration. In serum, it contains two complex carbohydrate chains, each with a sialic acid residue. Cerebrospinal fluid contains both this form of transferrin and one that lacks the sialic acid residues. The latter fraction of transferrin migrates in the β_2 region and has been used to distinguish leakage of cerebrospinal fluid from nasal or aural secretions.

β_1 lipoprotein (low-density lipoprotein) is more precisely evaluated by specific biochemical methods but may be seen in the β region on gel-based systems and in either the albumin or α_1 region on capillary electrophoresis methods. It is an enormous molecule measuring 2,750 kDa.

C3, the third component of complement and the only one readily visualized on serum protein electrophoresis, is the major β_2 region molecule. It consists of two chains, a 110-kDa α chain and a 75-kDa β chain. The level of C3 is elevated late during an acute-phase reaction. If the sample is not stored at 4°C, it quickly breaks down into smaller components.

Fibrinogen is a 340-kDa protein present in plasma but not in normal serum (Fig. 7). However, if the patient is anticoagulated, the sample is drawn into a tube containing an anticoagulant, or if the serum is separated before clotting is completed, the sample may have enough residual fibrinogen to give a band in the β-γ region that can be confused with an M protein.

C-reactive protein is a 135-kDa protein that migrates in the γ region. Its name derives from its ability to react with

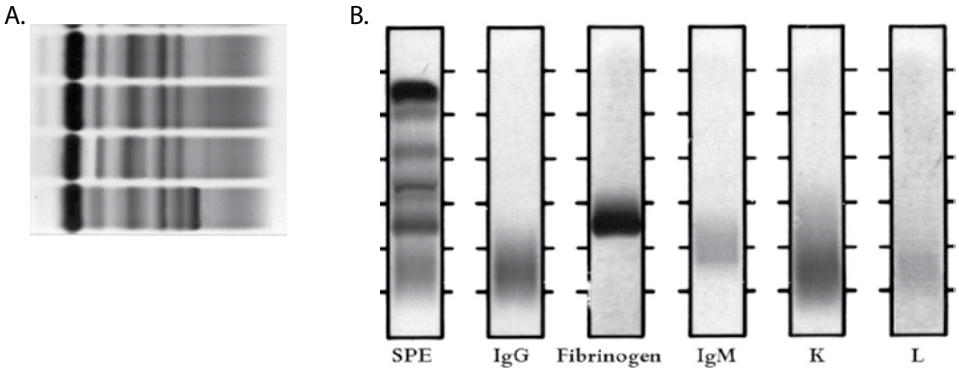

FIGURE 7 (A) Results of agarose gel electrophoresis for four samples are shown. The bottom sample has two unusual findings. The α_1 region shows two light staining bands that almost merge. This reflects the presence of an α_1 antitrypsin variant. In this case, it would be consistent with a faster-migrating variant (F) but needs to be confirmed by molecular studies. However, the second unusual feature is a densely staining band in the slow β region (β_2). This band could be an M protein; however, fibrinogen also migrates in this region. (B) IFE results for a sample similar to that shown in panel A are shown. Here the band reacts with anti-fibrinogen but not to anti-IgG, -IgM, -κ (K), or -λ (L) antisera.

the capsular polysaccharide of *Streptococcus pneumoniae*. It is an early indicator of an acute-phase reaction and is best measured by nephelometric techniques.

Immunoglobulins migrate mainly in the β and γ regions. IgG is the main serum immunoglobulin (700 to 1,600 mg/dl). It is a 160-kDa protein typically with a γ migration. It consists of four subclasses: IgG1, IgG2, IgG3, and IgG4. Because the body has many more B lymphocytes programmed to produce an IgG immunoglobulin after an appropriate antigen encounter, a neoplastic transforming event acting randomly on the available B cells will result in many more IgG M proteins than M proteins of the other major immunoglobulin classes (e.g., IgA or IgM). In multiple myeloma (MM), an IgG M protein usually produces a large γ region spike that is readily measured by densitometry on agarose gels or by a capillary electrophoresis electropherogram (Fig. 8). Polyclonal increases of IgG occur in chronic infections, liver disease, and some autoimmune diseases. These increases may be small or massive depending on the chronicity and severity of the condition. Typically, they are broad based, spanning the entire γ region and occasionally extending into the β-γ region (Fig. 9). However, a modest polyclonal increase in the IgG4 subclass gives a subtle, but noticeable, increase in the anodal portion of the γ region that, on occasion, may mimic an M protein (Fig. 10). Such polyclonal increases can be distinguished from M proteins by performing an immunofixation (IFE) or immunosubtraction (see chapter 9). IgG4-related systemic disease is a grouping of several conditions that share a diffuse lymphoplasmacytic infiltrate dominated by IgG4 plasma cells. The reports of this condition have included Mikulicz disease, autoimmune pancreatitis, sclerosing cholangitis, prostatitis, thyroiditis, and eosinophilic angiocentric fibrosis (23–25).

FIGURE 8 A capillary zone electropherogram is shown with a prominent M protein spike (shaded) and suppression of the normal gamma globulin. The spike measures 1.9 g/dl, and the total gamma globulin is 2.0 g/dl. Only 0.1 g/dl is accounted for by the gamma globulin not measured in the M protein spike. Ref., reference; T.P., total protein; A/G ratio, albumin-to-globulin ratio; H, high value.

IgM migrates in the β-γ region (40 to 230 mg/dl). It is a 900-kDa molecule that exists as a pentamer. It is the earliest immunoglobulin to respond to antigenic stimulation but does not appear to have a memory response. Uncommonly, an isolated polyclonal increase in IgM may produce a broad restriction in the anodal portion of the γ region.

IgA in the serum exists mainly as a 160-kDa monomer (70 to 400 mg/dl), but in mucosal secretions, it exists mainly as a dimer attached to secretory component (380 kDa). It is the second most common M protein involved in MM. A polyclonal increase in IgA results in a bridge between the β and γ regions. It can be quite prominent in some cases of cirrhosis, but more modest increases will occur in a wide variety of mucosal infections.

IgD is present mainly on the surface of lymphocytes, while in serum, only small quantities are found (0 to 8 mg/dl). IgD is the heavy chain type of 1 to 2% of MM cases. In such cases, it is often present in relatively small amounts, while the tumor secretes large amounts of MFLC.

IgE is present mainly on the surface of mast cells and basophils. Serum concentrations are measured only in patients with allergies, especially allergic bronchopulmonary aspergillosis, and in the extremely rare cases of IgE myeloma.

Free κ (25 kDa) and λ (50 kDa) light chains normally exist in the serum at concentrations too low to be visualized by serum protein electrophoresis. However, by using a sensitive nephelometric technique, they can be quantified in the serum (see chapter 7). Indeed, the ratio of free κ/free λ in serum can replace the necessity for urine in an initial screen for MM (26) (see chapter 11). However, follow-up for cases of light chain MM requires a measurement of the involved monoclonal light chain in a 24-h urine sample by protein electrophoresis with densitometric scanning and by IFE to establish κ or λ clonality.

PATTERN INTERPRETATION FOR SERUM

Although the main reason for performing serum protein electrophoresis is to detect and quantify M proteins, there are several other electrophoretic patterns that can be detected which may be of clinical use. Some of these findings were mentioned above with regard to each major protein; however, other important electrophoretic patterns are reviewed here.

Liver Disease Pattern

In patients with cirrhosis, synthesis of hepatocyte-derived proteins such as albumin, transferrin, and haptoglobin is decreased. As shown in the capillary electrophoresis electropherogram in Fig. 11, this usually forms a stepwise increase from the α_2 through the γ region. However, due to inflammation and rerouting of blood around the liver, other proteins may be increased. Typically, the serum demonstrates hypoalbuminemia. There may be anodal slurring of the albumin band if bilirubin is elevated. A decreased α_2 globulin may also occur with a prominent β-γ bridging due to a polyclonal increase in IgA and a broad increase in the γ region reflecting the polyclonal increase in IgG.

Protein Loss Patterns

With nephrotic syndrome, loss of protein occurs through damaged glomeruli. The serum shows hypoalbuminemia, low or low-normal α_1 globulin. On the electrophoretic pattern relative to albumin, there is a dramatically elevated

Gamma	43.0	8.8 - 19.2	3.8	H	0.6 - 1.4

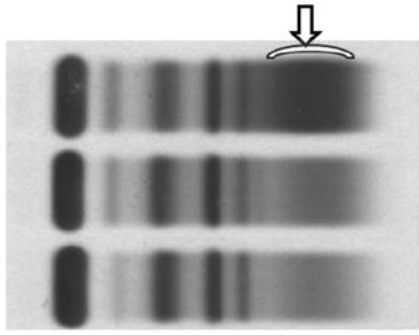

FIGURE 9 On the left, a capillary zone electropherogram demonstrates a slight decrease in albumin but a broad polyclonal increase in gamma globulins for a serum sample. On the right, three serum samples are shown on agarose gels. The top serum sample has a broad polyclonal increase in gamma globulins. The increased gamma globulins extend across the entire γ region. Ref., reference; T.P., total protein; A/G, albumin-to-globulin ratio; H, high value; L, low value.

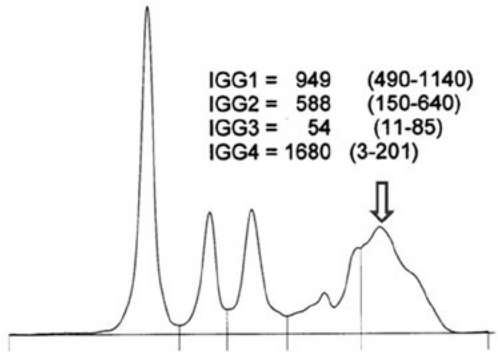
α_2 globulin due to retention of its large molecules, such as α_2 macroglobulin and haptoglobin, in the serum. On gel electrophoresis, the β region may be increased due to an elevated β_1 lipoprotein. However, on capillary electrophoresis, the lipoproteins migrate more anodally, often in the albumin region. By either method, the gamma globulin is in the low-normal range or hypogammaglobulinemia range, depending on the severity of the disease (Fig. 12).

In protein-losing enteropathy such as celiac disease, damage to the gastrointestinal tract can produce findings in



A/G 0.42
T.P. : 6.8

Fractions	%	Ref. %	g/dl		Ref. g/dl

Alpha 2	16.0	7.5 - 13.4	1.1	H	0.5 - 1.0
Beta	14.4	8.5 - 13.7	1.0		0.6 - 1.0
Gamma	27.9	8.8 - 19.2	1.9	H	0.6 - 1.4

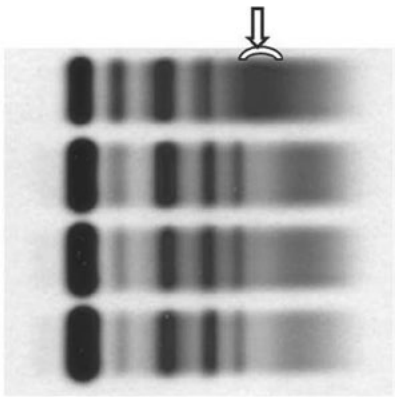

FIGURE 10 On the left, a capillary zone electropherogram is shown from a serum sample with an acute-phase reaction and a polyclonal increase in the IgG4 subclass. The acute-phase reaction is confirmed by the combination of low albumin (2.0 g/dl), increased α_1 and α_2 fractions, and a low transferrin (β_1) band. The γ region has relatively broad restriction, but it is limited to the anodal half of the γ region. This is a typical finding with a polyclonal increase in IgG4 subclass. As shown, the IgG4 subclass was increased 8-fold over the upper end of the normal range. On the right, four gel electrophoresis patterns are shown. The top one has a polyclonal increase in the IgG4 subclass. It shows a broad increase similar to that shown in Fig. 9, but this one extends from the slow β region to midway in the γ region. Polyclonal increases in the IgG4 subclass can be mistaken for monoclonal proteins unless an immunofixation electrophoresis is performed. Ref., reference; T.P., total protein; A/G, albumin-to-globulin ratio; H, high value; L, low value.

serum similar to those of the nephrotic syndrome with hypoalbuminemia, hypogammaglobulinemia, and occasionally elevated α_2 macroglobulin.

Milder patterns of protein loss may result in only decreased albumin and gamma globulin. Because most serum protein electrophoresis analyses are performed for patients for whom an M protein is in the differential diagnosis, when we see these findings, we recommend performing a urine protein electrophoresis and IFE to rule out MFLC, which may damage the glomeruli due to conditions such as AL amyloid (light-chain-associated amyloid), light chain deposition disease, or myeloma kidney.

Acute-Phase Pattern

An acute-phase reaction is the result of recent damage that may occur due to processes including infections, trauma, and inflammation, or it may result from therapeutic measures such as surgery. In the serum, largely due to the effect of interleukin-6, there is a decrease in albumin and transferrin (β_1 globulin) with an increase in α_1 acid glycoprotein (orosomucoid), α_1 antitrypsin, and haptoglobin (Fig. 10). In the mid- to fast-γ region, depending on the electrophoresis system being used, the C-reactive protein band may be seen. Later in the course of the inflammation, C3 increases. This has also been referred to as a subacute inflammation pattern.

FIGURE 12 This capillary zone electropherogram demonstrates a nephrotic pattern. The α_2 region is exaggerated by comparison with the dramatic decrease in albumin. Ref., reference; T.P., total protein; A/G, albumin-to-globulin ratio; H, high value; L, low value.

Hypogammaglobulinemia is never normal in an adult, even the elderly. When the total γ region value falls below the normal range of 2 standard deviations set in our laboratories, we note that hypogammaglobulinemia is present. This may be seen in a variety of conditions, including common variable immunodeficiency disease, chronic lymphocytic leukemia, well-differentiated lymphocytic lymphoma, light chain disease, and nonsecretory myeloma, or in patients who are receiving plasmapheresis or chemotherapy. About 10% of patients with isolated hypogammaglobulinemia defined in this manner will have an M protein that may be detected in serum and/or urine by IFE and/or by use of the serum free light chain test (27). Amyloid AL can sometimes be seen in cases of hypogammaglobulinemia. Measurement of the serum free light chains has been shown to help in detecting both cases of amyloid AL and cases of nonsecretory myeloma (see chapter 7) (28, 29).

Detection of M Proteins in Serum

Most M proteins belong to the IgG subclass and usually migrate in the γ region (Fig. 13, samples 6, 13, 14, 25, and 30). Since normal IgG migrates broadly throughout the slow β and γ regions, even a low concentration of M proteins measuring as little as 0.05 to 0.1 mg/dl can distort the pattern, especially in the presence of hypogammaglobulinemia. This is illustrated as the large β_2 region band in sample 24 of Fig. 13. Identification of the M protein requires immunologic demonstration that the M protein band is made up of only one heavy chain type and one light chain type. IFE and immunosubtraction electrophoresis are the two methods that are recommended for evaluating this condition.

M proteins, especially those of the IgA and IgM classes, are also commonly detected in the β region (Fig. 14). When there are M proteins in low concentrations, they can be more challenging to detect because of the presence of major proteins in that region, such as β_1 lipoprotein (on gel-based methods), transferrin, and C3 (Fig. 15). To detect

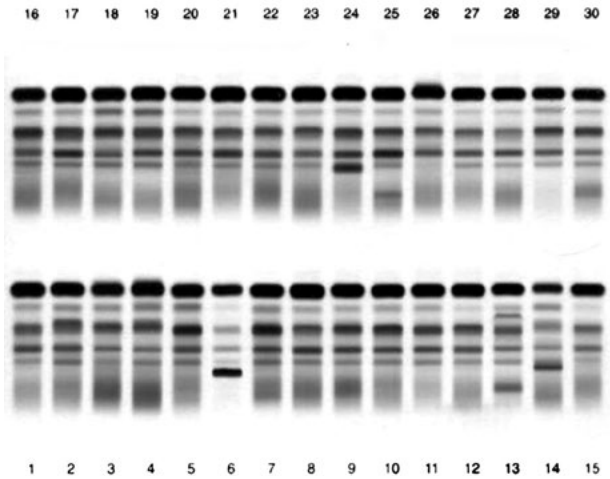

FIGURE 13 This agarose gel electrophoresis demonstrates 30 serum patterns. Samples 6, 13, 14, 25, and 30 demonstrate monoclonal restrictions in the γ region. Sample 24 shows an M protein overlying the usual C3 (β_2 region) band. When the usual β region bands appear fuzzy or enlarged, it often indicates the presence of an M protein. IFE is indicated.

such low amounts of M proteins, a high-resolution electrophoresis system is needed. When elevations of proteins are seen in the β region on densitometry or the electropherogram, in the case of capillary zone electrophoresis, that is unexplained by β-γ bridging (an illustration of this is the cirrhosis pattern), IFE or immunosubtraction electrophoresis is indicated to rule out an M protein. Occasionally, M proteins will appear as a shoulder to one of the other bands or even migrate directly on top of the band, producing an aberrantly large C3 or transferrin band.

M proteins may rarely reside in the α_2 region. These are difficult to detect because of the higher concentration of the proteins that normally migrate there. This is one reason why a negative serum protein electrophoresis does not rule out the presence of a detectable serum M protein. When a negative serum protein electrophoresis is found in a patient with a strong suspicion of having an M protein, an IFE of the serum should be performed. Indeed, the recommendation of the International Myeloma Working Group is to perform serum protein electrophoresis, serum IFE, and serum free light chain analyses for individuals suspected of having MM (see chapter 11).

An aggressive approach is recommended to further evaluate suspicious bands on a serum protein electrophoresis that does not have further testing requested by reflexing them to a serum IFE. Katzmann et al. have provided guidance as to the yield of M proteins for different types of suspicious bands (see chapter 11) (Table 3) (30). An M spike is extremely specific, with all electrophoretic patterns given that designation identified as an M protein by IFE in their study. Fuzzy bands are the finding that has the highest yield of the other suspicious findings. A fuzzy band is when one has a broadened or distorted major band, most often C3 or transferrin (Fig. 13, specimen 24). The increased size of the band is often due to an M protein that either comigrates with it, thus broadening it, or migrates slightly cathodal or anodal to it, giving the band (Fig. 15).

Quantification of Serum M Proteins

When using electrophoresis systems with sharp resolution, the lower limit of visualization of M proteins has been estimated at about 0.02 to 0.04 g/dl if the M protein is in the γ region (31, 32). Detection of low-concentration M proteins can be clinically significant. While most such M proteins will fall into the category of monoclonal gammopathy of undetermined significance (MGUS), some will be seen in patients with light chain myeloma, IgD myeloma, IgE myeloma, amyloid (AL), and other B-cell lymphoproliferative processes such as chronic lymphocytic lymphoma or well-differentiated lymphocytic lymphoma. Furthermore, even in cases of MGUS with M proteins considered too low in concentration to measure, but which were confirmed by IFE, Murray et al. found that slightly less than 1% of these cases progressed to a malignant plasma cell or B-cell proliferative disorder (33).

Once an M protein has been detected and characterized immunologically, one should try to quantify it if it is not too low in concentration. As a guideline, the International Myeloma Working Group uses 1.0 g/dl as the minimal amount measured when monitoring a response to therapy. This does not mean one cannot measure smaller amounts. However, care should be taken to consider the underlying polyclonal immunoglobulins in the γ region and the interfering proteins in the β region.

For γ-migrating M proteins that are clearly distinguishable from other proteins and with minimal background normal immunoglobulins, we recommend measuring the M protein band itself by densitometry for gel-based systems or by use of the electropherogram for capillary electrophoresis. The demarcation for the M protein is placed at the

notch it forms with the normal immunoglobulins (Fig. 8). For M proteins that are not high in concentration and whose base is obscured by other proteins such as transferrin, C3, or normal gamma globulins, we do not quantify the M protein level (Fig. 16). If one can make this distinction, the quantitative measurement will usually be better for monitoring patients with M proteins than a measurement by nephelometry of the total immunoglobulin of that class. The M protein measurement excludes most of the polyclonal immunoglobulins, whereas the nephelometric measurement will include them. This obscures to some degree the changes in the M protein on subsequent measurements. The use of immunosubtraction electrophoresis in capillary electrophoresis has helped to make this distinction in the α and β regions (see chapter 11). In addition, a new nephelometric procedure that measures heavy-light chain combinations, i.e., IgG(κ) versus IgG(λ), may prove useful for such challenging cases (34–37).

PATTERN INTERPRETATION FOR URINE

On 100-fold-concentrated urine samples, albumin in small amounts may be seen on protein electrophoresis in a variety of conditions. Normally, one may detect up to 150 mg of albumin during 24 h. The amount may be increased following strenuous exercise and in patients with diabetes.

FIGURE 16 Two capillary zone electropherogram patterns are shown. On the left, the C3 band appears enlarged and distorted. In a normal serum sample, it is usually equal to or less than the transferrin (β_1) band. Here, it is not only larger but shifted anodally compared to a sample from another patient (on the right). It is difficult to determine how much of this area is due to the M protein. However, if one can immunosubtract this band, one may be able to improve such measurements (see chapters 9 and 11). The serum sample for which results are shown on the right also has a distinct, though small, M protein in the γ region. It should be characterized by IFE, but it is too small to measure due to the relatively large amount of underlying polyclonal immunoglobulins. Ref., reference; T.P., total protein; A/G, albumin-to-globulin ratio; L, low value.

Mild glomerular damage will demonstrate the moderately sized major serum proteins that normally do not pass effectively through the glomerular barrier (Fig. 17). As long as the tubular reabsorptive function is intact, little or no faintly staining protein will be seen in the α_2 and β regions. When the capacity for the tubules to reabsorb protein is exceeded, small bands will be seen in these regions along with the faintly staining γ region. With severe nonselective renal disease, a pattern that resembles that of serum protein electrophoresis including, to a lesser extent, the large molecules in the α_2 region is found.

If only the tubules are damaged, the large amount of small serum proteins that normally pass through the glomerulus will not be reabsorbed and will appear in the urine. Typically, one will find a small amount of albumin and numerous bands of various sizes in the α_1, α_2, β, and γ regions (Fig. 17). After the interpreter gets used to the usual bands of tubular proteinuria, if a band is found in a different location, an IFE should be performed to establish electrophoretic homogeneity and κ or λ specificity. This identifies the presence of MFLCs.

When a large excess of a relatively small molecule is present, such as in myoglobin, β-microglobulin, hemoglobin, and lysozyme, if the amount excreted is greater than the tubular reabsorptive capacity, an overflow proteinuria pattern is seen. This situation must be studied by IFE to rule out the possibility that the band represents an M protein.

Detection of M Proteins in the Urine

MFLC (Bence Jones proteins) typically occur as monomers (~25 kDa) and dimers (~50 kDa), both of which pass into the glomerular filtrate. Uncommonly, free κ chains may exist as tetramers and free λ chains may exist as hexamers which are too large to pass into the glomerular filtrate.

An early morning void is the best urine specimen for the initial detection of MFLC. However, for initial detection of MFLC, measurement of serum free light chains (FLC) by means of nephelometric techniques is as effective for detecting patients with light-chain MM. They obviate the need for a urine sample (see chapter 7). However, once MFLC have been demonstrated in patients with light-chain-only MM, the International Myeloma Working Group recommends that they should be monitored by measuring the MFLC peak on the densitometric scan of 24-h urine collections.

While the serum FLC measurements may eventually be used to monitor these patients, the lack of linearity and problems with antigen excess effects have thus far limited the technique. Nonetheless, in cases where there is too low of a concentration of light chain present in a 24-h urine collection, serum FLC measurements have proven useful, especially in cases of AL amyloidosis and oligosecretory MM (29).

MFLC and M proteins may migrate anywhere from the α through the γ region on urine protein electrophoresis. Once one becomes familiar with the common patterns of glomerular and tubular proteinuria discussed above, unusual bands will become more apparent. This is more difficult with tubular proteinuria and its many bands from small proteins not reabsorbed than with glomerular proteinuria.

For optimal detection of MFLC, we recommend performing IFE and urine protein electrophoresis on all samples. For the initial detection of MFLC, we review our files on the patient to see if there is a known M protein in the serum. This is especially important in the case of unusual conditions such as IgD or IgE myeloma.

Commonly, both the intact M protein and the MFLC can be found in the urine of a patient with MM. The urine

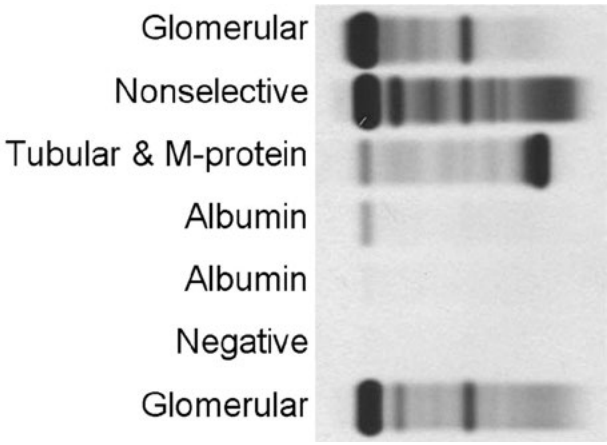

FIGURE 17 Several urine protein electrophoretic patterns are shown from concentrated urine samples. The arrow indicates the M protein in the third sample.

IFE is compared to the urine protein electrophoresis to determine which band is the MFLC. This band is measured by densitometry of the urine protein electrophoresis (Fig. 18). The concentration of the total protein in the urine is used with this measurement and the volume of the 24-h urine collection to determine the amount of MFLC per 24 h as follows: MFLC/24 h = (total protein concentration [mg/ml]) × (ml/24 h) × (% MFLC by densitometry).

The record of the urine protein electrophoresis and IFE is stored in a file with the serum protein electrophoresis, IFE or immunosubtraction (ISE), and serum FLC results.

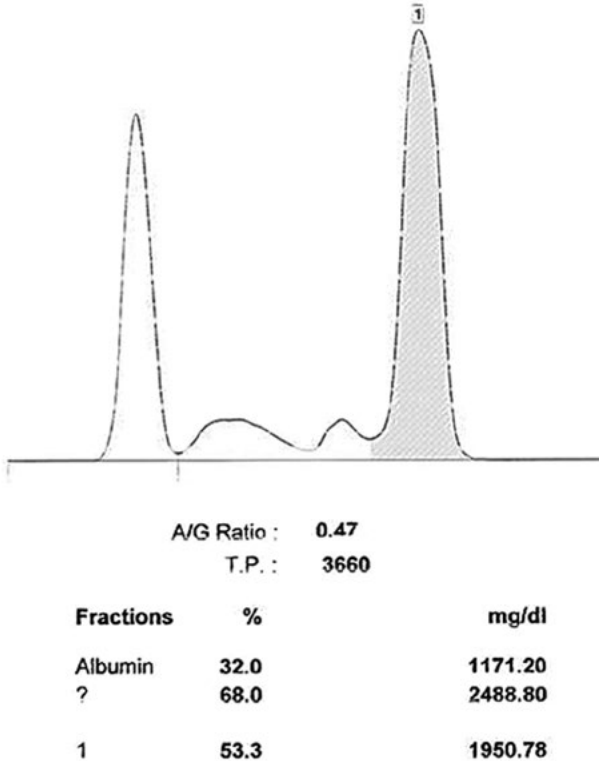

FIGURE 18 A densitometric scan of an agarose gel is shown from a urine sample with an MFLC measuring almost 2,000 mg/24 h. A/G ratio, albumin-to-globulin ratio; T.P., total protein.

This allows one to correlate the current results with previous results.

CLINICAL APPLICATIONS

Serum and urine protein electrophoresis are not general screening techniques. They are employed to detect M proteins in patients suspected of harboring plasma cell and B-lymphocyte proliferative disorders. For the initial detection of an M protein, serum protein electrophoresis, IFE, and serum FLC measurement are recommended to detect MM.

In occasional situations, such as suspicion of heavy-chain disease or AL amyloidosis in the face of negative serum and FLC studies, urine protein electrophoresis and urine IFE can provide useful information.

In addition to M proteins, however, performance of serum and urine protein electrophoresis often detects a wide variety of other abnormalities that can provide useful clinical information as described above. Therefore, attention to all regions of the electrophoretic pattern is needed, and such abnormalities should be included in the final report.

Avoiding False-Positive Results

Unexplained bands from the α through the γ regions may represent an M protein. However, before they are interpreted as being M proteins, this diagnosis should be secured by IFE or immunosubtraction (see chapter 9). In both capillary and gel-based electrophoresis, several proteins can produce bands that are not immunoglobulins but which may mimic an M protein. Fibrinogen, C-reactive protein, C3 variants, transferrin variants, hemoglobin-haptoglobin complexes, and markedly elevated β-lipoprotein can all be confused with an M protein band. Fibrinogen is commonly seen due to the presence of anticoagulants or an incompletely clotted specimen. It migrates in the slow β region on most gels, and because it is the only large band in that area that is not an immunoglobulin, it is easily ruled out by its position or by an IFE when in doubt (Fig. 7). Investigators quickly learn where fibrinogen and hemoglobin migrate on their gels. Other suspicious bands should be confirmed by IFE or immunosubtraction electrophoresis before being reported. When using capillary electrophoresis, interference from radiocontrast dyes and some antibiotics give deflections that may be misinterpreted as M proteins (Fig. 19). Some of these, such as sulfamethoxazole, produce a small deflection at the anodal end of albumin which should not be confused with an M protein (Table 1) (15, 17). Others, such as piperacillin-tazobactam (Tazocin; Wyeth), can produce a peak at the anodal end of the β region. One may remove these interfering substances by desalting or with activated charcoal (14, 38).

When performing IFE, the specificity of each new lot of reagent antiserum needs to be confirmed. The study of the antisera should include both serum and plasma. Even though plasma is not the specimen that is recommended for use, occasionally fibrinogen will be present for a number of reasons. These include the presence of anticoagulation therapy, inadequate time for the specimen to clot before the serum is removed from the clot, or drawing of the sample into a tube containing an anticoagulant. If the reagent antiserum against immunoglobulin contains reactivity for fibrinogen, a false-positive result may be recorded (39).

Correlation of Current with Previous Patient Results

Good quality assurance requires coordinating all available laboratory information on the patient. A record should be established for each patient the first time that an M protein is detected in the serum or urine. The record should contain the serum and urine protein electrophoresis and IFE or immunosubtraction electrophoresis gels and patterns along with key nephelometric studies, including serum FLC results and measurements of IgG, IgA, and IgM.

The patient's current specimen patterns should be compared with the first results obtained on the original M protein and also with the most recent previous sample. If the migration of the M protein matches that of the previous serum or urine sample, the amount of the M protein should be recorded on the report along with a statement as to whether it has increased, decreased, or remained unchanged since the previous sample. To have reproducible results, the International Myeloma Working Group requires M protein measurements of >1 g/dl to record a difference. It further defines a difference as a change of at least 25%. For urine MFLC measurements, they require at least 200 mg/24 h (40).

FIGURE 19 Two capillary zone electropherograms are shown. The one on the right is a control. The one on the left demonstrates the radiocontrast dye Omnipaque as a sharp band in the slow α_2 fraction (arrow). These samples require IFE or immunosubtraction electrophoresis to rule out a monoclonal protein. Ref., reference; T.P., total protein; A/G, albumin-to-globulin ratio; H, high value; L, low value.

With chemotherapy and/or stem cell transplantation, the original M protein usually declines and may disappear. This is accompanied by hypogammaglobulinemia, and occasionally, an oligoclonal response may be seen. Some oligoclonal bands may be as large as, or occasionally larger than, the M spike that can be seen with residual disease or a recurrence of the original M protein. However, as long as these oligoclonal bands do not have the same migration and isotype as the original M protein, they are not an indication of recurrence. Indeed, their presence may reflect recovery of normal immunoglobulin-producing clones and has been suggested as a favorable feature for event-free and overall survival by Alejandre et al. (41, 42).

The migration and the isotype identification of the M protein should be the same as that of the original M protein. If there is any change in migration, identification of the patient sample should be confirmed by IFE or ISE. If a new single M protein is identified, the clinician should be contacted to determine if the patient has had extensive chemotherapy and/or stem cell transplantation. Occasionally, one can find a very prominent band as part of an oligoclonal reaction. Usually, these will be transient. However, if there has been no significant change in the therapy, the appearance of a new M protein is highly unlikely. In that circumstance, it is recommended to repeat the SPEP on a freshly drawn sample to confirm that a likely patient identification error has occurred.

In the report, comment is also made about the remaining normal gamma globulins. Suppression of the gamma globulins is a negative prognostic indicator and, if severe enough, may predispose the patient to infections, possibly requiring gamma globulin replacement therapy (43).

Suppression of the normal immunoglobulins may be reported if the nephelometric measurements of the uninvolved immunoglobulin isotypes (IgA and IgM in the case of an IgG M protein) are below the normal range.

The International Myeloma Working Group recommends that if the intact M protein is present in the serum, its measurement should be used to monitor the response of the patient. However, about 20% of cases of MM only, or primarily, produce FLC. In that case, 24-h urine samples are indicated periodically (depending on the aggressiveness of the process and/or therapy) to monitor the tumor burden and to help estimate the degree of damage to the nephrons.

Patients with MGUS should have periodic urine and serum IFE depending on clinical judgment of the attending physician.

The availability of FLC testing in serum and urine has been shown to be useful both in the initial detection of MFLC and in monitoring patients with light chain disease (see chapter 7). The measurement of the FLC can replace the initial urine IFE for the detection of MFLC. Furthermore, serum FLC tests are useful to stratify the risk of progression to MM for individuals presenting with MGUS or smoldering MM.

The use of external quality assurance proficiency testing is essential to compare the results from one laboratory with those of others who are using the same system in the detection of M proteins and also to allow one to gauge the effectiveness of one manufacturer's electrophoretic system to correctly identify an abnormality versus the systems provided by other manufacturers.

Cost of Testing

Cost is mainly related to the number of samples assayed per day and selection of the most appropriate type of equipment used for the number of tests performed. In laboratories with relatively small volumes (2 to 4 serum samples per day), it may be worthwhile considering sending the test to a reference laboratory and using the resources of the laboratory for higher-volume testing or required stat testing. Laboratories with larger volumes (5 to 10 per day) may wish to use a manual assay and batch the testing once or twice per week. With a volume of about 20 per day, use of a semiautomated method decreases technologist time. At volumes of 40 or more per day, the bar-coded, automated capillary electrophoresis systems are highly efficient with excellent resolution.

Immunochemical Characterization of Immunoglobulins in Serum, Urine, and Cerebrospinal Fluid

ELIZABETH SYKES AND YVONNE POSEY

9

The characterization of immunoglobulins spans a spectrum of methods, including molecular analysis of gene usage and rearrangement, quantitation of immunoglobulin heavy chains as well as intact and free light chains, qualitative assessment and characterization of clonality, and identification of abnormalities that may be clinically significant, such as hyperviscosity syndrome, cryoglobulinemia, and amyloidosis (AL). This chapter focuses on qualitative methods for the assessment and characterization of clonality. The methods include agarose gel electrophoresis (AGE) with immunofixation, capillary electrophoresis (CE) with immunosubtraction (ISUB), and isoelectric focusing with immunoblotting or immunofixation. All three methods can be used to identify monoclonal, oligoclonal, and polyclonal immunoglobulin populations and to identify the heavy and/or light chains contained in the population. Immunofixation electrophoresis (IFE) and ISUB electrophoresis are diagnostic tools used for the identification of monoclonal gammopathies and, conversely, for the confirmation of polyclonal hypergammaglobulinemia. Isoelectric focusing with immunoblotting or immunofixation is a cerebrospinal fluid (CSF) diagnostic test for the identification of oligoclonal bands in multiple sclerosis (MS).

BACKGROUND

Intact immunoglobulins are products of clonal plasma cells that consist of two identical heavy chains (IgG, IgA, IgM, IgD, or IgE) and two identical light chains (kappa or lambda) (1). In order to ensure proper assembly, there is an approximately 40% excess of light-chain production; however, the free light chains are normally cleared and metabolized by the kidneys within hours of secretion (2, 3). In a normal immune response, each of the thousands of immunoglobulin idiotypes produced by plasma cell clones is present in a relatively small proportion. Because of the charge variability of the immunoglobulin molecules, they normally have a broad electrophoretic migration, described as polyclonal, on serum protein electrophoresis (PE). In contrast, a monoclonal gammopathy (paraprotein) represents a proliferation of a single plasma cell clone that produces an immunologically homogeneous protein commonly referred to as a monoclonal protein. It is essential that the laboratory distinguishes a monoclonal protein from a normal polyclonal distribution of immunoglobulins. Monoclonal proteins are often associated with a clonal process that is malignant or potentially malignant, whereas an increase in polyclonal immunoglobulins is due to an inflammatory or reactive process. Diagnoses associated with a serum monoclonal protein include monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma (MM), Waldenström macroglobulinemia, smoldering MM, AL, lymphoproliferative diseases, and plasmacytoma (4). Table 1 lists the distribution of diseases from 31,479 monoclonal gammopathies diagnosed by the Mayo Clinic's practice from 1960 to 2003. MGUS is the most common finding; however, MM is regarded as the hallmark malignant diagnosis (5).

Monoclonal proteins usually consist of an intact immunoglobulin; however, a plasma cell clone may produce only a monoclonal free light chain or, rarely, a monoclonal heavy chain. Because of the excess production of free light chains by plasma cells, it is not uncommon to find a small amount of monoclonal free light chain in addition to the intact monoclonal protein in the serum. The excess monoclonal free light chain may also be detected in the patient's urine. In IgG myeloma, for example, approximately three-fourths of patients have an excess of monoclonal free light chains that are excreted and detectable in the urine (6).

LABORATORY INVESTIGATION

Routine laboratory testing used to determine whether serum contains polyclonal immunoglobulins or a monoclonal protein includes agarose gel or capillary PE, IFE, and capillary electrophoresis with ISUB. The term immunosubtraction was patented by Beckman, so other companies have had to devise different terms for the procedure. However, this chapter uses the term ISUB for further discussion of the technique. Depending on initial findings and the patient's clinical presentation, additional investigations may include serum free light chain quantitations, urine PE, and urine IFE. Katzmann reviewed the ability of different test combinations to identify a monoclonal protein (7); details of that study are reviewed in chapter 11.

Both IFE and ISUB rely on the principles of immunoprecipitation; this refers to the interaction of multivalent antigen and antibody molecules that result in a lattice formation or precipitate (8). If too much antigen or too much

doi:10.1128/9781555818722.ch9

TABLE 1 Distribution of plasma cell proliferative disorders at the Mayo Clinic from 1960 to 2003[a]

Solitary or extramedullary plasmacytoma	2
Macroglobulinemia	2
Other	2

[a]*n* = 31,479 (5).

antibody is present, the lattice formation does not occur and a precipitate does not form. Therefore, manufacturers of commonly used gel-based IFE (Helena Laboratories, Sebia, Grifols [maker of InterLab]) and ISUB (Sebia, Helena) techniques produce antiserum in a concentration such that a precipitate forms with the immunoglobulin concentrations found normally in human serum. However, laboratories must be aware of the potential for antigen excess or antibody excess, which can still exist and allow a monoclonal protein to be missed. Serum samples for these procedures should be collected and stored refrigerated until analyzed. Refrigerated samples are stable for at least 2 weeks and can be frozen indefinitely.

Immunofixation

IFE is the composite of PE and immunoprecipitation. Proteins are first separated by agarose gel electrophoresis, and then antiserum is applied to precipitate the proteins of interest. When first introduced, IFE was a manual procedure; however, although more automation has now been introduced, technologists' techniques often still play an important role in the completed gel. Depending on the manufacturer, IFE gels are available in different sizes and configurations. Regardless of size, most IFE gels comprise six lanes for each serum sample; the first lane is used as the reference lane, and the remaining five lanes are used to evaluate IgG, IgA, IgM, kappa, and lambda. Serum of a specified dilution is applied to the application point of each lane. When IFE was first introduced, laboratories measured serum immunoglobulin concentrations in order to determine the appropriate serum dilution and avoid the problem of antigen or antibody excess. However, manufacturers' instructions for serum dilutions are now usually based on the gamma globulin fraction or total immunoglobulin concentration. It is advisable to pay close attention to these dilution protocols in order to avoid the problems of antigen excess (serum may need to be diluted more) or antibody excess (serum should be diluted less or perhaps not at all).

After the proteins have been separated by electrophoresis, the reference lane is overlaid with an acid fixative, fixing all proteins to the gel. Specific antisera are then applied to each of the other lanes (IgG, IgA, IgM, kappa, lambda) and the gel is incubated, allowing immunoprecipitation to occur. The kappa and lambda antisera are directed toward total kappa and lambda light chains (i.e., bound and free). The subsequent washing step washes away all proteins other than those in the reference lane that have been fixed to the gel, and immunoglobulins precipitated by the specific antisera. After drying, a protein stain, usually acid violet, allows the interpreter to determine whether the immunoglobulins are in a diffuse/polyclonal distribution or whether a discrete band or monoclonal protein is present. The evaluation of IFE gels is a qualitative skill that takes experience for correct interpretation, and gels should always be examined directly by the interpreter. Figure 1B shows a normal IFE with polyclonal immunoglobulins, and Fig. 2B shows serum containing an IgG lambda monoclonal protein. In Fig. 2, the IgG and lambda bands line up with the monoclonal protein in the reference lane. Both Fig. 1 and 2 include the corresponding electropherogram.

It is important to be aware of the normal distribution of immunoglobulins on IFE. IgG is located throughout the whole of the gamma region, IgA migrates in the beta and beta-gamma regions, and IgM stays at or near the origin. Kappa and lambda staining usually corresponds to IgG, although when there is a significant polyclonal increase in IgA, the kappa and lambda staining extends more prominently into the beta region. The kappa and lambda lanes normally show identical staining distributions, but the kappa lane usually appears denser than the lambda lane, reflecting the increased concentration of total kappa compared to the concentration of total lambda light chains. By knowing the normal IFE pattern, an interpreter should easily recognize the occasional mishaps that can occur, such as application of a specific antiserum to the wrong lane or not applying antiserum or serum to a specific lane. The latter problem results in a lane without any staining at all and may be easily missed by the novice interpreter, especially if it involves the far-right lambda lane (Fig. 3). As an alternative to the

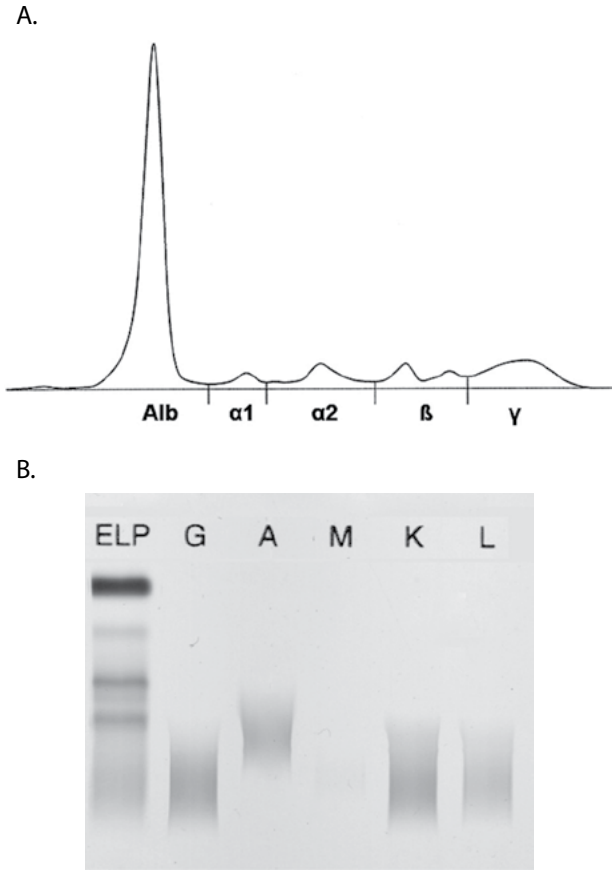

FIGURE 1 (A) Normal serum electropherogram; (B) normal serum immunofixation gel.

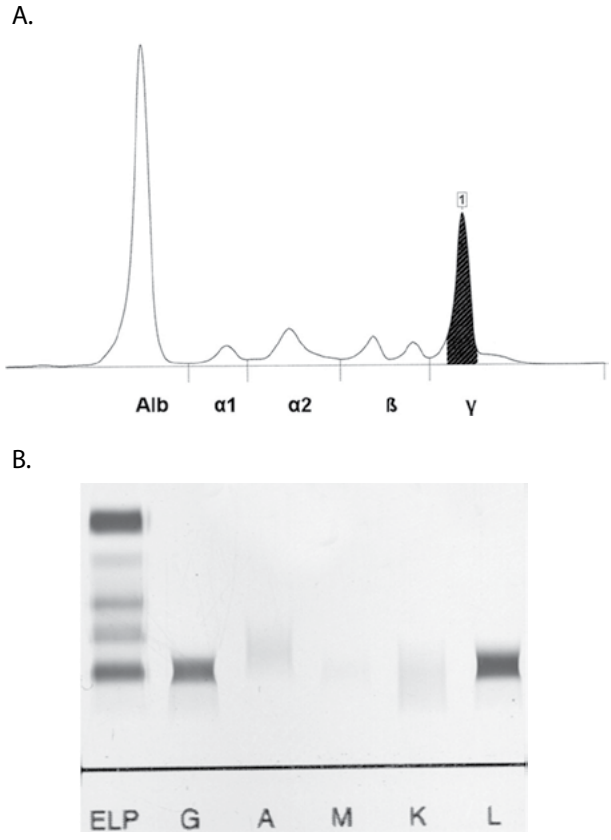

FIGURE 2 (A) Electropherogram with monoclonal protein in the gamma region; (B) immunofixation gel showing an IgG lambda monoclonal protein.

six-lane gel, manufacturers offer a pentavalent gel and antiserum. With this approach, a serum sample is applied only to a reference lane and one IFE lane. The reference lane is treated similarly to that of the six-lane IFE gel, but the IFE lane is overlaid with antiserum directed against a combination of IgG, IgA, IgM, kappa, and lambda. If a discrete band is noted in the IFE lane, a complete IFE must be performed to identify the monoclonal protein type. The immunofixation assay for urine studies is identical to the serum assay except that urine samples need to be concentrated to increase the detection sensitivity. Details of urine IFE will be described later in this chapter.

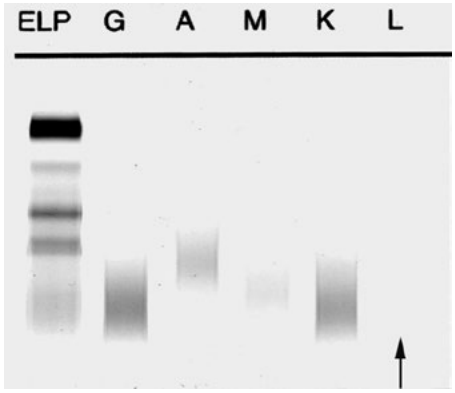

FIGURE 3 Serum immunofixation gel with no staining in the lambda lane due to lambda antiserum not being applied.

Immunosubtraction

Capillary electrophoresis is now used quite commonly to perform serum PE. It automates the electrophoretic procedure and allows for better positive-patient identification than some agarose gel approaches. Combining capillary electrophoresis with immunoprecipitation has resulted in the technique initially called immunosubtraction (ISUB). Because it is automated, ISUB is performed more rapidly than agarose gel IFE but is less sensitive for detection of small amounts of monoclonal protein (9–11). Beckman Coulter was the first company to introduce a commercial instrument for capillary electrophoresis; this was called capillary zone electrophoresis (CZE). However, Beckman no longer manufactures this particular electrophoretic instrument for routine clinical laboratory use, although they do manufacture other capillary electrophoresis systems, mainly for research purposes. CZE has now been replaced by other automated systems from Sebia and Helena. As indicated earlier, the term immunosubtraction was patented; therefore, Sebia uses "immunotyping" and Helena uses "immunodisplacement" for their specific techniques.

Manufacturers of the ISUB technique use prepackaged antisera against IgG, IgA, IgM, kappa, and lambda; these are placed on the instrument with the patient's serum sample. The process allows serum and each antiserum to mix and incubate. The exact contents of the antisera are proprietary, but they are thought to cause the precipitate of the patient's immunoglobulin and antiserum to be negatively charged and so they migrate anodally to albumin. After incubation, the pretreated samples undergo electrophoresis in the capillary columns. The resulting ISUB patterns are examined for polyclonal immunoglobulins or loss of a monoclonal peak, hence the term immunosubtraction. Figure 4 illustrates a normal serum ISUB pattern and Fig. 5 one with an IgG lambda monoclonal protein. In Fig. 4, the "subtraction" of IgG results in almost total removal of the gamma fraction except in the fast-gamma region, where IgA and IgM migrate. The anti-kappa and anti-lambda reagents decrease the gamma fraction by approximately two-thirds and one-third, respectively. The use of anti-IgA and -IgM decreases the background under the beta globulin and the beta-gamma

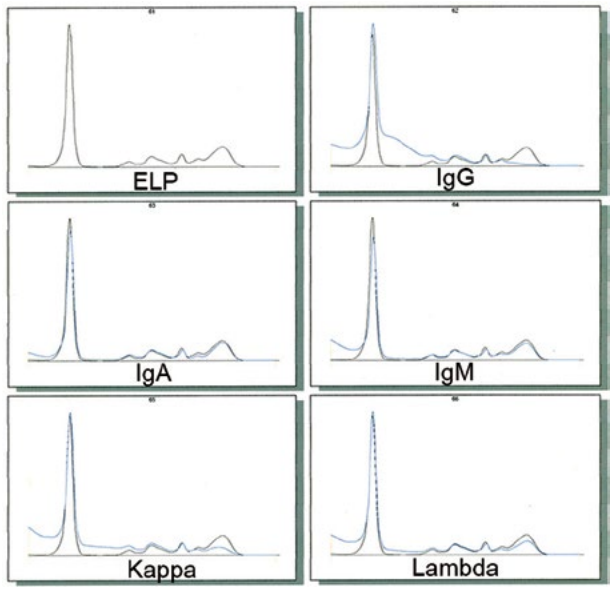

FIGURE 4 Normal serum immunosubtraction pattern.

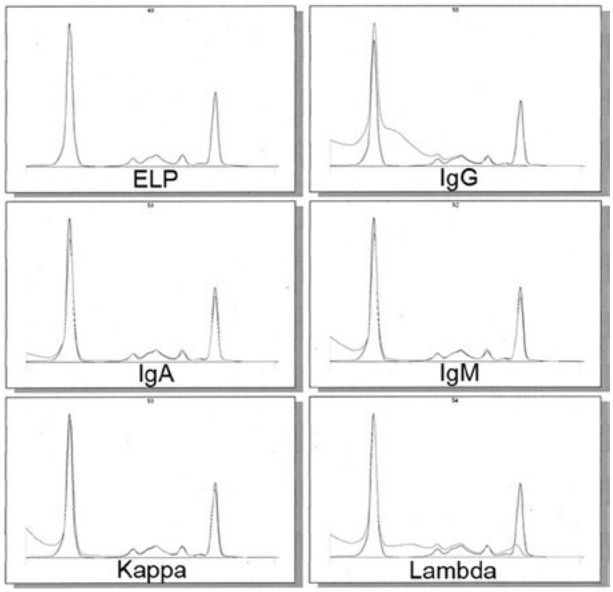

FIGURE 5 Serum immunosubtraction pattern with IgG lambda monoclonal protein.

globulin regions, respectively. In Fig. 5, the anti-IgG reagent removes the M spike as well as the polyclonal portion of the gamma fraction. The anti-lambda reagent removes the M spike as well as a portion of the polyclonal gamma fraction. Therefore, this is consistent with an IgG lambda monoclonal protein.

The main advantage of ISUB is that it is automated and so takes less technologist time and expertise to perform than current IFE gel procedures. However, as indicated earlier, ISUB is less sensitive at detecting small bands or small amounts of monoclonal protein because one needs to see the monoclonal antibody or peak on the reference electropherogram before one can say that it has been removed by ISUB (10, 11). In contrast, with the IFE procedure, other proteins have been washed away and a monoclonal protein is "amplified" because the protein stain stains a combination of the patient's immunoglobulin and the added antiserum. Therefore, as a screen to detect a small amount of monoclonal protein, IFE is preferred. Although many investigators have concentrated on the ability or inability of ISUB to detect small amounts of monoclonal protein, Schild et al. reported a case of a significant amount of IgM kappa monoclonal protein that was not detected by the Capillarys 2 (12). The authors concluded that the problem was caused by precipitation of the monoclonal by alkaline pH buffer and postulated that perhaps some of the reports of false-negative electrophoresis results may be related to pH-dependent precipitation. ISUB also has the current disadvantage of not being able to test for IgD or IgE monoclonal proteins or for other specific proteins. Whether the commercial companies will expand their ISUB capabilities is yet to be determined.

However, despite the disadvantages mentioned, ISUB does have some advantages compared to IFE. ISUB may more readily show which light and heavy chains are associated in serum containing two comigrating monoclonal proteins. This applies particularly to the situation where IgG, kappa, and lambda bands comigrate on IFE; these may represent IgG kappa and IgG lambda proteins or an intact IgG monoclonal protein plus a monoclonal free light chain. The ISUB procedure will clarify this type of IFE result. It can also be helpful in the identification of a small amount of monoclonal protein that migrates in a pattern of increased polyclonal immunoglobulins.

PATTERN INTERPRETATIONS AND CLINICAL DISORDERS

Polyclonal

Polyclonal increases in immunoglobulins occur in a variety of conditions, such as chronic infections, chronic inflammation, connective tissue disease, and chronic liver disease. Large increases may appear to have a restricted migration on PE, especially in capillary electrophoresis, and on occasion may be confused with a monoclonal gammopathy. However, use of IFE or ISUB should distinguish a polyclonal from a monoclonal gammopathy. Polyclonal increases in any of the immunoglobulins will appear as a darker, but diffuse, area of staining in the IFE heavy-chain lane(s) affected. There should also be a diffuse increase in staining for both corresponding kappa and lambda chains (Fig. 6). The ISUB pattern will be similar but more prominent than the normal ISUB polyclonal pattern described in the immunosubtraction section.

A marked polyclonal increase in the IgG4 subclass often results in an apparent band (agarose gel) or peak (capillary electrophoresis) in the beta-gamma region that may easily be misinterpreted as a monoclonal protein (8). However, IFE or ISUB should help clarify that there is a polyclonal distribution of IgG with both kappa and lambda light chains

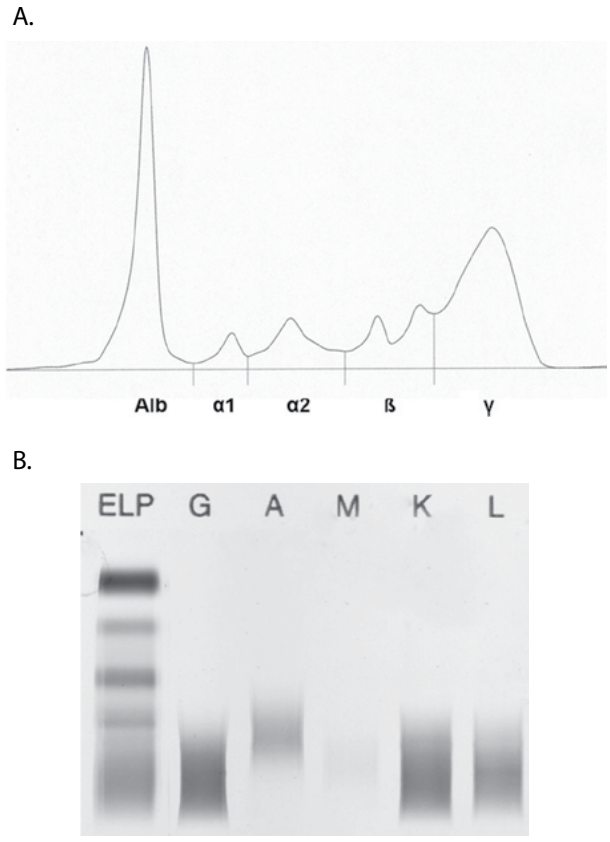

FIGURE 6 (A) Electropherogram with polyclonal increase in gamma globulins; (B) immunofixation gel with polyclonal increase in IgG (a "fuzzy" band is noted in the lambda lane).

increased (Fig. 7). Measurement of IgG subclasses will show a specific increase in the IgG4 subclass. A polyclonal increase in IgM may cause a similar localized staining (agarose gel) or a broad peak (capillary electrophoresis) in the beta-gamma region that can be initially misinterpreted as a broadly migrating monoclonal protein. In addition, with some of the smaller IFE gels, IgM migrates in a relatively short, localized region of the lane so that, on initial inspection, an increased IgM may suggest a monoclonal protein. Again, noting that both the kappa and lambda lanes also show an increase in staining corresponding to IgM will help clarify that this is a polyclonal increase. Interpretation of polyclonal increases in IgA is generally straightforward, occurring primarily in the beta region.

Because of the high protein content of sera with increased polyclonal immunoglobulins and the potential for rheumatoid factor to be present in these samples, sera may exhibit a point-of-application artifact on IFE. In addition, sera with polyclonal increases in immunoglobulins may exhibit several faint, fuzzy bands or restrictions in most or all of the IFE lanes. These may be interpreted as part of the polyclonal response to a particular stimulus; however, if they are sufficiently discrete, they can be referred to as oligoclonal bands. The bands (IFE) or small peaks (capillary electrophoresis) are assumed to represent increases in the production of specific immunoglobulins from a number of plasma cell clones.

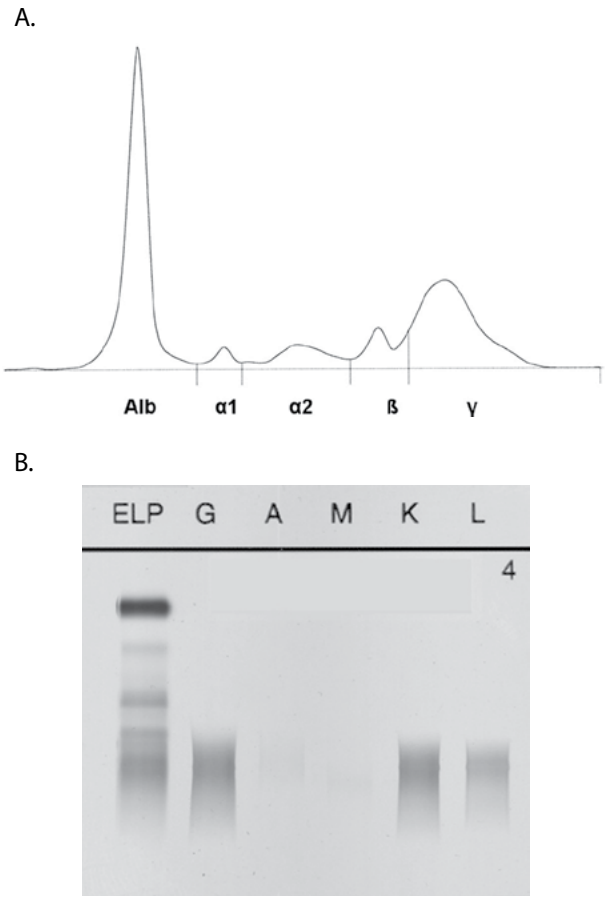

FIGURE 7 Polyclonal increase in an IgG4 subclass. (A) Electropherogram with a rounded peak in the beta-gamma region; (B) immunofixation gel showing an increase in staining in the beta-gamma region in the IgG and both kappa and lambda lanes.

Monoclonal Proteins

As described earlier in the chapter, monoclonal proteins are found under several conditions (Table 1). In addition, they are detected in the general population at a rate of approximately 3% (13, 14) in individuals above 70 years of age. Since IgG-producing plasma cells are present in the greatest numbers, it makes sense that IgG monoclonal proteins occur most frequently. A Mayo study showed that when all monoclonal proteins are considered, IgM monoclonals occur more frequently than IgA monoclonals. However, IgA predominates over IgM when only MM is considered (6); this is because most malignant IgM monoclonals are associated with Waldenström macroglobulinemia. IgD monoclonals are very uncommon and IgE monoclonals extremely rare. Waldenström macroglobulinemia (lymphoplasmacytic lymphoma) is associated with an IgM monoclonal that is readily detected by PE (7). In contrast, AL is usually associated with small amounts of a monoclonal free light chain, although in some patients no monoclonal protein is detected even by IFE.

Four percent of monoclonal proteins are biclonal or double gammopathies that result from two separate expanded clones of plasma cells (15). In order to use the term biclonal with confidence, one should have both a kappa and a lambda monoclonal protein. However, it is probably better either to simply describe the monoclonal protein types or to use the term "double gammopathy." If both bands are IgM, they likely represent monomeric and pentameric IgM (7S and 19S), and if they are identical IgA or IgG molecules, they are most likely monomers and dimers. For clinical purposes, the monoclonal protein quantitations are added together. An example of a sample containing both an IgG lambda and an IgA kappa monoclonal protein (two bands) is shown in Fig. 8; this also illustrates the problem of antigen excess. It is estimated that 0.09% of patients will have three monoclonal proteins.

Classically, a significant amount of monoclonal protein is seen as a relatively sharp spike on PE. In this situation, the monoclonal protein quantitation can be reported. However, some monoclonals have a broader distribution than others and can be confused with a polyclonal immunoglobulin pattern. In monoclonal protein cases, the IFE or ISUB pattern should show only kappa or lambda associated with the increased heavy-chain staining or peak. If only a small amount of monoclonal protein is present, it may be too small to fractionate; in this case, the report can indicate that there is

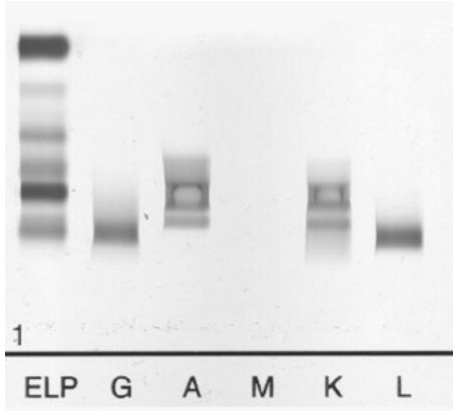

FIGURE 8 Serum immunofixation gel with a biclonal gammopathy (IgG lambda and IgA kappa). Antigen excess is also present in the IgA and kappa lanes.

a small amount of monoclonal protein within a polyclonal background or within the beta or alpha-2 globulin regions. Of course, in some cases, the monoclonal protein may be visible only by IFE.

Myeloma

Diagnostic criteria for MM are a clonal increase of bone marrow plasma cells of >10% or biopsy-proven plasmacytoma, together with any one or more of several myeloma-defining events that include evidence of end organ damage, serum free light chain ratio, focal lesions on MRI, or a clonal plasma cell count of >60%. A monoclonal quantitation is now only included in criteria for smoldering myeloma (16). Although the vast majority of MM patients have a significant amount of monoclonal protein at the time of diagnosis, nearly 3% have no detectable monoclonal heavy chain or light chain (17, 18). These nonsecretory MM patients have large numbers of plasma cells in their bone marrow. Most have clonal plasma cells with cytoplasmic kappa or lambda light chains, indicating a secretory defect. However, a small number of patients have no detectable cytoplasmic immunoglobulin in their plasma cells and are nonproducers. The most likely pattern on IFE or ISUB in nonsecretory MM is one of hypogammaglobulinemia. In cases of hypogammaglobulinemia, it is important to decrease the serum dilution, thus avoiding antibody excess and, potentially, missing a small amount of monoclonal protein.

Free Light Chain Diseases

Because free light chains are readily cleared from the plasma, patients with free light chain diseases often show only small or undetectable monoclonal proteins on serum PE. However, these diseases usually represent significant disorders that include light chain MM (light chain disease), AL, and light chain deposition disease. In a Mayo Clinic study, although monoclonal free light chains represented only 5% of all monoclonal gammopathies, light chain MM accounted for 20% of the MM cases (6). This overrepresentation of free light chains in multiple myeloma (20%) versus all monoclonal gammopathies (5%) emphasizes the importance of confirming small serum PE abnormalities by IFE or ISUB. It should be noted that free light chain monoclonal proteins are uncommon in MGUS.

Sera with monoclonal light chains will show a discrete kappa or lambda band (IFE) or peak (ISUB), but there will be no corresponding IgG, IgA, or IgM heavy chain (Fig. 9). Although IgD monoclonal proteins are uncommon and IgE monoclonal proteins are very rare, an apparent monoclonal free light chain result should be confirmed by retesting the sample with IgD and IgE antisera. This can be performed only by IFE in routine clinical laboratories because commercially available ISUB techniques do not currently provide reagents for IgD or IgE testing.

MGUS

Criteria for MGUS are bone marrow plasma cells of <10%, a monoclonal protein of <3 g/dl, and the absence of end organ damage that can be attributed to a plasma cell proliferative disorder (13). Progression to a significant plasma-lymphocytic disorder has been shown to occur if the monoclonal protein is ≥1.5 g/dl and there is a non-IgG isotype and an abnormal free light chain ratio (19).

Heavy Chain Disease

In heavy chain disease (HCD), monoclonal immunoglobulins are composed of truncated heavy chains that contain no light chain (20). These are often Fc regions with molecular masses ranging between 27 and 49 kDa. HCD disorders are named for the heavy chain involved: IgA (α HCD), IgG (γ HCD), and IgM (μ HCD). Because the heavy chain peptide is truncated, it may also be detected in urine. Each disorder has a different clinical presentation, and this should be taken into consideration at the time of interpretation. When PE is considered, the monoclonal band in γ HCD is often broad and not clearly localized; discrete bands have not been seen in α HCD, and hypogammaglobulinemia is often the only prominent feature of μ HCD.

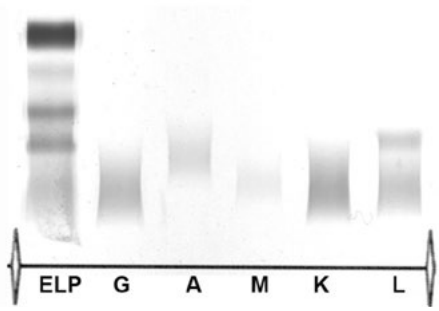

FIGURE 9 Serum immunofixation gel with a free lambda monoclonal protein.

In the past, identification of a monoclonal heavy chain was performed by immunoselection. This involved use of immunoelectrophoresis where anti-kappa and anti-lambda antisera were mixed into the agarose gel. Intact immunoglobulins precipitate at the application point, whereas free heavy chains electrophorese away from the origin. With the advent of IFE and ISUB, immunoselection is rarely used today. With IFE or ISUB, serum from a patient with HCD will show a heavy chain band or peak but no corresponding light chain abnormality (Fig. 10) (21). However, care should be taken with IFE, especially if α HCD is suspected. In some IgA myelomas, the corresponding monoclonal free light chain (frequently lambda) may not be clearly visible. This is thought to be due to the heavy chain covering the light chain determinant to which the antiserum is directed. The problem can usually be rectified by using a different manufacturer's antiserum or using a lesser dilution of the patient serum. In this situation, the possibility of antigen excess should also be considered.

Oligoclonal Banding

Oligoclonal banding refers to the presence of a few bands or peaks on PE, IFE, or ISUB. Each band or peak is caused by increased production of a specific immunoglobulin by a specific plasma cell clone in excess of the majority of other clones. The finding may be transient, may persist for months, and may change over time, with bands decreasing or disappearing, followed by the emergence of new bands. By IFE, it should be possible to line up heavy chain bands with either a kappa or a lambda band. On occasion, one band may be relatively prominent compared to the others; in such a case, it is appropriate to point this out and suggest repeat testing in 3 to 6 months to see whether the band regresses or, less likely, evolves into a monoclonal protein. Figure 11 illustrates an example of prominent oligoclonal banding by both ISUB and IFE.

Oligoclonal banding may be associated with a variety of conditions. When it occurs with a background of increased polyclonal immunoglobulins, the underlying condition is usually benign, e.g., chronic infections or autoimmune disorders. The sera of AIDS patients often exhibit prominent

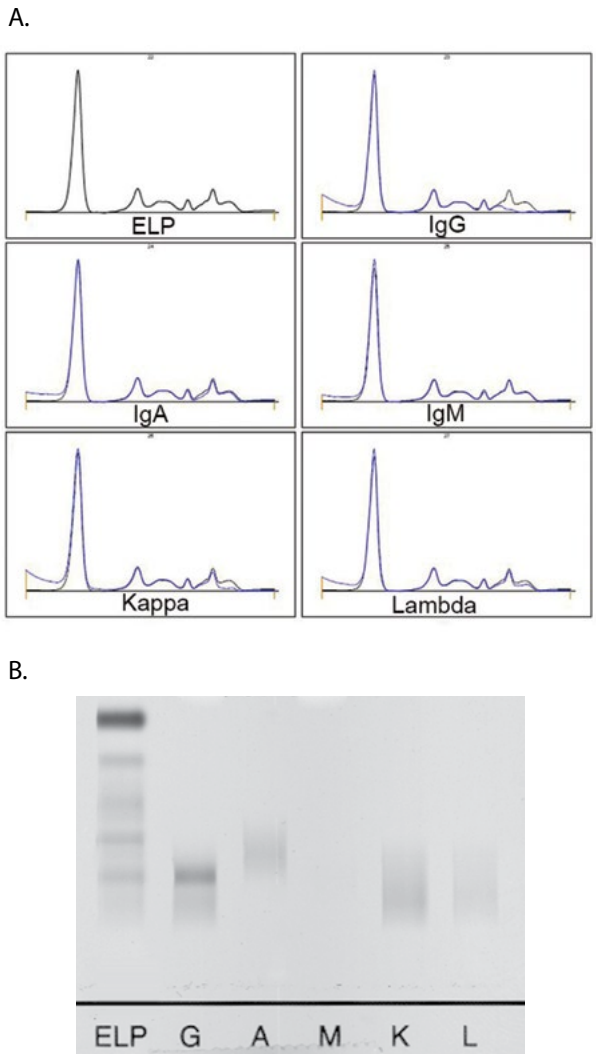

FIGURE 10 IgG heavy-chain disease. (A) Immunosubtraction showing removal of only IgG from the small gamma peak (no change is seen with kappa and lambda antisera); (B) immunofixation gel with only an IgG band.

oligoclonal banding; however, with the advent of better therapy, its prevalence in patients with HIV infection has decreased (22). When oligoclonal banding is seen with a background of decreased immunoglobulins, the possibility of a malignant condition should be considered. Examples include chronic lymphocytic leukemia and lymphoma. Patients who have undergone stem cell transplants or even cytotoxic therapy may also develop an oligoclonal banding pattern. If such a patient has a history of MM and one very prominent band or peak emerges in a pattern of oligoclonal banding, it is important to consider the type and location of the patient's original monoclonal protein.

Hypogammaglobulinemia

Hypogammaglobulinemia results in faintly staining lanes on IFE and relatively decreased gamma globulin fractions on ISUB. As noted previously, it is important to make sure antibody excess does not occur and that a monoclonal protein is not missed. In these cases, urine PE and IFE should be recommended.

Artifacts

Fibrinogen and hemoglobin-haptoglobin complexes can cause potentially confusing bands on PE, and radiographic contrast media (Fig. 12) can result in an extra peak using capillary electrophoresis (23, 24). The performance of either IFE or ISUB should provide evidence that no monoclonal protein is present in these cases. A very sharp band in each IFE lane at the application point indicates nonspecific staining that is due to protein not entering the agarose gel. This finding may represent immunoglobulin aggregates or cryoglobulins. The sample can be retested after treatment with a reducing agent such as 2-mercaptoethanol or dithiothreitol. If the application artifact persists, the patient should be investigated for cryoglobulinemia.

Very large amounts of monoclonal protein may give rise to the pattern of antigen excess (described where IFE is discussed), although this is not usually a problem with serum gels if the manufacturers' instructions are followed. Using IFE, the typical appearance of antigen excess (Fig. 8) is a band or block of staining with a "hole" in the middle; this absence of staining represents where there was an excess of the patient's immunoglobulin (antigen) such that the antigen-antibody complex was soluble and therefore washed away

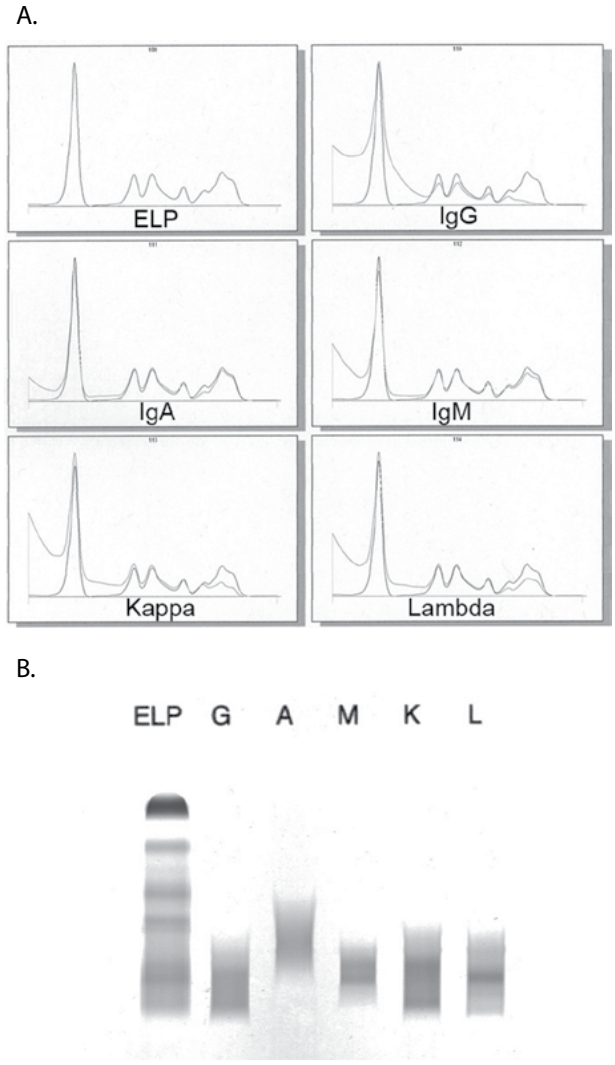

FIGURE 11 Prominent oligoclonal banding. (A) Immunosubtraction; (B) immunofixation gel.

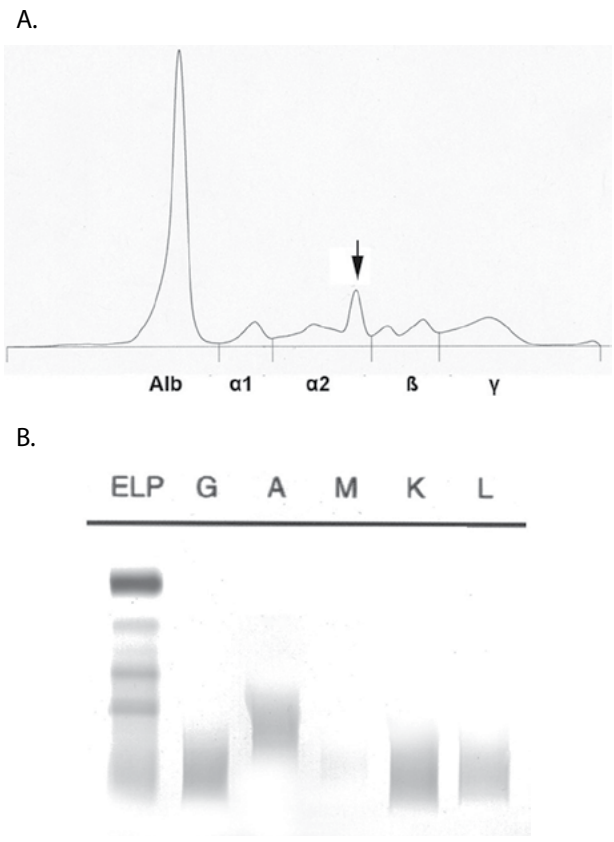

FIGURE 12 Contrast media artifact. (A) Electropherogram from capillary electrophoresis showing a peak (arrow) in the alpha-2/beta region; (B) immunofixation gel with no band corresponding to the contrast medium peak.

during the washing process. Large amounts of a monoclonal protein may also cause an IFE gel "shadow" artifact when it is not removed completely at the washing stage. Figure 13 illustrates this artifact in the case of a prominent IgG kappa monoclonal; here, a small band is detected in the IgA, IgM, and lambda lanes at the level of the monoclonal protein.

QUALITY CONTROL

New reagent lots should be tested against sera with known monoclonal proteins before being used for routine testing.

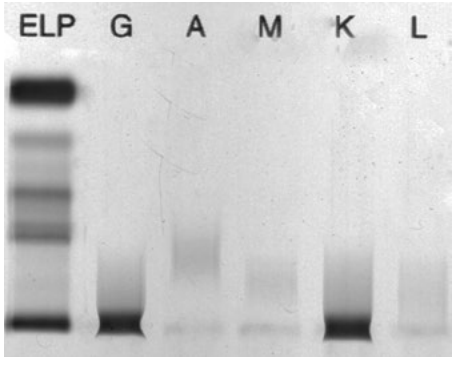

FIGURE 13 "Shadow" artifact on an immunofixation gel caused by incomplete washing of monoclonal protein from the gel (lanes IgA, IgM, and lambda).

In addition, antisera should be tested with a plasma sample to ensure that there is no cross-reactivity with fibrinogen. A sample containing a monoclonal protein of known immunotype should be tested each day. If a patient sample that has been previously immunotyped is part of the workload, that sample may serve as a daily control. The gels should be reviewed with respect to the sharpness of the bands and the correlation of the IFE bands with the monoclonal protein upon PE. IFE gels that are too faint or too dense should be retested with the appropriate dilution. In addition to the internal laboratory controls, external proficiency challenges are available for identification and characterization of monoclonal proteins. The College of American Pathologists' proficiency program supplies challenges, and its summary reports allow a laboratory to compare its performance with that of other laboratories as well as with those using other methods and reagents from different manufacturers.

URINE IMMUNOFIXATION

Monoclonal light chains without associated heavy chains are found in the sera of 5% of all patients with monoclonal gammopathies and 20% of patients with multiple myeloma (6). In monoclonal free light chain disorders, such as light chain multiple myeloma, AL, and light chain deposition disease, the serum concentration of the monoclonal free light chain is usually very low and the monoclonal protein is often not detected (7). However, because free light chains are freely filtered by the kidneys, monoclonal free light chains are far more likely to be found in the urine of patients with light chain disorders. In addition, about 75% of multiple myeloma patients with an intact monoclonal protein in their sera will have monoclonal free light chains in their urine (6). Because of this fact and because an increasing number of patients with smaller amounts of intact monoclonal protein in the serum (<1.5 g/dl) have been found with large amounts of clinically significant (>1 g/24 h) monoclonal free light chains in their urine (Fig. 14), we suggest that urine PE and IFE be performed on all patients with a measurable amount of serum monoclonal protein. Since urine monoclonal free light chains are uncommon in MGUS, urine PE and IFE can also be helpful in further defining this patient population. As indicated earlier, urine investigation is recommended for patients with hypogammaglobulinemia (gamma globulin fraction < 0.5 g/dl) who are older than 30 to 40 years.

It is important to note that routine urinalysis is not a reliable indicator of protein in urine containing immunoglobulin light chains. The dipstick test and some protein precipitation tests are biased toward detection of albumin; urine containing a significant amount of monoclonal protein may test negative for protein when a dipstick or protein precipitation method is used (8). In addition, the dye-binding methods used on many automated chemistry analyzers can have a variable ability to react with proteins of different charges. Despite this fact, dye-binding methods are widely used, and as long as the same assay is used consistently when an individual patient is followed, this is adequate for quantification of the patient's monoclonal protein (8). Methods used for the evaluation and detection of monoclonal proteins in urine are the same as those used for serum and include agarose gel PE, capillary electrophoresis (CE), and IFE. Because it is fairly common not to find an abnormality upon urine agarose gel PE or CE but still have a monoclonal free light chain in the urine, IFE is recommended as part of the screening and identification procedure. Our laboratory

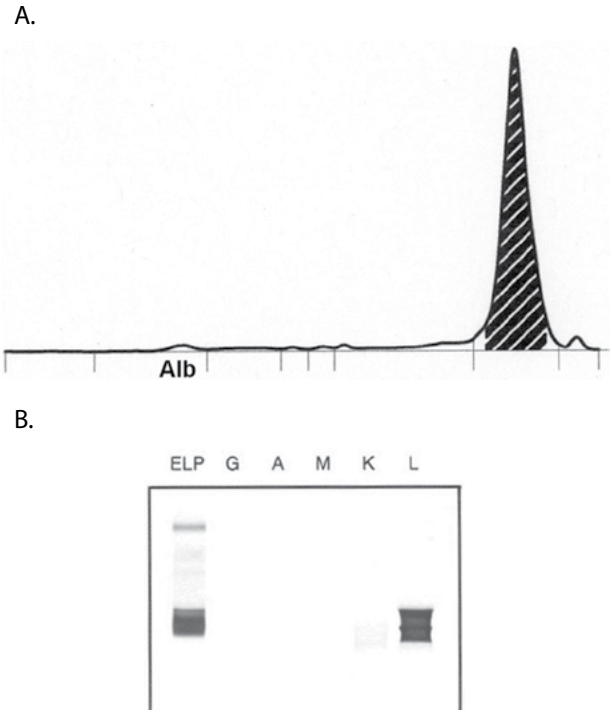

FIGURE 14 (A) Densitometric scan from a concentrated urine specimen showing a monoclonal protein (1,000 mg/24 h) in the gamma region on urine PE. The patient had 0.7 g/dl of IgG lambda monoclonal protein (including C3 complement) in the beta globulin region on serum PE/IFE. (B) Urine IFE performed on the specimen used in panel A demonstrates a free lambda monoclonal protein.

uses agarose gel PE and IFE with total kappa and lambda antisera as an initial screen; this is followed by a full immunofixation with antisera directed against IgG, IgA, and IgM heavy chains and total kappa and lambda light chains when a band is detected on the screening IFE.

Prior to the performance of electrophoresis, urine specimens need to be concentrated to increase monoclonal protein detection sensitivity. This is most often achieved through ultrafiltration. The final concentration of urine protein should be ideally between 1,000 and 8,000 mg/dl. We typically use a gravimetric ultrafiltration system augmented by placing the device on a rocker using the protocol outlined in Table 2. This allows for closer monitoring of the filtration process to achieve the desired concentration, but it is time-consuming and must be closely monitored to avoid under- and overconcentration of urine. Alternatively, we have used a procedure for concentrating protein on the gel by increasing the application time (Sebia method) or by increasing the number of applications (Helena method) of unconcentrated urine samples (if the urine protein is >100 mg/dl) or minimally concentrated urine samples (concentrated 10-fold if total protein is ≤100 mg/dl). Results with this approach were comparable to those obtained with our standard concentration procedure with respect to urine PE interpretation and monoclonal protein detection by IFE. The alternative procedures described allow for faster processing of the urine samples, but the disadvantage is that serum and urine samples cannot be conveniently run on the same gel. Other laboratories use centrifugal filtration systems, which are also faster, but monitoring to achieve the desired concentration can be difficult. If the urine is not concentrated enough, small but clinically significant monoclonal free light chains may not be detected. If the urine is overconcentrated, the sample may cause the gel or capillary to be overloaded and either obscure the monoclonal free light chains or cause the protein not to enter the gel or capillary at all. The limit of detection for monoclonal proteins in urine is 10 to 20 times higher than the detection limit for monoclonal proteins in the serum. The difference is a reflection of the lack of polyclonal background in many urine samples and the urine concentration step.

TABLE 2 Protocol for urine concentration used at Beaumont Laboratory

Total protein in urine (mg/dl)	Concn factor (multiple)
2–50	100 (maximal)
50–120	50
120–300	25
300–1,000	10
>1,000	10 to unconcentrated

A 24-h urine collection is recommended for monoclonal protein detection, quantification, and follow-up. However, for detection only, a first-void, early-morning urine specimen can be as sensitive but does not allow for quantification or follow-up of the monoclonal protein. Unpreserved urine samples collected over 24 h are the preferred specimens. They should be collected and stored refrigerated until analyzed. However, specimens are stable for 3 days at room temperature and also for 14 days refrigerated or frozen. Samples collected with a preservative should not be used. When monoclonal proteins are present on PE or CE in sufficient amounts, they can be quantified by densitometric scanning on PE or peak quantification on CE. Quantification of a monoclonal protein in urine should be based on a 24-h urine collection (mg/24 h) to effectively follow the patient's disease course. Quantification of a monoclonal protein based on urine protein concentration (mg/dl) can be misleading, as there can be wide fluctuations in urine concentrations collected at different times of day. Identification of monoclonal proteins in urine by ISUB has only recently been introduced; it works by the same principle as described for serum but is not widely used at the moment. Use of the free light chain immunoassay is not recommended (25).

On IFE, urine containing a relatively low protein concentration usually shows pale, diffuse staining in the kappa and lambda lanes corresponding to normal IgG migration. Kappa staining is slightly darker than in the lambda lane. In some cases, with urine protein concentrations that are very low, even if the urine has been maximally concentrated, it may not be possible to see any staining in the kappa and lambda lanes. As the urine protein concentration increases, it is common to see some polyclonal IgG and in some cases polyclonal IgA and IgM. With higher-resolution gels, such as the older Beckman IFE gels, it was common to see a few small bands (5 to 6) in both the kappa and lambda lanes, although the stain was generally darker in the kappa lane. The bands were equidistant and appeared like rungs of a ladder, hence the term "ladder pattern." We still see this occasionally on newer gels with lower resolution. The ladder pattern is caused by the relatively limited heterogeneity of normal polyclonal free light chains and should not be misinterpreted as monoclonal proteins. Identification of monoclonal proteins is generally straightforward using IFE. In addition to appearing as one kappa or lambda band on the IFE gel, some monoclonal free light chains may migrate as two discrete bands, representing monomers and dimers.

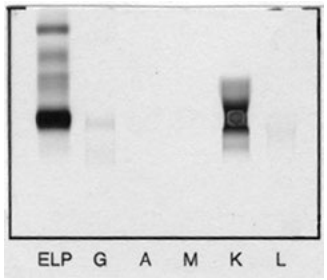

FIGURE 15 IFE of a concentrated urine specimen demonstrating a dominant free kappa and a smaller amount of IgG kappa monoclonal protein.

Occasionally, an intact immunoglobulin is also detected, although this is usually seen in patients with renal damage and significant glomerular or tubular proteinuria. Two relatively common findings in urine samples containing a large amount of monoclonal free light chains are those of antigen excess and the shadow artifact caused by the monoclonal protein not completely washing off the gel. Both these artifacts are described in the serum immunofixation section of this chapter. Bands on PE or peaks on CE, such as hemoglobin and beta-2 microglobulin, will be found not to consist of a monoclonal protein once the IFE is examined.

As discussed previously, most multiple myeloma patients with an intact immunoglobulin in the serum produce excess monoclonal free light chains. In these patients, the urine may reveal (i) monoclonal free kappa or lambda light chains, (ii) a monoclonal free kappa or lambda light chain and a smaller amount of intact monoclonal immunoglobulin (Fig. 15), and (iii) in the case of biclonal gammopathies, both monoclonal free kappa and free lambda light chains with or without intact monoclonal immunoglobulin(s) (Fig. 16). A small amount of monoclonal free light chain in the presence of nephrotic-range proteinuria due mainly to albumin is consistent with AL or light chain disposition disease (26). In 2 to 3% of patients with multiple myeloma, no monoclonal protein is detected by serum or urine immunofixation. Serum free kappa and free lambda light chain measurement by immunoassay has been found to be useful in these "nonsecretory" or "oligosecretory" cases. This assay may also provide a viable alternative to 24-h urine collections and follow-up of patients with light chain multiple myeloma (25).

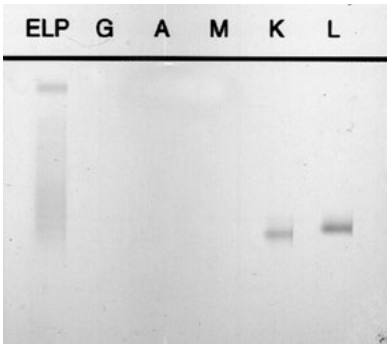

FIGURE 16 IFE of a concentrated urine specimen demonstrating a free kappa and a free lambda monoclonal protein in a patient with IgA kappa and IgA lambda monoclonal proteins detected on serum IFE.

If a monoclonal protein is found in the urine and a serum evaluation for monoclonal proteins has not been requested, then a serum evaluation should be recommended and vice versa. Quality control procedures for urine are similar to those described for serum except that the method used for urine concentration should be checked periodically to confirm that the total amount of protein expected is the amount recovered following concentration.

CEREBROSPINAL FLUID

The immunochemical characterization of immunoglobulins in the CSF is affected by the much smaller amount of proteins present in the CSF than in serum and the integrity of the blood-brain barrier. Adults typically have approximately 1/100th to 1/200th the amount of proteins in the CSF as there is in the serum. In evaluating patients for disorders associated with increased immunoglobulins in the CSF, an assessment as to whether the immunoglobulin increase is due to leakage of plasma proteins across a compromised blood-brain barrier or whether the increase is due to intrathecal production of immunoglobulins must be made. The pattern due to leakage of plasma proteins across the blood-brain barrier mimics that seen in serum whether it is polyclonal, oligoclonal, or monoclonal in nature. Because immunoglobulin-producing cells in the CSF tend to be more restricted in their heterogeneity than in serum, the pattern of immunoglobulin increase seen in disorders primarily affecting the central nervous system (CNS) tends to be oligoclonal. This is why it is important to evaluate any increase in immunoglobulins in the CSF with a corresponding serum collected at the same time.

The most common reason for evaluating immunoglobulins in the CSF is as an aid in the diagnosis of multiple sclerosis (MS). The CSF laboratory tests recommended by the National Multiple Sclerosis Society are the qualitative evaluation of oligoclonal banding and an increased CSF IgG index, both signs of increased intrathecal synthesis of immunoglobulins. In the past, high-resolution agarose gel electrophoresis (AGE) with protein staining was widely used to evaluate patients for oligoclonal banding in the CSF. Since 2003, based on a study by Fortini et al. (27), the National Multiple Sclerosis Society has recommended the use of isoelectric focusing with IgG immunoblotting over AGE for the evaluation of oligoclonal banding in CSF. Recent CAP surveys (2015) indicate that nearly 55% (77/141) of participants use isoelectric focusing as opposed to high-resolution AGE for detection of oligoclonal banding. Oligoclonal banding is detected in 60% of MS patients by high-resolution AGE and 90% of MS patients using isoelectric focusing with IgG immunoblotting with similar specificities (94% and 96%, respectively).

The finding of oligoclonal banding in other inflammatory diseases of the CNS, such as neurosyphilis, acute inflammatory polyradiculoneuropathy, Guillain-Barré syndrome, subacute sclerosing panencephalitis, viral encephalitis, CNS Lyme disease, transverse myelitis, and some fungal and parasitic encephalopathies, accounts for the decreased specificity (8). Therefore, the presence of oligoclonal banding for the diagnosis of MS must be interpreted in the appropriate clinical and radiological setting.

Laboratory Investigation

The Helena method uses isoelectric focusing on agarose gels with a pH gradient of 3 to 10. Five microliters of serum diluted 60-fold and 5 μl of CSF are applied to the gel. After electrophoresis, the separated proteins are transferred to a nitrocellulose membrane and blotted with an anti-IgG

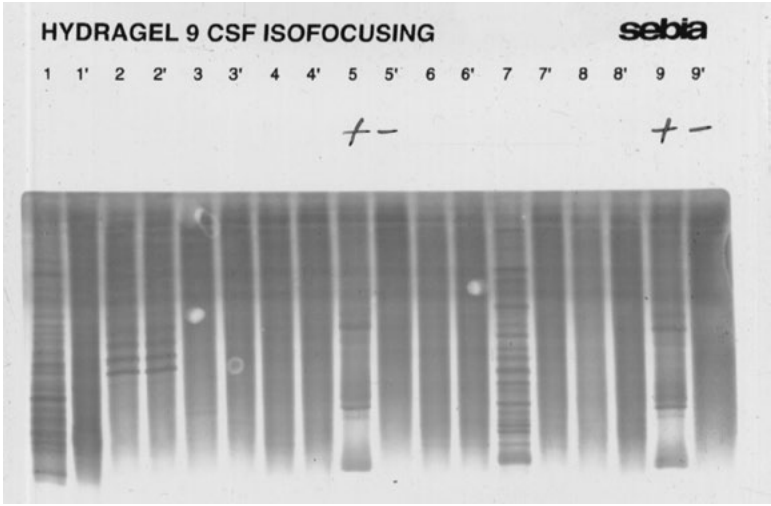

FIGURE 17 Seven paired CSF (lanes 1 to 4 and 6 to 8) and serum (lanes 1′ to 4′ and 6′ to 8′) specimens along with two positive CSF controls (lanes 5 and 9) and two negative CSF controls (lanes 5′ and 9′) were subjected to IEF for the detection of oligoclonal bands. The patient specimens in lanes 1 and 1′ and 7 and 7′ reveal oligoclonal bands consistent with MS. The pattern for the patient in lanes 2 and 2′ are consistent with the presence of a monoclonal protein (posttranslational changes account for the multiple monoclonal protein bands seen with IEF). The patterns in lanes 3 and 3′ have faint bands appearing in both the CSF and serum specimens; this is nondiagnostic. The patterns in lanes 4 and 4′ and 8 and 8′ are normal.

peroxidase conjugate for visualization. The IEF method developed by Sebia is similar except that visualization of bands is achieved by immunofixation. Oligoclonal bands are considered to be present if two or more bands are detected in the CSF but are not detected in the corresponding serum. Most patients with MS will have eight or more CSF-specific bands by this technique. Isoelectric focusing (Fig. 17) results in a greater number bands that are sharper, more distinct, and easier to interpret than those seen with agarose gel electrophoresis. Nondiagnostic patterns include (i) no bands present in paired CSF and serum samples, (ii) oligoclonal banding in the CSF, which is mirrored in the serum, (iii) a monoclonal band present in paired CSF and serum samples, or (iv) a single band seen in the CSF regardless of the serum pattern.

The IgG index, on the other hand, is based on a calculation using measured serum and CSF albumin and IgG. The equation is as follows:

$$\text{IgG index} = \frac{(\text{IgG})_{\text{CSF}}/(\text{IgG})_{\text{serum}}}{(\text{albumin})_{\text{CSF}}/(\text{albumin})_{\text{serum}}}$$

An IgG index of greater than or equal to 0.70 is considered to be consistent with MS. Ninety percent of MS patients have an elevated IgG index. Although neither test is specific for MS, the use of both the IgG index and oligoclonal banding increases the sensitivity to 90 to 95% (28).

As with all laboratory testing, quality control is essential. Every gel should contain a positive and negative CSF control sample with a known number of bands. The gel is acceptable if band resolution, separation, and staining allow identification of the appropriate number of bands. The number of bands detected in the controls should be none in the case of the negative control and within one band of the target for the positive control. All gels should be read independently by two readers. If the two readers do not agree on the test interpretation, then a third reader should be consulted. Proficiency testing should be performed by all members involved in the testing and interpretation of these gels on a periodic basis.

Cryoglobulins, Cryofibrinogenemia, and Pyroglobulins

PETER D. GOREVIC AND DENNIS GALANAKIS

10

CRYOGLOBULINS

Background

Cryoglobulinemia is one of a group of syndromes characterized by the induction of clinical and/or laboratory abnormalities by cold. Cryoglobulins are immunoglobulins (Igs) that precipitate out of solution below core body temperatures, either as a single isotype (simple cryoglobulins) or as immune complexes in which both antibody and antigen are Igs (mixed cryoglobulins). In some instances, cryoglobulinemia may coexist with other related but usually distinct forms of cold hypersensitivity, such as Raynaud's phenomenon, cold agglutinin activity, or cold-dependent activation of complement (CDAC) (1).

Simple cryoglobulins may be either an intact Ig or a cryoprecipitable Ig light chain (type I cryoglobulins) and are always clonal in terms of electrophoretic mobility or variable-region amino acid sequence. In mixed cryoglobulins, the antibody is almost always IgM (occasionally IgA), which may be monoclonal (type II) or polyclonal (type III) (2). The antigen in mixed cryoglobulins is usually polyclonal IgG, though in some instances, the IgG may be oligoclonal when analyzed as to subclass or as revealed by immunoblotting, immunofixation, or two-dimensional gel electrophoresis (3, 4). Mixed cryoglobulins are therefore cold-precipitable rheumatoid factors (RFs), with the serum often being positive when standard assays for IgM antiglobulin activity are used (5, 6). Many type II RFs have a predilection for the Cγ2-Cγ3 interface of the Fc portion of IgG and react with the binding site for staphylococcal protein A. Complexing of the two isotypes of Igs in mixed cryoglobulins is a prerequisite for *in vitro* cryoprecipitation. The binding affinity of the IgM RF and the stoichiometry of complexes formed by mixed cryoglobulins are significantly influenced by temperature (7). The relative frequency of the different types of cryoglobulins seen in a clinical immunology laboratory will vary significantly with the type of diseases referred for analysis and depending on how carefully sera are processed prior to study. The latter is particularly of concern in screening for type III cryoglobulins, which are generally present only at low levels and may require larger-than-normal volumes of serum for analysis (Table 1).

Concept

The decision to test a serum sample for cryoglobulins may be based on the knowledge that the patient has a specific known or suspected disease, be dictated by the evaluation of a particular clinical manifestation, or be carried out to clarify other abnormalities that have been uncovered in the course of a laboratory evaluation for another purpose. Type I cryoglobulinemia may be suspected in the presence of a known plasma cell dyscrasia (e.g., multiple myeloma, macroglobulinemia), immunochemical evidence of a monoclonal immunoglobulin (M-spike) or Ig light chain (Bence-Jones protein) in serum and/or urine, or clinical evidence of hyperviscosity, acrocyanosis, severe Raynaud's phenomenon, or ischemic vasculopathy. Type II cryoglobulinemia should be considered in B-cell neoplastic states that may be associated with RF and other autoimmune phenomena, in Sjögren's syndrome, and in chronic inflammatory liver diseases, particularly due to infection by hepatitis C virus (HCV) (1). Type III cryoglobulins have been associated with a wide variety of chronic infectious and autoimmune diseases, many of which are characterized by hyperimmunization and/or hyperglobulinemia. The presence of mixed cryoglobulins may be suggested by purpura or documented cutaneous vasculitis, clinical findings of or biopsy-proven glomerulonephritis, unexplained neuropathy or hepatitis, serum positive for RF, or markedly depressed C4 levels (1–3) (Table 2).

Other laboratory abnormalities may be consequences of the physicochemical properties of the cryoglobulins or reflect polyclonal B-cell activation or clonal B-cell proliferation often associated with these disorders. Since cryoprecipitation does not occur at core body temperatures and may begin within minutes of the cooling of serum, it is especially important to consider *ex vivo* artifacts in the interpretation of laboratory data in patients affected by these syndromes. The most important of these is the handling of the serum before separation (8), which can significantly affect quantitation, especially when the endpoint is to assess the effect of therapy by comparison of serial specimens. Others may be introduced in the handling of biopsy specimens, in measurements of serum viscosity (9), or by cooling of anticoagulated blood in processing for the Coulter counter (Table 3). The first clinical description of cryoglobulinemia in a patient with multiple myeloma in 1933 by Wintrobe (32) was based on the

doi:10.1128/9781555818722.ch10

TABLE 1 Classification of cryoglobulins[a]

Type	Frequency	% at a concn (mg/ml) of:		
		>1	1–5	>5
Simple (type I)	5–38	10	30	60
IgG, IgM, or IgA				
Ig light chain				
Mixed				
Monoclonal (type II)	14–72	20	40	40
Polyclonal (type III)	23–54	80	20	0

recognition of an apparently copious buffy coat fraction in an individual known to be cytopenic due to bone marrow replacement. In more recent experience, failure to recognize pseudoleukocytosis or pseudothrombocytosis due to a high-thermal-amplitude cryoglobulin during treatment with cytotoxic agents can significantly compromise care (10) (Fig. 1).

Procedures

Proper handling of blood samples is the single most important variable determining the success rate for identifying cryoglobulinemia and the most difficult to achieve. In the authors' experience, the best results have been obtained when the screen for cryoprecipitation is carried out by the individual in direct contact with the patient (i.e., the physician, house staff, or technician) and when proper attention is made to the importance of separating serum at 37°C from whole blood. Although less sensitive and specific than other tests for gammopathy or immune-complex disease, analysis of serum for cryoprecipitation has the advantage of simplicity, requiring minimal equipment, and is therefore very cost-efficient. It is also an excellent teaching instrument for students and other trainees, as all that is required is a "warm heart" (to keep the sample close to core body temperature and minimize *ex vivo* cryoprecipitation before separation), a refrigerator (in which to observe the sample overnight), and a source of warm running water (to prove that any precipitate that forms can be redissolved upon warming). Since cryoglobulins often come out of solution within 24 to 48 h, many sera can be efficiently screened within 1 to 2 days of collection, allowing the clinician to rapidly make further decisions regarding additional work-up.

Isolation, Quantitation, and Characterization of Cryoglobulins

1. Collect 10 to 20 ml of blood (2 red-top tubes) and keep them at 37°C for 30 to 60 min prior to separation. To ensure that cryoprecipitation does not occur *ex vivo*, the blood may be placed in a thermos kept at this temperature or put into a 37°C water bath prior to centrifugation (8). Patients previously found to have high levels of cryoglobulin may require lower volumes for serial studies, and those suspected of having type III cryoglobulins may require larger volumes for analysis. Occasionally, gel formation in the syringe or vacutainer tube may occur as the initial manifestation of cryoprecipitation (see also below). Serum is separated from the clot by centrifuging the specimen with warmth for 10 min at 2,500 rpm. Following separation, it should be carefully inspected for lipemia, which may complicate the visual inspection of the sample for cryoprecipitation over the several hours following collection. Serum thus collected antiseptically, or to which a drop of 0.1-g/liter sodium azide is added to prevent bacterial overgrowth, may be safely sent by overnight mail (even at room temperature) to a reference laboratory for detailed characterization.

2. Cryoglobulins are grossly apparent upon visual inspection down to the range of 50 to 100 μg/ml, depending on the volume of the serum sample submitted for analysis. Type I cryoglobulins are often apparent as flocculent, occasionally crystalline precipitates that are usually observed within 24 h of separation. Cryocrystalglobulins can be characterized as dense structured inclusions by light microscopy using Giemsa or hematoxylin and eosin stains, as extracellular material by electron microscopy using osmium and uranyl acetate stains, or as non-Congo red-binding birefringence visualized by polarizing microscopy. Type III cryoglobulins are usually gelatinous and may take up to a week to be fully apparent. Consequently, serum samples are observed at 4°C for 7 days after collection. This analysis may be facilitated by measurement of turbidity (e.g., using a jacketed spectrophotometer cuvette at 630 nm) at 15-min intervals, by cryoprecipitation from hypotonic media, or by flow cytometry for small diffracting particles (11). The kinetics of cryoprecipitation are variable, depending on the individual sample and the concentration of cryoglobulin present (12). This may reflect in part different mechanisms for cryoprecipitation, including lag periods overcome by nucleation events (2, 12). We have observed little variability when the kinetics of cryoprecipitation of serum, plasma, or isolated cryoglobulins have been compared by turbidimetric analysis (Fig. 2).

3. Positive sera are spun down in a refrigerated (4°C) centrifuge (Sorvall) at 3,000 rpm for 15 min and their supernatants removed for further analysis. The pellet is vortexed six times with 5 to 10 ml of ice-cold 0.15 M saline, each time with the precipitate spun for 15 min at 3,000 rpm; contaminating red blood cells may be lysed hypotonically. Finally, the sample is suspended in warm saline (1/10 to 1 volume of the initial serum) and incubated at 37°C for 1 h.

TABLE 2 Disease, clinical,[a] and laboratory associations

Type	Association(s) with:		
	Diseases[b]	Clinical syndromes	Laboratory manifestations
I	Macroglobulinemia, myeloma, idiopathic manifestations	Necrosis, Reynaud's syndrome, acrocyanosis	M-spike, increase in viscosity, cryocrystals
II	HCV infection, Sjögren's syndrome, CLL, lymphoma, macroglobulinemia	Purpura, neuropathy, keratoconjunctivitis	RF, nephritis, hepatitis, decrease in C4
III	Chronic infections, autoimmune disease	Vasculitis	RF, nephritis

[a]Reversible cyanosis of the helices of the ears and livedoid vasculitis are characteristics of IgG type I cryoglobulinemia, whereas purpura due to leukocytoclastic angiitis is characteristic of type II IgM(k)-IgG cryoglobulins.
[b]Idiopathic, no apparent underlying disease; CLL, chronic lymphocytic leukemia.

TABLE 3 Laboratory abnormalities in cryoglobulinemia

Findings and abnormality
Direct effects
Cryoprecipitation
Cryogel formation
Cryocrystalglobulins
Hyperviscosity
Present only with cooling
Accentuated by cooling
Immunochemical findings
Normal (frequent with type III)
Hyperglobulinemia
Diffuse elevation or M-spike on serum protein electrophoresis (SPEP)
Elevation of a specific isotype (IgG, IgA, or IgM) or subclass (type I)
Increased high (19S)- and low (7S)-molecular-weight IgM (type II)
Skewing of the normal (2/1) kappa/lambda ratio of Ig light chains (types I and II)
Hypoglobulinemia
Diffuse (occasionally with type II)
Noncryoglobulin isotypes (type I)
Clonal markers of B cells
Monoclonal gammopathy
Clonal populations of B cells revealed by surface Ig
Peripheral blood (heavy- and light-chain determinants)
Lymphoid aggregates in bone marrow (type II)
Evidence of Ig gene rearrangement
Antibody activity and immune-complex formation
19S IgM antiglobulins (RFs) (types II and III)
IgA (type II) or IgG (type I) RF
Elevated levels of circulating immune complexes, especially assays based on C1q binding activity
Antinuclear antibodies
Antiviral antibodies (Epstein-Barr virus, HBV, HCV)
Hypocomplementemia
Classical- or alternative-pathway activation as a manifestation of specific diseases (e.g., lupus)
In vivo/*ex vivo* activation by cryoprecipitates
Selective depression of C4
Cold-dependent activation independent of cryoprecipitation
Ex vivo artifacts (avoid by testing at 37°C)
Gelling of blood at the time of venipuncture
Increased erythrocyte sedimentation rate
Rouleaux formation of red blood cells
Pseudoleukocytosis
Pseudothrombocytosis
Pseudoerythrocytosis
Cytoplasmic inclusions in neutrophils and monocytes
Cryoprecipitation in biopsy material
Associated abnormalities
Proteinuria, hematuria, pyuria, casts
Abnormal liver function tests

Ideally, there should be complete dissolution of the precipitate with shaking. If this does not occur, the presence of fibrin or bacterial contamination should be considered; warm insoluble precipitate should be spun out at 37°C (3,000 rpm for 10 min) and the supernatant again cooled to 4°C and observed for cryoprecipitation.

4. The concentration of cryoglobulin can be determined as a cryocrit or as an absolute concentration of protein back-calculated for the initial volume of serum. Cryocrits are appropriate for serial measurements in individual patients (provided that the methodology is carefully reproduced between samples) and for the purposes of general comparison. Exact protein measurements are more accurate and can be compared to quantitation of specific Ig isotypes in serum, isolated cryoglobulins, and serum supernatant obtained following cryoprecipitation. To obtain a cryocrit, an aliquot of the initial warm serum is used to fill a disposable Wintrobe tube to the 10-mm mark. The tube is kept vertical at 4°C for the time period determined above for cryoprecipitation and then centrifuged cold at 2,000 rpm for 30 min; the percent total volume occupied by the pellet is then obtained by visual inspection. The total protein content of isolated cryoglobulin rigorously washed as described above is determined in our laboratory by the Bradford method using the bicinchoninic acid protein assay (Pierce). In some instances, repeated warming and cryoprecipitation lead to significant loss of material, and therefore quantitation is defined in terms of the initial isolation protocol for consistency.

5. Warmed dissolved cryoprecipitate is characterized by immunochemical analysis by agarose gel immunofixation electrophoresis (IFE). In addition to defining type I cryoglobulins, immunofixation may reveal the clonality of the IgM component or the oligoclonality of the IgG components of mixed cryoglobulins. Since the monoclonal components of type II cryoglobulins are almost invariably IgM(κ), the percent contribution of clonal IgM to total IgM present in a mixed cryoglobulin can be estimated by correlating the contribution of a clonal band to total immunoreactive IgM on a strip developed with anti-μ with the contribution of a band on a strip developed with anti-κ antiserum either by visual inspection or by densitometry (more-formal quantitation). Uncommon laboratory findings that may be predictive of occult and clinically significant cryoglobulinemia include a smeared M-spike in high-resolution agarose gel serum protein electrophoresis, precipitated protein at the point of serum application, >50% discrepancies between densitometric estimations of M-spike and its relevant serum Ig isotype, and smeared protein upon agarose gel IFE (13).

6. Other modalities which have been utilized include immunoblot analysis with anti-heavy- or -light-chain antisera of cryoglobulins separated under nondenaturing conditions on 4% polyacrylamide gels (which can also be used to demonstrate 7 S IgM in serum) or on composite agarose polyacrylamide gels. Immunoblotting combined with IFE can be performed on as little as 10 μg of material, can distinguish type II from type III mixed cryoglobulins, and may be particularly effective for the demonstration of the oligoclonality of each component of the complex. Another modality is two-dimensional gel electrophoresis, with the gel run under denaturing and reducing conditions in order to dissociate mixed cryoglobulins and separate Ig heavy and light chains by molecular weight and isoelectric focusing point. Two-dimensional polyacrylamide gel electrophoresis (PAGE) may be more sensitive than IFE for the demonstration of B-cell clonality in patients with cryoglobulinemia and has been combined with Fourier transform-ion cyclotron resonance mass spectrometry for the high-resolution analysis of cryoglobulin constituents (4, 14). A third modality is capillary zone electrophoresis, which has been adapted in some laboratories for the rapid characterization of cryoprecipitates. It may be particularly useful for type III cryoglobulins because of the sensitivity of the technique. Subtraction analysis of the gamma globulin curve before and after cryoprecipitation can be used as an alternative to protein and Ig determinations for quantitation (15).

7. The relative contributions of the different components of mixed cryoglobulins may be determined by nephelometry if sufficient material is available. This may be used to confirm the nature of mixed cryoglobulins and to show selective enhancement of specific antibody activity in cryoprecipitates compared to serum but is rarely of clinical significance. The power of this type of analysis has been significantly expanded in research studies through the use of capture enzyme-linked immunosorbent assays that employ both isotype- and idiotype-specific antibodies (16). Since most mixed cryoglobulins remain cryoprecipitable in the pH range 5.0 to 8.5, they can be dissociated under, e.g., acid conditions, and IgM can be separated from IgG and quantitated after ion-exchange chromatography, passage through specific immunoabsorbents (e.g., protein G columns), or size fractionation by high-pressure liquid chromatography or fast-protein liquid chromatography.

Assays for Specific Antibody Activities, Antigens, or Detection of Nucleic Acid

1. Mixed cryoglobulins contain IgM RF activity when tested by either standard assays or more-sensitive techniques (e.g., binding of radiolabeled aggregated IgG) (2). Unlike in rheumatoid arthritis, cryoglobulin RF activity, particularly in HCV-associated disease, is not associated with antibodies to cyclic citrullinated peptide. Although both cryo- and noncryoprecipitable RF activity can be detected, occasionally testing RF activity in serum may be invalid because it has been lost due to cryoprecipitation of a high-thermal-amplitude (i.e., one that rapidly cryoprecipitates above room temperature) mixed cryoglobulin (Fig. 1).

2. Individual case reports and small series have shown enrichment of a number of specific antibody activities, including binding to antigens such as IgG or HCV recombinant proteins, in cryoglobulins associated with specific disease states. Most of these antibodies (e.g., HCV antibodies [HCVAbs]) are associated with the IgG fraction of mixed cryoglobulins and can be quantitated by enzyme-linked immunosorbent assay, which should be normalized for total IgG quantitated in cryoglobulin relative to serum (16, 17). In some instances, we have found that a specific antibody activity was in fact not concentrated in the isolated cryoglobulin, as was the case for a patient with a type 1 IgG(κ) cryoglobulin without intrinsic HCVAb activity who developed HCV infection during the course of his illness.

3. The nature of mixed cryoglobulins as immune complexes in chronic infection by hepatitis B virus (HBV) and HCV is indicated by reports of selective enrichment of both antigens (e.g., HBV surface and HCV core antigens) and specific antibody activity in some isolated cryoprecipitates (16–18). Current experience is that 60 to 80% of type II cryoglobulins in patients with the syndrome of mixed cryoglobulinemia (purpura, arthralgias, renal disease) are associated with evidence of HCV infection, as assessed by anti-HCV antibody activity and/or amplification of specific nucleic acid using PCR following reverse transcription (RT). In our laboratory, HCVAb activity is assessed by recombinant immunoblot assay (RIBA) and the presence of HCV RNA determined initially by RT-PCR using nested primers framing conserved sequences in the 5′ untranslated region of the viral genome. RIBA for HCVAb measures primarily IgG antibody to HCV antigens. Controls include known positive and RF-positive HCVAb-negative sera; RT-PCR is also carried out with positive and negative samples, with care taken to control for carryover contamination. More accurate assessment of HCV copy number can be determined by commercially available quantitative assays, including those using competitive PCR (e.g., the Roche Amplicor system) or direct capture of viral RNA by complementary branched DNA (Chiron). Lower limits of detection for these assays are 600 and 615 IU/ml HCV RNA, respectively. Quantitative assays may be used to demonstrate selective enrichment of HCV RNA in cryoprecipitates (reported as being more frequent than enrichment of HCVAb), in some instances when serum supernatant is negative or below the level of detection of the particular assay, and to follow the clinical course and the effect of therapy with alpha interferon (IFN-α) (19). HCV genotype analysis is commercially available and may be used as one variable to anticipate the efficacy of therapy with IFN-α; however, its value for the evaluation of mixed cryoglobulinemia and other autoimmune manifestations of chronic infection is uncertain.

New HCV assays are likely to enhance the sensitivity and specificity of measurements of cryoglobulins associated with extrahepatic diseases associated with chronic infection. These include the quantitation of hepatitis core antigen (18) and real-time PCR assays for HCV RNA and the replicative intermediate (negative strand) (20). The former may be assayed by enzyme-linked immunosorbent assay (Chiron-Ortho Clinical Diagnostics) and has been found to be concentrated in isolated cryoprecipitates (18) and peripheral blood mononuclear cells; the latter may be a more sensitive marker for occult HCV infection in cryoglobulinemia (21) and a criterion for productive infection by virus in extrahepatic sites.

Complement Measurements in Cryoglobulinemia

Sera from type II mixed-cryoglobulinemia patients typically have low antigenic levels of the early components of complement, with relatively normal levels of C3 and factor B (6). Measurements are best made at 37°C in order to minimize artifacts introduced by *ex vivo* cryoprecipitation or activation by other complexes that may occur over time at 4°C. Serial studies have shown that hypocomplementemia

FIGURE 1 (A) Cryoglobulinemia was initially missed in a patient with cutaneous vasculitis documented by biopsy of a purpuric lesion on the right second digit (left). Because of deteriorating status, including renal failure, she was treated with high doses of steroids and then cytotoxic agents, with an apparently poor response in terms of an expected drop in white blood cell (WBC) counts. One weekend, while still in the intensive care unit, she was noted to have developed nasal purpura in the distribution of a cold-air oxygen mask (right). (B) The Coulter histograms obtained at 4°C, 25°C, and 37°C each display the leukocyte (top), erythrocyte (middle), and platelet (bottom) panels. The leukocyte panel shows small lymphocytes to the left (thin arrow) and larger polymorphonuclear leukocytes and monocytes to the right (thick arrow), with the ordinate displaying percentages of total cells; the platelet panels at 4°C and 25°C are unusual in having a long tail (*) after the expected narrow peak. Pseudoleukocytosis and pseudothrombocytosis are revealed at 37°C, which shows (i) all the leukocytes to be polymorphonuclear, with few lymphocytes, as expected in a patient on high-dose corticosteroids, and (ii) a narrow platelet peak. Both findings are reflected in the manual counts (right). Recognition of this artifact led to identification of a type II cryoglobulin with RF activity, with restricted IgM and kappa arcs by immunoelectrophoresis (C, arrowheads) and a high thermal amplitude of cryoprecipitation (D). OD@280, optical density at 280 nm.

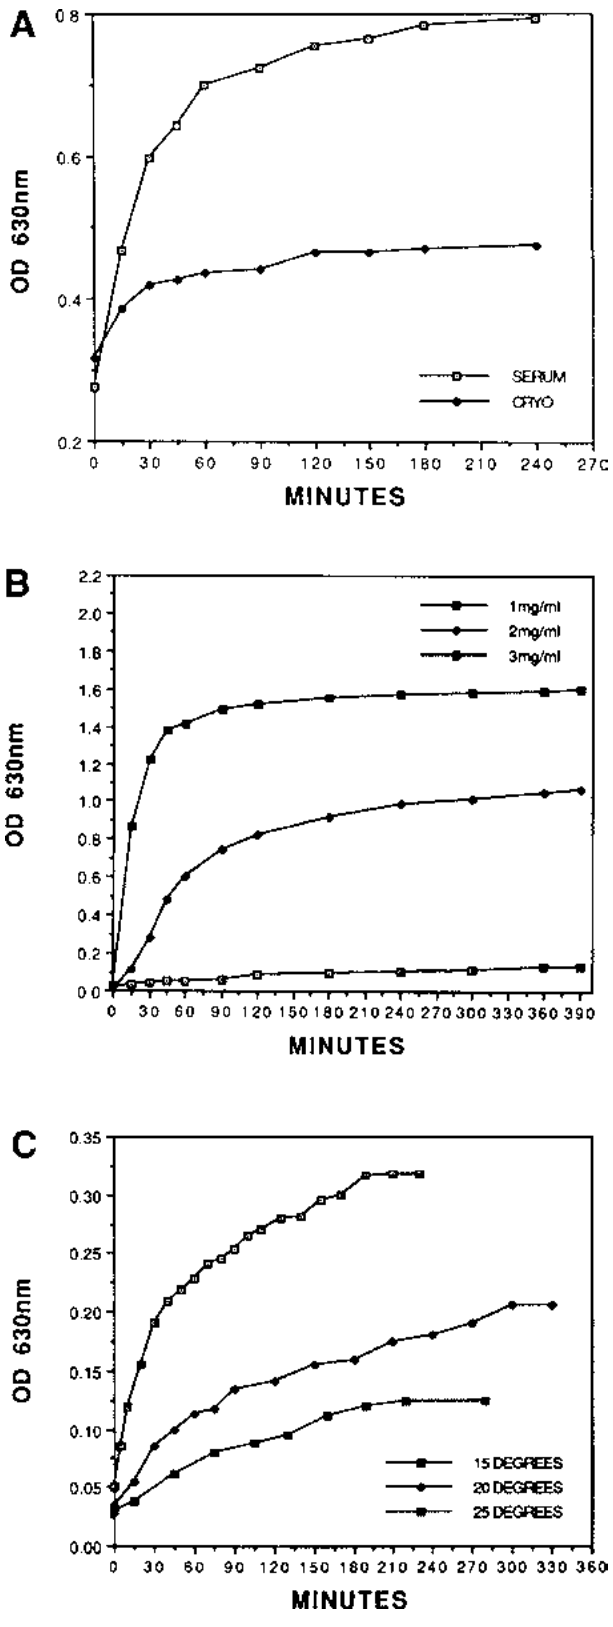

FIGURE 2 Kinetics of cryoprecipitation, assessed by turbimetric analysis, for a type II cryoglobulin, comparing serum and isolated cryoglobulin (A), different concentrations of isolated cryoglobulin (B), and different temperatures of cryoprecipitation (C). OD, optical density.

correlates only poorly with cryoglobulin levels. Most patients with type I cryoglobulinemia have normal complement levels, though occasional instances in which complement activation occurs and has been shown to be directly due to cryoprecipitate formation have been well described. In type III cryoglobulinemia, complement measurements may reflect abnormalities prevalent in the underlying disease (e.g., lupus erythematosus) or among the subset of patients predisposed to develop cryoglobulinemia (e.g., rheumatoid vasculitis, primary Sjögren's syndrome).

In sera manifesting CDAC, a similar profile of low CH_{50} and hemolytic C4 with normal hemolytic C5 to C9 is seen at 4°C, with normal values being obtained in EDTA-treated plasma and in serum kept at 37°C (the CH_{50} measures the total hemolytic activity of a test sample and is the reciprocal of the dilution of serum complement needed to lyse 50% of a standardized suspension of sheep erythrocytes coated with antierythrocyte antibody). Unlike in cryoglobulinemia, C1q and C4 antigenic levels are normal. CDAC may be a consequence of HCV antibody-monoclonal rheumatoid factor (mRF) complexes with differing stoichiometries, may be present in sera that do not contain detectable cryoprecipitates, and appears to correlate somewhat with liver damage and response to treatment with IFN-α (22). CDAC, RF, cryoglobulinemia, and elevated levels of IgM-containing immune complexes are all prevalent in HCV infection.

Conclusions

Although many clinical laboratories offer cryoglobulin determinations, rarely is testing rigorously carried out, and there is considerable interlaboratory variability (23). The most common sources of error are (i) false-negative results due to loss of cryoprecipitate during storage and (ii) false-positive results, usually due to residual fibrin in the sample, and failure to demonstrate redissolution of material with warming. In most instances, cryoglobulins are readily apparent by visual inspection of the specimen at 1 to 3 days. Many have thermal amplitudes characterized by 10^3- to 10^4-fold decreases in solubility occurring over a relatively restricted (<10°C) temperature range, which may be significantly influenced by the level of cryoprotein in the sample. Detailed characterization can be achieved using standard immunochemical techniques modified to be carried out above the temperature of cryoprecipitation.

CRYOFIBRINOGENEMIA

Background

The term "cryofibrinogenemia" denotes a circulating fraction of plasma that precipitates on incubation at refrigeration temperatures. The presence and/or increased levels of such a precipitate are associated with thromboembolic disease, chronic inflammation, malignancy, and occasionally connective tissue diseases, including cold-sensitive vasculitis (i.e., involving mostly exposed skin areas). A more accurate description of the origin of increased levels of plasma cryoprepreciptate might be hyperfibrinemia, since it reflects increased levels of soluble fibrin. In the presence of circulating fibrinogen, excess fibrin remains soluble by forming fibrinogen-fibrin complexes. Plasma cryoprecipitate typically redissolves at higher temperatures (e.g., 37°C). Its harvesting can be maximized by freezing plasma and thawing it at 4°C overnight, the standard procedure for manufacturing plasma cryoprecipitate for therapeutic infusion. It contains, in addition, major amounts of fibronectin, in and of itself a cryoprecipitable protein (Fig. 3). For precise quantitation,

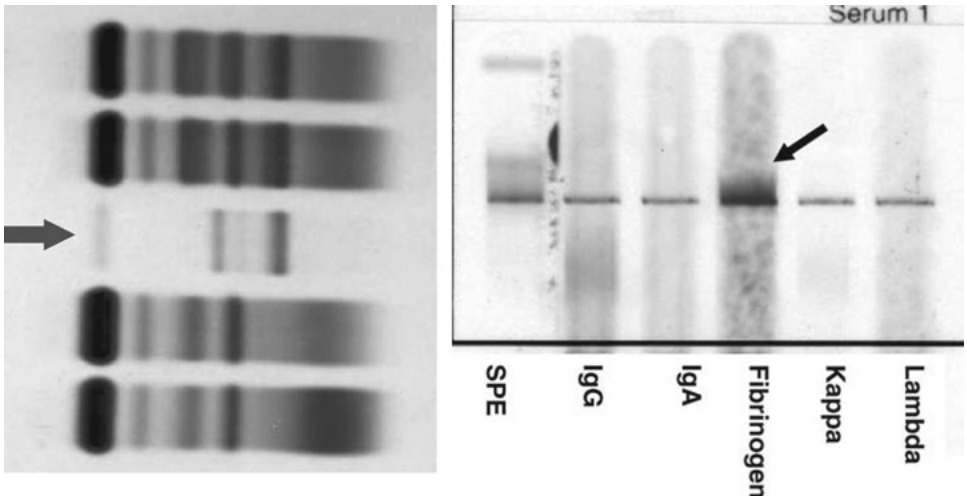

FIGURE 3 Isolated washed cryofibrinogen (arrows) visualized by agarose gel electrophoresis (left) and immunofixation (right). Gel electrophoresis reveals some residual albumin toward the anode, fibronectin in the beta region, an origin artifact, and fibrinogen, compared to serum samples in the upper and lower lanes. In the immunofixation on the right, an origin artifact is seen in all lanes due to precipitation on the cold gel. However, the antifibrinogen lane shows increased precipitate, thereby characterizing this as fibrinogen. SPE, serum protein electrophoresis. Courtesy of D. Keren, reproduced with permission.

the cryoprecipitate can be washed several or more times in cold buffer, such as phosphate-buffered saline, pH 6.4, redissolved at 37°C, and measured in a spectrophotometer at 280 nm. In summary, cryofibrinogenemia denotes circulating cold-precipitable complexes consisting of fibrin and fibrinogen which also contain fibronectin as the only other major constituent. Trace proteins, such as von Willebrand factor, factor VIII, and others, coprecipitate with these complexes. This precipitate may occur (i) when blood drawing is slow, allowing *ex vivo* thrombin generation that increases the level of soluble fibrin (24), (ii) in any disease in which increased levels of soluble fibrin occur (e.g., intravascular coagulation, sepsis, inflammation, cancer, thrombophilia), or (iii) in plasma obtained by use of plasmapheresis equipment, owing to prolonged extravascular exposure of blood.

Testing Considerations

The decision to test plasma for cryofibrinogenemia may be suggested by a variety of disorders. Some examples include purpura, particularly occurring on exposed skin associated with intolerance to cold temperatures, cold-induced urticaria, Raynaud's phenomenon, and evidence of thrombotic vasculopathy that cannot be explained by antiphospholipid autoantibodies or qualitative or quantitative clotting factor deficiencies. The test for cryofibrinogenemia may be part of a more general evaluation for causes of purpura, disseminated thrombohemorrhagic coagulopathy, other thromboembolic disorders, skin necrosis, chronic leg ulcers, or gangrene. Cryofibrinogenemia may be associated with neoplastic states and IgA nephropathy and is rarely familial; it has also been described in the absence of clear-cut underlying disease and in about 3% of random blood samples from hospitalized patients or asymptomatic healthy blood donors (25).

Examples of Cryofibrinogenemia

Case 1

A 14-year-old girl was evaluated for cold-sensitive vasculitic purpura, mainly of the extremities. The condition had become so severe that she required home tutoring throughout the year to avoid cold exposure. Her condition was followed by measuring her plasma "cryocrit," the column of insoluble material formed when citrated plasma was incubated at 4°C and centrifuged. This value rose markedly during exacerbations of her disease and decreased following each plasmapheresis treatment. Cryoprecipitate that formed when plasma was frozen and thawed at 4°C was also measured as another indicator of cryoprecipitable plasma protein. Relative to those of normal donors and to other patient plasma samples with similarly elevated fibrinogen levels, her cryoprecipitable protein was at least 3-fold higher during a quiescent period. Her isolated fibrinogen was functionally normal, as was that obtained from her parents. Her protease-free serum alone, or when it contained added fibrin-depleted fibrinogen isolated from her plasma or from that of a normal donor, did not form a cryoprecipitate.

Case 2

A 42-year-old man was referred for "cryogel" formation, occurring each time blood was drawn by venipuncture (Fig. 4). He was known to have chronic hepatitis due to HCV and had achieved only limited response to various regimens of IFN-α and ribavirin. Other significant clinical features were visual changes, purplish blotching notably involving the forehead, and erectile dysfunction. The initial coagulation profile disclosed a prolonged thrombin time and only partial correction when equal volumes of his plasma and normal donor plasma were mixed. Serial plasma dilutions yielded abnormally increasing thrombin times, consistent with the acquired dysfibrinogenemia of hepatic disorders. There was no family history of dysfibrinogenemia.

Repeated evaluations showed that drawn blood rapidly formed a gel-like material at 4°C that did not fully dissolve when rewarmed to 37°C; this gel did not contain significant Ig either by Ouchterlony analysis or SDS-PAGE. After removal, no further cryoprecipitation was observed; similarly, when plasma was clotted by the addition of thrombin at 37°C and the clot was synerized and removed after several

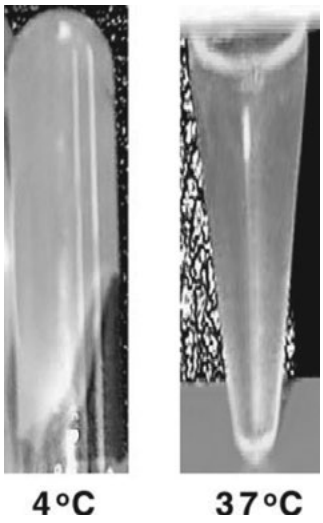

FIGURE 4 Reversible cryogel formation at 4°C (tube inverted) and 37°C (liquid).

hours, his serum formed no additional cryoprecipitate when left at 4°C. In contrast, citrated plasma cryoprecipitate obtained by conventional freeze-thawing was ~3-fold higher than that of normal controls.

All of the patient's symptoms improved following plasmapheresis but recurred progressively within 2 weeks or so, requiring repeat treatments. During the first few plasmapheresis, the intravenous line to the cell separator, as well as the plasma line to the disposal container, began to occlude with visible strands of clot; frequent flushing of lines with normal saline was only partially successful in overcoming this obstacle. The problem was solved by incorporating 6 to 10 U heparin/ml in the citrate anticoagulant solution used during the procedure. His plasma formed abnormally increased amounts of precipitate when left at 4°C overnight, whether obtained before plasmapheresis or after the procedure from the removed plasma. For testing, his serum was rendered protease free by addition of hirudin (20 U/ml), aprotinin (50 U/ml), and phenylmethylsulfonyl fluoride (100 mM); soluble fibrin was depleted by incubating fibrinogen solutions at 4°C, pH 6.4, and ionic strength 0.1 overnight, followed by removal of formed precipitates by centrifugation at 4°C. Such protease-free serum formed no cryoprecipitate with or without added fibrinogen that had been depleted of its soluble fibrin.

In subsequent weeks, the patient was placed on warfarin (Coumadin) and heparin was stopped; plasmapheresis was continued uneventfully over several months and eventually stopped without recurrence of symptoms.

Interpretation

In the first patient, pathologic fibrinemia was clearly related to the inflammatory vascular lesions and could be used as an index to follow the activity of the disease and its response to treatment. In the second patient, fibrinemia may have resulted from the delayed clearance of activated coagulant factors that is prevalent among patients with chronic liver disease. Paradoxically, dysfibrinogenemia may have contributed to the abnormal levels of circulating fibrin by allowing higher levels of soluble fibrinogen-fibrin complexes to accumulate, as fibrin monomers are normally soluble in high fibrinogen excess under physiologic conditions. Whether dysfibrinogenemia is congenital or acquired, such plasma often has a higher maximal capacity for soluble fibrin owing to defective coagulability or incoagulability of abnormal fibrinogen molecules.

Procedures

Choice of Anticoagulant

Various reports described use of either citrate or EDTA to collect blood for testing of cryofibrinogenemia. Paradoxically, EDTA is a potent inhibitor of fibrin polymerization in purified systems, demonstrable by decreased clot turbidity. In unpublished experiments by the author, clot turbidity was decreased to 1/8 that of the control. Similar previous observations led to a recommendation against EDTA use for such plasma tests. To address the differences between results from purified systems and those from EDTA-collected plasma, clotting of isolated fibrinogen was examined in the presence of 1% human albumin ($n = 3$) to simulate the plasma environment. Albumin incorporation consistently abolished the EDTA inhibition (Fig. 5). To assess this observation further, cryoprecipitates from nine randomly selected patient plasma samples from CBC (EDTA) tubes in the hematology laboratory were examined. These were obtained following plasma incubation at 4°C for several days and exhaustively washed by resuspending them in cold buffer, pH 6.4, and centrifuging them (4°C) to remove soluble proteins. SDS-PAGE analysis run under nonreducing conditions disclosed only fibrinogen/fibrin monomer bands in all cases. In a further experiment, plasma samples collected with citrate and EDTA from four normal donors were compared (Fig. 6). Their cryoprecipitates were harvested after freeze-thawing at 4°C overnight and exhaustively washed with cold buffer, pH 6.4. They were then dissolved in 6 M urea, pH 7.4, and the protein was measured spectrophotometrically (280 nm). The amounts of protein from plasma collected into EDTA ranged from 1.6 to 1.7 times that from its citrated counterpart. This established that EDTA is more sensitive than citrate when testing for cryofibrinogenemia.

Testing Procedures

1. To screen for cryofibrinogenemia, simultaneous plasma samples (normal and patient) are collected in EDTA at 37°C and allowed to stand at least overnight at 4°C. Blood should not be collected in heparin, unless care is taken to

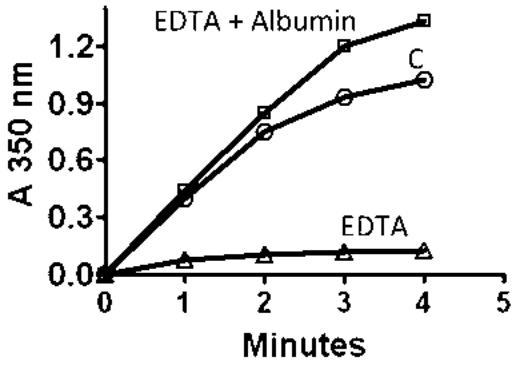

FIGURE 5 EDTA inhibition of fibrin polymerization abolished by albumin. Clotting was initiated by thrombin (final concentration, 0.2 U/ml) in a solution containing isolated (>96% pure) fibrinogen (1 μM in 0.15 NaCl, 0.01 M Tris-HCl, pH 7.4). Clots shown are the control (C), that containing EDTA (1 mM), and that containing EDTA plus human albumin (200 μM).

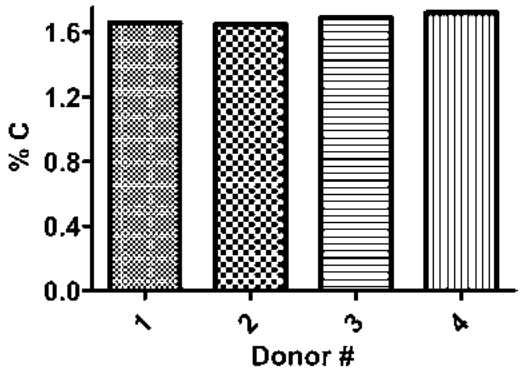

FIGURE 6 Higher cryoprecipitate contents in EDTA-collected than in citrate-collected plasma. Plasma from duplicate pairs of blood specimens from each of four normal donors was collected in tubes containing EDTA or citrate, frozen (−30°C) within an hour, and thawed overnight (4°C) to harvest cryoprecipitate. The cryoprecipitate was then washed and measured (280 nm) as detailed in the text. The protein content of cryoprecipitate from each donor is shown as a percentage of C, its citrate counterpart.

keep its concentration in collected blood at 3 U/ml or less. Significantly higher concentrations may induce increased incorporation of fibronectin in the cryoprecipitate (see item 6 below) and therefore yield false-positive results. To minimize *ex vivo* fibrin generation, blood should be collected rapidly in standard EDTA-containing vacuum or nonvacuum commercial tubes. The largest possible bore needle (e.g., 17 or 18 gauge) and a relatively short needle-to-tube plastic connector are ideal. Since cryoglobulins will also precipitate in plasma, the presence of a cryofibrinogen will be suggested by the absence of a comparable precipitate in a paired sample of serum (26).

2. Two alternative methods may be used to measure cryoprecipitable protein. One is to allow plasma collected in EDTA or citrate to remain undisturbed overnight or longer on ice or at 4°C, to centrifuge the plasma in a refrigerated centrifuge, and to measure the insoluble column as a percentage of total volume (cryocrit). This method, though imprecise, is useful when fibrinemia is pronounced. Another is to freeze the platelet-poor plasma sample shortly after its harvesting in a self-defrosting freezer (−8°C to 20°C) overnight (or for at least 6 h) and then thaw it at 4°C overnight. Centrifugation at cold temperatures yields insoluble material, which is harvested by discarding the supernatant. The cryoprecipitate can then be suspended in ice-cold, phosphate-buffered (pH 6.4 preferably) saline, in a 50- to 100-fold volume excess and recentrifuged to remove more noncryoprecipitable proteins. This washing should be repeated at least three times. More-exhaustive washing may progressively remove fibronectin as well. The final pellet is solubilized at 37°C or in 6 M urea; protein content is determined by diluting an aliquot in 6 M urea and measuring absorbance at 280 nm, which is compared to a control. To convert to milligrams of protein, an extinction coefficient (1%, 1 cm, 280 nm) of 14 or 15 (fibrinogen) can be used. Fibrinogen-fibrin remains as the major constituent protein, and washing tends to decrease the fibronectin content.

3. A third indicator of the fibrin content of plasma is the level of D dimers which can be measured by commercially available assay. Although the D dimer is a proteolytic fragment of the cross-linked clot, it also reflects soluble fibrin/fibrinogen polymers with cross-linked γ-γ chain contacts. That is to say, fibrinogen is an invariable component of soluble fibrin complexes whose solubility indicates that their intermolecular α-α chain contacts are not cross-linked by factor XIIIa, the thrombin-activated form of factor XIII. The D dimer, therefore, does not distinguish between soluble and insoluble fibrin/fibrinogen complexes. Elevated D dimer levels correlate with hypercoagulability and are widely used as indicators of pathologic thrombosis.

4. Fibrin-fibrinogen complexes in most, if not all, dysfibrinogenemic individuals can also be quantified by harvesting the cryoprecipitate obtained from frozen and thawed plasma as in item 2 above. This should also be washed in cold buffer as described above, prior to protein measurements. A unique feature of this cryoprecipitate is that it may contain mostly normal fibrinogen/fibrin (24, 27). That is to say, the overwhelming majority of dysfibrinogenemias occur in heterozygous individuals, and fibrinogen is a dimeric protein (27). Assuming random events during peptide synthesis, molecular assembly, and secretion, this means that the ratio of normal homodimers to hybrid dimers to abnormal homodimers is 1:2:1. Also, fibrin polymerization is typically impaired, so abnormal molecules may have a decreased capacity to polymerize, relative to their normal counterparts. As a result, fibrin-fibrinogen complexes are likely to consist of mostly normal molecules. An exception is abnormally formed fibrin-fibrinogen complexes owing to the specific structure defect. Such complexes will necessarily be incorporated into the cryoprecipitate, which has been observed by the author in one unpublished case. A different result may be encountered in very rare homozygous individuals with dysfibrinogenemia whose fibrinogen is incoagulable. In such instances, plasma may or may not form cryoprecipitate.

5. Commonly not appreciated is the increased *ex vivo* fibrinemia resulting from the use of blood cell separators in which the standard anticoagulant is citrate. By measuring cryoprecipitate content, the author observed up to five-times-higher levels in plasmapheresis plasma than in that from a blood donor whose plasma was harvested and frozen within 24 h or less. This is consistent with a similar effect produced by a very slow withdrawal of blood (24). If serum is harvested from such samples prematurely, it may subsequently form cryoprecipitates (i.e., at 4°C), which can be erroneously interpreted as "cryoglobulins." Its partial or complete failure to redissolve at 37°C may reflect cross-linked fibrin gel rather than cryoglobulin. This is easily demonstrable by failure of the precipitate to dissolve in 6 M urea or 2% acetic acid. A reasonable precaution is to allow whole blood to clot for at least 6 h at 37°C, remove the clot, and observe for another hour or so to ascertain that no further clot forms before harvesting serum to test for cryoglobulins. To confirm that no fibrinogen remains, one can perform a commercially available fibrinogen assay on the patient and a normal control serum.

6. If cryoglobulin analysis is performed on patients who are receiving heparin anticoagulation or on samples collected during plasmapheresis in which heparin has been administered, it is also important to be aware of the possibility of cryoprecipitation due to complexes between heparin and fibronectin (see above), which may increase cryoprecipitate formation; the relative contents of fibrinogen and fibronectin in isolated cryoprecipitates can be assessed by immunoblot analysis using monospecific antisera to these proteins (25). Although at *in vivo* therapeutic concentrations (i.e., <1 U of heparin/ml), this effect may be negligible, the heparin content of blood samples may range up to 5 U/ml or more, at which level it may contribute to cryoprecipitation. Moreover, either concentration range of heparin will

inhibit thrombin generation and thereby the formation of fibrin-fibrinogen complexes.

Summary and Conclusions

Cryofibrinogenemia usually results from elevated levels of fibrin-fibrinogen complexes in plasma, may reflect abnormally assembled complexes in dysfibrinogenemia, and on rare occasions result from complexes of fibrinogen and circulating antifibrinogen antibodies (28–30); in addition, fibronectin can form cold-insoluble complexes with Ig in various disease states (e.g., fibrillary glomerulonephritis) that may be associated with a granulomatous vasculitic component. Cryofibrinogenemia can be screened for by cryoprecipitating or freeze-thawing plasma collected in citrate or EDTA, notwithstanding the fact that the latter is more sensitive. Factors that minimize its *ex vivo* generation include thrombin inhibitors in the container anticoagulant and rapid withdrawal of blood to be tested. If heparin is used alone or incorporated in the anticoagulant to inhibit thrombin, its level should be <3 U/ml.

PYROGLOBULINEMIA

Background

Pyroglobulins are Igs that precipitate irreversibly as a gel when serum is heated to 56 to 60°C for 30 min; in contrast, heat precipitation of Bence-Jones proteins under similar conditions is reversible. Pyroglobulins are invariably single-component proteins and constitute <1% of monoclonal gammopathies overall and ~6% of Waldenström's macroglobulins.

Concept

Pyroglobulins of every Ig isotype (including IgD and IgE) have been reported in association with multiple myeloma, lymphoproliferative diseases, and plasma cell leukemia. Their occurrence has not been associated with specific clinical manifestations, though high levels of these proteins may also cause hyperviscosity or coagulopathies. A related phenomenon of heat-insoluble type 2 cryoglobulins has been described for patients with primary Sjögren's syndrome and as a cause of membranoproliferative glomerulonephritis (31).

Procedure

1. Pyroglobulins precipitate when warmed to 56°C and do not redissolve upon being heated to 100°C. They are usually apparent as an M-spike upon serum protein electrophoresis, which significantly decreases, or completely disappears, after pyroprecipitation. Serum immunofixation will thus define the specific M component forming the pyroglobulin, and this can be confirmed by SDS-PAGE of the isolated material.

2. As noted above, fibrinogen, fibrin, and their core proteins are also heat precipitable at these temperatures. Any remaining fibrinogen and/or fibrin due to dysfibrinogenemia (or an incompletely clotted blood sample) and their split products (typically containing the thermally sensitive D domain) will also form irreversible precipitates at 56°C. To control for this, serum can be treated with 2 IU or more of thrombin/ml and allowed to stand for 1 to 2 h at 37°C, and any clots formed can be removed by syneresis before the specimens are heated to 56°C.

3. Unlike with cryoglobulins, pyroglobulin formation is usually not significantly inhibited over the pH range 3 to 9 or by changing the ionic strength of the solution. Similarly, the effects of reducing (e.g., 2-mercaptoethanol) or dissociating (e.g., Triton X-100) agents on this phenomenon are varied. Occasionally, single patients have been described to have both cryo- and pyroglobulins.

Conclusion

Recognition of the laboratory phenomenon of pyroglobulinemia has importance as a potentially confounding factor for heat-based assays used to inactivate complement or to measure fibrinogen levels. Proper identification of a pyroglobulin as being a monoclonal component may in turn lead to the diagnosis of macroglobulinemia or plasma cell dyscrasia.

Strategy for Detecting and Following Monoclonal Gammopathies

JERRY A. KATZMANN AND DAVID F. KEREN

11

The preceding chapters in this section have dealt with several aspects of serum and urine protein analysis for immunoglobulins. Overwhelmingly, the single most important reason for performing these studies is to detect monoclonal gammopathies. This chapter briefly summarizes the various plasma cell proliferative diseases and then describes the use of the electrophoretic and nephelometric assays for the diagnosis, prognosis, and monitoring of monoclonal gammopathies. There are some general strategies for all laboratories as well as specific tests that are needed, depending on the disease presentation.

In plasma cell proliferative diseases, a monoclonal immunoglobulin (M protein) that can be used as a serologic "tumor" marker is usually secreted. Because of this secreted monoclonal immunoglobulin, these diseases are also referred to as monoclonal gammopathies. The secreted proteins can be used as a diagnostic tool for the identification of the clone of plasma cells as well as a quantitative marker to follow the course of the disease and response to therapy. Unlike many other tumor markers, M proteins are extremely diverse. Each M protein has a unique variable region sequence, and the molecules may run the gamut from pentameric IgM (~900,000 Da) to monomeric free light chains (FLCs) (~24,000 Da). In addition, although some plasma cell proliferative disorders present with M protein concentrations of grams per liter of serum, others have little or virtually no circulating M protein. The diversity of plasma cell proliferative diseases and of their secreted proteins and the concentrations of M proteins make M protein a challenging tumor marker. No single assay can effectively diagnose and monitor plasma cell proliferative diseases, and the laboratory needs to define strategies that encompass the spectrum of disease presentations. Protein electrophoresis (PEL), immunofixation electrophoresis (IFE), and immunosubtraction electrophoresis (ISE) of serum and urine have formed the hub of laboratory testing for detecting and monitoring monoclonal gammopathies (1–3). These electrophoretic assays provide analytic separation of immunoglobulins based on charge and size and allow the recognition and quantitation of M proteins distinct from the normal polyclonal immunoglobulins. In addition, quantitative immunoassays of immunoglobulins and FLCs (4) may be useful for diagnosis and/or monitoring disease.

CLASSIFICATION OF MONOCLONAL GAMMOPATHIES

Monoclonal gammopathies are disorders that include a diversity of plasma cell proliferative diseases. The diseases have different biological processes and may have different presentations, treatments, and outcomes. Once the laboratory has identified a monoclonal immunoglobulin, the clinician needs to make a specific diagnosis based on clinical presentation and perhaps bone marrow, imaging, or other tissue and blood studies. In Table 1 are listed the 39,929 monoclonal gammopathies that were detected in the Mayo Clinic practice between 1960 and 2008. The 18 diseases in Table 1 are listed by decreasing frequency of diagnosis. These disorders are often categorized as malignant, premalignant, and protein/low-tumor-burden diseases, as indicated in the table (5). The malignant disorders have large tumor burdens, which must be controlled or eradicated. The premalignant disorders have no clinical symptoms and need only be monitored for progression, and the protein/low-tumor-burden diseases may have low (or large) tumor burdens, but the secreted monoclonal proteins cause the disease processes. This classification of the various plasma cell proliferative diseases can be helpful in thinking about the biology of the diseases as well as the range of laboratory presentations.

Malignant Plasma Cell Proliferative Disorders

Multiple myeloma (MM) is the most common malignant plasma cell disease and is second to non-Hodgkin lymphoma as the most common hematologic malignancy (6). In the U.S. population, it is estimated that 22,350 new cases of MM were diagnosed in 2013. MM is a disease of older people, with the median age at diagnosis being 69 years, and it is rare in people younger than 40 (7, 8). The incidence is slightly higher in men and twice as high in blacks as in whites (9). The racial disparities as well as family studies suggest genetic factors, but environmental factors, such as exposure to agricultural and petroleum industry chemicals, have been shown to be risk factors as well (10). Myeloma cells reside in the bone marrow, often suppress other marrow elements, and may cause destructive bone lesions.

The presence of a large clone of bone marrow plasma cells (>10%) is not in itself sufficient for the diagnosis of MM. The diagnosis also requires symptoms that are due to

[a]MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering multiple myeloma; POEMS syndrome, syndrome with polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes; BHPW, benign hypergammaglobulinemia purpura of Waldenström's macroglobulinemia.

the plasma cell clone. In a series of 1,027 sequential patients, the symptoms at diagnosis were anemia (73%), bone pain (58%), elevated creatinine (48%), fatigue/weakness (32%), hypercalcemia (28%), and/or weight loss (24%) (7). The diagnosis of MM requires organ damage summarized by the acronym CRAB: increased serum calcium concentration, renal insufficiency, anemia, and lytic bone lesions. It is the manifestation of these clinical symptoms rather than pathology that distinguishes MM from the premalignant disorders of smoldering multiple myeloma (SMM) and monoclonal gammopathy of undetermined significance (MGUS) (11, 12).

The distribution of types of monoclonal immunoglobulins in a series of MM and MGUS patients is listed in Table 2. The immunoglobulin distributions are different between the two diseases. The most obvious difference is in the frequency of IgM. Most IgM disease that progresses to malignancy is classified as Waldenström's macroglobulinemia (WM). WM is a disease of clonal lymphoplasmacytic cells and is a clinicopathological entity distinct from MM. Another difference in the distributions of monoclonal proteins is that monoclonal FLCs and monoclonal IgD occur in MM at about 4-fold more than in MGUS. The laboratory detection of monoclonal FLCs or monoclonal IgD should always raise the suspicion of serious disease. Laboratorians who see samples that are mostly from MGUS patients and a few MM samples are almost always surprised by the relatively high frequency of light-chain multiple myeloma (LCMM) and nonsecretory multiple myeloma (NSMM) among MM patients.

The other malignant diseases listed in Table 1 include lymphoproliferative disease, plasmacytoma, plasma cell leukemia, and the heavy-chain diseases. A small percentage of B-cell lymphomas and leukemias will produce a monoclonal immunoglobulin usually found in low concentrations in serum. Plasmacytomas are solitary lesions that usually present with pain at the site of the lesion, which contains clonal plasma cells in the absence of any diffuse bone marrow involvement or CRAB symptoms. Plasmacytomas often have no or small amounts of secreted monoclonal protein and usually respond well to radiation. However, within 2 years, approximately 50% will recur as MM (13). Plasma cell leukemia is a rare and aggressive form of myeloma, with high numbers of circulating plasma cells. Interestingly, approximately 35% of plasma cell leukemia patients will have LCMM only and 10% will have NSMM (14). Heavy-chain diseases are exceedingly rare and are identified by the presence of a monoclonal heavy chain with no corresponding monoclonal light chain upon IFE (15). The heavy chain is often detected in significant concentrations in the urine, and urinary IFE is a useful confirmatory assay. Many heavy-chain disease patients have lost the ability to synthesize light chains, but some patients have mutations in the heavy chain that results in the inability to bind light chain. The latter patients may therefore present with an isolated monoclonal heavy chain detected by IFE plus monoclonal free light chain as detected by a significantly abnormal FLC kappa-to-lambda ratio (16).

TABLE 2 Distribution of monoclonal proteins in patients with multiple myeloma and monoclonal gammopathies of undetermined significance

Monoclonal immunoglobulin type or nature of disease	% of patients with[a]:	
	MM	MGUS
IgG	52	59
IgA	21	12
IgM	0.5	18
IgD	2	0.5
Biclonal	2	5
Light chain only	20	6
None detected	2.8	NA

Premalignant Plasma Cell Proliferative Disorders

Whereas small quantities of M proteins were once considered to be "benign monoclonal gammopathies," that term is no longer used. Conditions that were so categorized are now referred to as MGUS or SMM because they are precancerous lesions that can evolve to MM, WM, or other B-cell lymphoproliferative conditions. Both MGUS and SMM are monoclonal gammopathies that manifest no symptoms of MM or a related disease that can be attributed to the plasma cell clone or monoclonal protein. These laboratory disorders are therefore not diseases *per se*. They are called premalignant disorders because virtually all cases of MM are now considered to have been preceded by MGUS or SMM as many as 8 or more years earlier (17–19).

MGUS is an asymptomatic monoclonal gammopathy that is usually detected as an incidental finding when protein electrophoresis is done as part of laboratory studies for a wide range of symptoms (20). By definition, the monoclonal protein is <3 g/dl, and <10% of bone marrow (if tested) is monoclonal plasma cells. MGUS is a common disorder with a prevalence of 3% in the Caucasian population over the age of 50 (21). In the Mayo Clinic practice, MGUS represents 58% of all newly diagnosed monoclonal gammopathies (Table 1). Like MM, MGUS is a disorder of older people, occurs more frequently in men than in women, and is at least 2-fold more prevalent in Africans and African Americans than in Caucasians (22).

Long-term studies of the natural history of MGUS have indicated that MGUS patients have a 1%-per-year risk of progression, and the risk of progression remains at 1% per year regardless of the length of follow-up (23). MGUSs may be subdivided into three types based upon the M protein: non-IgM MGUS, IgM MGUS, and light-chain MGUS (24). Most cases fall into the category of non-IgM MGUS (usually IgG or IgA). These cases have an overall risk of 1% per year of progressing to SMM, MM, or light-chain amyloidosis (AL). Patients with IgM MGUS have a 1.5% risk of progressing mainly to WM but also to lymphoma or AL. Those with light-chain MGUS have an as-yet-undefined risk of progressing to light-chain MM and AL. A number of risk factors for progression have been identified in patients with IgG, IgA, and IgM MGUS. The risk factors include M-spike concentration, percent bone marrow plasma cells, heavy-chain isotype, urinary monoclonal protein, and FLC kappa-to-lambda ratio (23, 25, 26). Because few MGUS patients have their urine tested and even fewer have their bone marrow tested, the three serum factors of M-spike size, heavy-chain isotype, and FLC ratio have been combined into a risk stratification model for predicting MGUS progression. Low risk factors are an M-spike level of <1.5 g/dl, the presence of gamma heavy chain, and a normal FLC kappa-to-lambda ratio. In our study of patients in southeastern Minnesota, 42% of patients were low risk for all three factors and had a 0.1%-per-year risk instead of a 1%-per-year risk of progression (26). The risk for these patients is so low that laboratory monitoring is not needed.

SMM has also been known as asymptomatic myeloma, and until recently, individuals within this classification did not receive treatment. As with MGUS, it is distinguished from MM because there are no CRAB symptoms attributable to the plasma cell clone. SMM is distinguished from MGUS by having an M-spike level of >3 g/dl and/or >10% monoclonal bone marrow plasma cells (27). Whereas individuals with SMM superficially appear to be at some point between MGUS and MM, the kinetics of progression of SMM to MM suggests that SMM does not affect a uniform group of patients. In the first 5 years of follow-up, SMM patients progress at a rate of 10% per year and subsequently progress at approximately 1% per year (28, 29). SMM may affect a mixture of patients with early MM that have not yet manifested clinical symptoms and patients with MGUS. Factors that identify patients destined to progress within 2 to 3 years of diagnosis have been identified, and consensus is building to use these laboratory criteria to help define MM (30). High-risk SMM with >60% bone marrow plasma cells or an FLC ratio of >200 has a median time to progression of 7 months (31, 32). Mateos et al. recently evaluated treatment versus no treatment (the current standard of care) of 125 individuals at high risk for SMM. After a median of 40 months, they found that the treatment group had a significant prolongation of both the median time to progression and the 3-year survival rate and that the toxic effects of the therapy (lenalidomide plus dexamethasone) were mainly grade 2 or lower (33). Similar studies are ongoing at other centers. These patients break the pattern of MM being exclusively a clinical diagnosis. The distinctions of MGUS, SMM, and MM are made because the diseases have different biological processes. It should be recognized, however, that they have overlap. The critical distinction is when the decision is made to expose the patient to the risks that come with the treatment regimens for MM. As therapy moves to earlier forms of the disease, the significance of detecting and characterizing M proteins in asymptomatic patients attains greater relevance.

Protein (or Low-Tumor-Burden) Diseases

The protein diseases or low-tumor-burden diseases represent a group of monoclonal gammopathies in which there may not be a large clonal proliferation of plasma cells but in which the cell products cause pathology. In primary (light-chain) AL, the monoclonal free light chains deposit in organs as amyloid fibrils. Over many years of secretion of amyloidogenic light chains, amyloid fibrils slowly accumulate. At some point, the deposition of the amyloid may cause heart failure, nephrotic syndrome, hepatomegaly, or other organ dysfunction (34). The diagnosis of AL is dependent on demonstrating amyloid deposits in tissue and identifying monoclonal light chains as the predominant protein in the fibril. This is usually accompanied with evidence of a clonal proliferation of bone marrow plasma cells or a monoclonal protein in the serum or urine. The recognition of a monoclonal free light chain in the serum may be the first "red flag" to suggest AL. Although some patients with MM produce an amyloidogenic light chain, most AL patients have small clonal populations and small amounts

of secreted monoclonal light chain. A monoclonal serum protein can be detected in 75 to 90% of patients with AL, but an M-spike can be quantitated in only approximately 50% of them (35). The low serum and urine concentrations make early detection and hematologic monitoring very difficult and previously meant that organ function had to be used as an indirect monitoring method. The availability of quantitative serum FLC assays has made detection of FLCs more sensitive and allowed direct hematological monitoring of patients with AL amyloid (36, 37). Lambda light chain is found in 70% of patients with AL amyloid. In contrast, kappa light chain is the causative light chain in 90% of light-chain deposition disease (LCDD) patients. However, LCDD is a much rarer disorder than AL, and the light chains do not form amyloid fibrils. As with AL, the diagnosis is based on characteristic histopathologic features.

Because amyloid fibrils can slowly form in any number of tissues, the disease is often not diagnosed until very late in the disease process. The identification of a monoclonal light chain in the serum or urine is often the first clue to the diagnosis. When a biopsy specimen is obtained, stained with Congo red, and viewed under polarized light, the amyloid fibrils have an apple-green fluorescence. Because all types of amyloid give this result, it is important to identify the specific amyloidogenic protein. In AL amyloid for example, the amyloid fibrils are caused by immunoglobulin light-chain fragments, and therefore treatment needs to be directed against the plasma cell clone. This is important because MGUSs are so common in older individuals that an M protein in serum or urine may coexist with the rare (incidence about 1/100,000) familial forms of amyloidosis where the M protein is not related to the primary disease process. In familial AL, the most common amyloidogenic proteins are polymorphisms of transthyretin (also known as prealbumin). Transthyretin is synthesized in the liver, and the treatments are therefore unrelated to the bone marrow. The best method for identifying the type of protein in the amyloid tissue is the use of tissue microdissection combined with mass spectroscopy (38, 39). This proteomic method is rapidly replacing immunohistochemical staining, which has a low sensitivity and specificity. Because familial forms of amyloidosis are autosomal dominant conditions, their detection and appropriate characterization are important for genetic counseling.

Some patients with neuropathies harbor an M protein (usually IgM). About half of these patients have Waldenström's macroglobulinemia, with relatively large amounts of IgM in the serum. They usually present with symptoms of hyperviscosity. Another group of patients who suffer from motor or sensory peripheral neuropathies may have small amounts of M proteins in the serum that require immunofixation for detection. Some of these patients have POEMS syndrome (also called Crow-Fukase syndrome), an acronym for peripheral neuropathy, organomegaly, endocrine dysfunction, an M protein, and skin hyperpigmentation (40). Unlike with cases of MM or WM, cases of POEMS syndrome and individuals with peripheral neuropathies who have myelin-associated glycoprotein monoclonal antibodies require that immunofixation (IFE) be performed on serum for detection (41).

DIAGNOSTIC TESTING STRATEGY

The detection of M proteins relies predominantly on the ability to differentiate between monoclonal and polyclonal immunoglobulins. This has traditionally been done with electrophoretic assays (2). Agarose gel protein electrophoresis and capillary zone electrophoresis (CE) with resolution sufficient to clearly distinguish the beta 1 (transferrin) and beta 2 (C3) bands are relatively simple procedures that are used to detect monoclonal proteins based on their restricted migrations compared to those of polyclonal immunoglobulins (42, 43). Immunofixation electrophoresis in agarose and immunosubtraction electrophoresis in CE are used to identify and characterize the immunoglobulin heavy and/or light chains and therefore confirm the identity of the monoclonal protein. In the last few years, additional methods that complement the electrophoretic assays have been developed. Quantitation of serum kappa and lambda FLCs by nephelometric immunoassays supports some of the weaknesses of PEL and IFE (4, 44), and practice guidelines now include all three serum assays (45).

PEL separates proteins based on charge and size. Once the proteins have been separated by electrophoresis, they are precipitated in the gel and stained, the gel is washed and dried, and the distribution of the protein stain is digitized by scanning the gel and obtaining an electropherogram (Fig. 1). In normal serum, the gamma fraction has a broad Gaussian distribution due to the thousands of clones of plasma cells that secrete immunoglobulin into serum. The quantitation of the gamma fraction provides information about hypogammaglobulinemia or hypergammaglobulinemia, and the quantitation of the gamma fraction should be similar

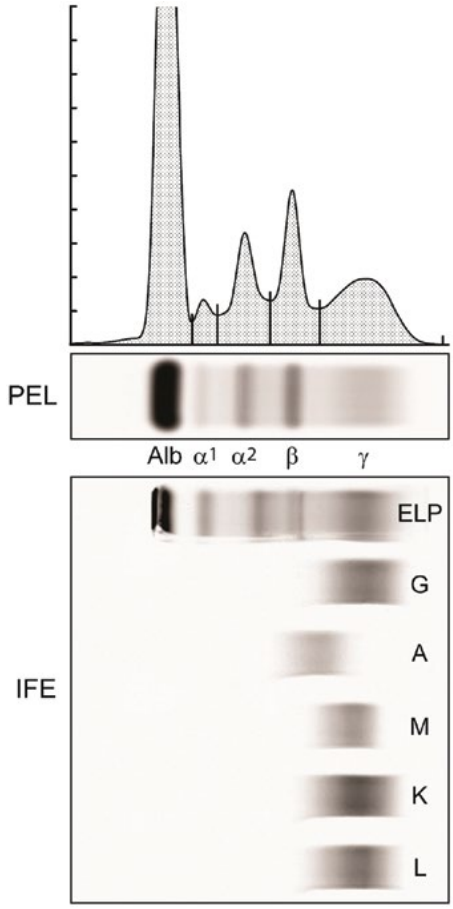

FIGURE 1 Normal serum protein electrophoresis (PEL) and immunofixation electrophoresis (IFE). The gel scan (electropherogram) is aligned above the PEL gel. Alb, albumin; ELP, electropherogram.

to IgG quantitation by immunonephelometric assays. In the serum of a patient with a monoclonal gammopathy, the monoclonal immunoglobulin is overrepresented and can be visualized as a restricted area of migration in the electrophoresis pattern (Fig. 2). All patients with a localized band or nonhomogeneous distribution upon serum PEL require IFE or ISE to confirm that the band is a monoclonal protein as well as to determine the heavy-chain class and/or light-chain type. A discrete band upon serum PEL is rarely a false-positive result. If the monoclonal protein migrates broadly or is at a low concentration, the PEL may appear to have a nonhomogeneous pattern. It is crucial to distinguish this from a restricted polyclonal response, and this can usually be done based on IFE.

In many patients, the use of serum PEL and IFE for the detection and quantitation of monoclonal proteins is very straightforward. There are, however, some types of monoclonal proteins that are more of a challenge. Patients with LCMM, for example, have lots of clonal plasma cells secreting monoclonal light chain, but the serum concentration may be low because the low-molecular-weight free light chain is quickly cleared into the urine. The PEL and IFE of serum and urine from a patient with LCMM are shown in Fig. 3. The serum PEL does not show an obvious M protein, although the IFE shows a discrete lambda band with no corresponding heavy-chain band. An additional IFE was performed with antisera to delta and epsilon chains and showed no reactivity suggesting IgD or IgE. Although this monoclonal lambda protein is detected in the serum by IFE, quantitation is not possible by serum PEL. The 24-h urine PEL, however, shows a large lambda M-spike that is easily detected and quantitated. When we envision serum from a patient with MM, we picture large serum M-spikes of intact immunoglobulin M protein; LCMM, however, represents 18 to 20% of patients with MM. It is because of patients like this that it is useful to test both serum and urine.

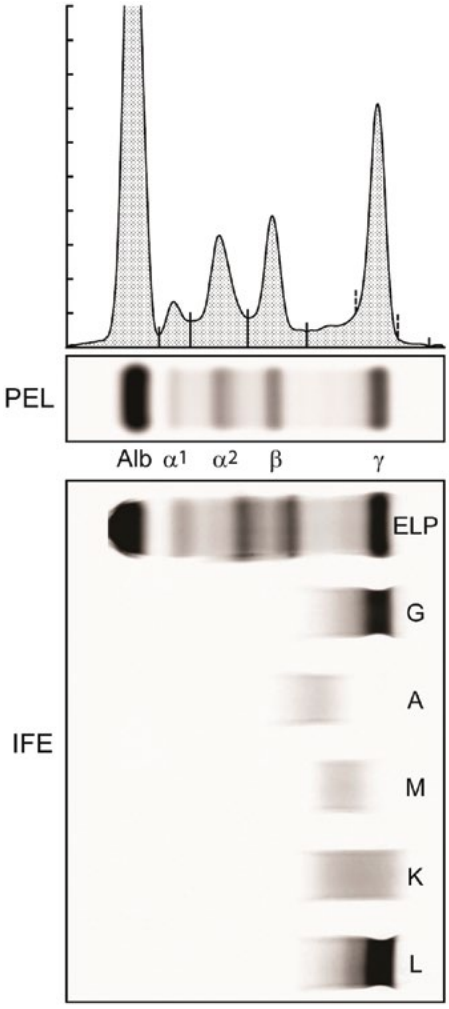

FIGURE 2 Monoclonal gammopathy serum protein electrophoresis (PEL) and immunofixation electrophoresis (IFE). The gel scan (electropherogram) is aligned above the PEL gel. The dashed lines on both sides of the M protein indicate the M-spike fraction.

Patients with nonmalignant low-tumor-burden diseases, such as AL, have serum and urine abnormalities that may be even more difficult for the laboratory to detect and quantitate. AL patients may have small numbers of bone marrow plasma cells and therefore small amounts of secreted monoclonal light chain. Examples of PEL and IFE of both serum and urine from an AL patient are illustrated in Fig. 4. Close examination reveals a faint monoclonal lambda band in the serum and urine. It is clear that if the concentration of the monoclonal lambda protein was slightly lower, we would not be able to see the abnormality. In addition, there is no way to quantitate and therefore monitor the abnormality. The introduction of quantitative serum FLC immunoassays has helped with the identification and quantitation of these monoclonal FLCs. Quantitative FLC assays use antisera directed against epitopes that are exposed only when the light chains are free (unbound to heavy chain) in solution. These cryptic sites are involved in the very tight noncovalent binding of light chains to heavy chains. The antisera have a 10,000-fold preference for FLCs over light chains contained within intact immunoglobulin molecules (4). That means that FLC immunoassays can be used to specifically quantitate FLCs even in the presence of large concentrations of polyclonal serum immunoglobulins. The approach is to quantitate the kappa FLCs and the lambda FLCs and use the ratio of kappa to lambda FLCs to detect unbalanced light-chain synthesis. This approach has proven surprisingly sensitive for detecting clonal free-light-chain diseases. Abnormal serum FLC ratios have been detected in 100% of patients with LCMM, 90% to 95% of AL patients, and 60% to 70% of patients with NSMM (46–48). In spite of the sensitivity of detection of FLC in free-light-chain diseases, abnormal serum FLC ratios have been detected in only 90 to 95% of patients with intact immunoglobulin MM and 40% of patients with MGUS (46). Although serum M proteins in these two patient groups have easily been detected by PEL and IFE, it is clear that not all monoclonal gammopathies secrete excess FLCs and that a combination of tests is needed to benefit from each test's strengths.

SCREENING PANELS FOR M PROTEIN DETECTION

There have been a number of studies identifying the best approach for detection of monoclonal proteins (49–54). The Mayo Clinic group performed a large study in which patients with an assortment of plasma cell proliferative diseases and who also had undergone serum PEL, IFE, and FLC tests were selected; urine PEL and IFE were also performed at the time of diagnosis. The cohort consisted of 1,851 patients with various monoclonal gammopathies (MM, WM, SMM, MGUS, plasmacytoma, POEMS syndrome, AL, and LCDD) (51). The data illustrated in Table 3 allow

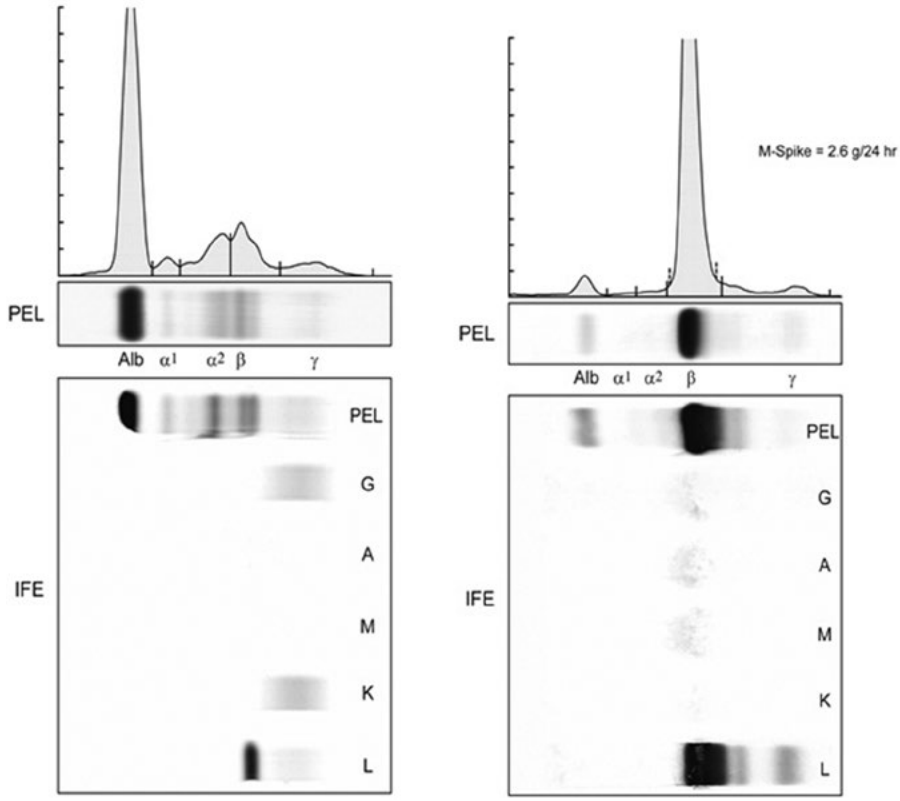

FIGURE 3 Light-chain multiple myeloma serum (left) and urine (right) tested by PEL and IFE.

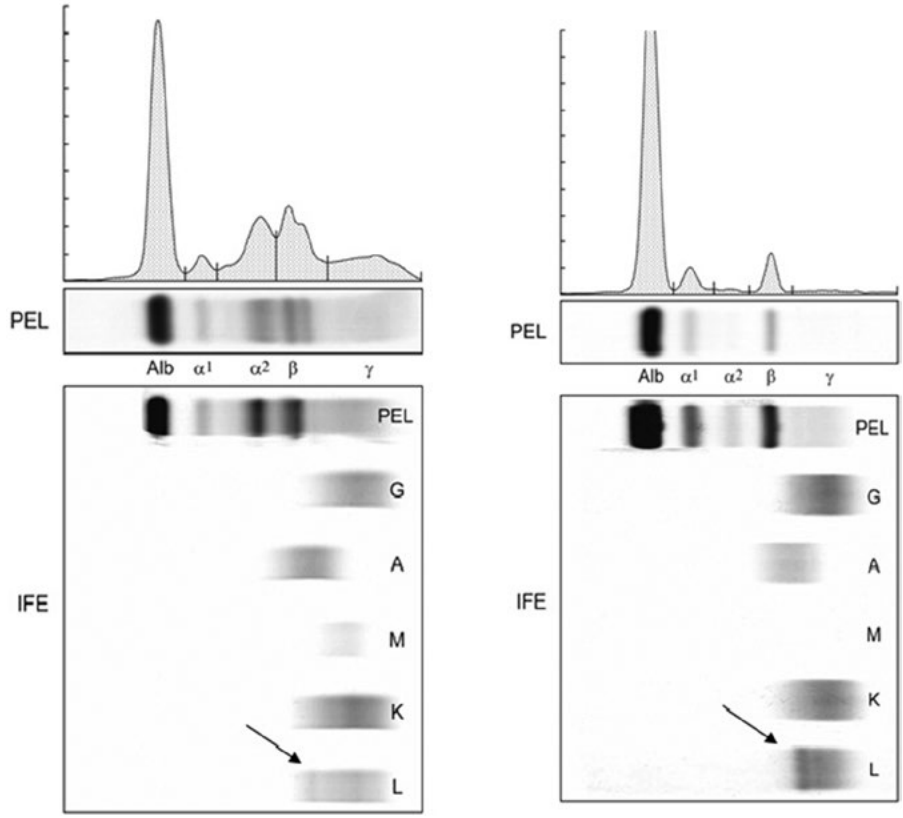

FIGURE 4 Primary amyloid tested by serum (left) and urine (right) PEL and IFE.

a retrospective determination of which patients would have had M proteins detected by the various tests singly or in combination. PEL, IFE, and FLC testing as single serum tests detected 79%, 87%, and 74% of the patients, respectively. A panel of all five assays detected 98.6% of the cases. Interestingly, if urine assays are removed from the diagnostic panel, there is no decrease in sensitivity for patients with MM, macroglobulinemia, plasmacytoma, extramedullary plasmacytoma, POEMS syndrome, or SMM. This and other studies have led the International Myeloma Working Group to recommend a screening panel of serum PEL, IFE, and FLC testing; panels that include urine are recommended if AL is suspected. In addition, once an M protein has been detected, analysis of urine may be required (45). This diagnostic panel of three serum assays simplifies the diagnostic algorithm and reduces costs for laboratories since only a single sample is transported and accessioned, and no preanalytic centrifugation or concentration of urine is needed. A simplified diagnostic panel of serum PEL and FLC testing is probably the bare-minimum screening panel that should be considered until we have more-sensitive detection systems.

STRATIFICATION OF RISK

The use of serum PEL, IFE, and FLC testing as a diagnostic panel also provides prognostic information for many plasma cell proliferative diseases. Survival in patients with MM is predicted by FLC testing, beta 2 microglobulin, and albumin (55); in AL, the FLC response to treatment predicts survival (36, 56), and in patients with plasmacytoma, the initial FLC result as well as the IFE results at 1 year predict relapse and survival (57). As mentioned earlier, the FLC ratio, PEL M-spike level, and IFE heavy-chain type predict progression to MGUS (26), and FLC testing and the percentage of bone marrow plasma cells predict the progression of SMM to MM (29, 32). The prediction of survival for patients with MM is important for stratifying clinical trials but has not yet broadly impacted treatment decisions. The predictions of progression to MGUS and SMM, however, play an important role in clinical practice. Recent demonstration of the efficacy of treatment in selected patients with high-risk SMM is changing the definition of MM. This allows SMM patients with FLC ratios of >200 to be treated before they return to the clinic with kidney failure and patients with >60% bone marrow plasma cells to potentially be spared anemia and bone lesions before the inevitable progression to symptomatic MM.

The effect of risk stratification for the low-risk MGUS patients is opposite to that for high-risk SMM. Progression rates of 0.1% per year for the low-risk MGUS patients mean that their physicians can reasonably tell them that they do not need continuous laboratory testing for progression to MM. This will save the patient time and money and will reduce anxiety about a malignant disease in their future. As electrophoretic methods have become more sensitive, we have detected monoclonal gammopathies at lower and lower concentrations, and the ability to define low-risk MGUS becomes increasingly important. We are detecting more of these smaller monoclonal proteins, and the laboratory is faced with a dilemma about reporting very small abnormalities. As indicated earlier, many very serious diseases may secrete low levels of monoclonal protein, but some apparent small monoclonal proteins may be part of a polyclonal immune response. The laboratory is therefore faced with trying to decide about reporting very low levels of monoclonal proteins and having clinicians reach monoclonal gammopathy overload. We have used the term IFE-MGUS to describe monoclonal proteins that are detectable by IFE but not readily by PEL. Fifteen to 20% of these IFE-MGUS abnormalities disappear with no treatment, but some eventually progress (12, 58). The use of FLC ratios and MGUS risk assessment may be useful tools to help us ignore some of the very small questionable abnormalities.

The addition of serum FLC testing to serum PEL and IFE is a good screening strategy and will detect almost all plasma cell proliferative disorders. The unknowns that remain for this three-assay diagnostic panel are as follows.

A. When should a urine sample be requested?
   1. If AL is part of the differential diagnosis, urine IFE may be needed if serum tests are normal.
   2. If heavy-chain disease is detected by serum IFE, urine IFE can be confirmatory.
   3. If a monoclonal protein is detected, 24-h urine studies are useful for documenting baseline renal function.

TABLE 3 Diagnostic sensitivities of monoclonal gammopathy screening panels with combinations of serum PEL, serum IFE, serum FLC, and/or urine IFE-PEL

Patient group	No. of patients	% of patients diagnosed by:					
		Serum PEL	Serum IFE	Serum FLC	All serum and urine tests	Serum PEL + IFE + FLC (no urine)	Serum PEL + FLC +
All	1,877	79.0	87.0	74.3	98.6	97.4	94.3
MM	467	87.6	94.4	98.6	100	100	100
WM	26	100	100	73.1	100	100	100
SMM	191	94.2	98.4	81.2	100	100	99.5
MGUS	524	81.9	92.8	42.4	100	97.1	88.7
Plasmacytoma	29	72.4	72.4	55.2	89.7	89.7	86.2
POEMS syndrome	31	74.2	96.8	9.7	96.8	96.8	74.2
Extramedullary plasmacytoma	10	10.0	10.0	10.0	20.0	10.0	10.0
AL	581	65.9	73.8	88.3	98.1	97.1	96.2
LCDD	18	55.6	55.6	77.8	83.3	77.8	77.8

B. When is a simplified screening panel of serum PEL and FLC testing sufficient?
   1. This two-assay panel efficiently detects MM and macroglobulinemia.
   2. If AL-, POEMS syndrome-, or MGUS-associated peripheral neuropathy is suspected, then serum IFE is needed.

MONITORING M PROTEINS

Once an M protein has been detected and a specific diagnosis has been determined, the quantitation of the M protein can be used as a marker of the plasma cell clone's response to therapy, stability, or progression. Just as there are multiple tests that may be required for diagnosing monoclonal gammopathies, there are multiple assays for measuring M proteins, and just as in diagnostic testing, the smaller the quantity of the M protein, the harder it is to quantify the abnormality. Quantitative tests include PEL for M-spike measurement and immunonephelometry for immunoglobulin quantitation, determination of FLC concentration, and heavy/light-chain measurements. If a serum M-spike (Fig. 2) and/or urine M-spike (Fig. 3) is present in a large enough concentration, it can easily be quantitated. The advantage of using the PEL M-spike when the abnormality is in the gamma fraction (as in Fig. 2) is that the fractionation of the M-spike separates the M protein from most of the polyclonal background. The International Myeloma Working Group defines serum M-spikes of >1 g/dl and urine M-spikes of >200 mg/24 h as being "measurable." "Measurable" means that the magnitude of the M-spike is large enough to be reliably quantified and is also large enough to document a decline in the M protein and, therefore, a hematological response. There are also disease presentations in which there is suppression of polyclonal immunoglobulin synthesis (Fig. 5). In cases where there is very little polyclonal immunoglobulin, the quantitation of immunoglobulin (IgG, IgA, or IgM) can also be used to monitor hematologic disease. Serum M-spike and immunoglobulin quantitations are not, however, always equivalent. In general, IgA monoclonal proteins have similar quantitations by immunonephelometry and M-spike testing, whereas monoclonal IgM protein concentrations are almost always higher by immunonephelometric quantitation than by PEL M-spike quantitation. It is important to realize that the two methods do not always correlate and that clinicians should not go back and forth between the methods. Many clinicians order both serum PEL and immunoglobulin quantitation as a quality check to see that both change in similar ways (59).

Not all patients can be monitored by levels of PEL M-spikes or quantitative immunoglobulins. Some patients have small concentrations of M protein (Fig. 6). In these cases, quantitation of the M protein will include substantial amounts of polyclonal immunoglobulins. The M-spike will be more enriched for the monoclonal protein than quantitative IgG, but the M protein will still be a minority of the M-spike. As this M-spike level gets smaller in response to therapy, the laboratory may still recognize the abnormality but has to make a judgment as to when to stop fractionating the M-spike. When the monoclonal protein appears to be less than one-quarter to one-third of the M-spike quantitation, we stop fractionating an M-spike and only report a "low concentration of monoclonal protein that we are unable to quantitate." That is not as satisfying as a quantitative result, but quantitation might be misleading as the polyclonal background changes.

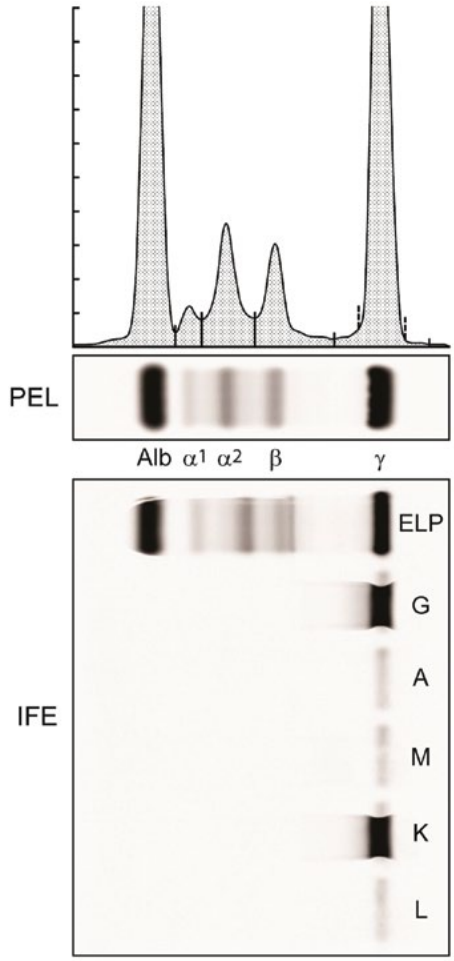

FIGURE 5 Large M protein with suppressed polyclonal immunoglobulins.

When small monoclonal IgA or IgM proteins migrate in the beta fraction instead of the gamma fraction, monitoring becomes more complex. In the case illustrated in Fig. 6, we might decide not to fractionate and quantitate, but we could still see the abnormality. If migration is in the beta fraction, we cannot visualize the protein because it is obscured by transferrin, C3, and other serum proteins. It is useful in these cases to use quantitative immunoglobulins to assist monitoring of IgA and IgM proteins. However, if one uses CE and ISE, which give good resolution of the beta 1 and beta 2 peaks, one may be able to isolate the abnormality or estimate the portion of the beta region that has been subtracted and provide a reliable value (Fig. 7) (60). Changes in the sizes of the beta fraction and the quantitative immunoglobulin or in the ISE-supported measurement should be concordant. New heavy/light-chain reagents that can separately quantify IgG kappa and IgG lambda, IgA kappa and IgA lambda, and IgM kappa and IgM lambda may be useful for these patients. The heavy/light, isotype-specific kappa-to-lambda ratio has been proposed as a potential monitoring method for M proteins migrating in the beta fraction. Even though the monoclonal protein is not visualized by PEL, an abnormal heavy/light kappa-to-lambda ratio indicates excess clonal synthesis analogous to the use of the FLC kappa-to-lambda ratio (61–63). The international guidelines do not address measurement of a low concentration monoclonal intact immunoglobulin.

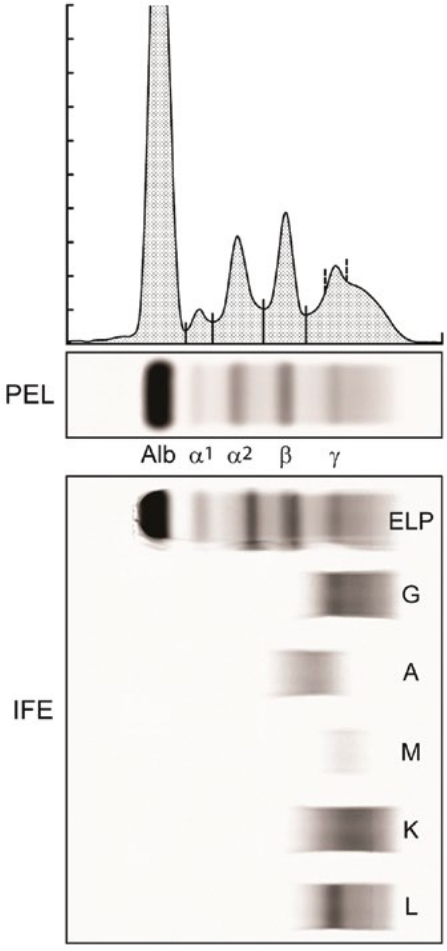

FIGURE 6 Small M protein within a background of polyclonal immunoglobulins.

The AL patient whose results are illustrated in Fig. 4 is an example of a case in which the lambda M protein cannot be quantified by serum or urine PEL M-spike, quantitative immunoglobulin, or heavy/light-chain assays. The FLC immunoassays, however, can be performed, and the lambda FLC concentration can be used to monitor this patient. The international guidelines for monitoring monoclonal gammopathies suggest that if the serum M-spike is less than 1 g/dl and the urine M-spike is less than 200 mg/24 h, only then should the FLC be considered for monitoring (45). The guidelines for FLC quantitation state that in order to monitor a "measurable" free light chain to document response to treatment, the FLC ratio should be abnormal and the concentration of the monoclonal FLC should be greater than 10 mg/dl (Table 4).

The international guidelines for "measurable" M proteins also define what changes are needed for partial, complete, and stringent responses when treating MM (Table 5) (64). A complete response is defined as a normal serum and urine IFE (as well as the absence of bone marrow plasma cells). A stringent complete response is a complete response plus a normal FLC kappa-to-lambda ratio. Partial responses are defined by the following decreases in measurable M proteins: a 50% decrease in the serum M-spike measurement, a 90% decrease in the urine M-spike measurement, and a 50% decrease in serum FLC concentration. In order to test

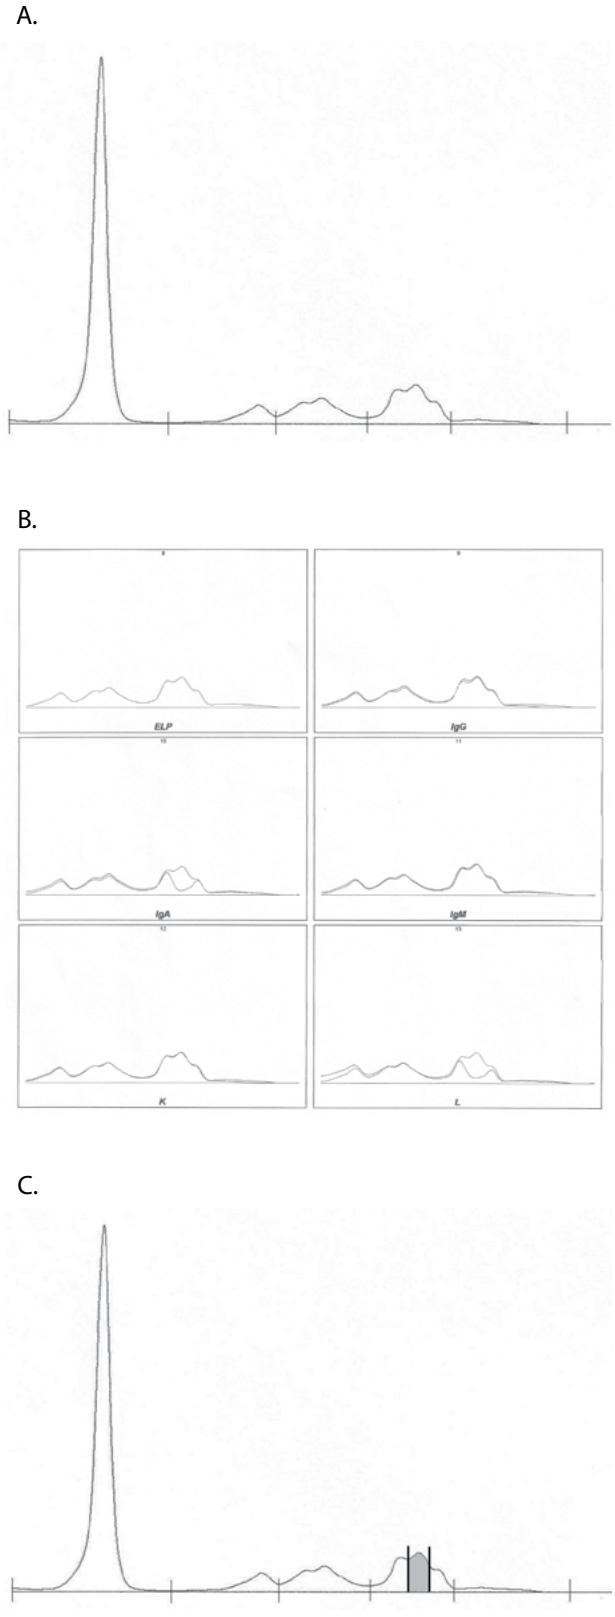

FIGURE 7 (A) Use of ISE to estimate the area of small beta-migrating M proteins. Capillary electropherogram with beta region restriction and hypogammaglobulinemia. (B) Immunosubtraction demonstrating that anti-IgA and anti-L subtract the M protein in the mid-beta region. (C) Use ISE data to demarcate and measure the M protein concentration.

TABLE 4 Response criteria for FLC determination[a]

Disease	FLC level and/or response or recommendation				
	Minimal measurable	Partial response	Complete response	Stringent complete response	Progression
AL without measurable serum or urine M protein	iFLC ≥ 10 mg/dl	50% reduction	Normal rFLC and bone marrow, complete response by IFE	ND	50% increase of iFLC to >10 mg/dl
MM without measurable serum or urine M protein	iFLC 10 mg/dl	50% reduction of dFLC	ND	Normal rFLC, complete response by IFE, and bone marrow	50% increase of dFLC
MM with measurable disease	Do not test FLC	Do not test FLC	Do not test FLC	Normal rFLC and bone marrow, complete response by IFE	Do not test FLC

[a]iFLC, involved free light chain; rFLC, ratio of free kappa/free lambda light chain; dFLC, difference between involved FLC types and uninvolved FLC types; ND, not determined. This table was modified from reference 66.

these partial-response guidelines, the Mayo group has studied the variability of long-term, sequential serum and urine samples in MM patients who have already reached stable, partial remissions (65). The study indicated that the biologic and disease-related variation in these stable patients was 8% for serum M-spike measurements, 12% for immunoglobulin quantitation, 28% for serum monoclonal FLC concentrations, and 36% for urine M-spike measurements. These variability data suggest that the serum FLC quantitation has variability that is more like that of the urine M-spike measurement. The concentrations of both serum FLC and urine M-spike depend on the synthesis and rapid clearance of the low-molecular-weight light chain. The serum M-spike depends on the synthesis and very slow clearance of intact immunoglobulin. The serum M-spike measurement has the lowest biological variability, and when possible, it is the parameter of choice for monitoring disease.

SUGGESTED ORDERING PATTERNS

Although plasma cell proliferative disorders are diverse, the suggested panel of serum PEL, IFE, and FLC provides relatively simple and sensitive diagnostic testing. However, a few suggestions that might encourage a more logical pattern of ordering based on initial presentation or monitoring needs are provided here. Order formats can provide several embedded clinical situations, allowing clinicians to request testing that is specific to their patient without needing to know details of the laboratory's armamentarium.

1. In an initial screen for MM, WM, or AL, perform a serum PEL-IFE-FLC three-assay screen. If the assay is negative, the clinician is sent a request to provide early-morning urine for urine IFE.
2. In an initial screen for POEMS syndrome or neuropathy (sensory or motor) suspected of being associated with an M protein, perform serum IFE only.
3. For follow-up for a known M protein in serum or urine, perform PEL only. If PEL is negative, resort to IFE.
4. For follow-up for abnormal serum FLC (includes oligosecretory MM and AL amyloid with no measurable urine light chains), perform serum FLC.
5. Confirm stringent complete remission by serum FLC.

SUMMARY

Depending on the particular monoclonal protein, the detection of M proteins may require serum PEL and IFE, urine PEL and IFE, and serum FLC quantitation. A diagnostic screening panel of serum PEL, IFE, and FLC has been recommended for detection of most plasma cell proliferative disorders. If AL is suspected, urine PEL and IFE should be included as well. The use of this diagnostic panel also guides laboratories and clinicians to the best approach to monitor disease.

TABLE 5 International Myeloma Working Group criteria for response to therapy

Response	IMWG criteria
Stringent complete response	Complete response, normal rFLC, and absence of clonal cells in bone marrow by immunohistochemistry or immunofluorescence
Complete response	Negative serum and urine IFE, disappearance of any soft tissue plasmacytomas, and ≤5% plasma cells in bone marrow
Very good partial response	Serum and urine M protein seen by IFE but not by electrophoresis or ≥90% reduction in serum M protein plus a urine M protein level of <100 mg/24 h
Partial response	≥50% reduction of serum M protein and reduction in 24-h urinary M protein by ≥90% or to <200 mg/24 h

COMPLEMENT *section C*

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: PATRICIA C. GICLAS

Introduction

PATRICIA C. GICLAS

12

The field of complementology has advanced remarkably in the past 2 decades, due to newly found connections between often subtle complement abnormalities and diverse diseases. This is reflected in the exponential growth of new publications and the development of novel therapeutics that were previously unavailable for treatment of patients with complement deficiencies or other abnormalities of the system (1). The interest in complement displayed by the pharmaceutical industry has been motivated not only by the desire to create therapeutics for patients with rare complement-mediated diseases but by the necessity to prevent undue adverse events caused by complement activation when new drugs or delivery systems are used *in vivo*. One of the first examples of this in humans was the development of an anaphylactoid response following the infusion of radiocontrast agents or exposure of blood to some of the early types of dialysis membranes that activated complement (2). Additional examples of complement activation by diverse compounds include liposomes, nanoparticles of various types, biologicals (mainly antibody based), and DNA- or RNA-based drugs such as phosphorothioate oligonucleotides (antisense) (3, 4). The term complement activation-related pseudoallergy, or CARPA, applies to some of these reactions (5).

Errors in the production of control proteins was beautifully demonstrated in the 1960s with the discovery of C1 inhibitor deficiency as the cause of hereditary angioedema (HAE) and the explanation of the two forms of deficiency: type I due to lack of production of the protein by the affected allele and type II caused by multiple polymorphisms in the gene sequence that result in production of dysfunctional protein (6, 7). Since the original classification, patients with hereditary forms of angioedema, but with normal C1 inhibitor, have continued to puzzle clinicians. Descriptions of the several forms of HAE have been published recently by international consensus groups. They include hereditary and acquired angioedema (HAE and AAE, respectively) with C1 inhibitor deficiency, idiopathic nonhistaminergic AAE, AAE related to angiotensin-converting enzyme, HAE with normal C1 inhibitor and factor XII mutation, and unknown HAE (8, 9, 10). Treatment is based on the administration of human plasma or purified or recombinant C1 inhibitor protein preparations to replace the missing inhibitor, or inhibitors of plasma kallikrein or a bradykinin receptor antagonist to prevent bradykinin production or activity. Older treatments still in use include epsilon aminocaproic acid (inhibitor of plasminogen) and its derivatives, and anabolic androgens that stimulate C1 inhibitor production (11).

A number of additional proteins involved in regulation of complement activity have been found to have dysfunctional forms. The availability of genetic analytical methods has made it possible to determine the exact defect responsible for a given deficiency as well as scan large portions of the genome. Interest in the inheritance of genetic factors that could be linked to age-related macular degeneration (AMD), a disease that causes debilitating loss of vision and eventual blindness in a large number of patients, led to the discovery of the involvement of complement in AMD pathology. The identification of a single nucleotide polymorphism in the gene for factor H that was associated with a high risk for AMD opened up a new approach to studies of complement in AMD (12, 13, 14). The discovery of the same polymorphisms in patients with certain rare kidney diseases, particularly those previously identified as forms of membranoproliferative glomerulonephritis, led to finding genes for proteins in control of the alternative pathway of complement that were also associated with risk. The treatment with monoclonal anti-C5 antibody has decreased the morbidity and mortality of these patients and offers a model for other therapeutic agents to control aberrant behavior by complement activity.

Another area of complement that has blossomed in the past 10 years is its connection through the lectin pathway to the primitive origins of innate immunity. Looking back through the ages, one can find complement-like activity in the early Cambrian era in ascidians and other creatures. They developed systems to trap invading microorganisms by a circulatory lectin system that first bound to the microbial surface sugars by way of pattern recognition and then initiated clotting of the hemolymph so that phagocytic cells in the circulation could ingest and destroy the potential pathogens. In the laboratory, scientists have taken advantage of this simple system from the horseshoe crab, using the lectin-binding, enzyme-activating ability to detect endotoxins in many compounds. As the acquired immune system evolved in vertebrates, the ability of C1q to recognize bound immunoglobulins gave complement the unique ability to identify a microbial target by means of lectin direct activation or classical pathway antibody-driven activation. As scientists, our ability to measure the latter event has been exploited in the laboratory in many different complement functional

doi:10.1128/9781555818722.ch12

assays, but the lectin pathway has not been widely explored as an adjunct to complement evaluation. A recent article by Atkinson and Frank discussed the ability of the lectin pathway to provide a bypass mechanism for generating C3 cleavage in serum deficient of C4 or C2, a mechanism that may explain the observation that patients lacking these proteins tend to have relatively mild disease (15). Chapter 14 in this section describes a new assay for analyzing the function of mannose-binding lectin that should be useful for further studies of this important system. More information about this system will be forthcoming in the near future.

The Classical Pathway of Complement

PATRICIA C. GICLAS

13

BACKGROUND

Complement evolved in parallel with coagulation as part of the primordial explosion of life in the Cambrian era. Remnants of this connection still exist in vertebrate animals as well as invertebrates. A classic example is the horseshoe crab, *Limulus polyphemus*, still sought after by scientists today to test substances for traces of bacterial lipopolysaccharide (endotoxin). The system used by the crabs had a molecule that recognized bacteria or other invaders that got into the hemolymph of the crab. An enzyme triggered by the first molecule induced local coagulation that served to trap the microbes so that they could be destroyed by phagocytes in the animal's circulation.

The complement system was discovered over 100 years ago by a group of scientists who detected its ability to kill bacteria that were injected into guinea pigs or exposed to fresh blood or serum *in vitro*. At that time, in the late 1800s to early 1900s, none of the components were known, and the phenomenon was described as an "activity" that was present in fresh serum but was destroyed by heat (1). We now understand how important the complement system is to innate and acquired immunity and its contribution to infection and the maintenance of health on many different fronts. The diversity of the complement system is displayed in its ability to rapidly react to a threat as part of innate immunity. As an illustration, the lectins, along with the classical complement pathway, are important components of the acquired immune response. They contribute to the alternative pathway's ability to amplify the power of complement activation.

Of the three pathways that initiate complement activation (Fig. 1), the classical pathway developed the ability to participate with evolving cellular and antibody responses of acquired immunity. It was this ability to complete, or "complement," the action of antibody-mediated defenses that gave the system its name. The following discussion will briefly describe the proteins and their interactions in the classical pathway and discuss some of the laboratory approaches to the diagnosis of patients with deficiencies in the classical pathway.

PROTEINS OF THE CP: C1q, C1r, C1s, C2, C4

Classical pathway (CP) activation is initiated when the C1 complex, comprising $C1q_1C1r_2C1s_2$+calcium, binds to an appropriate activator. C1q is a complex molecule that looks, on electron micrographs, like a bunch of six tulips. Using this analogy, the six stalks have protein sequences similar to collagen and are susceptible to collagenase. The six rigid stalks are each connected by flexible protein stems to the six "flowers" on their tips. It is the globular protein "flowers" that have binding specificity for immunoglobulins, apoptotic cell membranes, and several other surfaces.

The most common classical complement pathway activators are antibodies of the immunoglobulin M (IgM) or IgG class that are bound to antigen. The order of their binding affinity for C1q, in descending order, is as follows: IgM > IgG3 > IgG1 > IgG2. IgG4, IgA, and IgE antibodies do not activate C1. To start the classical complement pathway enzyme cascade, the C1q binds to at least two IgG antibodies, or one IgM antibody, by contacting the carbohydrate in the antibody's hinge region that was exposed when the antibody binds to its antigen. This causes a change in the C1q molecule so that the C1r and C1s proenzymes are released.

C1r rapidly converts to its active form and cleaves C1s. It is the latter molecule that was first identified as C1-esterase. The activity of these two enzymes is controlled in plasma by the serine protease inhibitor, C1-esterase inhibitor (C1-Inh) (2, 3).

The next two proteins to be activated in the CP are the two substrates of C1s: components C4 and C2. C4 is a major serum protein with some interesting properties. First, there are two forms of C4 in the circulation: C4A and C4B. These are named for their behavior as acidic or basic on separation by immunoelectrophoresis. The genes for C4A and C4B are on chromosome 6 within the class III region of the major histocompatibility complex, as are the genes for C2 and factor B of the alternative pathway. C4 molecules are synthesized primarily in the liver as a single chain. Posttranslational mature C4 has three chains (alpha, beta, and gamma) that are linked by disulfide bonds. The alpha chain is the site of an internal thioester bond that is critical for one of C4's primary functions: opsonization (4). C3 is the major opsonin of complement. It shares the thioester bond, which is a property that makes many of the reactions of complement possible (5).

The C3 convertase is generated from fragments of C4 and C2 after cleavage by C1s. First, the cleavage of C4 releases a small fragment, C4a, from the N-terminal end of the C4 alpha chain, causing the larger fragment, C4b, to reconfigure in a way that exposes the thioester bond and provides

doi:10.1128/9781555818722.ch13

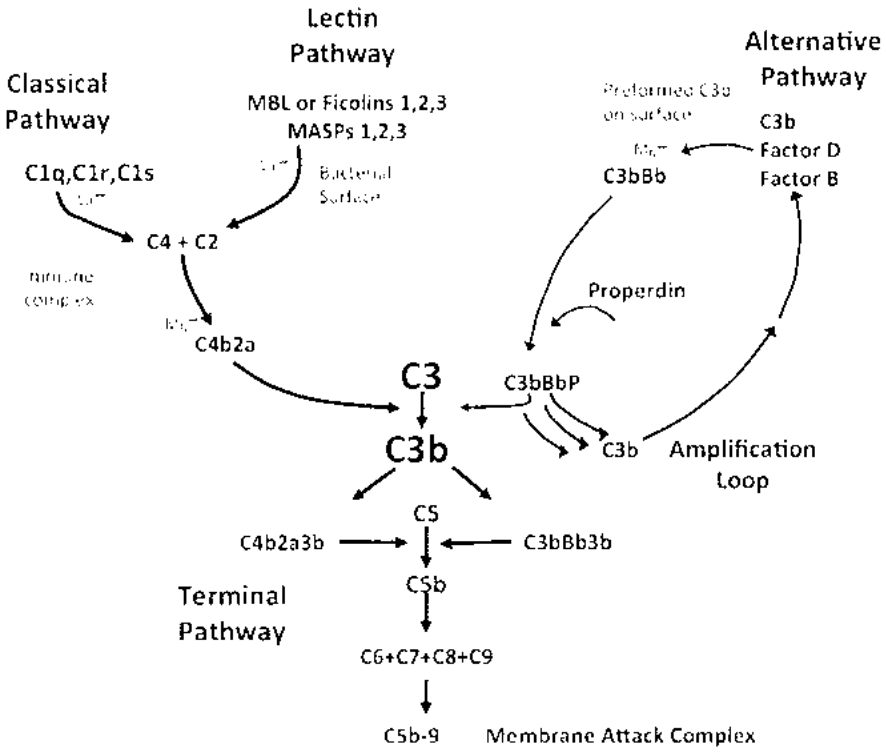

FIGURE 1 Schematic for the complement pathways of activation. The pathway initiators are shown at the top of each, with the components in sequence of their participation. Note the inclusion of the calcium- and magnesium-requiring steps as well as typical activators for each pathway. MBL, mannan-binding lectin.

a transient ability for C4b to bind covalently to nearby acceptor nucleophiles. The binding is in general nonspecific, but for C4b from the C4A haplotype, the preferred binding is to amino groups, while C4b from the C4B haplotype binds best to hydroxyl groups (6). The covalently bound C4b on cells, proteins, bacteria, virus particles, and other particulate matter acts as an anchor to which phagocytes, lymphocytes, and other scavenger cells with membrane C3/C4 receptors can bind, enhancing the efficiency with which these C4b-coated particles are cleared. The half-life of the thioester is only a few seconds, so the number of C4b fragments bound to the target is limited by the diffusion rate of the proteins. This time limitation also ensures that the C4b (or C3b) is deposited at the activation site in a cluster to which the phagocyte can achieve multiple attachments, thus increasing the avidity of the binding.

The surface-bound C4b also serves as the site of formation for the C3 convertase. C2 can bind loosely to the surface-bound C4b in a magnesium-dependent reaction, forming C4bC2, which is enzymatically inactive until the C1s cleaves the C2, releasing inactive C2b into the fluid phase and leaving C2a attached more stably to the C4b. C2a forms the catalytic unit of the C3 convertase, C4bC2a, while C4b acts as its cofactor. The reaction has a short time frame in which to occur. C4b deposits close to where it was formed when cleaved by C1s, and C2 has to bind to C4b while C1s is still near in order to be cleaved by it. C1-Inh is also in the vicinity and competes with the C2 for C1s. If the C1-Inh captures the C1s before it cleaves the C2, the loosely bound C4bC2 complex decays. The C4bC2a enzyme activity has a half-life of about 2 to 8 min before it decays. It is this inherent instability that acts as one of the major controls of the CP and contributes to the limitations on how much C3 conversion it can achieve (7).

CONTROL OF THE CP: C1-Inh, C4BP, CR1 (CD35), MCP (CD46), AND DAF (CD55)

The primary goal of control in complement is stopping the enzymatic activities before they do damage to host cell tissues, something of a balancing act. C1r and C1s are controlled by C1-Inh, a member of the Serpin family (*ser*ine *p*rotease *in*hibitor). The enzyme to be inhibited by Serpins cleaves a bait sequence on the inhibitor and is trapped by a subsequent tight bond with the enzyme. The complex of enzyme-inhibitor is cleared from the circulation, resulting in decreases in the local concentrations of both molecules. In hereditary angioedema patients, who already have low levels of C1-Inh, this additional decrease can trigger a reaction. C1-Inh is the only inhibitor for C1r and C1s, unlike the other enzymes that are susceptible to its action. These include the mannan-binding lectin-associated serine proteases (MASPs), factor XIIa, serum kallikrein, and other enzymes of the kinin-generating pathway that have additional inhibitors that can inactivate them.

There are two steps needed for inactivation of the C3 convertase. First, since C2a requires the cofactor C4b for activity, the C4bC2a complex must be dissociated. To accomplish this, C4BP (C4 binding protein) binds to a site on the C4b near where the C2a is bound and pushes C2a off the complex. C4b, being covalently bound to the surface, remains tied down, but C2a becomes inactive in the fluid phase. C4BP stays bound to the C4b and acts as a cofactor for factor I (FI). FI has trypsin-like activity that cleaves the

C4 alpha chain on both sides of the thioester bond, releasing the larger part of C4b as C4c. C4c contains about 80% of the C4 protein, and it is recognized by most of the polyclonal antisera used for measuring C4 in the circulation. If a large amount of C4 has been activated during an *in vivo* reaction, the C4c in the circulation adds to the mass of C4 measured and can give a value that is higher than the actual native C4 present. C4d, the small piece of the C4 alpha chain that contains the thioester bond, remains covalently bound to the original cell or other surface to which the C4b was bound. It remains attached by the thioester bond to the protein, immune complex, or whatever the C4b happened to bind to initially. Fluid-phase C4d can be detected in varying amounts in the circulation after classical pathway activation, but the C4d that is bound to erythrocytes or platelets is probably a better predictor of the amount of activation that has occurred (8, 9).

If the convertase has bound to host cell membranes, a similar reaction occurs except that host cell membranes are protected by membrane-bound complement control proteins: CD35 and CD46 have cofactor activity for FI and act in a similar fashion to C4BP to remove the C2a enzyme. Displaced C2a becomes rapidly inactive (C2ai), but unless the surface-bound C4b is inactivated, a new C2 could bind to it and start over. All except CD55 (decay-accelerating factor), which lacks cofactor activity for FI, completely inactivate C4b once the C2a has been removed from the enzyme complex. With the other control proteins, C2a is displaced into the fluid phase, where it remains inactive, and C4BP acts as a cofactor for FI cleavage to inactivate C4b. The first cleavage of C4b generates iC4b (inactive C4b), while further cleavage creates C4d and C4c. The small fragment C4d is at the location of the thioester bond and remains attached to the target. C4d is often found in stained tissue sections, since it is tightly bound to the surface. C4d on circulating cells, like erythrocytes and platelets, can be detected by flow cytometry, and it serves as a marker for the classical or lectin pathway activation (8, 9). Likewise, biopsy sections stained for C4d can indicate classical or lectin pathway activity. The large fragment C4c is not active. It represents about 80% of the protein mass of the original C4 and is recognized by most of the antibodies used for measuring C4 concentrations in clinical laboratories. C4a is converted to C4a-desArg by serum carboxypeptidase N. Unlike C3a and C5a with anaphylatoxin activity, C4a and C4a-desArg are both inactive.

SUMMARY OF THE CP AND BRIEF DESCRIPTION OF THE TERMINAL PATHWAY

- C1qrs binds to an immune complex containing IgM or IgG antibodies, or both, bound to antigens.
- The proenzymes C1r and C1s that were associated with C1q are released.
- C1r autoactivates and cleaves C1s, generating C1-esterase, the active form of C1s.
- C1s cleaves C4, generating surface-bound C4b (opsonin) and fluid-phase C4a (no known function).
- C2 binds to C4b and is cleaved by C1s to create fluid-phase C2b (no known function) and C4bC2a, the CP C3 convertase.
- C4bC2a cleaves C3, generating C3b (opsonin) and C3a (anaphylatoxin). Some of the C3b binds to the C4bC2a (through its thioester bond), generating C3bC4bC2a, the CP C5 convertase. The addition of the C3b to the C4bC2a provides a binding site for C5.
- C5 cleavage produces the potent anaphylatoxin C5a and the larger fragment C5b. C5b does not have a thioester bond like C4b and C3b, but it does have a short-lived hydrophobic region that can bind to C6, forming the nucleus for the membrane attack complex.
- C5b has an affinity for C6 and C7. The C5b67 complex binds to the lipid bilayer of nearby cell membranes, and the addition of C8 to this complex via the C8 beta chain causes insertion of the C8 alpha subunit of C8 into the membrane. The insertion of the C8 alpha chain starts the membrane perturbation that is accelerated when multiple C9 molecules then associate with the C5b678 on the membrane and polymerize to form the membrane attack complex C5b6789 (C5b-9). The resulting perturbation of the cell membrane induces osmotic lysis in susceptible cells. CD59 on host cell membranes inhibits C8 and C9 incorporation into the complex, and clusterin interacts with fluid-phase complexes and prevents lysis of "bystander" cells. The abbreviation sC5b-9 refers to the soluble form of the complex that is found in the circulation after activation of complement.

LABORATORY EVALUATION OF THE CP

The best approach to evaluating the CP is to start with measuring the function of the entire pathway: C1 to C9. In this test, the patient's serum is serially diluted (usually 3 to 5 dilutions) and mixed with a suspension of washed sheep erythrocytes (the target cells) that have been coated with antibodies (IgM or IgG) to antigens on the cell surface. This creates immune complexes that can bind C1q and start the activation process. The buffer used for this assay contains calcium and magnesium, both required by the CP. If the patient's complement is normal, the result will be lysis of the cells and the release of hemoglobin. The test tubes or microtiter plates are centrifuged to pellet the unlysed cells, and the amount of hemoglobin in the supernatant is measured on a spectrophotometer. The amount of lysis is calculated for each dilution for the specimen and reported as the reciprocal of the number (or percentage) of cells lysed for each dilution, compared to a buffer control as 0% and a distilled water control as 100%. The percentage of lysis is calculated for all of the dilutions run, and the point where dilution gives 50% lysis is reported as the CH50 (10, 11).

The functional activity of the intact pathway is best evaluated using the CH50 (above) or one of the many variants or equivalent assays that are available. The original hemolytic CH50 method is still useful for titrating the activity in sera, although the newer variations on the theme have faster turnaround times and can be used for high-throughput screens when large numbers of samples are to be run. It has been the experience in my laboratory that these methods are very good for screening the samples for possible defects or deficiencies. The CH50 hemolytic assay can be used as a backup method for confirming low results obtained by the other methods.

The alternative pathway assay that is the closest equivalent of the CH50 (complement 50% hemolysis) is the AH50 (alternative pathway 50% hemolysis). It is the same kind of test except that the cells used are rabbit erythrocytes that have a naturally charged surface that activates the alternative pathway. The buffer used for the AH50 contains EGTA, a chelator of calcium, to block any classical pathway activity, and magnesium needed for formation of the C3 convertase. The endpoint for this assay is similar to that of the CH50. Results are calculated from the 50%

TABLE 1 Interpretation of CH50 and AH50 test results

Location of defect	Result for:	
	CH50	AH50
Classical pathway	Low or 0	Normal
Terminal pathway	Low or 0	Low or 0
No defect	Normal	Normal
Alternative pathway	Normal	Low or 0

lysis. In addition to the CH50, the AH50 can be run on the same specimens to determine the status of the alternative pathway. Often, having both results saves time, the need for more tests, and expense. Interpretation of the two test results is straightforward (Table 1).

The individual proteins of the CP can be measured by standard immunoassays, including radial immunodiffusion using monospecific polyclonal antisera, enzyme-linked immunosorbent assay using monoclonal antibodies, and nephelometry for those components with relatively high serum concentrations.

C1r, C1s, and C2 are usually measured by radial immunodiffusion. C4 can easily be measured by nephelometry. A word of caution must be issued about C2, in particular. If the protein level is normal but the CH50 continues to be low, the function of C2 should be tested. There are several laboratories in the United States in which functional assays for individual complement proteins are available. With the advent of genetic screening, more polymorphisms are being found that affect the function of the components without altering the serum concentration. Like the situation with C1-Inh deficiency, it is often necessary to measure both the level and the function of the protein in question.

Looking back over the numbers of patients with complement deficiencies that were documented in my laboratory, there has been a trend toward increased disorders of function, particularly for C2 and C5 in the past 4 years. The number of samples that had normal levels of these proteins and low or no function has increased as a result of this. For C2, the answer is the discovery of more "silent" mutations that don't change the amount of protein produced but result in dysfunctional protein. Combined type I and type II C2 deficiencies have been found in several families in which the original finding was half normal protein but no function. For C5, I believe the trend is due to the increased use of eculizumab in treatment of paroxysmal nocturnal hemoglobinuria, atypical hemolytic-uremic syndrome, and other disorders of complement regulation. As more drugs are introduced in clinical practice, it will be a challenge to the complement analysts to separate the hereditary, acquired (including autoantibody induced), and medication-related deficiencies seen in the laboratory.

Analysis of Activity of Mannan-Binding Lectin, an Initiator of the Lectin Pathway of the Complement System

STEFFEN THIEL

14

The innate immune system has traditionally been described as the first line of the body's defense against invasive pathogens. Such a response then leads to an inflammatory response which may also include coagulation. Activation of the innate immune response is mediated by pattern recognition molecules, which may be membrane-bound (e.g., cell-associated Toll-like receptors, NOD-like receptors, and RIG-I-like receptors) or soluble proteins. Recognition of foreign or altered structures in the body by some of the soluble pattern recognition receptors may lead to activation of the complement system and thus trigger one of the innate antimicrobial defense mechanisms. Such complement-activating soluble pattern recognition molecules include the collectins (lectins, i.e., carbohydrate-binding proteins, that use a collagen helix for stabilization of the molecule), i.e., mannan-binding lectin (MBL, also known as mannose-binding lectin), collectin K1 (CL-K1), and collectin L1 (CL-L1), and the ficolins (proteins that contain a fibrinogen-like domain and use a collagen helix for stabilization of the molecule), i.e., H-ficolin, L-ficolin, and M-ficolin (1, 2).

MBL activates the complement system by binding to a defined carbohydrate pattern (1). The activation of complement by carbohydrate-binding proteins has been termed the lectin pathway of complement activation (Fig. 1). Two other complement pathways have been described previously and are discussed in other sections of this *Manual*; these are the classical and alternative pathways. In the classical pathway, the recognition molecule C1q recognizes a pattern of antibodies. The alternative pathway is initiated when a hydrolyzed form of C3 is cleaved, leading to deposition of the C3b fragment on a noninhibitory surface (Fig. 1), or whenever C3b is deposited on a surface without the ability to support inhibition of the complement system (3). Completion of any of the three complement pathways may eventually lead to death of the incoming microorganism by either lysis or phagocytosis (3). Activation of the complement system also leads to the initiation of other parts of the innate immune system, activation of humoral and cellular effectors, and identification and neutralization of the invasive pathogen (3).

It is of interest to estimate the level of MBL or the functional activity of MBL in human samples. Numerous reports have reported correlations between MBL deficiency or MBL pathway deficiency and various clinical conditions (4–8).

MBL is a large molecule that is found in blood as oligomers of a structural unit which itself contains three identical polypeptide chains. Each polypeptide chain contains one carbohydrate recognition domain (CRD) and one structural unit. Thus, the intact molecule contains 3 CRDs, and an oligomer of four (the predominant type) structural units contains 12 CRDs. Each CRD binds with low affinity, but the overall binding strength is high when multiple CRDs bind at the same time. MBL binds to microorganisms through the recognition of a pattern of certain sugars, e.g., mannose, glucose, L-fucose, and *N*-acetylglucosamine (1).

MBL is synthesized in the liver and the final product released into plasma, where it associates with the MBL-associated serine proteases (MASPs). These include MASP-1, MASP-2, and MASP-3, as well as two nonenzymatic proteins, MBL-associated protein of 19 kDa (MAp19) and MBL-associated protein of 44 kDa (MAp44) (1, 8). The MASPs are activated when MBL binds to a defined carbohydrate pattern. When MASP-2 becomes activated, it proteolytically cleaves complement components C4 and C2 (Fig. 1) and generates the C3 convertase C4bC2b. This leads to subsequent activation of the remainder of the complement system.

ASSAY OF MBL PATHWAY ACTIVITY

The following protocol describes how one can determine the ability of serum or plasma samples to mediate activation of complement factor C4 via the MBL pathway of complement. The method involves the detection of Eu^{3+}-labeled streptavidin in a time-resolved immunofluorometric assay (TRIFMA) (9). TRIFMAs are similar to enzyme-linked immunosorbent assays (ELISAs), with the only difference being the type of label used for the recorder molecule. Instead of the enzyme-linked antibodies or streptavidin routinely used in ELISAs, in TRIFMAs, Eu^{3+} attached to antibodies or streptavidin is used as a label. In ELISAs, a colorimetric reaction is detected, whereas in TRIFMAs, fluorescence is determined through time-resolved fluorometry. The TRIFMA format provides enhanced sensitivity, a broader dynamic range, and improved reproducibility over what can be achieved with an ELISA. An ELISA version of the assay has been described by Petersen et al. (10). The only difference with this assay is its use of enzyme-labeled streptavidin instead of europium-labeled streptavidin and the use of a colored substrate for the enzyme to produce a color reaction in the wells, which is then read by colorimetry.

doi:10.1128/9781555818722.ch14

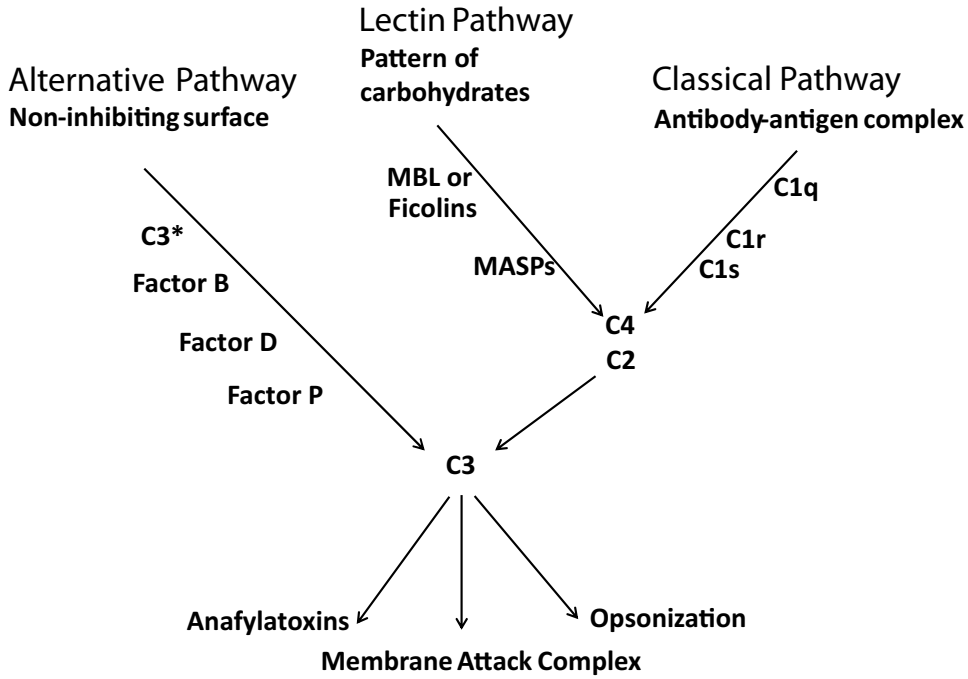

FIGURE 1 Complement activation pathways. The figure shows the events leading to the formation of enzyme complexes that cleave C3. The three pathways thus converge on C3. Thereafter, formation of the terminal membrane attack complex, opsonic factors (C3b), and chemotactic factors (e.g., C5a) may proceed. The classical pathway is activated by C1q in complex with C1s and C1r upon binding to antibody-antigen complexes. The lectin pathway is activated when MBL in complex with MASPs recognizes foreign carbohydrate patterns. As indicated in the figure, ficolins may activate complement via this pathway, but the assay described in this chapter is not influenced by these molecules, as they bind to a different set of ligands than those presented on the surface and used in the assay. The alternative pathway is constitutively activated by the formation of C3(H_2O)-factor B complexes and may be propagated on foreign surfaces by the other factors indicated. The assay described in this chapter measures the cleavage of C4 and the following deposition of C4b by MASP-2 bound to MBL.

A microtiter plate is coated with mannan, which is a preparation of carbohydrate structures from the surface of *Saccharomyces cerevisiae* and is used to bind MBL-MASP complexes from serum or plasma samples (Fig. 2). Any classical pathway activity that may occur due to the presence of anti-mannan antibodies in the sample can also result in C4 activation. This is inhibited by using a high-ionic-strength buffer that inhibits the binding of the C1q used in the assay. Since the activation of C4 by MASP-2 is inhibited by high-ionic-strength buffer, the assay requires a subsequent incubation with purified C4 in an isotonic buffer. After incubation with purified human C4 at 37°C, C4b deposition is detected with biotin-labeled antibodies against C4b and with europium-labeled streptavidin.

Preparation of Serum or Plasma

Whole blood from healthy individuals is drawn into serum Vacutainers and allowed to coagulate at room temperature for 1/2 h before centrifugation (2,000 × *g*, 10 min) and isolation of the serum. For the preparation of plasma, blood from healthy individuals is drawn into citrate-, EDTA-, or heparin-containing Vacutainers. The stabilized blood is centrifuged (2,000 × *g*, 10 min), and the plasma is removed. Serum and plasma aliquots are stored at −20°C until use or at −80°C for long-term storage. Both serum and plasma (with EDTA, citrate, or heparin) samples may be used, despite the presence of calcium in the dilution buffer (see below), since the high NaCl concentration in the dilution buffer inhibits coagulation. The high NaCl content also means that the assay is not influenced by possible variations of other serum factors, e.g., complement factor C4 or C1 inhibitor, which is a promiscuous serine protease inhibitor that also inhibits MASP-2 if present at physiological salt concentrations.

Materials, Reagents, and Equipment

Ninety-six-well microtiter plates (437958; FluoroNunc, Kamstrup, Denmark). When measuring europium in microtiter plate wells by time-resolved fluorometry, it is important that the plastic in the plates contains low levels of europium, as in FluoroNunc plates. The Maxisorb plates sold by Nunc and often used in ELISAs may contain substantial amounts of europium, which will give a high background in the assay.

Mannan (M7504; Sigma-Aldrich, St. Louis, MO)

Human serum albumin (HSA). HSA can be replaced with bovine serum albumin if this is more convenient. We use a stock solution of 200 mg/ml HSA that is normally used for infusion (10 96 97; CSL Behring, Marburg, Germany). Other sources of HSA may also be used.

Human complement C4 (A402; Quidel, San Diego, CA). If multiple assays are planned and cost is a problem, complement C4 can easily be purified from human plasma

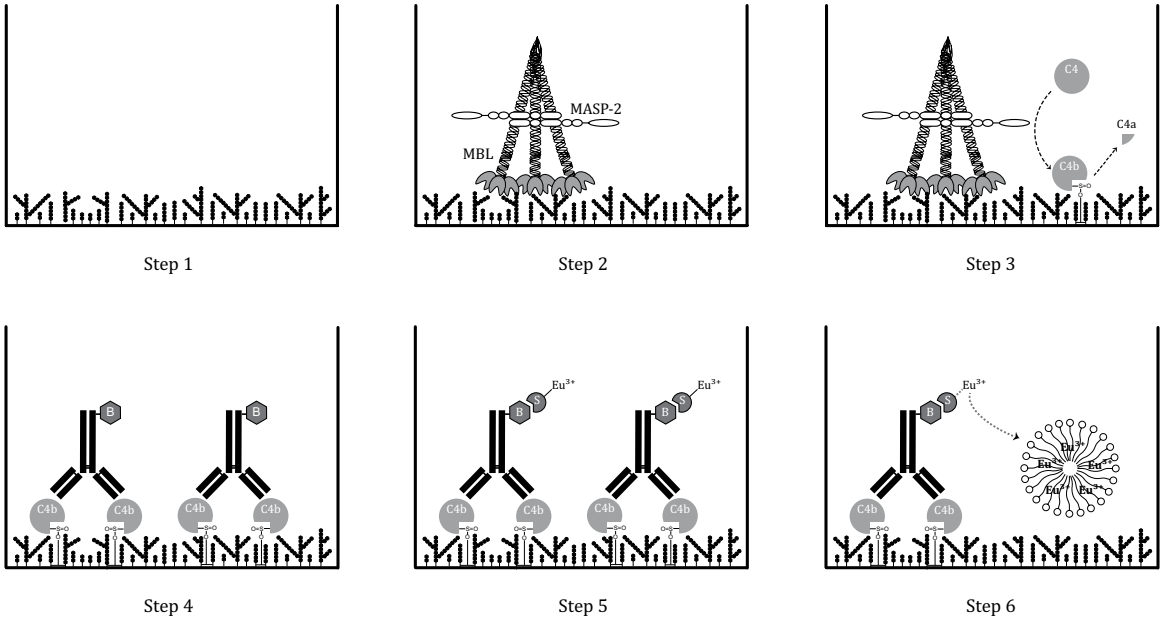

FIGURE 2 Assay of MBL pathway activity. Step 1, coating of the microtiter plate with mannan; step 2, MBL–MASP-2 complexes bind to immobilized mannan; step 3, incubation of C4, which is then cleaved, and deposition of C4b in the wells; step 4, anti-C4 antibody is bound to the deposited C4 fragment; step 5, binding of europium-labeled streptavidin to the biotinylated anti-C4 antibody; step 6, addition of enhancement solution to the wells, which is followed by reading of the plate by time-resolved fluorometry.

by conventional laboratory techniques, using a two-ion-exchange protocol that is described elsewhere (11).

Biotinylated anti-human C4 antibodies (e.g., rabbit anti-human C4 [lsqb]A0065; Dako, Glostrup, Denmark[rsqb]). If the investigator plans to produce this reagent, 1 mg of polyclonal anti-human C4c rabbit IgG (A0065; Dako, Glostrup, Denmark) is dialyzed against phosphate-buffered saline (see buffer composition below) for 2 h at room temperature. The dialysis tube is then transferred to phosphate-buffered saline, adjusted to pH 8.5 with 5% Na_2CO_3, and dialyzed for 3 h at room temperature. The dialysis tube is opened, and 167 μg fluorescein-5-ex *N*-hydroxysuccinimide ester (H1759; Sigma-Aldrich), which has been dissolved in dimethyl sulfoxide is added. The dialysis tube is closed and incubated for 4 h in the dark at room temperature with gentle rocking. The dialysis tube is then transferred to Tris-buffered saline overnight at room temperature and finally incubated twice for 2 h each in Tris-buffered saline–azide at room temperature.

Streptavidin-Eu^{3+} (1244-360; Perkin Elmer, Waltham, MA)

Time-resolved fluorometer, e.g., Victor X4 multilabel plate reader (Perkin Elmer), PHERAstar Plus instrument (BMG Labtech, Ortenberg, Germany), or similar equipment

Assay Solutions

1. NaN_3 is added to the following buffers as a bacteriostatic agent. If the buffers will not be stored for long periods, you can omit the addition of NaN_3 throughout the protocols. The sodium azide stock solution is 1.5 M NaN_3. Add 9.75 g NaN_3 to 100 ml water.
2. Coating buffer: 15 mM Na_2CO_3, 35 mM $NaHCO_3$, 15 mM NaN_3, pH 9.6. Add 500 ml water to a graduated cylinder. Weigh out 1.59 g Na_2CO_3 and 2.94 g $NaHCO_3$ and transfer them to the cylinder. Add 10 ml NaN_3 stock solution and add water to a volume of 900 ml. Mix and adjust the pH to 9.6 with HCl or NaOH. Bring the volume to 1 liter. Store at room temperature.
3. Blocking buffer: 1 mg/ml HSA in 10 mM Tris, 145 mM NaCl, 15 mM NaN_3, pH 7.4. Dissolve 1.21 g Tris and 8.47 g NaCl in 900 ml water. Add 10 ml NaN_3 stock solution and adjust the pH. Add 5 ml HSA (200 mg/ml) and bring the volume to 1 liter with water. Store at 4°C.
4. MBL binding buffer: 20 mM Tris, 1 M NaCl, 0.05% (vol/vol) Triton X-100, 10 mM $CaCl_2$, 15 mM NaN_3, 1 mg/ml HSA, pH 7.4. Dissolve 2.42 g Tris, 58.44 g NaCl, and 1.11 g $CaCl_2$ in 900 ml water. Add 10 ml NaN_3 stock solution and adjust the pH to 7.4. Add 0.5 ml Triton X-100 (9002-93-1; Sigma-Aldrich) and 5 ml HSA (200 mg/ml). Bring the volume to 1 liter and store at room temperature.
5. Washing buffer with calcium: 10 mM Tris, 145 mM NaCl, 5 mM $CaCl_2$, 15 mM NaN_3, 0.05% (vol/vol) Tween 20 (TW), 15 mM NaN_3, pH 7.4. Dissolve 1.21 g Tris, 8.47 g NaCl, and 0.55 g $CaCl_2$ in 900 ml water. Add 10 ml NaN_3 stock solution and 50 ml TW (8.17072; Merck, Darmstadt, Germany). Adjust the pH to 7.4 with HCl. Bring the volume to 1 liter and store at room temperature.
6. Washing buffer without calcium: As described above, but without the added $CaCl_2$.
7. C4 dilution buffer: 4 mM barbital, 145 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, pH 7.4. Dissolve 0.37 g barbital (B0375; Sigma-Aldrich), 4.24 g NaCl, 0.11 g $CaCl_2$, and 0.05 g $MgCl_2$ in 400 ml water. Adjust the pH to 7.4 and bring the volume to 500 ml.
8. The 0.4 M EDTA, pH 7.4, solution is made by adding 76 g EDTA tetrasodium salt dihydrate (Sigma-Aldrich) to 500 ml water and adjusting the pH.

9. Europium dilution buffer: 10 mM Tris, 145 mM NaCl, 0.05% (vol/vol) TW, 15 mM NaN_3, 25 μM EDTA, pH 7.4. Dissolve 0.48 g Tris and 3.4 g NaCl in 350 ml water. Add 4 ml NaN_3 stock solution, 17.5 ml TW, and 25 μl of a 0.4 M EDTA solution. Add water to a final volume of 400 ml and store at room temperature.
10. The enhancement solution may be purchased from Perkin Elmer (catalog no. 1244-104). Alternatively, it can be prepared with the following reagents: 0.57% (vol/vol) acetic acid, 1% (wt/vol) polyethylene glycol 6000, 0.1% (vol/vol) Triton X-100, 15 μM 4,4,4 -trifluoro-1-(2-naphthyl)-1,3-butandion (β-NTA), 50 μM trioctylphosphine oxide (TOPO), pH 3.2. Add 5.7 ml of glacial acetic acid to 900 ml water and adjust the pH to 3.2 with potassium hydrogen phthalate (0.1 M in water). Dissolve 10 g polyethylene glycol 6000 in the solution and add 1 ml Triton X-100. Add 2 ml β-NTA–TOPO solution (see below) and dilute to a final volume of 1 liter with water. The enhancement solution should be stored at 4°C and kept in the dark.
11. The β-NTA–TOPO solution is composed of β-NTA (343633; Sigma-Aldrich) and TOPO (223301; Sigma-Aldrich) dissolved in methanol. For this solution, 0.03993 g β-NTA is dissolved in 10 ml methanol, and 0.19333 g TOPO is dissolved in 10 ml methanol. The two solutions are mixed and kept at −80°C.

It is important that MBL is a calcium-dependent lectin. Thus, all buffers for dilution and washing need to contain 5 mM $CaCl_2$. The exception is the europium dilution buffer, which contains 25 μM EDTA to ensure that free Eu^{3+} ions present in the Eu^{3+}-coupled streptavidin solution are chelated and thus prevented from adsorption onto the microtiter plate. The low micromolar EDTA concentration is not enough, however, to dissociate the Eu^{3+} ion from the streptavidin-coupled chelator or to elute MBL from the mannan-coated surface.

Assay Procedure

Perform all procedures at room temperature unless otherwise specified.

1. Coat a FluoroNunc 96-well plate with mannan at 100 μl/well, using 10 μg mannan/ml diluted in coating buffer, and incubate the plate at room temperature overnight in a moist chamber (Fig. 2, step 1). A plastic box with a lid and a wet paper towel inside may be used as a moist chamber.
2. Empty the wells and block all wells with 200 μl/well of blocking buffer. Incubate the plate for 1 h at room temperature. After incubation, wash the plate three times with washing buffer with $CaCl_2$. If plates are to be stored for later use, empty the wells, add 200 μl/well of washing buffer without $CaCl_2$, and store them at 4°C in a moist chamber.
3. Dilute test specimens in MBL binding buffer, add specimens to their appropriate wells at 100 μl/well, in duplicate, and incubate the plate in a moist chamber overnight at 4°C (Fig. 2, step 2). Wash the plate three times with washing buffer with $CaCl_2$. Usually, a 1:200 dilution is adequate if specimens with a high MBL content happen to be included in the assay. The sample may give a result higher than those observed on the standard curve, and if a more exact value is needed, such samples may be diluted up to 1,000-fold. For comparison of the activities in the samples, a standard curve must be included in the assay. We use a dilution series of a serum with a high MBL content (see "Calculation and Interpretation of Results" below), starting at a 1/10 dilution followed by 3-fold dilutions to 1/21,870. Also include wells with only the MBL binding buffer for background evaluation.
4. Add C4 to all wells (Fig. 2, step 3). Thaw C4 on ice and dilute it in C4 dilution buffer immediately before use. We advise that C4 be kept in aliquots with only enough protein for a single assay (i.e., to fill one microtiter plate), as C4 subjected to freeze-thaw cycles severely loses its activity. Add 0.5 μg/ml human C4 diluted in C4 dilution buffer at 100 μl/well and incubate the plate for 1.5 h at 37°C. This incubation time is important and should not be shortened or extended unless a less or more sensitive assay, respectively, is desired. Wash the plate three times with washing buffer with $CaCl_2$. Note that different preparations of purified C4 may differ in their activity. It is thus recommended to initially try the analysis with several concentrations (e.g., 1 μg/ml, 0.5 μg/ml, and 0.25 μg/ml) of C4 before testing precious specimens.
5. Detect deposited C4b fragments with 0.2 μg/ml biotinylated anti-human C4 antibody (Fig. 2, step 4). Dilute the biotinylated antibodies in washing buffer with $CaCl_2$ and use 100 μl/well; incubate the plate for 2 h at room temperature in a moist chamber. Wash the wells three times with washing buffer with $CaCl_2$.
6. Detect bound biotinylated anti-C4 with 1 μg/ml streptavidin-Eu^{3+} diluted in europium dilution buffer; incubate the plate for 1 h at room temperature in a moist chamber (Fig. 2, step 5). After incubation, wash the plate three times in washing buffer with $CaCl_2$.
7. Add 200 μl/well of enhancement solution to release the europium from the streptavidin and incorporate it into micelles (Fig. 2, step 6).
8. Shake the plate on a microplate shaker for 5 min before reading the result on a fluorometer supporting time-resolved fluorometry.

Calculation and Interpretation of Results

For comparisons of different sera in terms of MBL pathway activity, a standard curve is required (as mentioned above). The MBL pathway activity of the standard serum is given in arbitrary units (e.g., 1,000 mU/ml). The MBL pathway activities of test sera are interpolated from the standard curve and multiplied by the dilution factor 200. The final MBL pathway activities of the tested serum specimens are provided in milliunits per milliliter.

The data obtained from the reading of the assay should be plotted as depicted in Fig. 3. Plot the serum concentration on the *x* axis (log scale) and the results of time-resolved fluorometry (counts per second) on the y axis (log scale). For data analysis and plotting of the data, it is convenient to use a graphical software program, such as Prism, SigmaPlot, or Excel. The standard curve should be S-shaped, and the curve should contain at least three data points in the near-linear portion of the S-shaped curve (Fig. 3).

Internal controls should be run in each assay. We usually use plasma or serum samples with known high, medium, and low activities. The reproducibility of the assay can be evaluated based on the internal controls. The calculated interassay coefficient of variation should be <20% for the high and medium internal standards but slightly higher if

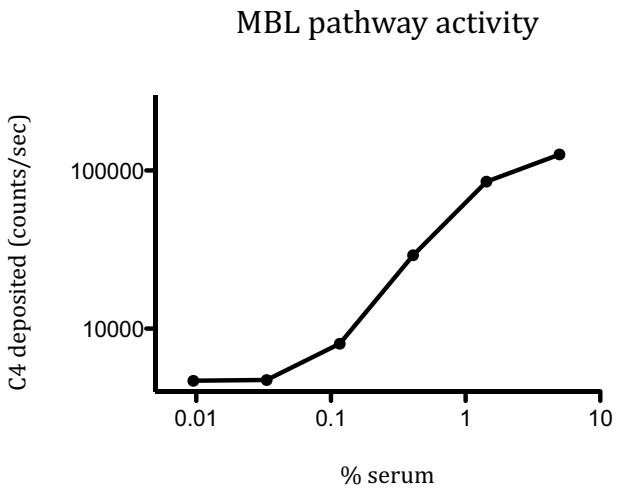

FIGURE 3 Appearance of a typical standard curve for the assay. The serum concentration is given on the *x* axis (log scale), and the signal is given on the *y* axis (log scale). In this figure, the highest serum concentration used is 1/20, followed by 3.5-fold dilutions. Other dilution schemes can also be used (e.g., 1/10 dilution followed by 3-fold dilutions).

the low internal standard is close to the lower end of the reference curve.

The time required to perform the assay as described above is 3 days. Preparing stocks of precoated plates with mannan can considerably shorten the process. The coated plates may be stored at 4°C for up to 2 months. We use overnight incubations for practical reasons, but the whole assay may easily be performed in 2 days, if desired, with precoated plates. Importantly, the incubation with C4 must be performed for the given time at 37°C.

Troubleshooting

If no fluorescence is seen, the possible errors could be as follows: (i) the enhancement buffer in the wells was discarded instead of left in the wells when the plate was measured in the fluorometer; (ii) the complement factor C4 was inactivated by incorrect storage (e.g., the freezer defrosted by itself or the C4 was thawed and frozen more than once); (iii) Ca^{2+} was omitted from the washing buffer, the sample buffer, or the C4 dilution buffer; or (iv) too much EDTA was present in the europium dilution buffer, i.e., 25 μM EDTA, not 25 μM EDTA, is to be used.

The MBL pathway activity closely follows the concentration of MBL in the sera tested. In rare cases, estimated to be 1 per 10,000 samples tested for a typical Caucasian population, a low MBL pathway activity in a serum with a normal MBL level may be found due to a deficiency of MASP-2 (7).

The Nature of the Diseases That Arise from Improper Regulation of the Alternative Pathway of Complement

RICHARD J. H. SMITH

15

The complement system is the cornerstone of innate immunity. As one of the first lines of host defense, it plays a major role in microbial killing, immune complex handling, apoptotic cell clearance, tissue homeostasis, and modulation of adaptive immunity (1–3). Critical to these functions is the sequential triggering of a series of cascades that result in the generation of metastable protease complexes and culminate in the formation of membrane attack complex (MAC) (4). Improper regulation of these cascades is associated with the development of multiple different diseases. In this chapter, we focus on the clinical consequence of dysregulation of the alternative pathway (AP) of complement. We first provide a review of the AP and then illustrate the consequence of its dysregulation by describing two ultrarare diseases: atypical hemolytic uremic syndrome (aHUS) and C3 glomerulopathy (C3G).

ALTERNATIVE PATHWAY OF COMPLEMENT

In the broadest terms, activation of complement occurs in five sequential steps. The first step is its initiation by one of three independent pathways: the classical pathway (CP), the lectin pathway (LP), or the AP. The second step is the formation of C3 convertase, which exponentially amplifies the initial triggering pathway (step 3) and leads to the generation of C5 convertase (step 4). In step 5, C5 convertase triggers the terminal complement cascade, with generation of the MAC and the potent anaphylatoxin C5a (4) (Fig. 1).

For each pathway, the initiating triggers are different. For example, the CP is most commonly triggered by binding of C1 to the Fc region of antibodies in antibody-antigen complexes (either two molecules of IgG or one molecule of IgM is required), although binding of C1 to some structures, like lipopolysaccharides, on target microbes also can be a CP trigger. In this sense, the LP is very similar to the CP since the LP is typically triggered by the binding of mannose-binding lectin (MBL) to microbial surfaces that express mannose-containing polysaccharides called mannans (5).

Compared to both the CP and the LP, the AP is unique because it is constitutively active secondarily to the slow spontaneous hydrolysis of a labile thioester bond in the thioester domain (TED) of C3 (6). This process, known as "tick-over," leads to the formation of C3(H_2O), an active "C3b-like" C3 molecule that can associate with factors B and D. In so doing, a metastable serine protease, C3(H_2O)Bb, that can cleave nearby C3 to generate C3a and C3b is formed. The availability of C3b amplifies the generation of the C3 convertase (C3bBb) in a positive amplification loop. In addition, the proteolytic cleavage of C3 to C3b exposes the unstable thioester bond in the TED, which quickly reacts with available amine or hydroxyl groups to attach C3b covalently to target surfaces and fluid-phase proteins (7).

On microbes, this C3b tagging step is amplified, but in the host, there are multiple regulators of complement activation (RCAs) that tightly control this process. RCA proteins typically control complement by modulating the generation and breakdown of the C3 and C5 convertases. This type of control is extremely important because covalent attachment of C3b to targets is a random and inefficient process, with only about 10% of activated C3b attaching to intended targets (8). In fact, the majority of C3b thioesters react with water in the fluid phase, which neutralizes the thioester and limits the deposition of C3b on both host cells and microbial surfaces (9). Plasma proteins like C4, properdin, and immunoglobulin also serve as C3b "sinks" to neutralize the thioester (10–12).

RCA proteins regulate complement activation in the circulation (fluid phase) and on cell surfaces and extracellular membranes (surface phase) (5). Many RCAs are also involved in other activities, such as cell adhesion and extracellular matrix interactions. Important fluid-phase RCAs are complement factor H (CFH) and complement factor I (CFI), which downregulate the AP, C1 inhibitor (C1INH), which downregulates the CP and LP, and C4 binding protein (C4BP), which downregulates the CP. Fluid-phase regulators of the terminal complement pathway include clusterin and vitronectin (5). Relatively recently, complement factor H-related protein 1, a member of the complement factor H gene family, has been shown to downregulate C5 activation (13).

Many RCA proteins, including CFH, C4BP, CFH receptor 1 (CFHR1), clusterin, and vitronectin, can also attach to cell surfaces and biomembranes like the glomerular basement membrane in the kidney and Bruch's membrane in the retina (14–16). This attachment adds to these surfaces a protective layer known as the surface zone, which limits formation of active complement products (5). Further protection against unintended complement activity is provided by membrane-bound RCA proteins like CR1 (complement receptor 1, CD35), CD55 (decay-accelerating factor [DAF]), CD46 (membrane cofactor protein [MCP]), CD59,

doi:10.1128/9781555818722.ch15

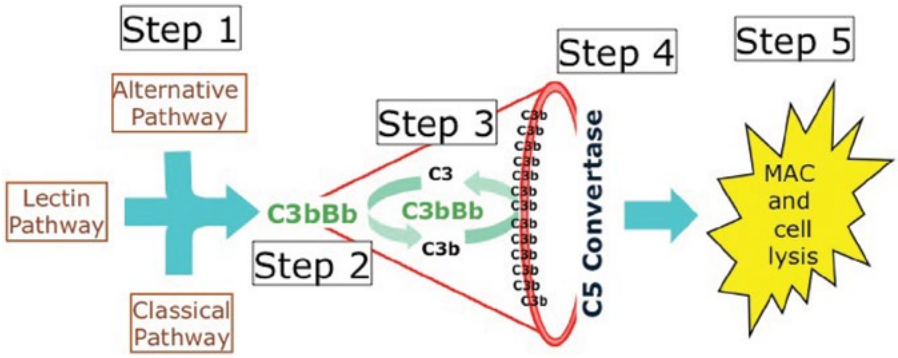

FIGURE 1 The complement system, an important arm of innate immunity, provides host defense and physiologic clearance of immune complexes and plays an adjuvant role in the immune response. Illustrated are the five steps in the complement cascade. Step 1 is the initiation of complement through one of three triggering pathways, the CP, LP, or AP. Step 2 is the formation of C3 convertase, C3bBb. Its amplification through a positive-feedback loop is step 3. The abundance of C3b leads to the generation of C5 convertase, C3bBbC3b, which is step 4. The final step is step 5, or the formation of the MAC. This step is initiated by the cleavage of C5 into C5a and C5b. Control of the amplification phase of complement is required to avoid complement-mediated host damage. This control is impaired in patients with aHUS and DDD. Eculizumab, an anticomplement drug, is a monoclonal antibody to C5. By binding to C5, it prevents C5 convertase-mediated cleavage of C5 to C5a and C5b. Because C5b is not formed, the MAC cannot be generated.

and the complement receptor of the immunoglobulin superfamily (CRIg, also known as VSIG4 [V-set and Ig domain-containing 4]) (17–24) (Fig. 2).

The cell specificities, levels of expression, and distributions of membrane-bound RCA proteins vary, which has important implications for complement-related diseases. In addition, an important distinction between fluid-phase and membrane-bound RCAs is that while the latter control all three initiating pathways by inactivating both C3 and C4 (CR1 and CD46, for example), in the fluid phase, RCAs

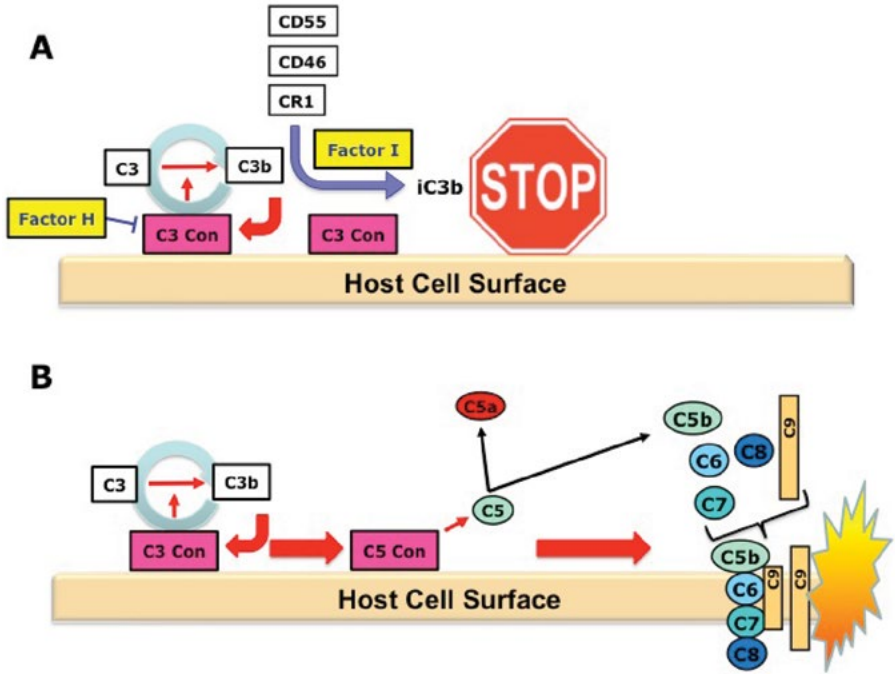

FIGURE 2 (A) Complement activity on host surfaces is prevented by RCA proteins in the "surface zone," which limits the formation of active complement products, and by membrane-bound RCA proteins, such as CR1, CD55, and CD46. CFH, an important RCA protein for fluid-phase control of the AP, also binds to surfaces to provide local control of complement activity. (B) In aHUS patients, host cell surface control of complement is abnormal. In some patients with aHUS, control is lost due to mutations in CFH, CFI, or CD46 that impair normal RCA protein function. In other patients, control is lost secondarily to the formation of autoantibodies to CFH that prevent CFH from binding to host cell surfaces. C3 and C5 Con, C3 and C5 convertase.

are pathway specific and control the AP, CP, or LP by acting exclusively on either C3 or C4 (5).

aHUS AND C3G

aHUS and C3G are prototypical examples of diseases that arise from improper regulation of the AP. aHUS is a type of thrombotic microangiopathy (TMA) in which the control of AP activity fails at the level of the glomerular and microvascular endothelial cell surface, with the clinical consequence being microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney failure (25). In C3G, in contrast, loss of AP control occurs in the fluid phase and C3 breakdown fragments deposit in the glomerulus. These fragments include inactive C3b, C3c, and C3dg and are detected by immunofluorescence (IF) using an antibody to C3c. Two broad subtypes of C3G are recognized: dense deposit disease (DDD) and C3 glomerulonephritis (C3GN) (26–28).

To understand the progress that has been made in our understanding of the pathophysiology of aHUS and C3G, it is essential to remember the following: (i) activation and regulation of the AP are focused on control of C3 cleavage to C3b, a change that is accompanied by a dramatic rearrangement of the domains of C3b; (ii) activation and regulation of the terminal complement pathway are focused on control of the C5 convertase and/or accessibility to C5; and (iii) C3 convertase operates upstream of C5 convertase, and therefore regulation of the latter will not impact the activity of the former, while the reverse is not true (preventing C3 convertase activity prevents the generation of C5 convertase).

Atypical Hemolytic Uremic Syndrome

HUS is a rare disease characterized by MAHA, thrombocytopenia, and acute renal failure. It is most frequently caused by infections of Shiga-like toxin-producing bacteria, such as *Escherichia coli* strains O157:H7, O111:H8, O103:H2, O123, and O26. In approximately 10% of HUS cases, however, there is no association with Shiga-like toxin (25). These cases are classified as aHUS and occur with an incidence of about 2 per million in the United States (29, 30). aHUS patients have a poorer prognosis than those with typical HUS, with acute-phase aHUS mortality being about 8% and with 50 to 80% of aHUS patients progressing to end-stage renal failure (25, 31, 32).

aHUS is often further subclassified as sporadic or familial. Familial aHUS is defined as the presence of aHUS in at least two members of the same family, with diagnoses at least 6 months apart. It accounts for less than 20% of all aHUS cases but nevertheless has provided important insights into our understanding of aHUS. From studies initially focused on familial aHUS, we now know that in both familial and sporadic aHUS, genetic and acquired abnormalities in the AP are present in up to 70% of patients. Gene mutations are most frequently found in complement genes, like *CFH*, *CFI*, *CFB*, *C3*, and *MCP*. The most frequently identified acquired abnormality is autoantibodies to factor H (FHAA). These are usually found in persons who are homozygous for deletion of two genes in the complement factor H gene family, *CFHR3* and *CFHR1*. Deletion of *CFHR3-CFHR1* is a common copy number variation in the general population, with one-third of European Americans carrying only one copy of these genes (33).

The consequence of genetic mutations in complement genes and factor H autoantibodies is the loss of AP control on endothelial cell surfaces, with endothelial damage secondary to the generation of C5 convertase and the MAC (Fig. 2). The recent development of eculizumab has proven life-saving for aHUS patients. Eculizumab is a monoclonal antibody that binds to C5, thereby making it resistant to C5 convertase-mediated cleavage into C5a and C5b. C5a is a potent proinflammatory peptide, so eculizumab has an anti-inflammatory effect, but because C5b is not generated, eculizumab prevents generation of the cytotoxic terminal complement complex C5b-9 (MAC) (34, 35).

Complement protein levels can be measured in aHUS patients; however, in about 60% of cases, all complement protein levels are normal (36). In these patients, if there is a complement-associated defect, it may be discovered by genetic analysis. Determining serum complement protein levels can, however, assist in the interpretation of genetic and functional data (Table 1). For example, low serum C3 with normal or decreased complement factor B (CFB) and normal C4 is consistent with AP-mediated complement activity. As a general rule, in aHUS patients, serum C4 levels are always in the normal range, while C3 levels are reduced in about 30% of patients. When C3 is reduced, the

TABLE 1 Interpretation of complement protein levels in aHUS[a]

Complement protein	Normal range (mg/liter) (−2 to +2 SD)	Measurement technique	Laboratory test	Interpretation
C3	660–1,250	Nephelometry	Basic	Severe complement consumption is indicated by very low levels of C3 and CFB in serum; however, usually only low levels of C3 are seen.
CFB	93–380	Nephelometry	Specialized	
CFH	330–680	ELISA	Specialized	CFH or CFI levels of <50% are consistent with quantitative deficiency.
CFI	40–80	ELISA	Specialized	
MCP	MFI	Flow cytometry analysis (FACS)[b] with anti-MCP PE-conjugated antibodies	Specialized	There is no MCP expression in patients with homozygous MCP deficiency. MFI in patients with a heterozygous deficiency is reduced by 50%.

[a]ELISA, enzyme-linked immunosorbent assay; MFI, mean fluorescence intensity; FACS, fluorescence-activated cell sorting; PE, phycoerythrin.
[b]Usually performed on granulocytes or peripheral blood mononuclear cells in EDTA-blood samples.

possibility of a C3 mutation should be considered. To date, 27 C3 mutations have been reported in 56 aHUS patients, with C3 reduced in 41 of 51 patients in whom serum C3 was measured. Serum levels of CFH and CFI can also clarify the mechanism of C3 consumption (36).

Although our understanding of aHUS has advanced significantly, familial aHUS has raised questions specifically regarding the high rate of incomplete penetrance. For example, about 50% of carriers of *CFH* and *MCP* aHUS-associated variants do not develop disease (37). The reason underlying this observation is unclear and means that at this point in time, disease penetrance cannot be predicted accurately, making genetic counseling imprecise. Efforts have therefore focused on identifying additional predisposing genetic variants and/or risk haplotypes in biological pathways that interact with the complement cascade to better understand factors relevant to disease onset in the face of environmental triggers, such as pregnancy, viral infection, cancer, organ transplantation, and the use of certain drugs.

In a recent study, targeted sequence capture and massively parallel sequencing of 85 genes in the complement and coagulation pathways in 36 European-American patients with sporadic aHUS identified 22 genetic variants previously associated with disease and an additional 20 variants predicted by multiple algorithms to be deleterious. As expected, nearly half of these 42 variants (19 or 45%) were in complement genes (*CFH*, *CD46*, *CFB*, *CFI*, and *C3*); however, *PLG*, a gene in the coagulation pathway, emerged as an important gene in the pathogenesis of aHUS (38).

This finding has refined our understanding of the pathogenesis of aHUS, with the key concept being a dysregulation loop driven by overactivation of complement or formation of thrombi in microvessels. Overactivation of complement causes endothelial cell lysis and leads to thrombus formation. Thrombi in microvessels cause mechanical damage to erythrocytes, with release of heme. Heme directly activates the AP and represses MCP and DAF expression on endothelial cells, making them more susceptible to complement damage and closing the loop. Dysregulation of complement and/or coagulation due to genetic abnormalities maintains the cycle (38) (Fig. 3).

It is hoped that these types of studies will continue to refine our understanding of aHUS and in so doing improve clinical care, make meaningful genetic counseling possible, and lead to the developmental of new therapeutic targets.

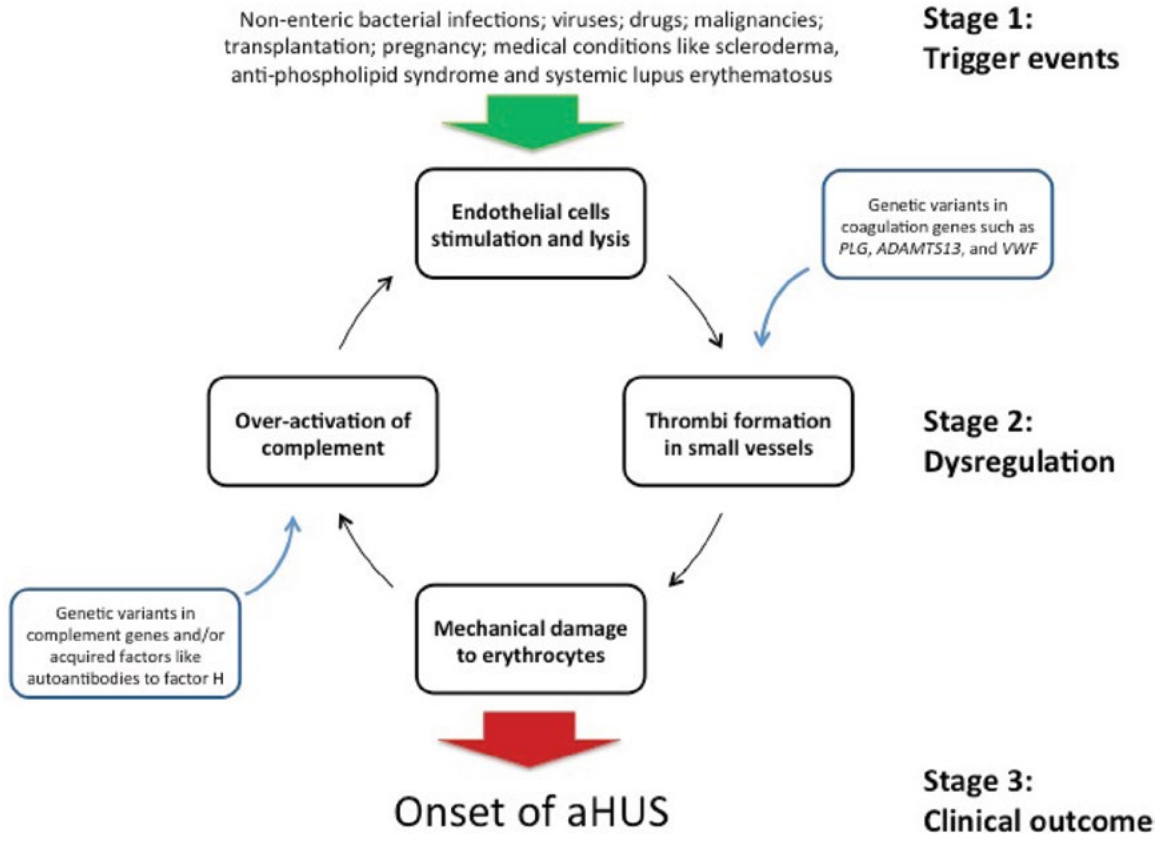

FIGURE 3 Environmental triggers of HUS include nonenteric bacterial infections, viruses, drugs, malignancies, transplantation, pregnancy, and medical conditions like scleroderma, antiphospholipid syndrome, and systemic lupus erythematosus. Following a trigger event, there is some degree of endothelial cell damage, with formation of microthrombi and activation of complement. Dysregulation can ensue if either the complement cascade, the coagulation pathway, or both are overactive. Overactivation of complement causes additional endothelial cell lysis and further clotting. Thrombi in microvessels in turn induce mechanical damage to erythrocytes, which then release heme. Heme directly activates the AP and also represses CD46 and CD55 expression on endothelial cells, which makes cells more susceptible to complement damage. The clinical consequence is aHUS.

TABLE 2 Biomarker assays for C3G

Assay	Measurement technique	Normal range	Company/reference
C3	Radial immunodiffusion	0.9 to 1.8 g/liter	The Binding Site
C3a	Direct sandwich ELISA	<122 μg/liter	Quidel Corp.
C3c	Direct sandwich ELISA	2.12 to 4.92 mg/liter	Palarasah et al. (45)
C3d	Direct sandwich ELISA	0.3 to 0.68 mg/liter	ProGen Biologics
Factor B	Indirect sandwich ELISA	155 to 250 mg/liter	Abcam
Ba	Direct sandwich ELISA	<0.9 mg/liter	Quidel Corp.
Bb	Direct sandwich ELISA	<2.5 mg/liter	Quidel Corp.
Properdin	Indirect sandwich ELISA	10 to 33 mg/liter	Hycult Biotech
C5	Indirect sandwich ELISA	55 to 125 mg/liter	Abcam
C5a	Direct sandwich ELISA	0 to 16 ng/liter	Quidel Corp.
C6	Indirect sandwich ELISA	63 to 145 mg/liter	Abcam
C7	Indirect sandwich ELISA	48 to 109 mg/liter	Abcam
C8	Indirect sandwich ELISA	24 to 121 mg/liter	Abcam
C9	Indirect sandwich ELISA	30 to 93 mg/liter	Abcam
sC5b-9	Direct sandwich ELISA	<0.3 mg/liter	Quidel Corp.

C3 Glomerulopathy

C3G designates a group of glomerular diseases characterized by an IF pattern of C3 dominance upon renal biopsy, with the descriptor "dominance" implying C3c IF intensity of at least 2 orders of magnitude greater than the intensity of any other immune reactant on a scale of 0 to 3 (including 0, trace, 1+, 2+, and 3+). The diagnosis of C3G carries with it the underlying assumption that these diseases are mechanistically related to an aberrant function of the AP, although this is not part of the formal definition (26–28).

Two major subgroups of C3G are recognized and are differentiated by differences in electron microscopy (EM) results. DDD is defined by the EM findings of extremely dense osmiophilic sausage-shaped discontinuous intramembranous glomerular basement membrane deposits; C3GN, in contrast, is defined by some combination of subepithelial, subendothelial, and/or less dense, discontinuous intramembranous and mesangial deposits not characteristic of DDD (28). Another term often associated with C3G is CFHR5 nephropathy, a subcategory of C3GN caused by a genetic rearrangement in *CFHR5* that leads to an abnormally long CFHR5 fusion protein (39, 40). A specific light microscopic pattern upon renal biopsy is not a part of the C3G disease definition.

C3G is driven by dysregulation of the C3 and C5 convertases, which can be substantially different from one patient

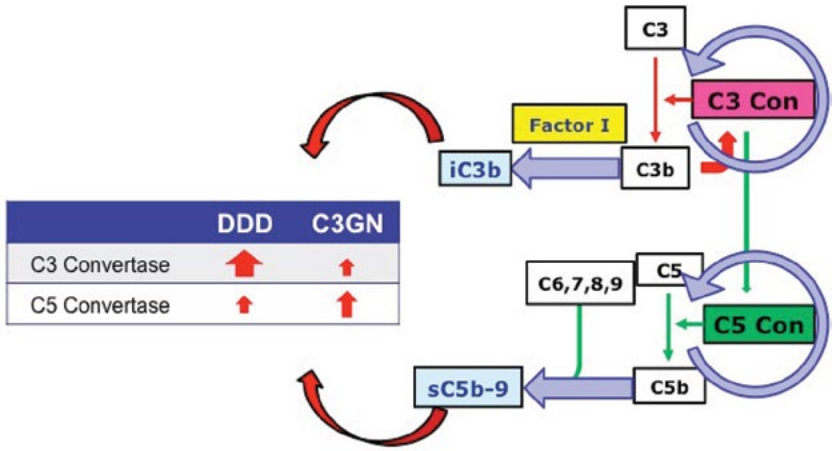

FIGURE 4 DDD and C3GN are driven by dysregulation of the C3 and C5 convertases, represented by the circular arrows. Biomarker profiling in these patients provides mechanistic insight into the degree of complement dysregulation. Serum C3 levels are significantly reduced in C3G patients compared to those in controls, with the reduction in C3 tending to be greater in patients with DDD. Although properdin is not shown in this illustration, it combines with and stabilizes C3 convertase, increasing its half-life about 10-fold. The addition of another C3b molecule to properdin-stabilized C3 convertase results in the formation of C5 convertase. C5 convertase cleaves C5 to form C5a and C5b, and in both C3GN and DDD patients, C5 levels are reduced compared to levels in normal controls. Because of the availability of eculizumab, the most important finding from a clinical perspective is the elevation in soluble C5b-9, a finding more often detected in patients with C3GN than in patients with DDD. The red arrows represent the relative degrees of convertase dysregulation in DDD and C3GN. iC3b, inactive C3b; sC5b-9, soluble C5b-9.

to the next (26, 27). For that reason, biomarker profiling in C3G patients provides detailed mechanistic insight into the underlying complement pathology and useful metrics to monitor in clinical management (Table 2). In both DDD and C3GN, serum C3 levels are significantly reduced compared to levels in controls, although the reduction in C3 tends to be greater in patients with DDD. In addition, and consistently with the continuous activation of the AP, there is a concomitant increase in C3d and a decrease in CFB, with an increase in its split products, Ba and Bb. Properdin levels are reduced in both patients with DDD and patients with C3GN, with the degree of reduction significantly greater in C3GN than in DDD patients.

Biomarker studies of C5 through C9 support a greater increase in terminal pathway activity and C5 convertase in C3GN patients than in DDD patients. In both C3GN and DDD patients, C5 is reduced compared to levels in normal controls, although only in C3GN is the level of its split product, C5a, elevated. In addition, and arguably the most important finding from a clinical perspective, soluble C5b-9 is elevated more often in C3GN than in DDD patients. This point is noteworthy because it predicts that some patients with C3G may benefit from treatment with eculizumab; however, because upstream dysregulation of the C3 convertase can still occur, eculizumab is more likely to lower the rate of disease progress than to be a curative therapy (26, 27, 41–44) (Fig. 4).

CONCLUSIONS

Dysregulation of the AP leads to a variety of diseases, two prototypical examples being aHUS and C3G. Although both of these diseases are ultrarare, detailed genetic and functional studies of the complement system have provided important mechanistic insights into the driving pathology. With aHUS, continued studies are required to understand the genetic complexity underlying issues such as reduced penetrance and whether long-term therapy with agents like eculizumab is universally required for all patients. With C3G, there is currently no effective disease-specific therapy, and as a consequence, treatment is focused on a variety of supportive measures. However, the availability of eculizumab supports efforts to identify C3G patients who may benefit from this drug by biomarker profiling of all patients carrying this diagnosis. In addition, as clinical trials for C3G evolve, biomarker changes must be monitored as primary efficacy endpoints of therapy and correlated with secondary clinical outcomes, such as changes in proteinuria or chronic kidney disease stage.

Flow Cytometry *section D*

VOLUME EDITOR: JOHN L. SCHMITZ
SECTION EDITOR: MAURICE R. G. O'GORMAN

Introduction

MAURICE O'GORMAN

16

Since the last publication of the *Manual of Molecular and Clinical Laboratory Immunology* almost a decade ago, developments in computer technology, digital electronics, and laser and fluorochrome chemistry have led to the manufacture, adoption, and common availability of clinical flow cytometers with the capacity to routinely analyze 10 (or more) parameters simultaneously. This "polychromatic flow cytometry" capability requires significant expertise in all phases of clinical flow cytometry, from antibody panel design and sample preparation to cytometer setup and acquisition and, finally, the complex task of analyzing highly parametric data files. The first chapter of this section, from Philip McCoy's laboratory at the National Institutes of Health, Bethesda, MD, provides a comprehensive overview of the technology, sample preparation, quality control, and analytical challenges involved in the design and analysis of polychromatic flow cytometry. This chapter provides insight into the considerations required for the design and analysis of highly parametric flow cytometry assays and alerts the reader to the quality control and quality assurance practices necessary to ensure consistent and reliable polychromatic flow cytometry assays.

After the first chapter, each of the following seven chapters focuses on current clinical flow cytometry-based applications, and the section concludes with a final chapter from Holden Maecker on the future of flow cytometry. Chapter 18, from the laboratories of Robert Sutherland, Michael Keeney, and Andrea Illingworth, discusses in detail the key steps required for the sensitive and reproducible detection of both red and white blood cell clones known to be associated with paroxysmal nocturnal hemoglobinuria (PNH). Flow cytometric detection of cells lacking expression of glycosylphosphatidylinositol-anchored surface molecules has become established as the method of choice for diagnosing and monitoring PNH patients. Efforts aimed at increasing both the sensitivity and standardization of PNH testing have recently received considerable attention (1–3). The details of the latter efforts are provided in this chapter.

Chapter 19, on standardized enumeration of CD34-positive stem cells, also from the laboratories of Robert Sutherland and Michael Keeney (the original authors of the International Society of Hematotherapy and Graft Engineering [ISHAGE] guidelines), provides us with an update on the clinical context of CD34 measurements, with a detailed commentary on both the gating strategy and reagents required for accurate single-platform CD34 stem cell enumeration. The authors also present a strategy for further defining the immunophenotypes of specific CD34-positive subsets and discuss the merits of such an approach.

Following these two chapters, I discuss the role of flow cytometry in the evaluation and diagnosis of congenital immunodeficiency disease in chapter 20. The continued discovery of new genes associated with immune abnormalities (adding to the 200-plus already known genes) suggests that large-scale exome or genome sequencing might be the ideal diagnostic approach. Unfortunately, at present, long turnaround times and high costs mean that deep sequencing is not the ideal approach for the diagnosis of congenital immunodeficiency, as rapid diagnosis and treatment have been shown to be extremely important in the outcomes and costs of treating such patients. For these reasons, flow cytometry will continue to be an ideal modality for the screening, diagnosis, and monitoring of patients with primary immunodeficiencies. The chapter reviews the clinical context for flow cytometry assay applications and briefly reviews four novel functional assays which have been developed for the rapid and inexpensive screening of specific immune abnormalities associated with congenital immunodeficiency diseases.

The next four chapters cover the laboratory's role in the immunophenotypic assessment of hematologic neoplasia. Probably the most significant development in this area has been the clinical validation of minimal residual disease (MRD) measurements as a prognostic marker and a key indicator of therapeutic stratification of B cell malignancies. The first of these (chapter 21), from the laboratory of J. DiGiuseppe, provides an excellent overview of the utility of flow cytometry for the evaluation of acute lymphoblastic leukemia and lymphoblastic lymphoma. The information presented is an excellent review of original publications documenting the flow cytometry application strategies for the diagnosis of B and T cell leukemia, MRD testing, and the relationship between specific phenotypic patterns and genetic abnormalities. Included in this chapter are representative flow cytometric dot plots of normal and abnormal lymphoblastic leukemia immunophenotyping results as well as examples of MRD assessment.

In chapter 22, Brent Wood of the University of Washington addresses the application of flow cytometric immunophenotyping to the diagnosis, subclassification, and MRD assessment posttreatment of acute myeloid leukemia

doi:10.1128/9781555818722.ch16

(AML). Wood reminds us of the cardinal rule in the immunophenotypic assessment of hematolymphoid malignancies that "knowledge of immunophenotype of normal hematopoietic maturation is key to understanding changes induced by neoplastic transformation." Antigen expression patterns are presented, from the earliest pluripotent stem cell through commitment and maturation along the seven main myeloid lineages. The biology, epidemiology, and subclassifications of AML are followed by important methodological considerations for preparation, acquisition, analysis, and reporting by the laboratory. Clear tables covering relevant antigens useful in the assessment of AML as well as common signature immunophenotypic expression patterns associated with specific subcategories of AML are presented along with figures illustrating both normal and abnormal immunophenotypes in diagnostic and posttreatment specimens.

Immunophenotypic assessment of chronic lymphocytic leukemia (CLL) is presented in chapter 23 by Heba Degheidy (FDA), Mary Alice Stetler-Stevenson (NIH), and their colleagues. Recent studies reviewed in this chapter indicate that specific immunophenotyping patterns in early disease have prognostic implications and that the detection of residual abnormal cells is associated with both the response to treatment and the prognostication of the overall time of survival. Key recommendations for sensitive and reproducible measurements of specific immunophenotypes and ZAP-70 expression levels and for MRD detection based on standardized methods established by the European Research Initiative on CLL are discussed. Figures showing both normal and abnormal populations, ZAP-70 expression level measurements in both positive and negative cases, and gating strategies for MRD analysis in CLL are presented.

The final chapter, on immunophenotypic assessment of hematologic neoplasia, provides a detailed and comprehensive overview of the flow cytometric approach to plasma cell disorders, where the role of flow cytometry remains controversial and in need of standardization. Alberto Orfao's group at the University of Salamanca has extensive experience in the progressive application of flow cytometry analyses for the identification, quantitation, and categorization of specific plasma cell subtypes in the context of their relationship to risk stratification. An overview of the diagnostic classification of plasma cell disorders, risk of progression within each of the categories, and the need for sensitive MRD detection is followed by a discussion of the role of a standardized flow cytometric approach in the characterization of normal/reactive plasma cells versus aberrant plasma cell immunophenotypes in each of the plasma cell disorders. A discussion of a novel experimental stepwise approach that was used by the Euroflow consortium to develop and establish a two-tube, eight-color antibody panel for the assessment of plasma cell disorders is included. The applications of flow cytometry for diagnosis, classification, prognostic stratification, and MRD monitoring are also addressed in detail. The chapter concludes with a plea for the adoption of "highly standardized approaches" for the attainment of "reproducible and robust" results. Included in this chapter are tables outlining the current classification of plasma cell disorders, the International Myeloma Working Group's diagnostic criteria and treatment response categories for the major categories of plasma cell disorders, and a list of the most relevant plasma cell surface markers and their relevant clinical values. The figures illustrate plasma cell immunophenotyping in normal bone marrow, a patient with multiple myeloma, and a patient with detectable MRD, using a standardized immunophenotypic approach (Euroflow).

The concluding chapter of the clinical flow cytometry section, chapter 25 by Holden Maecker of Stanford University's Human Immune Monitoring Center, provides a glimpse of some of the potential future technologies and applications currently being adopted for research use. A major expansion of the practice of polychromatic flow cytometry (presented in the first chapter of the section) is being made possible by the development of time of flight-mass spectrometry instrumentation. Mass cytometry has expanded "flow" capabilities from the 10- to 20-parameter range to the analysis of >50 parameters on single cells in a single tube. With the number of installations of this new technology approaching 100 units and the commercial availability of new reagents, we are beginning to see results and applications that may have potential for clinical adoption. The other field reviewed by Maecker is the increased flow cytometric assessment of complex signaling pathways that are operative in specific leukocyte subsets undergoing specific normal and abnormal immune responses. Signaling pathways are being studied by measurement of the phosphorylated/dephosphorylated forms of specific signaling proteins activated following exposure to specific stimuli in health and disease. We are already seeing the adoption of this technology, commonly referred to as "phospho-flow," in highly specialized clinical flow cytometry laboratories (see chapter 20). The combination of mass cytometry with phospho-flow has the potential to allow for assessments of normal and abnormal signaling cascades within specific cell subsets that were not previously possible by any technology. This type of laboratory assessment will arguably be adopted for the provision of novel information in the rapidly developing fields of individualized medicine and targeted therapies.

Flow cytometry continues to evolve as an integral technology in the clinical laboratory, and it is anticipated that the chapters included in this section will provide clinical laboratories with sufficient information to adopt new tests, improve current ones, and potentially develop new applications for the assessment of their specific patient populations.

Polychromatic Flow Cytometry

ANGÉLIQUE BIANCOTTO AND J. PHILIP McCOY, JR.

17

For nearly half a century, flow cytometry has been a tool used by biologists to study features of individual cells in a rapid and unbiased manner. The measurement of cellular features has relied upon intrinsic properties of the cells which can be examined by laser-light scattering or by the addition of extrinsic fluorescent probes, such as dyes or fluorochrome-conjugated antibodies that can make cellular features quantifiable. The early flow cytometers relied on only one or two lasers, or a mercury arc bulb, for excitation light, and generally measured only one fluorescent parameter. In the late 1970s, Stohr (1) and Dean and Pinkel (2) described dual-laser excitation for flow cytometry, which permitted the simultaneous use of two spectrally distinct fluorochromes, signaling the genesis of polychromatic flow cytometry. At roughly the same time, Loken and colleagues proposed a method to overcome the difficulties caused by the spectral overlap of fluorochromes excited off a single laser—a method we now refer to as "compensation" (3). These developments laid the foundation for future high-polychromatic flow cytometry, as the bases for both multi-laser excitations as well as exciting multiple fluorochromes off each laser had now been described.

Technological advances in lasers and fluorochromes, while tremendously important to the evolution of modern flow cytometry, were, by themselves, not sufficient to mature this technology. While flow cytometers today are most often controlled by desktop computers, with data captured, stored, and analyzed on these same computers, it should be appreciated that desktop personal computers were not widely available for the early flow cytometers (the IBM PC was introduced in 1981 and the Apple I in 1976). Flow cytometers of the 1970s had extremely limited capacities for data capture, storage, and analysis, and it was not unusual for data to be recorded as Polaroid pictures or strip-chart recordings of the oscilloscope traces. As computers became commonplace in flow cytometry, the need for standards for data files and for increasingly sophisticated software became evident. The first file standards, appropriately called "Flow Cytometry Standard" files (*.fcs), were introduced in 1984 and are periodically updated and enhanced (4). These advances, in turn, led to two notable advancements crucial to the development of high-polychromatic flow cytometry: software compensation and "offline" (retrospective) data analysis. Hardware compensation, as described by Loken and colleagues, had limitations in the practical number of colors that could be compensated, due to the complexity of the compensation matrix as the number of colors increased. Software compensation is, in theory, limitless in the number of colors that could be compensated (5). Similarly, analyzing high-polychromatic data is often quite complex and time-consuming, constraints that are greatly offset by offline data analysis on powerful computers with robust software.

Parallel to these technological advancements were great strides in our understanding of the complexity of cellular phenotypes and their underlying functional properties, due in no small part to the development of antigen-specific monoclonal antibodies (mAbs) by Kohler and Milstein in 1975 (6). For example, while at one point in time, discerning T lymphocytes from B lymphocytes may have been considered sufficient to understand the immune subsets in a particular disease, we now appreciate the myriad subsets present within each of these lineages as exemplified by naive and mature subsets, or regulatory and effector subsets whose functions are characterized by the production of cytokines or the expression of particular chemokines or cytokine receptors. As the complexity of the biology was better understood, so our need increased for higher polychromatic flow cytometry to identify these cells.

Today, flow cytometry studies have been performed using as many as 18 fluorescent markers, and even higher-dimensional data have been acquired using nonfluorescence-based methods such as CyTOF mass cytometer (7) (DVS Sciences, Toronto, Ontario). Staying within the realm of fluorescence-based flow cytometry, new instrumentation using multispectral flow cytometry has been described, which is likely to increase the number of fluorochromes to be run simultaneously, making 25- or 30-color cytometry practical. Hand in hand with the development of advanced instrumentation capable of high-polychromatic cytometry is the significant advancement in fluorochromes and stains. Viability stains (those dyes used to assess whether a cell is dead or alive), once primarily limited to propidium iodide or 7-aminoactinomycin-D, are now available in a broad range of excitation and emission spectra. Examples of these include the family of Live-Dead (Life Technologies, Carlsbad, CA), Zombie (Biolegend, San Diego, CA), and Horizon (Becton Dickinson [BD], San Jose, CA) stains. Similarly, new fluorochromes have been developed that permit more extensive use of 407 nm (violet laser, such as quantum dots [QD], Life Technologies) and the

doi:10.1128/9781555818722.ch17

brilliant violet (BV) family of fluorochromes (Sirigen, BD, San Jose, CA). These can permit the simultaneous analysis of five or more distinct markers using the violet laser, a laser previously used only minimally in phenotypic analyses due to the lack of appropriate fluorochromes.

The final piece of the polychromatic flow cytometry puzzle is data analysis. As one moves from two- or three-color analysis to 15 colors or more, data analysis becomes almost exponentially more difficult, beginning with compensation and extending to thoroughly "mining" data for all possible information. Fluorescence compensation is made easier by compensation "wizards" that are components of most contemporary analysis programs for flow cytometry. These wizards set compensation values after the user enters data for cells or beads unstained and stained with each individual fluorochrome into the program. This alleviates what would otherwise be an overwhelming task to appropriately set manually determined compensation for high-polychromatic studies. However, even these compensation matrices should be checked to ensure against artifacts, such as those caused by aggregates of quantum dots. The challenge of thoroughly analyzing high-polychromatic data is more daunting. Properly compensated data can readily be analyzed in a predetermined, or guided, manner in which the pathway of gating is predetermined for the quantification of cell subsets with established phenotypes. By contrast, the "discovery" mode of analysis, in which all possible cellular phenotypes contained within a population are identified, is more complex and time-consuming in high-dimensional studies. Vast numbers of populations are mathematically possible (but perhaps not biologically) in polychromatic data, as the potential number of populations increases exponentially with the number of parameters studied. Assuming all populations existed as combinations of positive and negative staining (disregarding the possibility of dim and bright subsets), 10-color data could yield over 1,000 cell populations. Manual analysis of all of these putative populations would be extremely cumbersome, and therefore considerable effort is being made at developing automated approaches for in-depth analysis of high-polychromatic data.

The uses of flow cytometry are widely varied, but none are more important than the clinical applications. In the first decade of flow cytometry, attempts were made to apply studies of DNA content and cell cycling to clinical problems. These efforts met with mixed success. The discovery and later commercialization of mAbs provided the impetus for a broader array of assays of potential clinical utility to be developed. Foremost among these were enumeration of $CD4^+$ T cells in the context of HIV disease and immunophenotyping for the classification of leukemias and lymphomas. These assays established the clinical utility of flow cytometry and continue to be the most frequent clinical applications, as these tests are essential components in the clinical management of patients with these diseases. Flow cytometry is also particularly well suited for the detection of minimal residual disease in patients with hematologic neoplasms. Here, patients are screened for small numbers of residual cells from their disease with the potential to cause a relapse. Flow cytometry is capable of high-throughput analysis of thousands of cells per second in sensitive, polychromatic approaches for identifying leukemic cells present in frequencies as low as 1 per million normal leukocytes.

Clinical assays using flow cytometry encompass a wide array of applications, such as quantification of hematopoietic stem cells (usually identified using CD34 or CD133), diagnosis of paroxysmal nocturnal hemoglobinuria (based on cells that lack glycophosphatidylinositol-anchored proteins such as CD55 or CD59), detection of primary immunodeficiencies, studies of platelets, and leukocyte adhesion deficiencies (usually based on CD11b and CD18 expression), to name a few (8).

Research applications for flow cytometry are even more varied and include numerous scientific disciplines. For example, in marine biology, flow cytometry is widely used to study phytoplankton, algae, and aquatic bacteria in water samples. Other disciplines using various applications of flow cytometry include plant biology, pathology, animal husbandry, and molecular biology, but perhaps the most common uses are in immunology and hematology. Within these disciplines, flow cytometry is used not only for immunophenotyping studies, but also for uses such as the detection of intracellular cytokines, phosphorylation of signaling proteins, cellular proliferation and apoptosis, calcium fluxes, phagocytosis, membrane potential, antigen colocalization, and many others.

TECHNOLOGY

Instrumentation Overview

To appreciate flow cytometry instrumentation, it is necessary to understand the basics of how flow cytometry works. The typical flow cytometer relies on placing cells in a single-cell suspension, then moving the cells single file in a tightly focused stream past a light source (or multiple light sources) and detectors for scattered light as well as emitted fluorescence (Fig. 1). Downstream, the cells may be sorted or not, depending on the type of cytometer. If the cells are not sorted, they generally go to a biohazard waste and are discarded. As will be discussed below, prior to being placed in the flow cytometer, the cells are appropriately treated and stained for the cellular features one wishes to study. The tightly focused cells pass through one or more laser beams one at a time in rapid succession, in a sample core chamber, and the intersection of each laser and particle is called the point of interrogation. The lasers excite various fluorescent probes that have been used to stain the cells, and the light emitted from these stains is sent to an array of detectors (as well as forward- and side-scatter light from one of the lasers). Prior to reaching detectors, the light is separated into various predefined wavelengths using a succession of mirrors and filters in order to distinguish the emission of each of the stains from all others. The separated light then strikes the detectors, generating a signal that is amplified and digitized for subsequent analysis.

Beyond the basic method of operation just described, flow cytometers can vary greatly in their specific design. For example, cells may be focused into a tight stream either by the use of a sheath stream or by acoustic focusing without sheath. Light sources can range from mercury arc bulbs to as many as seven lasers of different powers and wavelengths. Detectors are most often photodiodes or photomultiplier tubes, although recently one model was developed that uses charge-coupled device (CCD) cameras as detectors. The number of detectors varies widely, ranging from four to 20 or more. A fairly standard, middle-of-the-road flow cytometer today would use sheath-based focusing, have three lasers, and be capable of measuring forward- and side-light scatter as well as eight fluorescent parameters.

Although most cytometers are designed in a manner consistent with the description given above, the specific configurations of commonly available cytometers can differ widely in specific areas such as the types, number, and power of lasers, the choice of optical filters, and the layout and number of detectors.

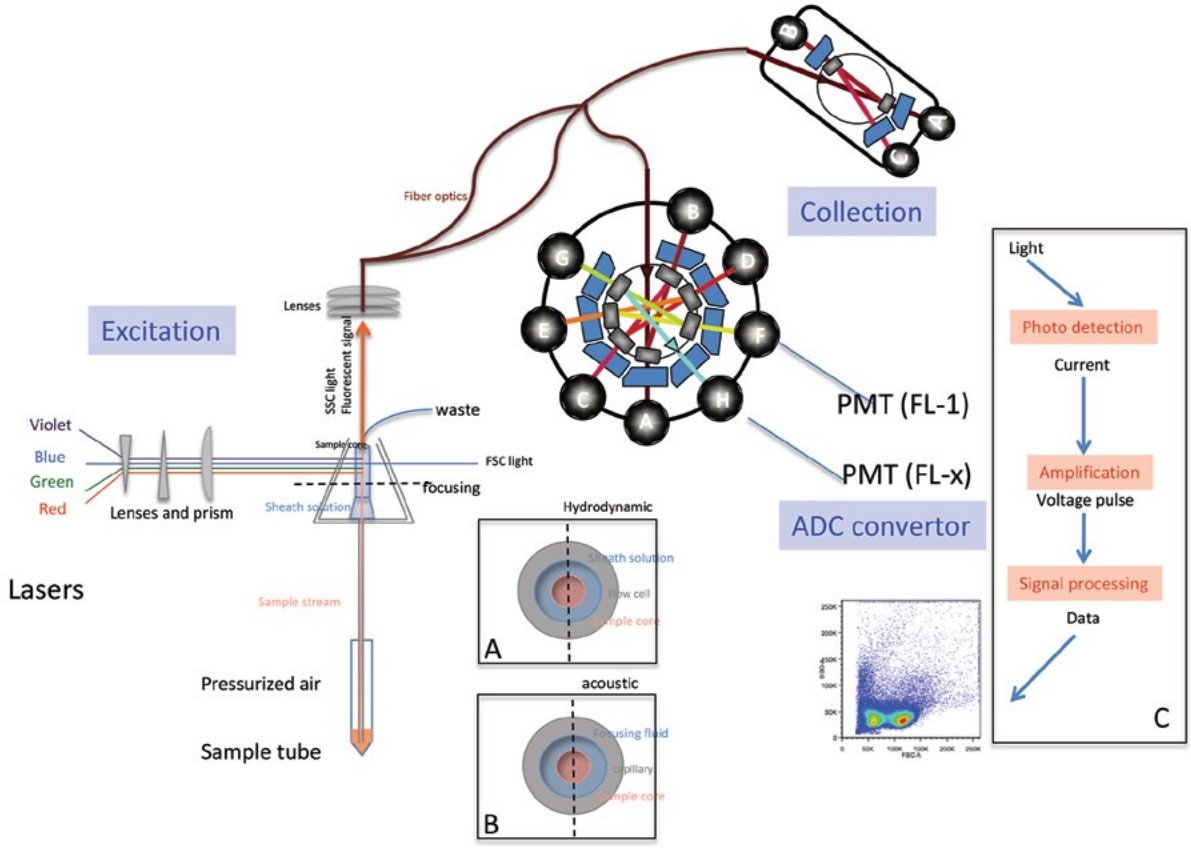

FIGURE 1 Schematics of the main components of a flow cytometer. A single-cell suspension goes through a tightly focused stream into the flow cell, where it encounters the different lasers. Insert A shows the position of different components of hydrodynamic focusing using a coaxial stream. Insert B shows the different components of acoustic focusing, where a capillary line of particles can be created using acoustic-radiation pressure. The signals emitted using the blue-laser excitation can measure physical characteristics of cells in addition to fluorescence measurements via transformation of fluorescence into voltage (see insert C). Each fluorescence channel measured is assigned to a PMT.

Fluidics

The role of fluidics is crucial to presenting the cells one at a time in a narrowly focused pattern to the laser beam. The fluidics system consists of a central channel in which the sample is injected, enclosed by an outer sheath that contains faster-flowing fluid (sheath fluid). As the sheath solution moves, it creates a massive drag effect on the narrowing central chamber. This alters the velocity of the fluid in the middle and the front becomes parabolic, creating a hydrodynamic focus (Fig. 1). Under optimal conditions (laminar flow) the fluid in the central chamber will not mix with the sheath fluid (see insert A in Fig. 1). After hydrodynamic focusing, each particle passes through one or more beams of laser light. The rate of the sample flow is regulated by a pressure regulator and may be continuously variable or fixed to defined settings (e.g., high, medium, and low), allowing speed-sample processing from perhaps 100 events per second to 20,000 events per second or more.

As an alternative to hydrodynamic focusing, other cytometers, such as the Attune cytometer, use acoustic focusing. This also results in the generation of a single-cell stream for passing the cells through to the laser beam, but without using sheath fluid. Cells are transported through a capillary system where an acoustic resonant device focuses them into a single tight line. The acoustic radiation is generated using a capillary coupled to a piezoelectric transducer (see insert B in Fig. 1) (9, 10).

Regardless of the type of focusing used, the single cells will encounter the laser beam in the sample core, where the point of contact between the particles and the laser is called the interrogation point.

Lasers

Most flow cytometers depend on lasers as a light source for excitation of fluorochromes as well as for light-scattering measurements. Light scattering provides information regarding cellular intrinsic properties such as granularity or size, while fluorescence emission (if the particle is labeled with a fluorochrome) provides information about cells' extended properties, such as the relative amount of a specific antigen present on the cell. As noted above, the mercury arc lamp is the most common alternative light source other than lasers in modern flow cytometry, although the increasingly low cost and minimal size of lasers are making the use of these lamps increasingly rare.

There are multiple types of lasers, and the choice of which laser to use on a particular cytometer is dependent on the needs, cost, size, and the performance of light-collecting detectors and optics (11–20).

Currently, there several types of lasers used in flow cytometry, with output wavelengths ranging from 300 to 700 nm. These include: water-cooled and air-cooled gas lasers (argon-ion, helium-neon [He-Ne], and helium-cadmium [He-Cd] lasers); diode lasers (in which laser light is generated by pumping electricity into a solid medium rather than a gas-plasma tube); diode-pumped solid-state (DPSS) lasers, which use a diode source to pump another crystalline material (frequently neodymium yttrium aluminum garnet, or ND-YAG); violet-diode lasers (VLD); and near-UV diode lasers (NUVLD). Indium-gallium nitride-laser diodes have been developed and extend the excitation range in the near-UV (370–385 nm).

Many flow cytometers are equipped with two or more lasers that permit the analysis of multiple fluorescent labels on each cell. In a system with multiple lasers, the lasers' spatial separation creates an issue that needs to be addressed, as a single cell intersects the multiple laser beams at different time intervals and therefore the fluorescence emissions from these different fluorochromes on the same cells arrive at their respective detectors at different time intervals. To assign the signals generated on different lasers to a particular cell, a function termed "laser delay" is used (Fig. 2). One laser, usually the blue (488 nm) laser, is used to obtain the forward- and side-scatter measurements and is considered the reference laser. Other lasers can be placed in a position so that a cell can pass through their beam either before or after the reference laser. Therefore, laser-delay setting can have either a positive or a negative value, depending on whether the cell passes through beams from the respective laser before or after the reference laser.

Once the lasers are chosen for a cytometer, their placement in relation to the reference blue laser needs to be adequate for optimal separation of the generated signals, as the time delay will be of importance when fluorescent signals are collected.

Optical Filters

The side-scatter light and fluorescence signals generated by the cells need to be directed to the appropriate detectors; for this purpose, various optical filters are used in a flow cytometer to direct the photons of the correct wavelength to the appropriate photo-multiplier tube (PMT). These filters block certain wavelengths from reaching the detector while permitting others (transmitting) to pass through. There are three major filter types: "long-pass" (LP) filters that allow passage of light above a defined wavelength while blocking lower-wavelength light; "short-pass" (SP) filters that allow passage of light below a defined wavelength and block higher wavelengths; and "band-pass" (BP) filters that transmit light

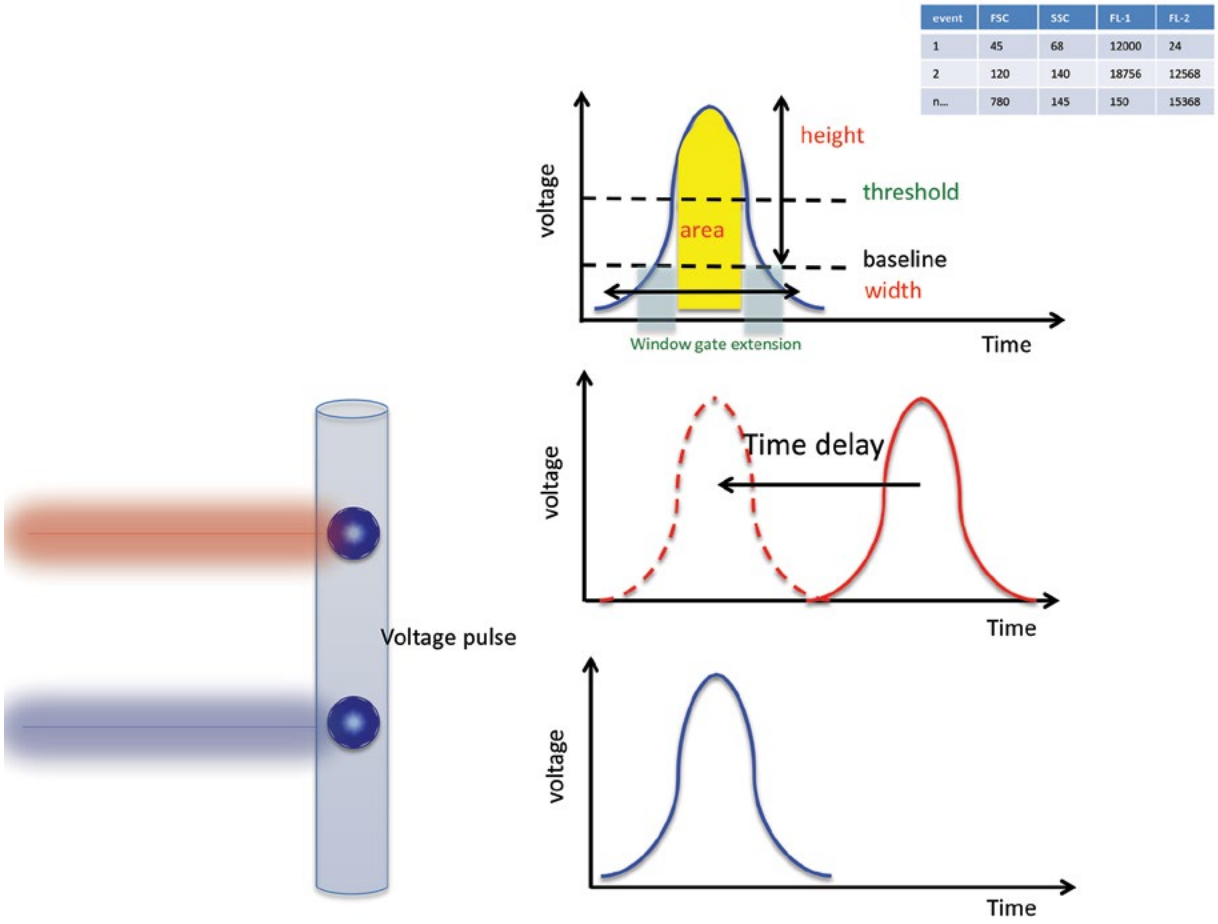

FIGURE 2 Schematics of the voltage pulse and time delay. Area, height, and width are the signals recorded for each single particle (text in red), and these measurements are influenced by the threshold and window-gate extension that are set up by the user (text in green). The voltage pulse generated by the red laser will need to be retrospectively assigned to the same particle-voltage pulse from the blue laser (time delay).

within a specified narrow range of wavelengths (termed a bandwidth) and are generally used immediately in front of a detector. Similar filters are positioned at a 45° angle to the light beam and are called dichroic filters/mirrors. In an LP dichroic filter, photons above a specific wavelength are transmitted straight ahead, while photons below the specific wavelength are reflected at a 90° angle.

For LP and SP filters, important performance parameters are the wavelength for 50% transmission (the cut-off for LP or the cut-on wavelength for SP), the peak transmission, and the slope at the cut-on or cut-off wavelength. For BP filters, important performance parameters are the peak wavelength of transmission, the percentage of light transmitted at the peak wavelength, and the bandwidth (measured as the separation of the 50%-transmission points).

Signal Processing and Configuration of Instrument Detectors

After excitation of the fluorochromes, the emitted light is filtered into specific wavelengths and then strikes a photodetector, which is a sensor capable of detecting photons. The photo-detector will generate a current whose associated voltage is proportional to the number of light photons striking the detector. Subsequently, this current goes through a series of amplifiers, which convert electrical current into a measurable electrical signal, the voltage pulse (see insert B in Fig. 1). Most amplifiers are analog-to-digital convertors (ADCs). The voltage pulse generated will be quantified by signal processors providing numerical values for area, height, and width (Fig. 2). The particle that will generate a signal is based on a threshold set up by the user.

The measurement from each detector is referred to as a "parameter": forward-scatter, side-scatter, or fluorescence. The configuration of an instrument is the assignment and location of each detector to each parameter.

Then, numerical data are processed by a computer system that will create list-mode files or FCS files and display data. The instrument configuration is the assignment of each detector to a given PMT.

Data Files and Analysis

When the cells or particles are interrogated by the lasers, signals are generated, amplified, digitized, and ultimately converted to a number that is proportional to the original light signals. This is stored in a computer in an .fcs format or list-mode file. Both list-mode and .fcs files are a list of sequential numerical values for each measured parameter of every individual cell. The data generated can be presented in single parameter (histogram) or double parameters (dot or contour plot).

Histograms are a direct graphical representation of the number of events occurring for the chosen parameters. The dot plot is a two-dimensional extension of the frequency histogram, where each cell is represented by *x*/*y* coordinates on *x*/*y* axes.

Other techniques can be employed to visualize three or more parameters in highly multiplexed parameter-analysis applications. Statistical analysis is performed by graphically applying regions of interest to data sets.

Flow Cytometer Standardization

Initial Performance Check

Prior to use, any flow cytometer should have its performance assessed for consistent, optimal measurement of fluorescent and light-scatter signals.

Quality assurance of the instrument's performance can be summarized in a three-step protocol including optimization, calibration, and standardization of laser components (laser power, laser delay), optical components (optical filter choices; dichroic-mirror reflection, dichroic-mirror transmission), and electronic components (PMT assignment, electronic noise, and window extension) (21, 22). Microspheres that contain dyes inside their core and have excellent photochemical and physical stability provide reliable reference signals for laser alignment, laser-beam focusing, and calibrating flow cytometers during the performance testing.

Laser Components

Flow cytometers depend on lasers as a source of excitation for all fluorochromes; alignment of lasers one to another is crucial for optimum fluorescence measurement. Microspheres are used to test laser alignment and to gauge the sensitivity and signal-to-noise ratios of detectors, laser power, and window extension (Fig. 3A). Laser-time-delay setup is crucial for accurate measurement of any type of sample.

Optical Components

The choice of optical filters that are used with each detector greatly influences the effective brightness of one fluorochrome versus another. Filter selection is a good news-bad news proposition: using a wider BP filter can increase the ability to detect a given fluorochrome, but may also increase the amount of spillover background contributed into that detector from other neighboring fluorochromes. Measurement of optical background (Br) should be assessed for each filter used in the instrument.

Electronic Components

Ideally, there is a linear relationship between voltage PMT and fluorescence intensity. To test the photoelectron efficiency, microspheres for a given PMT are run using different voltages, and plots of the variation of the voltage gain versus coefficient of variation (CV) of the mean fluorescence intensity are constructed. For each PMT, measurements are done in cascade using different voltages. Graphing the fluorescence intensity versus voltage will have an inflection point that shows minimum baseline voltage for optimal resolution between negative and positive measurements: this is detector efficiency (Qr) (11, 12, 17–19) (Fig. 3C). Microspheres are used with different graded levels of fluorescence, and their fluorescence measurements are used for the generation of calibration curves, establishing PMT settings, and evaluating sample fluorescence intensity (21, 23, 24). The most efficient PMT should be assigned to the detector that captures low-energy photons, in the longer wavelength, such as allophycocyanin (APC)-H7 or APC-Alexa 750 (21, 22, 25, 26).

It is convenient to visualize the instrument-performance checks over time to detect not only acute instrument failures, but also slow degradation of instrument performance. For this, the Levy-Jennings plot is most often used. This plot has time on one axis (which can vary to whatever length of time desired) and the quantitative measurements of one or more instrument-performance checks plotted on the *y*-axis (see Fig. 3D).

Daily Performance Check

To ensure accuracy and reliability of the fluorescence measurement, instrument performance needs to be calibrated daily.

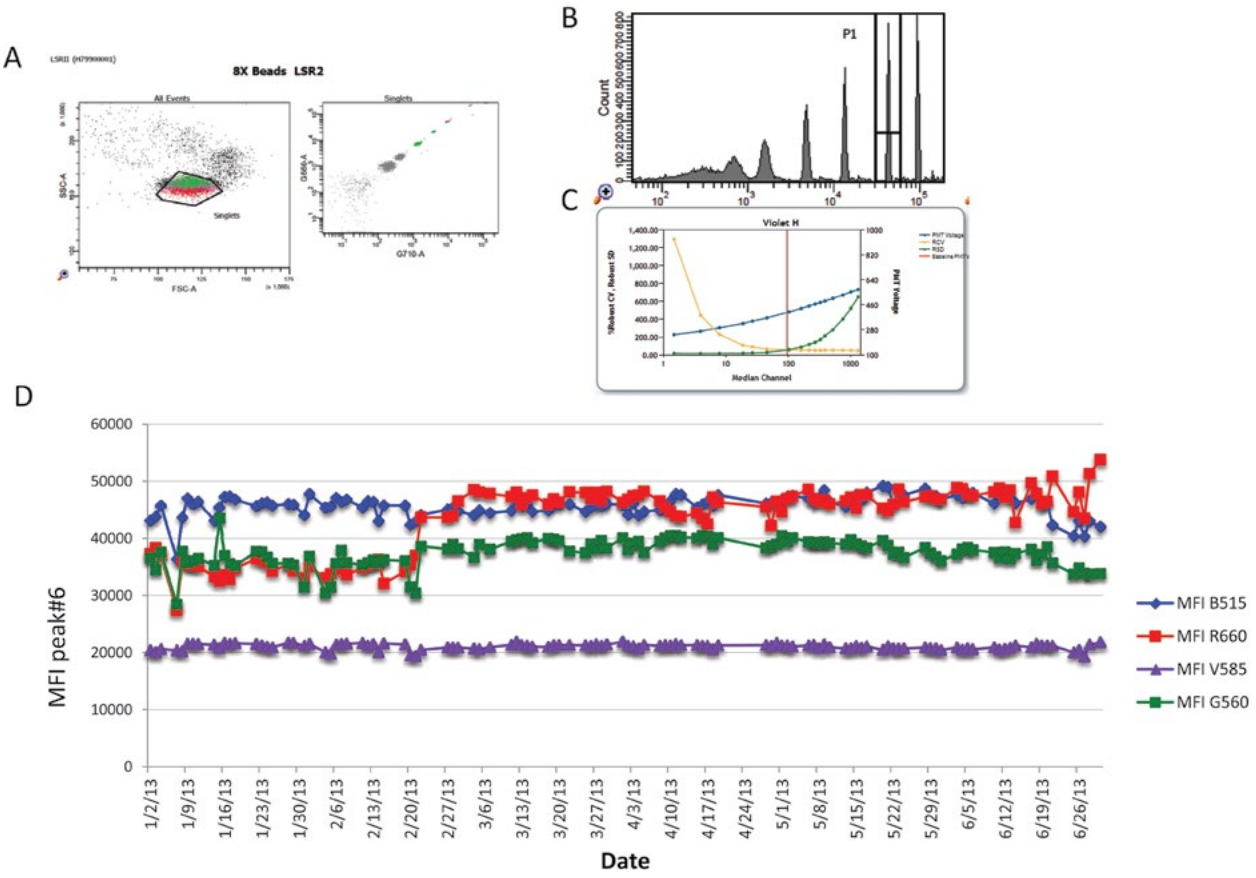

FIGURE 3 Example of dot plots generated by CST and QC Levy-Jennings. On a daily basis, eight peak beads are run on the cytometer after the CST performance check. (A) After doublet exclusion the fluorescence intensity is measured for each of the eight peaks in each detector. (B) Median fluorescence intensity of each PMT for each laser is generated by CST software (example of 1 Violet PMT V585). (C) Robust CV, robust SD of MFI of Violet PMT V585. Blue line represents the PMT voltage, the rCV is in yellow, rSD is in green, and the baseline PMT is the red line showing intersection of rCV with rSD. (D) Levy-Jennings plots, which display the performance characteristics of an instrument over time, are useful for assessing instrument variations. Here a Levy-Jennings plot of the MFI of bead standards at a constant voltage is shown for four PMTs across several months, with the performance of each detector shown in a different color.

Bead Setup and Tracking Features

Bead setup and tracking features are provided by the instrument manufacturer and include the beads and accompanying analysis software that uses algorithms to differentiate the fluorescence signals from each bead type based on size and fluorescence intensity in each detector for a specific instrument. The median fluorescence intensity (MFI) and percent robust CV (%rCV) are measured for each bead intensity in all fluorescence detectors (PMT). Linearity, detector efficiency (Qr), optical background (Br), electronic noise, and laser delays are all tracked. PMT voltages are then adjusted to maximize population resolution in each detector; PMT voltages should not vary more than 10 V from their baseline, and %rCV should be <6%. Levy-Jennings plots (PMT voltage over time) are used to facilitate monitoring of performance (Fig. 3D). One example of a manufacturer's performance check is the Cytometer Setting and Tracking (CST) beads from BD. CST beads are a set of fluorescent beads that can be used to assess the performance of the lasers and detectors, determine optimal values for laser delay, and determine optimal baseline voltages for every PMT.

In situations where automatic tracking features are not available or are not desired for a particular application, a similar generic approach can be used with third-party calibration beads. These beads are a mix of fluorescent beads with different intensities; for each bead, the %rCV of the MFI is measured and monitored. The acquisition of Spherotech beads (Spherotech, Lake Forest, IL) is performed at a constant voltage in which PMT values are fixed to arrive at a constants target channel (21, 23, 24, 27, 28).

SAMPLE PREPARATION

Sample Types and Requirements

Any single cell or particle suspension—which includes animal and plant cells, bacteria, yeast, dissociated tissue, peripheral blood leukocytes, bone marrow, cell lines, and cryopreserved cells—can be analyzed. Polystyrene beads can also be analyzed, and this is particularly useful if these are designed to capture soluble analyte for quantification (e.g., serum/plasma, cell culture supernatant, cell lysate, or other biological fluids).

To obtain single cells from tissues (e.g., tumor biopsies, lymph nodes), mechanical dissociation and/or enzymatic digestion is usually required. This is to break apart the cellular aggregates, to degrade extraneous material (such as collagen) from the tissue, and to facilitate optimal recovery of cells from the tissue. Conditions and enzyme requirements for digestion of each tissue of interest need to be determined empirically in order to keep the integrity of both the cells and antigens used for detection.

Certain cell types like monocytes, granulocytes, and adherent cell lines tend to be sticky and form aggregates. These aggregates can block the instrument's flow cell, and therefore samples containing these or other "sticky" cell types must be filtered to remove the aggregates or dispersed by some other method before being run on the flow cytometer.

Each type of sample needs to be carefully evaluated prior to preparation in order to ensure single-cell suspensions of intact cells for proper analysis (27–32).

Erythrocyte Lysis

In peripheral blood, erythrocytes outnumber white cells by 1,000 to 1. Due to their abundance and size, it is preferred to remove red blood cells from whole-blood samples if one only wishes to study leukocytes, as the presence of red cells will slow acquisition and create huge data files. It is not necessary to physically remove platelets and small debris, because these can be thresholded out during acquisition since a size threshold can be set empirically by the instrument operator. The effects of different erythrocyte-lysing methods commonly used in the analysis of human cells have been shown to influence recovery of certain cell types, such as blast enumeration, or consistency of CD4 and CD8 measurements (33–35).

Some of these methods allow for labeling of lymphocytes in whole blood, followed by erythrocyte lysis. Otherwise, using a solution of ammonium chloride (NH_4Cl), lysis can be performed prior to staining the lymphocyte subsets. The mechanism of lysis by this buffer is based on an osmotic shock of the red blood cells. Depending on the manufacturer, some of the ammonium chloride-based buffers include formaldehyde or diethylene glycol as fixatives.

For peripheral blood, the anticoagulant present in tubes into which the blood is collected (36–38), as well as the type of lysis reagent used for red blood cell removal, are among the factors that need to be evaluated prior to any experiment. It has been shown that a cytometric study of erythroid maturation requires a different method of specimen preparation than the red blood cell lysis methods commonly used to process blood and bone marrow. Commonly used lysing reagents leave only very early erythroid precursors (proerythroblasts) remaining in the sample (39).

Although the majority of clinical laboratories analyzing peripheral blood now use an ammonium chloride lysis method for whole blood prior to routine immunophenotyping, research laboratories wishing to measure lymphocyte functions or to cryopreserve samples for future analysis need to use lymphocytes obtained by Ficoll-Hypaque density-gradient separation (FDS).

Absolute Cell Counting

Absolute cell counting using flow cytometry is possible through the use of an internal microsphere-counting standard specific to the cellular sample. The microspheres can only be added to an erythrocyte-lysed sample, and these beads can be manually added to the sample (true-count beads) or the sample can be added to the beads lyophilized in a tube (true-count tube).

The concept to this counting approach is that a known number of cell counting beads are added to a known volume of cell sample. The beads are counted along with the cells but can be gated separately due to distinct light-scatter characteristics. During the acquisition, since the concentration of the beads is known, the number of cells per microliter is obtained by relating the number of cells counted to the total number of fluorescent-bead events. The rate of acquisition needs to be constant and not changed.

Some newer instruments, such as BD Accuri C6, contain a microprocessor-controlled peristaltic-pump system that accurately monitors the sample volume pulled per acquisition run, automatically calculating the cell counts per microliter for any gated population, without the need to index counting beads.

Density Gradients

Since the early 1970s, density gradients for the separation of mononuclear cells have become commonly used in numerous laboratories. These gradients are composed of a neutral, highly branched, high-mass, hydrophilic polysaccharide. The density gradient of Ficoll-Paque (1.077 g/ml) is optimized for the isolation of mononuclear cells from human blood. After the centrifugation step, Ficoll separates layers of blood, with lymphocytes and monocytes under a layer of plasma. Most importantly, this lymphocyte separation by density gradients leads to the separation of lymphocytes from granulocytes, the latter being cells of the innate immune system and which constitute the largest population of circulating white blood cells. However, the effects of granulocyte removal on immunophenotyping have not been thoroughly studied (Fig. 4).

Unfortunately, density-gradient techniques show only $60 \pm 20\%$ recovery of the lymphocytes present in the original blood sample, and the effects on specific subtypes of cells may be variable—thus the researcher should measure the effect of the Ficoll density gradient on each cell subtype of interest (40, 41). In density-gradient separation, adherence of cells to plastic test tubes and centrifugation and washing of the cells may contribute in part to cell loss and the degree of reproducibility of isolation. Selective loss of some T cells, NK cells, and other markers, such as chemokine receptors, occurs (40, 42). Density-gradient separation has also been reported to upregulate certain antigens such as CD54, CD62L, and CD11b (43) and to produce differences in the staining patterns of certain antigens (44–47).

Frozen Samples

In some instances it is impossible to stain and analyze fresh blood, and analysis of these samples is usually postponed by the use of cryopreservation. Cryopreservation is the use of low temperatures to preserve structurally intact living cells. Successful cryopreservation of cells requires that a standardized and reproducible protocol be followed, although each protocol may require optimization for a given cell type or line to achieve maximum viability upon thawing. The use of cryopreserved samples can introduce changes in antigen expression, and this needs to be carefully monitored (48–53).

Reagents

Fluorochromes

A fluorochrome is a chemical compound that absorbs light at one wavelength and re-emits light at higher wavelengths (spectrum). When a fluorochrome absorbs the light, its electrons become excited and move from a "resting state" to a maximal energy level called the "excited state." Subsequently, after energy is released as heat, the electrons fall to

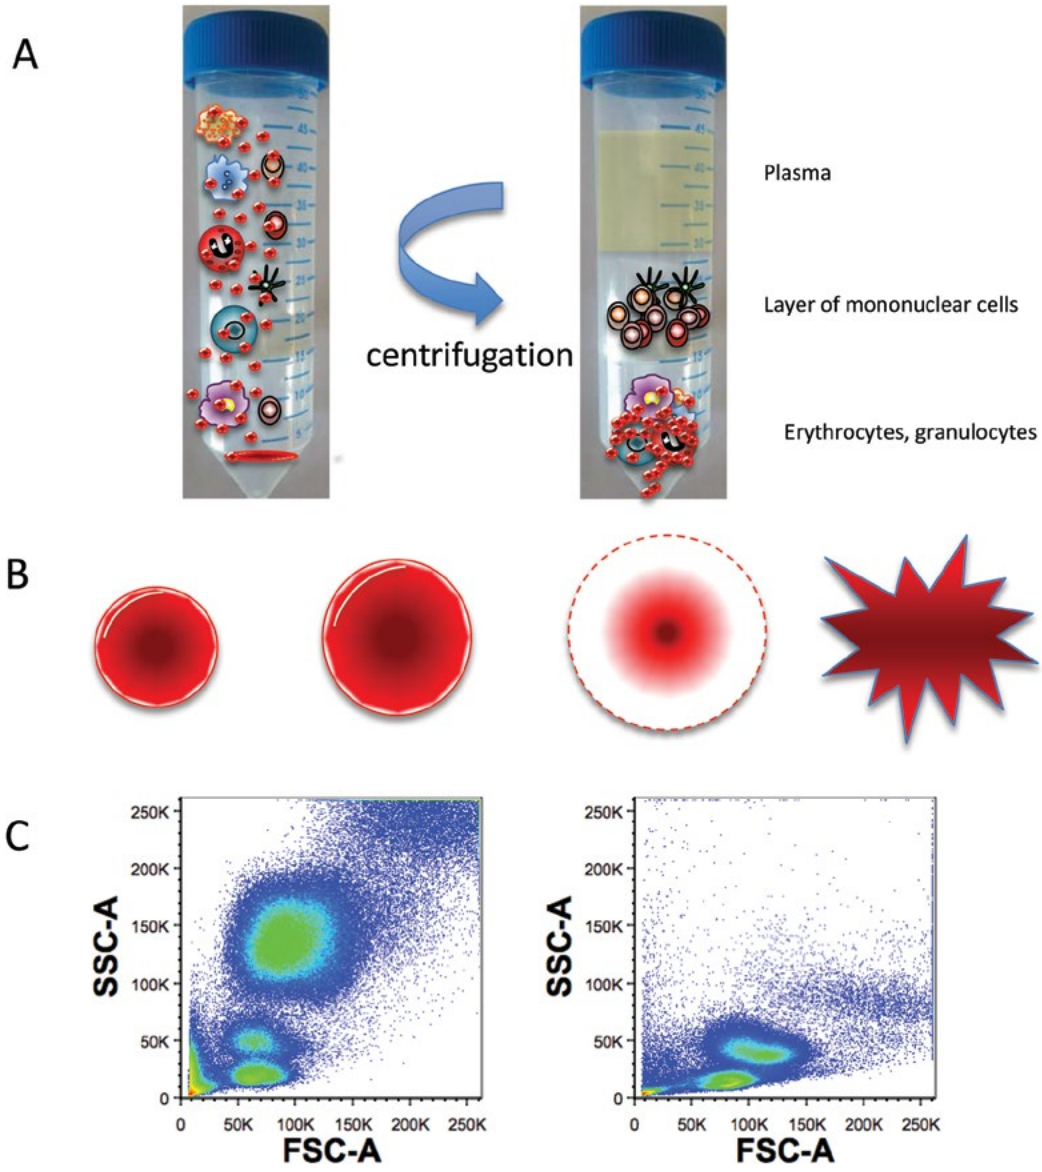

FIGURE 4 Illustration of Ficoll-Hypaque and whole blood as sample to stain. (A) Illustration of Ficoll-Hypaque. In noncoagulated blood after centrifugation in a Ficoll gradient, the plasma is on the top layer, followed by a layer of mononuclear cells, and then by a pellet of granulocytes and red blood cells at the bottom. (B) Illustration of red blood cell lysis. (C) A FSC versus SSC dot plot of the two types of samples: left, ammonium chloride-lysed sample; right, sample after a Ficoll gradient.

a lower, more stable, energy level called the "relaxed state." As electrons move back from the relaxed state to their resting state they release the remaining energy as fluorescence. The difference between the excitation wavelength and emission wavelength is called Stokes shift, and this wavelength value essentially determines how good a fluorochrome is for fluorescence studies. In addition to the Stokes shift, each fluorochrome is characterized by fluorescence quantum yield (ΦF). This is the ratio of photons absorbed to photons emitted through fluorescence, between the relaxed state and resting state.

For flow cytometry, most often fluorochromes are directly conjugated to mAbs specific for a cellular antigen. Direct conjugation of fluorochromes to antibodies permits one to be able to detect multiple antigens on the same cell at one time. A table of the common fluorochromes used in flow cytometry summarizes their excitation and emission range (Fig. 5).

As polychromatic flow cytometry uses several fluorochromes conjugated to several antibodies on one sample, the performance of each antibody-fluorochrome conjugate should be characterized individually and in combination with other conjugates.

The performance of an antibody-fluorochrome conjugate is measured by the mean fluorescence intensity (MFI) and stain index (SI) values (Fig. 6). MFI is the mean of the fluorescence intensity in the chosen fluorescence channel, and SI is the ratio of the difference between the positive signal and negative signal (D) and the width of the negative signal (W) ($SI = D/W$). Both MFI and SI should be obtained

FIGURE 5 Summary tables of the most common fluorochromes used in flow cytometry. The left table shows fluorochromes and cytosolic dyes while the right table shows dyes to stain nucleic acids.

for each antibody-fluorochrome conjugate used in a staining combination.

Once each antibody-fluorochrome conjugate is characterized alone, the background fluorescence should be measured in the other detectors. Indeed, fluorescence background in a particular detector is influenced by several factors: cellular autofluorescence, nonspecific staining, electronic noise, and optical spillover from other fluorochromes. To the extent that these factors each contribute noise and/or signal, they increase the width of a negative population. As such, a good normalized functional measure of reagent brightness is SI (Fig. 6).

Antibodies: CD Designations, Etc.

The term "antigen" originally came from *anti*body *gen*erator and was coined in the early 1900s. An epitope is the molecular feature of an antigen capable of being bound by an antibody (a.k.a. antigenic determinant). An antigen will often have hundreds of epitopes. An antibody will bind specifically to an antigen; however, polyclonal

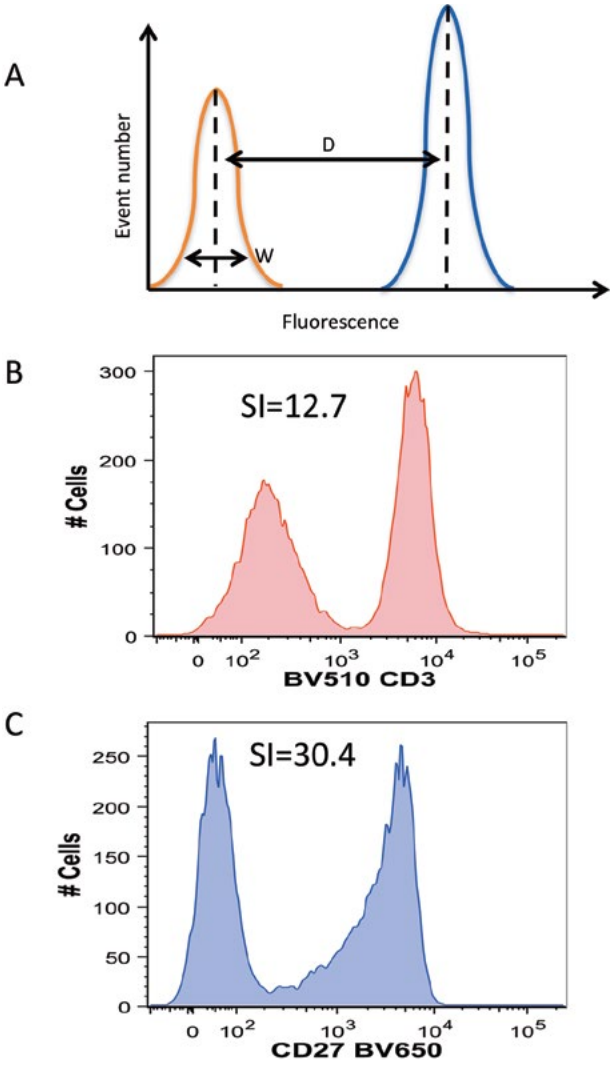

FIGURE 6 Illustration of the stain index. (A) Theoretical stain index (SI) representation. When testing different reagents, the effective brightness is measured using the stain index. SI = D/W, where D is the difference between the median fluorescence intensity of the positive and negative peaks of fluorescence, and W is the spread of the negative peak. (B) SI for CD3 BV510. (C) SI for CD27 BV650.

antibodies will recognize several epitopes of the same antigen while mAbs will recognize only one epitope. The latter are preferred for flow cytometry as they yield greater specificity. Cells can be characterized by their respective cell-surface antigens, and mAbs are made to recognize these cellular antigens. Since one cellular antigen could contain multiple epitopes and therefore be recognized by several different mAbs, a naming convention was needed for these reagents rather than simply calling these mAbs by their clone or trade names.

To address this issue, the 1st International Workshop and Conference on Human Leukocyte Differentiation Antigens (HLDA) was held in Paris in 1982 and organized by Human Cell Differentiation Molecules (HCDM), whose mission is to "characterize the function, structure and distribution of leucocyte surface molecules and other molecules of the immune system."

The cluster of differentiation (CD) nomenclature was proposed for the classification of the mAbs against epitopes on the surface molecules of leukocytes, usually transmembrane proteins. Indeed, the approach of the HLDA workshop was to code antibodies and to send them to multiple participating laboratories for blind analysis against multiple cell types. The data were collated and analyzed by the statistical procedure of "cluster analysis." This analytical method identified clusters of antibodies with very similar patterns of binding to leukocytes at various stages of differentiation, hence the "cluster of differentiation" (CD) nomenclature. The CD nomenclature allowed the scientific community to communicate results in a universal language. HLDA 10 is currently accepting antibodies submission, and the latest symposium was in December 2014 in Australia, with a particular emphasis on dendritic cells. Since its conception, the use of CD has expanded to many other cell types; for humans there are currently 363 CDs (54, 55).

In a recent study (56), based on a majority decision method, there are an estimated 5,539 human genes that code for membrane proteins, which corresponds to 26% of the human coding genes. Approximately 3,700 genes that coded for cell-surface transmembrane proteins (20% of all known genes) were identified (Table 1). Taking into account these numbers, as well as previous estimations on the number of plasma membrane proteins expressed by leukocytes (55, 57), it is very likely that the CD numbers will keep increasing (HCDM webpage, http://www.hcdm.org/) (58).

Many CD antigens are more than simply markers on the cell surface; they have functional roles and play an important role in immune reactions. They can act as receptors or ligands important to the cell, initiating a signal cascade and altering the behavior of the cell. Some CD antigens do not play a role in cell signaling but have other functions, such as cell adhesion. For example, CD4 is the coreceptor associated with the T-cell receptor (TcR) in T-helper cells and is important for T-cell activation; it is also expressed on monocytes and dendritic cells for other functions.

Viability Dyes

Exclusion of nonspecific binding of antibodies to dead cells is an essential component of any flow cytometry experiment. Multicolor flow cytometry often requires the measurement of low-frequency subtypes of cells, sometimes in cryopreserved samples. Dead cells in the sample may nonspecifically bind mAb-conjugates and cause significant artifacts; thus it is highly useful to exclude them during the analysis (29, 59–63). Fortunately, viability stains permit us to identify dead cells present in the sample and thus to be able to gate out the dead cells during analysis. Dead cells can compromise the integrity of the data and lead to misinterpretation of staining.

Several types of viability dyes are currently available, as follows.

Propidium iodide and 7-AAD cannot pass through intact cell membranes, but may freely enter cells with compromised cell membranes. Upon entering dead cells, propidium iodide will intercalate into double-stranded DNA or double-stranded RNA in a stoichiometric manner, while 7-AAD will intercalate only with double-stranded DNA. Because this intercalation is mediated by noncovalent forces, these dyes must remain present in the buffer used to resuspend cells for data acquisition so that dead cells will remain labeled.

Calcein dyes are nonfluorescent and membrane permeable. Upon entering the cells, the dyes are converted to membrane-impermeable, fluorescent compounds by

TABLE 1 List of the most abundant families of antigens and number of members with assigned CDs

Family name	No. of members	Members with CD	% of total

Leucine-rich repeat family	11	5	45

intracellular esterases. Dead cells will not have active esterase activity, nor will they retain the fluorescent dyes. Thus, the calcein dyes allow viable cells to be fluorescently labeled for analysis in standard cell surface-staining protocols.

Fixable viability dyes (Live-Dead-Fixable [Life Technologies, Carlsbad, CA], Zombie [Biolegend, San Diego, CA], Horizon [BD] stains) can be used to irreversibly label dead cells prior to cryopreservation, fixation, and/or permeabilization procedures. Cells labeled with fixable viability dyes can be washed, fixed, permeabilized, and stained for intracellular antigens without any loss of staining intensity of the dead cells. Thus, fixable viability dyes are fully compatible with intracellular staining for molecules of interest such as cytokines (Table 2).

Procedures

Antibody Titration

Antibodies are often used together in mixtures often referred to as antibody cocktails. Each antibody is present in the cocktail at a concentration that is determined by titration. Antibodies have a range of concentrations in which they optimally bind to antigens. If too little is used, there will be an inaccurate amount of light produced by the fluorescence and, depending on the magnitude, a cell positive for the antibody may not be detected. However, if too much antibody is used, the true amount of the target antigen in the sample may be masked and the fluorescence of the negative cells may increase. The "saturating" concentration is the lowest concentration that gives nearly maximal fluorescence. The "separating" concentration represents the concentration that gives the best separation between the positive and negative peak of fluorescence.

During titration, serial dilutions of antibody are used to stain identical aliquots of cells, and the saturating concentration can be determined by the highest fluorescence intensity. The separating concentration can be determined by the difference between the two fluorescence intensities (Fig. 7C). For titration, each staining can be viewed on different axes (Fig. 7A) or on the same axes using concatenation (Fig. 7B).

Once the optimal separating concentration is determined, an appropriate staining buffer should be tested. The incorporation into a staining buffer of a reagent to block the binding of antibody Fc regions to cells is very common in fluorescent-activated cell sorter (FACS) staining buffer. Human Fc receptors (FcR) are expressed on a variety of cells, such as monocytes, granulocytes, B cells, and dendritic cells. Cells expressing these FcR can give false-positive staining due to the FcR-mediated immunoglobulin (Ig)-Fc binding (mainly due to species-specific recognition, as the antibodies for staining are often produced in mice). Blocking the FcR-involved unwanted staining without interfering with antibody-mediated specific staining of the cells is highly recommended; to this end, serum is added to the staining buffer. Serum can be human, mouse, goat, or fetal calf serum, or even bovine serum albumin. These are often used at a concentration of 0.5%. In addition, serum or Fc block can be used to increase the specificity of staining of extremely rare target cells, such as antigen-specific T or B cells, fetal cells in maternal blood, hematopoietic progenitor cells, or disseminated epithelial tumor cells. Note that this is not necessary for staining of whole blood because serum is present in high concentration during staining.

Other considerations in antibody cocktails are the variations due to pipetting errors when the cocktail mix is prepared, and product deterioration over time. The development of flow reagents stable at room temperature, including premixed cocktails, Lyoplates, and DuraClone, directly addresses these concerns.

Premixed Cocktails

Based on titration, directly conjugated antibodies are premixed to allow usage of the same mix for multispectral flow of all experiments or measurements of an entire clinical protocol.

Lyophilization of Cocktails

BD Lyoplate technology is a plate-based lyophilization process that uses a matrix to stabilize antibody cocktails. A proprietary matrix preserves the ability to stain, stimulate, and resolve cellular data by flow cytometry. Automated dispensing and lyophilization of the antibody ensures that consistent and reproducible staining reactions are possible for the duration of an entire immunophenotyping study over many months.

Dehydration of Cocktails

Beckman Coulter Duraclone technology uses drying in a specific solution to preserve the antibody cocktails.

TABLE 2 Summary of types of dyes used in flow cytometry

Laser	Wavelength (nm)	Nonpermeable dyes	Permeable dyes	Cell cycle nonpermeable	Cell cycle permeable	Cell division/proliferation nucleoside incorporation

Intracellular Antigen Detection

A large number of applications require intracellular staining, such as monitoring of cell proliferation, cell signaling, apoptosis, chromosome analysis, and production of cytokines. The permeabilization protocol needs to be optimized for each application, as the size, stability, and intracellular locations of the targets can be highly variable.

Intracellular staining brings with it two major technical problems: (i) compatibility of the permeabilization method with the staining of all markers in a particular tube, and (ii) the loss of cells associated with this procedure. These problems are addressed by empirical testing of fixation/permeabilization reagents for changing intensity of staining of surface markers compared to staining of fresh unfixed cells, while at the same time permitting optimal staining of the intracellular antigen. In terms of cell loss associated with the fixation/permeabilization and stain procedure, we have shown that roughly 40% of the loss is associated with staining procedures (29).

When surface and intracellular staining are to be performed in the same sample, it is advisable that the surface staining be performed first, since fixation/permeabilization treatments might decrease the availability of surface antigens, and to ensure that only the surface antigens (and not the same antigen also expressed intracellularly) are stained.

Antibodies should be prepared in permeabilization buffer to ensure penetration into the cells during the intracellular staining procedure. When gating on cell populations, the light-scatter profiles of the cells on the flow cytometer change considerably after permeabilization.

There are several methods of permeabilization available, but all of them have in common a fixation that will stabilize the proteins, and then disruption of membrane by detergent: formaldehyde followed by detergent, formaldehyde followed by methanol, methanol followed by detergent, acetone fixation, and permeabilization.

The detergents commonly used in cytometry protocol are: Triton X-100, NP-40 (0.1 to 1% in PBS), Tween 20, saponin, digitonin, and Leucoperm, which are mild membrane solubilizers. These will also partially dissolve the nuclear membrane and are therefore very suitable for nuclear antigen staining.

Detection of secreted proteins is difficult, as the protein will be released from the cell before detection or may degrade rapidly. Brefeldin A and other compounds are often used for Golgi-complex blocking (59). Cells are incubated with brefeldin A, which prevents protein being released from the Golgi complex. Any cells expressing the protein can then be detected intracellularly.

Panel Design, One Approach

To immunophenotype both the incredible breadth as well as fine detail of the immune system in a comprehensive approach, we proposed the use of multiple individual tubes together in a panel of highly polychromatic cocktails. A reasoned approach to construction of a comprehensive leukocyte immunophenotyping panel (CLIP) would be to structure a series of individual tubes that provide in-depth characterization of a specific cell type, but at the same time have a sufficient number of recurring markers among the tubes that a concatenation of the numerous phenotypes within a lineage can be assembled. The goal of our panel was to obtain in-depth immunophenotypic profiling of as many circulating human leukocyte populations as possible, in order to build an encyclopedic database. Historically, there have been relatively few leukocyte subsets examined in clinical studies or clinical research studies and for which reference ranges exist (64). One example of such a panel developed to obtain a synoptic snapshot of the cellular phenotypes in the immune system has been reported (29).

In order to select the reagents for a multicolor panel that would yield optimal detection and staining intensities, numerous antibody clones directed against a specific antigen and multiple antibody-fluorochrome combinations need to be tested (24, 29). The levels of the intensity of expression

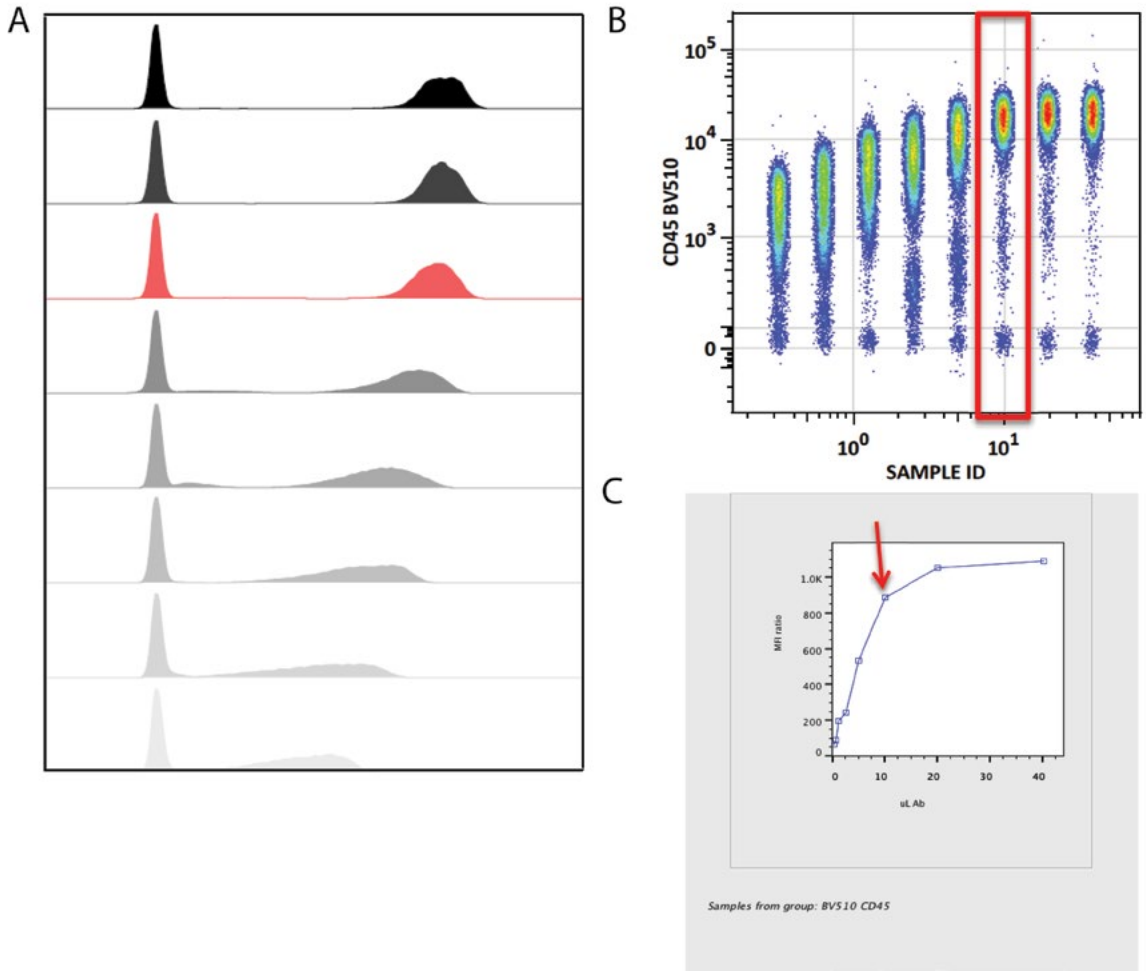

FIGURE 7 Illustration of titration of monoclonal antibody. An FCS file represented independently (A) or concatenated (B). (C) Determination of the separating concentration by graphing the ratio of the positive to negative peaks against the dilution. The histogram represented in red (A), or the dot plot highlighted by the red square (B) or red arrow (C), all mark the selected concentration for the given antibody.

for the selected markers should be established and then the optimal fluorochrome-antibody combinations may be selected based on their performance, i.e., discrimination of positive and negative populations, fluorescence intensity, percentages of positive cells, and ease of compensation. Generally, bright fluorochromes, such as phycoerythrin (PE) and APC, are preferentially chosen for weak antigens (or intracellular) where only low numbers of molecules are expressed per cell, or those that are expressed by only a very small fraction of cells, such as intracellular cytokines. Less bright fluorochromes are assigned to antigens that are expressed by a large proportion of cells and at a high molecular density, such as CD8.

Using the approach described above, we began to build our CLIP panel one 15-color tube at a time. This was done with the full understanding (i) that each tube represented only one small part of a comprehensive panel, (ii) that completely comprehensive analysis would not likely be achieved using the current approach, and (iii) that new markers and technologies would likely evolve to replace the current efforts.

CD45 is a transmembrane tyrosine phosphatase ubiquitously expressed by leukocytes and is important in modulating signals derived from integrin and cytokine receptors. The level of CD45 is expressed differentially throughout maturation, being lower on blasts and immature forms and highest on mature and lymphoid cells (39). Our approach was for each tube to have a specified purpose, but to have CD45 present in all tubes. Furthermore, within each lineage the tubes would have a number of recurring markers, both for quality-control purposes, but also in order for cross-tube concatenation of more detailed phenotypes. If viability, CD45, and CD3 are used for gating in each of the T-cell tubes, each of the T-cell tubes could yield 4,096 T-cell phenotypes (if one assumes all marker combinations could be expressed, and marker expression is defined only as positive or negative). Although not comprehensive for the entire immunome, the existing 14-tube CLIP panel could provide a breadth and depth of immunophenotyping not reported heretofore. To date, our panel consists of 14 15-color tubes (see complete list of the current tubes of the CLIP panel, along with the antibody clones and fluorochromes used, in Fig. 8).

Data Acquisition

During acquisition of the data, several factors can influence the quality of the data, as follows.

CHI CLIP panel

Excitation	Fluorochrome name	PMT name	T lineage				B lineage			NK lineage		Dendritic lineage	Mono lineage		Neutrophil lineage

FIGURE 8 Tubes (staining) of CLIP panel organized by lineage. In black are markers present in all stainings of one lineage, and in blue are markers specific to one staining. *, Lineage mix = CD3+CD19+CD20+CD56+CD16+CD14.

Numbers of Cells To Acquire, Statistics of Event Numbers (67, 68)

The number of events acquired can affect the rigor of the statistics associated with immunophenotyping, and thus the confidence that one has in the accuracy of the distributions.

Consider the general case of enumerating a total of N events with a variance (var) and a standard deviation (SD):

$$\mathrm{CV} = \frac{\{\sqrt{[\mathrm{var}(R)] \times 100}\}}{R}$$

where R is positive cells and the proportion of positives is $P = R/N$.

A preparation of human peripheral blood mononuclear cells is labeled with an antibody to detect T cells. Flow cytometry then indicates that 10% of the cells present are positive for this marker. If three data sets (list-mode files) were collected for 1,000, 5,000, and 10,000 events, we would expect to observe 100, 500, and 1,000 positive cells with variances of 90, 450, and 900, respectively. Expressed as SDs, these would be 9.5, 21.2, and 30, and as CVs, 9.5, 4.2, and 3, respectively.

Good experimental practice within the biological field usually results in CVs on the order of 5%. Hence, the example above indicates that a list-mode file of 5,000 events will provide that level of confidence as expected from the argument relating to dogma: for a subpopulation of 10%, a total of 5,000 events would be adequate. It is obvious that the reliability of the frequency determinations is dependent on the number of events observed, a particularly crucial issue for rare-event detection. Consequently, for a desired level of reliability (CV), the number of rare events to be counted can be calculated from $R = (100/\mathrm{CV})^2$. To match typical experimental variations of 5%, approximately 400 rare events need to be observed, which at the defined limit of rare events (1 in 20), a list-mode file of 8,000 would be required.

In the CLIP panel, since one of the goals is to be able to mine the data at a later date for unknown populations, we wanted to be able to have rigorous statistics for cell populations as low as 0.1%. For this reason, between 1 million and 2 million cells were used for staining within each tube, and in the case of dendritic-cell staining, up to 5 million cells per tube were used if sufficient sample was available. Between 500,000 and 5 million events were collected per FCS file, depending on the number of cells available, in order to have sufficient events for statistical analysis of rare subsets defined by multiple markers.

If the staining requires intracellular marker staining, the number of cells initially placed into each tube must be proportionally higher than the number placed into tubes not requiring intracellular staining in order for equivalent large numbers of cells to be collected on the cytometer (30 to 50% higher).

Live-Gating Techniques

In stainings that use intracellular detection, we needed to use a fixable viability dye that would not leak out of the cells when permeabilized. We decided to use amine-reactive dyes, which differ from other viability markers because they react with free amines in the cytoplasm. Live cells exclude these dyes thanks to the integrity of their cell membrane, unlike dead cells, where the bound dye remains inside the cytoplasm. This reaction is irreversible, and the dye will remain bound to the amine even when the cells are permeabilized for intracellular staining (62). Like all antibodies used in the panel, amine-reactive dyes need to be titrated.

Doublet Exclusion

One important aspect of accurate analysis is the ability to exclude cell doublets. Coincident events (doublets and aggregates) occur when two (or more) cells or particles are in the beam at the same time and are seen by the system as a single, larger particle.

Cell doublet profiles appear differently in a graphical display according to their orientation and the parameters used (height, area, width). In a digital cytometer, a dot plot representation of FSC or SSC versus either height or width will help identify two cells passing through the beam together. Singlet cells will have FSC-A and FSC-H that are proportional to one another and thus appear as a diagonal when graphed against each other in a dot plot. Cells not falling along that diagonal are therefore doublets and should be excluded from further analysis.

QUALITY ASSURANCE AND QUALITY CONTROL

All assays of biological samples, whether clinical or research in nature, need to be performed in a reliable manner that assures one that if differences are observed between specimens, the differences are due to a biological reality and not a technical artifact. For flow cytometric assays, ensuring quality must encompass several levels, such as preanalytical variables including the anticoagulant used (if the specimen is peripheral blood), sample preparation methods and reagents, instrument performance and stability, and assay validation. Thus, protocols and procedures must be implemented at each level to ensure that data from flow cytometry assays are meaningful and reproducible. Many of these elements have been described in previous sections of this text, and therefore only the crucial components of assay validation will be discussed here.

Requirements for validation of an assay include:

- accuracy
- precision (repeatability/reproducibility)
- analytic sensitivity (detection limit)
- analytic specificity (interfering substances)
- sample types and stability
- reportable range
- reference intervals
- calibration and control materials

In addition to these measures, it is the feeling of these authors that in research flow cytometry, validation should also include methods to confirm that cell types identified by a specific combination of antigenic markers have been accurately and correctly classified. Most often, this confirmation would be made by sorting the cell types in question and demonstrating the function or genomic content associated with the presumed cell type.

Returning to the validation requirements listed above, accuracy refers to how close the measured value is to true value. For immunophenotyping studies, this may not be a simple determination, as there are no other methods that can identify and quantify cell types based on high-polychromatic immunophenotyping. A surrogate, but far from perfect, approach to determine accuracy could be quantification of beads by flow cytometry in which known amounts were placed into tubes.

Precision refers to the reproducibility of an assay—how similar repeated measurements of the same sample will be to each other. This is a far easier and arguably more important

aspect of immunophenotyping assays to determine. By repeatedly running one specimen multiple times, one can determine the optimal instrument precision. Intra-assay precision can be determined by staining multiple aliquots of one specimen at the same time and then running these specimens on the cytometer. This accounts for variability that might be introduced by pipetting, washing, centrifugation, and other factors not directly related to the cytometer. Inter-assay precision can be determined by staining aliquots of the same sample (cryopreserved or stabilized cells) at different times and then comparing the data. Compared to intra-assay precision, this looks at other potential confounding factors such as temperature fluctuations, technician variability, instrument fluctuations with time, and so forth. The additional requirements listed above cover additional elements of the assays, ranging from instrument performance to broader population studies. To be rigorously validated, assessments of flow cytometric assays should consider elements of all phases of the testing. For high-polychromatic immunophenotyping, the assurance of instrument stability and standardization, discussed previously, cannot be emphasized enough. Population studies, the study of a large number of different individuals using the same assay, can be used to create reference range values—values for which specified cellular subsets are found throughout a large population. These ranges reflect the heterogeneity in immune composition and responses found in different individuals. Most often, 95% or 99% confidence intervals are determined as the ranges in which one would expect to find the values from any healthy individual within the same population. Reference range values can be dependent upon ethnicity, race, gender, and age, as well as other variables. Furthermore, reference values can be influenced by the clones of antibodies used in the assays, fluorochromes, and other technical variables; thus it is preferable that each laboratory establish its own reference values. Reference values can be expressed as either percentages of leukocyte subsets or as absolute cell counts, or both.

An additional component of quality assurance is proficiency testing, a procedure to determine a laboratory's performance of specific assays in comparison to reference standards or a consensus of results from similar laboratories. Although not available for every panel a laboratory may run, programs are available that encompass a number of different immunophenotyping endeavors. Examples of proficiency testing programs include those run by the College of American Pathology (CAP) and the United Kingdom National External Quality Assessment Service (UK NEQAS), although many more exist for specific nations.

DATA ANALYSIS AND INTERPRETATION

The analysis and interpretation of polychromatic flow cytometry data is arguably the most difficult aspect of performing these assays. Flow cytometry data are most often collected as list-mode data files in the .fcs format, and therefore most software is designed primarily to analyze this file type, although these programs may also have the capability for other less common, and possibly proprietary, file types. Key features of the .fcs file type are the inclusion of keywords that can identify specific aspects of how the data were collected and the listing of all the data collected for every event in an event-by-event manner. Collecting data in this manner permits experiments to be compensated and analyzed repeatedly, if desired. These data are visually displayed as one- or two-dimensional graphs or frequency histograms. Data are compensated, as discussed previously, before being further analyzed. A very useful aspect of .fcs data files is that they can be subjected to gating, a process in which one can isolate a specific population of cells from others (e.g., lymphocytes in whole peripheral blood) in the same sample for further analysis. Gates can be combined using Boolean logic to further specify populations to be studied. Thresholds for determination of positive versus negative fluorescence staining can be established through the use of negative controls, fluorescence-minus-one (FMO) controls, or isotype controls, although the use of this last is controversial, as control isotypes are seldom matched for both concentration and fluorochrome-to-protein ratio. FMO controls consist of a sample in which all markers and fluorochromes are present except for the one for which a threshold of positive staining needs to be determined. These are particularly useful for markers where the positive staining does not result in a discrete population of positive cells, but rather the staining appears as a continuum of events extending from the negative population (as frequently observed in staining for intracellular cytokines or markers of cellular activation).

By segmenting data displays with the use of markers—or, in the case of two-dimensional plots, quadrants—statistical information can be obtained about specific cellular populations, such as what percentage of the parent gate these represent; what percentage of the total these represent; the mean, mode, and peak fluorescence intensity of these cells; and the spread (CV) of the cells. These statistics can elucidate differences found among samples due to reasons such as interindividual variations or effect of some type of treatment or intervention.

Historically, data analysis has been performed manually, perhaps aided by the use of layout templates or "batch" processing, in which multiple data files can be sequentially introduced into a standard analysis layout. For low-dimensional studies this is a feasible, albeit subjective, approach for thoroughly analyzing the cell populations represented by these data. The issue of subjectivity in manual analysis should not be taken lightly. As illustrated by Maecker et al. (27, 28), one of the main sources of variability in interlaboratory comparisons of flow cytometry data arises from manual gating. When analyzing high-polychromatic flow cytometry data, the weaknesses of manual gating become glaring: the sheer numbers of potential populations make these data nearly impossible to thoroughly manually analyze, and the subjective nature makes variability unacceptably high, particularly in rare populations. Therefore, it is most common for these files to be analyzed in a guided (directed) manner, in which only predetermined immunophenotypes are studied and the gating strategies to study these populations are determined at the time of designing the panel. This tremendously simplifies data analysis, but may leave some novel findings undiscovered. To address the issues associated with manual gating, considerable effort has been directed at devising algorithms capable of semi- or fully automated analysis of flow cytometry data. Historically, this has been a difficult task, as populations of cells characterized by dim, heterogeneous, and/or nondiscrete staining presented significant obstacles for accurate identification. This effort has been facilitated in many cases by the use of open-source software from Bioconductor and consortium efforts such as FlowCAP (69–73). These resources alleviate the need to "reinvent the wheel" for every effort at automation by providing basic tools useful in many of these approaches and by providing sample data for "challenges" to understand how well any given approach is working.

SUMMARY

Recently, manufacturers have begun to develop cytometers that diverge from traditional paradigms in various manners. One example is the Imagestream flow cytometer developed by Amnis-EMD Millipore. This cytometer is capable of capturing multicolor images of every cell that passes through the instrument, while at the same time collecting multicolor immunophenotyping data. This is achieved by replacing photomultiplier tubes for the collection of fluorescence data with CCD cameras and through the use of prisms to separate different wavelengths of fluorescent light and time-delay integration to achieve bright, sharp image resolution.

Another novel approach to fluorescence-based flow cytometry is multispectral flow cytometry as exemplified by the SP6800 Spectral Analyzer recently developed by Sony Biotechnology. This instrument has standard laser excitation and focusing using sheath fluid, and for a flow cell (point of cell-laser interrogation) uses a microfluidic chip. More importantly, it uses an array of 32 detectors to capture the entire spectrum of emitted fluorescent light (currently from 500 to 800 nm) (65, 74). The result of this is to improve the understanding of spectral overlap among the emitted fluorescence signals and to better establish spectral compensation values, particularly between fluorochromes with similar, but distinct, emission spectra. By doing this, it is theoretically possible to run and analyze more fluorochromes (and hence cellular markers) within the same bandwidth compared to cytometers constructed with a more traditional approach.

Finally, it is worth noting that flow cytometers are beginning to be developed that are not based on the detection of fluorescence. The leading example of this is the CyTOF developed by DVS, Inc. (66). This instrument replaced fluorescence with a mass spectroscopy-based time-of-flight measurement of heavy-metal isotope labels. Elimination of fluorescence removes the need for fluorescence compensation, thus facilitating easier high-dimensional immunophenotyping, as well as for the collection of data on more parameters. Although this approach has technical drawbacks in terms of yield and throughput, it is a milestone in moving away from the reliance on fluorescence-based assays and the accompanying technical limitations.

High-Sensitivity Detection of Red and White Blood Cells in Paroxysmal Nocturnal Hemoglobinuria by Multiparameter Flow Cytometry

ANDREA ILLINGWORTH, MICHAEL KEENEY, AND
D. ROBERT SUTHERLAND

18

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare, life-threatening acquired hematopoietic stem cell disorder resulting from the somatic mutation of the X-linked phosphatidylinositol-glycan complementation class A (PIG-A) gene (1–4). In normal individuals, this gene encodes an enzyme involved in the first stage of glycophosphatidylinositol (GPI) biosynthesis. In PNH, as a result of the mutation(s) in the PIG-A gene, there is a partial or absolute inability to make GPI-anchored proteins, including complement-defense structures such as CD55 and CD59 on red blood cells (RBCs) and white blood cells (WBCs) (5–8). Absence of CD59 in particular (9, 10) and CD55 on RBCs is largely responsible for intravascular hemolysis associated with clinical PNH (reviewed in reference 11).

CLINICAL FEATURES OF PNH

Clinical features of PNH include intravascular hemolysis (that leads to hemoglobinuria), bone marrow failure, and thrombosis, with the latter being a major cause of morbidity and mortality (12, 13). Prior to the advent of the complement C5 inhibitor eculizumab, 35% of PNH patients died within 5 years of diagnosis even with the best available treatment (12).

There is a well-documented relationship between aplastic anemia (AA) and PNH (12, 13), and with modern, high-sensitivity assays, up to 70% of AA patients have shown PNH clones (14–16). Some reports suggest that PNH+ AA patients respond to immunosuppressive therapy (IST) (17, 18), while other studies show that 10 to 25% of AA patients will exhibit a PNH clonal expansion and progress to clinical PNH (19).

Small populations of GPI-deficient PNH clones have been reported in patients with early-stage myelodysplastic syndrome (MDS), particularly the refractory cytopenias with unilineage dysplasia (RCUD) variant (13, 17). Preliminary analysis of data from a large study of patients with AA, MDS, and other bone marrow failure syndromes (EXPLORE) showed a significant number of MDS patients to have GPI-deficient cells. However, statistical reanalysis of those data generated solely with high-sensitivity methodologies from the same study found much lower incidences of true PNH clones in MDS (20).

WHO SHOULD BE TESTED FOR PNH?

PNH is a very rare disease with a prevalence of about 16 cases per million and only about 1.3 new cases diagnosed per million per year (Hill A, Platts PJ, Smith A, Richards, SJ, Cullen MJ, Hill, QA, Roman E, Hillmen P, unpublished observations). Nevertheless, the life-threatening and progressive nature of PNH warrants testing of appropriate patient populations at risk of PNH with early diagnosis essential for improved patient management and prognosis in PNH (21, 22). Such groups include:

1. Unexplained cytopenias (with evidence of increased levels of lactate dehydrogenase (LDH), low haptoglobin, or elevated reticulocyte count)
2. All AA patients and refractory-anemia MDS (with evidence of elevated LDH or low haptoglobin).
3. Unexplained thrombosis (despite anti-coagulation, in patients <50 years of age, in unusual sites, e.g., cerebral, hepatic portal, dermal vein), with evidence of elevated LDH, low haptoglobin or elevated reticulocyte count, or with other clinical manifestations of PNH (abdominal pain, chest pain, dyspnea, dysphagia, severe fatigue).
4. All patients with unexplained Coombs-negative hemolytic anemia, hemoglobinuria, and/or hematuria.

EARLY METHODS TO TEST FOR PNH

Because PNH was initially recognized as a type of hemolytic anemia, the earliest assays focused on RBCs. These included the Ham test (23) and the sugar-hemolysis test (24), both of which demonstrated the increased sensitivity of PNH RBC to complement-mediated hemolysis. The more specific complement lysis-sensitivity test showed that PNH cells lysed at lower concentrations than did normal cells (25). This test also led to the recognition (26) that some PNH patients have a population of cells with intermediate complement sensitivity (type II), which show an intermediate life span between normal RBCs (type I, 120 days) and the most sensitive PNH-type RBCs (type III, 10–15 days). These tests were laborious, difficult to standardize, and neither specific nor sensitive.

EVOLUTION OF FLOW CYTOMETRIC METHODS TO DETECT PNH

Since the early 1990s, flow cytometric detection of cells lacking expression of GPI-anchored surface molecules has become established as the method of choice for diagnosing

doi:10.1128/9781555818722.ch18

and monitoring PNH. Because of the historical role of RBCs in the diagnosis of PNH, early flow cytometric methods to detect PNH relied on detecting the loss of CD55 and CD59, two GPI-linked structures expressed on normal RBCs and WBCs (27, 28). Most laboratories used FDA-approved kits (Cellquant and Redquant, BioCytex, Marseille, France) or developed in-house assays that used CD55 and CD59. Typically, RBCs were identified and gated by forward vs side scatter in logarithmic mode (FS log vs SS log) and assessed using single-parameter histograms for CD55 and/or CD59 expression. Flow cytometric analysis of RBCs in nontransfused patients was used to enumerate the type III (complete GPI-antigen deficiency) and type II (partial GPI-antigen deficiency) PNH clones. Type I (normal GPI-antigen expression) represented remaining normal RBCs.

Flow cytometric analysis of WBCs used light scatter in linear mode (FS Lin versus SS Lin) to gate neutrophils in lysed whole-blood samples with similar assessment of CD55 and/or CD59 expression using single-parameter histograms.

ISSUES WITH EARLY FLOW METHODS

Although the ability to rapidly detect GPI-deficient cells by flow cytometry (27–29) has led to improved diagnosis, patient management, and prognosis in PNH and related disorders, simple CD55/CD59-based approaches were neither accurate nor sensitive below the 1 to 4% clone size, rendering them inadequate to detect small PNH clones present in most PNH+ AA and MDS cases (30). Furthermore, with respect to RBCs, simple "routine" assays that do not employ CD235a (anti-glycophorin a) to gate RBCs are susceptible to the effects of inaccurate pipetting and poor sample mixing (30) as well as identifying CD55/CD59-negative events that are not RBCs. Such errors can result in false-negative staining with CD55/CD59 antibodies and potentially lead to misdiagnosis.

Inaccurate results ("false positives" and "false negatives") can also be generated by suboptimal instrument setup, selection of poor antibody clones/conjugates that exhibit suboptimal signal-to-noise ratio, selection of poor conjugates of otherwise good clones, inadequate selection of lineage-specific gating antibodies/conjugates, and poor gating strategies. Finally, inexperience in interpretation of results, together with the use of nonstandardized, potentially misleading reporting forms, can all lead to misdiagnosis and dangerous clinical consequences.

With respect to the detection of GPI-deficient WBCs, an increasingly wide range of monoclonal antibodies have become available to detect GPI-anchored proteins (31), potentially obviating some of the shortcomings of simple CD55/CD59-based assays. Additionally, a variety of more sensitive approaches have more recently been developed for PNH WBC detection based on the fluorescent derivative of bacterial pro-aerolysin (FLAER) (30, 32–36). FLAER-based assays, whether alone or cocktailed with other antibodies, are still not universally deployed, however, and recent data from external quality assurance programs have highlighted the variable capabilities of laboratories to accurately detect WBC PNH clones in stabilized whole-blood samples (37).

Over the last few years, a humanized monoclonal antibody against the terminal complement protein C5 (38) (Eculizumab; Alexion, Cheshire, CT) has been approved for the treatment of patients with hemolytic PNH. This drug significantly reduces hemolysis, transfusion requirements, and thrombosis. It has improved the quality of life of PNH patients (39, 40) and has had a major impact on life expectancy of those with PNH (41–43). Therefore, accurate detection and monitoring of PNH clones have become increasingly important priorities for clinical flow laboratories performing PNH screening.

ROUTINE VERSUS HIGH-SENSITIVITY FLOW CYTOMETRY

To address these issues, the International Clinical Cytometry Society (ICCS) published guidelines for the diagnosis and monitoring of PNH and related disorders by flow cytometry (22). A variety of approaches for "routine" and "high-sensitivity" analyses (required in cases of MDS or AA) were outlined therein for both RBC and WBC lineages. However, standardized-operating protocols (SOPs) utilizing specific assay cocktails were not identified and defined analytic strategies were not detailed.

The development and validation of sensitive, standardized methodologies are essential to reliably detect GPI-deficient PNH phenotypes, especially for PNH clone sizes of less than 1%. Preliminary data from one large study of over 10,000 patients has shown that 40% of samples positive for the presence of PNH cells contain GPI-deficient cells at a level of 1% or less (Illingworth A, unpublished observations). Given that standardized, robust, high-sensitivity assays have now been developed (see below), we believe the dichotomy between routine and high-sensitivity assays (22) to be a false one and, from the technical perspective, irrelevant. The same high-sensitivity assays that are required to accurately detect very minor populations of GPI-deficient cells can also be used to detect PNH in patients with large clones; the only difference is in how the assays are deployed with respect to the numbers of cells acquired for accurate and precise determinations of GP-deficient cell numbers.

HIGH-SENSITIVITY ASSAYS FOR PNH RBCs AND WBCs

General Requirements

For high-sensitivity RBC analysis in particular, where a CD235a and CD59 combination is required, it has been problematic to identify conjugates that in combination do not cause major aggregation of red cells while still maintaining a good signal-to-noise ratio and the ability to adequately separate type II and type III PNH RBCs from normal (type I) cells (30). It is also the authors' experience that there is much variability between different antibody clones/conjugates among reagents used in the analysis of PNH in WBC lineages.

To successfully develop highly sensitive assays that are also robust and reliable, careful selection and titration of antibody clones/conjugates for lineage-specific gating (RBCs, neutrophils, and monocytes) and specific GPI-antigen detection within each cell lineage is required. The detection of rare PNH phenotypes in RBCs, neutrophils, and monocytes also requires proper assay-specific instrument setup (light-scatter voltages, photo-multiplier tube [PMT] voltages, and optimal fluorescence compensation) and rigorously maintained instrument fluidics and clean cell-washing reagents. Once established, the frequencies of PNH phenotypes in all three lineages in multiple normal samples must be determined. Additionally, the sensitivities of the assays have to be validated by titrating ("spiking") a PNH sample into a normal sample. The essential elements of high-sensitivity RBC, neutrophil, and monocyte assays were recently published in the *Practical Guidelines* (44 and supplementary data).

High-Sensitivity RBC Assay

In the development of a robust high-sensitivity RBC assay, a variety of CD235a and CD59 clones/conjugates were tested from several vendors in order to optimize and standardize a two-color flow assay for the detection of PNH RBCs (44 and supplementary data).

Antibody Clone/Conjugate Selection for High-Sensitivity PNH RBC Detection

RBC-Gating Antibodies

CD235a (glycophorin A) is currently the only gating reagent available that specifically identifies mature RBCs. Preliminary screening of CD235aFITC and CD235aPE conjugates of clone KC16 (Beckman Coulter) showed the phycoerythrin (PE) version to cause far more aggregation of RBCs (even after extensive titration) than its fluorescein isothiocyanate (FITC)-labeled counterpart (30). We subsequently screened a number of other CD235a antibody conjugates for this assay. Recommended conjugates are listed in Table 1.

GPI-Specific Antibodies

While loss of the GPI-linked CD55 and CD59 structures was traditionally used to detect PNH RBCs (27, 28), CD55 is inferior to CD59 (22) due to its dim expression and inability to delineate type II and type III PNH RBCs. For the *Practical Guidelines* (44) we thus focused on identifying CD59PE conjugates that offered the best separation of type I, type II, and type III RBCs. Several conjugates have been evaluated, and those recommended are listed in Table 1.

As CD235a antibodies in particular are known to cause significant RBC aggregation, all CD235a and CD59 antibody conjugates were individually titrated against RBCs from normal individuals to minimize this effect, while still providing adequate separation of type I, II, and III cells. It is important to note that all CD235a conjugates and the CD59PE conjugates of MEM43 and OV9A2 required considerable dilution below saturating levels to obviate this problem. Once optimally titrated, individual CD235a and CD59 conjugates were admixed in two-color combinations. Combinations of CD235aFITC (clone KC16 or 10F7MN)/CD59PE (clone MEM43 or OV9A2) proved to be the best combination for delineating normal type I RBCs as well as type II and type III PNH populations in all samples tested.

Instrument Setup Considerations: RBCs

For light scatter and PMT voltage setup, a normal blood sample was diluted 1:100 with clean phosphate-buffered saline (PBS). Forward-angle (FS) and side-angle (SS) light-scatter voltages were established in log:log format such that the cluster of unstained normal RBCs could be identified towards the middle of the bivariate histogram (see Fig. 1A, plot 1). When voltages are set in this manner, the presence of red-cell aggregates and other debris can be readily addressed. The discriminator/threshold should be set to exclude as much debris as possible while not excluding any of the RBC-target population.

For setting the FL-1 and FL-2 PMT voltages, all compensation is set to zero and the PMT voltages are established without the use of "baseline offset" for instruments so equipped. Gated RBCs from region R1 of plot 1 were displayed on an FL-1 versus FL-2 plot and the PMT voltages were adjusted so that the cells were comfortably on-scale (see Fig. 1A, plot 2). Two-color compensation adjustments were performed with samples individually stained with CD235aFITC (Fig. 1A upper-right plot) and CD59PE (Fig. 1A, lower-right plot). Instrument setup was verified by analyzing a fresh normal sample stained, as outlined below, with the optimized CD235aFITC/CD59PE antibody cocktail (Fig. 1B, plots 1–3).

TABLE 1 Recommended antibody conjugates for high-sensitivity detection of PNH RBCs

Target cells	Antibodies and conjugates	Purpose	Clone and (vendor)
RBC	CD235-FITC	Gating RBCs	KC16 (BC) 10F7MN (eBio) JC159 (DAKO)
	CD59-PE	GPI-linked for RBC	OV9A2 (eBio) MEM-43 (Invitrogen)

RBC Staining Protocol using CD235aFITC/CD59PE Cocktail

Anti-coagulated (EDTA is preferred, but heparin can also be used) peripheral-blood samples should be less than 48 hours old.

1. Prepare a 1:100 dilution of the sample with clean PBS.
2. Prepare antibody cocktail: Add 15 μl (1.5 μl/test) of CD235aFITC (clone KC16 Beckman Coulter) and 5 μl (0.5 μl/test) of CD59PE (clone MEM43 Invitrogen) to 180 μl PBS*
   Comment: Based on individual titrations of single lots of CD235aFITC and CD59PE, a cocktail of these reagents should be prepared. Examples are shown in Fig. 1.
3. Pipette 100 μl of diluted blood sample into a test tube using reverse-pipetting to avoid aerosol generation.
4. Pipette 20 μl of this diluted cocktail and add directly into the blood in the test tube with gentle mixing by up-and-down pipetting.
5. After careful removal of the pipette tip to avoid touching the sides of the tube, mix the sample by gently swirling the sample using a slow-speed vortex, again taking care not to generate aerosols.
6. Incubate the sample in the dark for 20 min at room temperature (incubation up to 60 min has been validated).
7. Wash twice with PBS by centrifugation, as is required to optimize separation of type I, II, and III RBCs.
8. Resuspend in 0.5 to 1.0 ml of PBS.
9. "Rack" the sample (drag across a hard plastic or metal test tube rack several times) to disrupt any RBC aggregates generated by the staining/washing procedure immediately before acquisition on the cytometer.
10. Acquire sample immediately, as delays longer than 15 min after the final washing step can show decreased CD235a staining and increased levels of reaggregation.
11. Acquire a minimum of 100,000 RBCs (gated on FS log vs SS log) in list mode for clinical test samples.
12. If two or more events were displayed in the type III PNH RBC region, data acquisition should be continued until 1 million events are acquired.

An example of the assay performed on a known PNH case is shown in Fig. 1C. With appropriate sample processing, the level of observed aggregates could be kept to 1.5% or less.

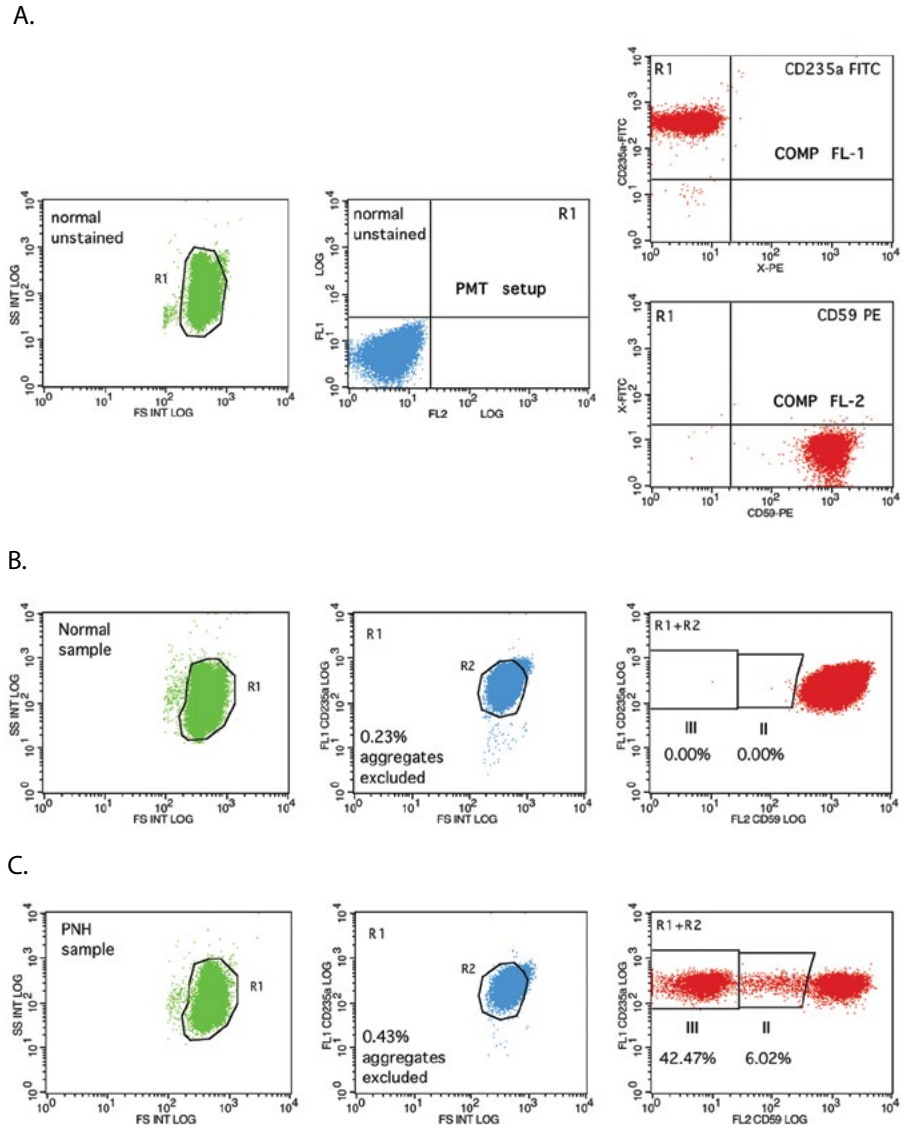

FIGURE 1 (A) Instrument setup for high-sensitivity RBC assay. Light-scatter voltages were established in logarithmic mode such that RBCs from a diluted normal PB sample clustered in the middle of the plot (left). Gated RBCs from region R1 were displayed on FL-1 versus FL-2 plot and PMT voltages were adjusted to get the unstained RBCs properly on-scale (middle). Samples were single stained with either CD235aFITC (top right) or CD59PE (bottom right) and compensation was adjusted to reduce spectral overlap. (B) Analysis of normal RBCs. Normal RBCs stained and acquired using the instrument settings established in panel A. RBCs gated in R1 (left) and displayed on CD235aFITC versus FS plot (middle). CD235a+ RBCs were gated in R2 and aggregated RBCs (see arrow; 0.23% of total) were excluded as shown. Cells from R1 and R2 were displayed on CD235aFITC versus CD59PE (right). A second sample stained only with CD235aFITC was analyzed to approximate the location of the type III gate (gate III). (C) Analysis of fresh PNH sample. A PNH sample was stained as described with the optimized RBC protocol as outlined in the Methods, and analyzed as described for the normal sample (panel B). Aggregated RBCs (0.43%) were excluded by gate R2. The sample contained 42.47% PNH type III cells and 6.02% PNH type II cells.

High-Sensitivity Four-Color WBC Assays

Antibody Clone/Conjugate Selection for Four-Color High-Sensitivity PNH WBC Detection

Gating Reagents for Neutrophils and Monocytes

In developing highly sensitive assays for neutrophils and monocytes, the ICCS Guidelines (22) stressed the need to use an antibody for gating each lineage as well as two GPI-specific markers for each lineage. While CD33 can be used to gate on both neutrophils and monocytes (30, 34), this reagent is not as effective as CD15 for delineating neutrophils or as effective as CD64 for delineating monocytes (44, 45), with MDS samples being particularly problematic (unpublished observations). Additionally, we have found occasional samples that failed to stain with CD33 conjugates regardless of which CD33 clone is used. Consequently,

TABLE 2 Recommended reagent conjugates for high-sensitivity detection of PNH WBCs: Beckman Coulter instruments

Target cells	Antibodies and conjugates	Purpose	Clone and (vendor)
WBC	FLAER-Alexa488	GPI-linked (all lineages)	NA (Cedarlane)
	CD24-PE	GPI-linked (neutrophils)	SN3 (eBio) ALB9 (BC)
	CD14-PE CD14APC-A700 (6-color)	GPI-linked (monocytes)	61D3 (eBio) RMO52 (BC)
	CD157-PE	GPI-linked (neutrophils and monocytes)	SY11B5 (eBio)
	CD15-PC5	Gating neutrophils	80H5 (BC)
	CD64-PC5 (4-color) CD64-ECD (5-color) CD64PC7 (6-color)	Gating monocytes	22 (BC)
	CD45-PC7 CD45-KO (6-color)	Debris exclusion and pattern recognition	J33 (BC)

conjugates of CD15 (for neutrophils) and CD64 (for monocytes) were selected for this purpose. Because of the variety of laser combinations available on legacy and newer-generation instruments, selection of specific clones/conjugates for gating neutrophils and monocytes must be done on an instrument-specific basis. Recommended gating reagents for neutrophils and monocytes for various instrument types are shown in Tables 2 and 3 for Beckman Coulter (BC) and Becton Dickinson (BD) instruments, respectively.

GPI-Specific Reagents for Neutrophils and Monocytes

Although CD55 and CD59 have been widely deployed to detect PNH since the development of the earliest flow-based assays (27, 28), recent studies using stabilized whole blood have shown that these reagents are not optimal for the detection of PNH neutrophils and monocytes (37). The ICCS Guidelines identified CD24, CD16, and CD66b along with FLAER as the most reliable reagents for PNH neutrophil detection. However, CD16 is polymorphic and is not expressed on eosinophils or immature neutrophils, rendering it less useful for the analysis of some MDS cases. With respect to CD66b, most conjugates of this reagent are incompatible with FLAER-based assays, and even PE-conjugated CD66b was found to be inferior to CD24 for delineating PNH neutrophils from their normal counterparts (46). Thus, we selected CD24 and FLAER as GPI-specific reagents for neutrophil assessment and CD14 and FLAER as GPI-specific reagents for monocyte assessment (44). For analysis on the FACSCalibur instrument (BD), CD15APC (clone HI98) and CD45PerCP (clone 2D1) (BD) were used together with FLAER and CD24PE.

In subsequent studies (47) performed to optimize four-color cocktails for both neutrophils and monocytes that could be used on BC and BD platforms, a large number of other clones/conjugates were extensively evaluated. The reagents found to be optimal for the four-color neutrophil and monocyte assays on BC and BD instruments are shown in Tables 2 and 3, respectively.

Instrument Setup Considerations: WBCs (Fig. 2 and 3)

For light-scatter voltage setup for WBC, 100 μl of a lysed and washed normal-blood sample was used. FS and SS light-scatter voltages were established in linear mode and the voltages were adjusted such that all major leukocyte subsets, including lymphocytes, were clearly visible above the FS threshold (see Fig. 2, plot 1, and Fig. 3, plot 1, for neutrophil and monocyte assays, respectively).

TABLE 3 Recommended reagent conjugates for high-sensitivity detection of PNH WBCs: Becton Dickinson instruments

Target cells	Antibodies and conjugates	Purpose	Clone and (vendor)
WBC	FLAER-Alexa488	GPI-linked (all lineages)	NA (Cedarlane)
	CD24-PE	GPI-linked (neutrophils)	SN3 (eBio) ML5 (BD)
	CD14-PE	GPI-linked (monocytes)	61D3 (eBio) MOP9 (BD)
	CD157-PE	GPI-linked (neutrophils and monocytes)	SY11B5 (eBio)
	CD15-APC (4-color)	Gating neutrophils	HI98 (BD)
	CD15-eFluor450 (5-color) or CD15-v450 or CD15-PerCP-eFluor710[a]	Gating neutrophils	MMA (eBio) MMA (BD) MMA (eBio)
	CD64APC	Gating monocytes	10.1 (BD) 10.1 (eBio)
	CD45-PerCP CD45-APC-H7[a]	Debris exclusion and pattern recognition	2D1 (BD)

[a]For two-laser Canto, use FLAER, CD157-PE, CD45APC-H7, CD64APC, CD15-PerCP-eFluor710.

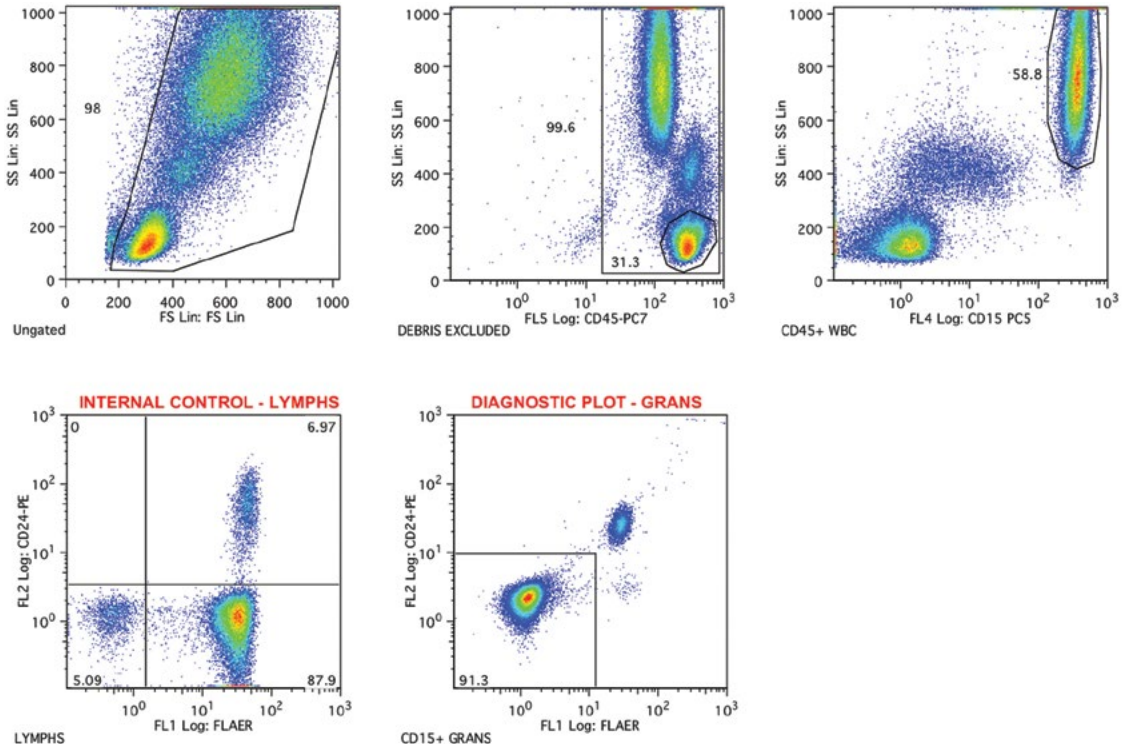

FIGURE 2 Example of high-sensitivity neutrophil assay. A sample from a long-term PNH patient was stained with FLAER, CD24PE, CD15PECy5, and CD45PECy7. Light-scatter voltages were established so that all nucleated cells were visible above the forward-scatter threshold (top left) and debris was excluded with a combination of light scatter and CD45 gating (top middle). CD45+ events were displayed on CD15 versus SS plot (top right) and neutrophils (bright CD15, high SS) were gated. Neutrophils displayed on a FLAER versus CD24 plot (bottom row, right) and PNH neutrophils (FLAER-negative, CD24-negative) were enumerated in the lower left quadrant. Normal neutrophils were enumerated in the upper right quadrant. Lymphocytes were gated by a combination of CD45/SS staining (top middle plot) and lack of CD15 expression (not shown) and assessed for PNH phenotypes in the lower-left quadrant. Normal T lymphocytes (FLAER+, CD24-negative) are visible in the lower right quadrant and normal B lymphocytes (FLAER+, CD24+) are visible on the upper right quadrant.

For BC instruments, setting the PMT voltages was performed with all compensation set to zero and the voltages were established with the baseline offset off. Because of the different emission spectra of Alexa488 and FITC, compensation was established using a FLAERAlexa488-stained sample in the FL-1 channel. Thus, the FL-1 PMT voltage was established using a PNH sample that contained some PNH lymphocytes. The sample was single-stained with FLAER-Alexa488, and the FL-1-PMT voltage was adjusted so that PNH lymphocytes were comfortably on scale. A second sample was stained with CD3PE, and the FL-2-PMT voltage was adjusted to ensure that non-T lymphocytes were also comfortably on scale. This procedure was repeated using CD3PECy5. The FL-5-PMT voltage was set using a sample stained with the pretitrated volume of CD45PECy7, and the PMT was set so that lymphocytes were positioned at the end of the 3rd decade of fluorescence of the 4-decade log scale of the FC500 cytometer. These voltages were used for the compensation process. Compensation adjustments on the FC500 were made using blood samples individually stained with either FLAER Alexa488 (FL-1), CD45PE (FL-2), CD45PECy5 (FL-4), or CD45PECy7 (FL-5). In the case of the CD45 conjugates, all individual reagents were pretitrated to so that lymphocytes were positioned at the end of the 3rd decade of fluorescence. Instrument settings were verified by analyzing a PNH sample and a normal sample stained with a FLAER, CD24PE, CD-15PECy5, and CD45PECy7 cocktail.

The methodology outlined above can also be used on a BC Navios instrument.

For BD FACSCalibur instrument set up, PMT settings were established for the FL-1 and FL-2 channel as described above for the FC500 platform. The FL-3 PMT was set with a sample stained with pretitrated volume of CD45PerCP and the voltage was adjusted to position the lymphocytes at the end of the 3rd decade of fluorescence. The FL-4 PMT was set as per FL-1 and FL-2 PMTs using a pretitrated volume of CD3APC. Compensation was performed with Calibrite beads and FACSComp software and verified with a PNH and a normal sample stained with a FLAER, CD24PE, CD-45PerCP, and CD15APC cocktail.

WBC Staining Procedure for Optimized Neutrophil and Monocyte Cocktails

All individual antibodies were verified for appropriate reactivity with target cells and titrated to optimize specific staining performance prior to being cocktailed for use in the high-sensitivity FLAER-based neutrophil and monocyte assays. The ICCS Guidelines recommended staining samples within the first 48 hours from sample draw (22) when white-cell viability is high.

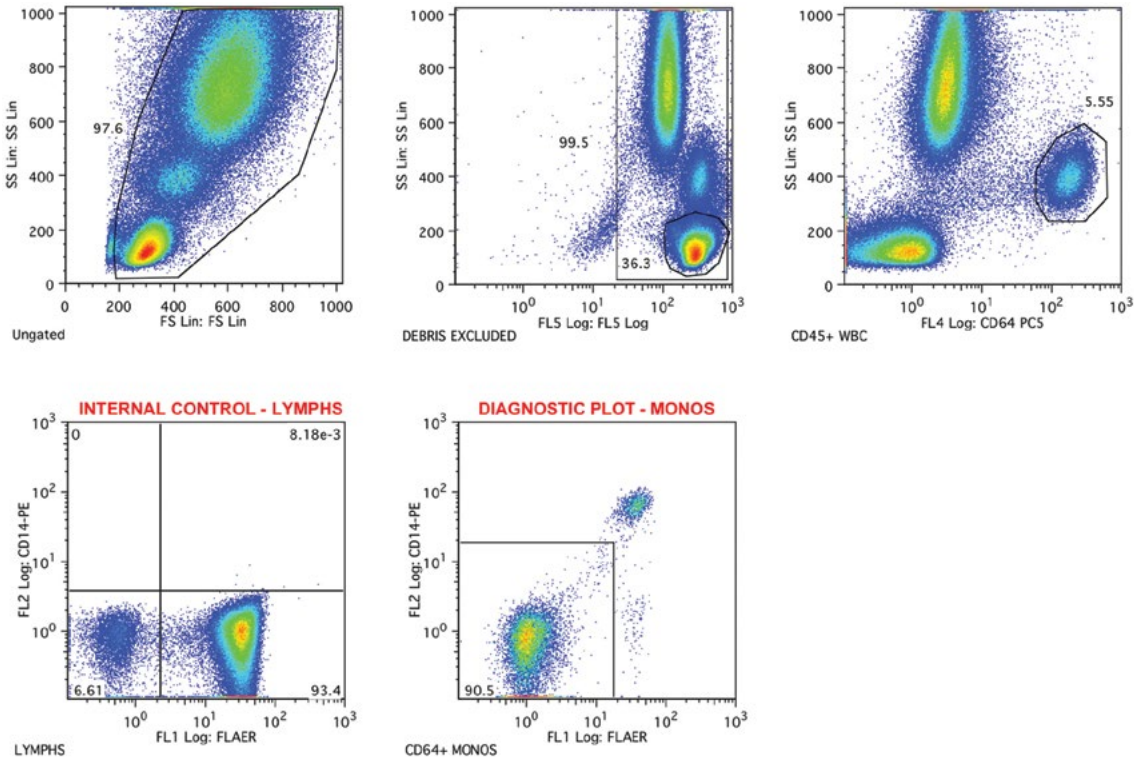

FIGURE 3 Example of high-sensitivity monocyte assay. A sample from a long-term PNH patient was stained with FLAER, CD14PE, CD64PECy5, and CD45PECy7 and analyzed in a manner similar to that shown for the neutrophil assay in Fig. 2. CD45+ events were displayed on CD64 versus SS plot (top right) and monocytes (bright CD64, intermediate SS) were gated. Monocytes were displayed on a FLAER versus CD14 plot (bottom row, right) and the PNH monocytes (FLAER-negative, CD14-negative) were enumerated in the lower left quadrant. Lymphocytes were gated by a combination of CD45/SS staining (top-middle plot) and lack of CD64 expression (not shown) and assessed for PNH phenotypes in the lower left quadrant. Normal lymphocytes (FLAER+, CD14-negative) are visible in the lower right quadrant.

1. Using reverse-pipetting, pipette 100 μl of fresh peripheral blood carefully into the bottom of a test tube without touching the side of the tube.
2. Add an appropriate volume of "neutrophil" (FLAER-Alexa488, CD24PE, CD15PECy5, and CD45PECy7) or "monocyte" (FLAERAlexa488, CD14PE, CD-64PECy5, and CD45PECy7) cocktail directly to the blood aliquot in the bottom of the tube and mix gently but thoroughly as described above for the RBC assay.
3. Incubate for 20 min in the dark.
4. Lyse the RBCs using an appropriate lysing agent. ImmunoPrep, Versalyse (BC), FACSLyse (BD), or ammonium chloride-based lysing agents are all acceptable; those containing fixatives may help retain cellular integrity better than those that do not.
5. After lysing, wash cells once with PBS.
6. Resuspend in 1 ml of PBS and acquire on the cytometer.
   Note: Samples should be acquired immediately, as delays can cause light-scatter changes, especially when fixative-free lysing agents are used.
7. Acquire a minimum of 50,000 neutrophils and 5,000 monocytes in list mode (neutrophil and monocyte assays, respectively) for clinical test samples.
8. If small numbers of GPI-deficient cells are observed, acquisition times should be increased until a statistically reliable number of "PNH phenotypes" are acquired (generally 50 to 100 PNH cells).

PRESENCE OF TYPE II POPULATIONS IN NEUTROPHILS AND MONOCYTES

The presence of RBCs with intermediate expression of CD59 (type II RBCs) has been reported extensively in the literature, describing RBCs with a partial protection from complement-mediated lysis, which have an intermediate life span between normal type I RBCs and type III PNH RBCs (complete absence of CD59). The presence of type II phenotypes in WBCs (neutrophils and monocytes) can also be seen in a subset of PNH patients since the advent of more modern, FLAER-based assays (Illingworth A, unpublished observations). The clinical significance of these type II populations in WBCs is uncertain at this time but, as for RBCs, it is important to include both type II and type III WBCs in a combined estimate of the total PNH-clone size. More recently, a greater range of GPI-specific reagents have been tested and optimized for use in combination with FLAER. CD14 (monocyte assay) and CD157 (neutrophils and monocyte assays) in particular can show a very pronounced separation between type II and type III WBCs when type II cells are present. The range of fluorescence intensities observed in samples containing type II cells can, in some cases, render very difficult the delineation of type II

PNH cells from normal type I cells. Two examples of samples containing both PNH type II and type III neutrophils and monocytes are shown in Fig. 4A and 4B.

High-Sensitivity Five-Color WBC Assays

Antibody Clone/Conjugate Selection for Five-Color High-Sensitivity PNH-WBC Detection

Other than CD24 and CD14 on neutrophils and monocytes, respectively, the expression of a variety of other GPI-linked structures on various blood cell lineages has been documented in peripheral blood (31, 47) and bone marrow (48). CD157 is another GPI-linked structure expressed on both neutrophils and monocytes that has been identified as a potentially useful reagent for the detection of GPI-deficient cells (31, 47, 48). However, until recently, CD157 was only available in FITC-conjugated form, ruling out its use in FLAER-Alexa488-based assays. The recent availability of a PE-conjugated version of CD157 (clone SY11B5, eBioscience) allowed direct comparison with CD24PE and with CD14PE in the 4-C neutrophil and 4-C monocyte protocols, respectively. It was subsequently shown that CD157PE was superior to CD24PE in the neutrophil assay and also compared favorably with CD14PE in the four-color monocyte assay. This study also showed that the four-color CD157 assays performed in an equivalent manner with similar sensitivities on PNH samples containing a wide range of clone sizes and exhibited similar low background rates on normal samples (46). Interestingly, the CD157-based assays tend to separate the type II neutrophils and type II monocytes from the type III neutrophils and type III monocytes more effectively compared to the CD24/CD14-based assays (see below).

Instrument Setup Considerations for Five-Color WBC Assay

The excellent performance of the CD157PE conjugate in both four-color neutrophil and monocyte assays raised the possibility that a single five-color combination of FLAER, CD157, CD64, CD15, and CD45 could be used to simultaneously evaluate GPI-deficient neutrophils and monocytes with a single tube for those with access to cytometers with five or more PMTs (46).

Beckman Coulter instruments

Light scatter and PMT voltages for the five-color assay on both FC500 and Navios cytometers were performed as above for the four-color assays except that the FL-3 PMT voltage was established using unstained B lymphocytes in a CD3ECD-stained sample. For compensation settings for the five-color assay, a sample stained with CD45ECD at pretitrated volumes was used. For FC500 and Navios platforms, the compensation matrix was verified with a PNH sample and a normal sample stained with a five-color cocktail comprising FLAER, CD157PE, CD64ECD, CD15PECy5, and CD45PECy7.

Becton Dickinson instruments

For FACSCanto II instruments with eight PMTs, light-scatter voltages were established using unstained cells. The PMT voltages for FLAER CD157PE, CD45PerCP, and CD64APC were established as described above. The PMT voltage for CD15eFluor450 (clone MMA, eBioscience) (or conjugate MMAv450, BD) was established using unstained lymphocytes in a CD15-stained normal blood sample. Compensation was performed with antibody-capture beads (UltraComp eBeads, eBioscience, or CompBeads, BD), except for FLAER, in which FLAER-stained lymphocytes were used. The compensation matrix was verified using a PNH sample and a normal sample stained with FLAER, CD157PE, CD45PerCp, CD64APC, and CD15eFluor 450 (Table 3). For FACSCanto instruments equipped with six PMTs and two lasers, a slightly modified reagent-conjugate cocktail is required (see Table 3) that utilizes FLAER, CD157PE, CD15PerCP-eFluor710 (clone MMA, eBioscience), CD64APC, and CD45APC-H7.

Staining Procedure for Five-Color High-Sensitivity Combined Neutrophil/Monocyte Assay

For analysis on BC instruments,samples were stained as above with a five-color cocktail comprising pretitrated volumes of FLAER, CD157PE, CD64ECD, CD15PECy5, and CD45PECy7. For analysis on a BD Canto II, a cocktail comprising FLAER, CD157PE, CD45PerCP, CD64APC, and CD15eFuor450 was used. All other sample-processing steps were performed as described above for the four-color neutrophil and monocyte assays. An example of a PNH sample stained with the five-color assay and analyzed on a BC Navios cytometer is shown in Fig. 5. Assays to validate the sensitivity (lower limits of detectability) and background rates of PNH phenotypes in 10 normal samples for the five-color assays were performed as described above for the four-color assays and were found to be essentially identical to the predicate four-color neutrophil and monocyte assays.

High-Sensitivity Six-Color WBC Assays

Antibody Clone/Conjugate Selection for Six-Color High-Sensitivity PNH WBC Detection

For laboratories equipped with cytometers with six or more PMTs, it is possible to design six-color assays for single-tube, simultaneous, high-sensitivity analysis of PNH neutrophils and PNH monocytes. Such reagent cocktails are composed of FLAER along with carefully selected and validated conjugates of CD15, CD64, CD24, CD14, and CD45. Instrument setup and compensation matrices are established along the lines outlined above for the five-color assays. An example of a six-color assay on a Navios cytometer is shown in Fig. 6 of a fresh PNH sample stained with FLAER, CD24PE, CD15PC5, CD64PC7, CD14APC-A700, and CD45KO. Assays to validate the sensitivity (lower limits of detectability) and background rates of PNH phenotypes in 10 normal samples for this six-color assay were performed as described above for the four-color assays and were found to be essentially identical to the predicate four-color neutrophil and monocytes assays (46).

QUALITY CONTROL AND ASSURANCE

Before deployment of high-sensitivity assays to detect GPI-deficient PNH cells in the clinical laboratory, it is important not only to optimize instrument and reagent performance, but to establish the sensitivity of the assay and establish the background level of PNH phenotypes in multiple normal samples (49, 50). In addition, ongoing quality control needs to be in place to ensure that established analytic specifications are controlled during patient testing.

Strategies for Ongoing Antibody-Conjugate Verification

For laboratories that perform testing for PNH only occasionally, it is recommended that staining cocktails for all deployed assays be checked on a normal sample at least once per month to ensure all antibody conjugates are staining in the expected manner (44, 49). It is also important to

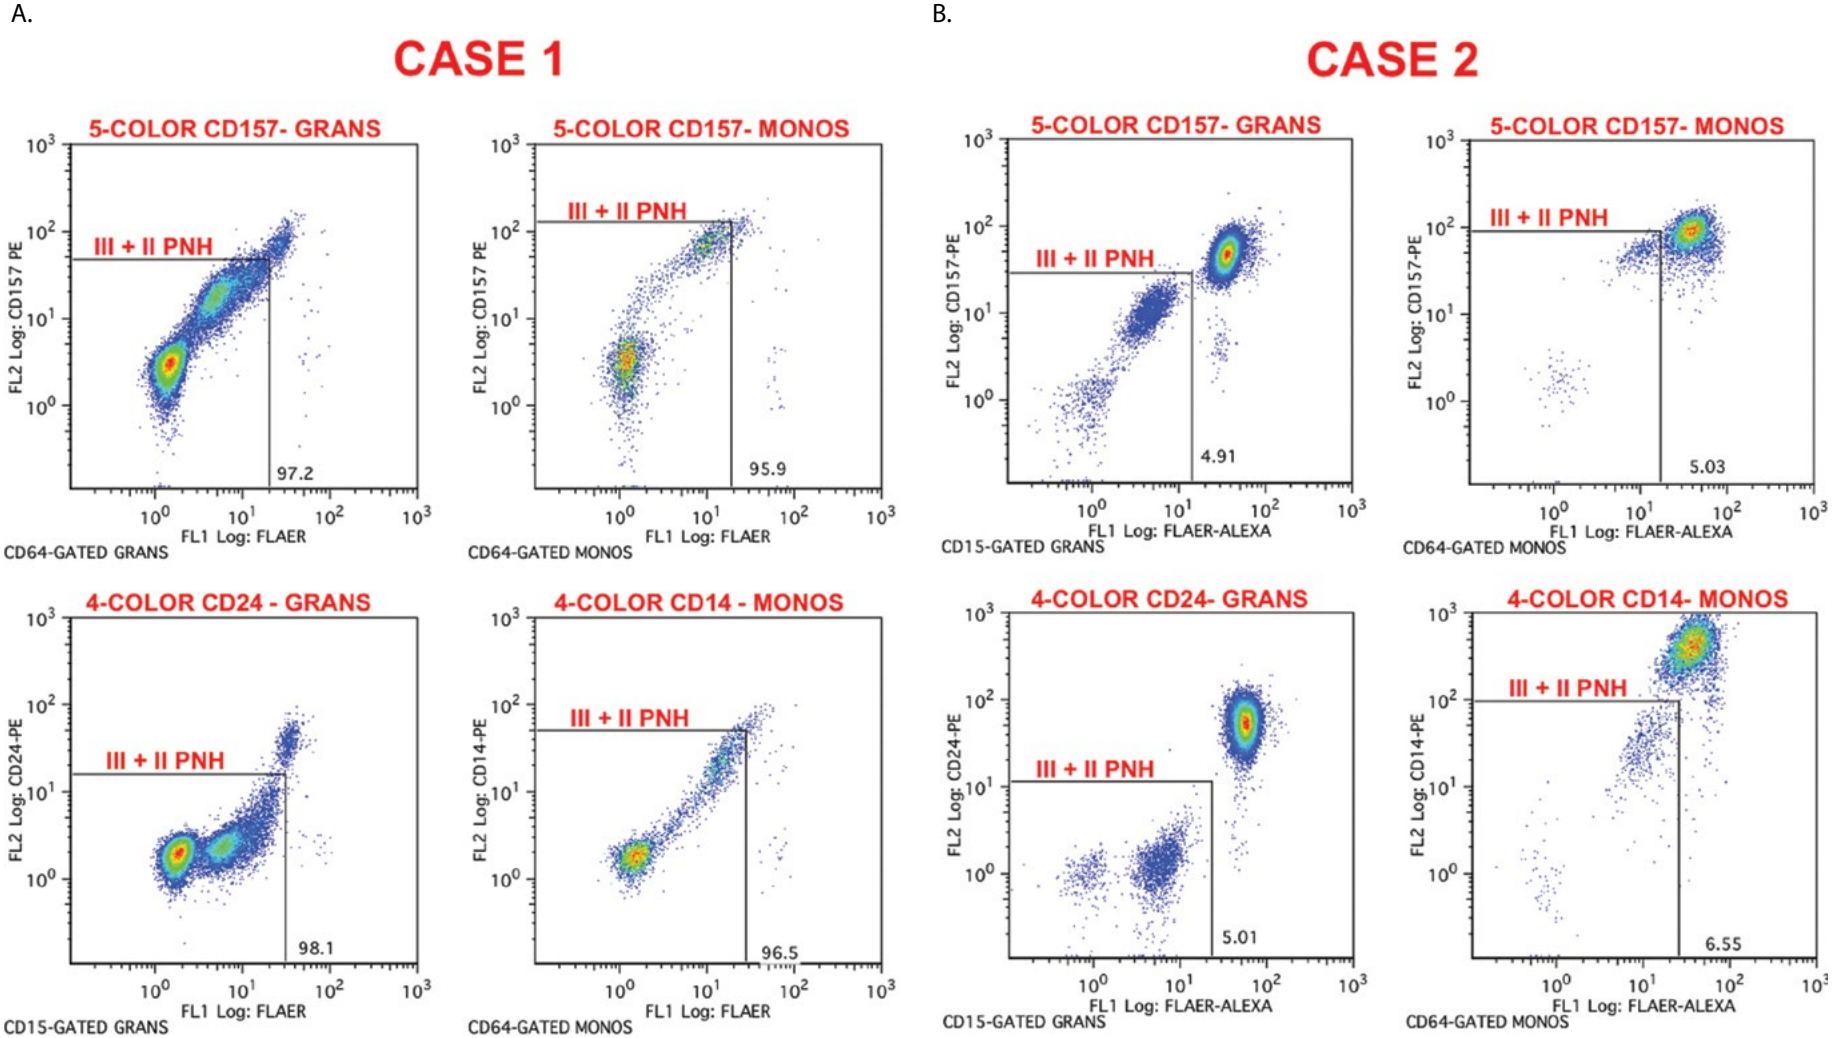

FIGURE 4 (A) Example of normal sample stained with high-sensitivity neutrophil assay. Normal sample stained and analyzed exactly as described in Fig. 2. Gated neutrophils displayed on FLAER versus CD24 plot (right) and zero PNH neutrophils were detected in the lower left quadrant. (B) Example of normal sample stained with the high-sensitivity monocyte assay. Normal sample stained and analyzed exactly as described in Fig. 3. Gated monocytes displayed on FLAER versus CD14 plot (right) and only 1 PNH monocyte phenotype was detected in the lower left quadrant.

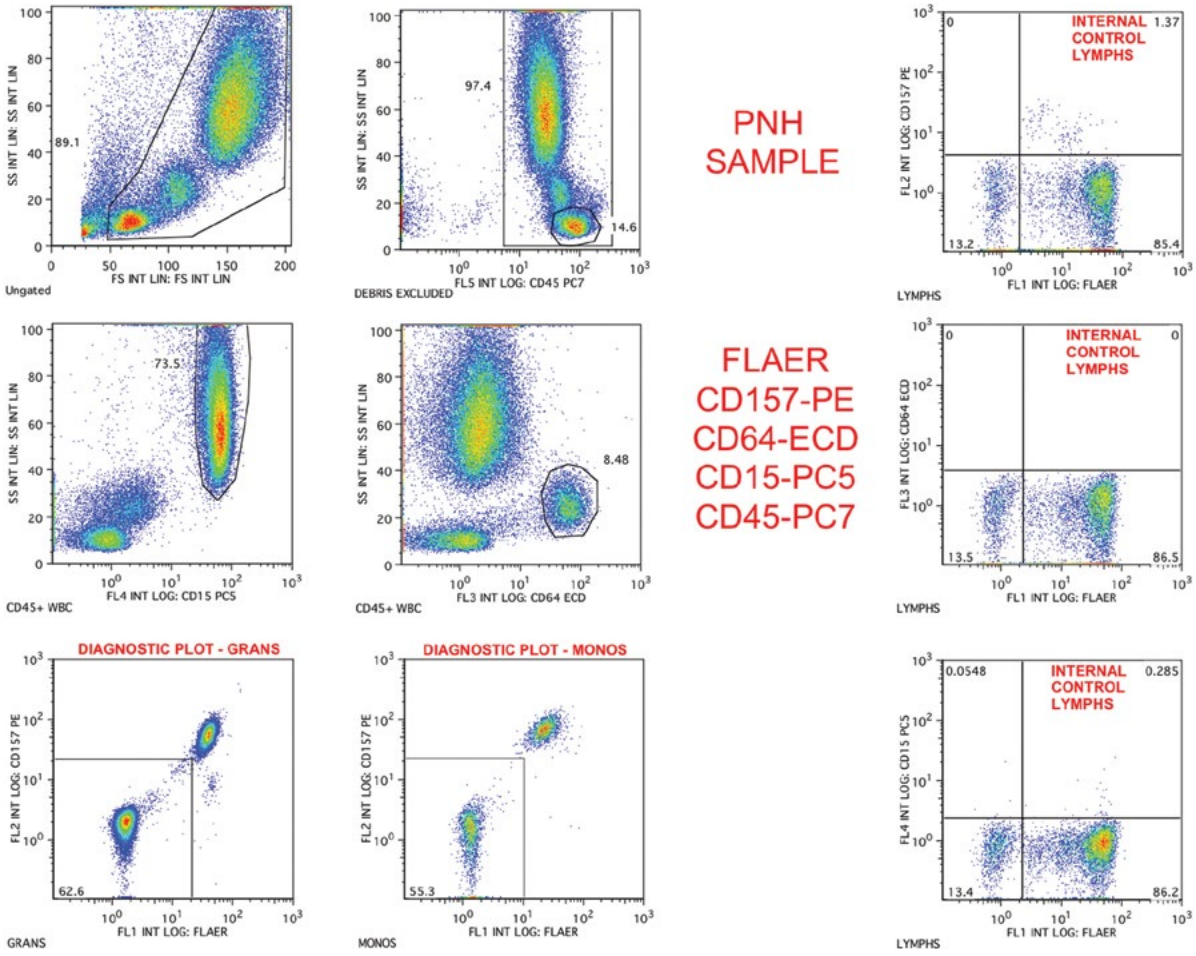

FIGURE 5 Five-color, single-tube, CD157-based assay for PNH neutrophil and monocytes. A fresh sample from a long-term PNH patient was stained with FLAER, CD157PE, CD64ECD, CD15PECy5, and CD45PECy7 and data were acquired on FC500. Debris was removed with light scatter (top row, left) and CD45 gating (top row, middle). Neutrophils (middle row, left) and monocytes (middle row, middle) were identified and gated based on CD15 and CD64 expression, respectively. Gated neutrophils (bottom row, left) and monocytes (bottom row, middle) were displayed on FLAER versus CD157 plots and PNH neutrophils and monocytes (FLAER-negative, CD157-negative) were identified. Gated lymphocytes (internal controls) were identified and sequentially gated based on CD45 and SS (top row middle) and lack of CD64 staining (not shown) and displayed on FLAER versus CD157 (top row, right) or FLAER versus CD64 (middle row, right) and FLAER versus CD15 (bottom row, right).

compare old lots of staining reagents with new lots, including cocktails (as recommended) to assure the performance of new reagent lots. Normal-blood samples are also adequate for this purpose.

For laboratories performing regular testing for PNH, it is not necessary to monitor assay performance in the aforementioned manner, as most samples that arrive for testing are normal with respect to PNH. Thus, normal RBCs serve as "internal controls" for instrument/reagent performance in the RBC assay. Similarly, performance of reagents used in four-color and five-color WBC assays can be closely monitored using internal controls. Lymphocytes provide excellent internal negative-control populations for all the critical reagents used in the four- and five-color WBC assays. For example, gating reagents CD15 and CD64 stain neutrophils and monocytes, respectively, while neither reagent should stain lymphocytes in the four-color assays. CD24 stains B lymphocytes (internal positive control) but not T cells (internal negative control) and CD14 stains normal monocytes (internal positive control) but not lymphocytes (internal negative control). Lymphocytes also serve as internal positive control for FLAER. Even for samples that contain effectively 100% PNH neutrophils and monocytes, lymphocytes can be observed to show that reagent performance is appropriate. While PNH lymphocytes can be found in patients who have had disease for some time, normal lymphocytes can always be detected that stain with FLAER, thus providing an internal positive staining control for this reagent. For the five-color WBC assay, CD157 stains both neutrophils and monocytes but does not stain lymphocytes.

Fluorescence-Minus Two Controls

Whichever WBC assays are employed, they should also be verified on a *bona fide* PNH sample when the opportunity arises. Sharing of such samples among laboratories is strongly recommended for this rare disease where feasible. If a PNH sample is unavailable, instrument settings can be checked by staining a "fluorescence-minus-two" (FM2)

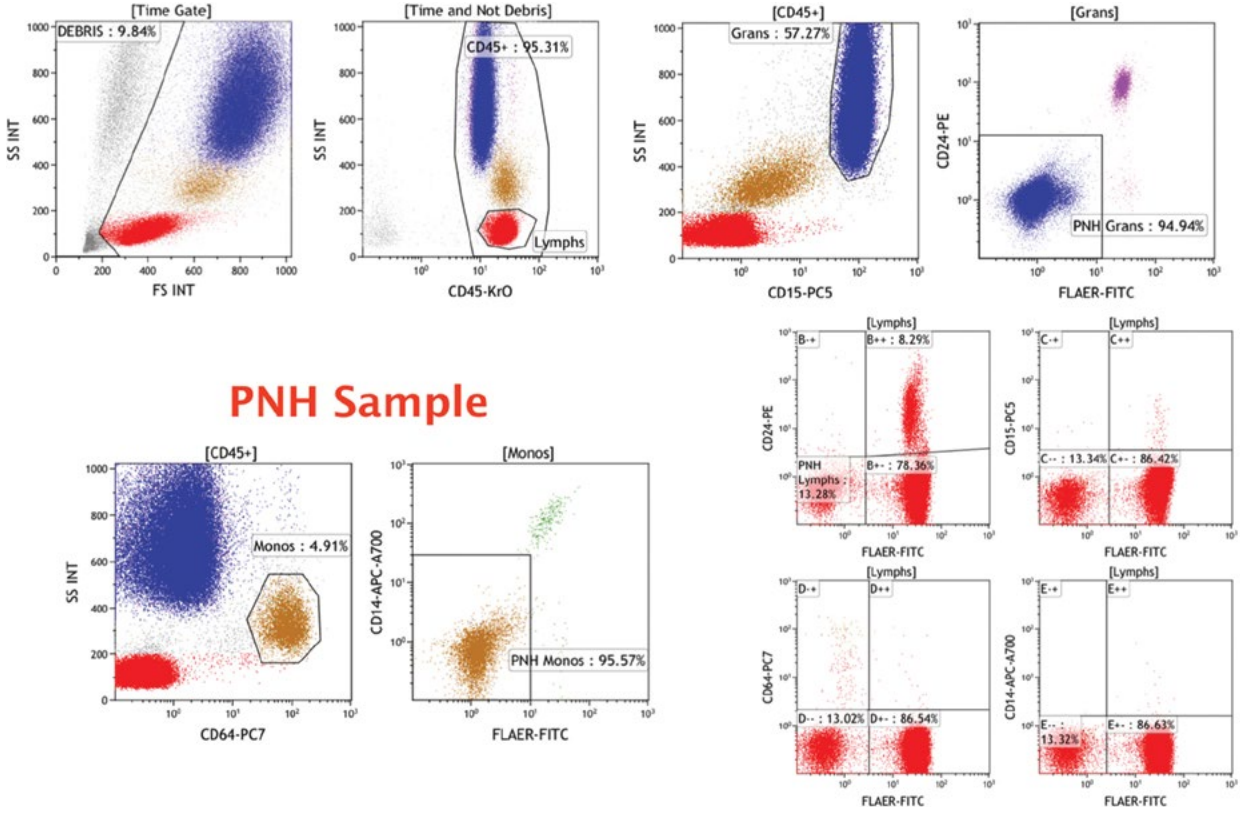

FIGURE 6 Six-color single-tube assay for PNH neutrophil and monocytes. Fresh PNH sample stained with FLAER, CD24PE, CD15PECy5, CD64PC7, CD14APC-A700, and CD45KO. Data acquired on Navios cytometer equipped with three lasers and 10 PMTs. Neutrophils were gated by sequential analysis of light scatter, CD45 gating, and CD15 expression (top row). Gated neutrophils were displayed on FLAER versus CD24PE plot (top right) to delineate PNH neutrophils (lower left quadrant) from normal neutrophils (upper right quadrant). Monocytes were sequentially gated by light scatter, CD45, and bright CD64 expression (bottom row, left). CD64-gated monocytes were displayed on adjacent FLAER versus CD14APC-A700 plot and PNH monocytes (lower left quadrant) were delineated from normal monocytes (upper right quadrant). Lymphocytes were gated by a combination of light scatter and CD45/SS staining and displayed on four bivariate dot plots (right lower and right bottom rows) displaying FLAER versus CD24, CD14, CD15, and CD64 to confirm optimal instrument setup/compensation and validate the performance of all antibody conjugate used in the assay.

sample in which only the gating antibodies CD45 and CD15 (neutrophil assay) or CD45 and CD64 (monocyte assay), or CD45, CD15, and CD64 (five-color assay), are used to stain a normal sample (in reference 44, see Fig. 9 and 10, respectively, of supplementary data). In FM2 stainings, all gated neutrophils, gated monocytes, and gated lymphocytes express a PNH phenotype since the GPI-specific reagents were not added. If these populations are not clearly visible and on-scale, PMT voltages and compensation matrices should be adjusted.

Ongoing Control of Assay Quality

Once the assay performance is established, the monitoring of internal cellular controls during patient-sample testing, as outlined above, is critically important. These internal-control cells verify not only antibody/reagent performance but can also indicate possible issues within the patient sample which may not be apparent in normal controls. Finally, rigorous monitoring of such internal cellular controls allows the cytometrist to monitor instrument performance, including PMT and compensation settings.

ASSAY VALIDATION

Using the standardized four-color neutrophil and monocyte assays described above on stabilized PNH whole-blood preparations, results have demonstrated very good interlaboratory performance characteristics among expert laboratories (51). Using fresh samples and the same standardized four-color assays, another recent study demonstrated good intra- and interlaboratory performance characteristics for both precision and reproducibility analyses and excellent correlation and agreement between centers for all target PNH clone sizes, even in laboratories with little prior experience performing PNH testing (52).

CONSIDERATIONS FOR VALIDATION OF HIGH-SENSITIVITY PNH ASSAYS

Verification of Instrument Set-Up and Antibody Performance

For instruments initially set up in the manner described above for RBCs ("High-Sensitivity RBC Assay"), the analysis of a normal sample will appear as shown in Fig. 1C.

For instruments initially set up as described above for four-color WBC assays ("High-Sensitivity Four-Color WBC Assays"), the analysis of a normal sample with the neutrophil and monocyte assays will appear as shown in Fig. 7A and 7B, respectively.

For those using the single-tube, five-color, CD157-based assay described above ("High-Sensitivity Five-Color WBC Assays"), the analysis of a normal sample will appear as shown in Fig. 6.

Determining Assay Sensitivity

Since very small numbers of PNH phenotypes can be detected in some cases of AA and MDS, it is important to know the sensitivity of the assays deployed in the clinical laboratory. Assay sensitivity is determined by two factors: the absolute lower limit of detectability of *bona fide* PNH cells, and the assay "background" on normal samples.

Lower Limit of Detectability of PNH RBCs

When the opportunity arises to test a *bona fide* PNH sample, it is recommended that a serial dilution or "spiking" experiment be performed in which the (1:100 prediluted) PNH blood is titrated into a similarly prediluted ABO blood type-matched normal-blood sample. Typically, a titration range of 1:10 through 1:10,000 is used (44). The spiked samples are stained in the normal manner, washed twice, racked, and acquired. Up to 1 million RBCs may need to be acquired on the more dilute samples to obtain the most statistically reliable results. Spiking experiments performed as above have established that as few as 20 type III PNH RBCs can be detected in a list mode file of 1 million RBCs with our assay (44).

Lower Limit of Detectability of PNH WBCs

A spiking experiment is used to establish the lower limit of detectability of PNH neutrophils and PNH monocytes in the same manner as that used for the high-sensitivity RBC assay, except undiluted blood samples are used. Spiked samples are stained in the normal manner with the four-, five-, or six-color reagent sets and washed twice, and the data are acquired on the cytometer. Data acquisition times of up to 15 min may be needed to obtain sufficient PNH phenotypes at the higher dilutions. Spiking experiments performed with the four-color neutrophil, four-color monocyte (44), and five-color combined assays (46), as well as the six-color combined assays, showed that the neutrophil assays could reliably detect as few as 10 PNH phenotypes per 100,000 neutrophils while the monocyte assays were slightly less sensitive due to the lower frequencies of monocytes in PB samples.

Verification of RBC and WBC Assay Backgrounds

Blood samples from normal individuals have been shown previously to contain very small numbers of neutrophils with PNH phenotypes (53). To establish background frequencies of PNH RBC, PNH neutrophil, and PNH monocyte phenotypes in normal-blood samples with our assays, 20 normal samples were screened with each assay in keeping with recently established International Guidelines (50, 54). For the RBC protocol, a range of two to six events falling in the type III RBC region per million RBCs was found (44) (see example shown in Fig. 1B). These data, together with the spiking experiments described above, establish the RBC assay sensitivity at better than 0.01%.

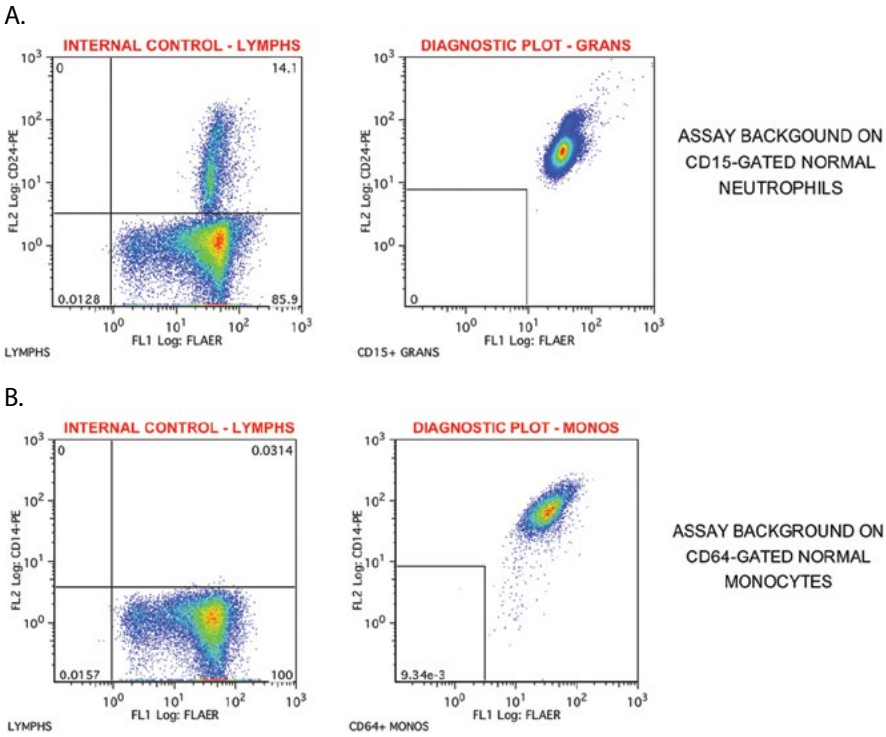

FIGURE 7 Examples of two samples containing type II neutrophils and monocytes. **(A)** Samples stained with five-color CD157-based assay (top row) or four-color neutrophil (bottom left plot) or four-color monocyte (bottom right plot) assays. CD157 separates PNH type II neutrophils from type III cells more effectively than CD24. When major populations of type II cells are present, as shown in case 1, this can lead to difficulty in delineating type I cells from PNH type II cells. This issue is also apparent in comparing CD157 (top right) and CD14 staining (bottom right) of monocytes.

For the four-, five-, and six-color neutrophil assays, frequencies of PNH phenotypes in normal samples were in the 0 to 6 per million range. Similar data were obtained from the four-, five-, and six-color monocyte assays. Thus the neutrophil and monocyte assays described here have sensitivities in the 0.01% and 0.04% ranges, respectively (44, 46).

With increasing deployment of the CD157-based five-color assays, we and others have detected rare non-PNH cases that failed to express (in total or in part) detectable CD157 in both neutrophil and monocyte lineages (Sutherland DR, unpublished observations). While the cause of this is currently under investigation, users of CD157-based assays should be aware of this issue. Given the built-in redundancy of the assays described herein, such cases were not misinterpreted as *bona fide* PNH, because FLAER expression on WBC lineages and CD59 expression on RBCs was entirely normal.

Standardized Flow Cytometry Assays for Enumerating CD34$^+$ Hematopoietic Stem Cells

D. ROBERT SUTHERLAND AND MICHAEL KEENEY

19

The pioneering studies of Thomas et al. in the late 1950s first established that a cellular component of syngeneic bone marrow was capable of regenerating multilineage hematopoiesis in cancer patients receiving supralethal doses of radiation (1, 2). For the next 20 or more years, the majority of autologous and allogeneic hematopoietic stem/progenitor cell transplants were performed utilizing bone marrow as a source of stem cells (reviewed in reference 3). Circulating stem cells were also detectable in steady-state peripheral blood but were extremely rare, as evidenced by their low plating efficiency relative to marrow leukocytes in early colony-forming cell assays (4). Although blood stem/progenitor cells could be collected from steady-state peripheral blood by leukapheresis, the number of procedures required to obtain sufficient cells for transplant initially precluded their widespread use (5). With the development of more sophisticated colony-forming cell assays, a variety of reports in the mid-1980s clearly demonstrated the feasibility of obtaining clinically useful numbers of peripheral blood stem/progenitor cells from cancer patients recovering from chemotherapy (6–8). The availability of a number of hematopoietic cytokines used either singly or in combination with other cytokines and/or chemotherapy (9) has facilitated the harvesting of peripheral blood stem cells (PBSC) to the point where it is a preferred alternative to marrow for autologous and, increasingly, allogeneic transplantation (reviewed in reference 10).

HEMATOPOIETIC STEM/PROGENITOR CELLS EXPRESS THE CD34 ANTIGEN

An important phenotypic characteristic of the stem/progenitor cells in marrow and peripheral blood responsible for multilineage engraftment in the transplant setting was initially established in the late 1980s with the development of two monoclonal antibodies: My10 (11) and B1.3C5 (12), which identified a small number (2 to 4%) of normal marrow leukocytes. This population contained the majority of colony-forming cells for myeloid and erythroid lineages and also contained a few cells exhibiting the phenotypic properties of primitive lymphoid cells. My10 and 3C5 identified similar molecular structures with molecular masses of about 110,000 (110 kDa) and were designated "CD34." Seminal studies using a CD34 antibody called 12.8 (13), which uniquely cross-reacted with a similar subset of baboon marrow cells, conclusively demonstrated that the CD34 antigen was also expressed on true hematopoietic stem cells that could reconstitute long-term multilineage hematopoiesis in lethally irradiated animals (14). Subsequent studies on humans (15) confirmed that CD34$^+$ cell transplants were safe, durable, and potentially therapeutically effective.

TRANSPLANTATION OF HEMATOPOIETIC STEM CELLS: MEASURING GRAFT ADEQUACY

When using bone marrow as a source of stem cells, a total nucleated cell count of 2.5×10^8 nucleated cells/kg patient weight will reliably permit hematopoietic reconstitution (16). However, the increased use of PBSC for autologous and allogeneic transplantation evolved in the absence of any consensus means to assess the engraftment potential of the stem cell product. In the past, the majority of centers performing PBSC transplants relied on the ability of harvested cells to form hematopoietic colony-forming units for granulocytes and macrophages (CFU-GM) in methylcellulose cultures to assess graft quality. Reinfusion of 10^5 CFU-GM/kg of body weight was usually sufficient for reconstitution of hematopoiesis following marrow ablative therapy. However, this assay takes at least 10 days to "read-out" and it cannot measure the most primitive stem cells in the graft that mediate long-term engraftment. Furthermore, due to technical differences in the way these assays were performed between different centers, it was difficult to perform meaningful comparisons on data obtained from different institutions. Thus, the minimum numbers of CFU-GM required to ensure durable and reproducible hematopoietic reconstitution were difficult to establish (17).

Clinically useful numbers of hematopoietic stem cells can also be found in umbilical cord blood (CB) (18, 19), and studies in animal models (20, 21) have indicated that CB represents a particularly rich source of hematopoietic stem/progenitor cells. Thereafter, a large number of CB banks were established worldwide that utilized a variety of methods of collection, processing (with or without T-cell depletion), and cryopreservation. In many cases, rapid, reliable, and standardized methods to measure the effects of such manipulations on the engraftment potential of the post-thawed CB product were not universally employed.

doi:10.1128/9781555818722.ch19

GRAFT ASSESSMENT BY CD34+ CELL ENUMERATION AND FLOW CYTOMETRY

Graft assessment by direct quantitation of $CD34^+$ cells using flow cytometry theoretically obviated the limitations of CFU assays, and the $CD34^+$ cell population encompasses the most primitive stem cells in addition to maturing, lineage-committed progenitors (22, 23). Furthermore, a standardized flow cytometry assay should generate data that are more directly comparable between different transplant centers. Multiparameter flow cytometry can address not just quantitative issues but can also allow a qualitative (i.e., $CD34^+$ cell subset) assessment of the PBSC product or of the level of T-lymphocyte contamination in a $CD34^+$ cell-selected product in the allotransplant setting. Thus, accurate enumeration of $CD34^+$ cells can provide crucial clinical information to the transplant physician. Currently, flow cytometry is the only methodology capable of rapidly measuring this most clinically useful surrogate marker of graft adequacy in all sources of hematopoietic stem cells.

CLINICAL ISSUES IN ENUMERATING STEM CELLS BY FLOW CYTOMETRY

Most transplant centers now determine graft adequacy based on the number of $CD34^+$ cells/kg of patient body weight. Early on, the absolute $CD34^+$ cell number was obtained by determining the percent $CD34^+$ cells by flow cytometry and multiplying it by the absolute leukocyte count as determined by an automated hematology analyzer (so-called two-platform methodology). Using such technology, the recommended minimum number of $CD34^+$ cells was 10^7/kg, although in the absence of a standardized assay to enumerate $CD34^+$ cells, a full consensus on the latter figure was difficult to establish (24, 25). In addition to determining the yield, the number of $CD34^+$ cells mobilized to the peripheral blood is also a predictor of the success of apheresis (26) and can be used to monitor the on-line yield of $CD34^+$ cells if necessary (27). Optimally timing the harvesting of $CD34^+$ cells may be particularly important in patients who have received extensive prior therapy and exhibit poor bone marrow function. For such "poor mobilizers," daily measurements of the $CD34^+$ cell concentration in the circulation to optimize early collection may have merit.

More recently, there has been a shift in interest from the minimum number of stem cells required, to attempts to maximize the $CD34^+$ cell dose, a factor that has been shown by several investigators to correlate inversely with time to engraftment of neutrophils and platelets (28). Furthermore, rapid reengraftment may correlate not only with total $CD34^+$ cell dose, but also with the presence or absence of certain specific subsets of $CD34^+$ cells (29). The clinical interest in subset analysis of rare populations of $CD34^+$ cells adds to the complexity of this assay and to demands on the clinical flow laboratory. Ultimately, the number of viable $CD34^+$ cells (or subsets thereof) actually reinfused to patients is the most clinically important variable determining graft success or failure. A systematic evaluation of viable stem cells from the time of collection to actual reinfusion would be ideal to the quality assurance of these products. We envision this process to involve measurements of peripheral blood $CD34^+$ cells in patients to optimally time apheresis, to evaluate the yield of viable cells postcollection, and to evaluate the number of viable $CD34^+$ cells postcryopreservation actually infused.

To be clinically relevant, any flow cytometric assay must meet the following criteria: (i) it must correlate with a clinically meaningful outcome such as time to multilineage engraftment; (ii) it must be applicable for the different stem cell products (i.e., peripheral blood, cord blood, and bone marrow); (iii) it must provide timely results (less than 2 hours) and must be reproducible between institutions; (iv) it should be sufficiently flexible to permit more sophisticated qualitative analysis of $CD34^+$ cell subsets using a multiparametric approach; (v) it should be able to determine the viability of the target (i.e., $CD34^+$) population; and (vi) it should be a single-platform assay (see below).

EARLY METHODS TO MEASURE CD34+ CELLS BY FLOW CYTOMETRY

Siena et al. (9) were the first to describe a flow cytometric method to measure percent $CD34^+$ cells. Initially, this method was based on mononuclear cell enrichment by density gradient centrifugation, followed by staining using indirect immunofluorescence techniques. The subsequent development of what became known as the Milan protocol (30) was due to the availability, around 1990, of CD34 antibodies which could be conjugated with fluorescein (FITC) without loss of binding activity. With the subsequent commercial availability of phycoerythrin (PE) conjugates of high-affinity CD34 antibodies, the accuracy and sensitivity of Milan-type protocols were slightly increased. The gating strategy utilized simple forward-angle (FSC) versus side-angle (SSC) light scatter to set a denominator. An isotype-matched control was used to set the positive analysis region for $CD34^+$ cells. In the CD34 antibody-stained sample, the number of events that stained brighter than the control and exhibited low to intermediate SSC were counted and used as the numerator in the calculation of percent $CD34^+$ cells. The total number of events counted was 50,000 or a minimum of 50 $CD34^+$ events.

Although a number of minor developments were subsequently incorporated to improve the Milan method, the inherent difficulties in enumerating *bona fide* $CD34^+$ cells in increasingly diverse sources of hematopoietic stem cells led to the development of more sophisticated methods utilizing multiparameter gating strategies. Bender et al. (31) developed a multiparameter assay in which an FITC-conjugated CD45 antibody which only stains nucleated white blood cells was used to generate a more stable denominator. Gated $CD45^+$ events were then analyzed in a manner similar to the Milan protocol, using an isotype control and CD34 staining versus SSC analysis to enumerate $CD34^+$ cells. Although early methods to enumerate $CD34^+$ cells were usually adequate for fresh peripheral blood and apheresis products in pristine condition, they were not sufficiently robust to be broadly applicable to the range of sample types that were increasingly being contemplated for use in the transplant settings (32, 33). Early assays were developed without taking into account the structural characteristics of the CD34 and CD45 molecules and the chemical composition of the epitopes detected by different monoclonal antibodies to these structures (see below). Not all conjugates of all CD34 antibodies were effective at detecting all glycoforms of the CD34 molecule (see below).

STATISTICAL ISSUES IN RARE-EVENT DETECTION

$CD34^+$ cell enumeration by flow cytometry is an example of rare-event analysis, and as such, Poisson statistics apply, where the standard deviation (SD) is equal to the square

root of the target events counted. Therefore, in order to ensure a coefficient variation (CV) of no higher than 10%, at least 100 $CD34^+$ cells need to be collected in the list-mode file. In other words, the lower the frequency of the target population, the larger the data file needs to be to satisfy Poisson statistics. Rare-event analysis also requires that the flow cytometer be rigorously cleaned and maintained, properly set up, and compensated for multiparameter analysis.

APPROPRIATE CONTROLS FOR RARE-EVENT DETECTION

Another key issue in rare-event detection is how to distinguish specific staining of such events from nonspecific staining of perhaps a greater number of events. Some isotype controls stain more events nonspecifically than are stained specifically in some samples, and modern $CD34^+$ cell enumeration methodologies have dispensed with their use entirely (34, 35). Instead, these methods have adopted a multiparameter approach utilizing Boolean gating strategies to distinguish specific from nonspecific staining. To further analyze subsets of already rare populations, modern strategies utilize the so-called "fluorescence-minus-one" (FMO) approach (36) in which all reagents are added to the control tube except for the key marker of interest. The control tube is analyzed for the same length of time and number of events as the test.

TECHNICAL ISSUES IN $CD34^+$ CELL ENUMERATION BY MULTIPARAMETER FLOW CYTOMETRY

CD34 Antigen: Structural Considerations and Choice of Fluorochromes

The CD34 antigen is a heavily glycosylated *O*-sialoglycoprotein (reviewed in references 37 and 38), the structural characteristics of which have important implications for the choice of an appropriate CD34 antibody clone for flow-based enumeration techniques (38, 39). Due to their dependence on terminal sialic acids, which are only found on the most fully glycosylated/processed forms of CD34, class I epitope-detecting CD34 antibodies generate the most aberrant data in clinical samples, whereas class II and class III reagents detect similar if not identical numbers of $CD34^+$ cells in a wide variety of normal and abnormal samples. Thus, for accurate enumeration of rare $CD34^+$ cells in hematopoietic samples, it is important to use a CD34 antibody that detects all glycosylation variants of the molecule, i.e., class II or class III antibodies (37–41).

It is generally advantageous to utilize an antibody conjugated to the brightest fluorochrome excitable, i.e., PE, by an argon laser-based flow cytometer. After parallel analysis of a large number of normal blood, cytokine-mobilized peripheral blood, cord blood, and normal marrow samples, as well as of $CD34^+$ cell lines that fail to express some class I CD34 epitopes, it is our experience that commercially made PE conjugates of the clones QBEnd10, 8G12, and 581 can be utilized with confidence (39–41). As described in detail elsewhere, if FITC conjugates of CD34 antibodies have to be used, only class III reagents such as HPCA2 and 581 can be recommended since these reagents detect similar if not identical numbers of $CD34^+$ cells in parallel analyses of clinical samples using the International Society of Hematotherapy and Graft Engineering (ISHAGE) protocol (see below) as their PE-conjugated versions (38, 39). In general, all potential conjugates that may be used should be rigorously evaluated alongside currently validated reagents before their introduction into the clinical laboratory. Overall, it is critically important to select an appropriate CD34 antibody clone that retains high specificity and avidity of binding after conjugation to the designated fluorochrome.

CD45 Antigen: Structural Considerations and Choice of Fluorochromes

Several protocols have been developed that use CD45 antibodies to gate total nucleated white blood cells, this number serving as the denominator in the calculation of percent $CD34^+$ cells. For such protocols, it is important that pan-CD45 antibodies that detect not just all isoforms, but all glycoforms, of this mucin-like molecule are used. In this respect, the clones J33, T29/33, and HLE-1 can be used with confidence (39–41). Note, however, that the peridinin chlorophyll protein (PerCP) conjugate of HLE-1, while usable on benchtop cytometers equipped with low-powered lasers, can be problematic if used on cell sorters equipped with higher-powered lasers. Of note, a very small fraction of $CD34^+$ cells that do not express CD45 comprises endothelial cells, which have been reported in increased numbers in the blood of patients with solid tumors (42). Although other pan-CD45 antibodies can be used for $CD34^+$ stem cell enumeration, the selected reagent should be carefully evaluated prior to routine use in clinical protocols, as at least one pan-CD45 clone (e.g., clone ALB12, Beckman-Coulter) has been shown to detect a glycosylation-dependent epitope (D. R. Sutherland, unpublished data).

$CD34^+$ CELL ENUMERATION USING SEQUENTIAL BOOLEAN GATING

Accurate enumeration of rare events such as $CD34^+$ cells in heterogeneous clinical samples by flow cytometry represents a serious challenge for both clinical and research laboratories. Cytometers measure events, whether they are white cells, red cells, platelets, dead cells, or debris. Therefore, to eliminate nonleukocytes and debris from the analysis and generate a much more stable denominator against which to measure $CD34^+$ cells, we used anti-CD45 as a counterstain as described previously (31). However, we also took advantage of the observations of Borowitz et al. (43) indicating that leukemic blast cells, which exhibit light scatter properties generally similar to those of lymphocytes, express lower levels of CD45 on their surfaces, thus providing a means of delineating lymphocytes from normal blast cells using this surface marker. Just as lymphocytes, monocytes, and granulocytes form discrete clusters on CD45 staining versus side-scatter analysis, so do $CD34^+$ cells. Thus, a sensitive and accurate multiparameter flow methodology was devised that utilizes the maximum information available of four parameters: CD34 and CD45 staining and forward- and side-angle light scatter. These four parameters were combined in a sequential or Boolean gating strategy that was usable on a variety of sources of hematopoietic stem cells (44). Thereafter, this basic protocol was incorporated into a set of clinical guidelines constructed for ISHAGE, now called the International Society for Cellular Therapy, to enumerate $CD34^+$ cells in peripheral blood and apheresis products (39).

The ISHAGE protocol is sensitive, being capable of detecting 10 to 20 $CD34^+$ cells per 100,000 $CD45^+$ nucleated white blood cells. The method is highly specific when appropriate pan-CD45 antibodies (that detect all isoforms and glycoforms) and CD34 conjugates (that detect all CD34 glycoforms) are used (see below). It is quick and can be performed on a variety of single- and dual-laser

flow cytometers, with only basic software being required for data analysis. The basic ISHAGE protocol can be used to enumerate $CD34^+$ cells in a variety of normal hematopoietic tissues, including marrow and cord blood, as well as in abnormal clinical samples from a variety of disease states. $CD34^+$ cells selected from both normal and abnormal marrow, cord blood, and peripheral blood samples can also be assessed for purity using this flexible method (45).

THE BASIC ISHAGE PROTOCOL AND GATING STRATEGY

The ISHAGE protocol and critical issues relating to the enumeration of $CD34^+$ cells have been published in detail elsewhere (39–41). Briefly, as shown in Fig. 1 on a 24-hour-old peripheral blood apheresis sample, the first gate (R1) is established from a plot of CD45 staining versus side scatter. As indicated above, this approach allows, during analysis of the list-mode data file, the exclusion of red cells, platelets, and other debris commonly found in hematopoietic samples, especially those prepared by lyse–no-wash methods. Sufficient events are acquired in region 1 (R1, histogram 1) such that at least 100 $CD34^+$ cells are displayed in the lymph-blast region, R4 (histogram 4). The acquired cells are then sequentially displayed on a plot of CD34 staining versus side scatter (histogram 2) and R2 is adjusted to include dim and bright $CD34^+$ events with low to intermediate side scatter. The events gated by both R1 and R2 are then displayed in turn on a plot of CD45 fluorescence versus side scatter (histogram 3), and true $CD34^+$ cells form a cluster characterized by low CD45 staining (relative to lymphocytes) and low to intermediate side scatter. It is this cluster that determines the size and location of gating R3. Excluded from this gated cluster (R3) are platelet aggregates, nonspecifically stained lymphocytes, monomyeloid cells, and debris. The cells gated within regions 1, 2, and 3 are then displayed on a light-scatter plot to confirm that the selected events fall into a generic lymph-blast region (R4). The optimal position of gate R4 is set using a duplicate plot 6 (containing a duplicate linked R4 gate) displaying lymphocytes gated from R5 on plot 1.

SINGLE-PLATFORM ABSOLUTE $CD34^+$ CELL COUNTING

While the original ISHAGE protocol was a dual-platform method requiring percent $CD34^+$ cells measured by flow cytometry and the absolute white blood cell count (from a hematology analyzer) to derive the absolute $CD34^+$ cell content of a sample, the use of dual-platform methods is prone to error, particularly if the sample is not in fresh condition, since platelet aggregates, dead cells, and other debris can compromise the accuracy of the absolute leukocyte count and the accuracy of the flow analysis. Furthermore, the variable presence of nucleated red blood cells in cord blood and other samples leads to an overestimate of the absolute $CD34^+$ cell count. By incorporating a known number of fluorescent counting beads in the flow cytometric analysis, an absolute $CD34^+$ cell count can be generated directly on a flow cytometer, thus eliminating the need for a nucleated cell count from a hematology analyzer (46). Assessment of the ratio between the number of beads and $CD34^+$ cells counted allows the direct calculation of the absolute $CD34^+$ cell count. This approach is used by Beckman-Coulter (Miami, FL) in their Stem-Kit assay, by Dako in their CD34 Count Kit, and by Becton Dickinson Biosciences (BD, San Jose, CA) in their single-platform variant of the ISHAGE protocol (SCE Kit) using TruCOUNT tubes (47). Regardless of which of these single-platform assays is used, accurate pipetting of samples (for sample dilution or aliquoting purposes) is required. For the single-platform ISHAGE protocol with Stem-Kit or CD34 Count Kit assays, careful resuspension and accurate pipetting of the beads are also critically important.

ISHAGE SINGLE PLATFORM INCLUDING VIABILITY ASSESSMENT

In the example shown in Fig. 1, from list-mode data acquired on a BD FACSCalibur cytometer, the basic ISHAGE method was modified to include a known number of Flowcount fluorospheres (Beckman-Coulter), and ammonium chloride lyse–no-wash sample processing was adopted. These modifications combine the accuracy and sensitivity provided by the sequential gating strategy of the original ISHAGE protocol with the capability to generate an absolute $CD34^+$ cell count directly from a flow cytometer (46). The number of $CD34^+$ cells are identified as above using gating regions R1 to R4 (gate 4 in gate statistics) and compared with the total number of singlet beads counted (concentration supplied by manufacturer) in the same list-mode file. In the example shown, total beads are gated in R6 of plot 5 and displayed on plot 7 (time versus forward scatter). Using Boolean gating logic (see Table 1 for details of logical gating setup on BD and Beckman cytometers), singlet beads are then gated in R7 (G7 in gate statistics). The calculation for generating an absolute $CD34^+$ cell count per microliter is: (number of $CD34^+$ cells $\times$ bead concentration $\times$ *DF*)/number of singlet beads, where the number of $CD34^+$ cells is determined from gate 4 (R1 through R4), the bead concentration is specified per lot, *DF* is the sample dilution factor, and the singlet bead count is determined from gate 7 (R6+R7).

The addition of the viability dye 7-amino-actinomycin D (7-AAD) to the single-platform ISHAGE method permits the determination of the absolute numbers of viable and nonviable $CD34^+$ cells from a sample (46). The ability to perform such sophisticated analysis has clinical utility in the accurate measurement of viable $CD34^+$ cells in packs that may have been manipulated (e.g., purged), potentially damaged by shipping to another site for analysis, or otherwise inappropriately stored prior to analysis. An example of how the 7-AAD is incorporated into the ISHAGE single-platform method is shown in Fig. 1, plot 8. Viable cells ($7\text{-}AAD^+$) are gated in R8 and only viable cells from R8 are displayed in plots 2, 3, 4, and 6. An absolute viable $CD34^+$ cell count of 157/μl is obtained.

When the $7\text{-}AAD^+$ (dead cells) are not excluded (by opening gate R8) as shown in Fig. 2, and the gating region R4 on plot 5 is adjusted to include all lymphocytes (live plus dead) from R5, a total absolute $CD34^+$ cell count of 286/μl is obtained.

Figures 1 and 2 were prepared using Cellquest Pro software (BD), and an expression editor is established to derive the absolute viable $CD34^+$ cell count from the above parameters. Other expression editors are designed to derive the other automatically calculated values shown in Fig. 1 and 2. Of these, the absolute viable $CD45^+$ cell count is very important as this value can be compared with the white blood cell count obtained from a hematology analyzer to confirm the accuracy of the single-platform flow methodology. As detailed above and elsewhere (39, 40, 46), for absolute counting of $CD34^+$ cells using bead-based methods, accurate pipetting of sample and beads (where appropriate)

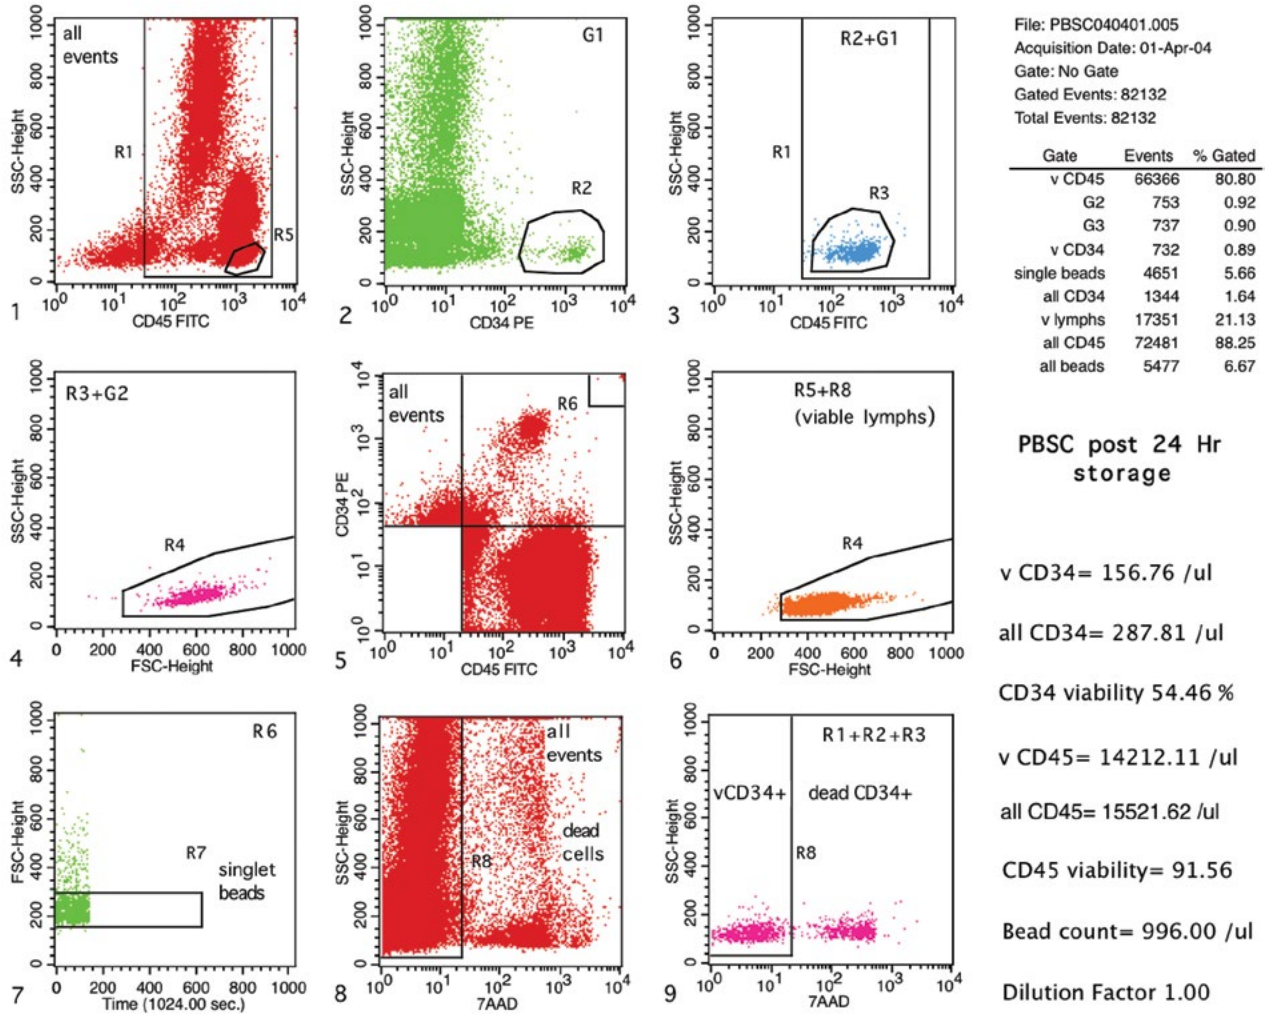

FIGURE 1 Enumeration of viable CD34$^+$ cells with the single-platform ISHAGE protocol (Stem-Kit) on a FACSCalibur cytometer equipped with CellQuest Pro, using 100 μl of a 24-hour-old PBSC sample diluted 1/10 with phosphate-buffered saline–1% bovine serum albumin and stained with CD34-FITC, CD45-PE, and 7-AAD (Stem-Kit) according to the manufacturer's instructions. After 25 min, the sample was lysed with 2 ml fresh NH_4Cl. After 10 min at room temperature, 100 μl of Flow-count beads was added and the sample was immediately analyzed on the FACSCalibur cytometer running Cellquest Pro 5.2, as described previously (44, 45, 50). Viable cells (7-AAD-) were gated in R8 of plots 8 and 9; only viable cells were analyzed by Boolean gating, as depicted in plots 2, 3, 4, and 6. The extra viability plot (plot 8) showing total CD34$^+$ cells (viable and nonviable) can be useful in samples containing large numbers of dead cells. This plot also confirms appropriate compensation between FL2 and FL3 PMTs, with the viable CD34$^+$ cells clearly visible and properly on-scale and dead cells excluded by R8. Viable lymphocytes (plot 6) are gated through R8 and R5 to set the lymph-blast region R4. As shown in the lower left quadrant of plot 5, the gate is set as a 'live' or 'not' gate prior to acquisition such that debris in this area resulting from the lyse–no-wash sample processing is excluded from the acquired list-mode file. Total beads are gated in R6 of plot 5 and singlet beads are identified in R7 of plot 7 (FSC versus time). A forward-scatter threshold or discriminator is set below the light scatter of the singlet beads so as to not exclude any beads from the data file (see plot 7). A total of 732 viable CD34$^+$ cells were counted in gate 4 (R8 and R1 through R4); 4,651 single beads were counted in gate 5 (R6 and R7), and the assayed bead concentration was 996/μl. Using expression editors, the sample contained 157 viable CD34$^+$ cells/μl and 14,212 viable CD45$^+$ cells/μl. CD34$^+$ cell viability was 54.46%.

is critically important to the reliability of the assay. In our standardized assay, 100 μl of sample and 100 μl of counting beads are used (44, 45).

The absolute viable CD34$^+$ value is multiplied by the apheresis pack volume (in liters) to convert this value to an absolute CD34$^+$ cell number $\times 10^6$ per apheresis pack. Note, plot 9 shows total CD34$^+$ cells (viable and nonviable) from gating regions R1+R2+R3 only and shows viable cells on-scale in about the first decade of fluorescence. This plot is useful when samples with poor viability are to be analyzed as it is easier to set R8 on plot 9 versus plot 8. Additionally, it shows that the fluorescence compensation between

photomultiplier tube (PMT) 2 (CD34-PE) and PMT 3 (7-AAD) is optimally set with the viable $CD34^+$ cells properly on-scale in the first decade or so.

The essential components and fine technical details of the single-platform ISHAGE with viability protocol (46) are embodied in the "Basic Protocol" constructed for *Current Protocols in Cytometry* (CPC) (40) and its updated version (41). They are also embodied in the recommendations from the European Working Group on Clinical Cell Analysis (48), the Clinical Laboratory Standards Institute document H42-A2 (49), and the American Association of Blood Bankers (50), as well as in several national guidelines.

Like earlier versions of the ISHAGE protocols, the single-platform derivatives have been developed to work on both Beckman-Coulter and BD flow cytometers. However, there are minor technical differences in the way the assay is set up on the different instruments (detailed in references 39, 40, and 46). Briefly, there are two main differences. On BD instruments, the singlet counting beads are visualized using forward angle light scatter versus time (see plot 7 of Fig. 1 and 2). Since the beads are detected as smaller events than lymphocytes on BD instruments, the forward scatter threshold has to be lowered so as not to exclude the beads. As shown in plot 7 of Fig. 1 and 2, the lower limit of the singlet beads cluster appears around channel 160, whereas the viable lymphocytes shown in plot 5 are found above channel 280. On the Beckman-Coulter instruments, the beads appear above channel 800, so there is no need to adjust the forward angle light scatter discriminator from its normal setting, just below the smallest lymphocytes (50). However, it is our recent experience that certain stabilized samples, which are routinely distributed for quality assurance (QA) or proficiency testing purposes, exhibit reduced forward scatter properties. For the analysis of such samples, it is advisable to increase the forward scatter gain of the Coulter instruments to ensure that all $CD45^+$ leukocytes are included in the list-mode file. Although the counting beads can be detected on the Coulter instruments using the same parameters of forward scatter versus time, the presence of an extra FL-3 PMT (optimized to detect phycoerythrin-Texas red conjugates) allows the counting beads to be detected on an FL3 versus time plot (see Fig. 3, plot 7). By setting the singlet bead gating region as a CAL region and inputting the bead lot count, the software running the FC500 automatically calculates and prints the absolute viable $CD34^+$ and $CD45^+$ (LEUKS) cell counts. The 7-AAD is detected in the FL4 channel (Fig. 3, plot 8) (50).

COMMERCIAL KITS FOR $CD34^+$ CELL ENUMERATION BASED ON ISHAGE GUIDELINES

1. The Stem-Kit from Beckman-Coulter was the first commercial kit to utilize ISHAGE gating criteria to identify $CD34^+$ cells. The kit contains CD45-FITC/CD-34PE, 7-AAD, and Flow-count fluorospheres and is used as described above in Fig. 1–3. The kit also contains a CD45-FITC/CD34 isoclonic control

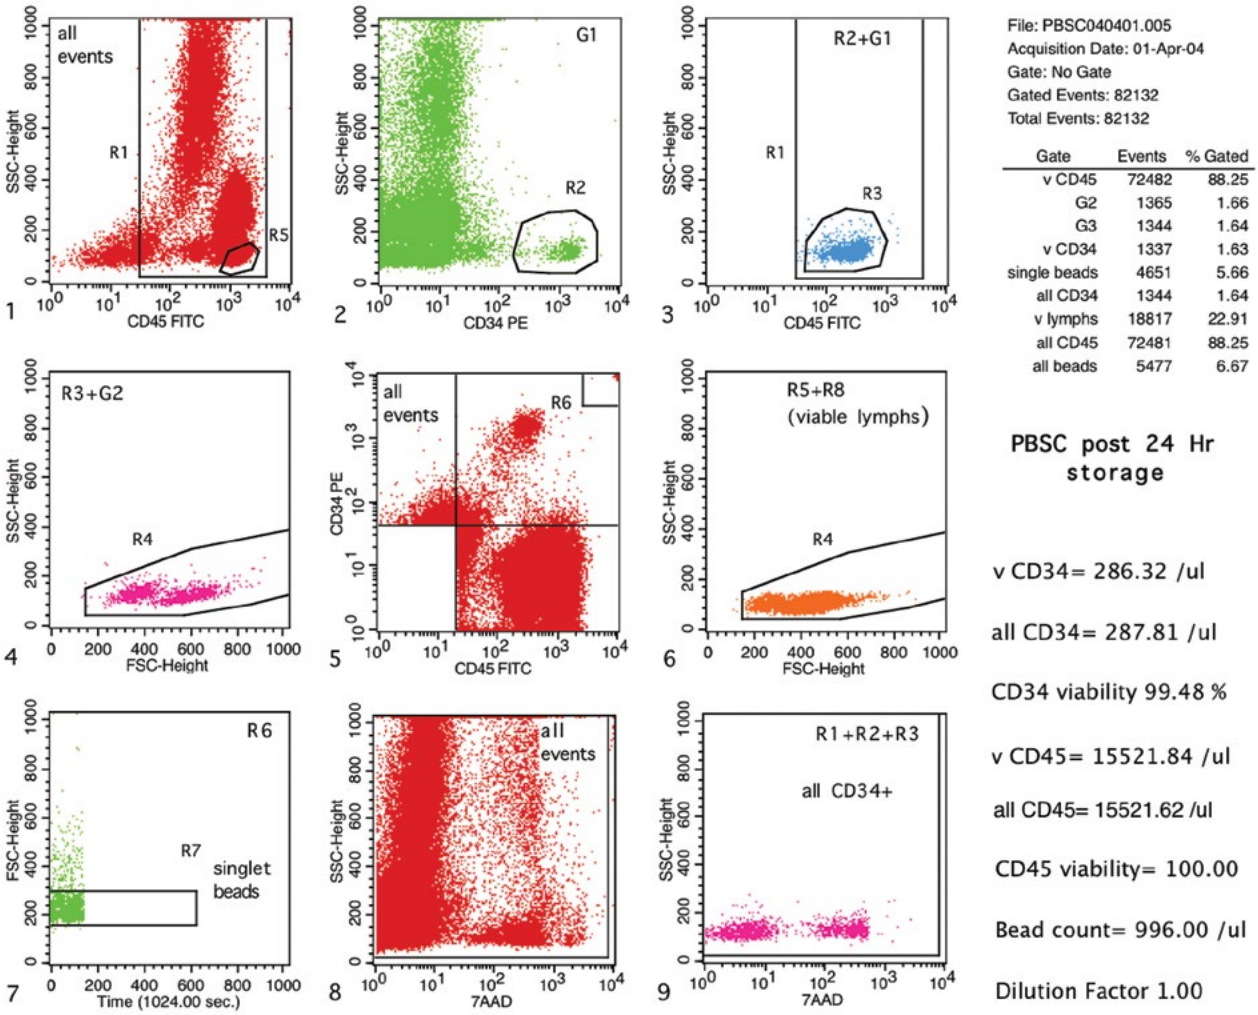

FIGURE 2 Importance of viability dye (7-AAD) inclusion in the analysis of non-fresh samples. Analysis of the same sample as in Fig. 1, except that viability discrimination with 7-AAD was NOT applied. When gating region R8 is expanded to include both viable and nonviable cells (plots 8 and 9) and region R4 is moved to include both live and dead lymphocytes (plot 6), both dead and live $CD34^+$ cells now cluster within the duplicate lymph-blast region R4 on plot 4. Both the absolute CD34 and CD45 counts are significantly increased versus the values obtained in Fig. 1. Note the extra population of both $CD34^+$ cells (plot 4) and lymphocytes (plot 6) with reduced forward-angle light scatter; these are the dead $CD34^+$ and dead lymphocytes, respectively. Sample contains 286 total (viable + nonviable) $CD34^+$ cells/μl.

to enumerate nonspecifically stained events. In this control, unconjugated CD34 antibody is present in large excess to block specific staining of PE-labeled CD34 present at the same concentration as the test. However, given the selectivity of the sequential gating strategy utilized in this protocol, we have not found that the isoclonic control makes a significant contribution to the accuracy and reliability of the assay (46) and, therefore, we consider this and other alternative negative antibody controls to be redundant (reviewed in references 34 and 35). Beckman-Coulter has developed a software package that automates instrument setup and compensation as well as automated data acquisition and analysis of samples prepared with the Stem-Kit. This software has been developed specifically for use on the Coulter Epics XL (Stem One) and, more recently, FC500 instruments (Stem CXP). Figure 3 shows an example of a sample analyzed with Stem CXP for viable $CD34^+$ cells in a fresh apheresis product. Almost identical values were obtained by manual gating (not shown). For samples in less pristine condition or that contain platelet aggregates, or for bone marrow samples or post-thawed samples, extreme care must be taken when using the Stem One and Stem CXP software, and manual analysis of the data file acquired with the autosoftware is often required. It is possible to use the Stem-Kit on Beckman-Coulter instruments using only manual software for both acquisition and analysis, and this is often preferred, especially for labs that regularly receive samples in less than pristine condition.

2. Dako (Denmark) has also produced the CD34 Count Kit, which contains CD45-FITC/CD34-PE, 7-AAD, an ammonium chloride-based lysing agent, and

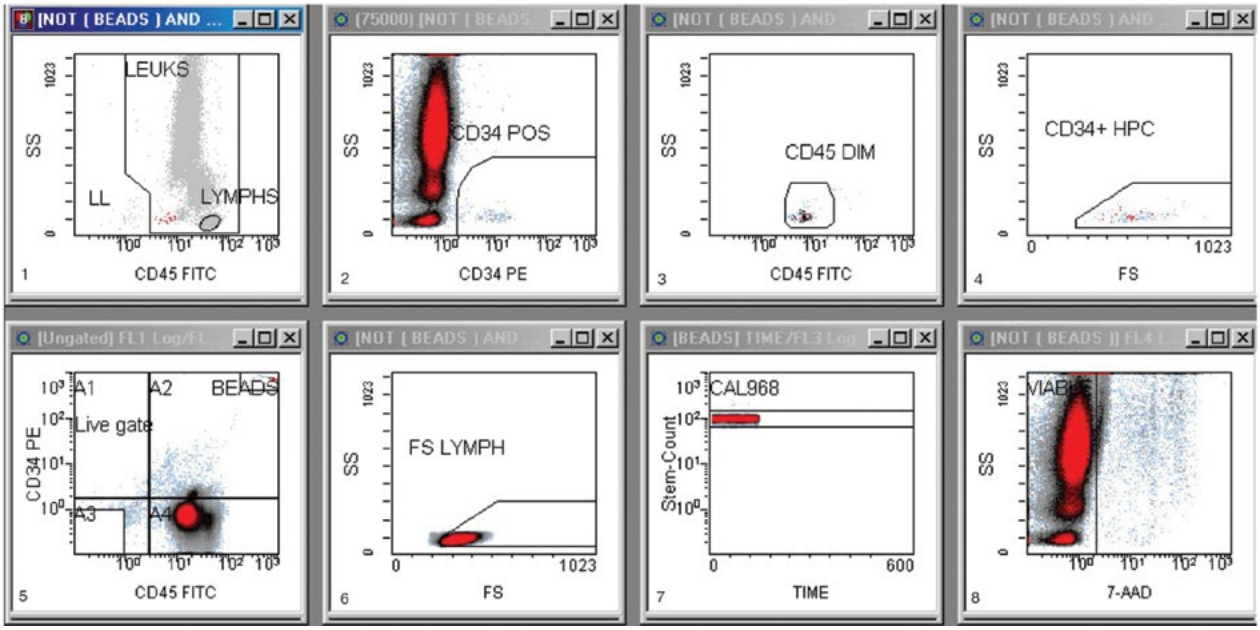

FIGURE 3 Enumeration of viable CD34+ cells with Stem-Kit and Automated STEM-CXP software analysis on a Beckman-Coulter FC500. Fresh apheresis sample diluted 1/10 with phosphate-buffered saline–1% bovine serum albumin. Plot 1: all CD45+ leukocytes, gated on 7-AAD negative (viable) events from histogram 8. Plots 2–4 are sequentially Boolean gated from plot 1. Plot 6 is gated on viable lymphocytes from plot 1 to allow the discriminator or threshold to be set on forward scatter. Total beads are gated as shown in plot 5 and Boolean gated on FL3 (stem count) versus time (plot 7) to enumerate singlets. A live gate in the bottom left corner of plot 5 is used to exclude debris from the list-mode file, as described for Fig. 1. The leukocyte count (CD45+, from plot 1) was 23.3 × 10^9/liter, and the absolute viable CD34 count was 23/μl (from plot 4). The overall CD45+ viability was 95.1% (from plot 8).

pipettable fluorescent counting beads for use alongside an ISHAGE gating protocol. The beads in this kit are too small to be used with a forward scatter threshold and the data are acquired using a threshold set on the FL-1 (CD45-FITC) channel. Additionally, like Flow-count beads, a Boolean gate is needed to gate the singlet beads.

3. As described by Brocklebank et al. (51), it is also possible to perform the ISHAGE protocol using TruCOUNT absolute counting tubes (BD) instead of a pipettable bead suspension such as used in the Stem-Kit and CD34 Count Kit. An advantage of this approach is that it eliminates the requirement to carefully suspend and accurately pipette the counting beads, as the TruCOUNT tubes contain a known number of freeze-dried beads. Becton Dickinson Biosciences has now developed the BD Stem Cell Enumeration Kit (SCE Kit) to closely follow ISHAGE gating criteria (47). Again, due to the small size of the beads, a threshold cannot be set on forward scatter, necessitating its setting on a fluorescence parameter (FL-1/CD45 FITC). However, accurate pipetting is still required if any predilution of the sample is required, as well as for the delivery of the sample into the TruCOUNT tube. Note that for TruCOUNT tubes, all beads (singlets and doublets) have to be counted (Fig. 4, plot 5, R6, or alternatively on plot 9, R9), so an extra Boolean gate is not required, in contrast to the singlet bead counts required for Stem-Kit and CD34 Count Kits. An example of the single-platform ISHAGE protocol performed on TruCOUNT tubes is shown in Fig. 4 (data acquired on Canto II instrument, then exported in FCS2 format for analysis in Cellquest Pro). Another modification that is required when using such small counting beads (TruCOUNT and CD34 Count) involves the setting of an exclusion or debris gate (R7 on plot 6). The reason for this is that very small debris and particles produced during the lyse–no-wash processing of the sample stain with the CD45-FITC reagent (plot 1), and these events can significantly increase the absolute CD45+ cell count in samples prepared this way. The debris-exclusion gate can be set as a 'not' gate or as a 'live' gate prior to data acquisition or later during analysis. In the example shown in Fig. 4 from a fresh PBSC sample, the debris-exclusion gate was applied after acquisition. However, if the gate is set prior to acquisition (which can significantly reduce the size of the list-mode file), care must be taken to ensure that no lymphocytes are excluded. In practice, the R7 gate can be set prior to acquisition in the 200 × 200 FSC/SSC setting and then optimized during analysis if required. Note, as per manual Stem-Kit analysis, plot 8 displays total CD34+ cells (viable and nonviable) from gating regions R1+R2+R3 and not R7 and shows viable cells on-scale in about the first decade of fluorescence. This plot is useful when samples with poor viability are to be analyzed, as it is easier to set R8 on this plot versus plot 7. Additionally, it shows that the fluorescence compensation between PMT 2 (CD34-PE) and PMT-3 (7-AAD) is optimally set. The absolute

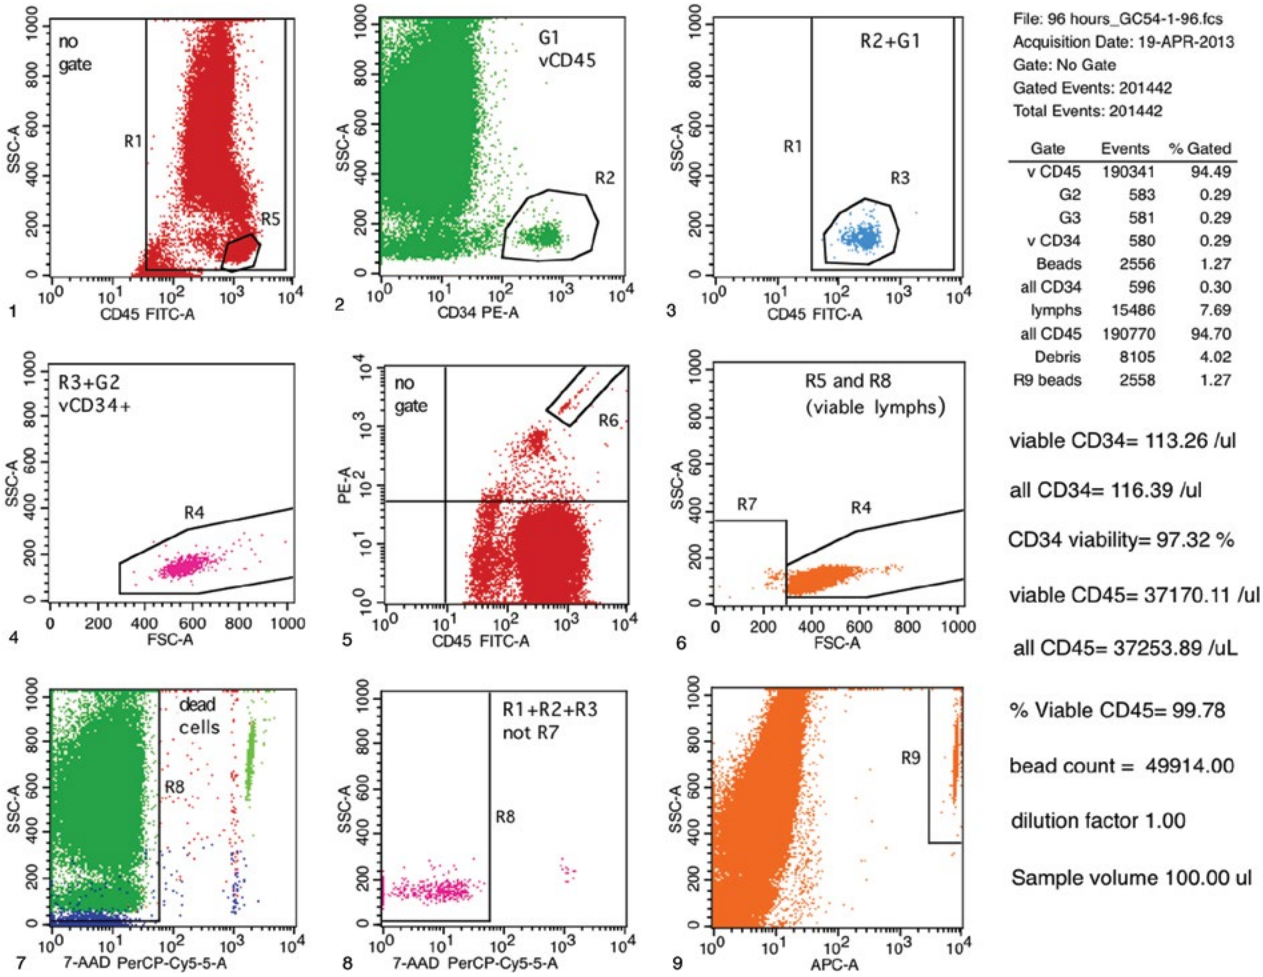

FIGURE 4 Absolute viable CD34$^+$ cell counting with the ISHAGE single-platform protocol using TruCOUNT tubes and BD FACSCanto II. We used 100 μl of a fresh PB sample stained with CD45-FITC, CD34-PE, and 7-AAD in a TruCOUNT tube (SCE Kit). A threshold was established on FL-1 (CD45-FITC, plot 1) because the size of the TruCOUNT beads precludes the use of an FSC threshold. A debris-exclusion gate (R7) is also necessary to remove fluorescent debris from the list-mode file (debris visualized in lower left of R1). This allows an accurate determination of absolute CD45$^+$ cells to be made. The total number of beads in the list-mode file is obtained from R6 of plot 5 (gate G5 = R6). An alternative means of enumerating the beads is shown in plot 9. This plot can be useful if aggregates of CD34$^+$ cells are present or if other debris contaminates R6 such that the beads cannot be accurately delineated, as can be the case in some CD34$^+$-selected samples or in samples containing large amounts of platelet aggregates. Other aspects of the analysis were performed as for Fig. 1. Canto II FCS3 data were exported as FCS2 files and analysis was performed using Cellquest Pro 6. Gate statistics were obtained from plot 1 (all events). The sample contained 113 viable CD34$^+$ cells/μl and 37,170 viable CD45$^+$ cells/μl.

viable CD34$^+$ cell numbers are automatically calculated using the expression editors in Cellquest Pro software according to the formula:

$$\text{absolute viable CD34}^+ = \frac{\text{vCD34} \times \text{bead lot count} \times DF}{\text{beads} \times \text{sample volume (μl)}}$$

One extra plot (plot 9) is shown in Fig. 4 to depict an alternative means of gating the beads collected during data acquisition. This allows the beads to separate better from debris, platelet aggregates, etc., which can occasionally contaminate the primary bead-gating region R6. We have found that for the analysis of purified CD34$^+$ cell fractions, where aggregates of CD34$^+$ cells can be present, separating beads from aggregates with R6 can be very difficult and R9 gating provides a more accurate way to delineate the beads (Sutherland, unpublished observations).

BENEFITS OF SINGLE-PLATFORM CD34$^+$ CELL ENUMERATION

By including an internal reference bead in the analysis, CD45 positivity is no longer used as a denominator in the calculation of absolute CD34$^+$ cells. The characteristic CD45 expression of CD34$^+$ cells is used solely as part of

the sequential gating strategy to accurately identify *bona fide* $CD34^+$ cells. It must be stressed that focused training is highly recommended for laboratory staff adopting single-platform flow methodologies. Notwithstanding the critical requirement for accurate pipetting in single-platform assays, addition of counting beads has the advantage of eliminating the potential introduction of errors in calculating the absolute $CD34^+$ cell count inherent in two-platform methodologies (40, 41). The flow cytometrist need not be concerned about the presence of nucleated red blood cells, platelet aggregates, and dead cells, which can be counted as leukocytes by some automated hematology analyzers. While the presence of significant numbers of nucleated red cells (which play no role in engraftment) in apheresis samples is quite rare, they are often abundant in CB collections and bone marrow aspirates, and single-platform analysis can significantly increase the accuracy of the absolute $CD34^+$ cell number in such cases.

NEGATIVE ANTIBODY CONTROLS

Many of the early methods of $CD34^+$ enumeration relied on the use of isotype controls to delineate specific from nonspecific staining (9, 25, 30, 31). However, for rare-event analysis such as $CD34^+$ cell enumeration, the use of isotype controls is not only redundant but can also lead to misleading results (32). Given the sequential gating strategy at the heart of the ISHAGE method, the use of isotype or isoclonic control antibodies to assess nonspecific binding of the specific antibody or to set the positive analysis region for $CD34^+$ cells would be inappropriate (32, 34, 35, 40, 41, 46). This approach has also been adopted by the European Working Group on Clinical Cell Analysis (48) and the Clinical and Laboratory Standards Institute (49).

LYSING AGENTS

While methods for sample preparation for flow cytometric enumeration of $CD34^+$ cells include both lyse–no-wash or lyse-and-wash steps, single-platform protocols can only be processed by lyse–no-wash methods. It is important to note that for some apheresis samples and post-thawed samples, red cell lysis is neither necessary (for fresh PBSC) nor recommended (for post-thawed samples), due to either the low concentration of red blood cells present (apheresis) or the lysis of the red cells inherent in the thawing procedure. As the measurement of viability is important in several sample types, lysing with simple ammonium chloride-based agents is necessary. However, samples lysed in ammonium chloride must be rapidly cooled on melting ice immediately after lysis (usually for 10 minutes). This will reduce apoptosis induced by prolonged exposure to ammonium chloride-based lysing agents. In any event, lysed samples must be acquired no later than 60 minutes post-lysis (40, 41, 46, 49, 50, 52).

QUALITY ASSURANCE OF $CD34^+$ CELL ENUMERATION

Quality control and quality assurance procedures are a necessary part of $CD34^+$ cell enumeration. Basic instrument setup and compensation are important, particularly as related to the use of 7-AAD as a viability dye. Clear attention must be paid to the CD34-PE and 7-AAD spectral overlap as under-compensation of this can lead to viable $CD34^+$ cells being classified as nonviable. Overcompensation, on the other hand, can lead to dead cells being included in the live-cell (7-AAD) region. Several manufacturers nowadays produce stabilized (fixed) whole blood control cells, which can be used as daily process controls. Their staining pattern with respect to CD34 and CD45 reagents can be used as an extra internal control to ensure that the FL1 and FL2 parameters of the cytometer are adequately set. However, as the cells in such preparations are fixed (i.e., dead), all cells take up the viability dye 7-AAD. In addition, the light-scatter properties of $CD34^+$ cells in stabilized controls are slightly different from those of fresh blood, and the degree to which this occurs varies between instrument manufacturers. Thus, it is important to take these issues into account as they have important implications for appropriate instrument setup for the analysis of stabilized samples. In general, it is important to ensure that the FSC gain and FSC threshold (if used) are appropriately set specifically for acquisition and analysis of such samples. Furthermore, if 7-AAD is used, the viability gating region R8 (BD instruments) must be opened fully so as not to exclude any cells. An example of the analysis of a stabilized whole-blood preparation with the SCE Kit on the FACSCanto II instrument is shown in Fig. 5.

Note that it is not recommended that acquisition of stabilized samples be performed using the automated version of Stem-CXP software on the Beckman-Coulter FC500 platform, as the viability gate is locked in an inappropriate position for the analysis of such samples.

Flow cytometric analysis of $CD34^+$ cells offers a potential means to quality assure all aspects of stem cell processing from mobilization to reinfusion. By analyzing list mode data by a variety of different gating strategies, Chang and Ma (53) demonstrated that gating strategies were a major contributing factor to result variability. For an individual sample, the use of different gating strategies could produce as much as a 2-fold variation in results. In their study, the gating strategy used in the ISHAGE protocol was the only method that gave reproducible results from all centers of within ±10% of the median $CD34^+$ cell value on both peripheral blood and PBSC collections. In a study undertaken by the European Working Group on Clinical Cell Analysis using the single-platform ISHAGE protocol, CVs of $<10\%$ were obtained by the majority of participating labs on a long-term stabilized blood sample with a target $CD34^+$ value of 170/μl (54). In a more recent study involving 36 participants from the Benelux countries, similar CVs were obtained. In contrast, the lowest between-laboratory CVs using dual-platform techniques were 16% (Benelux) and 21% (UK National External Quality Assessment Service) (55). Thus, the experience with $CD34^+$ cell counting confirms that the use of a common standardized protocol and targeted training, where needed, is able to significantly increase reproducibility and reduce variation between laboratories.

Data from the UK National External Quality Assessment Service for Leukocyte Immunophenotyping show that approximately 70% of users of this program are now claiming to use the ISHAGE gating strategy. Interestingly, a more in-depth survey found that up to 40% of the ISHAGE users were not deploying the method correctly. Further analysis between those groups that were correctly versus incorrectly applying the ISHAGE guidelines showed the latter group were 32% more likely to be flagged on a QA survey (56). As of 2010, 63% of those participating in the College of American Pathologists' CD34 external quality assurance program reported use of the ISHAGE gating strategy. In this North American program, interlaboratory CVs are routinely in the 10 to 15% range.

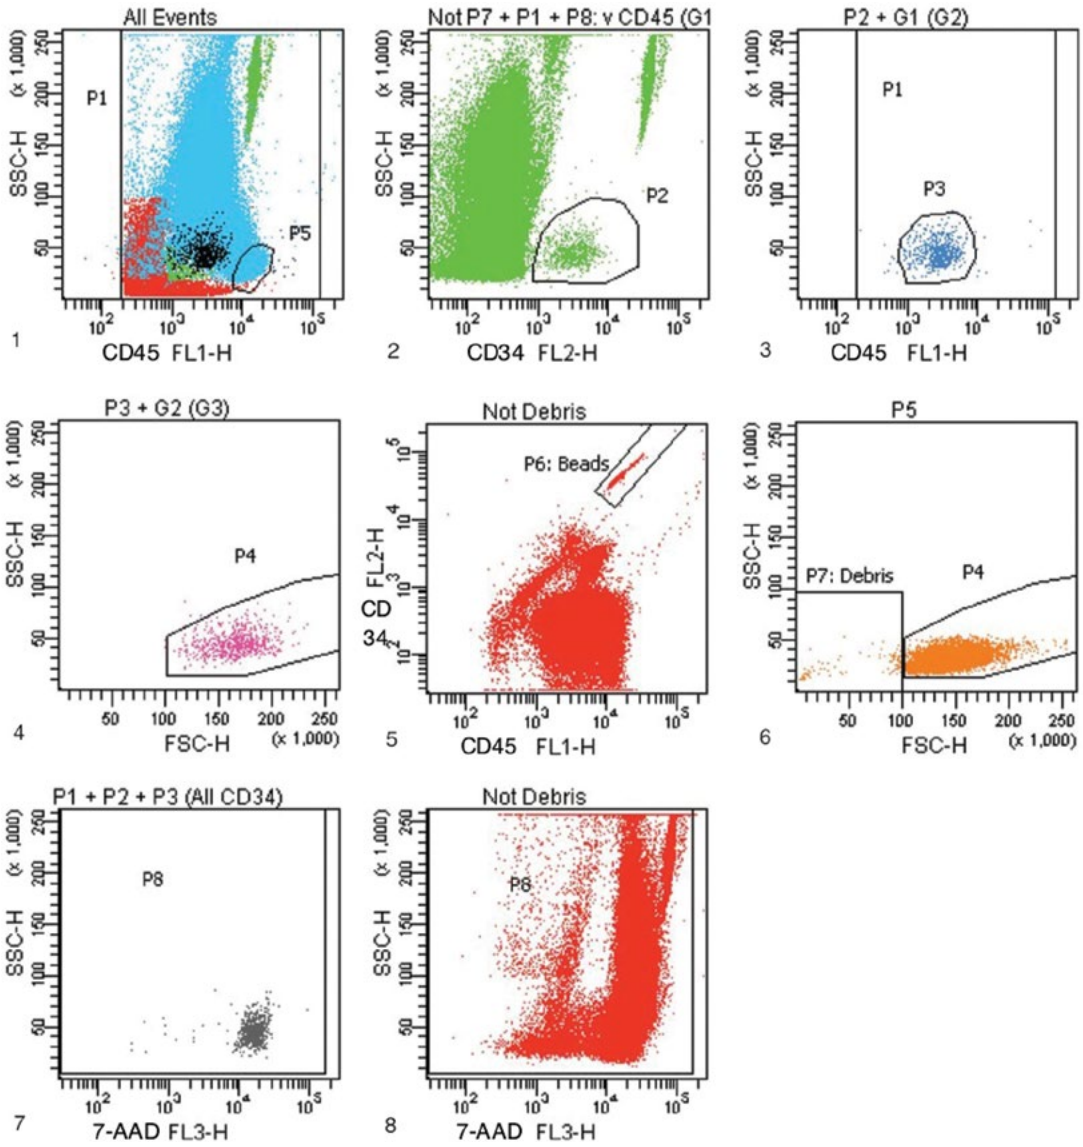

FIGURE 5 Absolute $CD34^+$ cell counting in stabilized PB sample with the ISHAGE single-platform protocol using TruCOUNT tubes and BD FACSCanto II. We used 100 μl of a stabilized whole-PB sample stained with CD45-FITC, CD34-PE, and 7-AAD in a TruCOUNT tube (SCE Kit). A threshold was established on FL-1 (CD45-FITC, plot 1) as was a debris-exclusion gate (R7) as described in Fig. 4. For analysis of stabilized (i.e., dead) samples, the viability gate P8 (plots 7 and 8) is fully opened so as to not exclude any cells (viable or nonviable) from analysis. The rest of the ISHAGE gating strategy is applied as shown in Fig. 4.

SIMULTANEOUS ENUMERATION OF $CD34^+$ AND $CD3^+$ CELLS IN THE ALLOGENEIC TRANSPLANT SETTING USING A MODIFIED SINGLE-PLATFORM ISHAGE PROTOCOL

An ability to accurately enumerate $CD3^+$ T cells at very low levels as well as $CD34^+$ and $CD45^+$ cells can be particularly useful in the allogeneic transplant setting, where reducing the number of $CD3^+$ cells in the graft has been shown to result in decreased severity of graft-versus-host disease. Phycoerythrin-cyanine 5 (PE-Cy5) or PerCP-conjugated CD3 antibody is added (in place of 7-AAD) as a third antibody conjugate. The CD3 conjugate is detected in the FL4 channel of a Beckman-Coulter XL or FC500 instrument and in the FL3 channel of the BD FACSCalibur cytometers. The modified assay can also be performed in the presence of counting beads, allowing the generation of absolute $CD3^+$ and $CD34^+$ cell counts from a single assay tube (44, 45). However, it may be important to retain the use of the viability dye in the assay, for example in situations where post-thawed cord blood units are to be used or if PBSC samples need to be shipped over large distances prior to infusion in the recipient, as is often the case. In this setting, the regular three-color with viability, single-platform ISHAGE protocol can be modified by the addition of CD3–PE-Cy7 (Beckman-Coulter instruments) or CD3-APC (BD Biosciences instruments). In Fig. 6, CD3-APC was added to the standardized TruCOUNT-based ISHAGE method on a BD FACSCalibur instrument. Viable $CD34^+$ cells were

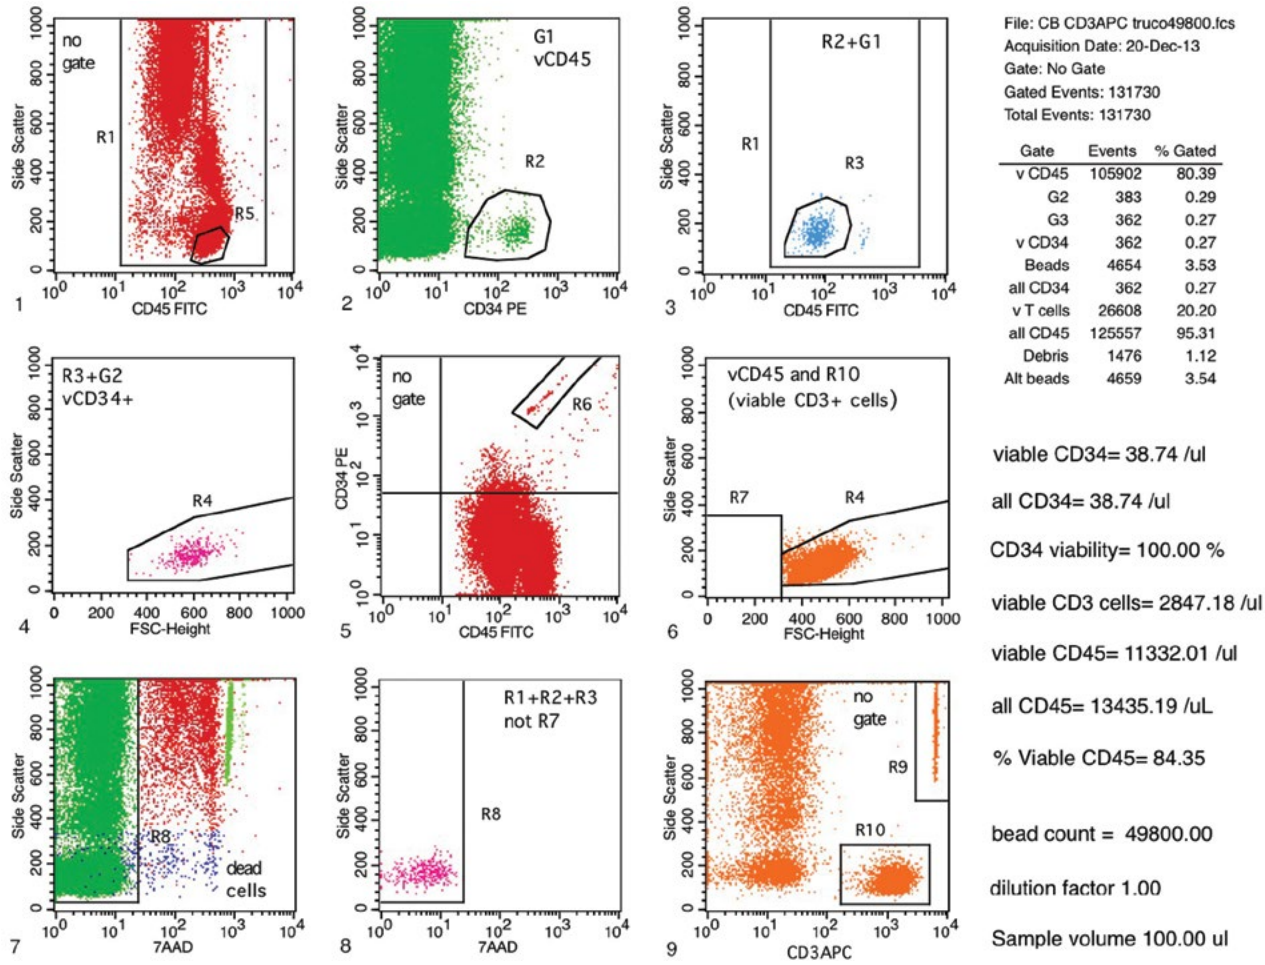

FIGURE 6 Simultaneous detection of absolute viable $CD34^+$ and $CD3^+$ cells using single-platform ISHAGE protocol in the allotransplant setting. PBSC sample for allotransplant stained with CD45-FITC, CD34-PE, 7-AAD, and CD3-APC. $CD34^+$ cells enumerated through Boolean gates R8 and R1 through R4 as in Fig. 4. $CD3^+$ cells enumerated through Boolean gates R10 (plot 9) and duplicate R4 (plot 6). TruCOUNT beads enumerated through gate R6 (plot 5) or alternatively with R9 (plot 9). Sample contained 39 viable $CD34^+$ cells/μl, 2,836 viable $CD3^+$ cells/μl, and 11,332 viable $CD45^+$ cells/μl.

enumerated exactly as described in Fig. 4 using gating regions R8 and R1 through R4 and not R7, while $CD3^+$ cells were enumerated from Boolean gates R10 (plot 9) and the duplicate region R4 (plot 6). The back-gated $CD3^+$ events are used to accurately set R4, rather than all lymphocytes from region R5 of plot 1 as shown in the three-color assay (Fig. 4). This template is also useful for enumerating residual $CD3^+$ cells and $CD34^+$ cells selected using $CD34^+$ cell immunomagnetic selection devices (57).

IMMUNOLOGICAL CHARACTERIZATION OF $CD34^+$ STEM CELLS

In vitro and *in vivo* models of hematopoiesis have shown that the cells responsible for sustained multilineage engraftment are contained in the most primitive subsets of $CD34^+$ cells. Such subsets of $CD34^+$ cells in bone marrow express very low levels of antigens associated with lineage commitment (lin–) (13) and are found in the CD34hi, $CD90^+$ (58, 59), $CD133^+$ (60), and CD38/CD71/HLA-DR^{dull}/negative fractions (61, 62). Several clinical trials using highly purified lin–$CD34^+CD90^+$ populations have shown rapid and sustained engraftment when as little as 8×10^5 selected lin–$CD34^+CD90^+$ cells/kg body weight were given to patients with breast cancer (63), non-Hodgkin's lymphoma (64), and multiple myeloma (65).

While this work showed that highly purified subsets of $CD34^+$ cells can be effective in certain circumstances, selection and high-speed sorting of $CD34^+$ subsets are expensive, technically demanding, and not suitable for routine deployment in the clinical setting. Since virtually all patients receiving the minimum dose of 2×10^6 to 2.5×10^6 $CD34^+$ cells/kg body weight engraft in a timely manner, it is unlikely that monitoring subsets in patients receiving at least the minimum target dose will provide any additional clinical information.

Furthermore, standardizing an assay to perform subset analysis is even more problematic since most antigens used to identify subsets of $CD34^+$ cells are not expressed on discrete, non-overlapping populations, but instead display a continuum of antigen density from negative to weakly positive. The approach we developed (detailed in references

40 and 41) makes use of the auto-fluorescence of the gated CD34$^+$ cells in an FMO approach (36) to define the lower FL intensity limit of the positive analysis region, following which the experimentally stained sample is to be analyzed (Fig. 7). Though this will not completely account for low-level nonspecific binding of the PE-conjugated antibody used to identify subsets of CD34$^+$ cells, it nevertheless greatly improves the ability to standardize the analysis of weakly stained subsets of CD34$^+$ cells (44, 45) on an individual instrument-specific basis.

In the example shown in Fig. 7, a fresh PBSC sample was stained with a combination of CD34-FITC and CD45–PE-Cy5. *Bona fide* CD34$^+$ cells were identified and gated as per ISHAGE protocol shown in Fig. 1 in R4 of plot 4 and displayed on a bivariate plot of CD34-FITC versus FL2 (Fig. 7, plot 1). Since no PE-conjugated antibody is present in this sample, the natural or auto-fluorescence in the PE (FL2) channel of the gated CD34$^+$ cells is used to establish the subset positive-gating region for the CD90 PE-stained sample shown in R5 of plot 2. The CD90$^+$ cells express the highest levels of CD34 and exhibit very uniform light-scatter characteristics (plot 3), in keeping with known characteristics of the most primitive CD34$^+$ cell subsets (58, 59).

All gating regions remain identical between the unstained (plot 1) and stained tubes (plot 2, CD90; plot 6, CD133; and plot 7, CD33). On a technical note, it is crucial to the reliability of the data generated that the flow cytometer be properly set up and compensated. As shown in plots 4 and 5, respectively, the fluorescence of lymphocytes from the unstained control (plot 3) and that of lymphocytes from the CD90 PE-stained sample (plot 4) are virtually identical with respect to their fluorescence in the FL2

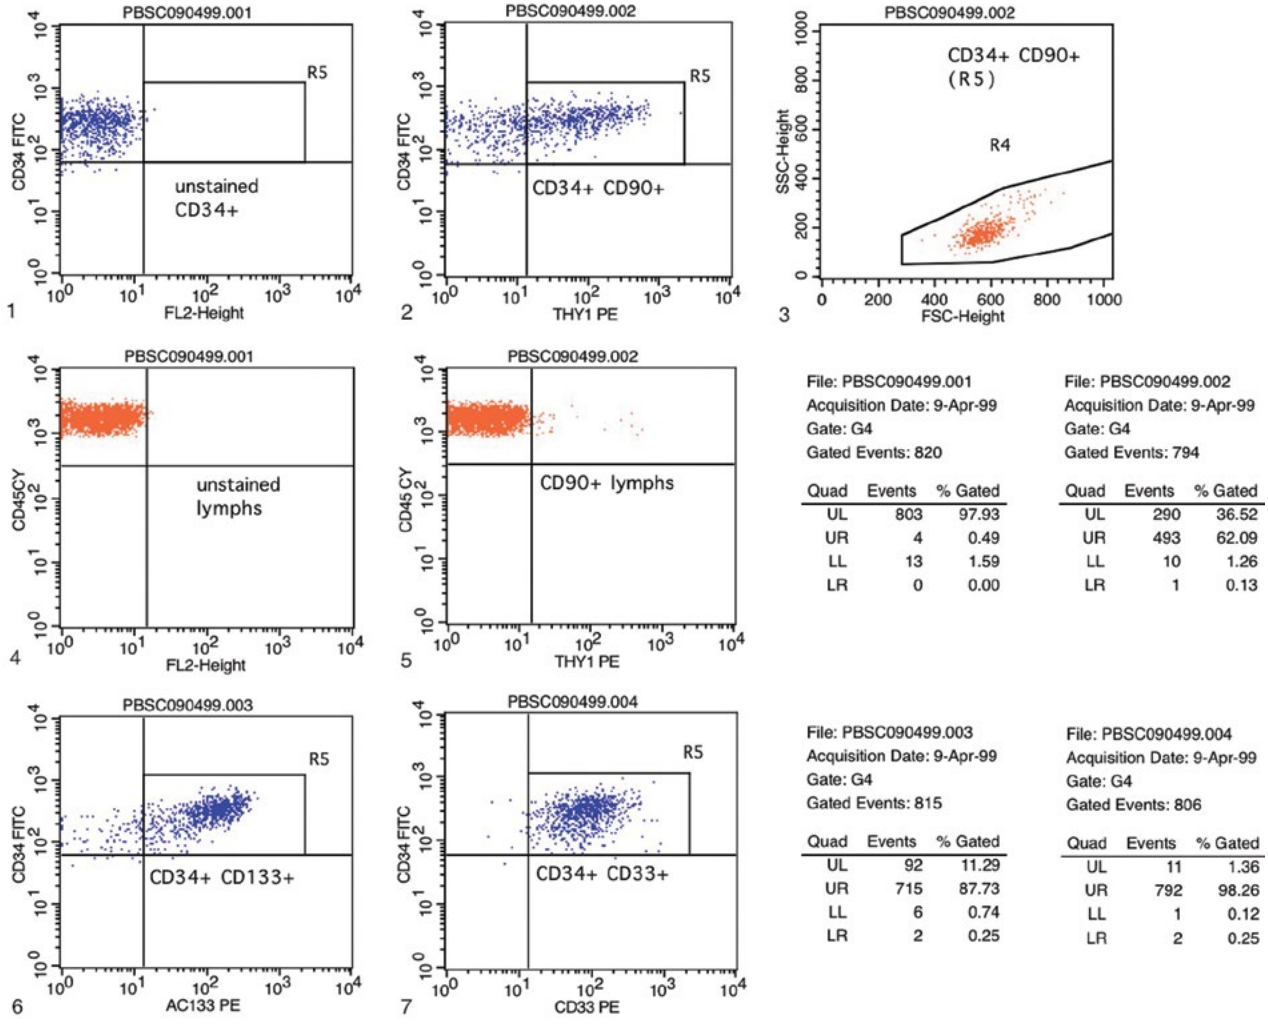

FIGURE 7 Identifying CD34$^+$ cell subsets using the CPC Support Protocol (44, 45). PBSC sample stained with CD34-FITC and CD45–PE-Cy5. CD34$^+$ cells (1.01% of the gated CD45$^+$ events) were identified as described in Fig. 1, plots 1–4, and displayed on CD34 versus FL2 to establish positive cell analysis region R5 (plot 1). Lymphocytes from the same list-mode file were also gated as described in Fig. 1 and displayed (plot 4) on a duplicate CD45 versus FL2 plot. Note the back-scattered lymphocytes (plot 4) have similar auto-fluorescence as gated CD34$^+$ cells (plot 1) and cluster parallel with horizontal axis, indicating optimized FL2/FL3 fluorescence compensation. Plots 2 and 5 show the staining of CD34$^+$ and lymphocytes, respectively, with CD90/Thy–1-PE. Plot 3 shows the light-scatter characteristics of the CD34$^+$ and CD90$^+$ cells. Plots 6 and 7 show the staining of the CD34$^+$ cells with CD133-PE and CD33-PE, respectively.

channel (apart from a small number of lymphocytes that have stained specifically with CD90, in keeping with known characteristics of a small subset of T cells). These plots not only demonstrate proper instrument setup and fluorescence compensation, but also show that the CD90 antibody used is optimally titrated and that, indeed, the staining of the subsets of interest is specific.

DOES ENUMERATING CD34+ SUBSETS HAVE CLINICAL UTILITY?

Whether enumerating specific CD34+ subsets has utility as a predictor of rapid re-engraftment remains somewhat controversial. Since several studies have shown that the rate of platelet engraftment is generally rapid in patients given at least 5×10^6 CD34+ cells per kg (28), it is unlikely that monitoring subsets in patients receiving this target dose (or greater) will provide any additionally useful clinical information. At the Toronto Hospital, we monitored CD34+ subsets on those patients in whom the target value of 5×10^6/kg CD34 cells was unlikely to be met. In this way, we hoped to enumerate specific subsets that correlated best with speed of engraftment. Subsets enumerated included CD90, CD133, CD38dim/−, CD33dim/−, and on some samples, CD109+ and CD117+. However, subsequent analysis showed that all patients transplanted with CD34+ cells in the 2×10^6 to 5×10^6/kg range engrafted platelets and neutrophils by days 12 to 14 (unpublished observations).

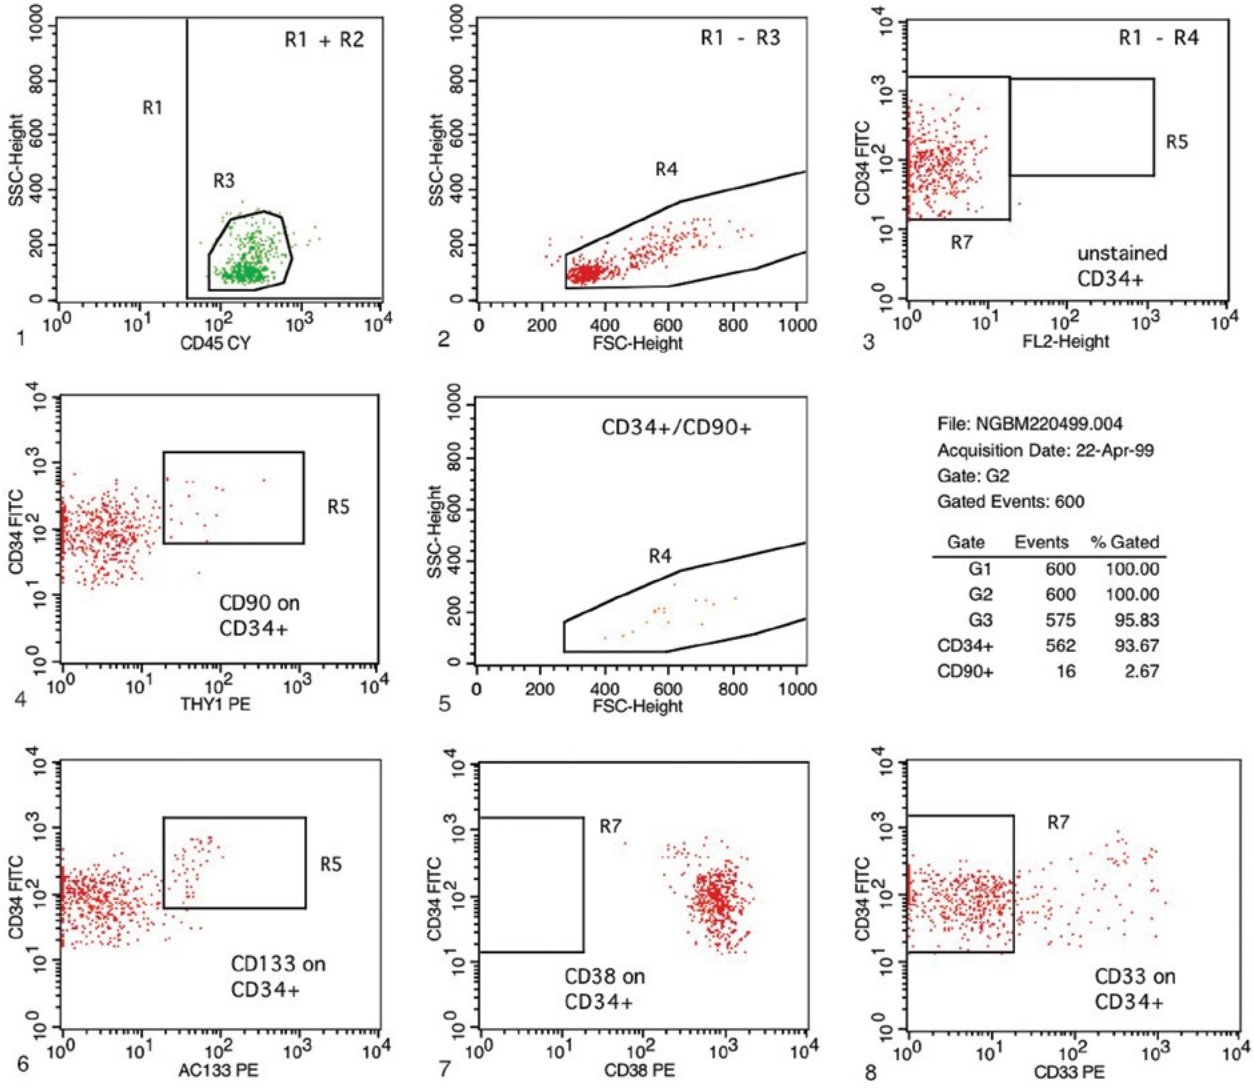

FIGURE 8 Identifying CD34+ cell subsets in the marrow of a poor mobilizer. CD34+ cells (2.00% of the total CD45+ events) were identified as shown in plots 1–4 of Fig. 1. Plots 1 and 2 show the equivalent of plots 3 and 4 from Fig. 1. The majority of CD34+ cells exhibit light-scatter characteristics of prelymphoid cells. An unstained control (no PE conjugate) of the gated CD34+ cells from R4 (plot 2) was used to establish gating regions R5 and R7 (plot 3). Plots 4, 6, 7, and 8 show the staining of gated CD34+ cells with CD90/Thy-1 (plot 4), CD133 (plot 6), CD38 (plot 7), and CD33 (plot 8). The light-scatter plot (plot 5) shows the light scatter of the CD34+/CD90+ cells. Most of the CD34+ cells exhibit staining and light-scatter characteristics of primitive B cell progenitors or hematogones. Very few CD34+ cells exhibit phenotype of primitive candidate engrafting cells ($CD34^{bright}$, CD90+, CD133+, $CD38^{dull/-}$).

In a study of patients with multiple myeloma undergoing PBSC treated with cyclophosphamide and a combination of methionyl human granulocyte colony-stimulating factor and methionyl human stem cell factor, the mobilization kinetics of $CD34^+$ subsets were monitored (66). Of 65 evaluable patients, 57 were considered not heavily pretreated and 96.5% obtained a target of $\geq 5 \times 10^6$ $CD34^+$ cells/kg in one collection. Subset analysis demonstrated the number of $CD38^-$, $CD33^-$, and $CD133^+$ subsets of $CD34^+$ cells peaked at day 11, while $CD34^+$, $CD90^+$ subsets peaked at day 10. The optimum day for leukapheresis was determined to be day 11. However, it must be noted that stem cell factor is not widely used nowadays to augment G-CSF mobilization due to safety concerns, and when it is employed, it has to be administered on an inpatient basis.

Given all of the above, it would appear that performing accurate enumeration of $CD34^+$ cells is perhaps more relevant to predicting platelet engraftment than is the qualitative composition of the $CD34^+$ cells, at least for patients receiving at least 2×10^6 to 2.5×10^6 $CD34^+$ cells/kg. In light of this analysis, it may be informative to analyze subsets only in patients whose collections are in the 1×10^6 to 3×10^6/kg range.

$CD34^+$ CELL SUBSETS IN BACKUP MARROW OF POOR MOBILIZERS

Other potential clinical applications for $CD34^+$ subset analysis might include evaluating poor mobilizers with inadequate or marginal CD34 collections, in addition to measuring qualitative differences in response to different cytokine regimens and quality assuring selected stem cell products during cell processing.

A number of studies have indicated that the use of back-up bone marrow cells does not improve engraftment in patients who failed to mobilize sufficient PBSC $CD34^+$ cells, perhaps suggesting that poor PBSC mobilization is reflective of poor marrow function (67). We analyzed the back-up marrows from a number of patients who had failed to mobilize an adequate number of PBSC $CD34^+$ cells. In the example shown in Fig. 8, $CD34^+$ cells were gated from a patient with poorly mobilized acute myeloid leukemia, and strikingly, as shown in plots 1 and 2 (the equivalent of plots 3 and 4 of Fig. 1), the majority of the $CD34^+$ cells identified exhibited the characteristics of pre-B cell or hematogones (i.e., low forward- and side-scatter signals). Subset gating regions R5 and R7 were established using the unstained sample (FMO control). When subset analysis was performed using CD90 (plot 4), CD133 (plot 6), CD38 (plot 7), and CD33 (plot 8), there was a demonstrable lack of $CD34^+$ cells exhibiting the composite phenotype of primitive candidate stem cells, with very few $CD34^+$ cells expressing the $CD34^{bright}/CD90^+/CD133^+/CD38^{dull}$ phenotype. Additionally, virtually all $CD34^+$ $CD33^{dull/-}$ cells exhibited the light scatter of lymphoid progenitors. Similar data were obtained from other poorly mobilizing patients (Sutherland, unpublished observations).

USE OF PLERIXAFOR IN PATIENTS WHO FAIL TO MOBILIZE WITH G-CSF

In 2008, the novel agent plerixafor, a CXCR4 chemokine receptor antagonist, was approved for use by the Food and Drug Administration in the United States. Plerixafor is indicated for first-line mobilization of hematopoietic stem cells into the peripheral blood for collection and subsequent autologous transplantation in patients with non-Hodgkin's lymphoma and multiple myeloma (reviewed in 68). The use of this mobilizing agent has greatly improved the ability to collect an engrafting dose of $CD34^+$ cells in patient groups known to be at risk of poor mobilization using G-CSF or its analogues alone. Several studies, including the initial phase III trials of plerixafor and G-CSF compared with G-CSF and placebo, have demonstrated that plerixafor can overcome some of the known risk factors for poor stem cell mobilization (69, 70). However, the extra cost involved in the use of plerixafor has, to date, somewhat limited its widespread use (68).

Functional Flow Cytometry-Based Assays of Myeloid and Lymphoid Functions for the Diagnostic Screening of Primary Immunodeficiency Diseases

MAURICE R. G. O'GORMAN

20

Primary immunodeficiency diseases represent an extremely diverse group of disorders caused by mutations in genes that code for multiple components of both the innate and adaptive immune systems. These mutations adversely affect immune homeostasis ultimately leading to increased susceptibility to infections, autoinflammatory disorders, and other symptoms of immune dysregulation. Although there are now more than 200 diseases that have been officially classified (1), diagnosis of primary immunodeficiency remains challenging and is often delayed due to the extremely broad range of signs and symptoms, variations in the severity and range of symptoms at presentation, and the overlap of presenting clinical symptoms of immunodeficiency with the clinical signs and symptoms of common illnesses. The extremely broad and large number of genetic abnormalities that make up the primary immunodeficiency disorders would suggest that DNA sequencing of the exome or genome should be the ultimate diagnostic modality. A recently published article describes how such an approach (i.e., DNA sequencing of the whole exome) resulted in an increased ability to detect genes associated with both known and new immune disorders (2).

Although there are exemplary cases where deep sequencing has resulted in successful diagnoses of very complex cases, challenges to the broad and routine implementation of whole exome/whole genome sequencing as it stands today include the following: (i) the technology is still in its infancy and although the sequencing technology and genetic databases continue to improve in accuracy and automation, standardized phenotypic databases lag behind particularly in terms of standardization; (ii) the technology is expensive and reimbursement remains challenging; (iii) the turnaround times are very long ranging from several weeks to months; and (iv) there is a wide range of variability in the quality and quantity of interpretation of the extremely large amount of data generated. Because of these challenges and limitations, nongenomic laboratory testing technologies will continue to have a role in the diagnostic evaluation of patients suspected of primary immunodeficiency disease. Flow cytometry represents one such essential and powerful technology and will remain so for the foreseeable future.

Laboratory evaluation and the selection of appropriate testing for a patient suspected of a primary immune deficiency should be guided by the presenting signs and symptoms, physical exam, and a careful history. First line screening tests available in most laboratories include a complete blood count and differential, evaluation of serum complement with immunoglobulin levels, and basic flow cytometric evaluation of the proportions and absolute numbers of the major lymphocyte subsets (B, T, T-helper, T-cytotoxic, and NK cells). The results of these screening tests help to guide the next level of laboratory investigation. This chapter will present a few highly specialized functional flow cytometry based tests used in the diagnosis of specific primary immunodeficiency disorders.

Table 1 provides a list of some of the functional flow cytometry-based assays available from the diagnostic immunology laboratories of four different pediatric academic medical centers and the primary immunodeficiency disorders with which they have been associated (Seattle Children's, http://www.seattlechildrens.org/healthcare-professionals/access-services/diagnostic-services/laboratories/immunology-diagnostic-laboratory/; Cincinnati Children's, http://www.cincinnatichildrens.org/service/i/immune-deficiency/diagnostic-lab/; Lurie Children's in Chicago, https://www.luriechildrens.org/en-us/care-services/specialties-services/pathology-laboratory-medicine/specialties-laboratories/Pages/index.aspx; Milwaukee Children's, http://www.chw.org/medical-care/immune-deficiency/clinical-immunodiagnostic-research-laboratory). Individuals interested in the services of these laboratories should contact them directly to inquire about specimen requirements for specific tests.

FLOW CYTOMETRIC EVALUATION OF PHOSPHORYLATED KINASE SUBSTRATES TO EVALUATE ABNORMALITIES IN IMMUNE SIGNALING PATHWAYS

Cell signaling via cytokine, chemokine, and antigen receptors on the surface of cells of the immune system is controlled in part by the phosphorylation and dephosphorylation of an ordered series of kinase and phosphorylase targets along well defined pathways leading the transcription of specific target genes. Signaling via these surface molecules controls many functions of the immune response including proliferation, differentiation, cytotoxicity, cytokine secretion, antibody production, and apoptosis. The advent of reagents to detect specific phospho-epitopes within the cytoplasm and nucleus along with standardized methods of fixing and permeabilizing cells has led to a new line of functional "phospho-flow cytometry" based assays designed to assess signaling defects

doi:10.1128/9781555818722.ch20

TABLE 1 Functional flow cytometry-based assays which have been used as aids in the diagnosis of specific primary immunodeficiency diseases

- STAT1 phosphorylation in response to IFN-γ (screening test for IFN-γ receptor deficiency, in patients suspected of Mendelian Susceptibility to Mycobacterial Disease)
- STAT3 phosphorylation in response to IL-6 (hyper IgE syndrome screening)
- STAT4 phosphorylation in response to IFN-α and IL-12 (screening test for IL-12 receptor deficiency and Tyk2 deficiency)
- STAT5B phosphorylation in response to IL-2 (screening test for common gamma chain deficiency [X-linked SCID] and Janus kinase 3 deficiency)
- STAT5B phosphorylation in response to IL-7 (screening test for IL-7 receptor alpha deficiency)
- IκBα phosphorylation/degradation assay (screening for anhidrotic ectodermal dysplasia with immunodeficiency)
- Beta 2 leukocyte integrin upregulation on granulocytes (screening assay for LAD-1)
- *In vitro* assessment of CD40 ligand upregulation (screening assay for CD40 ligand deficiency [XHIM])
- Lymphocyte apoptosis, Fas-mediated (screening test for autoimmune lymphoproliferative syndrome)
- Apoptosis assays (screening test for autoimmune lymphoproliferative syndrome)
- Neutrophil oxidative burst assay (screening test for chronic granulomatous disease)
- NK cell function (screening for hemophagocytic lymphohistiocytosis (HLH))
- Cytotoxic T-cell degranulation (CD107a) assay (screening test for HLH)

in specific signaling pathways. For example, primary immunodeficiency diseases associated with mutations in signaling molecules (e.g., STAT1 and STAT3) or cytokine receptor genes (e.g., common gamma chain, gamma interferon [IFN-γ] receptors, and interleukin-7 [IL-7] and IL-12 receptors) can be screened by stimulating peripheral blood cells with specific agonists and comparing activation induced phosphorylation levels with baseline levels. Examples include the measurement of phosphorylated STAT5 following IL-2 stimulation to screen for abnormalities in the IL-2 signal transduction pathway associated with abnormalities in the common gamma chain, Janus kinase 3, or IL-7 receptor (Seattle Children's Website). Another example involves the measurement of STAT1 phosphorylation levels following IFN-γ stimulation to screen for abnormalities in the type 1 cytokine signal transduction pathway associated with chronic mucocutaneous candidiasis or recurrent atypical mycobacterial infections.

A relatively simple flow cytometric approach to assess abnormalities in STAT1 phosphorylation as the molecular etiology of disease in patients with chronic mucocutaneous candidiasis or patients suspected of Mendelian susceptibility to mycobacterial disease is presented.

INDUCTION AND MEASUREMENT OF STAT1 PHOSPHORYLATION LEVELS AS A SCREEN FOR TYPE 1 CYTOKINE SIGNALING ABNORMALITIES ASSOCIATED WITH PRIMARY IMMUNODEFICIENCY

Severe and recurring infections in family members with intracellular organisms including Bacille Calmette-Guerin (BCG) and nontuberculous mycobacteria (*Mycobacterium avium, Mycobacterium fortuitum, Mycobacterium chelonae*) led to the identification of mutations in genes involved in the type 1 cytokine signaling pathway (3, 4). This pathway involves IFN-γ receptors (IFN-γR1 and IFN-γR2), IL-12 (IL12p40), and IL-12 and IL-23 receptors (IL-12Rβ1). IL-12, secreted primarily by monocytes/macrophage, stimulates T cells and NK cells to synthesize and secrete INF-γ, which in turn activates macrophage and further stimulates cytolytic $CD4^+$ T cells and effector $CD8^+$ T cells, which then kill infected macrophage (5). Decreased IL-12 receptor expression and both increases and decreases in the level of expression of the IFN-γ receptors have been reported and can be detected by flow cytometry (3, 4, 6). In the dominant form of inheritance, mutations in the gene encoding the IFN-γ receptor leads to an increase in cell surface expression of the IFN-γ receptor due a deletion encompassing both the signaling and the recycling domains. The lack of specificity in associating surface receptor expression levels to specific genetic mutations has led to the development of surrogate functional flow cytometry assays based on the ability to detect phosphorylated STAT1 following *in vitro* stimulation with IFN-γ (3). Lack of STAT1 phosphorylation, as detected by flow cytometry following *in vitro* stimulation with IFN-γ, indicates either abnormal IFN-γ receptor molecules (IFN-γR1 or IFN-γR2) or abnormalities in STAT1 itself, whereas normal *in vitro* STAT1 phosphorylation levels in a patient with repeat atypical mycobacterial infections might suggest abnormalities in either the IL-12 gene or the IL12 receptor genes. Either result allows for the focused determination of the genes to be sequenced. The determination of the specific underlying genetic mutation is very important since (i) the prognosis is associated with the different forms of genetic lesions and (ii) the specific defect has implications for the design of optimal therapeutic interventions (7). Although the detection of intracellular phosphorylated STAT1 following *in vitro* stimulation with IFN-γ is relatively straightforward, development of a standardized, reproducible clinical procedure is relatively complex, is performed only in more specialized flow cytometry laboratories, and has been used primarily to help focus on the potential defect so that only a limited number of likely genes needs to be sequenced.

FLOW CYTOMETRIC DETERMINATION OF STAT1 GAIN-OF-FUNCTION ALLELES IN PATIENTS WITH CMCD

More recently, a modification of the STAT1 functional flow cytometry procedure was published that describes a relatively simple diagnostic approach to identify gain-of-function STAT1 mutations in patients with chronic mucocutaneous candidiasis (CMCD) (8). Patients with CMCD suffer from difficult-to-treat and recurrent infections with *Candida albicans* of the nails, skin, and mucous membranes. It has been reported that some patients with CMCD have mutations in the IL-17 pathway; however, this represents only a minority (8). More recently, gain-of-function mutations in STAT1 have been associated with a majority of patients with CMCD (9). Mizoguchi describes a modified flow cytometry

procedure for the measurement of STAT1 phosphorylation (8). Basically, peripheral blood mononuclear cells (PBMCs) are stimulated with IFN-γ in the presence of the tyrosine kinase inhibitor staurosporine, and the fluorescence intensity (mean fluorescence intensity) of STAT1 in CD14-labeled monocytes is assessed. The monocytes of patients with gain-of-function mutations in STAT1 exhibited significantly higher levels of phosphorylated STAT1 than the healthy controls both at baseline (unstimulated) and in the presence of staurosporine following IFN-γ stimulation. The abnormal decrease of phosphorylated STAT1 in patients with CMCD indicates that the dephosphorylation process is impaired. Although currently not commonly available, this assay may prove useful for screening patients with CMCD. Patients with abnormally high levels of phosphorylated STAT1 in the presence of staurosporine should be sequenced to confirm the abnormalities in the STAT1 gene.

CELL SURFACE ADHESION MARKER UPREGULATION AS A SCREEN FOR LAD-1

LAD-1, CD18 Deficiency

Leukocyte adhesion deficiency type-1 (LAD-1) is a rare inherited disorder of the innate immune system caused by an inability of immune cells to adhere to the endothelium and migrate to the site of infection. It is characterized clinically by defective wound healing, cold infections (i.e., no pus) with Gram-negative bacteria, delayed umbilical cord separation, gum disease (gingivitis and/or periodontitis), and very high peripheral blood white blood cell counts. These abnormalities are associated with mutations in the gene encoding the beta chain (CD18) of the β2-class of leukocyte integrins. The absence of the beta chain (CD18) results in its inability to complex with the alpha chains CD11a, CD11b, CD11c, and CD11d, resulting in the functional abnormality of four key cell surface receptors involved in the innate immune response (i.e., LFA-1 [CD18/CD11a], Mac1 [also known as complement receptor 3/CR3, CD18/CD11b], CR4 [CD18/CD11c], and CD18/CD11d [of which little is known]) (10).

Flow Cytometric Assessment of Cell Surface Adhesion Marker Upregulation as a Screen for LAD-1

A patient with a clinical history and laboratory findings (very high white blood cell count) consistent with LAD-1 presented to the emergency room and proved to have cell surface abnormalities consistent with LAD-1. With the patient's informed consent, our laboratory studied various stimuli (to measure both baseline and activated levels) and monoclonal antibody combinations to each of different beta-2 integrins in an effort to develop a whole blood flow cytometry-based diagnostic test (11). An efficient whole blood procedure was developed and remains in use in our laboratory. Briefly, an optimized concentration of phorbol myristate acetate is added to EDTA anti-coagulated whole blood for 15 minutes (stimulated sample) followed by the staining of the stimulated sample and a non-stimulated sample with anti-CD11b (CD11b-PE, BD Bioscience). A fluorochrome matched non-human antigen-specific monoclonal isotypic control is used to set the background level of fluorescence of the granulocyte cluster (by gating on forward versus right angle light scatter parameters). Note that the background fluorescence will be higher on the granulocytes than the level of fluorescence generally observed when gating on the lymphocyte cluster. The level of CD11b expressed on the surface of gated granulocytes is then measured (as the median fluorescent channel) on both resting (non-activated) and *in vitro* activated granulocytes (see gating and results of typical flow assay in Fig. 1). A normal range was established based on a group of 30 non-diseased control subjects and is used to evaluate the patient's results. Patients with LAD-1 can express CD11b significantly below normal on both resting and stimulated granulocytes. Performing *in vitro* stimulation is recommended, as occasionally patients with LAD-1 will have levels of CD11b on resting granulocytes that are consistent with normal; however, this level does not increase following stimulation. Patients with severe LAD-1 do not survive infancy and express no detectable CD18, CD11a, CD11b, or CD11c protein on the cell surface, whereas patients with the moderate form of LAD-1 express 1 to 10% of the level of normal and can survive into adulthood (12).

MEASUREMENT OF THE UPREGULATION OF CD40 LIGAND ON ACTIVATED T CELLS AS A SCREENING DIAGNOSTIC TEST FOR CD40 LIGAND DEFICIENCY (FORMALLY KNOWN AS XHIM)

The proliferation of B cells and their differentiation into plasma cells secreting IgG, IgA, and IgE (immunoglobulin gene class switching) requires a complex series of cellular interactions and molecular processing of the immunoglobulin genes. Immunoglobulin class switching and somatic mutation of the immunoglobulin genes are required for a functionally effective antibody response and normal humoral immunity. Patients with mutations in the genes involved in immunoglobulin gene class switching are unable to produce immunoglobulins other than IgM and suffer from infections very similar to those of patients with hypogammaglobulinemia. The CD40 ligand expressed on the surface of activated T-helper cells is essential for the proliferation, maturation, and differentiation of B cells to immunoglobulin class-switched plasma cells. Patients with mutations in the gene encoding CD40 ligand also suffer from opportunistic infections due to an abnormal T-cell response resulting from a failure of cross talk (co-stimulation) between activated T cells and B cells. These patients can also experience significant neutropenia (CD40 receptor is expressed on neutrophils) although the exact mechanism of neutropenia is not well understood. Our laboratory has developed a relatively rapid functional assay to assess the ability of T cells to upregulate the CD40 ligand. This assay has been successfully adopted to diagnose patients with CD40 ligand deficiency (X-linked hyper IgM syndrome or type 1 hyper IgM syndrome [XHIM]) as well as their X-linked carrier mothers (13).

MEASUREMENT OF CD40 LIGAND ON *IN VITRO*-ACTIVATED T-HELPER CELLS AND CD40 RECEPTOR ON B CELLS AS A SCREENING DIAGNOSTIC TEST FOR THE CD40 LIGAND DEFICIENCY

Following the discovery of the underlying cause of XHIM (i.e., mutations in the gene encoding the CD40 ligand) and the commercial availability of monoclonal antibody specific for CD40 ligand, our laboratory designed, developed, and validated a clinical flow cytometry procedure for the screening diagnosis of XHIM patients and carriers (11). Briefly, whole blood is stimulated with phorbol ester and a calcium ionophore for 4 hours, followed by the staining of

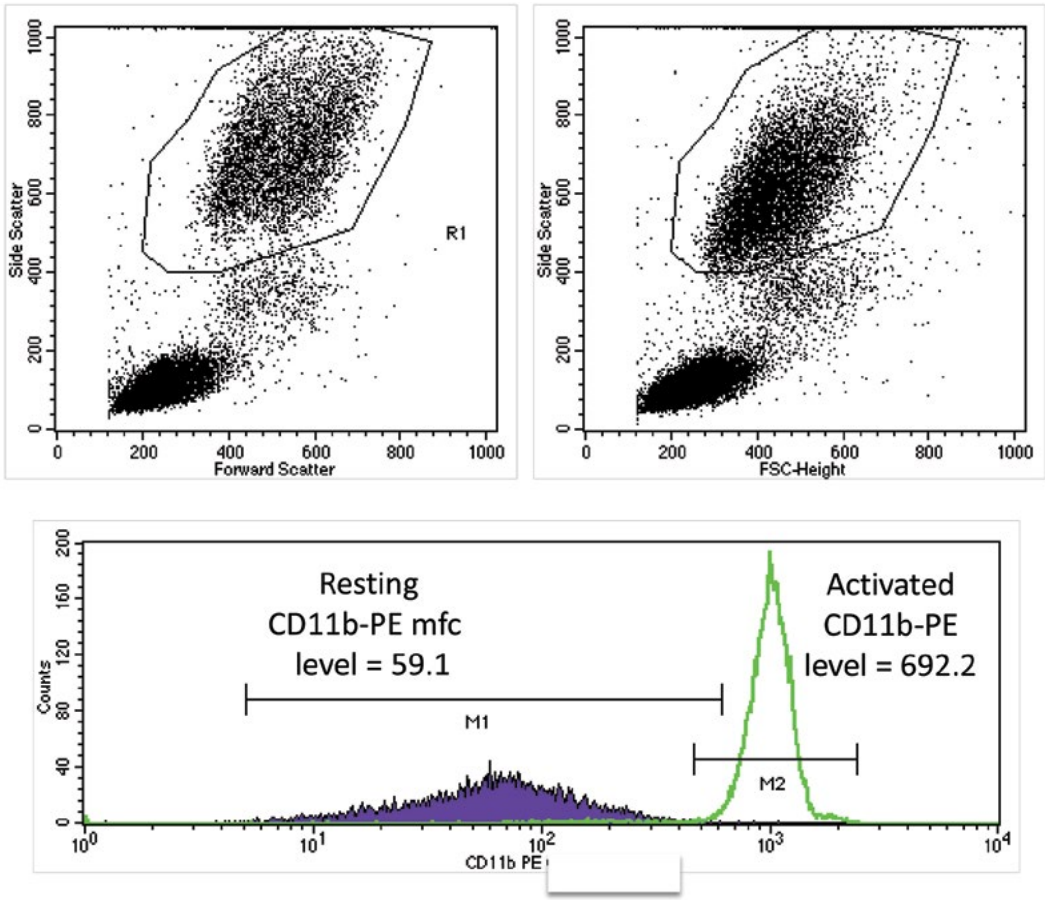

FIGURE 1 Flow cytometry-based LAD screening assay on a nondiseased healthy donor. Granulocytes are gated based on their innate forward and right angle light scatter properties. The level of CD11b-PE fluorescence on resting (purple) versus PMA-stimulated granulocytes is displayed. Note that in LAD-1 both the resting and activated levels of CD11b are considerably lower than normal. Normal ranges for the level of CD11b, expressed as the geometric mean fluorescence, were determined on 30 healthy nondiseased control patients. Normal CD11b was expressed as greater than the 5th percentile of normal.

lymphocytes with a panel of monoclonal antibodies including CD3, CD8, CD40 ligand (TRAP-10 clone conjugated with phycoerytherin, Pharmingen, San Diego, CA), and CD69 (as an *in vitro* stimulation control). Following the labeling procedure, the red blood cells are lysed, the cells are fixed, and the samples are acquired and analyzed on the flow cytometer using a novel gating strategy (see Fig. 2). During the development of this assay we observed the following *in vitro* induced immune alterations. Phorbol 12-myristate 13-acetate (PMA) induces the rapid modulation of the CD4 molecule off the cell surface. This requires a negative gating strategy (i.e., $CD3^{+}CD8^{-}$ cells). The process of PMA-induced CD40 ligand cell surface expression (transcription and translation) is calcium dependent. Therefore, EDTA anticoagulated blood is not recommended.

Abnormal CD40 ligand expression had been detected in all of our patients with mutations in the CD40 ligand gene until recently. Although a nonsense mutation in the gene was confirmed in one patient, the level of CD40 ligand detected was consistent with normal. Others have reported this observation in the past (14). This false-negative result led to a modification of the procedure to include the measurement of CD40 ligand expression levels using a directly fluoresceinated chimeric CD40 receptor reagent in addition to measuring CD40-ligand expression levels by the monoclonal antibody. To date, all patients with mutations in the CD40 ligand gene have had abnormal CD40 ligand protein expression in the modified assay. Most laboratories with a moderate amount of flow cytometry experience could perform this assay.

Mutations in the gene encoding the CD40 receptor (formerly classified as HIGM3) lead to a clinical phenotype virtually identical to the X-linked form of the hyper IgM syndrome. Abnormal expression of the CD40 receptor is detected by gating on B cells (CD19 or CD20) and measuring the percentage of CD40 positive events (normal range is defined as >90% of B cells expressing CD40 [unpublished data from our laboratory]). The latter form of autosomal recessive hyper IgM syndrome is very rare (15).

A FLOW CYTOMETRY-BASED OXIDATIVE BURST ASSAY AS A SCREEN FOR THE DIAGNOSIS OF CGD

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is the most common of the phagocyte primary immunodeficiency disorders. The genetic abnormalities in CGD result in a severely reduced capability to generate superoxide and other reactive oxygen

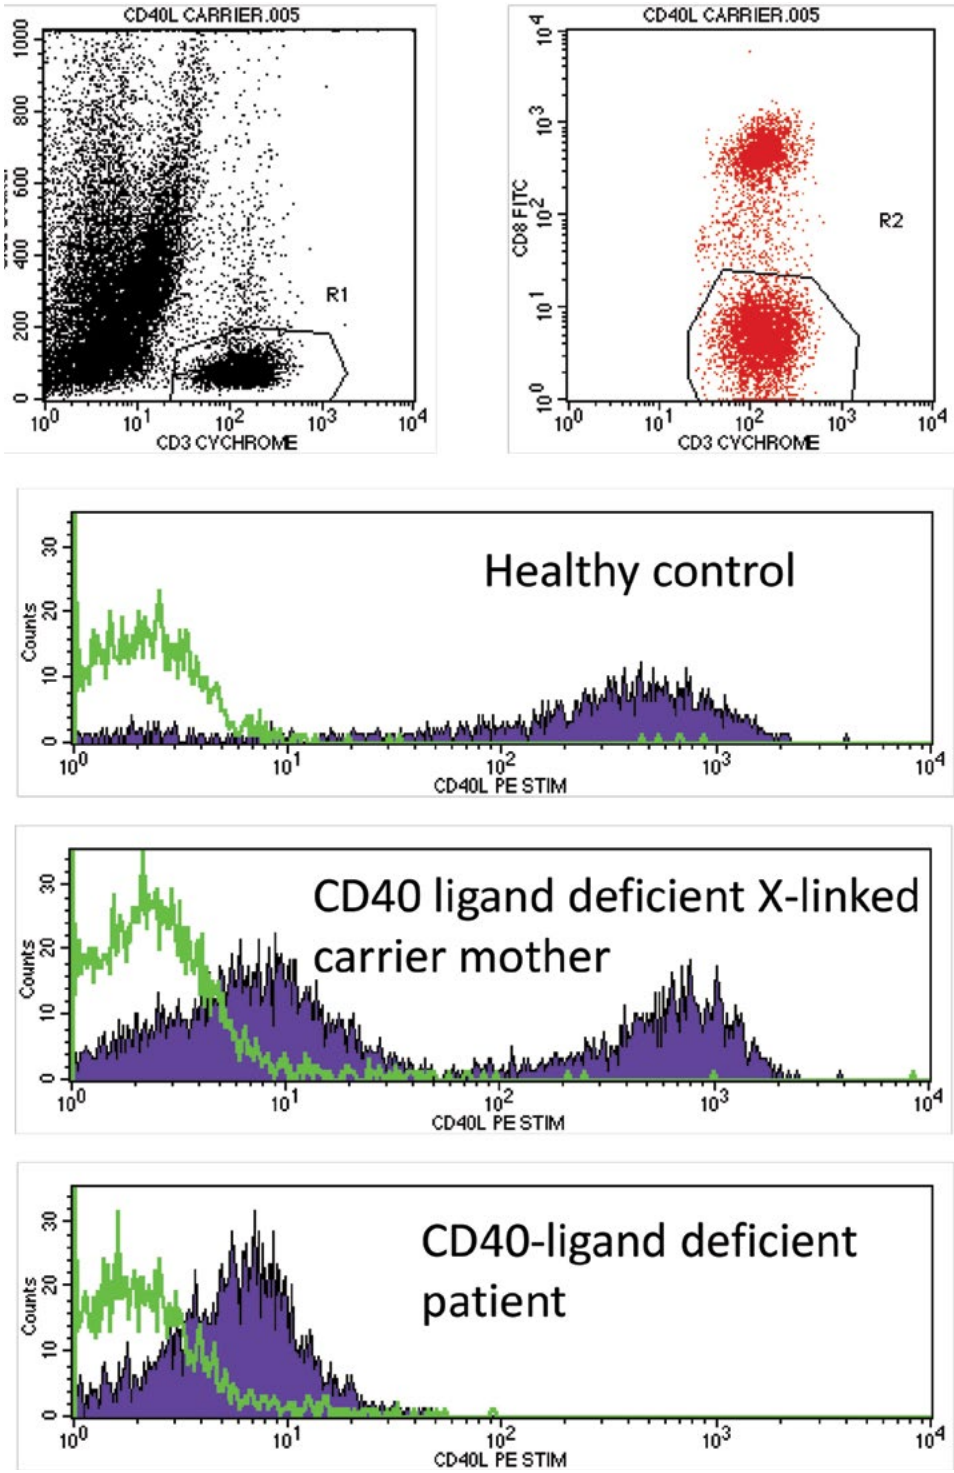

FIGURE 2 Gating algorithm and histogram display of CD40-ligand upregulation on *in vitro* activated CD4 positive T cells. (Upper left) Dot plot of right angle light scatter versus CD3 (T cells). A gate is drawn around the CD3 positive cluster (R1). The events within R1 are then displayed on a dot plot of CD3 (*x*-axis) vs. CD8 (*y*-axis). A gate is drawn around the CD3 positive events and the CD8 negative events which contain primarily CD4 positive T cells. The expression of CD40 ligand is then assessed on the $CD3^{+}CD8^{-}$ T cells. Each dot plot illustrates the level of CD40-ligand (purple) overlaid on an isotype control (green). Note the middle histogram displays the results from the CD40-ligand deficient patient's mother, who is an X-linked carrier. Note the two populations of T cells, one with a normal level and one with a level essentially overlapping the CD40 ligand level observed on the activated T cells of her son. These results are essentially diagnostic of the X-linked hyper IgM syndrome.

species, which in turn results in abnormal microbial killing within phagocytes. Abnormal phagocyte NADPH oxidase activity is caused by mutations in one of five known NADPH subunit genes, i.e., CYBB (gp91^{phox}), CYBA (p22 ^{phox}), NCF1 (p47 ^{phox}), NCF2 (p67 ^{phox}), and NCF4 (p40^{phox}). The most common form of CGD is caused by mutations in the X-linked gene, *gp91phox* (70% of CGD cases); the remainder of the cases occur as a result of mutations in the autosomally encoded genes: *p22phox* (the other component of membrane flavocytochrome b558), *p47phox*, and *p67phox* (16). Patients with mutations in any of these genes have a common phenotype, including susceptibility to recurrent bacterial and fungal infections as well as granuloma formation and other associated autoimmune complications. Most patients, if not diagnosed and treated, will succumb to the disease.

The Oxidative Burst Assay as a Screening Test for the Diagnosis of CGD

The principle of the flow cytometry-based oxidative burst assay is the detection of an increase in fluorescence from a nonfluorescent oxygen-sensitive dye following the induced exposure to reactive oxygen intermediates generated during an oxidative burst. Patients with CGD are unable generate an oxidative burst and are easily identified because they cannot oxidize the dye (i.e., dye will remain nonfluorescent). The first flow cytometry-based procedures utilized dichlorofluorescein diacetate (DCFH-DA), which was added to PBMCs following their isolation, washing, and counting. Our laboratory developed a simplified procedure using the uncharged nonfluorescent dye dihydrorhodamine 123 (DHR-123), added directly to whole blood. This modification simplified the procedure, allowing for the use of less blood and a much faster turnaround time than previously published methods (17, 18). The assay developed in our laboratory has become widely adopted internationally. Briefly, appropriately titered DHR-123 is added directly to diluted whole blood and incubated in a shaking water bath at 37°C for 15 minutes, followed by the addition of PMA for an additional 15 minutes at 37°C. After these incubations, the red blood cells are lysed (ammonium chloride-based solutions are preferred to prevent the dye from leaking out of the cells too quickly), the remaining cells are fixed in 1% paraformaldehyde, and samples are run immediately on the flow cytometer. Results are expressed as a ratio of the fluorescence in stimulated cells to the fluorescence observed in unstimulated cells, which is referred to as the normal oxidative index (NOI). It is recommended that laboratories performing this assay develop their own normal ranges. In the absence of confirmed CGD in a family member, abnormal results require follow-up genetic testing to confirm mutations in one of the known components of the phagocyte NADPH oxidase system. Generally patients with the autosomal form of CGD (p47phox) have significantly higher NOI than the patients with X-linked CGD (gp91phox) and the fluorescence levels can be more variable (increased CV) than those in both the X-linked CGD patients and healthy non-diseased controls (19). It is important to note that false-positive results (i.e., result is consistent with CGD) have been observed in patients with complete myeloperoxidase deficiency (20). It is recommended that MPO levels be assessed in all patients with a positive flow cytometry result (consistent with CGD).

The assay also successfully identifies patients who are carriers of the X-linked form of CGD. X-linked CGD carriers with less than 15% normal granulocytes can be readily identified in the flow cytometry based DHR123 assay, whereas such patients cannot be reliably diagnosed in the nitroblue tetrazolium CGD assay. Parents of CGD patients with the autosomal forms of the disease will have oxidative burst assay results that are consistent with normal (personal experience). The DHR-based flow cytometry oxidative burst assay is very sensitive. Vowells (19), using a similar flow-based DHR 123 procedure, was able to consistently detect 0.1% normal granulocytes when they were mixed with a CGD patient's cells. The gating and the results obtained from a normal control, an X-linked CGD patient, and the X-linked CGD patient's mother (an X-linked carrier) are presented as Fig. 3.

Measurement of Abnormal T Cell and NK Cell Cytotoxicity as an Aid in the Diagnosis of Patients Suspected of FHL Syndromes

Hemophagocytic lymphohistiocytosis (HLH) represents a life-threatening hyperinflammatory syndrome caused by the over-activation of T cells and macrophage. Primary or familial hemophagocytic lymphohistiocytosis (FHL) is fatal, and the only current treatment is bone marrow transplantation. Secondary HLH occurs in the setting of systemic autoimmunity, hematologic malignancy, and severe infection. Secondary HLH is clinically indistinguishable from FHL but has been successfully treated with immunosuppression. Both forms of the disease are triggered by infection and are very difficult to differentiate unless the underlying genetic etiology is identified. However, sequencing is expensive and can take several weeks, and not all genetic causes have been identified. An early test to differentiate primary versus secondary HLH would allow for the initiation of appropriate therapy early in the course of disease.

Killing by cytotoxic T cells and NK cells represents a significant immune function responsible for the elimination and control of virus-infected cells and transformed tumor cells. A surrogate of killing potential can be assessed by the stimulation and subsequent measurement of specific markers associated with the cytotoxic granule degranulation process expressed on the surface of NK cells and cytotoxic T cells (21). Flow cytometry-based degranulation assays have become available for the rapid diagnostic assessment of patients suspected of FHL syndromes. A recent prospective evaluation of a standardized functional assay of cytotoxic degranulation suggests this assay can provide a rapid and reliable method to help classify patients suspected of primary (FHL) versus secondary HLH (22).

MEASUREMENT OF CELL SURFACE CD107A AS A SURROGATE OF THE DEGRANULATION PROCESS INVOLVED IN T CELL AND NK CELL CYTOTOXICITY

CD107a is present in the lysosomes of NK cells and T cells along with perforin and is expressed on their cell surface following the engagement of the T cell receptor and activating receptors on NK cells. The induced expression of CD107a on the cell surface is thought to reflect exocytosis of lytic granules from these cells. Four European reference laboratories developed a standardized a procedure to measure the surface expression of CD107a on T cells and NK cells as a surrogate measure of cytotoxic degranulation and prospectively evaluated the ability of the assay to detect and differentiate primary (familial) from secondary HLH (20). The test is performed as follows. PBMCs are isolated from whole blood and rested either overnight in culture media with or without IL-2 (NK cell cytotoxicity) or in culture for 2 days with phytohemagglutinin (T cell cytotoxicity). Following the incubation period, the PBMCs (both resting

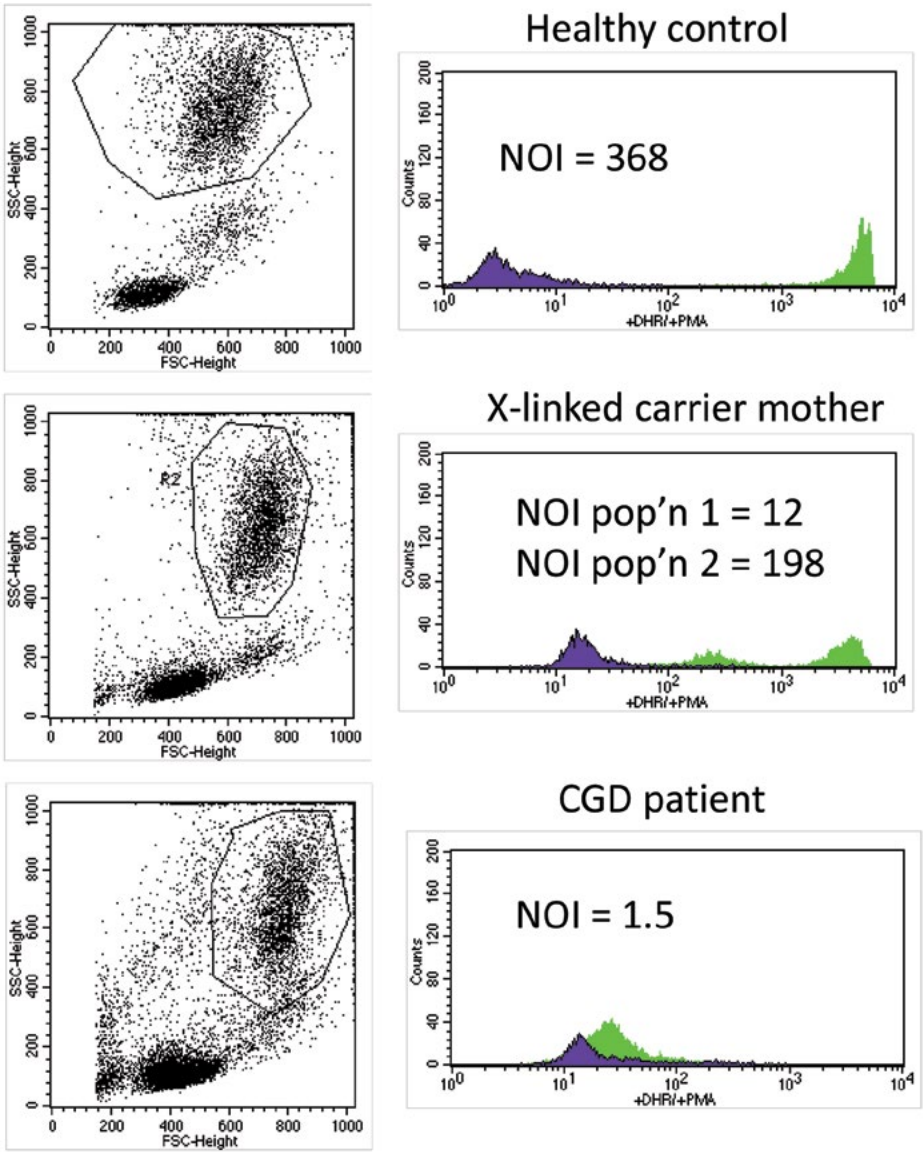

FIGURE 3 The flow cytometry oxidative burst assay for normal healthy control father (top), X-linked CGD carrier mother, and CGD patient. Granulocytes are gated on their innate forward and right angle light scatter properties (left column). The right-hand column presents histograms of the DHR (FL1/FITC) fluorescence levels of unstimulated whole blood granulocytes incubated with the dye (purple) overlaid on PMA-stimulated granulocytes that had been preincubated with DHR (green). Note the middle histogram results of the X-linked carrier mother with two populations of granulocytes, ne with a normal NOI (NOI = 198) and one with an abnormal NOI (NOI = 12). Normal NOI is >30 (developed in our laboratory by testing 35 normal healthy controls).

and activated) are cultured with and without K562 cells for 2 hours at 37°C and then stained for cell surface expression of CD107a and NK markers ($CD3^{-}CD56^{+}$). Cytotoxic T cell activity is assessed after 48 hours of incubation with phytohemagglutinin followed by staining with CD107a and cytotoxic T cell markers ($CD3^{+}CD8^{+}$).

Results are expressed as delta percent CD107a for NK cell cytotoxicity (difference in the percent positive between the NK cells cultured with versus NK cells cultured without NK-sensitive K562 target cells) or the delta mean fluorescent intensity of CD107a for activated T cells. The results of a prospective study of patients suspected of primary or secondary HLH indicated that the resting NK cell degranulation assay (not stimulated by IL-2 overnight) was 96% sensitive and 88% specific for reliably classifying patients as having primary HLH. Although the CTL assays performed equally well, the authors (20) suggest that CTL assays are optional and more useful for patients with very few NK cells. There are only a few institutions in the United States currently performing degranulation assays to help diagnose and classify HLH.

SUMMARY

Diagnosis of any of the more than 200 primary immunodeficiency diseases remains challenging due to the scope of genetic defects and variations in clinical presentations. The

ability to measure functional immune parameters *in vitro* has allowed for the development of flow cytometry procedures that aid in the diagnosis of specific primary immunodeficiency diseases, provide important adjunct information towards a diagnosis, or can serve to significantly limit the time, cost, and scope of the diagnostic odyssey. This chapter presents an overview of specific immunodeficiency diseases where relatively simple flow cytometry-based procedures have been developed to aid in their assessment.

Acute Lymphoblastic Leukemia/Lymphoma: Diagnosis and Minimal Residual Disease Detection by Flow Cytometric Immunophenotyping

JOSEPH A. DiGIUSEPPE

21

Acute lymphoblastic leukemia (ALL) and lymphoblastic lymphoma are malignant neoplasms of progenitor cells committed to B-lineage or T-lineage lymphopoiesis, termed lymphoblasts (1). Distinction between lymphoblastic leukemia (predominantly bone marrow with or without peripheral blood involvement) and lymphoblastic lymphoma (predominantly mass-forming nodal and/or extranodal disease) is largely clinical; however, the presence of greater than 25% bone marrow blasts generally prompts the designation of "leukemia" in most protocols, regardless of the presence of a mass lesion (2, 3). In the most recent World Health Organization (WHO) classification (2–4), B lymphoblastic leukemia/lymphoma is further subclassified on the basis of recurrent genetic abnormalities, while T lymphoblastic leukemia/lymphoma, despite the existence of recurrent genetic abnormalities, is not further subclassified (Table 1).

On the basis of morphology alone, B and T lymphoblastic leukemia/lymphoma cannot be distinguished from one another; nor, in many instances, can either be distinguished from acute myeloid leukemia (AML). With an appropriate panel of monoclonal antibodies, though, immunophenotyping by flow cytometry enables accurate resolution among these diagnostic entities in a matter of hours, thereby permitting the institution of appropriate therapy in a timely fashion. In certain instances, flow cytometric immunophenotyping may also anticipate recurrent genetic abnormalities. Finally, flow cytometry has been used to identify rare leukemic cells in patients who have achieved remission by conventional clinical and pathologic criteria. The presence of such "minimal residual disease" (MRD) is strongly associated with risk of recurrence (5–7), and its early detection enables more precise risk stratification in the selection of postinduction therapy.

NORMAL COUNTERPARTS

Antigenic expression by neoplastic lymphoblasts resembles, albeit imperfectly, that of their normal counterparts. It is therefore helpful to understand the spectrum of antigenic changes that occurs during normal B-lymphopoiesis in the bone marrow and T-cell maturation in the thymus.

Although earlier stages in B-cell ontogeny have been detected in small numbers in normal human bone marrow (8, 9), as a practical matter, surface-membrane CD19 expression identifies a preponderance of bone marrow cells committed to B-lymphopoiesis. Immunophenotypic patterns of maturation among $CD19^+$ B-cell precursors (historically referred to as "hematogones") are characteristic (10–12) and are illustrated in Fig. 1. As maturation proceeds, expression of CD19, CD20, and CD45 increases, while that of terminal deoxynucleotidyl transferase (TdT) (not shown), CD10, CD34, and CD38 is lost (Fig. 1). Many of these changes are coordinated in a stepwise fashion such that early, intermediate, and late stages can be described (12). Polytypic surface-membrane immunoglobulin light chain expression is first detectable on intermediate- or late-stage precursors, after the loss of TdT and CD34, while mature B cells are $CD10^-$, with bright CD20 and CD45 (Fig. 1).

T-cell maturation in the thymus likewise proceeds through a series of immunophenotypic stages (11, 13). As with B-cell precursors in bone marrow, the earliest thymic T-cell precursors are TdT^+, $CD10^+$, $CD34^+$, and $CD45^{(dim)+}$ (Fig. 2). CD3 is expressed in the cytoplasm, but not on the cell membrane, in these $CD4^-/CD8^-$ ("double-negative") T cells, the least differentiated of which are termed early T-cell precursors (ETPs) (14). With maturation, there is progressive expression of CD4, which is subsequently accompanied by that of CD8 in so-called "double-positive" cortical thymocytes. Acquisition of CD4 and CD8 expression is accompanied by CD1a expression, an increase in CD45 density, and loss of TdT, CD10, and CD34. Loss of CD1a, acquisition of surface-membrane CD3, and loss of CD8 or CD4, respectively, yield mature $CD4^+$ or $CD8^+$ T cells.

DIAGNOSIS

As noted previously, flow cytometric immunophenotyping with an appropriate panel of monoclonal antibodies permits distinction of B- and T-lymphoblastic leukemia/lymphoma from each other and from AML. Although each clinical laboratory typically develops its own panel of antibodies, certain antigens are generally acknowledged as being most useful for the diagnosis of ALL/lymphoblastic lymphoma (reviewed in references 1–4, 15, and 16). More recent studies have identified additional antigens useful in the context of MRD detection (17–22). Table 2 lists the antibody combinations used in our laboratory. Not all of these are required in every case, though. Combinations 1, 2, and 8 through 10 would suffice to establish a diagnosis of B lymphoblastic

leukemia and to exclude mixed-phenotype acute leukemia, while combinations 1 and 6 through 10 would permit the diagnosis of T lymphoblastic leukemia and exclusion of mixed-phenotype acute leukemia. Antibody combinations used for the detection of MRD in B and T lymphoblastic leukemia are also indicated in Table 2.

Important methodologic and quality-control issues that are generally applicable to flow cytometric immunophenotyping have been discussed in detail separately (Biancotto and McCoy, chapter 17, this volume). However, a few specific practices are recommended to improve the quality of the immunophenotypic data acquired in acute leukemia: exclusion of cellular doublets and other coincident events, exclusion of debris and nonviable cells, and identification of an appropriate blast gate for the leukemia in question. When fluorochrome-conjugated antibodies bound to more than one cellular event are simultaneously excited by the laser, whether due to statistical coincidence or cellular aggregation, the resulting signals do not accurately reflect the phenotype of any single cellular population. These artifactual data can be excluded by gating on singlet events whose area, height, and width signals are highly correlated (23) (Fig. 3). Nonspecific binding of labeled antibodies and/or fluorochromes to cellular debris, platelets, and nonviable cells is another cause of spurious fluorescence signals. The latter can be reduced by gating on singlet events with the light scatter properties of viable cells (Fig. 3); however, care must be taken to ensure that the neoplastic cells are not inadvertently excluded. Finally, since lymphoblasts commonly express CD45 more weakly than their mature lymphoid counterparts (24), a blast gate comprising $CD45^{(dim)+}/SSC^{(low)}$ events frequently permits exclusion of mature lymphocytes and other cells that could contaminate a conventional mononuclear-cell gate (15) (Fig. 3).

A general principle in the design of antibody panels for lymphoblastic leukemia/lymphoma is that no single surface-membrane antigen is both sensitive and specific for B or T lymphoblastic leukemia. In the case of B lymphoblastic leukemia, CD19 and CD22 are the most commonly expressed lineage-related surface antigens and CD7 is essentially always expressed in T lymphoblastic leukemia. However, all three antigens may also be expressed in AML. Other surface antigens useful in the diagnosis of B lymphoblastic leukemia include CD10 (positive in the vast majority of cases), CD20 (relatively specific for B-cell lineage, but not sensitive), CD34 (positive in most cases), and HLA-DR (which is virtually always positive). In the case of T lymphoblastic leukemia, useful lineage-related surface

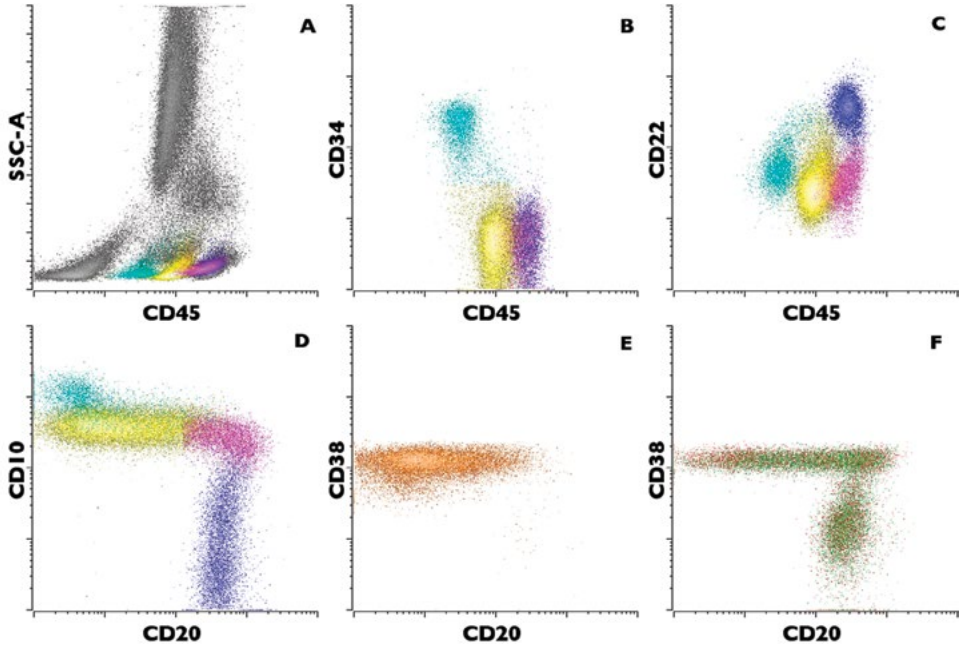

FIGURE 1 Immunophenotypic patterns of normal B-cell maturation in bone marrow. (A) Gated on all viable cells; B-cell maturational stages denoted by different colors. (F) Gated on $sCD3^+$ T cells.

antigens include CD1a, CD2, CD3, CD4, CD5, and CD8. The most sensitive of these (CD2) is not specific, while the most specific (CD1a, CD3, and CD8) are seen in fewer than half of cases. CD10, CD34, and HLA-DR may also be expressed in T lymphoblastic leukemia but at a lower frequency than in B lymphoblastic leukemia.

Although no single surface antigen defines T-cell lineage, cytoplasmic expression of the epsilon chain of the T-cell receptor (cyCD3) is both sensitive and specific for T lymphoblastic leukemia (though activated adult natural killer cells apparently may also express cyCD3-ε; 25). A caveat to the use of cyCD3 to define T-cell lineage, however, is that polyclonal antibodies to CD3 commonly used for immunohistochemistry may also react with the zeta chain of the T-cell receptor, which is expressed in natural killer cells (26). In defining B-cell lineage, cytoplasmic CD22 expression is sensitive and relatively specific, though a cross-reacting protein has been reported in AML (27). In contrast, whereas cytoplasmic CD79a is often regarded as a specific pan–B-cell antigen, it is not uncommonly expressed in T lymphoblastic leukemia and in certain forms of AML. TdT is a nuclear antigen that is useful in distinguishing precursor neoplasms

[a]Column headings refer to the specific fluorophore to which each monoclonal antibody is conjugated; dashes indicate the absence of a specific fluorophore-conjugated antibody.

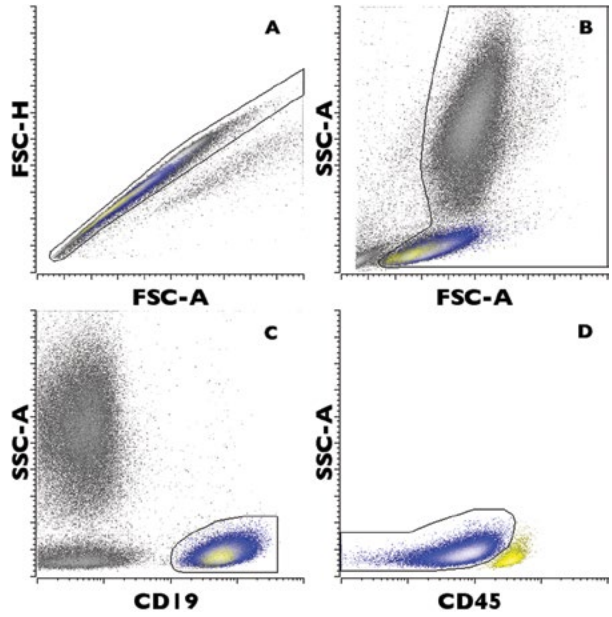

FIGURE 3 Typical gating strategy in B lymphoblastic leukemia. (A) All events displayed; a gate defining single events is illustrated. (B) All single events resulting from the gate shown in panel A are displayed; a gate defining viable cells is illustrated. (C) All viable single events are displayed; a gate defining all $CD19^+$ B cells is illustrated. (D) All viable, single $CD19^+$ B cells are displayed; blasts (blue) may be distinguished from mature B cells (yellow) by gating on CD45-negative to $CD45^{(dim)+}$ events.

from mature B- or T-cell non-Hodgkin lymphomas. TdT is positive in a preponderance of cases of B lymphoblastic leukemia and in somewhat fewer cases of T lymphoblastic leukemia. Since a significant minority of cases of AML also express TdT, though, this antigen cannot be used to distinguish lymphoblastic leukemia from AML.

The prototypic case of B lymphoblastic leukemia is $CD10^+$, $CD19^+$, $CD22^+$, and $CD34^+$, with absent, weak, or partial expression of CD20, dimmer CD45 than mature B cells, and absent immunoglobulin light chains (Fig. 4). Phenotypic variations are common, though. For instance, CD45 expression is highly variable, ranging from essentially absent to levels only slightly dimmer than those seen among mature lymphocytes (28). Monotypic immunoglobulin light chain expression is also a recognized phenotypic variant which is reported in a small minority of cases (29, 30). Expression of myeloid antigens (e.g., CD11b, CD13, CD15, CD33), which is generally weak and/or partial, represents a common phenotypic aberration in both B and T lymphoblastic leukemia and should not, in isolation, be regarded as evidence of mixed-phenotype acute leukemia (26).

Normal T-cell maturation has been used as a framework to distinguish several immunophenotypic patterns seen in T lymphoblastic leukemia/lymphoma (3, 15). Cases resembling pro-T and pre-T stages are negative for CD1a, surface CD3, CD4, and CD8; in fact, cytoplasmic CD3 and CD7 may be the only phenotypic features of T-lineage differentiation in such instances. Expression of CD1a and coexpression of CD4 and CD8 without surface CD3 typify the cortical thymic or "double-positive" phenotype (Fig. 5), while a more mature T-cell phenotype (i.e., CD1a/surface $CD3^+$ with either CD4 or CD8 expression) recapitulates the medullary T stage. Although T lymphoblastic leukemia/lymphoma seldom conforms precisely to these models in clinical practice (e.g., note the paucity of CD1a expression in the otherwise typical example of T lymphoblastic leukemia with a cortical thymic phenotype shown in Fig. 5), a specific immunophenotype corresponding with that of so-called early T-cell precursors (ETPs) appears to define a subset of cases with a distinct gene-expression profile and poor prognosis (31). ETP leukemia may be recognized phenotypically by an absence of CD1a and CD8 expression,

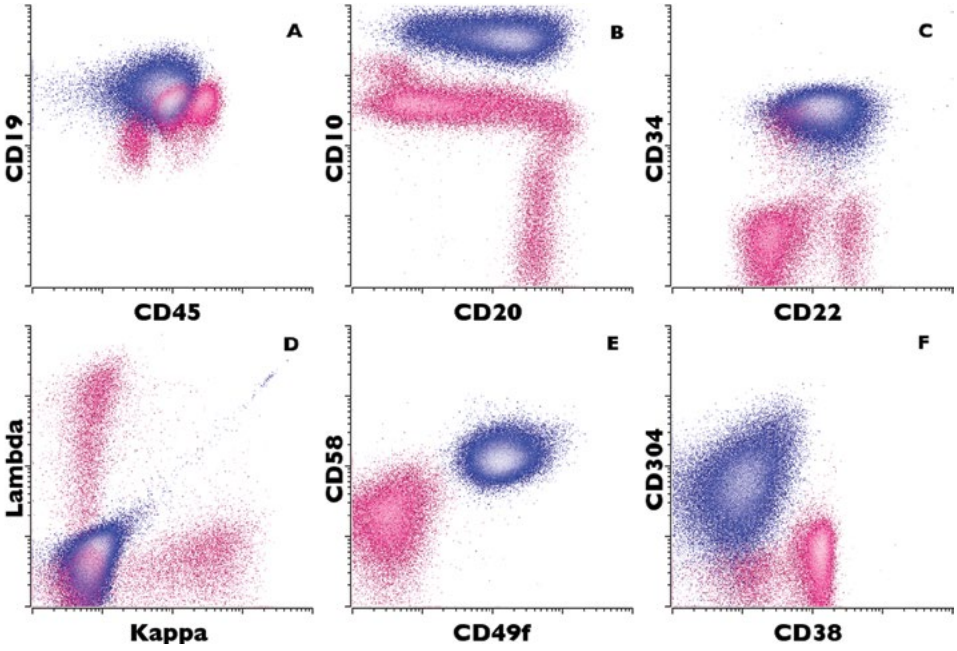

FIGURE 4 Example of B lymphoblastic leukemia. Phenotypic patterns of neoplastic B lymphoblasts (blue, gated as in Fig. 3) are compared with those of normal bone marrow B cells (pink).

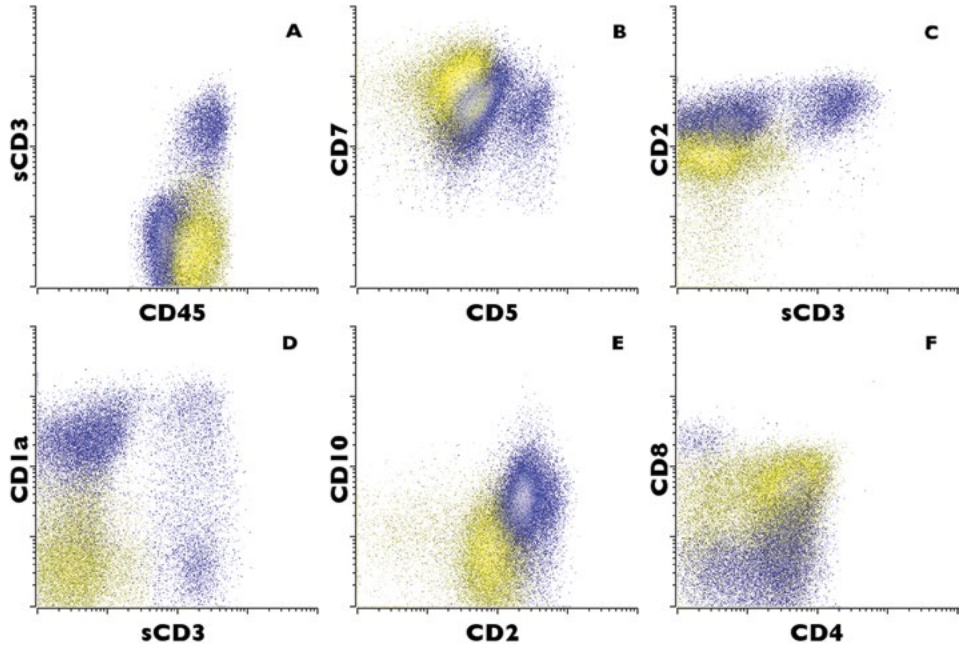

FIGURE 5 Example of T lymphoblastic leukemia. Phenotypic patterns of neoplastic T lymphoblasts (yellow) are compared with those of normal thymic T cells (blue).

with only weak, partial CD5 expression and expression of one or more of the following antigens: HLA-DR, CD11b, CD13, CD33, CD34, CD65, or CD117 (31) (Fig. 6). Since the mutational spectrum of ETP leukemia resembles that of myeloid leukemias, and its gene-expression profile is similar to those of both normal and myeloid leukemic hematopoietic stem cells, it has been speculated that the addition of myeloid-directed therapies might improve the poor prognosis of ETP leukemia (32).

Despite the application of an appropriate antibody panel, unequivocal lineage assignment (i.e., B-lymphoid, T-lymphoid, or myeloid) remains problematic in a small percentage of acute leukemias. Two general immunophenotypic patterns are seen in such cases, which have been

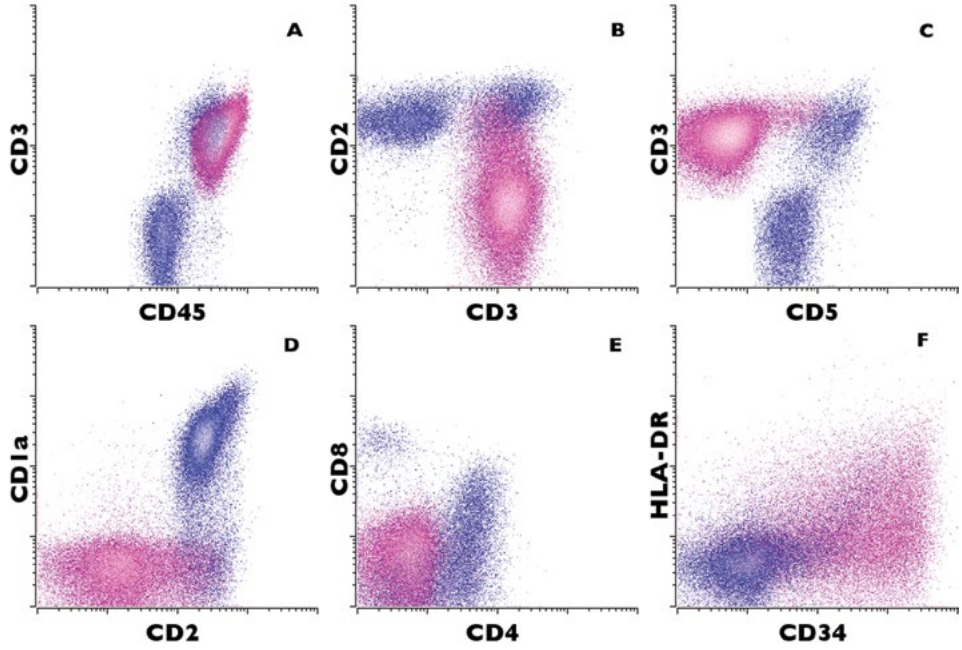

FIGURE 6 Example of early T-cell precursor (ETP) leukemia. In this example, the neoplastic T lymphoblasts (violet) are positive for surface-membrane CD3, with weak CD5 expression in significantly less than 75% of the blasts. CD1a and CD8 are negative, and at least 25% of the blasts express one or more myeloid or stem-cell marker (in this case, CD34). Normal thymic T cells are shown for comparison in blue.

designated "mixed-phenotype acute leukemia" (MPAL) in the most recent WHO classification (26). In the first of these patterns (formerly referred to as bilineal), two immunophenotypically distinct blast populations can be resolved, each with clear immunophenotypic evidence of differentiation along a different lineage (e.g., separate populations of B-lymphoblasts and myeloblasts). In the second pattern (formerly referred to as biphenotypic), a single population of blasts expresses antigens indicative of differentiation along more than one lineage. Since, as noted above, myeloid antigen expression is not unusual in B and T lymphoblastic leukemia, the WHO requirements for assigning more than one lineage to a single blast population are relatively strict: myeloperoxidase or two or more monocytic markers (from among CD11c, CD14, CD64, NSE, and lysozyme) for myeloid lineage; cytoplasmic or surface CD3 for T lineage; and CD19 plus strong expression of at least one (if CD19 is strong) or two (if CD19 is weak) from among CD10, cytoplasmic CD22, and cytoplasmic CD79a for B lineage (26). Notwithstanding the inconsistent definitions and treatments historically applied to MPAL, it appears that the prognosis of these leukemias is significantly worse than that of pediatric ALL (33, 34), though MPAL patients who fail an AML-type regimen may be successfully treated with an ALL-type regimen (33).

IMMUNOPHENOTYPIC-GENOTYPIC AND PROGNOSTIC CORRELATIONS

In certain instances, immunophenotypic features of the lymphoblasts may be associated with specific genetic abnormalities and/or prognosis (Table 3). For example, CD25 expression is significantly more frequent in cases of adult B lymphoblastic leukemia with *BCR-ABL1* than with *BCR-ABL1*-negative cases (35). Cases of B lymphoblastic leukemia with *MLL* rearrangement, and in particular those with *MLL-AF4*, are usually negative for CD10 and at least partially negative for CD24; many also express CD15 (36). B lymphoblastic leukemia with *TCF3-PBX1* is strongly associated with a composite immunophenotype characterized by homogeneous expression of CD9 and CD10, with at least partial absence of CD20 and complete absence of CD34 (37). By comparison, B lymphoblastic leukemia with *ETV6-RUNX1* does not display quite so stereotypic a composite immunophenotype; however, the expression of no more than partial CD9 and CD20 has a positive predictive value of nearly 50% for this translocation (38).

As noted previously, a subset of cases of T lymphoblastic leukemia displays an immunophenotypic profile reminiscent of that seen in normal ETPs. This composite immunophenotype (CD1a-negative, CD8-negative, with no more than weak, partial CD5 and one or more myeloid or stem-cell markers) (Table 3), which has been used to define ETP leukemia, predicts not only a specific gene-expression profile and mutational spectrum but also a poor prognosis (31, 32). Expression of CD13 is also an adverse prognostic factor in T lymphoblastic leukemia, independent of other conventional risk factors (39). Since the adverse prognostic effect of CD13 expression is limited to the subset of cases with a cortical/mature phenotype, it appears not to be attributable simply to its association with the ETP phenotype (39). In contrast, the apparently favorable prognostic effect of CD1a expression (40) could potentially be indirect, as CD1a expression is by definition limited to non-ETP leukemias. Finally, CD11b expression (20) and comparatively bright expression of CD20 (28) and CD45 (28, 41) are associated with poor prognosis in B lymphoblastic leukemia, independent of other risk factors; bright CD45 expression is also an independent adverse prognostic factor in T lymphoblastic leukemia (41).

MRD

With contemporary therapy, an overwhelming preponderance of children and a great majority of adults with ALL achieve disease remission, which is defined as the presence of fewer than 5% morphologic bone marrow blasts and restoration of normal hematopoiesis (42, 43). Nonetheless, an important principle in the curative therapy of patients with ALL is that treatment must continue for an extended period (typically for at least 2 years) in order to prevent an unacceptably high incidence of relapse (42, 43). These observations imply the persistence of residual leukemic blasts at submicroscopic levels in many patients who have attained remission. Indeed, it has been estimated that the total-body leukemic burden of patients with ALL in remission may be as high as 10^{10} (44). It has become clear that the precise quantification of such MRD is among the strongest prognostic factors in ALL and that flow cytometric immunophenotyping is well suited for MRD detection (reviewed in references 45 and 46).

In principle, the immunophenotypic detection of MRD relies on differences in antigen expression between leukemic cells and their normal counterparts. Phenotypic patterns of normal B- and T-lymphopoiesis have been well documented (10–13), and recent work has expanded the range of potentially informative antigens (17–22) such that at least 95% of cases of ALL (45, 46) and virtually all cases of B lymphoblastic leukemia (21) are now detectable by their abnormal immunophenotype (often referred to as a leukemia-associated immunophenotype). In early studies, the specific leukemia-associated immunophenotype documented at diagnosis was sought in posttreatment samples. It has since become apparent, though, that treatment induces phenotypic changes in

TABLE 3 Immunophenotypic-genotypic associations

Diagnostic entity	Phenotypic association(s)
B lymphoblastic leukemia with *BCR-ABL1*	$CD25^+$
B lymphoblastic leukemia with *MLL-AF4*	$CD10^-$, $CD15^+/^-$, $CD24^{-/partial+}$
B lymphoblastic leukemia with *TCF3-PBX1*	CD9 and $CD10^+$, $CD20^{-/partial+}$, $CD34^-$
B lymphoblastic leukemia with *ETV6-RUNX1*	CD9 and $CD20^{-/partial+}$
Early T-cell precursor (ETP) leukemia	CD1a and $CD8^-$, weak $CD5^+$ (<75% of blasts), >25% of blasts positive for one or more of the following: CD11b, CD13, CD33, CD34, CD65, CD117, HLA-DR

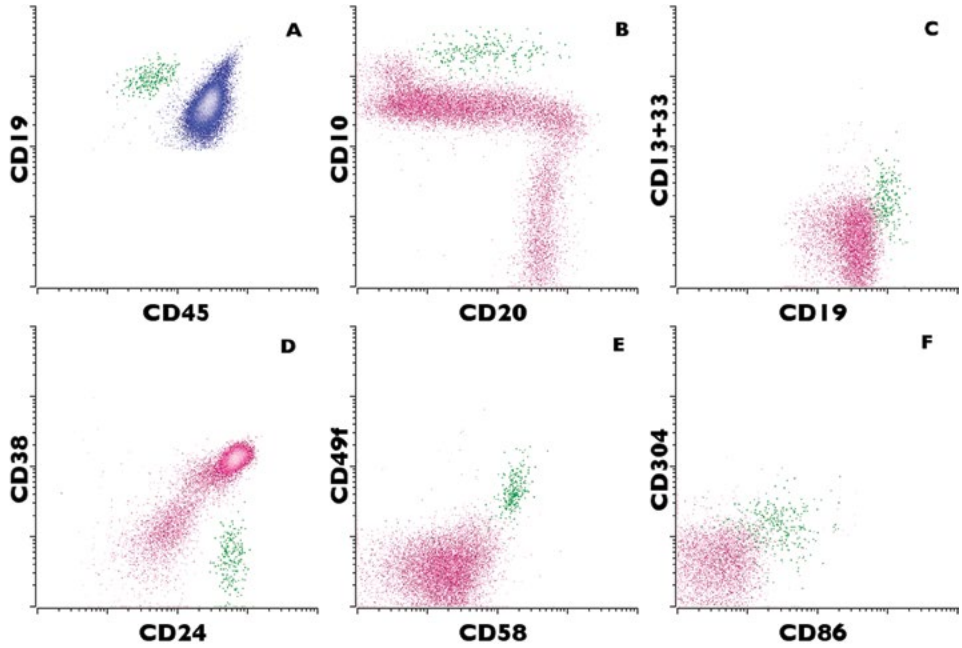

FIGURE 7 Detection of minimal residual disease in B lymphoblastic leukemia. (A) All viable, single $CD19^+$ bone marrow B cells are displayed; a small cluster of cells (0.04% of viable singlets) with comparatively dim CD45 expression (green) can be distinguished from a predominant population of normal B cells (blue). (B through F) Phenotypic features of the minimal residual disease (green, gated as in panel A) are compared with those of normal bone marrow B cells (pink). Compared with normal B-cell precursors, the residual neoplastic cells express abnormally bright CD10, CD19, CD49f, CD58, CD86, and CD304 and are further positive for CD13 and/or CD33. CD38 expression, moreover, is lost.

the leukemic blasts, termed immunophenotypic drift. These phenotypic changes generally reflect maturation of the blasts, an effect thought to be mediated by corticosteroids (47), and have been documented in both B lymphoblastic and T lymphoblastic leukemia (47, 48). As a practical matter, one must not simply evaluate posttreatment samples for the specific phenotype seen at diagnosis, but rather identify populations with a composite immunophenotype that differs from that of normal B- and T-cell precursors.

Although incorporation of several newly identified markers into MRD panels may yield a sensitivity of 0.001%, or 1 in 100,000 cells (21), a level previously attainable only by PCR-mediated amplification of antigen-receptor genes (49), most studies demonstrating the clinical significance of MRD in ALL have reported a sensitivity of 0.01% (1 in 10,000 cells). Visual recognition of a cluster of events in multiparametric space as a distinct cellular population depends both on the magnitude of antigenic deviation from normal and the extent to which antigen expression is homogeneous. However, in general, confident identification of MRD is difficult when fewer than 20 events comprise the putative cluster of cells. Since a sensitivity of 1 in 10,000 cells is required clinically, it is essential that no fewer than 200,000 viable cells be acquired. In our laboratory, as many as 1 million total events are acquired for each antibody combination; when fewer than 250,000 viable cells are collected in a given case, the report indicates that the sensitivity of the assay is compromised. It is also important to be mindful of spurious signals that could simulate a population of MRD. For instance, clinical flow cytometers may have carryover in the range of 0.1%, an order of magnitude higher than the expected analytic sensitivity of the assay. To mitigate the potential for carryover, tubes containing only saline may be placed between those containing antibody-labeled cells.

As noted above, many antigens are differentially expressed in leukemic lymphoblasts relative to normal lymphoid precursors. As a rule, though, these differences are quantitative rather than qualitative. Therefore, when a new antibody combination for MRD detection is implemented, it is essential to document the range of normal patterns of immunoreactivity using control samples from patients without leukemia, including samples from patients with active marrow regeneration following chemotherapy. The immunophenotypic properties of putative MRD populations may then be compared with these previously documented normal patterns to confirm or refute a diagnosis of MRD. The principal antibody combinations used for MRD detection in our laboratory are listed in Table 2 (3, 4, and 5 for B lymphoblastic leukemia; 6 and 7 for T lymphoblastic leukemia). Examples of MRD compared with normal patterns of antigen expression using these combinations are illustrated in Fig. 7 and 8.

SUMMARY

Flow cytometric immunophenotyping comprises an essential component in the diagnosis of ALL, enabling its reliable distinction from AML and acute leukemia of ambiguous lineage. In certain instances, the composite immunophenotype of the leukemic blasts may be associated with specific genetic abnormalities and/or prognosis. Finally, flow cytometry is well suited for the detection of MRD, one of the strongest prognostic factors in ALL.

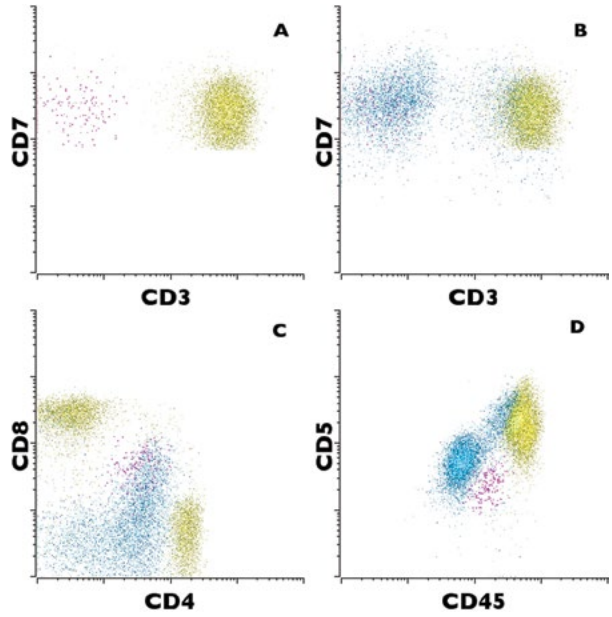

FIGURE 8 Detection of minimal residual disease in T lymphoblastic leukemia. (A) All viable, single bone marrow T cells are displayed; a small cluster of cells (0.2% of viable singlets) with loss of surface CD3 (violet) can be distinguished from a predominant population of normal $sCD3^+$ T cells (yellow). (B through D) The phenotypic features of the minimal residual disease are compared with those of normal thymic T cells (light blue) and the normal mature ($sCD3^+$) T cells contained in the bone marrow sample (yellow). With respect to absence of sCD3 (B) and weak coexpression of CD4 and CD8 (C), the neoplastic T cells resemble normal thymic T cells; however, T cells with a thymic immunophenotype are not detectable in normal bone marrow by flow cytometry. The combination of weak CD5 and intermediate CD45 seen in the minimal residual disease (D), though, differs from both normal thymic T cells and mature T cells. The residual leukemic cells were also partially positive for CD1a and CD10 (not shown).

Acute Myeloid Leukemia: Diagnosis and Minimal Residual Disease Detection by Flow Cytometry

BRENT WOOD AND LORI SOMA

22

Flow cytometry is an integral tool in both the diagnosis and posttherapy evaluation of acute myeloid leukemia (AML). The strength of the technology is its capacity for rapid, sequential single-cell analysis with simultaneous evaluation of multiple antigens, thus providing a comprehensive immunophenotype for discrete cellular subpopulations. As a result, it has become the methodology of choice for determining blast lineage and immunophenotype. Cytochemical or immunohistochemical evaluation, although useful and even required in some settings, has been surpassed by flow cytometry for the evaluation of blood and marrow in most instances (1, 2). Nevertheless, flow cytometric findings must be used in conjunction with morphology, molecular, and cytogenetic findings for the complete diagnosis and subclassification of AML. Evaluation of posttherapy samples for residual acute myeloid leukemia allows enumeration of blasts as low as 1% by morphology; however, distinguishing normal or regenerating progenitors from leukemic blasts rarely can be performed by morphologic examination alone. Flow cytometry not only allows a more sensitive assay, in some cases reaching a sensitivity of 0.01% (3–5), it is also able to identify aberrancies on the leukemic blast population that allow discrimination from normal or regenerating progenitors (2, 6, 7). These attributes make flow cytometry an ideal method for evaluating for minimal residual disease (MRD) in the posttherapy setting.

NORMAL MYELOID MATURATION AND ANTIGEN EXPRESSION

Knowledge of the immunophenotypic findings seen during normal hematopoietic maturation is critical to understanding the changes induced by neoplastic transformation and is the basis of all neoplastic immunophenotyping. The ability to distinguish leukemic blasts from normal progenitors, either for initial diagnosis or posttherapeutic monitoring, requires correlation of immunophenotypes from specific maturational stages of a particular lineage with the population of interest (Table 1) (8–10).

Hematopoietic maturation begins in the bone marrow with the hematopoietic stem cell, a cell having the properties of self-regeneration and multilineage differentiation potential. This stage of maturation is characterized by expression of high CD34, low to absent CD38 and CD133, low to intermediate levels of CD13 and HLA-DR, and relatively low levels of CD33, CD117, and CD123 (11–13). CD45 expression is low in comparison to mature lymphocytes, although it is higher than later CD34-positive myeloid progenitors. Hematopoietic stem cells also do not express markers of definitive lineage commitment, such as the myeloid antigens CD11b, CD14, CD15, CD16, or myeloperoxidase, the early B-cell antigens CD19 or CD10, or the elevated level of CD71 characteristic of early erythroid differentiation (Fig. 1) (2).

As the hematopoietic stem cell matures to early forms committed to the various lineages, the levels of CD34 and CD45 decrease slightly as CD38 increases to a relatively uniform intermediate level. This early CD34-positive progenitor devoid of lineage-specific antigenic expression is the prototype for what is often termed a "myeloid blast"; following this stage, the progenitors begin to express antigens characteristic of commitment to specific lineages. It is hypothesized that a common myeloid progenitor gives rise to the seven main myeloid lineages—erythroid, granulocytes, eosinophils, basophils, monocytes, megakaryocytes, and dendritic cells—but this is difficult to observe by routine immunophenotyping. However, it can readily be observed that the uniformly CD34-bright progenitors slightly increase expression of CD13, CD33, CD117, and HLA-DR as they move toward myelomonocytic differentiation, while early erythroid, B-cell and plasmacytoid dendritic cell lineages rapidly reduce their expression of CD13 and CD33 (2, 8, 14, 15). When observing immunophenotypic expression along myeloid lineages, it is important to note that the maturational patterns are a continuum with progressive gains and losses of antigens rather than static discrete populations characterized by the presence or absence of markers (Fig. 1).

As monocytic maturation arises from the early CD34-positive progenitor, the monoblasts/promonocytes express the highest levels of HLA-DR and CD33 seen on any hematopoietic population, with early expression of CD15 and CD64 at a moderate level and a rapid decrease of CD34 and CD117 (8, 9, 14, 15). At these early stages, CD13 expression is variably reduced from that seen on the bright CD34-positive progenitors; it then begins to increase in parallel with CD14, with both expressed at the highest level on mature monocytes.

Early erythroid progenitors express CD34 and show increasing levels of CD71 (transferrin receptor) with slightly later acquisition of CD36. Expression of CD117 is retained

doi:10.1128/9781555818722.ch22

TABLE 1 Antigens commonly evaluated in the diagnosis of acute myeloid leukemia

Designation	Associated lineage
CD4	Monocytic, T cells
CD5	Pan T cell, aberrant expression in some AML
CD7	Pan T cell, aberrant expression in some AML
CD11b	Myeloid, NK cells, some B and T cells
CD11c	Myeloid, NK cells, some T cells
CD13	Myeloid
CD14	Myelomonocytic
CD15	Myelomonocytic
CD16	Granulocytes, NK cells
CD19	B cells
CD33	Myeloid cells
CD34	Immature hematopoietic cell, stem cell
CD36	Monocytes, basophils, early erythroids, megakaryocytes
CD41	Glycoprotein IIb, platelets and megakaryocytes
CD42	Platelet glycoprotein, platelets and megakaryocytes
CD45	Leukocyte common antigen
CD56	NK cells, aberrant expression in some AML
CD61	Glycoprotein IIb/IIIa, platelets and megakaryocytes
CD64	Monocytes, activated granulocytes
CD71	Transferrin receptor, erythroid (CD71 bright) and cycling cells, not present on anucleate erythroid cells
CD117	Immature myelomonocytic and erythroid
CD123	Plasmacytoid dendritic cells, basophils, immature B cells
CD203c	Basophils
HLA-DR	Myeloid blasts, monocytes, B cells, activated T cells
Glycophorin A	Maturing erythroid (levels increase with erythroid maturation)
MPO	Myeloid (strongest on granulocytic) lineage
TDT	Lymphoid blast

by the pronormoblasts, which also express CD38 with loss of CD13, CD33, and CD34 (2, 15, 16). CD71 expression remains high throughout erythroid maturation and is lost upon extrusion of the nucleus to form the mature erythrocyte; however, the level of CD71 seen is dependent on processing with red cell lysing reagents, which often result in variably reduced levels of CD71. Glycophorin A (CD235a) is acquired slightly later than high CD71 but is maintained throughout maturation with expression on anucleate erythrocytes (10).

Discrete stages of megakaryocytic maturation are not as well identified by routine immunophenotyping. However, early megakaryocytic progenitors coexpress CD41 (glycoprotein IIb) and CD61 (glycoprotein IIIa), with expression of CD42 (glycoprotein 1b) acquired with maturation (17).

OVERVIEW OF AML

Biology and Epidemiology

AML is a myeloid stem cell neoplasm resulting in a clonal proliferation of bone marrow precursors having the expression of myeloid-associated antigens in the absence of lineage-defining lymphoid antigens (18). This includes apparent maturational arrest at variable progenitor stages up through the promyelocyte, promonocyte, or proerythroblast stages. AML is more frequently seen in adults, with a peak incidence in the 6th decade, although it can occur at any age. Risk factors associated with the development of AML include exposure to radiation, chemotherapy (particularly alkylating agents and topoisomerase II inhibitors), toxins (benzene, smoking), development of lower-grade myeloid stem cell disorders (myelodysplasia, chronic myeloproliferative neoplasms), and some congenital/inheritable factors (such as Fanconi anemia, Down syndrome, and familial *RUNX1* and *CEBPA* mutations) (19).

Classification

Historically, AML was classified based on the French-American-British (FAB) criteria, a cooperative effort to standardize the diagnosis and classification of acute leukemia. The FAB was first published in 1976 and required ≥30% myeloid blasts (or blast equivalents) in the bone marrow or peripheral blood by morphology (20). Cytochemical stains and morphologic features were used to define lineage at that time. Subsequently, the diagnostic criteria were revised in 2001 with the publication of the World Health Organization classification system for hematopoietic and lymphoid tumors (21). The morphologic blast percentage required for the diagnosis of AML was decreased to ≥20% in the bone marrow or blood, from the prior FAB criteria of ≥30%. Subclassification of AML in the 2001 and 2008 World Health Organization systems is based largely on recurrent genetic abnormalities, with less reliance on

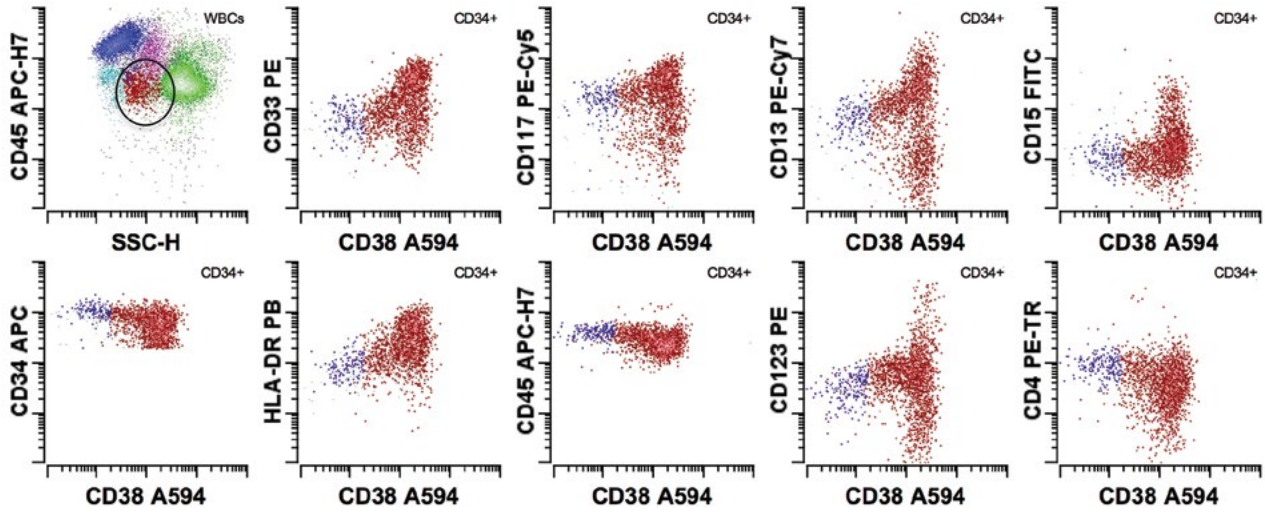

FIGURE 1 Example dot plots of normal, early stem cells (purple) and normal CD34-positive blasts (red). Upper left dot plot shows CD45 versus side scatter (blue: lymphocytes; pink: monocytes; green: maturing granulocytes; aqua: hematogones) with circled area defining the blast region. Remaining dot plots are selectively displaying CD34-positive progenitors only. Myeloid progenitors show increasing expression of CD13, CD33, CD117, and HLA-DR.

morphologic and immunophenotypic characteristics (18), although the latter continue to play a role for certain specific AML subtypes (see Table 2).

In the current era, flow cytometry and morphology are the mainstays in diagnosing AML, with molecular and cytogenetic findings providing further subclassification (1, 2, 18). Flow cytometry allows for: (i) identification and enumeration of an immature progenitor population; (ii) lineage assessment based on phenotypic expression; and (iii) assessment of aberrant antigen expression that can be used for subsequent posttherapeutic monitoring. Most AML demonstrates an immunophenotype similar to that seen on normal myeloid progenitors, often expressing CD13, CD33, CD34, CD117, and HLA-DR, with low CD45 expression (Fig. 2). However, the intensity of these antigens may be increased or decreased compared to a normal progenitor population, and they may be more homogeneous in expression, indicating a lack of the normal maturational spectrum that would be expected in a reactive/regenerative setting. Myeloid blasts in AML may also show abnormal asynchronous expression of mature myeloid antigens, such as CD11b, CD15, or CD64, as well as aberrant expression of lymphoid-associated antigens including CD2, CD5, CD7, CD19, or CD56 (2).

A complete description of AML subclassification using flow cytometry is beyond the scope of this chapter, and the reader is referred to a more comprehensive source (22). However, four subtypes of AML are worth specific mention because of their characteristic immunophenotypic findings:

TABLE 2 Immunophenotypic characteristics associated with certain AML subtypes

AML subclassification	Associated immunophenotypic nuance of blasts
AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*	High levels of CD34, expression of CD19 and TdT
APL with t(15;17)(q22;q12); *PML-RARA*	Lack of CD15, CD34, and HLA-DR; expression of high levels of CD33 and MPO; expression of CD2; increased right-angle light scatter
AML with t(6;9)(p23;q34); *DEK-NUP214*	TdT expression
AML with inv3(q21;q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*	CD7 expression; subsets may express CD41/CD61
AML with FLT3/ITD	May lack CD34 and HLA-DR
AML with NPM1 mutation	May lack CD34 and express higher CD33
AML with monocytic or monoblastic differentiation	Bright CD33, CD64, and HLA-DR; often lacks CD34 and CD117; variable CD14
Acute erythroid leukemia	Bright CD71 and expression of CD235a (glycophorin-A); variable expression of CD117 but often lacks CD34; variably lacks CD13 and CD33
Acute megakaryoblastic leukemia	Expression of CD41 and CD61; often lacks CD13, CD33, CD34, and CD117

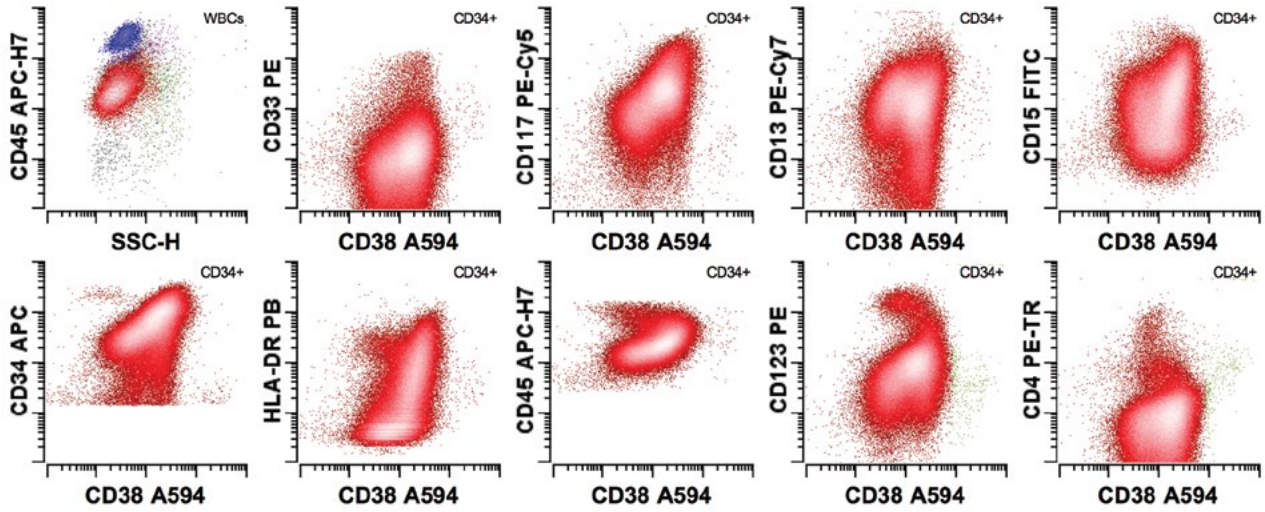

FIGURE 2 Example dot plots of acute myeloid leukemia (red). Upper left dot plot shows CD45 versus side scatter with blast population highlighted in red. Remaining dot plots are selectively displaying CD34-positive leukemic blasts only. Notice, compared to normal myeloid blasts in Fig. 1, these abnormal, leukemic blasts demonstrate lower side scatter, variably increased CD13, early/abnormal expression of CD15, decreased to absent CD33, variably increased CD34, variably decreased CD45, variably increased CD117, and variably decreased HLA-DR.

acute promyelocytic leukemia (APL), acute monocytic leukemia (AMoL), acute erythroid leukemia (AML-M6), and acute megakaryoblastic leukemia (AML-M7) (see Table 2).

AML with t(15;17) (APL) is an acute leukemia consisting of a marked expansion of promyelocytes (blast equivalents) without further granulocytic maturation (1, 2, 18). This is a particularly important subtype of AML to recognize due to the increased early death rate secondary to disseminated intravascular coagulation and its complications. However, this subtype is exquisitely sensitive to therapy with all-*trans* retinoic acid and arsenic trioxide, making it the AML with the highest overall disease-free survival rate if successfully supported through initial treatment (23, 24). Like normal promyelocytes, APL is characterized by variably high right-angle light scatter, high levels of myeloperoxidase, relative lack of HLA-DR, and low to intermediate CD64, and it most typically lacks CD34 and CD11b expression. However, unlike normal promyelocytes, APL typically demonstrates low to absent expression of CD15, abnormally increased CD33, and variable CD117. The microgranular variant of APL has a variant immunophenotype with somewhat lower right-angle light scatter, more frequent expression of CD34, and CD2 expression on a subset of cases.

AMoL (acute monocytic leukemia) shows an immunophenotype similar to promonocytes with intermediate to high right-angle light scatter and bright CD33, findings often seen in APL, but with a higher level of CD64, more frequent expression of HLA-DR, and low to absent myeloperoxidase (1, 2, 18). Monoblasts and promonocytes also generally lack CD14, CD34, and CD117, although they typically express a moderately high level of CD15, CD64, and HLA-DR. Additionally, monocytic leukemia will often show some degree of further monocytic maturation, including a subset of maturing/mature monocytes (with increased CD14 and CD45 expression) in addition to the immature promonocytic component. Aberrant CD56 expression is often seen on the monocytes (mature and immature) in AMoL.

Acute erythroid leukemia (AML-M6) consists of a proliferation of proerythoblasts either with or without a subset of abnormal myeloid progenitors (1, 2, 18). The proerythoblasts show decreased to absent CD45 expression, often with intermediate right-angle light scatter, often variably lack CD13, CD33 and CD34, but typically express some combination of CD36 and CD71 and may show expression of CD235a (glycophorin-A). Care must be taken in the assessment of CD71, as proliferating cells (including leukemic blasts) express CD71 (transferrin receptor); however, erythroid progenitors typically express CD71 at an exquisitely high level, with the caveat that this may be abnormally reduced in erythroleukemia. The progenitor antigen CD117 is typically expressed on erythroid progenitors.

Acute megakaryoblastic leukemia (AML-M7) is similar to AML-M6 in that the blasts often show decreased to absent CD45 expression, often with intermediate right-angle light scatter, and expression of CD36 and CD71 (1, 2, 18). Additionally, the blasts may lack CD34 as well as CD13, CD33, or CD117. However, by definition, the blasts must show expression of platelet-associated antigens such as CD41 and CD61 and must lack CD235a. When evaluating CD41/CD61 expression, care must be taken to exclude adherence of activated platelets to the cells of interest.

PREPARATION AND EVALUATION OF DIAGNOSTIC SAMPLES IN AML

Specimen Requirements and Processing

The diagnosis of AML is usually made on a bone marrow aspirate or peripheral blood sample; however, bone marrow biopsies or involved tissue samples may be evaluated. The samples should be obtained in a sterile manner. Bone marrow aspirate and peripheral blood should be collected in sodium heparin or EDTA anticoagulant, with sodium heparin providing more stability in samples that are more than 24 hours old. Bone marrow biopsies or tissue samples

should be placed in tissue culture media (25). If analysis is to occur within 24 to 48 hours, maintaining the sample at room temperature is appropriate (16 to 28°C). However, if a delay in evaluation beyond 48 hours is anticipated, refrigeration of the sample will delay sample degradation. Samples that are refrigerated should be brought back to room temperature prior to labeling. Prior to processing, sample cellularity should be assessed to ensure provision of the appropriate number of cells for analysis. This may require increasing the volume of low-cellularity samples or diluting highly cellular samples to maintain antibodies within an appropriate titer. In general, most antibodies are titered for use with 1 million cells, and this serves as a useful target for sample cellularity.

Antibodies are added to the aliquot of sample, preferably as a pretitered cocktail, and the mixture is incubated for 15 minutes at room temperature in the dark. After labeling, samples are processed with red blood cell lysing reagents, e.g., buffered ammonium chloride, followed by washing in order to obtain a single cell suspension of white blood cells with as little contamination by mature erythrocytes as possible, largely to allow efficient sample acquisition (26). Of note, if the sample is a bone marrow biopsy or tissue sample, it must initially undergo disaggregation to obtain a single cell suspension prior to further processing, usually by mechanical disaggregation with a scalpel, forceps, or mesh screen, although enzymatic digestion may also be used (27).

Reagent Panels

The reagent panels used for both AML diagnosis and MRD detection should ideally be similar and optimized to demonstrate both the early stages of myeloid progenitor maturation and common antigenic abnormalities seen in AML, e.g., expression of lymphoid-associated antigens (28). However, the diagnostic panel should be supplemented with lymphoid-associated antigens sufficient to definitively determine lineage. Some redundancy in reagents between aliquots is desirable to allow identification of similar populations between aliquots. There is currently poor standardization of reagent panels for AML diagnosis and MRD detection, but antigens that are commonly evaluated in the diagnosis of AML are listed in Table 1. We refer the reader to another source for a recommended AML (and AML MRD) panel (29). Although the simultaneous evaluation of three to four antigens has previously been standard, the use of six- to 10-color flow cytometers is becoming increasingly common (30). The use of increased numbers of simultaneous fluorochromes is less important for initial diagnosis where the blast population is easy to identify, but it can clarify maturational relationships and becomes more important to confidently identify small abnormal blast populations when evaluating for MRD (7).

Data Acquisition

In order to characterize all populations of interest, one must collect enough total events to allow evaluation of the least frequent population of interest in the sample. If the population of interest is present in high numbers, for instance at the time of AML diagnosis, evaluation of lower numbers of events will yield the information needed for correct identification/classification. However, if the population of interest is infrequent, for instance at the time of posttherapeutic monitoring, a larger number of events is needed for identification, characterization, and enumeration. Although the operator can make this decision in real time as the sample is being acquired, establishing a consistent number of events to acquire based on the diagnostic question is an approach better suited to a busy clinical laboratory. Acquisition of a specified number of total events allows one to consistently achieve the desired degree of sensitivity for a particular application.

Determination of the number of events to acquire is governed in large part by two factors: the number of events required to identify and enumerate a population, and the frequency of the population of interest, the latter being directly related to the desired analytical sensitivity of the assay. Although the identification of a population is possible with a very small number of events (<10) of the appropriate type, enumeration at this level is governed by Poisson counting statistics, and the precision can be estimated as:

$$\text{Coefficient of variation (CV)} = \sqrt{\frac{(n)}{n}}$$

where n is the number of events in the population. Consequently, with a target number of 100 events ($n = 100$), the CV is 10%, and this serves as a reasonable goal for most MRD assays. Increasing the number of events will decrease the CV and hence increase precision. When evaluating initial diagnostic samples, an analytical sensitivity of 0.1% (1 cell in 1,000) is an appropriate target to allow detection of unexpected, abnormal populations. Therefore, 100,000 total events should be acquired to provide 100 events in a population having a frequency of 0.1%. In contrast, for MRD applications, the clinically relevant target is currently 0.01%, in which case 1,000,000 events are required to achieve a similar level of reproducible enumeration. An additional consideration is carryover. Running a small amount of water through the cytometer, not only between patient samples but also between aliquots of the same sample, will reduce contamination that could produce artifactual small populations and be misinterpreted; this is particularly an issue for MRD analysis.

Data Analysis

Evaluation of immature populations is enhanced by specifically gating on the region where normal progenitors are expected to be present on a CD45 versus side-scatter dot plot, a gate often referred to as a "blast" gate. This method allows separation of the nucleated cells into six basic components: lymphocytes, monocytes, granulocytes, myeloid progenitors, lymphoid progenitors, and erythroid forms. Inclusion of CD45 in each aliquot/tube allows for consistency in progenitor or blast identification and is an approach almost universally used in clinical laboratories for acute leukemia diagnosis. This analytical approach allows more focused evaluation of progenitors by the exclusion of maturing forms from most lineages. However, gating in this way makes the assumption that neoplastic myeloid blasts share similar CD45 and right-angle light-scatter characteristics with their normal counterparts, which is not always the case. Therefore, one should not overly adhere to strict gating strategies but should examine regions outside of the blast gate and allow for variation in its location when warranted.

Reporting

In AML diagnosis, the blast percentage is very important. As stated previously, the current World Health Organization classification generally requires morphologic identification of $\geq$20% of blasts of marrow cellularity to be considered diagnostic of AML (18). However, when enumerating progenitors by flow cytometry, the denominator is potentially confounded by three competing factors: hemodilution,

reduced enumeration of erythroid precursors, and differences in the definition of blasts/progenitors between flow cytometry and morphology. Hemodilution is inevitable during marrow aspiration but is increasingly pronounced beyond 1 to 2 cc of marrow aspiration unless the needle is repositioned. The consequence of hemodilution is a relative increase in peripheral blood cells, which is particularly problematic in cases where relatively few progenitors are in the circulation, such as during MRD assessment. The net effect is a reduction in progenitor enumeration. In contrast, the use of erythrocyte lysing reagents compromises nucleated erythroid cells, resulting in a decrease in forward scatter that can cause underestimation of the total number of nucleated cells if either the acquisition threshold is too high so that they are not acquired or if viability gates are used and nucleated red cells are excluded from the denominator during analysis. It is often assumed that nucleated erythroid cells are lost with the use of red cell lysing reagents, but this is not the case if fixative-containing lysing reagents are used and wash steps are optimized for cell recovery. Due to this concern, the blast percentage has historically been reported as a percentage of white cells (CD45-positive events) by flow cytometry, but this practice needs to be reevaluated. Finally, cells that are considered blasts or blast equivalents by morphology consist of a variety of different immunophenotypic subsets by flow cytometry, so one must sum the appropriate immunophenotypic subsets if one is attempting to correlate with morphology. This problem may be particularly pronounced for progenitors that lack CD34 or CD117 expression, such as monocytic leukemia. Ultimately, the flow cytometric blast count must be correlated with a morphologic blast count for a definitive diagnosis of AML, particularly if the blast percentage by flow cytometry is not significantly above 20% and/or the sample is bone marrow. In peripheral blood samples where nucleated red blood cells are usually not present and hemodilution is not relevant, the flow cytometric progenitor count may more closely correlate with morphology.

In addition to reporting the percentage of myeloid progenitors, their immunophenotype should be reported (28). The immunophenotypic data should clearly identify the population being evaluated and how it was defined. Antigen expression should be reported in a way that relays relative intensity and whether the findings are normal or abnormal for a particular lineage of cells at a defined stage of maturation, something that is particularly important when assessing samples for subsequent MRD testing. The reporting of percentage positivity for each antibody tested is still common but is actively discouraged by consensus conferences as it does not convey either the relative intensity or pattern of expression, nor does it provide an indication of abnormality. Finally, the report should contain an interpretation of the results that attempts to integrate this complex immunophenotypic data with clinical findings to provide useful clinical information that can direct therapy.

POSTTHERAPY EVALUATION OF AML (MRD)

Evaluation for minimal residual disease after therapy is an important prognostic predictor in AML (7). The presence of minimal residual disease, even with levels <0.1%, is associated with adverse outcome (31).

Specimen Requirements, Processing, and Reagent Panels

The specimen requirements are similar between diagnostic and MRD AML testing. Although some have suggested that peripheral blood is an adequate sample for MRD analysis, the level of AML MRD detected is roughly 1 log lower in blood than in marrow, and current practice is to evaluate bone marrow aspirate samples (32, 33). The sample should be processed in the same way as a diagnostic AML sample, including the use of red cell lysis; however, it is important that sufficient cells are prepared to allow acquisition of the appropriate number of events for the desired degree of sensitivity (25, 26). For low-cellularity samples, this will require either concentration or evaluation of larger total amounts of sample.

Reagent panels for MRD testing need to be optimized to allow discrimination of normal progenitors from residual leukemic progenitors; this usually requires the use of backbone gating reagents that facilitate dissection of maturational subpopulations into relatively discrete stages where normal immunophenotypes are somewhat more homogeneous (6, 7). An important example is evaluation of the immunophenotype of hematopoietic stem cells ($CD34^{+}$, $CD38^{Low}$) via the use of CD34 and CD38 as gating reagents, as residual AML often persists as cells having this immature immunophenotype and can be overlooked if only total CD34-positive cells are evaluated (Fig. 3). Using an increased number of simultaneous fluorochromes facilitates this process. In addition, evaluation for AML MRD also allows for a more directed reagent panel to be utilized, in contrast to the assessment of more extensive lineage-associated antigens performed in a diagnostic setting for definitive lineage assignment.

More broadly, it is helpful if the same or similar panel of reagents is evaluated at both diagnosis and at MRD assessment, as this facilitates comparison between diagnostic and MRD samples and generally results in a single assay that can be well validated and its performance characteristics understood (we refer the reader elsewhere for a recommended AML MRD panel) (29). The creation of custom reagent combinations in an attempt to detect abnormalities noted at diagnosis is to be avoided as these represent unvalidated assays whose performance characteristics will not be well understood. In addition, limited or custom reagent combinations also presume constancy of immunophenotype posttherapy, which is known to not be the case in a significant subset of acute leukemia, including AML (7, 34–36).

Data Acquisition and Evaluation

Data acquisition and evaluation in AML MRD is essentially similar to that in AML at diagnosis, although a few important caveats should be noted. Unlike diagnostic samples where the population is usually present in sufficient numbers to confidently identify when acquiring 100,000 events, posttherapy or MRD analysis will hopefully be looking for populations that represent less than 1% of total cells. Therefore, a target for acquisition of 500,000 to 1,000,000 total events is desirable in order to allow reproducible identification and enumeration (see above). As a quality-control measure, when evaluating for small populations, identification of the population in more than a single reagent combination is helpful to confirm that the population is not a spurious or nonspecific finding, as well as to allow a more accurate estimate of population frequency. As mentioned previously, running water between each aliquot will decrease the risk of inter- and intrasample carryover, which could lead to a false-positive result and is of paramount importance when enumerating small populations.

The sensitivity of MRD testing is directly related to: i) the leukemic phenotype, ii) the presence of normal or

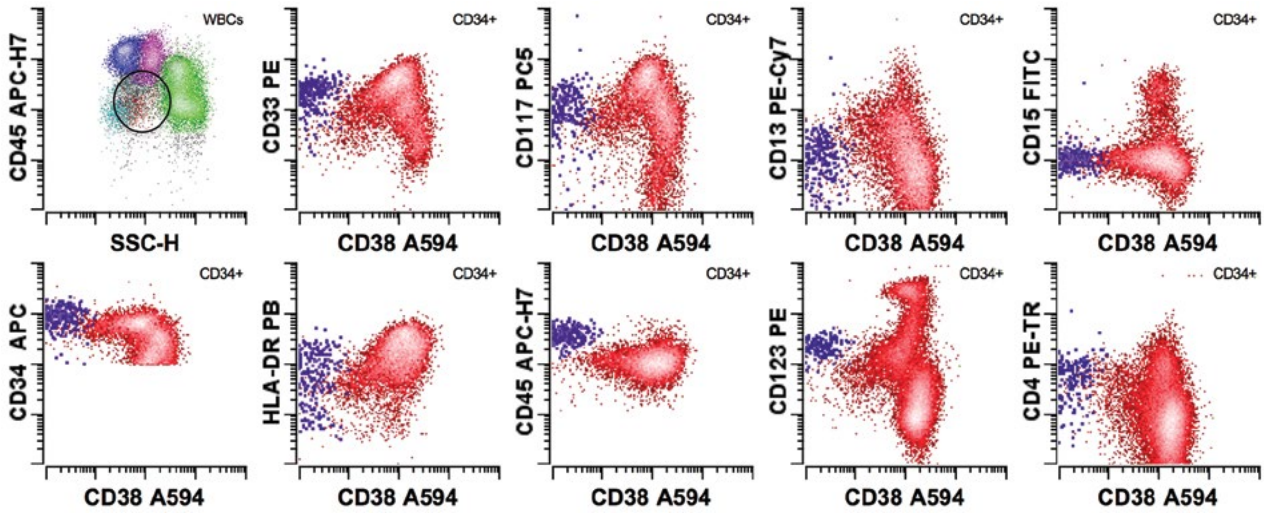

FIGURE 3 Example dot plots of minimal residual disease (MRD; purple population visualized on CD34 gating) with associated regenerating normal myeloid blasts (red). Upper left dot plot shows CD45 versus side scatter (blue, lymphocytes; pink, monocytes; green, maturing granulocytes; aqua, hematogones) with circled area defining the blast region. Remaining dot plots are selectively displaying emphasized, CD34-positive progenitors only. The MRD-positive population (purple) shows abnormal expression of CD4, decreased to absent CD13, uniform CD33, increased CD34, absent CD38, increased CD45, and subset CD56 (not shown) with normal expression of CD117 and HLA-DR and normal lack of CD15. Although the total CD34-positive population accounted for 2% of the white cells, the abnormal, MRD-positive population accounted for 0.03% of the white cells.

regenerating populations of similar immunophenotype, and iii) interpreter expertise. This assumes use of a sufficiently informative antibody combination and acquisition of an appropriate number of total events. It can be quite helpful to evaluate the diagnostic sample in the same laboratory performing evaluation for MRD, in order to understand the diagnostic immunophenotype using a procedure similar to that being used for MRD. However, it is important to recognize that changes in immunophenotype often occur as a result of therapy, and rigid reliance on stability of the original immunophenotype is unwise (2, 7, 14, 34–37). In particular, the use of predefined gates based on the diagnostic immunophenotype, as advocated by a strict leukemia-associated immunophenotypic approach, is to be avoided. Nevertheless, evaluating for an abnormal immunophenotype similar to the diagnostic sample is a useful starting point for evaluation when supplemented by evaluation for discrete abnormal populations having immunophenotypes that differ from normal or regenerating progenitors. Given the immunophenotypic heterogeneity of the myeloid blast population in AML, it is difficult to predict which component may be resistant to or undergo selection by therapy, further suggesting that reliance on single or presumed static immunophenotypic abnormalities is unwise. In some circumstances, the leukemic immunophenotype may be quite similar to normal progenitors, and differentiation between the two populations can be quite challenging with overlap of the populations. The use of increasing numbers of colors/fluorochromes allows evaluation of more antibodies in one tube, permitting more confident identification of small populations and improved separation from the normal myeloid progenitors by selective gating.

Lastly, the timing of MRD evaluation and the presence of regenerating populations are interrelated and can create difficulty in confident MRD assessment. Particularly problematic are marrows near day 21 after therapy when early regeneration is predominant, and posttherapy marrows when patients have been receiving granulocyte colony-stimulating factor therapy. With active marrow regeneration, the percentage of normal CD34-positive progenitors can be substantially increased, even exceeding 20% of cellularity in blood or marrow, and may exhibit mild immunophenotypic changes such as an increase in CD33, increased expression of CD7, and/or low level of CD5 (both generally variable on a small subset of the progenitors). With granulocyte colony-stimulating factor therapy, CD56 expression can be significantly increased on myelomonocytic progenitors and may extend even earlier to involve a subset of CD34-positive progenitors (14). CD56 expression is also constitutively seen on CD34-positive and myelomonocytic progenitors in Down syndrome and should not be mistaken for antigenic aberrancy (38).

Reporting

Reporting in AML MRD is similar to AML at diagnosis. Accurate enumeration of abnormal myeloid progenitors, currently as a percentage of white cells, is most important. Also important is a description of the immunophenotypic findings that identify the population as abnormal, i.e., that distinguish it from similar normal progenitors. As stated previously, it is critical that the immunophenotypic changes are interpreted in light of the patient's clinical setting (timing of therapy, growth factor therapy, transplant status) to reduce the risk of overinterpreting regenerative antigenic changes.

Chronic Lymphocytic Leukemia, the Prototypic Chronic Leukemia for Flow Cytometric Analysis

HEBA DEGHEIDY, DALIA A. A. SALEM, CONSTANCE M. YUAN, AND MARYALICE STETLER-STEVENSON

23

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is a neoplasm of mature B lymphocytes involving peripheral blood (PB), bone marrow (BM), spleen, and lymph nodes (LN). CLL is the most common lymphoproliferative disorder in western countries and is primarily a disease of adults, often occurring during or after middle age. The diagnosis is established by blood counts, blood smears, and immunophenotyping by flow cytometry (FC) of circulating B lymphocytes (1). Although usually an indolent disease, some patients have a more rapid disease progression and require treatment earlier. Survival in patients varies from 1 year to 20 years with an 82% 5-year survival rate (2). FC demonstration of the typical CLL immunophenotype is vital for diagnosis. The differential diagnosis of CLL/SLL would primarily include monoclonal B-cell lymphocytosis (MBL) and mantle cell lymphoma (MCL), although B-prolymphocytic leukemia, marginal zone lymphoma, diffuse large B-cell lymphoma, and lymphoplasmacytic lymphoma can on occasion have some features of CLL/SLL (Table 1) (3).

CLL cells are small, mature round lymphocytes with scanty cytoplasm and a dense nucleus with clumped chromatin. Other larger, atypical, cleaved cells or prolymphocytes may be present but only up to 55% of the PB lymphocytes. Smudge cells (bare nuclei) are a characteristic morphologic feature (1). Diagnosis of CLL requires the presence of $\geq 5 \times 10^3$ circulating monoclonal B lymphocytes with a CLL immunophenotype/μl in the peripheral blood for at least 3 months. The diagnosis of CLL can be made with fewer circulating CLL lymphocytes in patients with cytopenias or disease-related symptoms. The term SLL designates nonleukemic cases where disease is primarily tissue based (4).

ROLE OF FC IN DIAGNOSIS OF CLL

FC immunophenotyping is pivotal in the diagnosis of CLL. CLL typically demonstrates a distinctive immunophenotype, expressing CD5, CD19, dim CD20, dim CD22, CD23, bright CD43, dim CD45, dim-to-negative CD79b, dim CD81, and dim monoclonal surface immunoglobulin (Ig), making it easy to differentiate this disease from normal B cells (Fig. 1) (5, 6). Typically, CD11c expression is dim or dim to negative and CD25 is expressed, but CD10, CD103, and CD123 as well as other T-cell and myeloid antigens are negative (1, 3, 7). MBL usually has an immunophenotype identical to that of CLL, but there are fewer than 5×10^3 circulating monoclonal B lymphocytes/μl (8). This is an important distinction, as MBL has a different prognosis, with the majority of patients failing to develop a hematolymphoid malignancy (9). CD200 is uniformly expressed in CLL while the majority of MCL are CD200 negative (10). Positivity for CD200 and CD23 in combination with dim CD20, CD22, CD45, CD79b, and CD81 as well as bright CD43 differentiates CLL from MCL. Infrequent immunophenotypic variations have been observed in CLL, such as lack of CD5 and CD23, increased intensity of CD11c, CD20, and CD79b, and aberrant expression of CD10 and T-cell (CD2 and CD7) and myeloid (CD13 and CD33) antigens (11–13). The expression of these aberrant antigens in CLL is seen as a single variation in a monoclonal B-cell population that otherwise has a typical CLL immunophenotype.

ROLE OF FC IN PROGNOSTICATION

In addition to its role in the diagnosis of CLL, FC can provide important prognostic information. Although clinical staging using the Rai and Binet prognostic scoring systems has been used to predict the behavior and address the biological diversity of this disease, neither of these is sufficient to predict aggressive disease in early stages of CLL. Ig variable heavy chain (IgVH) mutational status can be used to stratify the risk of progression in CLL (14). CLL patients can be divided into two subgroups based on the degree of somatic hypermutation of IgVH genes in the CLL cells, with CLL patients with somatic hypermutation exhibiting prolonged survival over those with the unmutated IgVH gene (15). Although a potent prognostic indicator, determination of Ig mutational status is labor-intensive, costly, and not widely available. For this reason, CD38 and ZAP-70 (zeta chain-associated protein kinase 70) have been heavily investigated because of their association with the lack of IgVH mutation.

CD38 expression in CLL was first noted to correlate with an aggressive clinical course and later was shown to correlate with IgVH mutational status (16–19). Unmutated cases displayed a higher percentage of $CD38^+$ cells than mutated cases, suggesting that CD38 may serve as a surrogate marker. The cutoff for the level of CD38 positivity for poor prognosis varies in the literature, with some investigators

doi:10.1128/9781555818722.ch23

reporting 30% CD38 positivity as an independent prognosticator (17, 18, 20) while others report that CD38 is discriminatory at lower levels (19). As there is typically a continuum of CD38 expression from moderate to negative, the percentage of CD38-positive cells is measured by gating on the CLL cells and using quadrant statistics to determine the percentage of CLL cells only that express CD38 above negative controls.

ZAP-70 is a member of the Syk–ZAP-70 protein tyrosine kinase family-linked T-cell receptor. FC detection of ZAP-70 in CLL was found to be the strongest surrogate biomarker for IgVH mutational status and is an independent prognosticator (21–23). Nevertheless, several technical issues have hindered the adoption of ZAP-70 testing for clinical use, including variations in anti-ZAP-70 antibody clone and fluorochrome conjugate, fixation and permeabilization procedures, appropriate and effective controls (either internal patient or external normal donor), gating strategies, and reporting methods, which currently lack standardization. ZAP-70 and CD38 provide complementary prognostic information. Patients who express both markers would have a poor prognosis, while those in whom both of these markers are negative would have good outcome.

Cytogenetic abnormalities can be detected in approximately 82% of CLL patients using interphase fluorescence in situ hybridization, several of which are well characterized and used to stratify CLL patients into three broadly recognized risk groups: (i) low-risk (del 13q14); (ii) intermediate risk group (normal cytogenetics or trisomy 12); and (iii) high-risk patients with del 17p or del 11q (24). FC quantification of the level of CD20 expression in CLL has been shown to be predictive of cytogenetic abnormalities with a significantly lower level of CD20 expression in $11q^-$ cases, while trisomy 12 cases had a significantly higher level of CD20 expression. In addition, elevated levels of CD20 expression correlated with an improved response to rituximab therapy (25).

In the past, CLL was considered an indolent disorder, receiving mainly palliative therapy. As more effective intensive and/or combination therapies were developed, long-standing clinical remissions were achieved in the majority of patients. Minimal residual disease (MRD), which is the detection of disease in the absence of cytologic and histologic evidence of disease, was studied in patients, and MRD levels during and after therapy were shown to be independent predictors of progression-free and overall survival in CLL (26–28). Since eradication of MRD is associated with prolonged survival and quantitation of MRD levels improves the prediction of outcome and may even be used to direct therapy, this assay has achieved clinical importance in monitoring CLL patients (26–28). Sensitive detection of MRD in CLL is currently possible through PCR-based or FC MRD testing. FC is generally more broadly available, faster, and less labor-intensive and requires less specialized equipment. CLL MRD detection using FC relies on the recognition of small numbers of cells with the unique immunophenotype of CLL.

SAMPLE PREPARATION FOR FC ANALYSIS: GENERAL

Appropriate samples for CLL FC include PB, BM, and LN biopsy or fine-needle aspiration (FNA). In general, proper collection, processing, analysis, and correlation with ancillary testing are all crucial to FC diagnostic evaluation of any hematolymphoid neoplasm (see reference 29 for additional technical details). Blood and BM specimens must be

collected in an appropriate anticoagulant such as sodium heparin (preferable), EDTA, or ACD (acid citrate dextrose) (PB only, not appropriate for BM). PB samples are stable at room temperature for up to 72 h in sodium heparin and ACD but only up to 24 h in EDTA. BM samples are stable in sodium heparin for up to 24 h, while specimens placed in EDTA should be processed within 12 h. A LN biopsy specimen must be made into a cell suspension using mechanical tissue disaggregation (achieved by slicing, mincing, and teasing apart the tissue using commercial devices or manual tools). FNA samples usually do not require further disaggregation and can be directly stained. Adverse storage conditions before staining could damage the cells of interest, and overnight shipment of specimens (potentially exposing specimens to temperature extremes) has been shown to alter antigen expression (29–31). Viability should be assessed (especially in LN and FNA specimens) and samples with less than 75% viability rejected unless the sample is irreplaceable, in which case every effort must be made to obtain diagnostic information. Minimizing sample treatment before staining and timely sample processing greatly reduce the risk of losing cells of interest (especially in the case of CLL MRD) and maintain cell viability and integrity. However, the cells must be washed with warm or room temperature phosphate-buffered saline before staining for light chains to remove serum immunoglobulin and cytophilic antibody. Erythrocytes should be removed by lysis, not density gradient separation (29).

DIAGNOSIS OF CLL

CLL has a distinctive immunophenotype and can be diagnosed based upon FC testing in combination with complete blood count results. The antibody panel should always include a screening tube that allows identification of abnormal B, T, NK, granulocytic, and monocytic cells as well as the presence of blasts, even in patients with a confirmed diagnosis of CLL, as the patient might have a second neoplastic process (32). There are two general approaches, namely use of a minimal screening panel followed by a larger specific panel based upon preliminary results or use of a more extensive panel up front. The best approach in panel design depends on issues facing an individual laboratory, and these are discussed elsewhere (32). In the initial diagnosis of CLL and exclusion of other T- or B-cell lymphoproliferative disorders (Tables 1 and 2), we evaluate the following antigens up front: CD2, CD3, CD4, CD5, CD7, CD8, CD10, CD11c, CD19, CD20, CD22, CD23, CD25, CD38, CD43, CD45, CD56, CD57, CD79b, CD81, CD103, CD123, CD200, T-cell receptor γδ (TCR-γδ), surface kappa light chain (sIgκ), and lambda light chain. Since there is no screening tube, CD2, CD3, CD4, CD5, CD7, CD8, CD45, CD56, CD57, and TCR-γδ allow the identification of a T- or NK-cell lymphoproliferative process (Table 2). The Euroflow consensus panel utilizes a screening tube followed by a B-cell-specific panel which adds the additional antigens CD27, CD31, CD39, CD49d, CD62L, CD95, CD185, CD305, HLA-DR, and sIgM but does not evaluate CD25 and CD123 on B cells or CD2, CD7, and CD57 (T- and NK-cell processes are not evaluated after the initial screening tube) (33).

Diagnosis of CLL/SLL and exclusion of other B-cell lymphoproliferative disorders (Table 1) depends upon FC demonstration of the characteristic CLL immunophenotype. Analysis of FC data should first involve examination of all cells. B cells can then be further characterized in a lymphocyte gate based upon forward scatter (FSC) versus side scatter (SSC) (after validating, the gate includes T, B, and NK cells) augmented by a CD19 versus SSC gate. If

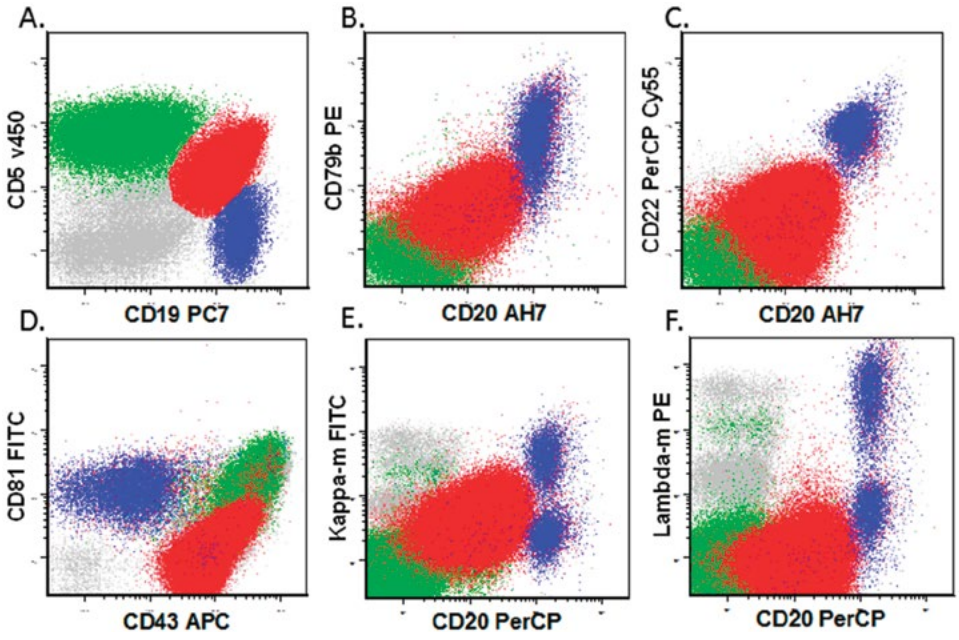

FIGURE 1 Peripheral blood specimen with CLL cells (red), patient's residual nonneoplastic B cells (blue), and T cells (green). (A) The red CLL cells are CD19 and CD5 positive. The blue nonneoplastic B cells are CD19 positive but CD5 negative. The normal T cells are CD5 positive but CD19 negative. (B) The nonneoplastic B cells (blue) show normal levels of CD20 and CD79b expression. The CLL cells (red) have dim CD20 and dim CD79b expression. (C) The nonneoplastic B cells have normal levels of CD20 and CD22, while the CLL cells are dim for both. (D) The nonneoplastic B cells have normal CD81 intensity and are dim to negative for CD43. The CLL cells are negative for CD81 and have bright CD43 expression. The normal T cells (green) provide an internal CD81 and CD43 positive control. (E, F) CD20 on the *x* axis helps to separate the B cells from non-B-cell elements and the CLL cells from the nonneoplastic B cells. The nonneoplastic B cells are polyclonal for kappa and lambda, while the CLL cells have dim kappa expression but are negative for lambda. PE, phycoerythrin; PerCP, peridinin chlorophyll protein; FITC, fluorescein isothiocyanate; APC, allophycocyanin v450, violet 450; PC7, phycoerythrin cyanin 7; AH7, allophycocyanin H7 (analog dye to APC-cyanin 7 dye).

CD45 gating is used, care must be taken to not gate out the dim CD45-positive cells. In nontreated CLL, CD19- and CD5-positive monoclonal (i.e., restricted to kappa or lambda light chain) B cells predominate and have dim expression of sIg, CD20, CD22, CD45, CD79b, and CD81 but moderate CD23 and bright CD43 (Fig. 1). In addition, they express CD200 but are negative for CD10, CD103, and CD123. Therefore, for interpretation of results, one must know the normal intensities of these antigens within the individual laboratory, since residual normal B cells can be rare in CLL and therefore not available for comparison. Comparison of CD43 and CD81 to expression on normal T cells can be helpful. Infrequently, an immunophenotype that is atypical for CLL is observed (lack of CD5 or CD23; aberrant CD10, T-cell, or myeloid antigens; normal expression of a B-cell antigen or sIg); however, some aspects of the typical CLL immunophenotype are usually present, giving a clue as to the correct diagnosis (11–13). Morphology, molecular studies, cytogenetics, and clinical history are helpful in such cases. In blood, the number of CD5-positive monoclonal B cells must be $\geq 5 \times 10^3/\mu l$ to meet the diagnostic criteria for CLL ($<5 \times 10^3/\mu l$ would be MBL), so correlation with complete blood count results is optimal.

Although CD19- and CD5-positive monoclonal B cells are also observed in MCL, there is moderate expression of CD20, CD22, CD45, and CD79b, while CD23 is dim or negative and CD200 is not expressed in MCL (10). Furthermore, detection of cyclin D1 also may be helpful in confirming MCL diagnosis. Some hairy cell leukemia cases may express CD5, but they express bright B-cell markers together with CD11c, CD103, and CD123 (34). CD5-positive follicular lymphoma has also been described, but again, the typical CLL immunophenotype is missing and CD10 expression is observed (35).

ZAP-70 ANALYSIS IN CLL

ZAP-70 is a labile protein that degrades over time, so specimens should be processed within 24 h of sample collection. Furthermore, rapid processing is necessary to maintain cell viability and reduce the risk of losing cells of interest. Washing the cells with 5% fetal bovine serum in phosphate-buffered saline is recommended, and lysis of red blood cells in bloody specimens is an essential step.

ZAP-70 Antibody Clone, Fluorochrome, and Methods of Permeabilization

The quality of FC ZAP-70 testing depends upon the combination of anti-ZAP-70 antibody clone (Fig. 2), fluorochrome conjugate, and method of fixation or permeabilization utilized. The ZAP-70 clone or conjugate should be selected based on its ability to highly discriminate between the levels of desired signal to the level of noise (signal-to-noise ratio). Validated permeabilization methods for ZAP-70 assessment include Triton (36), a saponin-based method (37), and the commercially available Fix & Perm (38). However, the

optimal fixation and permeabilization method may depend upon the antibody clone and fluorochrome conjugate utilized. The SBZAP-phycoerythrin (PE) clone had the highest known signal-to-noise ratio using a Triton-based method for permeabilization (36, 39, 40). Also, 1E7.2 AF488 was extensively used in a clinical laboratory and reported to have the best results using saponin as a method of permeabilization (37). It is recommended to test the specific ZAP-70 antibody clone or conjugate with permeabilization methods on normal donor cells before selecting the system to be utilized for ZAP-70 assessment.

Method of ZAP-70 Analysis and Reporting

Since the ZAP-70 protein is expressed at low levels, it is sometimes difficult to determine if CLL cells are negative or if there is dim expression. Several methods have been used to address this issue in ZAP-70 analysis, including the isotype method, determining the percent positive using the residual internal T-cell population (Fig. 2), using normal donor T cells as a reference point for the determination of percent positive (Fig. 2), and ratios using mean fluorescent intensity (MFI) (21, 23, 39, 41–44). The isotype method involves staining a specimen with an isotype control and with anti-ZAP-70 antibody. Positivity is defined as cells staining more intensely with the anti-ZAP-70 antibody than with isotype control with a cutoff value of 11% or higher ZAP-70 positivity (39, 41). Since normal T cells express ZAP-70, residual normal T cells can be used as an internal positive control to determine ZAP-70 positivity (21, 39). As residual normal T-cells may be low in number, others have used T-cell ZAP-70 positivity in a parallel normal donor specimen to determine the cutoff point for positivity (23, 39). A cutoff value of 20% has been utilized to determine percent positive using either the patient's residual normal T cells or normal donor T cells. Others have used a ratio of the MFI of ZAP-70 staining by the CLL cells and other populations, such as the ZAP-70 MFI in the patient's residual normal T cells/MFI in CLL cells (39, 42, 43), the MFI in normal donor T cells/MFI in CLL cells (39, 44), the MFI in the CLL cells/MFI in normal residual B cells (39, 42), and the MFI in the CLL cells/MFI in normal donor B cells (45). A cutoff value of <3.0 was considered positive for the ratiometric method using either patient or normal donor T cell MFI/MFI of CLL cells, and a value of >1.4 was considered positive using the ratio of MFI in CLL cells/MFI in B cells from either patients or normal donor. Shankey et al. developed the CLL-Z index for analysis of ZAP-70 in CLL (36). The CLL-Z index uses the MFI of ZAP-70 in the patient's CLL cells, residual normal B cells (negative for ZAP-70), and residual normal T cells.

$$\text{CLL-Z index} = \frac{(\text{CLL clone MFI} - \text{B-cell MFI})}{(\text{T-cell MFI} - \text{B-cell MFI})} \times 100$$

The CLL-Z index would need to be validated within an individual laboratory using the specific reagents. Shankey

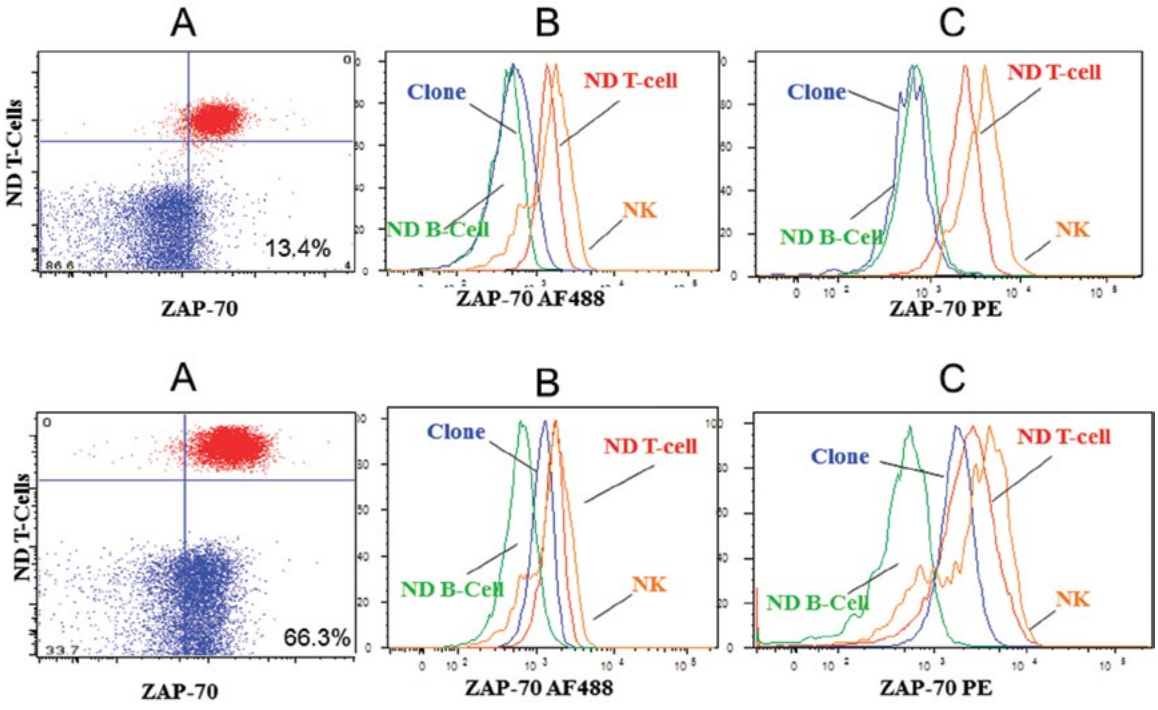

FIGURE 2 Flow cytometric analysis of ZAP-70 expression. The upper row is an example of a ZAP-70-negative case, while the lower row is an example of a ZAP-70-positive CLL case. Different methods of ZAP-70 reporting are shown. Panel A shows the percentile method, where the marker was placed so that the gated T cells ($CD3^+$, $CD19^-$) and natural killer (NK) cells ($CD16/56^+$, $CD19^-$) with a high level of ZAP-70 expression would appear in the upper right quadrant. Gated CLL cells ($CD19^+$, CD20 dim, $CD5^+$) were plotted using the same quadrant, and the percentage of CLL cells that showed ZAP-70 positivity (the lower right quadrant) was calculated using 20% as a cutoff value for positivity. Panels B and C show histograms demonstrating the overlay of normal donor (ND) B cells (green), CLL clonal cells (blue), ND T cells (red), and ND NK cells (orange) using ZAP-70 1E7.2 AF488 (B) and SBZAP PE (C). Note the high signal-to-noise ratio seen with the SBZAP PE clone compared to ZAP-70 1E7.2 AF488.

et al. reported values of 0.3 as negative, 6.0 as low positive, and 27.0 as high positive ZAP-70 expression in their laboratory (36).

Variability in ZAP-70 Testing

The reported level of ZAP-70 expression varies greatly depending not only on the antibody but also the method used to express the results. Studies have observed a difference in the percentage of CLL cells stained positive for ZAP-70 when different monoclonal antibodies were used, even when the same gating strategy was used on the same CLL population. Studies indicate that the ratiometric method results in a much lower interlaboratory variation than other reporting strategies and is recommended for multicenter studies (39, 46). The observed variation in ZAP-70 testing led to the concept that a scoring system combining four methods of analysis (including percent positive and ratiometric methods) and using two clones for assignment of ZAP-70 expression would improve the precision of testing (44). The rationale is that if one clone was unable to clearly assess ZAP-70 expression by four methods of analysis, the addition of a second clone might aid in this assessment. Even if ZAP-70 expression is positive by three or four methods of analysis, the confirmation by a second reagent enhances the analytic precision and improves its correlation with the two major primary prognostic CLL biomarkers: IgVH and cytogenetic abnormalities (44). It is important to note that using several methods of analysis, even with just one antibody, improves ZAP-70 expression assignment. The combined ZAP-70 score using two reagents permitted the assignment and resolution of equivocal cases that could not be solved using one reagent (44). A normalization step of adding B cells from a pool of normal donor peripheral blood mononuclear cells constitutes a second step toward improving test precision (23). More recently, the concept of combining normal donor cells and CLL patient samples in one tube was proposed in order to have an internal negative control (normal donor B cells) and positive control (normal donor T cells) (47). Using this combined sample, two anti-ZAP-70 clones that target different epitopes and simultaneous assessment of ZAP-70 expression by five methods of analysis allowed a

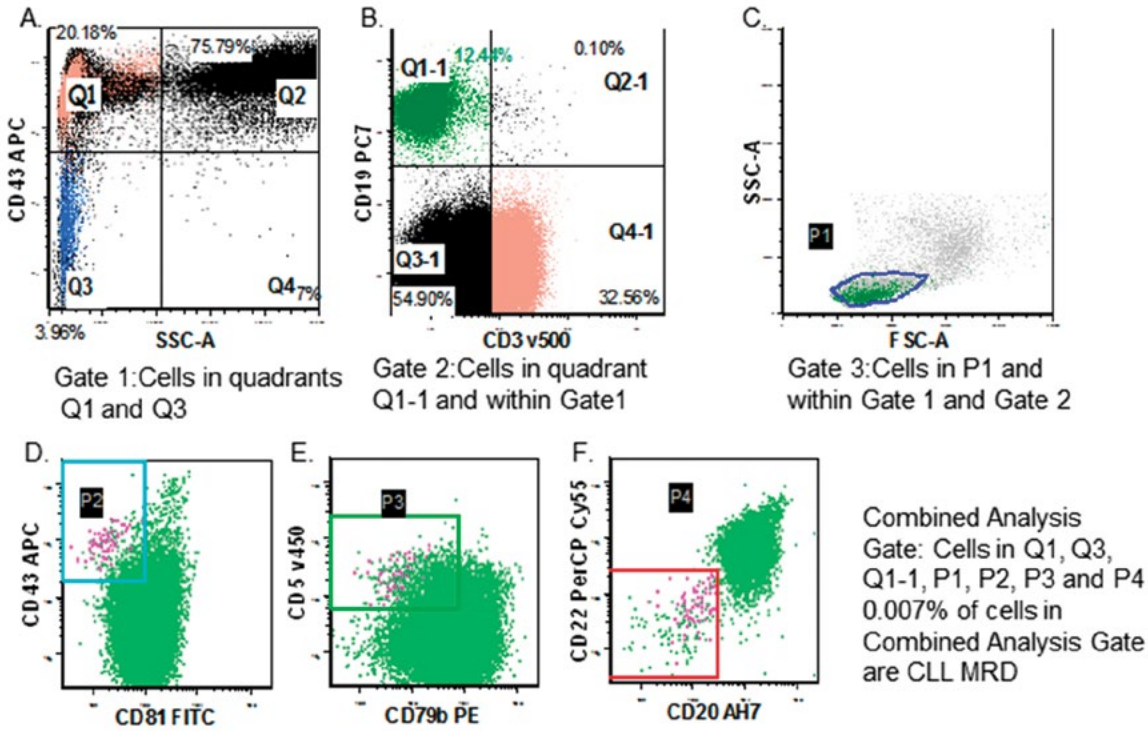

FIGURE 3 ERIC method of flow cytometric CLL MRD analysis. (A) All cells shown. A quadrant type of gate (gate 1) is set including the lymphocytes and monocytes in quadrant Q1 and quadrant Q3 (gate 1: $CD43^+$ and $CD43^-$, low SSC). (B) Cells from gate 1 shown. Gate 2 is restricted to the cells in gate 1 and the CD19-positive and CD3-negative cells in quadrant Q1-1 (gate 2: $CD19^+$, $CD3^-$, $CD43^+$, and $CD43^-$, low SSC). (C) Cells from gate 2 shown. Gate P2 targets abnormal CD43-bright and CD81-dim-to-negative cells in gate 3 (gate 3: $CD19^+$, $CD3^-$, $CD43^+$, and $CD43^-$, low SSC, FSC consistent with lymphocytes). (E) Cells in gate 3 shown. Gate P3 targets abnormal CD79b-dim-to-negative and CD5-positive cells in gate 3 (gate 3: $CD19^+$, $CD3^-$, $CD43^+$, and $CD43^-$, low SSC, FSC consistent with lymphocytes). (F) Cells in gate 3 shown. Gate P4 targets abnormal CD20-dim and CD22-dim CD19-positive cells in gate 3 (gate 3: $CD19^+$, $CD3^-$, $CD43^+$, and $CD43^-$, low SSC, FSC consistent with lymphocytes). The final combined analysis gate for CLL MRD includes only cells in gates 1, 2, 3, P2, P3, and P4 which are CD19 positive, CD3 negative, CD43 bright positive, CD81 dim to negative, CD79b dim to negative, CD5 positive, CD20 dim positive, CD22 positive, with low SSC and FSC consistent with lymphocytes.

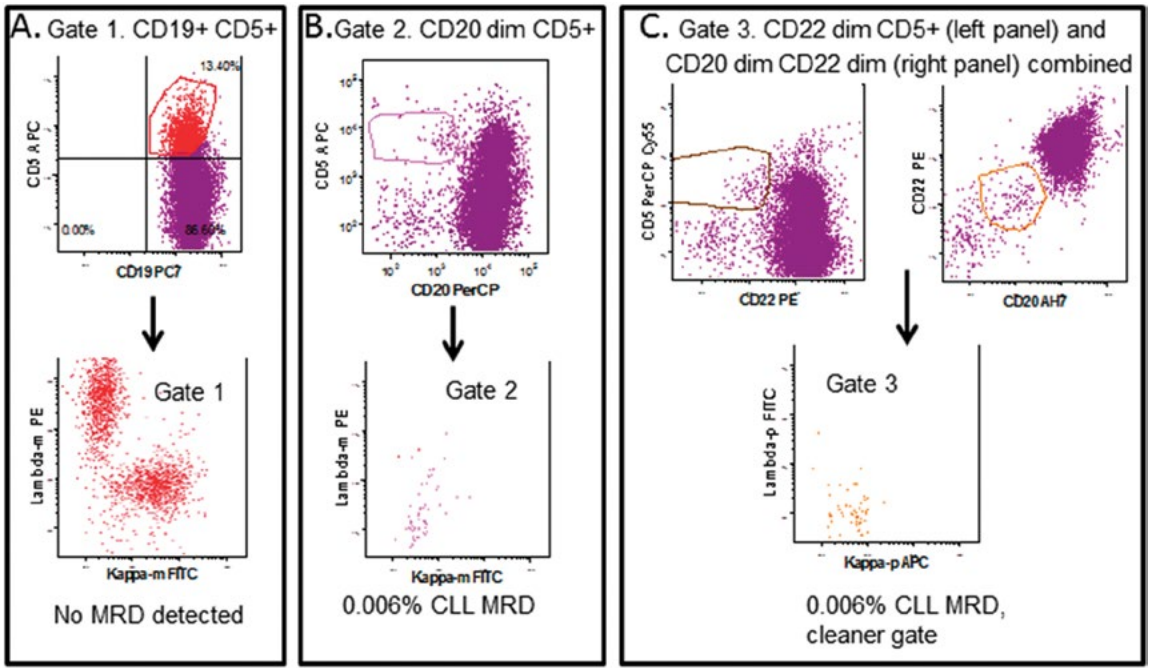

FIGURE 4 (A) CD19-positive lymphocytes (upper panel) and CD19- and CD5-positive cells (lower panel) are shown. In the upper panel, the CD19-positive and CD5-positive B cells are gated (in red), and in the lower panel, the lack of light chain restriction is demonstrated. No CLL MRD was detected. (B) CD19-positive lymphocytes (upper panel) and CD20-dim and CD5-positive cells (lower panel) are shown. In the upper panel, CD20-dim and CD5-positive B cells are gated (light purple), and in the lower panel, CLL MRD is demonstrated by light chain restriction. (C) CD19-positive lymphocytes (upper panel) and CD20-dim, CD22-dim, and CD5-positive cells (lower panel) are shown. In the upper panel, CD22-dim, CD5-positive, CD20-dim, and CD22-dim cells are gated (brown). In the lower panel, CLL MRD is demonstrated by light chain restriction and a cleaner analysis gate is achieved.

precise improved evaluation of ZAP-70 expression in one tube (47).

ZAP-70 and CD38 provide complementary prognostic information.

CLL MRD DETECTION

FC CLL MRD detection is performed in a manner similar to diagnosis of CLL with certain modifications. The simple historical approach incorporating analysis for CD19/CD5 coexpression coupled with clonality assessment using surface kappa/lambda expression is inadequate for CLL MRD studies. Several FC MRD CLL detection approaches have been previously described using different combinations of antibodies (5, 26, 48–51). Later, an international standardized approach was developed in 2007 and further expanded into the European Research Initiative in CLL (ERIC). This method is highly reproducible and has been validated in multicenter randomized clinical trials (5, 27, 50, 52, 53). The number of cells analyzed is critical for sensitive CLL detection. One million leukocytes is the lowest acceptable minimum number of cells to be acquired per tube, and a sensitivity of 0.001% can be attained with 1.8 million or higher acquisition (50, 51).

The ERIC approach to analysis involves a Boolean gating strategy in which CD19-positive B cells are evaluated and a series of analysis regions (called gates) created in areas where normal B-cell populations are not observed. This is utilized to detect very low numbers of abnormal B cells consistent with CLL (Fig. 3) (50). Simply looking at CD5- and CD19-positive B cells is not adequate (Fig. 4A). We have utilized methodology in which abnormal B-cell populations have been identified and kappa or lambda light chain restriction demonstrated (Fig. 4). This has been shown to be as effective as the ERIC method (54).

Plasma Cell Disorders

JUAN FLORES-MONTERO, LUZALBA SANOJA, JOSÉ JUAN PÉREZ, FANNY POJERO, NOEMÍ PUIG, MARÍA BELÉN VIDRIALES, AND ALBERTO ORFAO

24

Clonal plasma cell disorders (PCDs) encompass a heterogeneous group of distinct entities characterized in common by a clonal expansion and accumulation of plasma cells (PCs) in the bone marrow (BM) and/or other tissues, which is associated in the vast majority of cases with the presence of their product(s) (monoclonal immunoglobulin [Ig], M component) at detectable amounts in serum or urine (1). Although the so-called diseases of immunoglobulin deposits (e.g., primary light chain [AL] amyloidosis) and lymphoplasmacytic lymphoma (e.g., Waldenström macroglobulinemia) also belong to this heterogeneous group of disorders, its most representative diagnostic subtypes include monoclonal gammopathy of undetermined significance (MGUS), solitary plasmacytoma, multiple myeloma (MM), plasma cell leukemia (PCL), and several subvariants of these entities (1, 2) (Table 1). The last four diagnostic categories of PCD are the main focus of this chapter.

Current diagnostic and classification criteria for PCD are largely based on the cytomorphological/histopathological demonstration of PC infiltration of BM (or other tissues such as the bone), the presence, subtype, and amount of the M component, and the occurrence of organ damage (e.g., the CRAB criteria, consisting of hypercalcemia, renal failure, anemia, and/or bone lesions) (Table 2). In contrast to what occurs in most other hematological malignancies, the clinical utility of flow cytometry immunophenotyping in the diagnosis and classification of PCDs remains frequently limited to a small subset of cases in which the PC nature of the tumor cell remains indefinite by other approaches. Despite this, the immunophenotypic features of the PCs infiltrating the BM and the pattern of involvement of the B lymphopoiesis in the BM by flow cytometry remain of major relevance for prognostic stratification of PCD patients and minimal residual disease (MRD) monitoring during and after therapy.

In this chapter, we review the clinical utility of multiparameter flow cytometry (MFC) immunophenotypic identification, quantification and characterization of PCs, and the discrimination between clonal and normal/reactive PC phenotypes in the diagnosis, prognostic stratification, and monitoring of patients with PCDs.

DIAGNOSTIC SUBGROUPS OF CLONAL PLASMA CELL DISORDERS

Important advances have been achieved in the last decades as regards the identification of distinct diagnostic categories of PCD such as MGUS, MM, solitary plasmacytoma, and their subvariants (Table 1). From all diagnostic subtypes of PCD, MGUS is by far the most frequent one, with a prevalence of ~5% among the general population of more than 70 years of age. At present, MGUS is defined by the presence of an M component of <30 g/liter, associated with low-level infiltration of BM by PCs (<10%) in the absence of end organ damage or signs of an underlying related lymphoma. Depending on the type of M component, three variants of MGUS are currently recognized: secretory IgM, secretory non-IgM, and light-chain MGUS; whereas all three may (rarely) evolve to systemic AL amyloidosis, the first most frequently transforms to Waldenström macroglobulinemia at a rate of 1.5% per year, and the last two typically evolve to MM at slightly lower rates (1% and 0.3% per year, respectively) (2–5). In contrast, the presence of a localized PC tumor is a rare disease condition that defines solitary plasmacytoma. From a diagnostic perspective, solitary plasmacytomas may occur in the absence or in the presence of minimal BM involvement by clonal PCs with a variable but greater rate of progression to MM than MGUS; e.g., at 3 years, 10% to 60% of cases evolve to MM (2, 6, 7). Finally, MM is defined by an M component greater than 30 g/liter and/or BM involvement by >10% PCs; the absence versus the presence of end organ damage (i.e., the CRAB criteria) distinguishes smoldering MM (SMM) from symptomatic MM (MM), except if there is massive BM involvement by PCs (>60%) which is a stand-alone criterion for MM, even in the absence of end organ damage (2). A summary of the different disease categories and their diagnostic criteria is included in Table 2. Similarly to MGUS, isolated plasmacytoma and MM are also more prevalent in the elderly, with a predominance in men over women and a higher incidence among the African-American population (1, 8). Thus, MM shows an age-adjusted incidence of 4 to 6 cases/100,000 inhabitants/year (twice as much among the African-American population as among the Caucasian and Asian populations), with a mean age at diagnosis of 70 years and a male-to-female ratio of 1.4:1 (1, 8). Finally, PCL is a rare and highly malignant PCD condition, which may occur *de novo* or through transformation of a previously diagnosed MM; from a clinical point of view, diagnosis of PCL requires the presence of a significant number (>20% or >2,000 PCs/μl) of circulating PCs in peripheral blood (PB) (Table 2).

doi:10.1128/9781555818722.ch24

TABLE 1 Current classification of clonal plasma cell disorders according to the WHO 2008 criteria refined by the IMWG in 2014[a]

MGUS
Non-IgM MGUS
IgM MGUS
Light-chain monoclonal MGUS
MM
Smoldering MM
Symptomatic MM
Plasma cell leukemia
Plasmacytoma
Solitary plasmacytoma
Solitary plasmacytoma with minimal marrow involvement
POEMS syndrome
Systemic AL amyloidosis

PROGRESSION OF MGUS, SOLITARY PLASMACYTOMA, AND SMM TO SYMPTOMATIC MM

Despite the clear-cut definition that currently exists for the distinct diagnostic subtypes of PCDs at present, MGUS, isolated plasmacytoma, SMM, symptomatic MM, and PCL are all viewed as a spectrum of the same disease; thus, the first three entities are considered to include premalignant disorder states of PCD (9), which may progress to symptomatic MM at variable rates. For example, SMM shows a yearly risk of transformation to MM of 10% (versus 1% for MGUS) during the first 5 years after diagnosis; thereafter, while the risk of progression of MGUS remains the same, the risk of SMM to progress decreases to 3% in the following 5 years and to 1% thereafter (2, 6, 8, 9); similarly, isolated plasmacytoma has been shown to progress to MM at various rates, depending on the absence versus the presence of low levels of clonal PCs in the BM and, among the latter, the specific location of the plasmacytoma (soft tissue versus bone), with an overall 3-year rate of progression of around 10%, 20%, and 60%, respectively (6, 7).

In this regard, it should be noted that until now, treatment of PCD patients has been typically restricted to the malignant conditions (e.g., symptomatic MM and PCL), while for premalignant states such as MGUS and SMM, it is recommended to wait and see, before deciding on the administration of active treatment. Despite this, recent studies suggest that early administration of therapy in high-risk SMM could be of significant clinical benefit (10). Therefore, identification of SMM patients (and potentially also of MGUS cases) at high risk of progression becomes of the utmost clinical relevance.

ROLE OF FLOW CYTOMETRY IMMUNOPHENOTYPING IN PCD

For decades now, the use of MFC immunophenotyping has been mandatory for the diagnosis and classification of most hematologic malignancies, particularly of acute leukemias and chronic lymphoproliferative disorders (11–14). In contrast, the diagnostic utility of MFC in PCD still remains controversial, and its usage varies widely among different clinical diagnostic laboratories (14, 15). In part, this is due to the initial lack of PC-specific markers and the lower percentages of PC detected in aspirated BM samples by MFC than by cytomorphology (16, 17), together with the disturbing levels of variability initially reported as regards the phenotypic characteristics of normal versus clonal PCs, due to a large extent to methodological differences and the lack of standardized flow cytometry procedures (18–22). In parallel, flow-cytometric assessment of MRD (flow-MRD) has become the preferred method for high-quality evaluation of complete remission (CR) and to monitor the effect of therapy in MM. From a practical point of view, usage of MFC immunophenotyping in PCDs requires accurate identification (and potentially also quantitation) of PCs in BM and other tissues, with the ability to discriminate between clonal and normal/reactive PC phenotypes, even when pathological PCs are present in very low numbers (21–29).

IMMUNOPHENOTYPIC IDENTIFICATION OF PLASMA CELLS

Mature PCs lack expression of most pan-B-cell-associated markers. For years, with the exception of cytoplasmic Ig (CyIg), no other PC-associated marker was identified (30, 31). Because of this, PCs were originally considered to be antigenically silent B cells. Later on (i.e., in the 1980s), CD38 emerged as a reliable and robust candidate PC-associated marker.

CD38 is a multifunctional ectoenzyme involved in cell adhesion, signal transduction, and calcium signaling (32), which is relatively broadly expressed across different hematopoietic cells and cell lineages, including the great majority of $CD34^+$ hematopoietic stem and precursor cells (20). Thus, CD38 is strongly upregulated on $CD34^+$ cells, where it can be seen at particularly high amounts in the B-cell committed precursors (33). Along the B-cell maturation pathway, CD38 expression is downregulated in the BM at the transitional/immature B-lymphocyte maturation stage, to become undetectable in naive B cells (34). Later on, B lymphocytes, which are activated by their antigen, reexpress and upregulate CD38 towards very high levels observed on germinal-center (GC) B cells (11, 34); further maturation of these $CD38^{hi}$ GC B lymphocytes into memory B cells leads to downregulation of CD38; in contrast, PC differentiation of GC B lymphocytes is associated with a further increase on CD38 positivity, leading to a uniquely strong expression of this marker ($CD38^{hi+}$) at levels significantly greater than those of GC B cells (34). In fact, normal PCs express CD38 at much higher levels than any other $CD38^+$ hematopoietic cell present in the PB and BM, e.g., monocytes, NK cells, activated T lymphocytes, or $CD34^+$ precursors and B-cell progenitors (e.g., hematogones) (20). Because of this, CD38 has long been considered one of the few (most) reliable markers and it is currently recommended for the identification of PCs by flow cytometry (15, 35).

Other markers that have been described to be either PC associated or PC specific include, for example, CD138, CD229, and CD319. Among them, CD138 (i.e., syndecan 1) (36) is the most well suited and preferred marker for the identification of BM PCs, in combination with CD38; importantly, CD138 is expressed at similar levels on both normal/reactive BM PCs and PCD PCs (15). In contrast to CD38, expression of CD138 within the hematopoietic system seems to be restricted to PCs and a small subset of lymphocytes, making it a rather specific PC marker (Fig. 1 and Table 3) (36). Nevertheless, downregulation of CD138 expression has been recurrently reported, particularly for aged samples (37) and on PCs from heparin- (in contrast to EDTA-) anticoagulated samples (because of potential binding of heparin to CD138 and possible epitope masking) (38).

TABLE 2 IMWG diagnostic criteria for the major categories of PCDs[a]

Disease category	% and site of infiltration	Type, amt of M component	PCD disease-caused end organ damage	Other criteria
MGUS				
Non-IgM MGUS	<10% BM cPCs	Serum non-IgM, <30 g/liter	No	
IgM MGUS	<10% BM LPC	Serum IgM, <30 g/liter	No	Absence of disease, constitutional symptoms, hyperviscosity, lymphadenopathies, or hepatosplenomegaly
Light-chain MGUS	<10% BM cPCs	Nondetectable by IF, <500 mg/24 h in urine	No	Abnormal FLC ratio <0.26 (if increased λ FLC) or >1.65 (if increased κ FLC) No amyloidosis
MM				
Smoldering MM	10–60% BM cPCs	Serum IgG or IgA, ≥30 g/liter or ≥500 mg/24 h in urine	No	Absence of MM-defining events or amyloidosis
Symptomatic MM	≥10% BM cPCs (or cPCs in bone or soft tissue by biopsy[d] + any MM-defining events)		Yes[b] Hypercalcemia: serum Ca >0.25 mmol/liter (>1 mg/dl), above the upper limit or >2.75 mmol/liter (>11 mg/dl) Renal failure: creatinine clearance <40 ml/min or serum creatinine >177 μmol/liter (>2 mg/dl) Anemia: >20 g/liter below the lower limit or Hb <100 g/liter Bone lesion(s) on skeletal X rays, CT, or PET-CT	Presence of biomarkers of malignancy[b] ≥60% BM cPC[d] Involved/uninvolved FLC ratio ≥100 (involved light chain ≥100 mg/liter) by Freelite assay[c] >1 focal (>5mm in size) lesion on MRI studies
Plasmacytoma				
Solitary plasmacytoma	Presence of cPCs in bone or soft tissue by biopsy Absence of BM cPCs		No	Otherwise normal skeletal survey and MRI (or CT), but for the presence of the solitary lesion
Solitary plasmacytoma with minimal BM involvement	Presence of cPCs in bone or soft tissue biopsy specimen, <10% BM cPCs		No	Otherwise normal skeletal survey and MRI (or CT), but for the presence of the solitary lesion
PCL	>20% PB PCs or $>2 \times 10^9$ PB PCs/liter

[d]Clonality should be demonstrated by light-chain restriction by flow cytometry, immunohistochemistry, or immunofluorescence.

Based on all the above, a consensus has now existed for several years that combined use of CD38 and CD138 is mandatory for adequate identification of BM PCs, in both normal/reactive and PCD patient samples, in the diagnostic and MRD settings (15). In addition, for optimal exclusion of other non-PC events potentially contaminating the $CD38^{hi}$ $CD138^{+}$ PC gate, CD45 should also be stained simultaneously and used for PC gating purposes, in addition to right-angle light scatter (RALS) and forward-angle light scatter (FALS) (Fig. 1) (15, 35, 39).

Despite the above consensus regarding the most reliable combination of flow cytometric parameters for efficient PC identification, alternative markers may be required under specific circumstances, such as in MM patients undergoing new antibody-based targeted therapies (40). For example, the benefits of CD38 (daratumumab, SAR650984, and MOR 202) humanized antibody treatments are now being investigated in several clinical trials (41–45). Consequently, usage of CD38 as a PC identification marker in the context of MRD evaluation of patients treated with such novel antibody-based therapies is compromised and alternative markers/clones to the conventional CD38 (and also CD138) reagents have been investigated in the MRD settings. In this regard, CD229 and CD54, in addition to CD319, have emerged as potential candidate markers to replace CD38 and/or CD138 in MRD antibody combinations for the identification of PCs (Table 3) (46–49). However, further extensive testing, in large series of samples, of distinct clones and fluorochrome conjugates of CD54, CD229, and CD319 is still needed before they can be recommended in routine practice as valid alternative PC identification markers. In this regard, it might also be possible to replace currently used CD38 reagents with other CD38 antibody clones directed against different epitopes of the CD38 molecule from those targeted by the therapeutic humanized reagents, instead of changing CD38 with another PC-associated marker. Once again, further studies are still required to define which are (or might be) such alternative CD38 clones, since treatment with daratumumab, for example, appears to mask the binding of virtually all commercially available antibody clones evaluated so far (J. Flores-Montero, L. Sanoja, and A. Orfao, unpublished observations).

IMMUNOPHENOTYPIC CHARACTERISTICS OF NORMAL PLASMA CELLS

PCs represent the last stages of maturation of B lymphocytes into antibody-producing cells. Thus, PCs typically derive from antigen-activated B lymphocytes that have undergone a multistep maturation process that usually starts in secondary lymphoid tissues such as the lymph nodes, spleen, BM, and mucosa-associated lymphoid tissues (50). Recently produced PCs leave their tissue of origin and migrate to PB; from there, they reach and populate those tissues in which long-living PCs can be usually detected, such as the BM and the gastrointestinal mucosa, among other peripheral

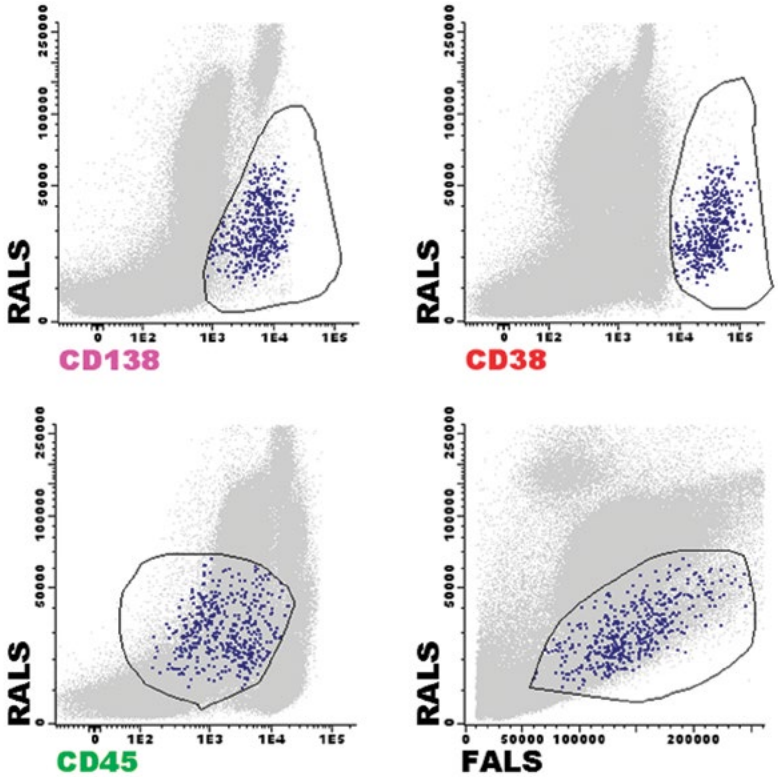

FIGURE 1 Normal bone marrow (BM) plasma cells (PCs) in an illustrating example of a consensus PC-gating strategy. Classic bivariate dot plots showing the minimal set of parameters recommended for accurate identification and gating of total BM PCs (dark blue dots). A combination of sequential gating, which must include CD138, CD38, and preferably CD45, together with light scatter properties, is recommended for accurate identification of PCs in BM samples. Once identified, PCs can be quantitated (0.12% of total nucleated cells in the illustrated example [gray dots]) and further characterized on phenotypic grounds. Abnormal PC populations may display lower levels of CD38 expression than normal BM PCs.

TABLE 3 List of the most relevant plasma cell (immunophenotypic) markers and their respective clinical values

Target	Normal BM PC expression pattern	MAP	% of MAP expression cases	Main recognized clinical utility
CD19	−/+ (% of $CD19^+ \approx 64\%$)	−	96	Phenotypic characterization of clonal versus normal PCs Differential diagnosis between PCDs versus B-CLPDs and IgM versus non-IgM MGUS Risk stratification in MM MRD detection
CD20	− (% of $CD20^+ \approx 4\%$)	dim^+	17–30	Phenotypic characterization of clonal versus normal PCs Differential diagnosis between PCDs versus B-CLPDs and IgM versus non-IgM MGUS Marginal utility for MRD detection versus other MRD markers
CD27	+ (% of $CD27^{dim}$, NR)	− or dim^+	40–68	Phenotypic characterization of normal versus clonal PCs MRD detection
CD28	− (% of $CD28^+ \approx 15\%$)	+	15–45	Phenotypic characterization of clonal versus normal PCs Risk stratification in MM MRD detection
CD33	− (% of $CD33^{dim} \approx 6\%$)	+	18	Phenotypic characterization of clonal versus normal PCs Marginal utility for MRD detection versus other MRD markers
CD38	Bright+	dim^+	80	Mandatory PC identification marker Phenotypic characterization of clonal versus normal PCs MRD detection Monoclonal antibody-based therapeutic target
CD45	−/+ (% of $CD45^+ \approx 6\%$)	−	73	Highly recommended PC identification marker Phenotypic characterization of clonal versus normal PCs Differential diagnosis between PCDs versus B-CLPDs and IgM versus non-IgM MGUS MRD detection
CD54	+	dim^+	60–80	Potentially useful PC identification marker Marginal utility for MRD detection versus other MRD markers
CD56	−/+ (% of $CD56^{dim} \approx 10\%$)	++	60–75	Phenotypic characterization or clonal versus normal PCs Differential diagnosis between PCD versus B-CLPD and IgM versus non-IgM MGUS MRD detection
CD81	+	− or dim^+	55	Phenotypic characterization of clonal versus normal PCs Risk stratification in MM MRD detection
CD117	−	+	30–32	Phenotypic characterization of clonal versus normal PCs Risk stratification in MM MRD detection
CD138	+	NR		Mandatory PC-specific identification marker Monoclonal antibody based therapeutic target
CD200	−/+ (% of $CD200^+ \approx 49\%$)	+/++	≥70	Phenotypic characterization of clonal versus normal PCs Marginal utility for MRD detection versus other MRD markers
CD229	+	NR		Potentially useful PC identification marker Potential monoclonal antibody-based therapeutic target
CD307	+	++	NR	Phenotypic characterization of clonal versus normal PCs Potentially useful for MRD detection
CD319	+	dim^+		Potentially useful PC identification marker Marginal utility for MRD detection versus other MRD markers Monoclonal antibody based therapeutic target
SmIg	−	+	<5	Differential diagnosis between PCDs versus B-CLPDs and IgM versus non-IgM MGUS Marginal utility for MRD detection versus other MRD markers

[a]BM, bone marrow; PC, plasma cell; MAP, myeloma-associated phenotype; PCD, plasma cell disorder; B-CLPD, B cell chronic lymphoproliferative disorder; MRD, minimal residual disease. locations (50, 51). Therefore, early-stage PCs (also termed plasmablasts) can be detected in secondary lymphoid tissues, as well as PB, while terminally differentiated PCs are more typically found in the BM (50, 51). Previous studies have shown that in fact, a continuous spectrum of immunophenotypic changes associated with a progressively higher degree of maturity can be observed, once PCs from several different tissues such as tonsils, PB, and BM are merged and phenotypically compared (34); however, whether the $CD38^{hi}$ PB PC compartment comprises both newly generated plasmablasts and PCs that recirculate from the BM still remains a matter of debate (51).

Overall, PB plasmablasts/PCs and the PCs that can be identified in BM show clear phenotypic differences between them (15, 24, 34, 51, 52). In contrast to BM PCs, circulating PB plasmablasts/PCs are all positive for both CD19 and CD45, and they completely lack CD56 expression; moreover, normal/reactive PB plasmablasts/PCs display slightly lower levels of CD38 than normal/reactive BM PCs, and they have variable and heterogeneous expression levels of both CD20 and CD138 (34, 52). Additionally, most PB plasmablasts/PCs (>70%) show surface membrane Ig^{lo} ($SmIg^{lo}$) expression of distinct Ig isotypes, at variable levels (51). Interestingly, such distinct and variable patterns of antigen expression observed both in the PB and the BM PC compartments are now considered to translate phenotypes of PCs at slightly different maturation stages. For example, $CD138^+$ PCs in PB typically show a more mature phenotype than the $CD138^-$ plasmablast/PC PB compartment: higher expression of CD38 and CyIg and lower levels of expression of CD45 and SmIg, in the absence of CD20 (51). In contrast, similar patterns of antigen expression have been reported for the $CD138^-$ and $CD138^+$ PB plasmablast/PC compartments regarding several adhesion molecules (e.g., ITGα4, ITGβ1, and ITGβ7) and chemokine receptors (e.g., CXCR4/CD184 and CCR10) (51). Interestingly however, both compartments show high Ki-67 staining (51), suggesting that these cells are still capable of undergoing proliferation, and therefore, they are still on the way to completing their maturation.

Despite what is described above for steady-state PB plasmablasts/PCs, it has been shown that newly generated PB plasmablasts/PCs after vaccination (e.g., after exposure to tetanus toxin) might show slight phenotypic differences, towards a more mature protein expression profile than that of steady-state PB plasmablasts/PCs; in this regard, such cells simultaneously show high CD38 and CD138 positivity, and they systematically lack CD20 (34). Altogether, these findings support the notion that CD138 expression on PB PCs is more likely related to post-GC maturation (51) and/or BM-driven migration (53), whereas it would not be a surrogate marker for PCs that recirculate from the BM into PB and back into the BM or other tissues; in such a case, CD138 cannot be seen as a marker that would discriminate between plasmablasts that have migrated to PB from secondary lymphoid tissues (e.g., lymph nodes) and BM recirculating PCs. Interestingly, once compared to more-mature BM PCs, PB plasmablasts/PCs also show clear positivity for CD229 together with a more heterogeneous pattern of expression of both CD54 and CD319 (49).

Similarly to what has been described above for the plasmablast/PC compartment circulating in PB, BM PCs also consist of several different, phenotypically well-defined subpopulations that display characteristic maturation-associated features (54, 55). As a whole, BM PCs typically lack expression of most pan-B-cell markers (e.g., CD20 and CD22) and SmIg; in contrast, they have heterogeneous expression of CD19, $CD45^{lo}$, and $CD56^{-/lo}$, together with higher levels of expression of both CD38 and CD138 than PB PCs (15, 24). Thus, most normal/reactive BM PCs express CD19, but around one-third of them are $CD19^-$; similarly, most $CD19^+$ and $CD19^-$ normal/reactive BM PC are $CD45^+$, $CD56^-$, and $CD81^+$, but small subsets of $CD45^-$, $CD81^-$, and $CD56^+$ normal/reactive PCs have also been detected whenever enough BM PCs are evaluated; these infrequent PC phenotypes can be specifically more prominent among the $CD19^-$ compartment of BM PC (Table 3) (29, 54, 55). Although the precise physiological significance of these small subsets of normal BM PCs still remains to be determined, recent results suggest that they might be associated with distinct maturational stages of BM PCs; in this regard, an increasing maturity of BM PCs would typically be associated with progressively lower cell numbers, for example, from the major $CD19^+$ $CD56^-$ subpopulation to the minor $CD19^-$ $CD56^-$ and $CD19^-$ $CD56^+$ subsets of PCs detectable in normal steady-state BM (56).

ABERRANT PLASMA CELL PHENOTYPES IN PCDs

Pathological PCs from PCDs such as MGUS, MM, PCL, and solitary plasmacytoma have long been shown to display phenotypes that deviate from those typically seen in normal PCs, particularly in normal and reactive BM PCs (18, 54, 57) (Fig. 2 and Table 3). In the past, markers that were frequently described to be aberrantly expressed on PCD PCs included CD19, CD56, CD45, CD38, CD27, and to a lesser extent also CD20, CD28, CD33, CD117, and SmIg (Table 3) (15, 21, 22, 24, 54, 58). More recently, other markers have been identified as aberrantly expressed on PCs from various percentages of MM and other PCD cases. Among the latter set of markers, CD81 (29), CD200 (59), CD54 (60), and CD307 (61) have emerged as (potentially) the most informative ones (Table 3). The frequencies at which individual markers have been reported to be aberrantly expressed on clonal PCs are listed in Table 3. However, it should be noted that such frequency may depend not only on the specific marker evaluated but also on the specific fluorochrome-conjugated antibody reagent used; sometimes even variable frequencies of altered patterns of antigen expression on pathological PCD PCs can be obtained with distinct antibody clones directed against the same marker, or when similar reagents from different commercial sources are used (21, 58). Altogether, this highlights the relevance of the specific reagents used in a panel, in addition to their CD codes, as regards the identification of a given phenotypic alteration (62). Briefly, typically described aberrant PCD-associated PC phenotypes include (i) underexpression of CD19, CD27, CD38, CD81, and/or CD45, (ii) overexpression of CD33, CD56, and/or CD28, and (iii) asynchronous expression of CD20 and/or CD117 (Table 3) (18, 19, 22, 23, 25, 63, 64). Despite this, it should be emphasized that such definitions of the PC-associated aberrant phenotypes are an oversimplification of the aberrant patterns of protein expression detected on PCD PCs versus normal/reactive PCs. Actually, very few truly aberrant PC markers exist, and evaluation of the utility of individual markers has always to be considered in the context of a multiparameter definition of aberrant phenotypes, where multiple individual markers synergistically contribute to an improved clear-cut distinction between normal/reactive and PCD PCs (65). For this purpose, the

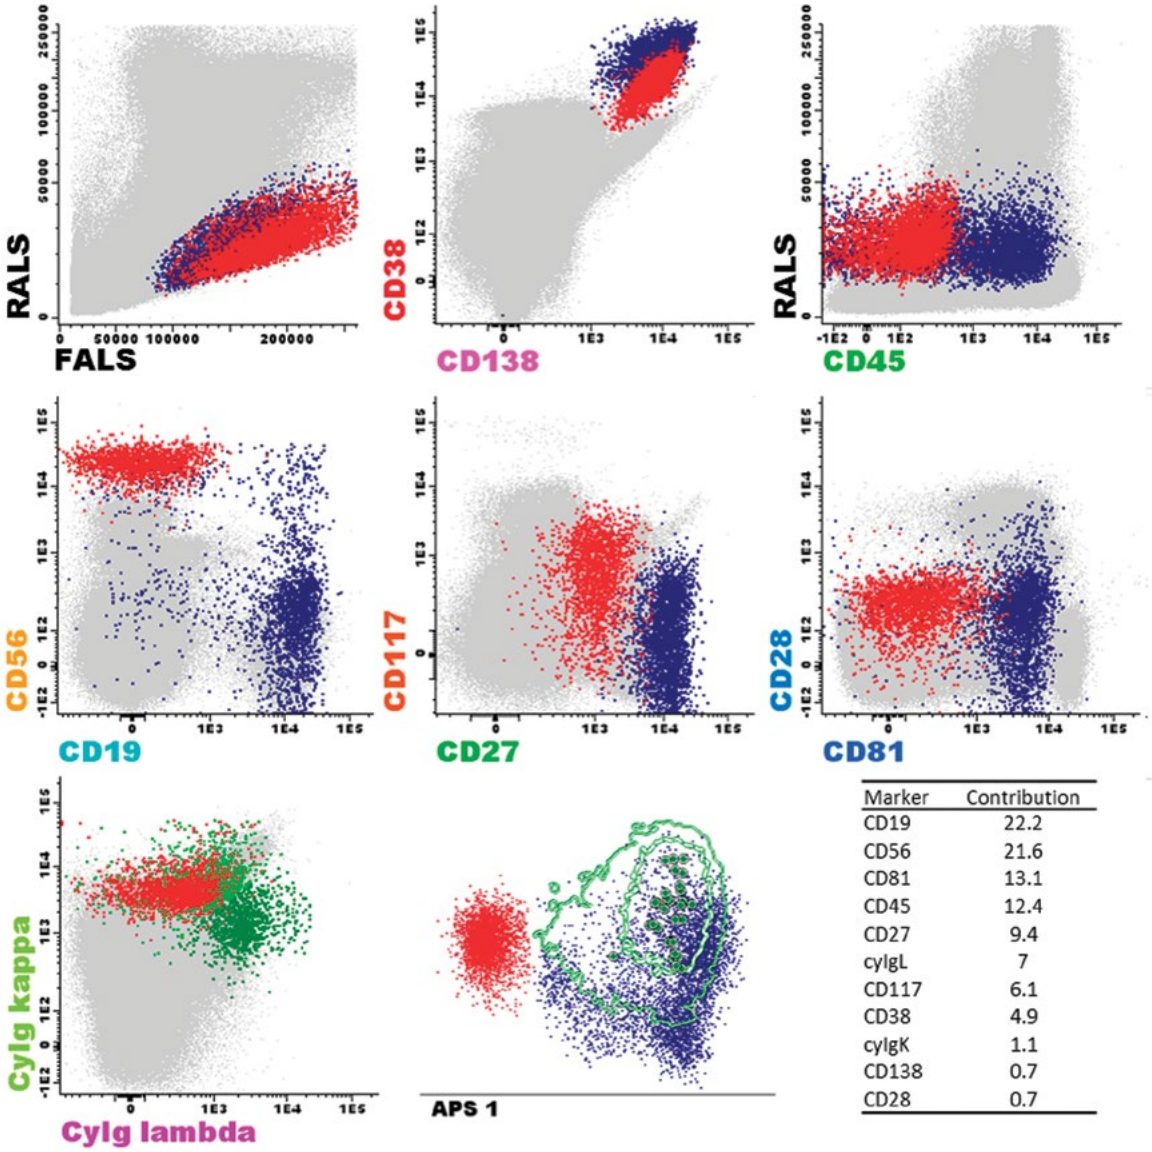

FIGURE 2 Illustrating example of a bone marrow (BM) sample from a multiple myeloma (MM) patient whose clonal plasma cells (PCs) aberrantly expressed several typical phenotypic markers, as may be seen through comparison against the immunophenotypic profile of normal PCs coexisting in the same BM sample. Classical bivariate dot plot representations illustrate the normal phenotypic characteristics of polyclonal PCs (dark blue dots) for surface membrane markers. The same dot plots also illustrate the aberrant phenotypic profiles expressed by the patient clonal PCs (red dots), i.e., $CD38^{dim}$, $CD45^{-}$, $CD19^{-}$, $CD56^{++}$, $CD117^{+}$, and $CD81^{-}$. In addition, the normal and myeloma PC populations were further discriminated by their cytoplasmic (Cy) expression of immunoglobulin (Ig) light chains, highlighting the polyclonal nature of normal PCs ($CyIg\kappa^{+}$ and $CyIg\lambda^{+}$ [ratio of 1:3], dark and light green events, respectively) versus the monotypic expression of CyIgk of clonal PCs (red dots). The middle bottom panel displays the automated population separator (APS) view of principal component 1 versus principal component 2 (*x* and *y* axes, respectively) specifically obtained for the two populations of BM PCs (normal versus myeloma PCs, red and blue dots, respectively) when compared to a set of normal/reactive PCs from 31 reference BM samples; circles represent the median fluorescence intensity of all fluorescence parameters stained, while dotted and continuous borders represent 1 and 2 standard deviations of the distribution obtained for the reference normal PC population; please note how normal PCs from the sample (blue dots) cluster within the reference population cloud, while phenotypically aberrant PCs (red dots) are clearly separated. The right panel in the row in the bottom shows the rank of individual markers and their contribution for the discrimination shown in the APS 1 plot for principal component 1. The overall PC populations correspond to 0.6% of all nucleated BM cells in the sample (gray dots). Normal PCs were 59.9%, while clonal PCs represented 40.1% of all BM PCs.

use of new graphical representations of flow cytometry data processed by multivariate analysis (e.g., principal component analysis or canonical analysis) facilitates the definition of the combined marker profiles that allow distinction from an interrogated population of PCD PCs and reference data for normal/reactive PCs (Fig. 2).

In fact, the majority of markers that have proven to be useful in detecting aberrant PC phenotypes are not strictly aberrant on their own. For example, although CD19 recurrently emerges among the most frequent aberrantly expressed (downregulated) markers in PCDs (15), there is a significant fraction of all normal/reactive BM PCs (around 30%) that are also negative for CD19 (Table 3) (39, 54). Similarly, CD56 has long been claimed to be aberrantly overexpressed in MGUS and MM PCs (15, 21); however, there is also a small subset (6 to 9%) of normal/reactive BM PCs that show unequivocal expression of CD56 at variable levels (Table 3) (39, 56). Similarly, other aberrant phenotypes defined by individual markers that are frequently observed in clonal PCs (e.g., $CD28^+$, $CD45^-$, $CD81^{-/lo}$, $CD27^{-/lo}$, or $CD200^+$) may also be detected in well-defined subpopulations of normal BM PCs (Table 3): the median frequency of normal PCs being $CD28^+$ is 15% (range, 0% to 59%), that of being $CD45^-$ is 22% (range, 0% to 69%), and that of being $CD200^+$ is 49% (range, 31% to 68%) (Flores-Montero et al., unpublished). In contrast, no $CD117^+$ PCs have been reported so far in normal/reactive BM (maximum sensitivity of $<10^{-4}$), while this marker is aberrantly expressed on clonal BM PC from around 30% of all symptomatic MM, 45% of SMM, and $>$ 70% of all MGUS cases (Table 3) (57).

MULTICOLOR PCD PANELS OF ANTIBODY REAGENTS

At present, a consensus exists that the identification of aberrant phenotypes in a significant fraction of all PCD cases requires a minimum combination of CD138 (for PC identification) and CD38 as well as CD45 (additional identification markers whose mean expression levels are frequently downregulated in clonal versus normal/reactive PCs), together with CD19 (negative in virtually every PCD case) and CD56 (expressed in around 60 to 75% of all PCD patients) (Table 3). The percentage of PCD cases in which a robust and sensitive discrimination between normal and clonal PCs may be achieved increases significantly when additional aberrant phenotypes are also investigated simultaneously. Such additional aberrant PC phenotypes include abnormally low expression levels of CD27 and CD81, plus overexpression of CD117. Based on these characteristics, accurate identification and enumeration of clonal versus normal/reactive PCs can be achieved in virtually every PCD patient (Fig. 2), as recently demonstrated by the EuroFlow Consortium (62). The only exception would be that of clonal PCs from secretory IgM-MGUS and Waldenström macroglobulinemia. In patients with the latter diseases, clonal BM PCs typically show an immature $CD45^+$ $CD19^+$ phenotype with variable levels of expression of CD20 and/or SmIgM, in the absence of the most characteristic aberrant patterns of protein expression observed in other PCD cases (e.g., absence of CD56 and CD117 expression and/or strong levels of expression of CD27 and CD81), similarly to what may be observed in other lymphoplasmacytic lymphomas (26, 65).

In order to define and establish the 8-color, 2-tube antibody combinations proposed for the diagnostic screening and classification of PCDs, the EuroFlow Consortium used for the first time an experimental stepwise comprehensive approach. Thus, the PCDs EuroFlow antibody panel was not based just on the experience and knowledge of experts and their consensus opinions (62). The process involved an initial selection phase for a list of potentially useful markers based on literature data and the experience of the groups involved (n = 14 markers); subsequently, careful selection of optimal antibody clones and high-quality conjugates led to a first configuration of the panel that was prospectively evaluated. Afterward, detailed analysis of the performance of the initial set of markers in such combinations against local panels led to the identification of the most informative combination of markers (CD138, CD38, CD45, CD19, CD56, CD81, CD27, CD117, CD28, β2-microglobulin, CyIgκ, and CyIgλ), using multivariate statistical comparisons. Further testing focused on identifying optimal fluorochrome positions and combinations of the selected markers; for this purpose, a total of seven rounds of evaluation, redesigning, and reevaluation were performed, until optimal configuration and performance were reached. Prospective evaluation of this marker combination based on the last configuration proposed by the EuroFlow Consortium for the diagnostic screening of PCDs showed occurrence of ≥1 aberrant phenotypic profiles in virtually all MM and MGUS cases evaluated who had abnormal/clonal PC populations (97%). In a small percentage of cases (3%), definitive definition of a clonal PC population might need the simultaneous assessment of PC clonality through detection of monotypic CyIg light-chain-restricted PC populations, as defined by the previously mentioned set of aberrant markers (62). Figure 2 presents an illustration of the performance of the proposed antibody panel in a diagnostic BM sample from an MM patient. Of note, the illustrated antibody combination also includes markers that allow efficient quality control of the BM sample analyzed through, e.g., the identification of normal residual BM cells such as mast cells ($CD117^{hi}$), myeloid precursors ($CD117^+$ $CD45^{lo}$ $CD38^+$) and hematogones ($CD19^+$ $CD45^{lo}$ $CD38^{hi}$ $FALS^{lo}$ $RALS^{lo}$ cells).

Despite all the careful evaluation steps performed as summarized above, further refinement of the specific fluorochrome-conjugated reagents and antibody clones employed in the above EuroFlow panel was required for MRD purposes. This was mainly due to usage of different sample preparation methods (e.g., bulk lysis procedures versus a single-tube fluorescence-activated cell sorter [FACS] lysing [BD Biosciences, San Jose, CA] approach) for MRD versus diagnostic BM samples, because of the requirement to interrogate many more BM cells and larger volumes of BM sample than in routine flow-MRD ($>5 \times 10^6$ BM cells). Thus, it can also be concluded that any change in the protocol involving the type of sample, the sample preparation method, and/or reagents might require full reevaluation (and potentially also redesigning) of a panel, in order to ensure its optimal performance as defined under those conditions under which it was initially evaluated and established.

FLOW CYTOMETRY QUANTITATION OF PCs IN BM ASPIRATED SAMPLES

The overall PC count in BM is a major diagnostic criterion for PCD. Currently, for diagnostic purposes, PC counts rely on conventional morphological assessments (1). In this regard, flow cytometry has never been considered a reliable surrogate approach for counting BM PCs, given the well-known discrepancy observed between the overall cytomorphological (or histopathological) and the MFC results, with a median bias of around 15% due to lower MFC than morphological PC counts (15–17, 66). Despite such

bias, the enumeration results of total BM PCs by the two techniques correlate well (66). Although there is no definitive explanation for such differences, several factors appear to be relevant. Thus, usage of second aspirates of the same BM for flow cytometry rather than first-pulled BM aspirated samples for cytomorphology (67), the high expression levels of adhesion molecules on PCs, and the selective loss of PCs during centrifugation all appear to contribute to the reported differences more than the potential existence of heterogeneous patterns of BM infiltration (14, 15, 66, 68). Of note, such differences most likely also affect other diagnostic techniques such as molecular/genetic methods (15).

In any case, in order to get sufficient representation of the PC population under study, an acquisition (in a single step) of at least 1×10^5 events from the whole (e.g., BM) sample cellularity is typically required in normal BM or in diagnostic BM samples for a sensitivity of at least 10^{-3} (detection of at least 1 cell in a total of 1,000 BM cells) (68). In turn, in the case of hypocellular BM samples, highly (hemo) diluted samples, or under MRD conditions, acquisition of significantly higher numbers of cells (e.g., $>5 \times 10^6$ cells in the MRD setting) is frequently needed in order to get a minimum population of 20 (preferably 30 to 50) PCs for their unequivocal identification, their reliable quantitation, and accurate characterization (15, 35).

CLINICAL UTILITY OF MFC IMMUNOPHENOTYPING OF PCDs

At present, it is well established that MFC immunophenotyping contributes to the diagnosis or to the classification, prognostic stratification, and monitoring of patients suspected of having a PCD or who have already been diagnosed with a PCD, respectively. Such clinical utility derives from the ability of MFC immunophenotyping to specifically identify and quantitate clonal/aberrant versus normal/reactive PC populations and to provide detailed characterization of their protein expression profiles.

In this section, we sequentially review the utility of MFC immunophenotyping of PCs for (i) the diagnostic screening and classification of PCD, (ii) its prognostic stratification, and (iii) monitoring of the effects of therapy in depleting tumor PCs and maintaining them under control at undetectable or very low levels (MRD monitoring).

MFC Immunophenotyping in the Diagnosis and Classification of PCD

For decades now, it has been well established that demonstration of the presence of phenotypically aberrant PCs with clonal features is an unequivocal sign of an underlying PCD, independently of where those aberrant PCs are located (e.g., BM, PB, lymph nodes, peripheral tissues, or distinct body fluids such as cerebrospinal fluid). Therefore, MFC immunophenotyping is considered a complementary tool in the diagnostic screening of patients suspected of having a PCD, and it may be applied to the study of virtually any type of sample. In this regard, it should be emphasized that at present, single 8-color stainings (see "Multicolor PCD Panels of Antibody Reagents" above), which ensure detection of aberrant/clonal PCs in virtually every PCD case, can be used, even when the pathologic PC population(s) is present at seemingly low levels (e.g., 0.1% of the whole diagnostic sample cellularity).

In turn, a more detailed characterization of the aberrant/clonal PC population identified may further contribute to the classification of PCDs. Thus, the presence of CyIgM-expressing PCs with an aberrantly immature BM PC phenotype ($SmIgM^{-/+}$ $CD20^{-/+}$ $CD19^+$ $CD45^+$) is typically observed in IgM-MGUS; whenever such a PC population is further accompanied by a $SmIgM^+$ clonal mature B-cell population, malignant transformation should be suspected and the diagnosis of Waldenström macroglobulinemia/lymphoplasmacytic lymphoma considered. Conversely, the presence of a population of non-IgM clonal PCs displaying aberrant phenotypes such as those described above in this chapter (e.g., $CD19^-$, $CD45^-$, $CD56^+$, $CD27^{-/lo}$, $CD81^{-/lo}$, and $CD200^+$ PCs) is characteristic of other PCD including non-IgM and light-chain MGUS, isolated plasmacytoma, SMM, MM, and/or PCL. In such cases, when the presence of clonal/aberrant PCs is restricted to a tissue other than BM or PB, diagnosis is fully compatible with solitary plasmacytoma. In solitary plasmacytoma patients, further sensitive analysis of the BM (and potentially also the PB) might contribute to subclassify the disease into solitary plasmacytoma with versus without BM involvement (Table 2). Of note, if only the BM is studied in such a case, the pattern of BM involvement associated with solitary plasmacytoma may fully mimic (and cannot be distinguished from) that of non-IgM and/or light-chain MGUS, in which a few clonal aberrant PCs typically coexist at various percentages (usually <95% of all BM PCs) with normal BM PCs (typically >5% of all BM PCs).

In contrast to solitary plasmacytoma and MGUS, SMM and particularly MM show greater levels of infiltration of BM by clonal aberrant PCs than by normal residual PCs. Thus, while in the majority of MGUS patients (>80%) the number of normal PCs exceeds 5% of the total BM PC compartment, this occurs only in a minority of MM cases (<15%) (5, 69). Consequently, identification of >5% normal PCs of all PCs in a BM sample is strongly associated with MGUS (or solitary plasmacytoma), whereas the opposite (<5% normal PCs among all BM PCs) is typically associated with MM; SMM shows an intermediate (mixed) profile, which more frequently overlaps with that observed in MM. A pattern similar to that of MM is also observed in PCL, usually in association with very high levels (>20%) of infiltration of PB. Of note, PB involvement by lower PC numbers is a hallmark of MM, whereas it is present in only a fraction (20 to 35%) of MGUS cases with conventional flow MRD-like approaches.

Regarding the specific immunophenotypic profile of aberrant PCs in (non-IgM or light-chain) MGUS versus SMM, MM, and PCL, it should be noted that no disease-specific PC phenotypes have been identified so far. However, for some aberrant phenotypes, different frequencies have been reported in the distinct diagnostic categories of PCDs. For example, the frequency of cases showing $CD117^+$ PCs progressively decreases from MGUS (70%) to SMM (45%) and MM (30%), while PCL typically shows a $CD56^-$ $CD117^-$ immunophenotype with stronger expression of CD45 than in SMM/MM and MGUS cases (21, 70, 71).

Based on all of the above, it may be concluded that the utility of MFC immunophenotyping for the diagnostic classification of PCD relies on a combination of the phenotypic features of the aberrant/clonal PC population, the precise tissue(s) involved, and the level of PC infiltration within the BM PC compartment.

Prognostic Stratification of PCD Patients

At present, the prognostic stratification of MGUS, isolated plasmacytoma, and SMM patients, including the identification of those cases that will more likely progress to symptomatic myeloma, remains a relevant clinical challenge that

has been only partially addressed. In addition, identification of biological and clinical subgroups of MM patients with significantly different outcomes and who could potentially benefit from distinct treatment modalities is also an active field of research.

As already stated above, the level of involvement of the BM PC compartment is significantly different in MGUS, SMM, and MM; despite this, within each disease category, it remains rather heterogeneous with, e.g., some MGUS cases showing an MM-like profile and vice versa. In fact, use of the same MFC diagnostic threshold as the one described above (i.e., <5% of normal PCs/total PCs) identifies a minor subgroup of MGUS and a significant proportion of SMM patients with higher risk of progression to MM, with respect to a majority of cases who show higher percentages of normal PCs in the BM (>5% of all BM PCs). From the prognostic point of view, these subgroups of MGUS and SMM patients also show significantly different rates of progression to symptomatic MM: 5-year progression rates of 25% versus 5% for MGUS and 64% versus 8% for SMM with >5% versus <5% normal PCs/total PCs, respectively (5); subsequently, high-risk SMM cases defined on the basis of the BM aberrant versus normal PC distribution and the presence of immune paresis have been shown to benefit from early therapy. In turn, the few symptomatic MM patients who show >5% normal PCs of all BM PCs display more favorable prognostic features and a better overall outcome; thus, they show (compared to other MM cases) lower levels of total BM PCs and M component, higher hemoglobin levels, a lower frequency of immune paresis, and a lower frequency of high-risk cytogenetic abnormalities, they more frequently achieve CR after a high-dose therapy with autologous stem cell transplantation (HDT/ASCT) treatment regimen, and they display longer progression-free survival (PFS) and overall survival (OS) rates (69).

In line with these observations in MM and despite the differences observed in the relative numbers of total BM PCs obtained by cytomorphology and by MFC, the overall percentage of PCs from the whole BM sample cellularity (as detected by MFC) has also been associated with patient outcome. In this regard, a study performed in a large cohort of MM patients evaluated at diagnosis showed that a threshold of 15% PCs from all nucleated BM cells in the sample discriminated two groups with a significantly different outcome: patients with <15% PCs showed a significantly longer PFS and OS than cases with >15% PCs (median PFS of 43 months in contrast to 36 months, and median OS of 97 months in contrast to 54 months, respectively) (66). Of note, the most informative MFC cutoff identified in this study was equivalent to a 30% PC threshold by cytomorphology; however, in contrast to MFC, cytomorphological PC BM counts did not emerge as an independent prognostic factor in the multivariate analysis (66).

In addition to the level of infiltration of the BM by clonal PCs, the prognostic impact of the immunophenotypic profile of abnormal PCs has also been extensively investigated (21). Thus, in a large cohort of uniformly treated MM patients, the patterns of expression of CD19, CD28, and CD117 were shown to provide prognostic information. In this study, positive staining of tumor PCs for CD19 and CD28 and absence of CD117 were associated with a significantly poorer outcome (shorter PFS and OS) (21, 70). Of note, when these markers were simultaneously considered, their prognostic value was enhanced; thus, based on the patterns of expression of both CD28 and CD117, 3 different risk groups, which were associated with significantly different outcomes, were defined: (i) CD28 and $CD117^+$ cases showed the longest PFS and OS; (ii) $CD28^+$ and $CD117^-$ samples had the shortest; (iii) and CD28/CD117 double-positive or double-negative samples constituted an intermediate risk group (21). More recently, $CD81^+$ expression in MM PCs has also been described as an independent adverse prognostic factor that negatively impacts PFS and OS, and at the same time it is associated with lower response rates after induction therapy. Of note, CD81 expression allowed discrimination between groups of patients with different prognostic risks both within MM patients with standard-risk and with high-risk cytogenetics (29). In turn, an association between lack of expression of CD200 on abnormal PCs and clinically aggressive disease has been recently reported (59).

In addition to the prognostic implications of the above-described PC numbers and phenotypes, MFC has recently proven to be of great clinical utility in the prognostic stratification of MM patients because of its ability to identify altered phenotypes on myeloid BM cell compartments, which fully overlap with those seen in myelodysplastic syndrome (MDS) patients (e.g., hypogranular neutrophils and $CD56^+$ monocytes). Such altered myeloid phenotypes have proven to be closely related with the presence of MDS-associated cytogenetic features and an age-independent poorer outcome. Further studies in large series of MM patients treated within randomized trials are needed to confirm the actual prognostic relevance of these MDS-associated phenotypes present in myeloid BM cell compartments of a significant percentage of all MM (and also MGUS) patients.

MRD Monitoring in MM

Major achievements have been reached in the last decades in the treatment of MM. Such advances have also fostered the development and implementation of standardized (and progressively more sensitive) MRD methods to evaluate responses to therapy. In addition to imaging techniques, which play a key role in detecting extramedullary disease, flow-MRD is currently considered the preferred method to evaluate BM MRD levels in MM (72–74). This is due to a large extent to the well-suited features of flow cytometry for monitoring MRD in MM patients' BM. Briefly, flow-MRD has the greatest applicability in MM since the presence of PC-associated aberrant phenotypes can be demonstrated in BM PCs from virtually every patient (62, 65); this implies that such aberrant phenotypes are also highly specific for disease persistence (reappearance) with an established sensitivity in routine clinical practice of at least $\geq 10^{-4}$ (i.e., detection of one tumor cell among ≥10,000 BM cells) (65). In addition, due to the increasing availability of clinical flow cytometers to the diagnostic hemato-oncology laboratories, the method has become (widely) available around the world, at acceptable costs. In turn, the spread of new digital flow cytometers with increasingly higher multicolor and software capabilities into clinical diagnostic laboratories also allows for the analysis of millions of cells in a few minutes, supporting fast diagnoses based on highly sensitive and robust flow-MRD in clinical routine (14).

Compared to flow-MRD, molecular techniques are recognized as more technically demanding (e.g., they require a diagnostic sample), and they are more time-consuming and less broadly applicable (<50% to 90% versus 100% for MFC), although they show a higher sensitivity than conventional flow-MRD (typically, 10^{-5} and 10^{-4} for molecular methods and MFC, respectively) (66, 73). In this regard, however, it should be noted that highly sensitive (and innovative) next-generation flow-MRD (NG-MRD) methods have been recently developed and led to a sensitivity beyond

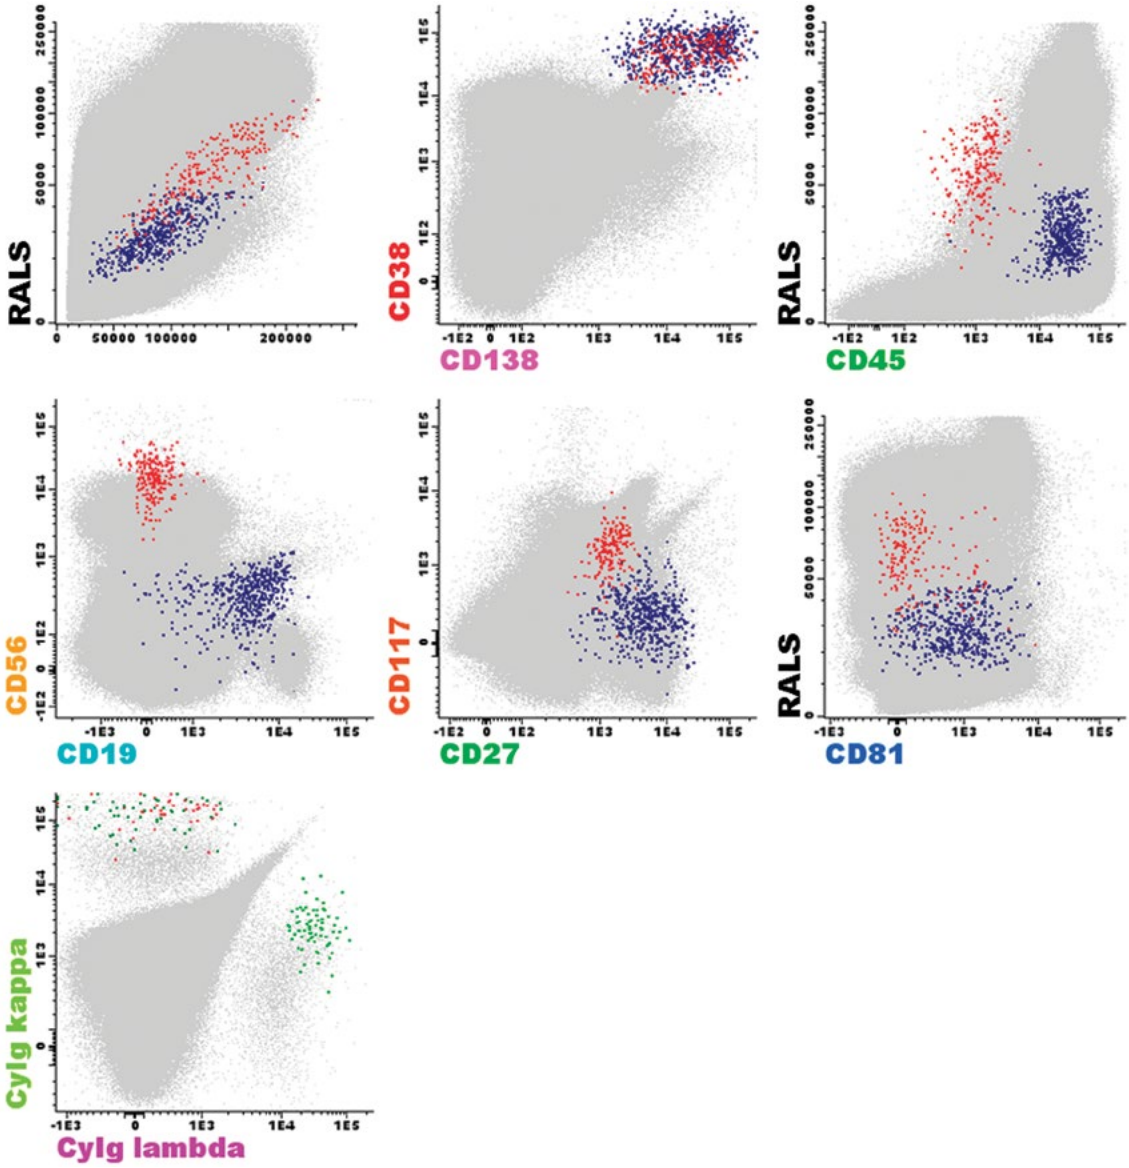

FIGURE 3 Highly sensitive minimal residual disease (MRD) detection in a bone marrow sample from a multiple myeloma (MM) patient. Bivariate dot plot representations of merged files from two different sample aliquots/tubes stained with the EuroFlow-International Myeloma Foundation MM MRD panel to illustrate the highly sensitive detection of aberrant/clonal myeloma plasma cells (PC; red events) coexisting with normal/polyclonal BM PCs (8×10^6 total BM events measured). Normal PCs display a characteristically normal phenotypic profile for surface membrane markers (dark blue dots). In turn, clonal PCs (red dots) from the same individual displayed a distinct pattern characterized by several myeloma-associated phenotypes (MAP; i.e., $CD45^-$, $CD19^-$, $CD56^{++}$, $CD117^+$, and $CD81^-$) in addition to higher forward and sideward scatter properties. Normal and abnormal PC populations could be further discriminated by their cytoplasmic (Cy) expression of immunoglobulin (Ig) light chains, highlighting the polyclonal nature of normal PCs ($CyIg\kappa^+$ and $CyIg\lambda^+$ [ratio of 0.8], dark and light green, respectively) versus monotypic expression of CyIgκ of clonal PCs. The overall BM PC population in this patient corresponded to 0.01% of all nucleated cells in the sample (gray dots); normal PCs were 0.008%, while clonal PCs represented 0.002% (227 dots) of all BM cells.

that of conventional flow-MRD approaches and even that of molecular techniques (between 10^{-5} and 10^{-6}), close to the sensitivity reached by next-generation sequencing approaches (65, 75). These NG-MRD methods (65, 75) have also addressed the need for standardization of conventional 4- to 8-color flow-MRD approaches, regarding antibody panels, sample preparation procedures, data acquisition and analysis, and interpretation of the results.

In the past, antibody combinations for flow-MRD were typically constructed as patient-specific immunophenotypic probes (25, 68). Nonetheless, the concept evolved to alternative approaches using fixed 4- to 6-color antibody panels that

TABLE 4 IMWG criteria for treatment response categories including those proposed for defining immunophenotypic and molecular CR[a,b]

Response category	Defining criteria
Progressive disease (PD)	Increase of <25% in any of the following: Serum M component (≥0.5 g/dl minimum absolute increase) or absolute level of ≥1 g/dl if the baseline value was ≥5 g/dl Urine M component (≥200 mg/24 h minimum absolute increase) Difference in involved and uninvolved FLC level (if M component is not measurable in serum or urine; >10 mg/dl minimum absolute increase) BM PCs (if serum or urine M component and FLC are not measurable; >10% minimum percentage increase) New bone lesion or plasmacytomas or increase in the size of preexisting ones Appearance of PCD-related hypercalcemia (>11.5 mg/dl)
Stable disease (SD)	Absence of CR, VGPR, PR, or PD criteria Lack of evidence of new or progressive bone lesions by imaging[c]
Partial response (PR)	Reduction of ≥50% of serum M component and ≥90% (or total <200 mg/24 h) in urine M component Reduction of ≥50% of involved and uninvolved FLC levels (if M component is not measurable) Reduction of ≥50% in BM PCs (baseline ≥30%; if neither M component nor FLC are measurable) Reduction of ≥50% in plasmacytoma size if present at diagnosis Absence of image evidence of new or progressive bone lesions[c]
Very good partial response (VGPR)	Negative M component by electrophoresis but detectable by IF Reduction of ≥90% in serum M component and urine M component <100 mg/24 h Absence of image evidence of new or progressive bone lesions[c]
Complete remission (CR)	<5% BM PCs Negative IF in serum and urine Nondetectable plasmacytomas Lack of evidence of any new or preexisting bone lesions by imaging[c]
Stringent complete remission (sCR)	CR status plus Normal FLC ratio Absence of BM cPCs by IHC or MFC (2–4 colors) Lack of evidence of new or progressive bone lesions by imaging[c]
Immunophenotypic CR	sCR plus Absence of phenotypically aberrant PCs by MFC in the BM[d]
Molecular CR	sCR plus Negative ASO-PCR in the BM (sensitivity of 10^{-5})

[a]Two consecutive evaluation studies are needed to establish the response categories. CR category if disease is measurable only by serum FLC is indicated by a normal FLC plus the other criteria listed. VGPR category if disease is measurable only by serum FLC is indicated by >90% reduction of the difference between involved and uninvolved FLC levels. BM evaluation in PD is required only if M-component and FLC levels are measurable. Data from reference 84.

[d]A minimum of 1×10^6 BM cells analyzed with >4-color flow cytometry.

cover those aberrant phenotypes common to most (>90%) MM cases, without the requirement for a diagnostic sample (27, 76, 77). In the meantime, consensus recommendations have been reached about the most informative markers that are essential for the identification and further characterization of BM PCs as carrying normal/reactive versus aberrant phenotypes (15). Despite this, so far, only a small number of MRD panels have been both technically and clinically validated (27, 76, 78–82). Detailed analysis of such panels shows that the transition from 4- to 6-color panels led to a more reliable identification of MRD at the 10^{-4} level; 8- to 10-color panels have also brought increased sensitivity whenever their usage is associated with the measurement of enough cells/tube (e.g., $>5 \times 10^6$ cells/tube) as proposed by the EuroFlow group (Fig. 3) (28, 82; J. Flores-Montero, B. Paiva, L. Sanoja-Flores, N. Puig, O. García, S. Böttcher, J. J. Pérez-Morán, M. B. Vidriales, M. V. Mateos, R. García-Sanz, C. Jimenez, M. Gonzalez, J. Martinez-López, M. C. del Cañizo, J. F. San Miguel, B. Durie, J. J. M. van Dongen, and A. Orfao, unpublished data). The specific way in which consensus MRD markers (e.g., CD38, CD138, CD45, CD19, CD56, CD27, CD81, and CD117 for identification of myeloma versus normal/reactive PCs, plus CyIgκ and CyIgλ for assessment of clonality within suspicious PC subsets identified with the

previous CD markers) are combined in a panel is a critical step in the success of flow-MRD (see above). In this regard, the use of highly sensitive fluorochromes is typically required for dimmer markers such as CD56, CD138, and CD117; in contrast, low-sensitivity fluorochromes are preferred for antigens highly expressed on PCs such as CD38; exactly the same principles that apply for MRD should be considered for diagnostic PCD panels, as well.

The clinical utility of flow-MRD in MM was first demonstrated in 2002 by both the Salamanca (Spain) and the Leeds (United Kingdom) groups (25, 83). They both showed that MRD detected by MFC was clinically relevant for the definition of patient groups with distinct PFS rates. The prognostic impact of MRD in MM has been further confirmed by the same groups and by other groups in more-recent treatment protocols for both ASCT-eligible and -noneligible MM patients (27, 65, 80–82). Thus, MRD detection by flow cytometry is currently considered one of the most relevant independent predictors of outcome in MM patients receiving HDT/ASCT (27, 81), independently of other prognostic factors such as tumor cytogenetics (27, 80, 81). Similarly, in the non-transplant-eligible patient group, detection of residual disease by flow-MRD has also been demonstrated to be a strong predictor for PFS, but differences in OS did not reach significance (76). In addition, a negative flow-MRD status after salvage therapy of relapsed MM patients was also shown to be associated with a significantly longer time to progression, specifically in the case of patients not included for allogenic stem cell transplant, while no differences were observed in the allogenic stem cell transplant group (79). Therefore, flow-MRD has been incorporated as a criterion for the definition of different levels of response to treatment categories (Table 4). Despite all this information, surrogate markers for a cure of MM are still needed, particularly as therapy improves and the rate of long-survivor MM patients is likely to increase in parallel.

CONCLUDING REMARKS

At present, the value and clinical relevance of MFC in the study of PCD patients are becoming increasingly recognized; thus, flow cytometry immunophenotyping has become an essential tool in the diagnostic work-up and the classification and monitoring of PCD patients. This is mostly due to the fact that MFC immunophenotyping allows accurate identification but also quantitation and detailed characterization of PCs in BM and other types of human samples, with clear-cut discrimination between (potentially) coexisting populations of normal/reactive PCs and clonal (phenotypically aberrant) PCs. Therefore, MFC identification, quantitation, and characterization of pathological (versus normal/reactive) PCs provide clinically relevant information that complements and completes optimal PCD patient evaluation by other standard approaches, both at diagnosis and during follow-up. In detail, MFC immunophenotyping contributes to the diagnostic screening of PCDs, its classification into the multiple different diagnostic subtypes of the disease and their variants, and prognostic stratification of preleukemic states such as MGUS and SMM; at the same time, MFC immunophenotyping also helps in defining the level of tumor PC depletion reached with therapy in MM and in monitoring MRD levels thereafter. Monitoring of flow-MRD levels also contributes to the prognostic stratification of MM patients after therapy, through the identification of patient groups at different risks of showing progressive disease. However, to take optimal advantage of MFC immunophenotyping in PCD, the use of highly standardized approaches, together with both technically and clinically validated panels in combination with new, innovative software tools, is critical for obtaining reproducible and robust results.

Future Cytometric Technologies and Applications

HOLDEN T. MAECKER

25

The past several years have seen a rapid evolution of flow cytometry technology, moving toward more parameters with the development of instruments containing smaller and less expensive lasers and with the discovery of new dyes that extend the range of emissions that can be detected by those lasers. This is exemplified by the emergence of violet diode lasers (1) and associated quantum dot nanocrystals (2) and brilliant violet dyes (3) that are excited by violet (and most recently by UV) lasers. These developments make flow cytometry in the range of 15 or so parameters more practical than ever.

In the last few years, a competing flow cytometry platform, termed mass cytometry, has also emerged (4–6). This technology uses heavy metal ion labeling in place of fluorophores, with detection by time-of-flight mass spectrometry (Fig. 1). A commercial instrument (CyTOF; DVS Sciences) has been developed for this purpose. The benefits of this technology are twofold. First, the number of parallel parameters that can be measured is increased tremendously (currently to about 40 but potentially 50 or more) (7). Second, the spillover common to fluorescence-based detection is all but eliminated, making compensation between detector channels unnecessary (Fig. 2). The combined impact of these two benefits is enormous. Forty-parameter panels can now be designed with much fewer problems than would be encountered with 10- to 15-parameter panels on fluorescence-based instruments. To be sure, there are still caveats (8), including sensitivity considerations for very low abundance targets; a small amount of signal contamination due to oxidation, isotopic impurities, sample contaminants, and detector infidelity; and a considerable cell loss in the instrument. However, these issues are often a reasonable trade-off for the exponentially increased information content that can now be derived from a single cell sample.

One can ask whether 40-plus parameters are needed in flow cytometry, especially in the clinical realm. However, recent publications using mass cytometry have already uncovered tremendous diversity of phenotypes and functions within hematopoietic cells, which can only be appreciated by the parallel application of many probes to dissect the various subpopulations (9–11). Furthermore, there are clinical cytometric applications, such as leukemia and lymphoma analysis, that currently require several multicolor staining cocktails for precise diagnosis (12). These could certainly be simplified, and even extended, by the use of highly multiparametric mass cytometry.

As alluded to above, it is not only the cell surface phenotyping markers that are of interest in analyzing immune cells. There are also a myriad of intracellular markers, many of which correspond to phosphorylated signaling states (13) or cytokines (14) that can be induced by short-term *in vitro* stimulation. The availability of flow cytometry-compatible antibodies to these markers, and the development of protocols to analyze them, has been another area of advancement in recent years. The number of research laboratories now routinely performing such functional cytometric assays is at an all-time high. Thus, the marriage of highly multiparametric flow or mass cytometry with functional readouts such as phosphoepitopes, is creating a new era of cellular immunology, with an unprecedented level of information content. The mining of this information will undoubtedly provide new biomarkers for the diagnosis and prognosis of disease and immunological monitoring of diseases and therapeutic interventions. This chapter will describe the underlying technologies in some detail, with emphasis on how they may eventually affect clinical flow cytometry.

MASS CYTOMETRY

The use of time-of-flight mass spectrometry to perform multiparameter analysis of single cells was first described by Tanner et al. (4). The implications of this technology for immune cell analysis were truly demonstrated in the Nolan laboratory, beginning with the seminal publication by Bendall et al. (9) and continuing with a series of publications thereafter (15–20). However, other groups are joining this revolution (10, 11, 21), and the number of installed instruments should reach 100 by the time of this publication.

Logistic Considerations

Along with the benefits of highly multiparametric, compensation-free experiments, come a number of logistical and technical caveats. On the logistical front, the instrumentation is expensive and requires physical adaptations of facility ventilation and power. There is a considerable usage of ultrahigh-purity argon, and the machine requires regular tuning and maintenance, including periodic replacement of the detector.

doi:10.1128/9781555818722.ch25

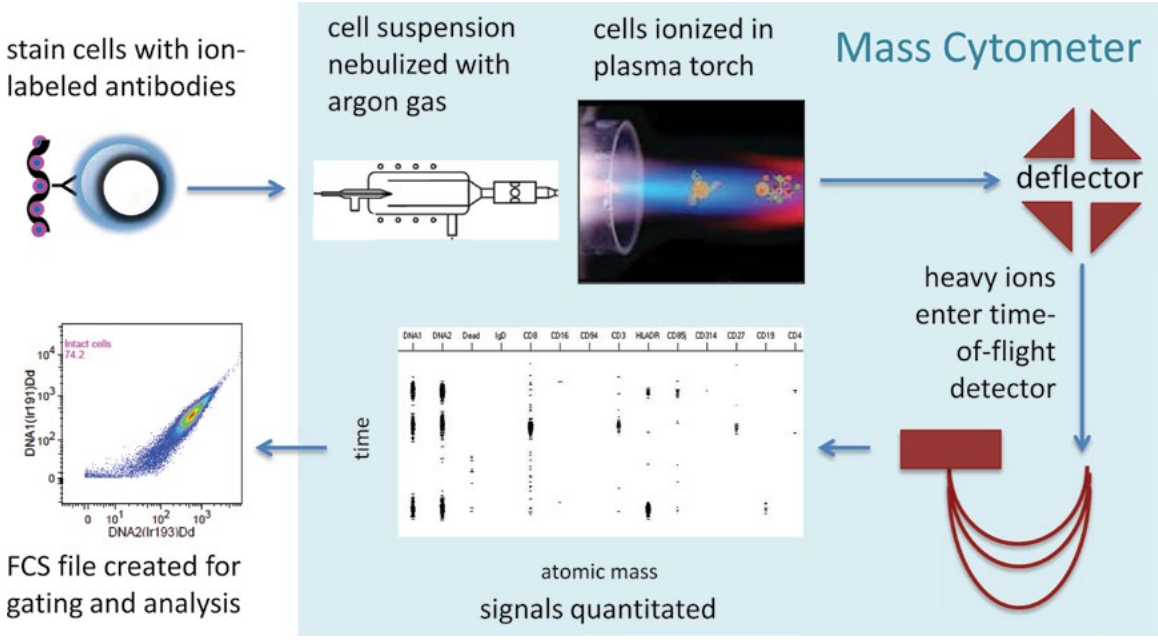

FIGURE 1 Mass cytometry workflow overview. A cell suspension is first stained with antibodies labeled with heavy metal ions, via covalently coupled chelator molecules. The stained cell suspension is then nebulized and directed into a plasma torch in the mass cytometer, using a stream of argon gas. The extremely hot plasma breaks cellular components into elemental ions, and the heavier ions are focused into a time-of-flight detector. The signals from this detector are recorded over time, and pulses corresponding to cell events are quantitated. The data for each cell event is transcribed into a Flow Cytometry Standard (FCS) file, such that it can be gated and analyzed with traditional flow cytometry software.

Acquisition Speed

Technically, there are caveats to the performance of mass cytometry experiments as well. Perhaps most significantly, the speed of acquisition is currently limited to <1,000 events/s (7), although practically, we find the optimum for heterogeneous cell populations to be even lower (300 to 500 events/s). This is to avoid too many coincident events (doublets), which are not easily removed from the analysis and which, if retained, could lead to spurious results. Because mass detection is done from a diffused ion cloud, rather than an intact cell, there are fundamental limitations to the detection speed of this platform, although one could hope for improvements in the form of optimally timed introduction of cells to the machine.

One way to improve doublet discrimination is through sample barcoding, which has been adapted from fluorescence to mass cytometry (16). By labeling a number of related samples (e.g., different stimulation conditions from the same donor), each with a unique combination of mass labels, the samples can be combined, stained, and analyzed as a single composite sample. In addition to equalizing the staining condition of the barcoded samples and conserving the amount

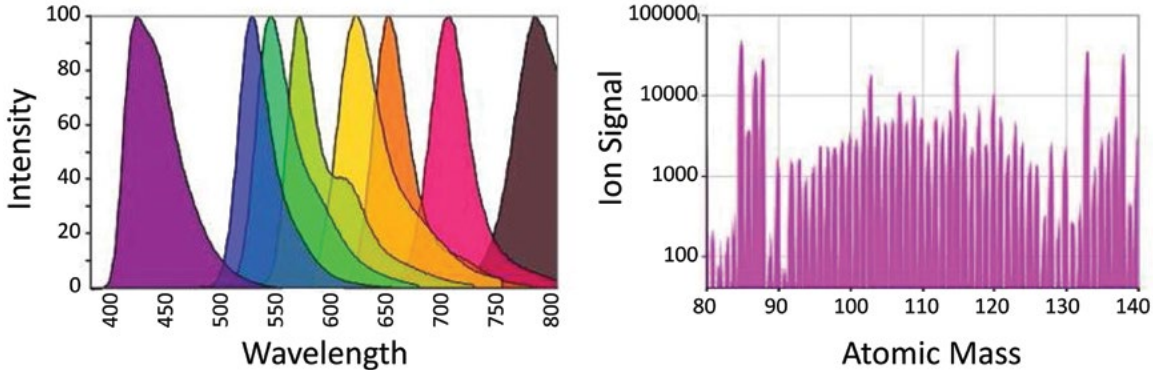

FIGURE 2 Comparison of fluorescence emission spectra (left) and mass spectrometry (right). The latter allows for the detection of many more discrete labels, with very little spillover between detector channels.

of antibody used, barcoding has two additional side benefits. One is that cross-contamination of the barcoded samples is largely avoided, allowing for less between-sample cleaning. A second is that, when deconvolving the composite sample, doublets of two different barcodes are eliminated. If 10 barcodes are combined to make a composite sample, this theoretically should eliminate 9/10 of the cell doublets (as doublets of the same barcode would still remain).

While barcoding can have an impact on doublet discrimination, it has little effect on the overall speed limitations of the CyTOF. To partly alleviate this issue, preenrichment of rare populations can be done, e.g., with magnetic beads. This strategy has effectively been used for analysis of major histocompatibility complex-peptide tetramer binding by mass cytometry (10, 21). In one of these studies, tetramers labeled with multiple metal ions have been used to increase the number of tetramers that can be studied with a limited number of mass channels as well as to increase the specificity of identifying tetramer-positive events (21). An analogous method was previously described for fluorescence-based tetramers (22).

Cell Loss

Another limitation of CyTOF comes from the instrument fluidics, which consist of nebulized droplets focused by an argon makeup gas. This system results in about two-thirds of the introduced cells being lost before entering the plasma torch. To be fair, cells are conserved relative to fluorescence flow cytometry by the ability to condense multitube panels into a single tube with 40 or so markers. However, this level of cell loss is a consideration for very small samples, for which losing the majority of cells may simply not be tolerable.

Sensitivity

There are also limitations to the sensitivity of mass cytometry as currently implemented. Bendall et al. have compared the sensitivity of mass and fluorescence cytometry (7) and make two important points. First, there is no mass channel with equal resolution sensitivity to the brightest available fluorophores. However, this can be partially overcome by the use of multiple markers to define cell populations. Second, while there is a range of sensitivity according to atomic mass, it is considerably less than the sensitivity difference between the brightest and dimmest commercial fluorophores. Thus, one is left with a platform that can analyze many parameters in combination but that is not always sensitive enough for reliable single-channel resolution of populations displaying the least-abundant cellular markers.

Spillover and Contamination

Finally, there is the issue of signal contamination. The notion that there is no spillover in mass cytometry is not formally correct. Spillover between mass channels can come from a variety of sources. One is isotopic impurity; while the vast majority of isotopes sold for mass cytometry are highly pure, there are some that contain a few percentages of contaminating ions of known, and different, atomic mass (AM). Another source of spillover is detector infidelity, which results most frequently in a small signal in the next-highest AM channel (so-called M+1 spillover). This has purportedly been improved with the second generation of the CyTOF instrument. A third source of spillover is oxidation, whereby incomplete plasma ionization results in oxidation products, which are seen in the M+16 channel. This is controlled, albeit to a variable degree, by optimal tuning of the makeup gas flow rate (23). It is also most pronounced in the lower atomic mass range, with insignificant oxidation above AM 170. Observed spillovers across the mass range of the CyTOF, using antibody conjugate-labeled capture beads, are shown in Fig. 3. In addition to these sources of spillover, there can also be frank contamination of the sample with extraneous heavy metals, which can derive from sources such as the plasticware, buffers, or carryover from previously run samples.

Because of the presence of minor spillover in at least some mass cytometry experiments, panel design still requires certain considerations, though not to the same degree as highly multiparametric fluorescence flow cytometry. Guidelines for panel design have been recently published by our group (8).

Data Analysis

It seems unfair to list as a limitation the overwhelming amount of data generated by mass cytometry, since this is inherently an advantage. Yet, making sense of such complex data does provide a challenge. Fortunately, there are already several visualization approaches that have proven helpful for displaying and interpreting these data sets. The first and most widely used is SPADE (15), which is a clustering algorithm that organizes the found clusters by their relatedness in a dendrogram that can then be compared between samples. An example is shown in Fig. 4.

A similar visualization approach, but one which displays the relatedness of individual cells, rather than clusters, is viSNE (20). Both SPADE and viSNE have been shown to be capable of identifying and tracking rare cell populations, including hematopoietic stem cells and minimal residual leukemia cells, respectively.

Heat maps and principal component analysis (PCA) have also been used to display and analyze mass cytometry data (10). These both allow for display of individual cells, although heat maps become overwhelming with high numbers and complexity of cells. PCA is very useful for showing differences between cell populations but does not immediately show the parameters responsible for the differences. These can, however, be inferred from examination of the factors contributing to weighting of the PCA components.

PHOSPHO-FLOW

The use of antibodies to quantitate phosphorylated forms of signaling proteins is often termed "phospho-flow." It is a technology also pioneered in the Nolan lab (24), several years before the rise of mass cytometry. Like other functional assays, such as intracellular cytokine staining, phospho-flow has the advantage of not only enumerating cell lineages and cell surface phenotypes but also simultaneously quantitating their responsiveness to various kinds of stimuli. This can yield more robust differentiation of normal and disease states than is possible by examination of resting cells alone (24, 25). Phospho-flow has been applied in particular to the study of lymphomas (24, 25) and systemic lupus erythematosus (26) as well as normal immune cell subset differentiation (27). It has also been shown to be useful for *in vitro* drug screening (28).

Technical Considerations

Functional assays such as phospho-flow are more complex than phenotypic assays in that they involve a biological activation step as well as fixation, permeabilization, and intracellular staining. All of these steps can increase variability compared to an assay that requires only cell surface phenotyping. Methodological reviews have been published (13),

FIGURE 3 Spillover across the mass window of the CyTOF. Antibody capture beads were labeled with antibody conjugates for each of the indicated metals and collected on the CyTOF in cell mode. The relative percentage of signal in each detector channel is as shown. Note the major signals outside of the primary channel tend to occur in M+1 and (for certain isotopes) M+16 channels. The former is largely due to detector infidelity, while the latter is due to oxidation, a partially preventable consequence of incomplete plasma ionization. Occasional signals are seen in other channels, and these are generally a result of specific isotopic impurities. Data courtesy of Michael Leipold, Stanford University.

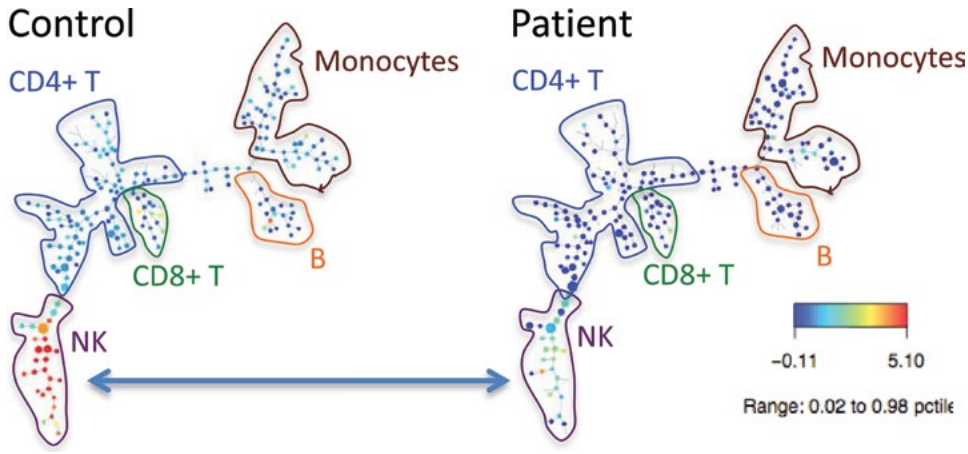

FIGURE 4 Example of SPADE analysis. Peripheral blood mononuclear cells from a healthy donor and a cancer patient were stained for surface and intracellular markers and analyzed by CyTOF. Clustering was performed in SPADE (15) using major cell surface lineage markers. The major cell lineages were annotated by examination of the staining patterns of these markers. The distribution of other markers can then be visualized, as shown here for granzyme B. Note the lack of granzyme B expression in the cancer patient relative to the control. pctile, percentile. Data courtesy of Serena Chang and Holbrook Kohrt, Stanford University.

so a complete discussion will not be attempted here. Rather, selected key considerations will be presented.

Optimization of a phospho-flow assay requires selection of stimulus concentration, timing of stimulation, selection of appropriate antibodies, titration of antibodies, selection of fixation and permeabilization buffers, and choice of staining conditions (especially pre- versus postpermeabilization staining).

Stimuli

Stimuli can include cytokines, antibodies to B-cell and T-cell receptors, and Toll-like receptor agonists, among others. These stimulations are sometimes measured in the presence or absence of a drug (28) to measure *in vitro* pharmacodynamics at a single-cell level. While most signaling events are measured in a time scale of minutes, we have seen phospho-flow assays that perform optimally with as little as 2 to 4 min of stimulation (e.g., pPLCγ2), while others are readily detectable even after 2 h (e.g., pS6). Most stimuli, such as cytokines, are usually used at saturating concentrations, but in some cases, dose-response effects may be of interest and titered doses can be used.

Antibodies

Commercially available phosphospecific antibodies, when marketed for use in flow cytometry, generally perform acceptably, but there can be clone-specific and vendor-specific differences. While many antibodies are sold pretitered, some are not, and performance of a titration curve is advisable in any case.

Fixation and Permeabilization

There are multiple fixation and permeabilization buffers on the market, since not all phosphospecific antibodies perform equally well with a single buffer system. In general, detection of intranuclear targets, such as pSTAT molecules, requires harsher permeabilization (usually methanol). Detection of cytoplasmic targets (pErk and pAkt, etc.) is compatible (and sometimes even optimal) with gentler, detergent-based permeabilization (e.g., saponin).

Staining of Cell Surface Epitopes

A conundrum in phospho-flow protocols is whether to stain for cell surface epitopes before or after permeabilization. In fact, there are a very limited number of antibody clones to cell surface markers that perform well on methanol-permeabilized cells, and even saponin permeabilization compromises most cell surface epitopes. Yet staining prior to permeabilization has two caveats: it still must be performed postfixation (to preserve the phosphorylation state of the cells), and protein fluorophores can be destroyed by alcohol-based permeabilization buffers. The latter issue is avoided fairly easily by using small-molecule fluorophores for cell surface staining. The former issue, however, means that some cell surface epitopes will be poorly detected in phospho-flow and should be relegated to live cell-staining assays only. Even antibodies to some relatively bright major lineage markers, like CD14 and CD16, can suffer tremendously when used on fixed epitopes. In these cases, choice of an optimal clone and careful titration are necessary. There is also online information from manufacturers to help in this regard (e.g., http://www.bdbiosciences.com/documents/antibodies_human_cellsurface_marker.pdf#search=phospho-flow).

Data Analysis

In general, phospho-flow experiments are analyzed by sequential gating to deconvolve barcoded populations (if applicable) and to identify the cell subsets of interest. This is followed by quantitation of the phosphospecific antibody-staining intensities in each of these cell populations. These intensities have been summarized as either the median or 90th percentile fluorescence; the latter statistic has the advantage of being more sensitive to detecting shifts in fluorescence involving only a minor subset of the cells. From these fluorescence values, relative change (stimulated/unstimulated) can be calculated and displayed in a heat map. Software such as Cytobank and SPADE can automatically calculate and display relative change heat maps (Fig. 5).

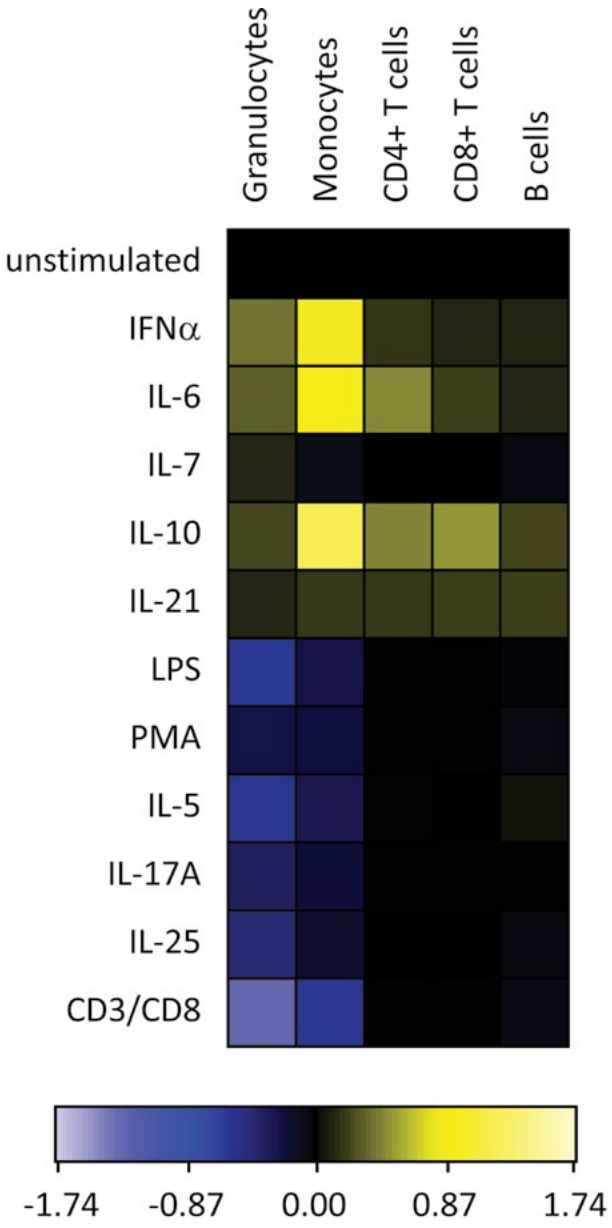

FIGURE 5 Example of heat map calculation in Cytobank. Upon analysis of phospho-CyTOF data, readout of phosphorylation signal changes in each sample can be displayed as a heat map. Here we see pSTAT5 induction in five major cell lineages (columns) with 12 different stimulation conditions (rows), for a healthy control peripheral blood mononuclear cell sample. For CyTOF data, an arcsinh transformation of the median intensity signal was performed in the software and the arcsinh ratio relative to the unstimulated sample was displayed using the color scale indicated. Relative change using medians or percentile statistics, along with other data transformations, are also available in the software. IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; PMA, phorbol myristate acetate. Data courtesy of Rosemary Fernandez, Stanford University.

Combining Mass Cytometry and Phospho-Flow

The first application of mass cytometry to in-depth analysis of the immune system actually combined cell surface phenotyping and phosphoepitope analysis (9). However, in our experience, this has been the most difficult assay to optimize on the CyTOF platform. This is mainly because of the issue, mentioned above, that most antibodies to cell surface determinants show compromised staining of fixed epitopes. Since a major point of using mass cytometry for this application is to do a detailed phenotyping in combination with signaling analysis, there is a desire to use antibodies to cell surface markers beyond the most robust major lineage markers, and these are often the most difficult to resolve after fixation. Combined with this, the fact that CyTOF sensitivity is less than that of the best fluorophores in the fluorescence world means that very low abundance proteins (including some of the phosphoepitope targets) are very difficult to detect. Nevertheless, we have successfully created a panel that allows dissection of approximately 32 cell subsets (from Tregs to plasmablasts to pDCs) while simultaneously interrogating 8 different phosphorylated signaling intermediates (Table 1). When used with a panel of 8 standard stimuli, this results in a matrix of 2,048 potential readouts per sample. We are now using this panel with immune cells from a variety of diseases.

Such detailed fingerprinting of not only cell phenotypes but their underlying signaling capabilities will doubtless be useful for diagnosis, prognosis, and elucidation of disease mechanisms, provided it can be adequately standardized. We are already using a customized robotic liquid-handling system to help reduce staining and cell handling variability. A side benefit of this system is the ability to use less antibody, due to reproducibly lower residual volumes after washing and aspiration, with the robot than with manual handling.

CLINICAL APPLICATIONS

Will technologies as complex and demanding as mass cytometry and phospho-flow make it into the realm of clinical flow cytometry? I believe this is just a matter of time and of the right disease application. There are certainly many assays that do not require 40 parameters and for which simpler platforms will suffice. In general, mass cytometry should probably remain a research tool, with its ability to broadly probe the immune system, liberated from specific hypotheses. When biomarkers of clinical interest are identified, they can be transferred for clinical practice to a simpler (and less expensive) platform such as fluorescence flow cytometry or other methods.

However, a case can be made that some clinical applications are ready-made for mass cytometry. A seemingly obvious one is leukemia and lymphoma diagnosis. Here, the use of multiple fluorescence panels, often performed in succession based on the outcome of an initial screening cocktail, could be obviated by a single-tube mass cytometry staining. On the one hand, this would waste reagents, as it would use "all antibodies, all the time." But labor is usually far more costly in the clinical lab than reagents, and a single-tube staining would certainly save time. With one cocktail for complete diagnosis, this approach would be sample-sparing as well. Finally, given the already established importance of signaling for prognosis of B-cell lymphomas (25), the addition of phosphorylation analysis could increase the value of flow cytometry to clinical diagnosis of these tumors. Perhaps this could tip the scales towards raising flow cytometry from a second-line diagnostic for most leukemias and lymphomas to become the technology of choice.

As for the phospho-CyTOF assays, these might be thought of as yielding a "fingerprint" of the immune system at a cellular level. Whether we eventually derive relevant metrics of disease from these fingerprints, and whether the assays then make it into clinical practice (using CyTOF or

a simpler platform), can only be speculated at present. But laboratories that provide research level assays for human studies might wish to learn the technologies of phospho-flow and CyTOF, as it's only with the accumulation of relevant human data that we have a chance of turning the speculation into reality.

I thank Michael Leipold, Serena Chang, Holbrook Kohrt, and Rosemary Fernandez for providing example data for figures.

Functional Cellular Assays

section E

VOLUME EDITOR: BARBARA DETRICK
SECTION EDITOR: STEVEN D. DOUGLAS

Introduction

STEVEN D. DOUGLAS

26

A number of remarkable and seminal advances in basic immunology, molecular biology, cellular physiology, and molecular diagnosis have led to the development of new and unique assays. These techniques, in many instances, have been applied to both research and clinical laboratories. They afford unique sensitivity and specificity for a panoply of diagnostic laboratory procedures. This section of the *Manual* focuses on the laboratory-based assays related to functional cellular assays and their application to clinical diagnoses (Fig. 1). The chapters in this section include major aspects of these assays.

Adriana Weinberg presents a state-of-the-science approach to cryopreservation of peripheral blood mononuclear cells. This methodology offers several major advantages for *in vitro* studies, including assaying multiple samples in single runs (thus avoiding interassay variability), cost reduction through efficient utilization of labor and reagents, and meaningful comparisons for longitudinal studies.

Roshini Sarah Abraham has addressed, in detail, the methodology for the approach to studying lymphocyte activation. In this comprehensive chapter, she has provided the major approaches used in the diagnostic immunology laboratory, namely immune-phenotyping of cell surfaces or intercellular activation markers following a variety of stimuli and functional assays. These approaches include direct assessment of cell proliferation, downstream effects of lymphocyte activation, and lymphocyte cytotoxicity. These assays permit a determination of the activation status and immune competence of T cells as well as their interactions with other cells, including B cells, NK cells, and dendritic cells. Abraham has shown the interrelationships for the assessment of T cell antigen recognition, activation, expansion, proliferation, and postactivation functions related to effector and memory T cells. In addition, this chapter provides a basis for identification of natural killer cells and their subsets.

Moon H. Nahm and Robert L. Burton have described a series of methods for determining functional assays for B cells and antibodies. In this chapter, the types of B cells and their characterization are discussed. In addition, the functions of the humoral response related to the class of antibody and the differentiation states of B cells are analyzed. These include cell surface expression, the relationship of immunoglobulin class switching, and functional assays for B cell antibody defects. Approaches toward understanding B cell development as well as impairment of B cells in primary and secondary immune deficiencies are briefly considered. Functional titers for measuring serum antibodies are discussed, including those related to typical vaccine components of tetanus, diphtheria, pneumococcus, and *Haemophilus influenzae*. A series of assays, including whole-blood lymphocyte proliferation as well as those that utilize bactericidal function for antibodies and opsonophagocytosis assays, are considered. These B cell system analyses also require determination of the protein, to include immunoglobulin function, and they measure phagocytic killing of the various organisms. The chapter provides a wide array of approaches for determining functional assays for B cell function. In addition, a companion chapter is found in section K of this *Manual*, describing the approach toward severe combined immune deficiency newborn screening, by James Verbsky and John Routes. These authors review methods for determination of T cell receptor excision circles to screen for T cell lymphopenia, as well as various forms of severe combined immune deficiency (see chapter 74).

A methodology for the determination of antigen-specific T cells, by enzyme-linked immunosorbent spot (ELISPOT) assay, is described in chapter 30 by Barbara Shacklett and Douglas Nixon. In this chapter, the ELISPOT technology, as well as intracellular staining and tetramer staining, is discussed. The simplest of these, ELISPOT, offers some advantages over intracellular cytokine staining and major histocompatibility complex (MHC) class I tetramer staining. The ELISPOT assay has been modified to detect cytokine-secreting cells using nitrocellulose membranes and cytokine-specific monoclonal antibodies. ELISPOT detects both CD8 and CD4 T cell responses to antigens from a broad range of infectious agents, vaccine preparations, tumor antigens, and autoantigens. This technology is useful toward the comprehensive mapping of the T cell epitope.

The chapter by Theresa Whiteside is a detailed consideration of regulatory T cell (T-reg) assays. Whiteside provides a segue, determining the frequency and functions of the T-reg cells in relation to clinical disease. T-regs are a minor subset of CD4 cells, which can be phenotyped using flow-based phenotyping and their standardization, namely CD3, CD4, CD25, and Fox P3. In addition, negative expression of CD127 is relevant. Further, a variety of suppressor assays have had significant utility in determining the profile of regulatory T cells. These assays have been summarized in comprehensive tables of the characteristics of both N T-reg and

doi:10.1128/9781555818722.ch26

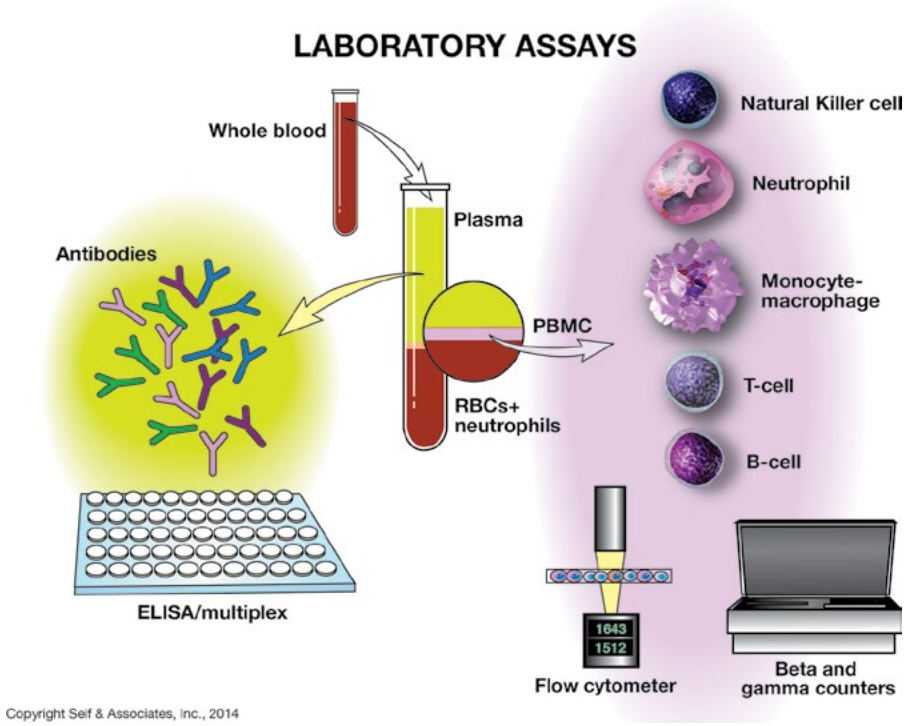

FIGURE 1 Laboratory-based assays related to functional cellular assays and their application to clinical diagnoses.

I T-reg cells and CD4 conventional T cells (see Table 1 in chapter 31). In addition, Whiteside has provided a summary of the functional assays for human N T-reg and I T-reg.

Samuel Chiang and Yenan Bryceson present a detailed chapter for the determination of NK cells, using multiparameter flow cytometry and assays for flow-cytometric measurements of NK phenotype and development. In addition, this chapter discusses the determination of functional responses of NK cells using a variety of target cells. Detailed procedures are provided for studies of the NK phenotype, using state-of-the-art-methodology.

Debra Long Priel and Douglas Kuhns report on the functional assays for the diagnosis of chronic granulomatous disease. Assays using activation of the NOX2 complex by phagocytic cells by flow cytometry are described in detail. In addition, the techniques for isolation and characterization of polymorphonuclear neutrophils are provided. Priel and Kuhns also provide molecular methodology for this diagnosis through immunoblot analysis of the phox subunits of NOX2. Their discussion is augmented by referring to a chapter in section K by Steven Holland (chapter 78), which discusses the overall clinical approach to neutropenia and neutrophil defects.

Related chapters in the sections on flow cytometry and immune deficiency closely interface with this section on functional cellular assays. A schematic overall diagram is provided to introduce the section of functional cellular assays (Fig. 1).

Cryopreservation of Peripheral Blood Mononuclear Cells

ADRIANA WEINBERG

27

The utility of cryopreserved peripheral blood mononuclear cells (PBMC) in clinical and diagnostic immunology is widely recognized. The use of cryopreserved PBMC offers multiple advantages for *in vitro* studies. The ability to batch specimens permits significant cost reductions through efficient utilization of labor and reagents and permits testing of multiple samples in a single run, thus avoiding interassay variability and providing more meaningful comparisons in longitudinal studies.

Immunologic assays on cryopreserved PBMC provide important endpoints for studies of natural history of disorders that may affect the immune system and clinical trials of therapeutic interventions and vaccines (1).

Transportation of frozen PBMC to laboratories for highly specialized tests has certain advantages over shipping fresh blood. Certain populations of blood cells have a limited life span outside the human body, whereas cryopreserved PBMC are stable for prolonged periods when adequately stored or shipped in liquid nitrogen tanks (2–4).

Tests developed after the collection of clinical samples can be applied to cryopreserved PBMC. This allows for utilization of archived samples obtained from well-characterized study subjects to answer new scientific questions and avoids costly and unnecessary repetition of clinical studies (3).

Finally, cryopreserved PBMC are used to treat congenital or iatrogenic immune defects. For example, *ex vivo* generation of anti-cytomegalovirus, anti-Epstein-Barr virus, or anti-adenovirus cytotoxic T lymphocytes (CTL) can be used to protect stem cell transplant recipients against these infections (5).

The utility of cryopreserved cells depends on the viability and function retention of PBMC after freezing and thawing (6–10). To achieve optimal results in this respect, technical aspects are critical, but the intrinsic fragility of PBMC subpopulations can also play a role (11–16). Training and monitoring of personnel in clinical sites that perform the cryopreservation have taken the forefront effort in recent years, leading to the development of successful models (17–24).

TECHNICAL ASPECTS OF PBMC CRYOPRESERVATION

The goal of the cryopreservation is to freeze and thaw the PBMC without compromising the cell viability. Cryoprotective agents are essential in order to avoid water crystals and cell burst with freezing. Both glycerol and dimethyl sulfoxide (DMSO) can provide this function, but only DMSO has been extensively studied for cryopreservation of PBMC. Other critical steps of the cryopreservation procedure include inhibiting cell metabolism while in the presence of DMSO, rate-controlled freezing to avoid cell dehydration, rapid thawing, and resuspension in serum-containing medium, which protects the cells against osmotic trauma.

To maintain the viability and functionality of cryopreserved PBMC, it is critical that blood be processed within 8 hours of collection. Ficoll-Hypaque-separated PBMC are washed at 4°C, counted, and resuspended in cold fetal calf serum containing 10% DMSO at 10^7 PBMC/ml. The cell suspension is aliquoted into cryovials kept on ice, which are then inserted into a Nalgene "Mr. Frosty" freezing apparatus, BioCision CoolCell alcohol-free freezing containers, or a Cryomed freezing chamber. The cells are gradually cooled at a rate of −1°C/min during the first 24 h down to −70 or −80°C and kept at this temperature for a short time until shipped to the testing laboratory or repository center on dry ice or in liquid nitrogen (LN_2) Dewar tanks. It is important to note that although the cell viability does not change over up to 12 weeks of storage at −70 to −80°C, the functionality decreases after the first week. To preserve both viability and functionality for prolonged times, PBMC need to be transferred and stored in LN_2 tanks or −150°C freezers. At these ultralow temperatures, cryopreserved PBMC typically maintain their viability and functionality for decades. However, after storage at ultralow temperatures, cells need to be shipped in LN_2 Dewar tanks to fully preserve their functional characteristics (10). Dry ice shipment of PBMC that have been kept at ultralow temperatures is not advised because it is associated with a loss of functionality (2, 7).

Multiple clinical trials and vaccine networks developed programs to ensure that processing of PBMC is adequate for immunological assays. These quality control programs have been highly instrumental in providing adequate PBMC for immunological endpoints (17, 19, 21, 22).

For thawing, cryovials are incubated with agitation in a 37°C water bath until almost all the cryovial content has become fluid. The cell suspension is then transferred to a 15-ml polypropylene conical tube, and warm RPMI containing 10% fetal calf or human AB serum is slowly added, at a rate of approximately 1 ml/min for the first 5 min, followed by

doi:10.1128/9781555818722.ch27

rapid addition of another 5 to 10 ml of medium. Benzonase (Novagen) or other DNases can be added to the thawing medium to avoid excessive clumping. While the use of these products may improve PBMC recovery, it does not affect viability or function. Thawed cells are washed 2 or 3 times by centrifugation, counted, and assessed for viability before being used in immunologic assays (6).

FUNCTIONAL ASSAYS USING CRYOPRESERVED PBMC

Lymphoproliferative Assays

Lymphoproliferative responses measure mainly CD4-dependent immune responses. Severely impaired CD4 responses confer broad immunodeficiency. More subtle CD4 deficits impair defenses against certain pathogens, such as viruses, mycobacteria, yeast, and certain protozoa, that are highly dependent on cell-mediated immunity.

Several studies compared responder cell frequency (RCF) and lymphocyte proliferation assays (LPA), traditionally used to assess CD4 responses, in cryopreserved versus fresh PBMC collected from immunocompromised patients or normal hosts (6, 8). These investigations showed that antigen- and mitogen-induced proliferation of fresh and frozen cells were highly correlated, despite the loss of responders or decrease in stimulation indices in cryopreserved cells compared with fresh cells (Fig 1). In Fig. 1, which shows a plot correlating CMV-specific responders in fresh and frozen PBMC, the majority of the data points fall below the line of equivalency, illustrating the loss of responders in cryopreserved preparations.

The viability of cryopreserved PBMC significantly affects the results of proliferative assays (6, 7, 9). Data from studies of normal hosts and HIV-infected patients, illustrated in Fig. 2, show that a viability of ≥70% of cryopreserved PBMC is necessary to reproduce the LPA results obtained with fresh cells. In contrast, LPA responses of PBMC with a viability of <70% increase or decrease with the viability of the cell preparation, introducing a variable that is extraneous to the immunity of the host. In addition, the cell recovery of cryopreserved PBMC and the CD4 cell numbers of the donor do not affect the results of lymphoproliferative responses in cryopreserved PBMC by comparison with fresh cells.

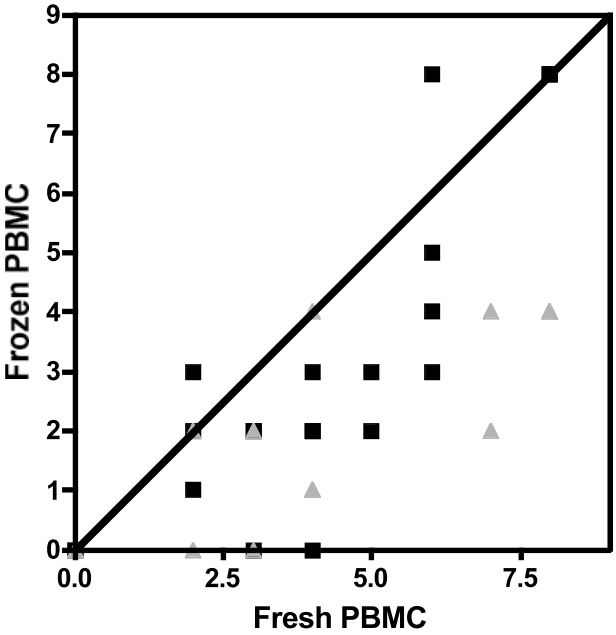

FIGURE 1 CMV-specific RCF in cryopreserved versus fresh PBMC from HIV-infected patients and uninfected controls. Data were derived from samples from HIV-infected patients (HIV+, triangles) and uninfected controls (HIV−, squares). The diagonal represents the slope of equivalence between fresh- and frozen-cell assays.

Cytotoxic Assays

Defenses against viral infections and malignancies rely predominantly on cytotoxic immune responses. Several studies in bone marrow transplant patients have shown that protective immunity against cytomegalovirus coincides with the return of specific CTL (5). Exogenous generation and transfusion of specific CTL can protect immunocompromised hosts against several viral infections and malignancies (5).

The CTL activity of cryopreserved PBMC is comparable with that obtained with fresh cell assays. The use of cryopreserved PBMC allows for better scheduling of these complex assays that involve effector and target preparation.

Natural killer cell (NK) activity, in contrast to CTL, is more labile in response to freezing and thawing. Several investigators, but not all, have found significant changes of NK-mediated lysis following cryopreservation (13). Because of these conflictive data, the use of cryopreserved PBMC for NK assays is recommended only after carefully controlled experiments validate this procedure locally.

Cytokine-Based Assays

Cell-mediated responses are modulated by cytokines released by mononuclear phagocytes, NK cells, and T lymphocytes. These cytokines, which regulate many cell surface recognition molecules and affect the recruitment of inflammatory cells into an area of infection, are likely to play a pivotal role in the expression of cell-mediated immunity. PBMC make a range of cytokines in tissue culture following mitogen and antigen stimulation, which have been used to characterize their functional status.

Inducible cytokine assays measure the amount of cytokine released by stimulated PBMC in the culture supernatant. Studies in HIV-infected patients and uninfected controls show that gammainterferon (IFN-γ) production is essentially the same in fresh and cryopreserved PBMC (Fig. 3) (8). There are conflicting data on interleukin 2 (IL-2) levels in frozen versus fresh cell cultures, and more studies are necessary to clarify this subject (16). However, the rank correlation between either IFN-γ or IL-2 released by cryopreserved compared with fresh cells is highly significant, indicating that inducible cytokine assays on cryopreserved cells are suitable for comparative analyses of the immune response, such as longitudinal observations.

Single-cell intracellular cytokine assays use flow cytometry to enumerate antigen- or mitogen-stimulated PBMC that synthesize cytokines. The single-cell intracellular cytokine assays provide a sensitive and specific indication of the cell-mediated response. Furthermore, the single-cell assay can analyze the phenotype of the cytokine-producing cells, thus further characterizing the immune response. The findings with viable frozen PBMC in these assays are highly correlated with those obtained with fresh PBMC (6, 12, 14). However, a key measure to ensure accurate results is to gate on viable cells only, because dead cells tend to nonspecifically bind

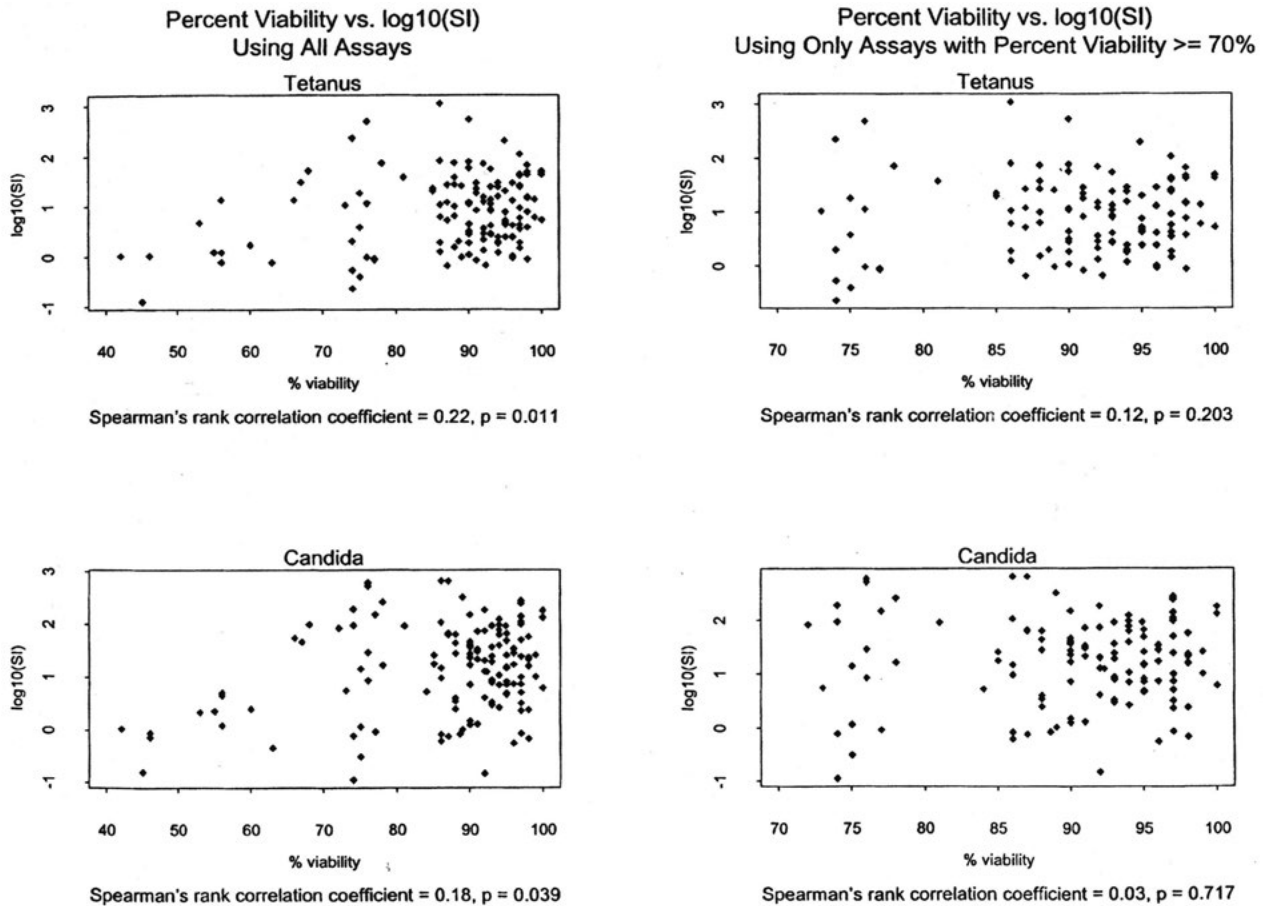

FIGURE 2 Effect of viability on cryopreserved PBMC LPA results. Data were derived from samples from HIV-infected patients. The panels on the left show that when analyzing all samples, the LPA results significantly increase with higher viability. A breakpoint in the distribution pattern can be observed at a viability of 70%. The panels on the right show that when analyzing only samples with a viability of ≥70%, the LPA results are independent of the PBMC viability. SI, stimulation index.

fluorochrome-conjugated antibodies (25). Flow-cytometric assays on cryopreserved PBMC can be reproduced across laboratories, such that quality control programs of intracellular cytokines regularly use cryopreserved PBMC.

The enzyme-linked immunosorbent spot (ELISPOT) assay is yet another format for quantifying cytokine-producing cells. This assay detects captured cytokines diffusing from single antigen- or mitogen-stimulated cells. The assay is extremely sensitive and versatile. It can be performed using fractionated PBMC, such as purified CD8 or CD4 cells. The ELISPOT assay has traditionally measured IFN-γ-producing responder cells but has been adapted to detect other cytokines, including IL-2, IL-17, granzyme B, tumor necrosis factor alpha, and others. ELISPOT is commonly performed on cryopreserved PBMC because the results are comparable with those obtained with fresh cells and there are considerable cost savings when assays are done in batches. Similar to other functional assays, reliable and reproducible T-cell ELISPOT results require a PBMC viability of ≥70% (7). In addition, optimal results are obtained when PBMC are rested overnight before setting up ELISPOT assays.

SURFACE MARKERS ON CRYOPRESERVED PBMC

Immunophenotyping by Flow Cytometry

Enumeration of PBMC subsets by flow cytometry provides important information on the immune capacity of the host. As such, flow cytometry-based immune phenotyping is a standard procedure in the evaluation of immunodeficiency disorders. The distribution of major surface markers, such as CD3, CD4, CD8, CD19, and CD14, is essentially unchanged by cryopreservation. The percentage of cells in fresh and cryopreserved PBMC typically shows statistically significant correlations, despite the fact that fresh-cell assays are typically performed on whole blood, whereas frozen-cell assays use PBMC separated by Ficoll-Hypaque. The percentage of cells bearing certain immune phenotypic markers (CD4, CD8, etc.) was stable over many decades of frozen PBMC storage in the Multicenter AIDS Cohort Study. As with LPA, cell recovery does not influence the distribution of T cell phenotypes on cryopreserved PBMC. However, gating on viable cells only is critical. Results of cryopreserved PBMC phenotyping are stable across a wide range of

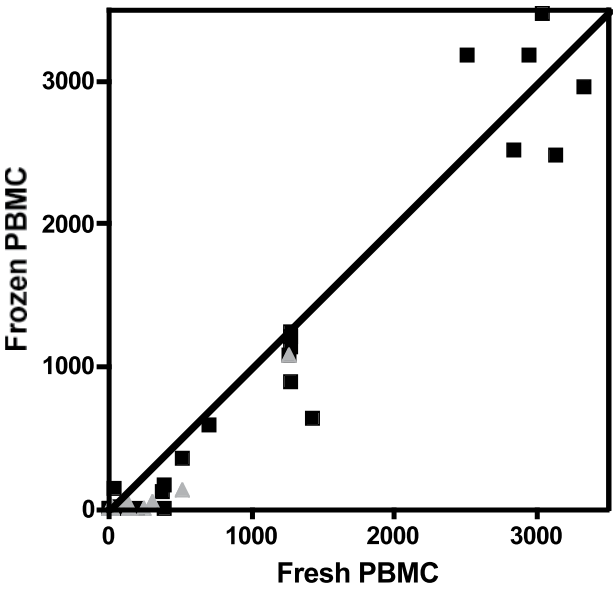

FIGURE 3 CMV-specific IFN-γ in cryopreserved versus fresh PBMC from HIV-infected patients (triangles) and controls (squares). Data were derived from samples from HIV-infected patients and uninfected controls. The diagonal represents the slope of equivalence between fresh- and frozen-cell assays.

baseline CD4 cell numbers, demonstrating the robustness of this complex procedure.

Cell membrane markers used for immunophenotyping, such as CD21, CD22, CD28, CD38, HLA DR, CD95 (Fig. 4A), and CD45RA and RO are well preserved during the freezing and thawing processes. In contrast, CD62L, which is commonly used for the identification of naive T cell populations, is present in a significantly lower amount on the surface of cryopreserved PBMC than on fresh ones (Fig. 4B). Hence, it is desirable to avoid the use of anti-CD62L monoclonal antibodies for advanced immunophenotyping of cryopreserved PBMC. CXCR5 is another marker that may be cleaved during the process of PBMC separation and, therefore, shows lower representation in cryopreserved PBMC than in whole-blood fresh-cell assays.

TCR Vβ Repertoire

Definition of the T cell receptor repertoire (TCR) has become increasingly prevalent in studies of the maturation and senescence of the immune system. These assays can provide valuable information about immune deficiency stages and immune restoration. Flow cytometry- and PCR-based methods are used for TCR characterization. The two techniques seem to yield similar results when performed on fresh and cryopreserved PBMC.

B-Cell Functional Assays

Cryopreserved PBMC are significantly less sensitive than fresh cells for detection of plasmablasts both by flow cytometry using phenotypic markers and by ELISPOT assay using functional properties. Hence, it is safe to conclude that plasmablasts survive poorly the process of cryopreservation. In contrast, memory B cells can be readily detected in cryopreserved preparations. Both flow cytometry assays based on the detection of antigen-specific B-cell receptors and ELISPOT assays that measure immunoglobulin production against specific antigens have been successfully performed using cryopreserved PBMC. A viability threshold has not been established for B-cell assays, but based on

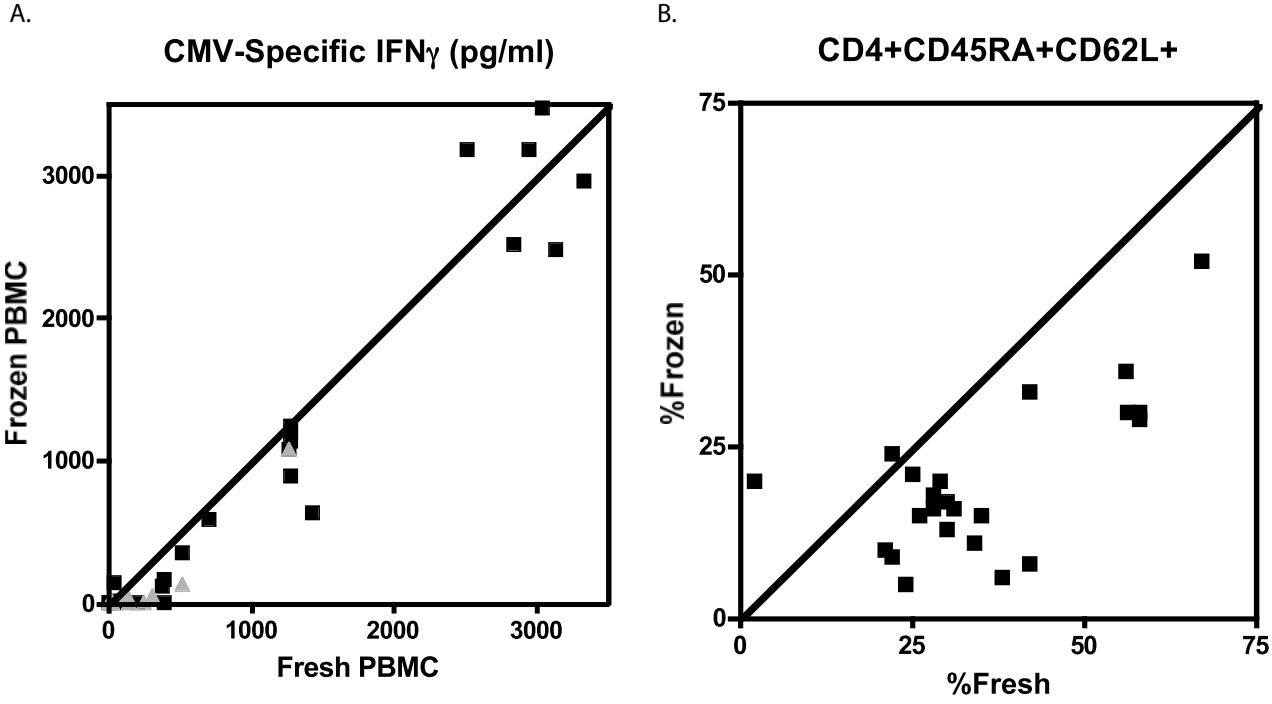

FIGURE 4 Effect of cryopreservation on flow cytometric immunophenotyping. Data were derived from samples from HIV-infected subjects (triangles) and controls (squares). The diagonal represents the slope of equivalence between fresh- and frozen-cell assays. (A) Example of a cell surface marker that is well preserved during cryopreservation (CD95). (B) Loss of CD62L during cryopreservation.

the cumulative experience with other functional assays, it is reasonable to assume that PBMC with high viability provide the most reliable results. It is important to note, however, that after *in vitro* nonspecific stimulation that aims at stimulating immunoglobulin production, many PBMC become apoptotic, compromising the overall viability of the stimulated cells. The implications of this effect are not known, but it may be prudent to take into account only the viable cells when setting up the immunoglobulin detection assays.

mRNA Quantification Assays

The mRNA quantification assay is a very powerful technique that has been increasingly utilized to study innate and adaptive immunity. Although ideally cells should be cryopreserved in special buffers such as Trizol to maximize the yield of mRNA, cryopreserved PBMC can be used for next-generation sequencing or microarray assays. After RNA extraction, the quantity and quality of the nucleic acids can be evaluated to determine the adequacy of the sample for mRNA studies.

Anne Sevin (deceased) performed the statistical analysis of the data presented in Fig. 2 and prepared these illustrations.

Lymphocyte Activation

ROSHINI SARAH ABRAHAM

28

Measurement of lymphocyte activation is a key diagnostic component in the work-up of several immunological diseases: either primary in nature or altered as a result of immune-modifying therapies or other diseases that are not genetic immune deficiencies. There are many ways to measure lymphocyte activation, but the two main approaches in the diagnostic immunology laboratory include immunophenotyping (measurement of cell surface or intracellular activation markers after lymphocyte stimulation) and functional assays (where there is direct assessment of a certain function, e.g., proliferation after lymphocyte activation or cytotoxicity). Among the lymphocyte subsets that are typically assessed for activation status as a measure of immune competence, T cells are the most common, though in some contexts it is also appropriate to evaluate B cell and NK cell activation or function. This chapter focuses primarily on discussing assays and methods related to measurement of T cell activation and function.

T CELL ACTIVATION AND FUNCTION

Naive T cells recognize antigens and become activated in peripheral lymphoid organs (1). This process results in expansion of the antigen-specific T cell pool and differentiation of cells into effector and memory T cells. Activation of effector T cells takes place in secondary lymphoid organs or the periphery (nonlymphoid tissue) through antigen recognition in the local milieu, resulting in propagation of their effector functions. T cells typically require antigen-presenting cells (APCs) for activation, especially for initiation of antigen-specific responses. APCs provide both the cognate signal (a peptide in the context of major histocompatibility complex [MHC] class I or class II molecules) and "secondary" (costimulatory) signals (2). The requirement for naive T cell activation is more stringent than that for effector T cells; hence, antigen presentation to naive T cells is usually accomplished only by "professional" APCs, such as dendritic cells and macrophages. Antigen-experienced effector T cells have a lower threshold for activation and therefore can "recognize" antigens from a larger pool of APCs. Certain global T cell stimulants, such as mitogens and superantigens, do not require the classical process of antigen presentation for T cell activation (3). Once T cells are activated through their T cell receptor (TCR), they serially express activation markers that include chemokine and cytokine receptors, adhesion molecules, costimulatory molecules, and MHC class II proteins (4). There is also a difference in CD4 T cell expression when T cells are stimulated with phytohemagglutinin (PHA) *in vitro* over time, for a maximum of 72 h, while CD8 expression remains unchanged. However, stimulation with phorbol myristate acetate (PMA) and ionomycin results in a complete loss of CD4 expression on T cells within 24 h, while CD8 expression on T cells remains unchanged even at 72 h of stimulation.

The two most commonly used markers of immediate early activation of T cells are CD69 and CD40L (CD154). Both of these cell surface markers can be measured by flow cytometry (5). CD69 is a signaling membrane glycoprotein involved in inducing T cell proliferation. CD69 is expressed at very low levels on resting CD4 and CD8 T cells (<5 to 10% of T cells in a peripheral blood mononuclear cell [PBMC] preparation); however, it is rapidly upregulated (within 1 h) by TCR stimulation or by use of T cell activating agents, such as phorbol esters (PMA), which stimulate T cells via a protein kinase C-dependent pathway (6, 7). Expression of CD69 peaks within 16 to 24 h and then declines, and it is close to undetectable 72 h after removal of the stimulus. However, the kinetics of CD69 expression can vary depending on the stimulant used. There is no expression of CD69 at 2 h and 4 h with PHA stimulation; however, on both CD4 and CD8 T cells, CD69 is induced at 24 h and expressed through 72 h poststimulation. On the other hand, CD69 expression is induced early, at 2 h, with PMA-ionomycin stimulation and is maintained until 72 h, though the number of cells expressing CD69 in the CD4 T cell compartment decreases over time. The inability to upregulate CD69 following TCR activation may be associated with impaired T cell function. CD40L (CD154) is another cell surface costimulatory protein that is expressed on activated T cells. CD40L binds its receptor, CD40, on APCs and activates several signaling pathways, including mitogen-activated protein kinase, NK-κB, and STAT3 pathways. CD40L expression is induced within 1 to 2 h after TCR stimulation (through the activity of NFAT and AP-1), peaks at approximately 6 h poststimulation, and declines by 16 to 24 h. Just as with CD69, the kinetics of CD40L expression on CD4 T cells is different with PHA versus PMA-ionomycin stimulation, and expression on CD8 T cells is extremely weak. CD40L expression is biphasic, and the addition of anti-CD28 costimulation or exogenous

doi:10.1128/9781555818722.ch28

interleukin-2 (IL-2) along with TCR stimulation leads to sustained expression of CD40L for several days. Expression of CD40L on resting CD4 and CD8 T cells is very low (<1% PBMCs), and this is substantially increased on CD4 T cells upon T cell activation. The inability to upregulate CD40L on T cell activation could be multifactorial but ultimately leads to T cell dysfunction and impairment of downstream T cell activity. Further, the function of the CD40L molecule can be assessed by flow cytometry by evaluating its ability to bind to a soluble receptor (CD40-muIg), and this function is often used in the diagnosis of CD40L deficiency, which is associated with X-linked hyper-IgM syndrome (8). There are other T cell activation markers that are often measured in the clinical laboratory, including CD95 (Fas), CD25 (IL-2Rα), and MHC class II (HLA DR) (3).

Direct Measurement of T Cell Activation by Using Functional Assays

Measurement of T Cell Proliferation by Using [^{3}H] Thymidine

The method of determining impaired T cell function by culturing human PBMCs *in vitro* with mitogenic plant lectins (mitogens), such as PHA and pokeweed mitogen (PWM), has been part of the diagnostic immunology repertoire for many years. A widely used method for assessing lymphocyte proliferation hitherto has been the measurement of [^{3}H] thymidine incorporated into the DNA of proliferating cells. The disadvantages of the [^{3}H]thymidine method of lymphocyte proliferation are as follows: (i) the technique is cumbersome due to the use of radioactivity, (ii) it does not allow discrimination of responding cell populations in response to stimulation, and (iii) it does not provide any information on the contribution of activation-induced cell death to the interpretation of the final result. Further, decreased lymphocyte proliferation could be due to several factors, including an overall diminution of T cell proliferation, a decrease in proliferation of only a subset of T cells, or an apparent decrease in total lymphocyte proliferation due to T cell lymphopenia and an underrepresentation of T cells in the PBMC pool. None of these can be discriminated by the thymidine uptake assay, but they can be assessed by flow cytometry, which uses antibodies to identify specific responder cell populations (Fig. 1A). Cell viability can also be measured within the same assay, without requiring additional cell manipulation or sample volume (Fig. 1B), using both annexin V and 7-aminoactinomycin D (7-AAD). Measurement of cell viability by flow cytometry is more accurate than using dye-exclusion methods, such as trypan blue staining, since the latter is unable to differentiate between apoptotic cells and viable cells and therefore can overestimate the number of viable cells.

Flow Cytometric Measurement of T Cell Proliferation

The flow cytometric methods for measuring cell proliferation include the use of fluorescent dyes to identify proliferating cells. One of the more commonly used dyes, carboxyfluorescein diacetate succinimidyl ester (CFSE), must be used carefully for measuring lymphocyte proliferation *in vitro*, since it can be toxic to cells and nonoptimal labeling conditions can affect the measurement of cell proliferation and the interpretation of results (9, 10). CFSE is a fluorescent, cell membrane-permeating dye similar in physical properties to the commonly used fluorochrome fluorescein isothiocyanate (FITC). Alternatives to CFSE include related compounds, such as cell trace violet and the cell proliferation dye eFluor 670, which have excitation and emission spectra that are different from those of CFSE. These dyes can be used for tracking of lymphocyte proliferation status *in vivo* in animal models and can also permit measurement of up to 11 cell divisions (11). Another alternative to CFSE and its related dyes is the use of a thymidine analog, 5-ethynyl-2′-deoxyuridine (Edu), which can combine with a fluorescent azide in a copper-catalyzed cycloaddition reaction (referred to as "click" chemistry) and permits flow cytometric evaluation of lymphocyte proliferative responses by assessment of its incorporation into cellular DNA (12–14). Edu labeling has been shown to be a fast and sensitive method for measuring cell proliferation and also facilitates identification of dividing cells. Edu is relatively more photo-stable than CFSE and is added to cells after completion of the stimulation period, and its measurement is comparable to the thymidine method in that gain of signal is the endpoint. It is relevant that while CFSE, as previously mentioned, can be toxic to cells at certain concentrations (37 nM to 10 μM) due to an increase in cell death, it also modulates the expression of activation markers, resulting in decreases in CD69, HLA DR, and CD25 (15). Also, it has been reported that there is an increase in the number of false-positive results with CFSE and that this method is therefore unsuitable for measuring lymphocyte proliferation in patients with severe cellular immunodeficiencies (15). The Edu assay has not shown such limitations and has been used to evaluate lymphocyte proliferation in a spectrum of patients, including those with severe combined immunodeficiencies. In fact, this assay has been particularly useful for discriminating between functional T cells and nonfunctional T cells in the context of severe T cell lymphopenia, which cannot be achieved with the standard thymidine assay. All the proliferation data shown in this chapter were obtained by this Edu-based measurement of T cell proliferation.

Ki-67 Assay

Another approach to measuring cell proliferation involves the use of an intracellular (nuclear) protein involved in regulation of cell division, i.e., Ki-67 (16). Ki-67 is frequently used in the field of tumor biology to measure the proliferative capacity of tumor cells (17), since this protein is expressed at all active phases of cell division but not during DNA repair or cell quiescence. More recently, the use of Ki-67 to measure antigen-specific T cell proliferation after vaccination has gained traction (16, 18–20). Ki-67 expression in T cells has been shown to be a specific and quantitative indicator of proliferation and provides results comparable to those obtained with other methods (Fig. 2), and though it is not widely used in the diagnostic immunology laboratory at present, it is likely to gain entry in due course as flow cytometry replaces the thymidine method for assessing lymphocyte proliferative responses.

Cytokine Production

In addition to cellular proliferation as a readout for T cell function, the production of cytokines by activated T cells is another important component for evaluating T cell functional activity. T cells typically are not monofunctional, producing a single cytokine on activation, but rather are multi- or polyfunctional, and their cytokines are produced in a sequential manner rather than simultaneously, though a population of stimulated T cells will have individual T cells producing different cytokines in a temporally regulated manner (21–23). These cytokines can be measured by intracellular flow cytometry after T cell activation with mitogens for both CD4 and CD8 T cell subsets. Typically, the cytokines produced include IL-2, gamma interferon (IFN-γ) and tumor necrosis factor alpha (TNF-α). Figures 3A and B

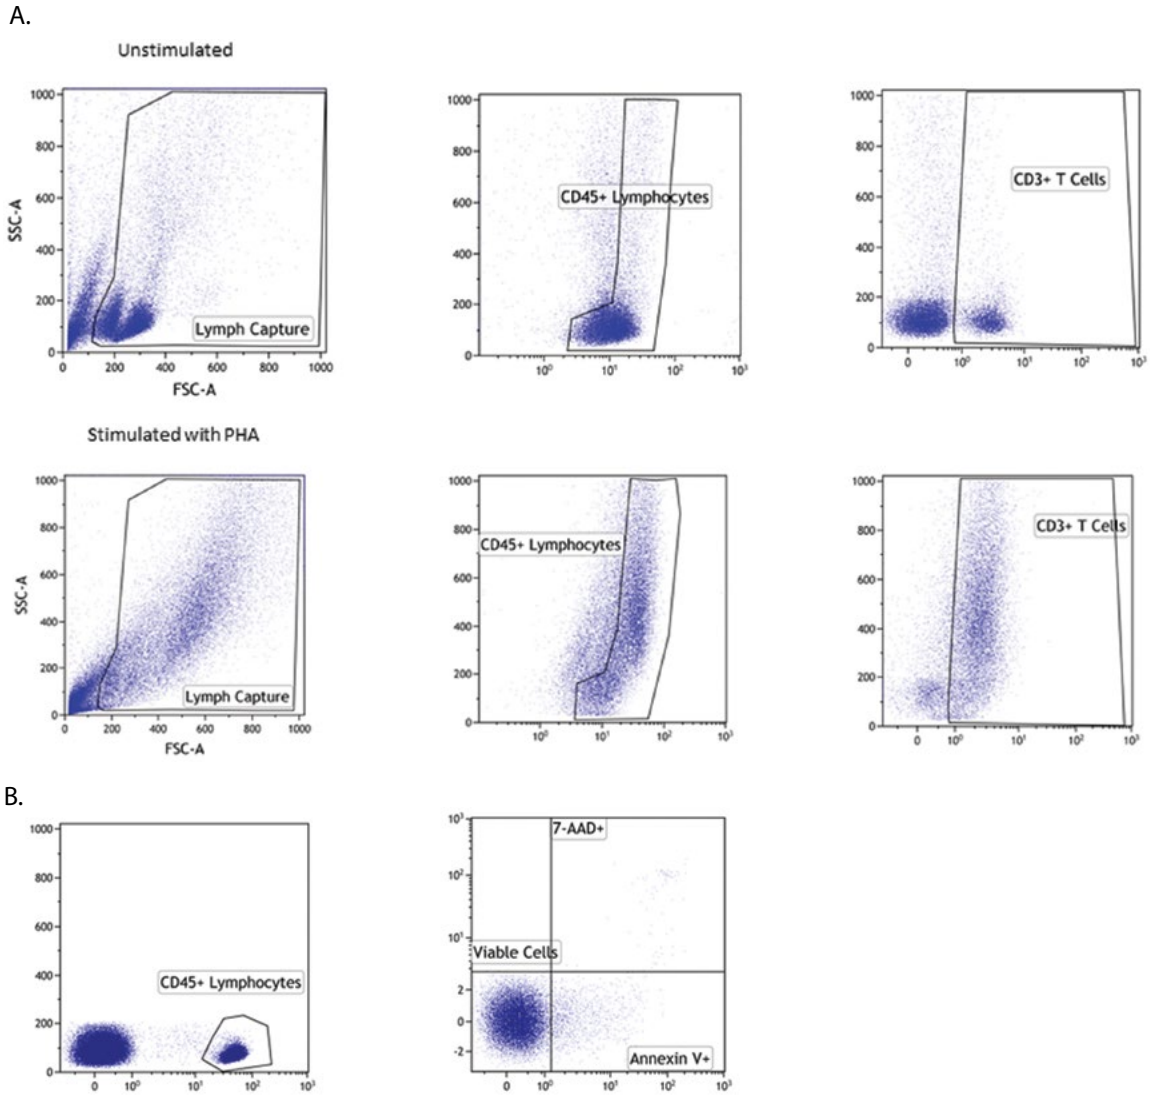

FIGURE 1 (A) Flow cytometric measurement of cellular proliferation with Edu. The flow cytometry results show a detailed assessment of proliferating lymphocytes after stimulation with PHA. Proliferating cells are apparent in comparing the unstimulated (upper panels) to stimulated (lower panels) samples, and the use of specific antibodies (CD45, total lymphocytes; and CD3, total T cells) allows further characterization. (B) Assessment of cell viability for lymphocyte proliferation assays. The CD45 marker is used to identify lymphocytes. Viable, apoptotic, and dead cells are identified in the original sample used for cell proliferation, prior to initiation of cell culture, by using a combination of two fluorescent dyes: annexin V and 7-AAD. Viable cells are negative for both markers, while dead cells are positive for both annexin V and 7-AAD. Only apoptotic cells are positive for annexin V alone.

demonstrate the production of multiple cytokines by CD4 and CD8 T cells, respectively, after PMA-ionomycin stimulation of cells from a healthy donor and a patient.

Mitogens and Antigens Used To Drive Proliferation

Mitogens are very potent stimulators of T cell activation and proliferation, independent of their antigenic specificity. It has been suggested that mitogens can induce T cell proliferative responses even if the cells are incapable of responding adequately to antigenic (physiologic) stimuli. Therefore, abnormal T cell responses to mitogens are considered a diagnostically less sensitive but more specific test of aberrant T cell function (24). Lectin mitogens have been shown to bind the TCR, which is glycosylated through its carbohydrate moiety, thereby activating quiescent T cells (25). Mitogenic stimulation has been shown to increase the intracellular calcium (Ca^{2+}) level in T cells, which is absolutely essential for T cell proliferation. While PHA is a strong T cell mitogen (Fig. 4A), PWM is a weak T cell mitogen, but it also induces B cell activation and proliferation (Fig. 4B). While mitogens such as PHA activate T cells by binding to cell membrane glycoproteins, including the TCR-CD3 complex, there are a number of mitogenic or comitogenic antibodies, including those directed against the CD3 coreceptor, that can stimulate T cell proliferation (26). Typically, anti-CD3 antibodies provide an initial activation signal but do not induce significant proliferation (Fig. 5A and B) (27), and the addition of a costimulatory

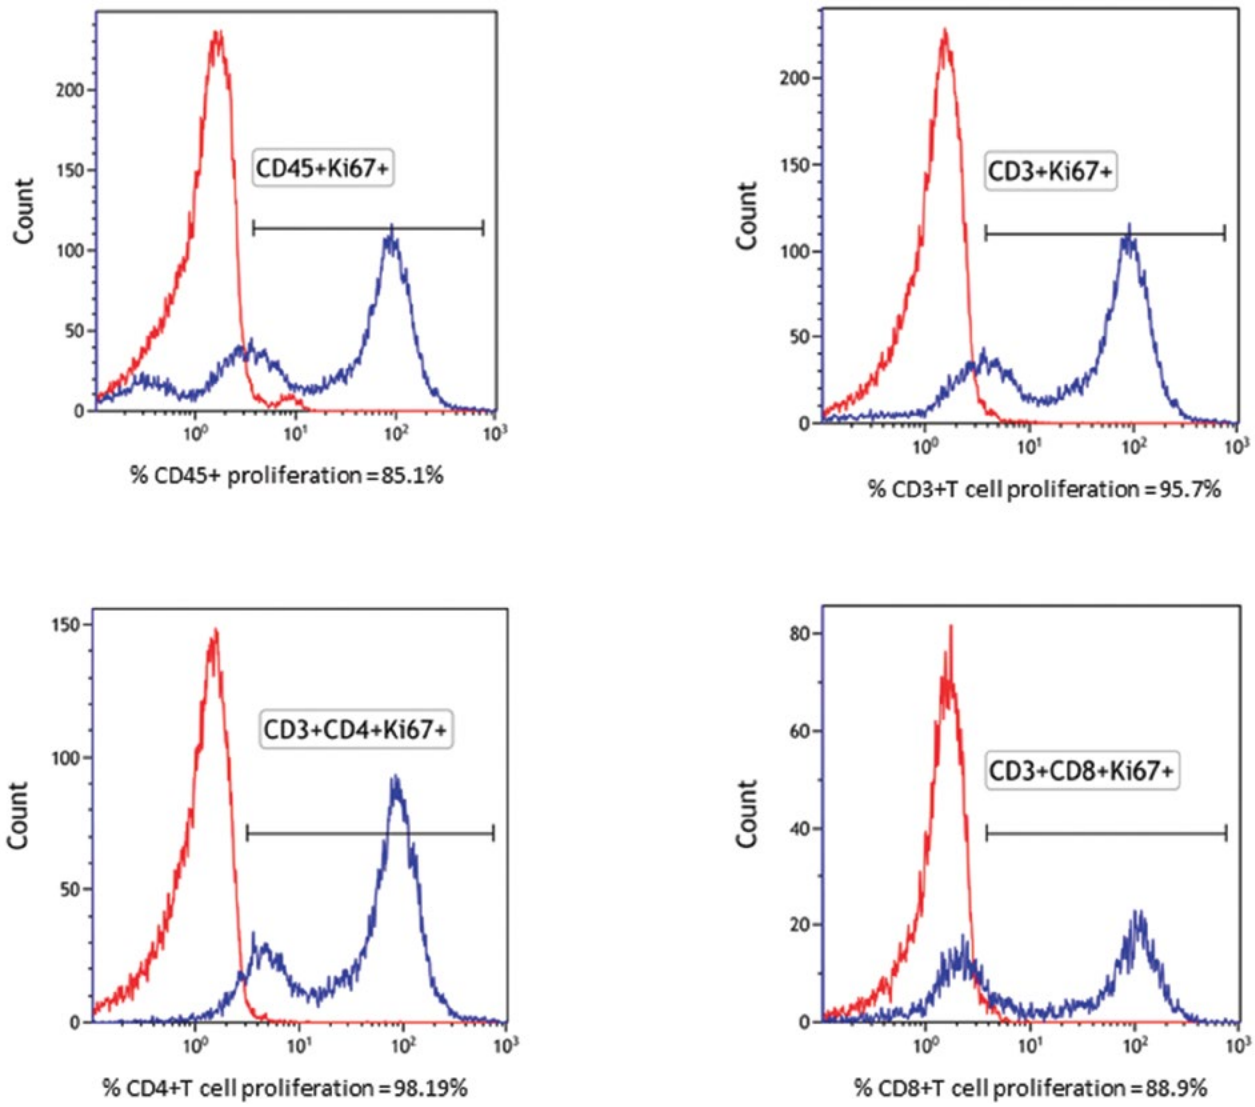

FIGURE 2 Ki-67-based cell proliferation. There are several markers available for flow cytometric measurement of cellular proliferation, including CFSE, Edu, and Ki-67. Ki-67 is a nuclear marker that assesses cell proliferation, and the use of specific antibodies in conjunction with this marker permits identification of proliferating subsets of T cells.

antibody (anti-CD28) provides the stimulus for robust proliferation (28) (Fig. 5A and B). An exogenous T cell growth factor, such as IL-2, may also be used as an alternative to anti-CD28 costimulation, and for patients with suspected IL-2 receptor-associated signaling defects, it may be more helpful than the use of anti-CD28 (Fig. 5A and B). IL-2, an autocrine cytokine, has been demonstrated to be critical for T cell proliferation and regulation of T cell growth (29–31). IL-2 stimulates T cell proliferation by binding to a heterotrimeric receptor complex consisting of 3 chains—α, β, and γ (IL-2Rα, IL-2Rβ, and IL-2Rγ)—on the surfaces of T cells. Triggering of the TCR leads to synthesis of IL-2 in certain T cell subsets and to induction of high-affinity IL-2Rs on antigen- or mitogen-activated T cells, and the binding of IL-2 to IL-2R ultimately leads to T cell proliferation. The use of exogenous IL-2 in association with anti-CD3 allows discrimination of whether T cells which cannot proliferate in response to other mitogenic signals can respond to a potent growth factor, such as IL-2. Stimulation of T cells with soluble antibodies to anti-CD3 (and the associated TCR complex) causes mobilization of cytoplasmic calcium and translocation of protein kinase C from the cytoplasm to the cell membrane. This stimulation also causes induction of phosphatidylinositol metabolism and subsequent IL-2 production for proliferation. T cell activation induced by anti-CD3 antibody requires prolonged stimulation of protein kinase C, which apparently can be achieved by the concomitant use of the anti-CD28 antibody for costimulation, without addition of other mitogenic stimuli, such as PMA. PMA can stimulate T cells by direct activation of protein kinase C (32).

Antigens such as *Candida* and tetanus toxoid (TT) have been used widely to measure antigen-specific recall (anamnestic) T cell responses for assessing cellular immunity. In fact, these methods may be more revealing about cellular immune compromise than assessing the response of

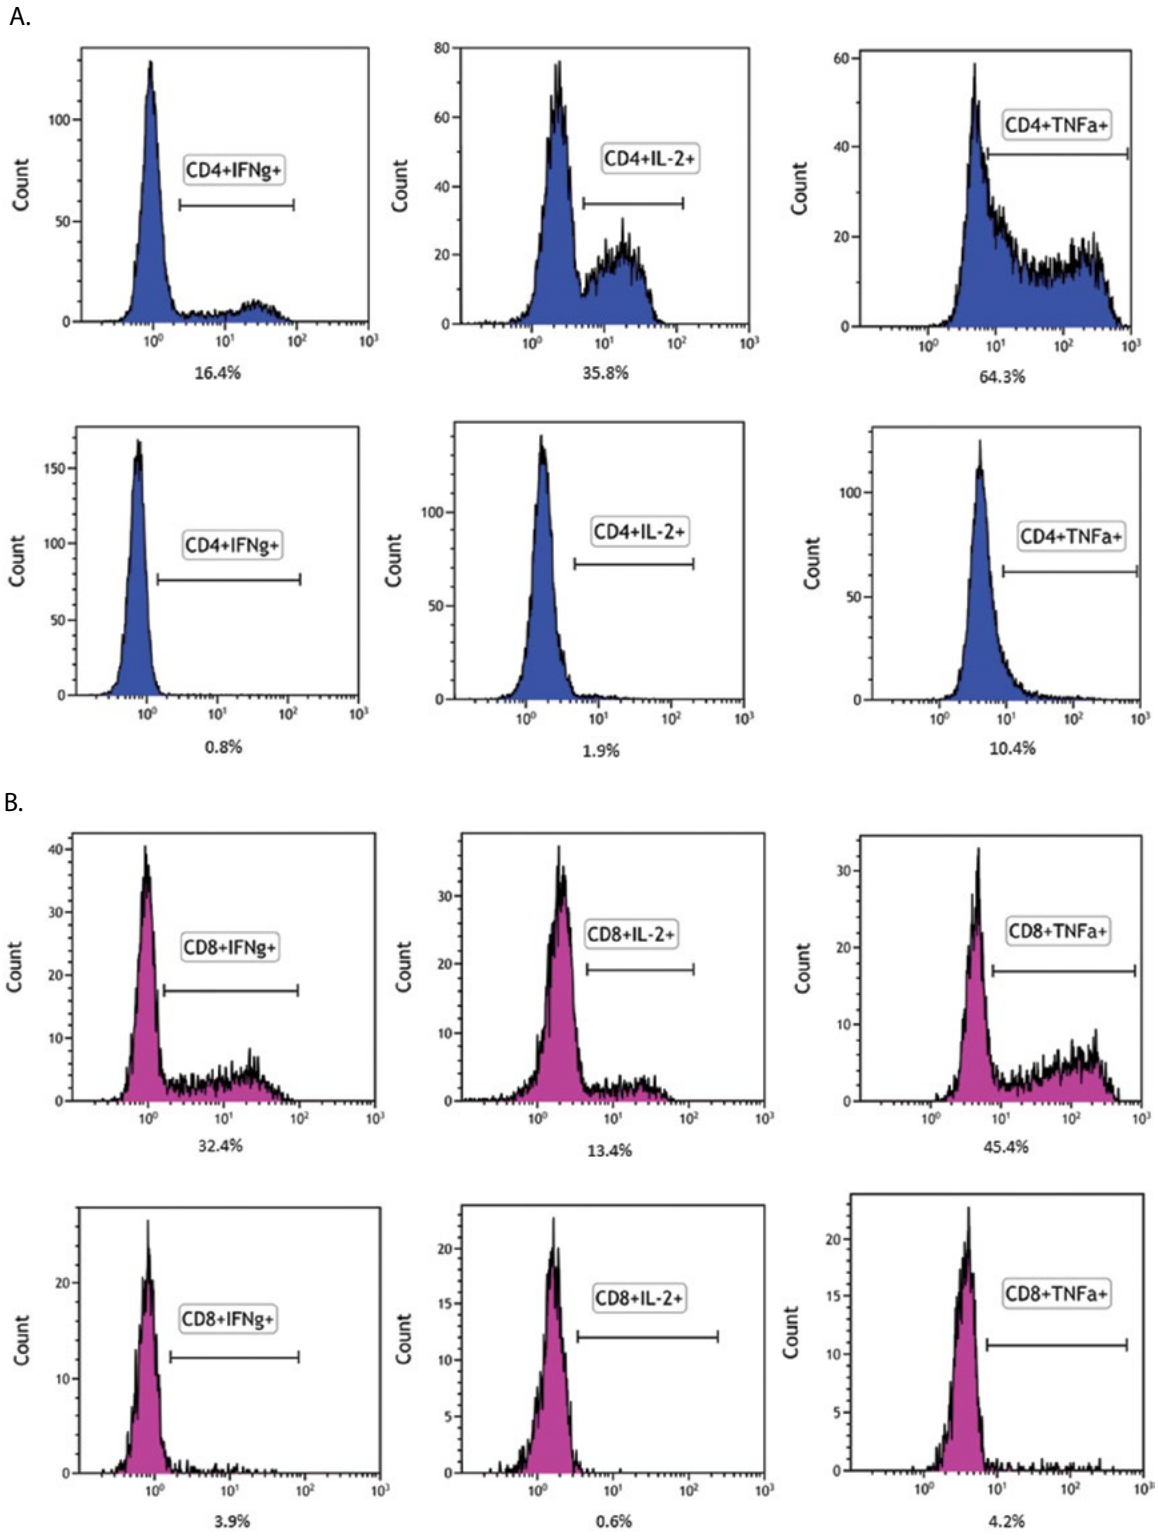

FIGURE 3 Activated T cells produce various cytokines in a temporally regulated manner. The important cytokines produced during the temporal course of T cell activation and differentiation include IL-2, IFN-γ, and TNF-α. (A) Polyfunctional T cell analysis of $CD4^+$ T cells. The cytokines are measured by intracellular flow cytometry analysis of $CD4^+$ T cells. The top panels show normal production of these cytokines in activated $CD4^+$ T cells from a healthy donor after cell stimulation *in vitro* with PHA. The bottom panels show the absence of cytokine production after stimulation of $CD4^+$ T cells from a patient with compromised cellular function. (B) Polyfunctional T cell analysis of $CD8^+$ T cells. The cytokines are measured by intracellular flow cytometry analysis of $CD8^+$ T cells. The top panels show normal production of these cytokines in activated $CD8^+$ T cells from a healthy donor after cell stimulation *in vitro* with PHA. The bottom panels show the absence of cytokine production after stimulation of $CD8^+$ T cells from a patient with compromised cellular function.

lymphocytes to mitogens, because the latter can induce T cell proliferative responses even if the T cells are incapable of responding adequately to antigenic (physiologic) stimuli. Therefore, abnormal T cell responses to antigens are considered a diagnostically more sensitive but less specific test of aberrant T cell function (24). Antigens used in recall assays measure the ability of T cells bearing specific TCRs to respond to such antigens when they are processed and presented by APCs. The antigens used for assessment of the cellular immune response are selected to represent antigens seen by a majority of the population, either through natural exposure (*Candida*) or as a result of vaccination (TT).

Cytotoxicity Assays

Functional assays of cytotoxic T cells include measurement of degranulation (exposure of cytotoxic granule membrane proteins on the cell surface after T cell activation) and direct assessment of cytotoxicity (33–35). Measurement of cellular degranulation is an assay that is currently available in some clinical immunology laboratories and involves flow cytometric analysis of CD107a and CD107b, which are cytotoxic granule membrane proteins that are expressed on the cell surface during degranulation following T cell activation (36) or in NK cells, the difference being that cytotoxic granules are organized in CD8 T cells only following antigen exposure and activation and are not present in naive CD8 T cells. NK cells constitutively possess cellular granules capable of participating in cytotoxic function. Cellular degranulation is a feature of antigen-experienced cells (37); however, contrary to popular conception, it does not always serve as a surrogate marker of cellular cytotoxic function, since the ability to mediate cytotoxicity depends on cytotoxic granule protein content rather than the actual degranulation process. At least half of the patients with perforin (*PRF1*) deficiency associated with familial hemophagocytic lymphohistiocytosis type 2 in one study (38) had normal degranulation but abnormal cytotoxic function due to the absence of a key cytotoxic protein, perforin. Degranulation is not only a function of cytotoxic T cells but also part of the mechanism of cytotoxic activity of NK cells. Degranulation is often used in the diagnostic setting for assessment of patients with suspected hemophagocytic lymphohistiocytosis, particularly the familial forms (38). Detailed procedures for measuring T cell cytotoxicity and NK cell cytotoxicity can be found in chapters 32 and 79, by Chiang and Bryceson and by Risma and Marsh, respectively.

ASSESSMENT OF Treg FUNCTION

While assays for measuring T and NK cell activation and function are relatively widespread in the diagnostic immunology realm, there is a growing recognition of the need for assays to evaluate and measure human regulatory T cell (Treg) function *in vitro* to facilitate diagnostic work-up in the appropriate clinical contexts (autoimmunity, primary immunodeficiencies, transplantation, and cancer), as well as adoptive immunotherapy approaches. Human Tregs, conventionally identified as $CD4^+$ $CD25^{high}$ $CD127^{low}$ $FOXP3^+$, are critical to maintaining the balance essential for immunological tolerance and normal immune function (39, 40). Tregs have a suppressive effect on T cell activation and proliferation by effector cells, and this feature can be exploited in the development of *in vitro* diagnostic tests to measure Treg function (41, 42). A rapid diagnostic test for Treg function involves Treg-mediated inhibition of the T cell activation markers CD69 and CD40L (CD154) on activated T cells stimulated with immobilized anti-CD3 and anti-CD28 for 7 h of coculture (42). There are several other protocols available for measuring Treg function (43, 44) that are amenable to adaptation for the clinical laboratory. Tregs suppress effector T cell activity in a cytokine-dependent manner both *in vivo* and *in vitro* (45–48). Treg suppression assays require purification or sorting of Tregs to coculture with effector cells, and this can be achieved via flow cytometry-based cell sorting (BD Biosciences, San Jose, CA) or magnetic bead sorting (Stem Cell Technologies, Vancouver, Canada; Miltenyi Biotec Ltd., Surrey, United Kingdom). While there are some varied reports in the literature as to whether bead-isolated Tregs have a suppressive function (41, 49), advances in magnetic bead sorting indicate that it is a viable process for deriving purified populations of Tregs for use in *in vitro* assays. A detailed procedure for Treg assays can be found in chapter 31 by Whiteside.

SUMMARY

The preceding sections provide ample evidence that lymphocyte activation is a complex process and a key component to maintaining normal immune function. The clinical relevance of studying and measuring lymphocyte activation is particularly noteworthy in the context of primary immunodeficiencies, caused by monogenic defects that affect various components and functions of the immune system. There are several genetic defects identified in recent years that affect T and/or NK cell function, including DOCK8, MAGT1, p85α, IL-17RA, IL-17F, and STAT3 deficiencies (50), and this is not a comprehensive list of such defects. Also, measurement of lymphocyte activation is relevant to solid organ transplantation, recovery of immune function in hematopoietic cell transplantation, and assessment of immune competence in patients on biological or pharmacological immunosuppressive therapies. This chapter provides a primer on the concepts and practical approaches to assessing T and NK cell function in the clinical immunology laboratory.

METHODOLOGY FOR MEASURING LYMPHOCYTE ACTIVATION IN THE LABORATORY

Note that the following methods are not laboratory standard operating procedures or complete protocols. They are meant only to provide broad guidelines on how various lymphocyte activation assays are performed. Please consult an actual standard operating procedure or protocol for specific details on setting up and validating these assays for the clinical laboratory.

FIGURE 4 (A) Flow cytometry analysis of T cell proliferation in response to PHA. PHA is a commonly used mitogen for global assessment of T cell function. The top panels show normal proliferative responses to PHA for a healthy individual, and the bottom panels show decreased T cell proliferation for a patient with T cell dysfunction. (B) Flow cytometry analysis of cell proliferation in response to PWM. PWM is a relatively weak T cell mitogen compared to PHA. However, PWM also induces B cell proliferation; hence, it is still used in the clinical laboratory. The top panels show normal proliferative responses to PWM for a healthy individual, and the bottom panels show decreased proliferation in both T and B cells for a patient with immunodeficiency.

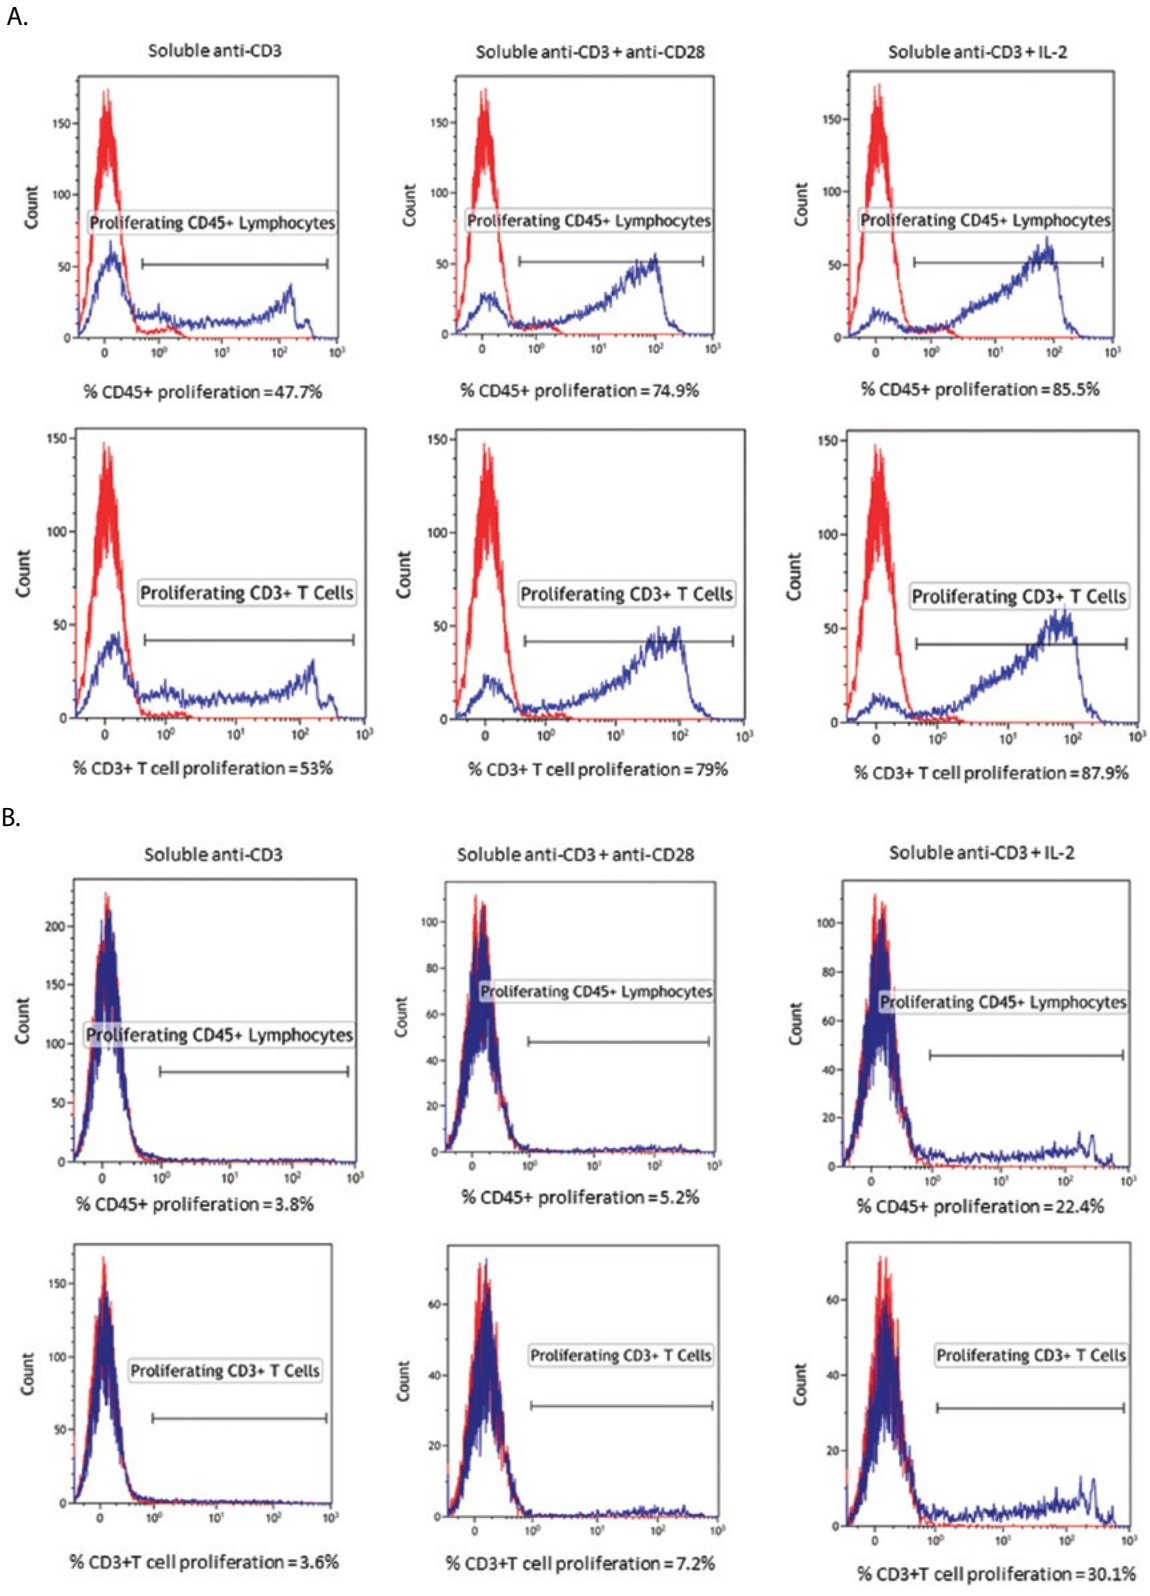

FIGURE 5 (A) Flow cytometry analysis of T cell proliferation in response to anti-CD3 stimulants for a healthy donor. Anti-CD3 antibody is often used to assess T cell functional competence, particularly in contexts where a detailed evaluation of T cell proliferative responses is essential. Soluble anti-CD3 alone delivers a weak mitogenic signal, although the addition of anti-CD28 or exogenous IL-2 to soluble anti-CD3 improves the proliferative response, as shown here. (B) Flow cytometry analysis of T cell proliferation in response to anti-CD3 stimulants in a patient with immunodeficiency. Soluble anti-CD3 alone delivers a weak signal, and addition of anti-CD28 does not show incremental proliferation. However, addition of exogenous IL-2 to soluble anti-CD3 modestly improves the proliferative response, though it remains outside the normal values for age.

Lymphocyte Proliferation Assay Using Edu-Based Flow Cytometry (Fig. 1)

1. PBMCs are isolated from sodium heparin-blood from patient or healthy donor samples by using a manual or automated method.
2. Cells are resuspended in medium with 5% human AB serum to a final concentration of 0.5×10^6 cells per well in a 48-well flat-bottom plate for mitogens alone. Cells are resuspended in medium with 5% human AB serum to a final concentration of 1.0×10^6 cells per well in a 48-well flat-bottom plate for antigens and the anti-CD3 panel.
3. Cells are incubated with various concentrations of PHA (0.5 to 20 μg/ml), PWM (0.5 to 20 μg/ml), *Candida*, TT (1 to 20 μg/ml), soluble anti-CD3 alone, anti-CD28 (5 to 25 ng/ml), or soluble anti-CD3 with IL-2 (5 to 25 ng/ml with 40 standardized units of IL-2/ml) for 3 days at 37°C in a 5% CO_2 incubator.
4. On day 3 of culture with mitogens or anti-CD3 panel stimulants (72 h of stimulation), the cells are pulsed for 18 to 24 h with 10 μM Edu (final concentration) in the presence of copper to obtain a covalent bond with the fluorescent azide AlexaFluor488. For antigens, cells are cultured for 6 days before pulsing for 18 to 24 h.
5. Following pulsing, the cells are harvested and analyzed by flow cytometry for viable, apoptotic, and dead lymphocytes by using a combination of anti-human CD45 antibody (identification of lymphocytes along with the side scatter parameter), annexin V (apoptotic cells), and 7-AAD (dead cells are positive for both annexin V and 7-AAD, while viable cells are negative for both markers). Cell proliferation is assessed by staining the cultured cells for CD45 (lymphocytes), CD3 (T cells), and CD19 (B cells only for PWM proliferation) along with CD69 (T cell activation marker). The percentage of proliferating cells in each category (total lymphocytes [$CD45^+$], $CD3^+$ T cells, and $CD19^+$ B cells) is determined by identifying the proportion of Edu-positive cells relative to the total parent population. The delta percentage is derived by subtracting the proliferation in the background (medium control) wells from that in the stimulated wells.
6. The flow cytometric analysis can be performed on any 6-, 8-, or 10-color digital flow cytometer (BD FACS Canto A or Canto II or Beckman Coulter Gallios).
7. The flow cytometric assay typically collects 20,000 events in the lymphocyte or $CD3^+$ T cell category, though the assay shows linearity and precision for a range of 200 to 20,000 events.
8. Standard flow cytometry practices must be followed to ensure instrument and assay performance.
9. Ki-67 proliferation can be measured in a manner similar to that described above, with the following differences. Following stimulation with PHA, similar to that described above, the cells are washed with 1% bovine serum albumin (BSA) and then stained for cell surface antigens for 15 min at room temperature with the following antibodies: CD45RA–phycoerythrin (PE)–Cy7 (optional), CD45RO–FITC (optional), CD3-allophycocyanin-AF750, CD4-PE (optional), and CD8-PB (optional). Following incubation, 1 ml FACS Lyse solution (BD Biosciences, San Jose, CA) is added to each tube for 15 min, and the sample is subsequently washed with 2 ml stain buffer (BD Biosciences) and resuspended in 500 μl of Fix/Perm buffer for 30 min (BD Biosciences). An additional wash is performed with 2 ml Fix/Perm wash buffer (BD Biosciences). The cells are stained with Ki-67–allophycocyanin for 30 min at room temperature and then washed again with 2 ml Fix/Perm wash buffer and resuspended in 500 μl of 1% paraformaldehyde.

Assessment of Cell Surface Markers on T Cells after Activation with Mitogenic Stimuli (Fig. 4)

1. PBMCs are isolated from sodium heparin-blood from patient or healthy donor samples by using a manual or automated method.
2. Cells are incubated in 48-well plates in 5% human AB serum-enriched medium to a final cell concentration of 0.5×10^6 cells/ml.
3. Cells are stimulated with either PHA (final concentration of 5 μg/ml) or PMA plus ionomycin (125 ng/ml and 5 μg/ml, respectively).
4. Cells are cultured for either 2, 4, 24, 48, or 72 h at 37°C in a 5% CO_2 incubator. At each time point, cells are harvested and washed with 1% BSA-containing phosphate-buffered saline for 5 min at $500 \times g$ and then resuspended in 100 μl of 1% BSA.
5. The following antibody cocktail is added: CD45-KO, CD3-PE-Cy7, CD69-allophycocyanin, CD40L-PE, CD25-allophycocyanin-Cy7, CD4-peridinin chlorophyll protein, CD8-PB, and HLA DR-FITC. Cells are incubated with the antibodies for 15 min at room temperature, followed by a wash with 1% BSA–phosphate-buffered saline for 5 min at $500 \times g$. The cells are resuspended in 1% paraformaldehyde.
6. Samples are analyzed on a 10-color Beckman Coulter Gallios flow cytometer collecting 20,000 $CD45^+$lymphocytes, and analysis is performed using Kaluza v.1.2 software (Beckman Coulter).

Measurement of Polyfunctional T Cells after Stimulation with Mitogens (Intracellular Cytokine Production by CD4 and CD8 T Cells after Activation) (Fig. 3)

1. Each patient sample is prepared in a set of three tubes: unstimulated, stimulated with PMA-ionomycin, and stimulated with PHA.
2. Stimulants and other reagents are prepared to the final concentrations indicated below in RPMI medium.
   - PMA, 25 ng/ml
   - Ionomycin, 20 μg/ml
   - PHA, 20 μg/ml
   - Brefeldin A (BFA)/Golgi Stop, 1:5 for BFA and 1:15 for Golgi Stop (add 2 μl/ml of BFA and 0.7 μl/ml for Golgi Stop)
3. BFA and Golgi Stop are added to each tube.
4. PMA-ionomycin or PHA is added as appropriate to the relevant tubes.
5. To each of the tubes, 1 ml sodium heparin-blood is added and mixed gently.
6. The tubes are incubated at 37°C in 5% CO_2 for 3 h.
7. The samples are then removed from the incubator and brought back to room temperature.
8. The following antibodies are added to appropriately labeled tubes for flow staining: CD45-KO, CD3-allophycocyanin-AF750, CD4-allophycocyanin, CD8-PB, and CD14-FITC.
9. To each tube, 100 μl blood is added and incubated at room temperature in the dark for 20 min.

10. One milliliter of 1 × lysis buffer is added to each tube, vortexed immediately, and incubated at room temperature in the dark for an additional 10 min.
11. To each sample, 2 ml stain buffer is added, and cells are washed, fixed, and permeabilized using Fix/Perm solution.
12. Following this, cells are mixed and incubated for 20 min in the dark at room temperature.
13. Cells are washed in Perm/Wash buffer and stained with the following antibodies by mixing and incubating for 20 min in the dark at room temperature: IFN-γ–PE, TNF-α–PE7, and IL-2–peridinin chlorophyll protein–Cy5.5.
14. Cells are washed in Perm/Wash buffer and resuspended in 1% paraformaldehyde.
15. Flow cytometry analysis is performed on a Beckman Coulter Gallios instrument, and data analysis is performed using Kaluza v.1.2 software (Beckman Coulter, Miami, FL).

All figures were generated in my Cellular and Molecular Immunology Laboratory, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN. from flow cytometry analyses using healthy donor or patient samples.

Functional Assays for B Cells and Antibodies

MOON H. NAHM AND ROBERT L. BURTON

29

The primary cells of the adaptive immune system are T cells, B cells, and natural killer cells. These lymphocytes assist the host in eliminating both intracellular pathogens (T cells and NK cells) and extracellular pathogens (B cells) through B cell-T cell interactions, as well as interactions with other cells and molecules of the innate immune system. B cells recognize foreign antigen by the B-cell receptor (BCR), a membrane-bound immunoglobulin generated through a complex genetic recombination process (1). The BCR recognizes conformational protein antigens as well as nonprotein antigens. Two types of B cells have been described based on expression of cell surface molecules and function. B1 ($CD5^+$) B cells are thought to be a more "natural" type of B cell which respond to T-cell-independent forms of antigen (i.e., bacterial polysaccharides) (2, 3). B2 B cells respond to T-cell-dependent antigens, such as the classic protein antigens tetanus and diphtheria toxoids. Both classes of B cells respond to BCR binding of antigen by proliferation, differentiation into antibody-secreting plasma cells, and formation of memory B cells.

The function of the humoral immune response differs depending on the class of antibody produced and the differentiation state of the B cell. Naive B cells express CD19, CD20, and surface IgM and IgD (Table 1). After BCR stimulation, B cells become memory cells or plasma cells, which express unique antigens. In addition, immunoglobulin class switching occurs and IgG, IgA, or IgE is produced. Each of these immunoglobulin classes has distinct functions. IgM can bind pathogens and activate complement. IgG can directly neutralize bacterial toxins, block adhesion of pathogens, and also activate complement. IgA can also neutralize toxins and block adhesion of pathogens, but it functions primarily at mucosal sites, while IgE plays a role in the immune response to parasites. After BCR stimulation, the immunoglobulin produced by B cells also increases its affinity for antigen, therefore improving the functionality of the humoral response.

Primary defects in the humoral components of the immune response are often manifested early in life. Certain types of infection, or frequent or incompletely cleared infections, are signs of possible B cell/antibody defects (Table 2). Primary immunodeficiencies are covered in greater detail in chapters 75 and 76. A more immediate concern to most physicians is the increasing incidence of secondary immune deficiencies due to infections such as HIV (covered in chapter 72), cancer (multiple myeloma), chronic renal failure, autoimmune processes, or posttransplantation immunosuppression.

In some patients, the absence of B-cell function is simply due to a lack of B cells. In many cases, patients may have B cells, but their function is abnormal because the B cells are either tolerized or anergic. There is also a need to measure functionality of antibodies since not all antibodies are protective. Very young children, elderly adults, and HIV-positive individuals may be more prone to producing ineffective antibodies. These ineffective antibodies may express inappropriate isotypes or V regions, resulting in low-avidity antibodies or the inability to activate complement.

APPROACHES FOR ASSESSING B CELL FUNCTION

A complete blood count (CBC) is often the first test performed in the evaluation of the humoral immune response. However, the CBC is clearly not a good indicator of underlying disease, as often the total lymphocyte count in humoral immunodeficiencies is normal or only slightly decreased. Therefore, the next step in the evaluation of a possible humoral immunodeficiency is the measurement of antibody production.

In Vivo B-Cell Function

Immunoglobulins

The most direct measure of *in vivo* B-cell function is immunoglobulin secretion by plasma cells. Serum immunoglobulin concentrations (routinely IgG, IgA, and IgM) are most commonly measured by automated nephelometry or turbidimetry (described in detail in chapter 7). The normal ranges for serum immunoglobulins vary depending on both the age and gender of the individual (4). A significant seasonal variation in serum IgA levels has also been described (5). In addition to the measurement of total serum immunoglobulin concentrations, levels of subclasses of IgG and IgA can also be determined by automated nephelometry. Patients have been reported to have deficiencies of one or more subclasses of IgG even though they have normal levels of total serum IgG. However, the true biological significance of IgG subclass deficiencies remains controversial (6, 7). Conversely, the incidence of bacterial infections is increased in some individuals

doi:10.1128/9781555818722.ch29

TABLE 1 B-cell markers used in flow cytometry

Marker	B-cell population
CD19	Early B cells to B-cell blasts
CD20	Pre-B cells to B-cell blasts
CD23	Activated B cells
CD27	Memory B cells
CD5	B1 B cells
Surface IgM	Immature, mature, and memory B cells
Surface IgD	Mature and memory B cells
Surface IgG, IgA, and IgE	Isotype-switched memory B cells
CD138 (syndecan 1)	Plasma cells

with normal IgG subclass concentrations, such as IgG2 in patients with Wiskott–Aldrich syndrome who cannot produce antibodies to many bacterial polysaccharides (8).

The presence of antibodies against common antigens is indicative of an intact humoral immune system in patients. The levels of anti-A or anti-B isohemagglutinin IgM antibodies are often determined for this purpose. The presence of these antibodies against blood-group antigens depends on both the age of the patient and the patient's blood group (i.e., no blood-group antibodies are found in the serum of blood type AB individuals). As IgM is produced by the newborn, this type of testing can be performed earlier than testing for vaccine-induced immunoglobulins. A titer of 8 or above is considered normal (9).

It is more clinically significant to measure serum antibody levels to typical vaccine components, such as tetanus, diphtheria, pneumococcus, or *Haemophilus influenzae* type b. If immunoglobulin titers against common vaccine antigens are low, then specific antigen challenge should be performed. Serum samples are obtained before and 2 to 4 weeks after vaccination. These paired sera are then tested simultaneously and a patient is generally considered to mount an adequate response if a 4-fold or greater rise in specific titer is seen. This type of challenge can be performed with neoprotein antigens such as bacteriophage ϕX174 or keyhole limpet hemocyanin, but clinically available vaccines such as pneumococcal vaccines are often used (10–12).

To quantify antibody levels against pneumococcal capsular polysaccharides (PSs), an enzyme-linked immunosorbent assay (ELISA) has been developed and well characterized (reviewed in reference 13). The current WHO consensus protocol (described in more detail in the Methodologies section "Pneumococcal ELISA" below), which includes absorption with cell wall polysaccharides (C-PS) and capsular PS from serotype 22F, has been used extensively in licensure studies for pneumococcal conjugate vaccines. Inclusion of 22F PS for absorption increased the assay specificity, especially when testing samples from children for vaccine serotypes. One limitation of this method is that it is used to quantify the IgG response only. There is mounting evidence of a significant IgM response to pneumococcal conjugate vaccine (14, 15). Thus, inclusion of IgM antibody levels against vaccine antigens may be needed for a complete evaluation of response to pneumococcal vaccines.

TABLE 2 Associations with humoral or B-lymphocyte deficiencies

Infectious agents
Streptococcus pneumoniae
Streptococcus pyogenes
Haemophilus influenzae
Ureaplasma urealyticum
Giardia lambia
Clinical conditions
Recurrent otitis
Recurrent pharyngitis
Recurrent sinusitis
Recurrent bronchitis
Recurrent conjunctivitis

In order to determine the overall response to pneumococcal vaccination, antibody levels to multiple serotypes must be determined. Thus, many reference laboratories that analyze clinical samples have developed multiplexed immunoassays for pneumococcal antibodies, most based on the technology described by Pickering et al. (16). A recent comparison study found significant differences in antibody levels from different laboratories using multiplexed assays, although the study concluded that the clinical classification of patients as "protected" or "nonprotected" was comparable between the laboratories (17), with additional commentary (18). Thus, absolute antibody levels may be not be suitable as a determinant of an adequate immunological response to vaccine, but fold increase may still be useful provided pre- and post-vaccine levels are determined by the same laboratory.

Peripheral Blood B Cells

The actual number of B cells in the peripheral blood cannot be determined by the CBC. B cells can, however, be identified through the use of flow cytometry (refer to chapters 18 and 20). In this technique, cells are characterized by their expression of cell surface markers, and the percentage and absolute cell number of B cells expressing certain immunophenotypes is compared to age-matched reference intervals (19). The most classic B-cell surface markers are CD19 and CD20 (Table 1). CD19 is a critical signal transduction molecule that regulates B lymphocyte development, differentiation, and activation. It is expressed on B cells from the earliest recognizable B lineage (early Ig gene rearrangements) to B-cell blasts. However, the expression is lost upon plasma cell maturation. CD20 is expressed on B cells from the pre-B stage to the B-cell lymphoblast stage but is not found on early B-cell progenitors or plasma cells. In general, $CD19^+CD20^+$ cells are between 5 and 10% of the total peripheral blood lymphocyte pool. Upon antigen activation, a number of cell surface markers are detected on B cells (Table 1). The presence or absence of these markers can be useful in the evaluation of B cell deficiencies in patients. One such example is the absence of $CD27^+IgD^-IgM^-$ mature class-switched memory B cells in X-linked hyper-IgM syndrome and a sub-population of patients with common variable immunodeficiency (20–22). It has also been shown that flow cytometry can identify antigen-specific B cells through BRC binding of labeled specific antigen (23).

In Vitro B-Cell Function

Flow cytometric analysis of B-cell populations is only useful for identifying defects in the actual numbers of B cells. In order to identify functional abnormalities, additional studies must be undertaken. The classic evaluation of B-cell function is through the isolation of peripheral blood lymphocytes from the patient and culturing them with agents known to activate normal B cells. This assay is known as the lymphocyte proliferation assay (LPA) (24, 25). In the LPA, either whole blood or purified peripheral blood mononuclear cells (PBMC) are cultured with a variety of stimulants

to determine the B-cell response. The cells are cultured with the stimulants for 3 to 7 days, and the effects of this activation can be measured by cellular proliferation and/or antibody secretion. The agents that specifically activate B cells are listed in Table 3. B cells can also be exposed to protein antigens such as tetanus toxoid, and the specific antibody (and isotype) secreted into the media can be characterized. As the amount of antibody secreted is low, these levels cannot be detected by nephelometry—ELISA (see chapter 35) or enzyme-linked immunosorbent spot assay (ELISPOT, see chapter 30) must be used instead. As LPAs are not available in most clinical immunology laboratories, this testing must often be performed on patient samples that are shipped to a specialized testing facility. This sample transport introduces a significant concern regarding sample integrity, as the testing requires live, functional B cells for accuracy. Many laboratories performing LPAs consequently require a normal sample to be shipped with the patient sample, to control for such transport issues. A complete LPA protocol can be found in the Methodologies section below.

Cellular Proliferation

The ability of B cells to proliferate in response to stimulation in the LPA is usually presented as the stimulation index (SI). Currently the proliferative response is measured by the incorporation of tritiated thymidine ([^{3}H]thymidine) into DNA of replicating cells. Therefore the SI is expressed as the counts per minute (cpm) of the stimulated wells divided by the cpm of the control wells (wells with B cells, but no stimulus). A second method of reporting is the net cpm, which is the cpm of the stimulated wells minus the cpm of the control wells. An alternative method for the measurement of proliferation in the LPA is the analysis of the cell cycle by flow cytometry (26). In this readout of proliferation, stimulated and control cells are permeabilized and stained with propidium iodide, and the number of cells in the S phase of the cell cycle are counted. Normal ranges for proliferation in the LPA have been difficult to establish due to a high degree of variability in assay culture conditions in different laboratories. Therefore the LPA is best utilized as a qualitative indicator of lymphocyte function, rather than as a quantitative assay.

Secretion of Soluble Mediators

In addition to proliferation, stimulation of B cells in the LPA induces B cells to produce and secrete immunoglobulins. Measurement of mitogen or antigen-induced immunoglobulin secretion will assess whether the immunoglobulin class or isotype of interest is produced in the amounts expected by age or disease state. The total culture levels of immunoglobulins are assayed by ELISA (see chapter 35). The amount of immunoglobulins produced may also be assayed at the single-cell level by enzyme-linked immunosorbent spot assay, but this assay is most useful for determining antigen-specific B-cell frequency, which is not determined by proliferation or total immunoglobulin assays.

TABLE 3 *In vitro* activators of B cell proliferation and immunoglobulin production

Activator[a]	Target	Dose	Source[c]	Reference
SAC	BCR	0.004%	Calbiochem	50
Anti-IgM	BCR	10 μg/ml	BioRad	50
PWM	See below[b]	1–10 μg/ml	Sigma	51
Tetanus Toxoid	BCR	1–20 μg/ml	Pfizer	51

[a]SAC, *Staphylococcus aureus* Cowan I; PWM, pokeweed mitogen.
[b]PWM requires T cells to be present for its mitogenic effect on B cells. Therefore, it is not a specific assay of B-cell function.
[c]Multiple sources exist for some products.

APPROACHES FOR ASSESSING ANTIBODY FUNCTION

Antibodies provide protection to the host in a variety of ways. They can neutralize toxins (e.g., tetanus toxin, diphtheria toxin), neutralize viruses (e.g., influenza A), prevent the adhesion of bacteria to the host cells (e.g., *Escherichia coli*), kill bacteria in the presence of complement (e.g., *Haemophilus influenza* type b), and opsonize bacteria for phagocytes (e.g., *Streptococcus pneumoniae*) (27–31). Antibodies can also opsonize host cells for lysis, primarily by NK cells, in a process known as antibody-dependent cell-mediated cytotoxicity (reviewed in reference 32). Consequently, a variety of assays have been developed to measure antibody function. While antibody function assays can be performed in experimental animals, *in vivo* assays are impractical and, thus, *in vitro* assays are widely used. Two such assays, *in vitro* bactericidal assays and *in vitro* opsonization assays, are described in detail below. Also, an antibody-dependent cell-mediated cytotoxicity assay kit has recently become available (www.promega.com).

Bactericidal Assays

In serum bactericidal assays (SBAs), test serum is mixed with bacteria and complement. If present, antibodies in the test serum bind to the bacteria and activate the complement cascade resulting in formation of the membrane attack complex and ultimately death of the bacteria. The number of surviving bacteria can be determined by plating a sample of reaction mixture on an agar plate. By testing the bactericidal activity of the serum samples at multiple dilutions, a titer can be determined, with titer defined as the highest dilution of serum that kills ≥50% of the target bacteria. This mechanism is primarily relevant in the study of antibodies to Gram-negative bacteria, although there have been examples seen in Gram-positive bacteria (33).

SBAs were extensively used in the development of meningococcal vaccines (34). Studies with meningococcal antibodies have shown that the source of the complement used in the SBA can influence the results. For example, when used as a complement source, rabbit serum produces higher bactericidal titers than human serum in SBAs for antibodies to meningococcus (35, 36). This discrepancy has been associated with the fact that meningococci bind to human factor H but not to rabbit factor H (37).

A major technical problem associated with the use of the bactericidal assay is enumeration of surviving bacteria. The classical approach is to plate a sample on an agar plate and manually count the bacterial colonies. However, manual colony counting is too tedious, especially for a large number of samples. Thus, a significant effort has been made to automate the counting of bacterial colonies. Additionally, other investigators have explored the use of dyes that either develop color or become fluorescent in proportion to the number of live bacteria (38–40). Quantifying the survival of bacteria is relevant for opsonophagocytic killing assays as well (see below).

Opsonophagocytosis Assays (OPAs)

Opsonophagocytosis is the primary protective mechanism of antibodies against Gram- positive bacteria. Various methods have been developed to measure the opsonizing capacity

of antibodies *in vitro*, including the "killing-type" OPA and the "uptake-type" OPA developed for *Streptococcus pneumoniae*. The classical approach is to perform the killing-type OPA where target bacteria are opsonized (coated) with antibodies and complement (41). The opsonized bacteria are subsequently internalized and killed by phagocytes, and the number of surviving bacteria is then determined. As with the bactericidal assays mentioned previously, if multiple dilutions of serum are tested, a titer can be calculated for each serum sample.

In an attempt to increase automation, an alternate approach, the uptake-type OPA, was developed. In this assay, target bacteria are fluorescently labeled, and the uptake of bacteria by phagocytes is measured with a flow cytometer by monitoring the increase in fluorescence of the granulocytes (42, 43). Fluorescent bacteria can be prepared by chemical tagging with a fluorochrome or by inserting a gene for a fluorescent protein. Because the assay is complex, it is primarily used for phagocytosis research.

Since the development and licensure of pneumococcal vaccines involve testing a large number of samples for multiple (7 to 23) serotypes that are included in the vaccines, there is a need for functional assays to study antibodies against multiple serotypes simultaneously. Such multiplexed assays would reduce not only the amount of work and expensive reagents, but would also reduce the volume of serum needed for testing. This reduction in serum volume is important when studying children, especially with the increasing valency of pneumococcal conjugate vaccines. Consequently, multiplexed killing-type OPAs were developed using antibiotic-resistant target bacteria (31, 44–46). As an example, this methodology may use one serotype susceptible to optochin but resistant to streptomycin and use a second serotype that is susceptible to streptomycin but resistant to optochin. If these two serotypes are tested together, the number of surviving bacteria of each strain can be determined by using agar plates containing either antibiotic. This strategy is simple to use and has been successfully implemented for up to seven target bacteria (44).

The increased use of functional assays has shown the importance of standardization. Early versions of the killing-type OPA utilized peripheral blood granulocytes as phagocytes. However, peripheral-blood granulocytes can differ depending on the donor's genetic traits (e.g., Fc receptor allelism) or health status. Thus, the use of a cell line, such as HL-60, was promoted. It should be noted that even the source of the cell line must be standardized because samples of the same cell line from different sources appear to have different biological properties (47). Using differentiated HL-60 cells as phagocytes, the CDC previously coordinated a collaborative study demonstrating that functional assays can be standardized if various aspects of the assays (e.g., protocol and reagents) are carefully controlled (48). Since it is not feasible to have a common lot of OPA reagents for all users, there is an ongoing study to examine the possibility of standardizing data from different laboratories (that use different protocols and different lots of critical reagents) by inclusion of a reference serum pool (such as pneumococcal reference serum, lot 007sp, from the U.S. FDA). Results of this study are expected in 2016.

METHODOLOGIES

Pneumococcal ELISA

A detailed consensus protocol for the WHO pneumococcal ELISA can be found at www.vaccine.uab.edu. It is important to note that many reagents used in the assay (microtiter plates, capsular PS used for coating plates, and secondary antibody) must be screened. Additionally, the optimal concentrations of the capsular PS and secondary antibody must be determined for each reagent lot, including microtiter plates.

When coating plates with PS, it is critical to use highly purified water for the coating buffer. Any contaminants found in the coating buffer (LPS, fungal components, etc.) may adhere to the microtiter plate and will be detected if antibodies to these contaminants are present in the test serum.

Finally, it is important to closely adhere to the incubation times and temperatures. For example, we have found that incubating plates coated with PS from serotype 3 at room temperature for 18 hours produces inconsistent results (unpublished data). Thus, we incubate plates coated with type 3 PS for 2 hours at room temperature.

In Vitro Whole-Blood Lymphocyte Proliferation Assay

Materials and Reagents

Unless specified, any supplier should suffice.

RPMI 1640 ("RPMI")
L-Glutamine
Human AB serum (heat-inactivated at 56°C for 1 hour)
Penicillin and streptomycin solution (P/S)
Mitogens/activators (see Table 3)
Tritiated thymidine ([^{3}H]thymidine) sterile, aqueous solution
96-well round-bottom tissue culture plates with lids (sterile)
Scintillation fluid
Pipette tips (sterile)
Ficoll-Hypaque (density 1.077 g/liter)
Phosphate-buffered saline (PBS, sterile)
Centrifuge tubes (15 ml)
Pipettes (sterile)

Procedure

1. Obtain fresh heparinized venous blood sample. The sample should be held at room temperature prior to analysis and should be analyzed within 24 hours of draw. A normal healthy control should be drawn at the same time as the patient sample and treated in a similar manner.
2. Dilute blood 1:2 with sterile PBS and transfer 10 ml to 15-ml sterile conical centrifuge tubes.
3. Underlay the Ficoll-Hypaque solution, using 3 ml Ficoll-Hypaque per 10 ml blood/PBS mixture.
4. Centrifuge 20 minutes at 400 × *g* in a refrigerated centrifuge at 18 to 20°C, with no brake.
5. Harvest the PBMC from the interface using a sterile pipette and wash three times in PBS (200 × *g*, 10 minutes, 18 to 20°C).
6. Resuspend PBMC in RPMI with 10% AB serum, P/S, and L-glutamine at 1×10^6 live cells/ml (viability can be ascertained by trypan blue exclusion). Use PBMC within 1 hour.
7. Add 100 μl of each antigen/mitogen concentration being tested to wells of a 96-well tissue culture (round-bottom) plate. These need to be tested in triplicate.
8. Add 100 μl of the diluted PBMCs to each well.
9. Replace the plate lids and incubate plates at 37°C with 5% CO_2.

10. To determine cell proliferation by tritiated thymidine incorporation, on the morning of day 3, each well is pulsed with 0.5 μCi of tritiated thymidine in 20 μl RPMI (no serum). After 6 hours the cells are harvested on glass fiber filters using a cell harvester. The filters are placed into scintillation fluid and counted on a beta scintillation counter. Triplicates are averaged and the stimulation index is reported.
11. To assay for total antibody production, the plates are incubated for 7 days at 37°C with 5% CO_2. Remove the culture supernatant and use for ELISA determination (see chapter 35).

Serum Bactericidal Assay for Functional Antibodies against *Haemophilus influenzae* Type b

This procedure was adapted from Dr. Romero-Steiner's protocol used by the U.S. CDC (30).

Materials and Reagents

Unless specified, any supplier should suffice.

96-well, round-bottom microtiter plates

Cryovials

Chocolate II agar plates (Becton Dickinson)

Fildes enrichment (Becton Dickinson) (Note 1)

Brain heart infusion (BHI) broth

1× Hanks' balanced salt solution (HBSS) with Ca^{2+} and Mg^{+} (Invitrogen)

Target bacteria (*H. influenzae* type b, strain Eagan or GB3292)

Baby rabbit complement (Pel-Freez Biologicals)

CBER standard serum (lot 1983, a serum standard from U.S. FDA with 70 μg of antibody/ml).

Intravenous immunoglobulin (any commercial preparation, for quality control purposes)

Glass vials (50 ml)

Glycerol

Prepared solutions

Dilution Buffer

Add 1 ml of Fildes enrichment to 49 ml of 1× HBSS with Ca^{2+} and Mg^{2+}

Procedure for Preparing Bacteria

1. Inoculate bacteria onto a chocolate II agar plate and incubate the plate overnight (~16 hours) at 37°C in a 5% CO_2 incubator.
2. Transfer about 10 isolated bacterial colonies to 20 ml of BHI broth with 2% Fildes enrichment (49) in a 50-ml glass vial and incubate at 37°C and 5% CO_2 until the optical density at 600 nm becomes 0.4 to 0.5 (Note 2).
3. Add 3 ml of sterile glycerol to the bacterial culture (20 ml). Mix well. Dispense 0.5 ml into each cryovial.
4. Quickly freeze all cryovials (except one) at −70°C. Once frozen, store the vials at −70°C until use. The nonfrozen vial will be used in step 5.
5. Determine the bacterial recovery from frozen vials (it should be greater than 80%).
   a. Thaw a vial of frozen bacterial aliquot (step 4); vial should be frozen at least 2 hours.
   b. Dilute both the nonfrozen and thawed bacteria (step 4) 10^{-6}, 10^{-7}, and 10^{-8} in dilution buffer.
   c. Plate 100 μl from each dilution on a chocolate II agar plate.
   d. Incubate the plates overnight at 37°C in a candle jar.
   e. Count the colonies.
   f. Determine the ratio of the number of thawed bacteria to the number of nonfrozen bacteria. If the ratio is <0.8, the working stocks should be discarded and new stocks prepared.
6. Determine the dilution necessary to get ~1000 CFU per 20 μl.
   a. Prepare 6 tubes with 0.9 ml of dilution buffer
   b. Rapidly thaw an aliquot of bacteria.
   c. Add 100 μl of thawed bacteria to dilution buffer in tube #1.
   d. Perform 10-fold serial dilutions by transferring 100 μl from tube #1 to #2. Continue through tube #6.
   e. Plate 10 μl from each tube, in triplicate, onto a chocolate II agar plate.
   f. Incubate the plates overnight at 37°C in a candle jar.
   g. Count the colonies and determine the average of the triplicates.
   h. Determine the bacterial density and calculate the dilution factor required to yield 1000 CFU per 20 μl.

Assay Procedure (see Note 4)

1. Prepare 2-fold serial dilutions (8 to 10 dilutions) of antisera (heat-inactivated at 56°C for 30 minutes) with dilution buffer.
2. Add 10 μl of diluted antiserum to duplicate wells of a microtiter plate.
3. Thaw an aliquot of bacteria.
4. Dilute the thawed bacteria in dilution buffer to prepare a solution containing ~1000 CFU/20 μl.
5. Add 20 μl of the diluted bacterial suspension to all wells.
6. Incubate at 37°C for 15 min in a 5% CO_2 incubator.
7. Add 25 μl of baby rabbit complement (Note 3).
8. Add 25 μl of dilution buffer.
9. Incubate the plates at 37°C for 60 min in a 5% CO_2 incubator.
10. Plate 5 μl of the reaction mixture onto chocolate II agar plates.
11. Incubate the plates at 37°C in 5% CO_2 for 16 h.
12. Count the number of surviving bacteria.
13. Determine the serum dilution that kills ≥50% of the bacteria.

Assay Notes

Note 1. Fildes enrichment is a peptic digest of sheep blood. It is rich in hemin and NAD. Although 5% supplement is usually used (44), we found that 2% supplement is sufficient for bactericidal assays.

Note 2. Bacteria will be in the exponential phase of growth. It takes about 2 to 3 hours. The broth acquires an amber color.

Note 3. Complement lots should be qualified prior to use in the assay. Both active and heat-inactivated baby rabbit complement are used to show that no non-specific killing occurs during the 1-hour incubation period.

Note 4. Serum growth controls (all reagents except complement source) should be included when the serum source is unknown or it is suspected to contain antibiotics (or other inhibitory substances).

Multiplexed Opsonophagocytic Killing Assay (MOPA4) for Functional Antibodies against *Streptococcus pneumoniae*

This procedure was adapted from the procedure described by Burton and Nahm (31). A detailed protocol can be found at www.vaccine.uab.edu.

Materials and Reagents

Unless specified, any supplier should suffice.

Tissue culture flask, vent cap (150 cm^2)

Microtiter plate (round bottom, tissue culture treated) (no. 3799; CoStar)

Square petri dish (12 cm by 12 cm by 1.5 cm) (no. 688102; Greiner Bio-One)

N,*N*-Dimethylformamide (DMF)

2,3,5,-Triphenyltetrazolium chloride (TTC) (no. T-8877; Sigma)

Streptomycin sulfate (no. S-6501; Sigma)

Optochin (ethylhydrocupreine HCl) (no. E-9876; Sigma)

Spectinomycin dihydrochloride pentahydrate (no. S-9007; Sigma)

Trimethoprim (no. T-7883; Sigma)

Todd-Hewitt broth (no. 249240; Becton Dickinson)

Yeast extract (no. 212750; Becton Dickinson)

Bacto Agar (no. 214010; Becton Dickinson)

10× HBSS (without Ca^{2+}, Mg^{2+}, or phenol red) (no. 14185-052; Invitrogen)

10× HBSS (with Ca^{2+} and Mg^{2+}, without phenol red) (no. 14065-056; Invitrogen)

RPMI-1640 ("RPMI")

GlutaMax-1 (100× solution) (no. 35050-061; Invitrogen)

Bovine serum (Fetalclone 1, for HL-60 cell maintenance) (no. SH30080.03; HyClone)

Premium fetal bovine serum (FBS, for preparation of assay buffer [OBB]) (no. 11150; Atlanta Biologicals)

Baby rabbit complement (BRC) (no. 31061; Pel-Freez Biologicals)

HL-60 cell line (no. CCL240; ATCC)

Blood agar plates

Glycerol

Gelatin

Dimethyl sulfoxide (DMSO)

Target bacteria (see Table 4)

Prepared Solutions

Streptomycin stock solution

Prepare a 300 mg/ml stock solution in water. Sterile filter and prepare 1 ml aliquots. Store at −20°C. See Note 5.

Optochin stock solution

Prepare an 8 mg/ml stock solution in water. Sterile filter and prepare 1 ml aliquots. Store at −20°C. See Note 5.

Trimethoprim stock solution

Prepare a 25 mg/ml stock solution in DMSO. Prepare 1 ml aliquots and store at −20°C. See Note 5.

Spectinomycin stock solution

Prepare a 300 mg/ml stock solution in DMSO. Prepare 1 ml aliquots and store at −20°C. See Note 5.

Glycerol stock (~80%)

Mix 20 ml of water and 100 g glycerol. Autoclave and store at room temperature (RT).

TABLE 4 Pneumococcal target strains for the MOPA[a]

Strain name	Serotype	Selective antibiotic
SPEC1	1	Spectinomycin
STREP2	2	Streptomycin
OREP3	3	Optochin
OREP4	4	Optochin
STREP5	5	Streptomycin
TREP6A	6A	Trimethoprim
SPEC6B	6B	Spectinomycin
SPEC6C	6C	Spectinomycin
SPEC6D	6D	Spectinomycin
OREP7F	7F	Optochin
STREP8	8	Streptomycin
SPEC9N	9N	Spectinomycin
EMC9V	9V	Streptomycin
OREP10A	10A	Optochin
TREP11A	11A	Trimethoprim
TREP12F	12F	Trimethoprim
STREP14	14	Streptomycin
TREP15B	15B	Trimethoprim
OREP17F	17F	Optochin
OREP18C	18C	Optochin
TREP19A	19A	Trimethoprim
SPEC19F	19F	Spectinomycin
SPEC20B	20B	Spectinomycin
TREP22F	22F	Trimethoprim
EMC23F	23F	Trimethoprim
STREP33F	33F	Streptomycin

[a]Any four target strains can be tested simultaneously, provided each strain has a unique antibiotic resistance (for example, SPEC1 and SPEC6B cannot be tested together). Also, members of the same serogroup should not be tested together (for example, TREP6A and SPEC6B should be tested separately).

Gelatin stock solution (1%)

Add 1 g of gelatin to 100 ml of water. Autoclave and store at RT.

TTC stock solution

Prepare a 25 mg/ml solution in water. Sterile filter and store at 4°C, protected from light, for up to 2 months.

Todd-Hewitt yeast broth (THY broth)

Add 30 g of Todd-Hewitt broth and 5 g of yeast extract to 1 liter of water. Sterile filter, and store at 4°C for up to 1 month.

Todd-Hewitt-yeast agar plate (THYA plate)

Add 30 g of Todd-Hewitt broth, 5 g of yeast extract, and 15 g of Bacto agar to 1 liter of water. Autoclave and allow to cool (to about 56°C). Add 25 ml to each square petri dish, and allow the plates to cool to RT. Store at 4°C in a humidified chamber for up to one month.

Overlay agar

Add 30 g of Todd-Hewitt broth, 5 g of yeast extract, and 7.5 g of Bacto agar to 1 liter of water. Autoclave and allow to cool (to about 56°C). Keep in 56°C water bath until needed (up to 12 hours).

Opsonization assay buffer B (OBB)

In a sterile tube, combine 40 ml water, 5 ml 10× HBSS (with Mg^{2+} and Ca^{2+}), 5 ml gelatin (1% stock

solution), and 2.6 ml premium FBS (previously inactivated at 56°C for 30 minutes). Keep at RT until needed (up to 12 hours).

Procedures

Initiation of HL-60 Cultures

1. Quickly thaw master stock vial and transfer contents to sterile tube containing 10 ml of RPMI with 20% Fetal Clone I and 1% glutamine.
2. Centrifuge at ~350 × *g* for 5 minutes.
3. Remove supernatant, and suspend pellet in 70 ml of RPMI with 20% Fetal Clone I and 1% glutamine. Transfer to T-150 flask and place flask into tissue culture incubator (37°C, 5% CO_2, See Note 1).
4. After 3 to 4 days, add 50 ml of fresh media (RPMI with 20% Fetal Clone I and 1% glutamine).
5. Every 3 to 4 days, remove 60 ml of cells and discard. Add 60 ml of fresh media (RPMI with 20% Fetal Clone I and 1% glutamine).
6. After cells have been in culture for 2 weeks, begin feeding with RPMI with 10% Fetal Clone I and 1% glutamine (every 3 to 4 days, remove 60 ml of cells, discard, and add 60 ml of fresh media [RPMI with 10% Fetal Clone I and 1% glutamine]).
7. After cells have been in culture for 3 to 4 weeks, the cell concentration needs to be adjusted. This is best done on a Wednesday or Friday. If done on Wednesday, count cells and adjust concentration to ~8×10^5 cells/ml in old culture supernatant. Aliquot 40 ml of cells to each T-150 flask and add 80 ml of fresh media (RPMI with 10% Fetal Clone I and 1% glutamine). If done on Friday, count cells and adjust concentration to ~8×10^5 cells/ml in old culture supernatant. Aliquot 20 ml of cells to each T-150 flask and add 60 ml of fresh media (RPMI with 10% Fetal Clone I and 1% glutamine).
8. Begin routine propagation schedule below.

Routine HL-60 Propagation

1. On Mondays, add 40 of fresh media (RPMI with 10% Fetal Clone I and 1% glutamine) to each T-150 flask.
2. On Wednesdays, remove 80 ml of cells from each flask. The removed cells can be pooled and differentiated (see below) or discarded. Add 80 ml of fresh media (RPMI with 10% Fetal Clone I and 1% glutamine) to each flask.
3. On Fridays, remove all but 20 ml from each flask (i.e., remove ~100 ml). The removed cells can be pooled and differentiated (see below) or discarded. Add 60 ml of fresh media (RPMI with 10% Fetal Clone I and 1% glutamine) to each flask.

HL-60 Cell Differentiation

1. Centrifuge the HL-60 cells at ~350 × *g* for 5 to 10 min at RT.
2. Remove supernatant, and suspend the cell pellet in differentiating medium (RPMI with 10% Fetal Clone I, 1% glutamine, and 0.8% [v/v] DMF).
3. Adjust the cell concentration to ~4×10^5 cells/ml with differentiating medium, and add 100 ml of cells to each T-150 flask.
4. Incubate the flasks (lying flat) in a tissue culture incubator (37°C, 5% CO_2) for 5 to 6 days. Do not feed the culture during this period.

Preparing Target Bacteria Working Stocks

1. Inoculate bacteria on a blood agar plate and incubate overnight in an incubator (37°C, 5% CO_2, Note 3).
2. Pneumococci yield alpha-hemolytic colonies that can be identified by a green halo surrounding the colony. Transfer 20 to 30 isolated colonies to a sterile tube containing 50 ml of THY broth. Incubate the tube for 3 to 8 hours in a 37°C water bath until the top of the culture broth (i.e., do not mix) has an optical density at 600 nm of ~0.6 to 0.9.
3. Harvest the top 10 ml of the broth from the tube and transfer to a sterile tube.
4. Add 5 ml of glycerol (80% stock solution) and 10 ml of fresh THY broth. Mix well, and prepare 0.5 ml aliquots in cryovials. Store the vials frozen at −70°C until used (up to ~18 months).
5. Determine the dilution necessary to get about 100 CFU/10 µl, see Note 2.

MOPA4

1. Incubate the serum samples to be tested at 56°C for 30 min to inactivate the endogenous complement. Also, a small volume (0.1 ml) of heat-inactivated BRC will be needed for the assay.
2. Dry the THYA plates (eight THYA plates will be needed for every assay plate) by removing the lids and placing the plates in a laminar-flow hood for 30 to 60 minutes (see Note 4). After plates are dry, replace lids to prevent overdrying, and keep at RT until needed.
3. Prepare overlay agar (~200 ml will be needed for every assay plate), OBB (1 tube as prepared above is sufficient for 4–5 assay plates), 50 ml of 1× HBSS (without Ca^{2+}, Mg^{2+}, or phenol red), and 50 ml of 1× HBSS (with Ca^{2+} and Mg^{2+}, without phenol red).
4. Prepare the microtiter assay plates (see Fig. 1 for assay plate layout):
   a. For plate 1, add 20 µl of OBB to rows A through G, columns 1 through 12. Also, add 20 µl of OBB to row H, columns 1 and 2 only. For all other assay plates, add 20 µl of OBB to rows A through G, columns 1 through 12.
   b. For plate 1, add 30 µl of heat-inactivated serum samples (in duplicate) to row H, columns 3 through 12, according to the plate layout. For all other assay plates, add 30 µl of heat-inactivated serum samples (in duplicate) to row H, columns 1 through 12. Serum samples added to row H are undiluted. Serum samples yielding a high titer may have to be retested at a higher starting dilution.
   c. Perform 3-fold serial dilutions by transferring 10 µl from H to G, mixing, and transferring 10 µl from G to F, etc. After transferring 10 µl from B to A, mix the contents of A, and discard 10 µl. Repeat for all assay plates.
5. Prepare the target bacteria.
   a. Rapidly thaw a frozen aliquot of each of the four target bacterial strains.
   b. Wash each of the target strains with 1 ml of OBB by centrifugation.
   c. After the final centrifugation, remove the OBB and suspend the pellet in 0.5 ml of OBB.
   d. To 10 ml of OBB, add the desired volume of each of the four target strains according to the dilution factors calculated earlier (Note 2) in OBB.
6. Add 10 µl of the diluted bacterial mixture to each well, including all control wells.

Sample Dilution

FIGURE 1 Assay plate layout.

7. Incubate the microtiter plates at room temperature for 30 min with shaking (700 rpm).
8. During this time, remove the BRC from the freezer to thaw.
9. Also, during this incubation, prepare the differentiated HL-60 cells:
   a. Transfer the DMF-differentiated HL-60 cells from the culture flasks to 50 mL centrifuge tubes.
   b. Centrifuge the HL-60 cells at 350 × *g* for 5 min at RT.
   c. Remove the supernatant and wash the cells with 50 ml of 1× HBSS (without Ca^{2+} and Mg^{2+}) by centrifugation as above.
   d. Remove the supernatant and wash the cells with 50 ml of 1× HBSS (with Ca^{2+} and Mg^{2+}) by centrifugation as above.
   e. Remove the supernatant, and suspend the cells at 1×10^7 cells/ml in OBB. Keep the cells at room temperature until needed.
10. Following the 30-minute incubation above, prepare a 1:4 mixture of heat-activated BRC and HL-60 cells by mixing 100 μl of heat-inactivated BRC and 400 μl of HL-60 cell suspension. Add 50 μl of this mixture to plate 1, column 1, rows A through H.
11. Prepare a 1:4 mixture of active BRC and HL-60 cells (~5 ml of mixture will be needed for each assay plate). Add 50 μl of this mixture to all rows of plate 1, columns 2 through 12. Also, add 50 μl of this mixture to all wells of remaining assay plates.
12. Incubate the microtiter plates on a shaker (700 rpm) for 45 minutes at 37°C, 5% CO_2.
13. After the incubation period, place the microtiter plates on ice for 15 to 20 minutes (to stop the phagocytic process).
14. Using a 12-channel pipettor, spot 10 μl from the wells of row H onto each of four replicate THYA plates. After spotting the 10 microliters onto the plate, immediately tilt the plate to allow the spot to form a small strip of fluid (~1.5 to 2 cm long). Repeat the spotting procedure for rows G, F, and E onto the same set of four THYA plates. Rows D, C, B, and A are spotted onto a second set of four THYA plates. Continue this procedure for the remaining assay plates.
15. Leave the plates at RT for 10 to 20 minutes to let the excess fluid seep into the agar.
16. Aliquot the desired volume of overlay agar (cooled to 56°C) to four glass bottles. Add TTC to each bottle to a final concentration of 25 mg/liter.
17. To one bottle, add optochin to a final concentration of 8 mg/liter. Add 25 ml of this overlay to the first replicate of the THYA plates spotted above.
18. To one bottle, add spectinomycin to a final concentration of 300 mg/liter. Add 25 ml of this overlay to the second replicate of the THYA plates spotted above.
19. To one bottle, add streptomycin to a final concentration of 300 mg/liter. Add 25 ml of this overlay to the third replicate of the THYA plates spotted above.

20. To one bottle, add trimethoprim to a final concentration of 25 mg/liter. Add 25 ml of this overlay to the fourth replicate of the THYA plates spotted above.
21. After the overlay has solidified (~10 min), place the plates, upside down, in an incubator (37°C, 5% CO_2) and incubate overnight. Colonies that grow on the THYA plates with the optochin overlay are bacteria of the optochin-resistant serotype; those that grow on the THYA plates containing streptomycin are bacteria of the streptomycin-resistant serotype, etc.
22. Count colonies and calculate the opsonization titer of each serum. The opsonization titer is the final dilution of serum that results in a ≥50% reduction in the number of colonies when compared to the Control-B (no serum control) wells. If an undiluted serum sample kills 55% of the bacteria in dilution 1, but the next dilution (3-fold) kills 15% of the bacteria, then the opsonization titer is 4 (e.g., 20/80 = 1:4 dilution; where 20 is the volume of serum in microliters and 80 is the total volume of the reaction in microliters).

Assay Notes

Note 1. It is important to maintain the CO_2 concentration at ~5% as HL-60 cells are sensitive to subtle pH changes that can occur when the CO_2 concentration changes. It is recommended the percent CO_2 be checked regularly with an outside reference (such as a FYRITE gas analyzer produced by Bacharach, Pittsburgh, PA).

Note 2. BRC and/or HL-60 cells can influence the number of CFU. Therefore, the optimal dilution of each strain must be determined in assay conditions (without test serum). This can be easily accomplished by testing multiple bacterial dilutions using the MOPA procedure. The desired colony number in Control B is 100 to 150 CFU/spot.

Note 3. To maintain the integrity of the pneumococcal bacterial stock cultures, remove the stock vial(s) containing bacteria from the freezer, quickly remove a fleck of ice from the stock vial, and immediately streak onto a blood agar plate. Replace the stock vial into the freezer promptly.

Note 4. Drying the THYA plates for the correct amount of time is very important. Usually 30 to 60 minutes is sufficient, although drying times vary depending on the humidity in the air. Underdrying the plates results in an excess number of colonies around the perimeter of the spot. This can affect the counting of the colonies. Overdrying the plates can cause the spots to run together when the plates are tilted.

Note 5. We have found differences in potency between different lots of antibiotics. Therefore, the potency of each batch must be determined using all targets of interest.

Methods for Detection of Antigen-Specific T Cells by Enzyme-Linked Immunospot Assay (ELISPOT)

BARBARA L. SHACKLETT AND DOUGLAS F. NIXON

30

$CD3^+CD8^+$TcR αβ thymus-derived T cells form the major effector cell component of the immune response against intracellular pathogens. Naive $CD8^+$ T cells encounter antigen, expand, and divide, and effector cells mediate a range of functions. These include major histocompatibility complex (MHC) class I restricted killing of infected host cells, noncytolytic suppression, and release of soluble cytokines and chemokines. After the acute infection is contained the number of active effector cells declines, but antigen-specific memory $CD8^+$ T cells persist, ready to expand rapidly upon antigen re-exposure. Most $CD8^+$ antigen-specific T cells recognize viral antigen as a peptide presented by an MHC class I molecule. The T-cell receptor of the antigen-specific $CD8^+$ cell interacts with the MHC class I antigenic peptide complex on the surface of the antigen-presenting cell (1).

Antigen-specific $CD8^+$ T cells can be detected by identification of a specific T cell receptor which will interact with a unique MHC-class I peptide complex, or functionally, through effector activities after stimulation with specific antigen. The traditional method for the detection of antigen-specific $CD8^+$ T cells has been the ^{51}Cr release assay. This assay detects the ability of an effector cell population to lyse a target cell population labeled with the gamma emitter ^{51}Cr. Over the past 2 decades, other approaches have been developed to study antigen-specific $CD8^+$ T-cell responses. These include intracellular cytokine staining (2, 3), MHC class I tetramer staining (4), and enzyme-linked immunospot, abbreviated as ELISPOT. These newer assays present numerous advantages including ease of use, rapidity, and sensitivity (5, 6). The simplest and most cost-effective of these methods is the ELISPOT assay. This assay detects the secretion of cytokine after specific stimulation, usually a specific peptide or recombinant vaccinia virus with a foreign gene insert. The sensitivity of the assay has been estimated as 50 or fewer antigen-specific T-cells per 1×10^6 lymphocytes, at least 1 $\log_{10}$ more sensitive than traditional limiting dilution analysis or bulk ^{51}Cr release assay (7).

The ELISPOT assay was first described in 1983 as an alternative to the plaque-forming assay for the detection of antibody-secreting cells (ASC) (8). In the initial report, spleen cells from immunized mice were incubated in antigen-coated, 96-well polystyrene plates. After removal of the cells, bound antibodies were detected by an immunoenzyme procedure. In areas of the plate where antibody production had occurred, the substrate was deposited in circular zones (spots), which could then be enumerated (8). It was not long before the ELISPOT assay was modified for the detection of cytokine-secreting T-cells, using nitrocellulose membranes and cytokine-specific monoclonal antibodies (9). ELISPOT is now used to detect both $CD8^+$ and $CD4^+$ T-cell responses to antigens from a broad range of infectious agents and vaccine preparations (10–16), as well as tumor antigens (14, 17) and autoantigens (18). ELISPOT has also become the method of choice for comprehensive mapping of T-cell epitopes (19–22).

ENZYME-LINKED IMMUNOSPOT ASSAY (ELISPOT) PROTOCOL

The protocol given below is for the detection and enumeration of gamma interferon (IFN-γ)-secreting T cells from individuals infected with HIV-1, after specific stimulation of PBMC with recombinant vaccinia viruses expressing HIV-1 gene products (23). This assay may be adapted for use with synthetic peptides, including overlapping peptide pools, as described in detail elsewhere (19, 20, 24). Studies comparing the recombinant vaccinia-based ELISPOT to the peptide-based method suggest that these two variants provide similar results (25, 26).

Day 1: Coating of ELISPOT Plates

1. Mix 25 μl anti-IFNγ mAb clone 1-D1K (1 mg/ml; Catalog #3420-3-1000, Mabtech AB, Nacka Strand, Sweden) with 5 ml sodium bicarbonate buffer, pH 9.6 (2.93 g $NaHCO_3$, 1.59 g Na_2CO_3, 0.2% NaN_3 in a volume of 1 liter H_2O, sterile filtered). (Note that some laboratories use standard phosphate-buffered saline [PBS] as a coating buffer.)
2. Add 50 μl of the above primary antibody solution to each well of a sterile MultiScreen 96-well filtration plate (#MAHA S4510; Millipore, Billerica, MA), ensuring that the bottom of each well is entirely covered; refrigerate at 4°C overnight.
   Note: Coated plates must be left in the refrigerator for a minimum of 5 hours, or can remain at 4°C for up to 5 days before proceeding to the next step. Care should be taken to limit evaporation from peripheral wells, for example by wrapping plates with plastic film.

doi:10.1128/9781555818722.ch30

Day 2: Addition of Cells and Stimulating Antigen

3. Invert the plate to discard unbound primary antibody and pat down firmly onto paper towels to remove excess liquid from wells. Using a multichannel pipettor, add 200 μl PBS to each well. Avoid touching the bottom of wells with pipette tips. Invert the plate to discard liquid, and again pat down firmly onto paper towels. Repeat the above washing step with PBS three more times. (Note: plates may also be washed using a hand-held squirt bottle.)
4. Mix 5 ml heat-inactivated pooled human AB serum (PHS) with 45 ml RPMI 1640 medium and sterile filter. Add 50 μl of the above blocking solution to each well and incubate plate at 37°C, 5% CO_2 for 1 hour.
5. While plate is incubating in blocking solution, prepare cells for adding to plate. Either fresh or frozen PBMC can be used. Usually 1×10^5 to 2×10^5 cells are required per well, and each condition is assayed in triplicate. As an example, an assay in which responses to the HIV antigens Env, Gag, Pol, and Nef are being measured will require 4×3 wells in addition to triplicate background and one positive control well (four additional wells). If the optimal 2×10^5 cells are added per well, 3.2×10^6 cells are required. Frozen cells may be thawed, or fresh PBMC may be isolated from whole blood, followed by washing 3× in RPMI 1640 supplemented with 15% FCS, and resuspending cells in 5% PHS solution (same as blocking solution in step 4) at a concentration of 1×10^5 to 2×10^5 cells per 100 μl.
6. After the 1-hour incubation in step 4, add 100 μl cell suspension to each well. It is not necessary to remove the blocking solution.
7. If using recombinant vaccinia virus (rVV) to stimulate cells, add rVV to appropriate wells at a multiplicity of infection (MOI) of 2. Note: For consistency it is recommended that all rVV be diluted to the same concentration; a versatile concentration is 2×10^8 rVV/ml. If using peptide to stimulate cells, add peptide such that the final concentration of the peptide in each well (150 μl total volume) is 10 μg/ml. For a positive control, add phytohemagglutinin (PHA) to the well such that the final concentration of PHA is 10 μg/ml. Incubate plate at 37°C, 5% CO_2 for 1 hour. (If not using vaccinia viruses, incubate overnight at 37°C, 5% CO_2, then proceed to step 9.)
8. If using vaccinia viruses, add 30 μl filtered fetal calf serum to each well. Return plate to incubator at 37°C, 5% CO_2 and incubate overnight (14–20 hours).

Day 3: Assay Development

9. Aspirate the contents of each well, being careful not to touch membrane at the bottom of the well. Add 200 μl 0.05% Tween solution to each well (250 μl Tween 20, 500 ml PBS). Invert plate to discard washing solution and pat firmly on paper towels to remove excess liquid from wells. Repeat wash three more times.
10. Mix 5 μl biotin-conjugated anti-IFNγ mAb clone 7-B6-1 (1 mg/ml Mabtech #3420-6) with 5 ml PBS. Add 50 μl of the above secondary antibody solution to each well and incubate plate at 37°C, 5% CO_2 for 2 hours.
11. At least 20 minutes before the end of the 2-hour incubation, prepare the avidin-peroxidase complex solution (Vectastain ABC kit; Vector Laboratories Elite PK-6100 Standard, Burlingame, CA). Add 1 drop each solution A and B to 5 ml 0.1% Tween solution (the washing solution used in step 12). This complex must be prepared at least 20 minutes prior to use.
12. Invert plate to discard unbound secondary antibody and pat firmly on paper towels to remove excess liquid from wells. Add 200 μl 0.1% Tween solution to each well (500 μl Tween 20, 500 ml PBS). Discard wash solution as above and repeat wash three more times.
13. Add 50μl of this ABC solution (prepared in step 11) to each well and incubate at room temperature on a flat surface for 1 hour.
14. Wash wells 4× as in step 12.
15. Add 50 μl stable diaminobenzidine (DAB) (#750118; Life Technologies, Carlsbad, CA) to each well. Incubate at room temperature for 5 minutes on a flat surface.
16. Invert plate to discard DAB into waste receptacle. Rinse wells thoroughly with tap water 3×. Remove the plastic underdrain, wipe the back of plates gently with absorbent paper towels, and allow the plate to air dry. Count spots under an inverted microscope or with the aid of an automated reader (such as AID ELISPOT Reader Classic ELR07; Autoimmun Diagnostika GmbH, Strassberg, Germany, and San Diego, CA).
17. Analyze ELISPOT data by subtracting the average spot-forming cells (SFC) in triplicate background wells (stimulated by media alone) from the average SFC in test wells. Convert the result to spot-forming cells per 10^6 cells by multiplying by 5 (in the case of 2×10^5 cells/well) or 10 (in the case of 1×10^5 cells/well).

METHODS OF ENHANCING ELISPOT SENSITIVITY

In an effort to increase the sensitivity of ELISPOT, several groups have developed modifications of the standard protocol involving the addition of exogenous cytokines, costimulatory antibodies, or antigen-presenting cells. A partial listing of these methods is given in Table 1; for additional details the original references should be consulted.

Positive Controls

Considerable methodological variation exists among laboratories; however, in recent years there has been an effort to standardize laboratory procedures in view of large-scale clinical trials (7, 17, 24, 27–31).

As a positive control for cytokine release, many laboratories rely on polyclonal stimuli (PHA or staphylococcal enterotoxin B [SEB]). However, these reagents may give rise to a nearly confluent lawn of spots. Currier and colleagues developed a control peptide pool consisting of 23 peptides derived from influenza virus, cytomegalovirus (CMV), and Epstein-Barr virus (EBV), corresponding to known CD8 epitopes restricted by a variety of MHC class I alleles (32). This pool, known as "CEF" (CMV-EBV-Flu), is recognized by approximately 85% of the general population and is available through the NIH AIDS Reagent Program, Germantown, MD, or commercially through JPT Peptide Technologies, Berlin, Germany.

The quality of ELISPOT results may be affected by cell viability, cell concentration, addition of antigen-presenting cells, source of stimulating antigen, length of stimulating peptides, DMSO content of peptide preparations, infectivity of vaccinia stocks, operator variability, reader variability,

TABLE 1 Methods of enhancing ELISPOT sensitivity

Method	Comments	Reference(s)
Costimulatory antibodies	May increase background	Ott et al. (41)
Monocyte-derived dendritic cells	Mature DC are more efficient than immature DC	Larsson et al. (42)
B cells	May increase background	Altfeld et al. (43)
IL-2, -7, and/or -15	May increase background	Calarota et al., Chitnis et al., Kim et al., Jennes et al. (15, 44–46)
MHC class I/II transfected K562 cells	Reduces background; requires specialized reagents	Britten et al. (47)

and numerous other factors. These issues are addressed in detail by several reports, as shown in Table 2.

Interpreting ELISPOT Data: Establishing Background Levels and Identifying Positive Responses

Statistical methods for evaluating ELISPOT results and determining the appropriate positive cutoff have varied considerably between laboratories. Although many research laboratories continue to rely on empirical approaches, several recent reviews have addressed the need to standardize ELISPOT data analysis for Phase I and II clinical trials. A summary of analytical methods reported in the literature is given in Table 3.

Research and Clinical Applications of the ELISPOT Assay

Since the first reports describing the T-cell ELISPOT assay more than 20 years ago, ELISPOT has been used to detect T-cell responses to antigens from a variety of infectious agents, including bacteria, viruses, and protozoa (10–16). During this time, advances in cellular immunology have revealed a surprising level of functional heterogeneity and developmental plasticity among mammalian T-cell subsets (33–35). These advances have led to a new awareness of the complex roles played by $CD4^+$ and $CD8^+$ T-cells during an adaptive immune response. While many vaccine studies continue to focus on a limited repertoire of cytokines, notably IFN-γ and interleukin-2 (IL-2), commercial reagents now permit the detection of a broad range of factors. These include IL-1β, IL-2, IL-4, IL-5, IL-6, IL-9, IL-10, IL-12, IL-13, IL-17, IL-23, IL-31, IFN-γ, granulocyte macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor alpha (TNF-α), TGF-β, RANTES/CCL-5, CXCL8/IL-8, MIG/CXCL9, IP-10/CXCL10, Granzyme B, Perforin, and FAS ligand/TNFSF6. Multi-color ELISPOT (36) and "fluorospot" (37) protocols have been developed, permitting the simultaneous detection of two to three secreted factors using specialized ELISPOT readers.

As ELISPOT technology has become more accessible, there has been increasing awareness of the potential sources of intra- and interassay variability. The necessity of harmonizing protocols for adoption by network-based clinical trials has led to a series of coordinated efforts to standardize assay validation (7, 27, 28). Several recent validation studies have been conducted by large, multi-laboratory consortia, including the Cancer Vaccine Consortium (CVC/SVI), the Clinical Trials in Organ Transplant (CTOT) Consortium, and the NIH-funded ELISPOT Collaborative Study Group (38–40). As ELISPOT protocols continue to

TABLE 2 Parameters influencing ELISPOT assay variability

Parameter	Comments	Reference(s)
Background	Assays with background >120 SFC/10^6 considered invalid	Mwau et al. (27)
Cell number (PBMC)	Optimal number is 2×10^5/well	Russell et al. (7)
Cryopreservation	Average recovery 60%; viability 90%	Russell et al. (7)
	Positive responses remain detectable	Russell et al. (7)
	Magnitude of responses diminished	Mwau et al. (27)
	Controlled stepwise freezing is optimal	Mwau et al. (27)
Detection threshold	50 SFC/10^6 PBMC (0.005%)	Russell et al. (7)
ELISPOT reader	Automated readers superior to manual counting	Herr et al., Janetzki et al. (29, 48)
Incubation time	16–20 hours	Russell et al. (7)
Peptide preparations	DMSO <1%	Mwau et al., Russell et al. (7, 27)
	Optimal length: 15-mers	Russell et al. (7)
	Effect of concentration: 2 μg/ml adequate	Russell et al. (7)
	5–10 μg/ml maximal; 20 μg/ml inhibitory	
	Peptides should be filtered	Karlsson et al. (49)
Vaccinia viruses	Titer on susceptible cell line	Larsson et al., Sun et al. (23, 25)
	Routinely verify expression of foreign protein by Western blot	

TABLE 3 Methods of analyzing ELISPOT data

Data analysis method	Reference
Empirical approaches	
Positive response: ≥3× mean of negative control wells and >50 SFC/10^6 PBMC	Addo et al. (20)
Positive response: >2× mean of background wells and >20 SFC/10^6 PBMC	Currier et al. (32)
Positive response: ≥5 more SFC/well than negative controls and >2× mean of negative control wells	Ewer et al. (16)
Positive response: >2× average of background wells and >50 SFC/10^6 PBMC	Mwau et al. (27)
Positive response: >4× mean background; > mean background + 3 standard deviations of negative control; >55 SFC/10^6 PBMC	Streeck et al. (24)
Statistical approaches	
Unpaired T-test to determine whether SFC are significantly greater in test wells than controls	Herr et al. (48)
Exact binomial test to determine whether SFC are significantly greater in test wells than controls	Russell et al. (7)
Compares several statistical methods; recommends a permutation-based criterion using a resampling adjustment for multiple comparisons.	Hudgens et al. (28)
Uses within-plate differences between negative control and test wells; defines positivity threshold based on their statistical distribution over each plate.	Alexander et al. (50)

improve and research applications continue to proliferate, the trend towards increased standardization and validation is likely to continue to accelerate in the future.

Regulatory T Cell (Treg) Assays: Repertoire, Functions, and Clinical Importance of Human Treg

THERESA L. WHITESIDE

31

Regulatory T cells (Treg) are a small subset (<5%) of circulating $CD4^+$ T cells. Due to their ability to suppress functions of other lymphocytes, Treg are responsible for maintaining immune responses in balance. This system of immune checks and balances exists to protect us from autoimmune diseases, prevent tissue damage resulting from intense inflammatory responses induced by infectious or non-infectious injuries and to contain chronic inflammatory reactions that might promote tumor development (1). Treg seem to be capable of fulfilling all these functions, largely due to their plasticity, which allows them to readily adjust to conditions in the local microenvironment (2). Viewed in this context, Treg can be considered as a protective mechanism designed to limit inflammatory tissue damage, but also as a potentially dangerous suppressor of immune responses that benefit the host. For example, in chronic viral infections such as HIV-1 infections, Treg could either suppress excessive immune activation, thus benefiting the host, or limit antiviral immunity needed by the host to contain the infection. Today, the role of Treg in HIV-1 remains highly controversial (3). In cancer, Treg are emerging both as contributors to cancer progression, because of their ability to block anti-tumor immune responses, and also as inhibitors of cancer progression via their ability to suppress cancer-promoting inflammation (4). It is unclear whether the anti-inflammatory activity of Treg or their suppression of antitumor immunity contributes to disease outcome, and the mechanisms responsible for regulation of Treg functions remain unknown. Factors that govern Treg behavior *in situ* are being intensely investigated in various human diseases. An excess of Treg (e.g., in some cancers) or their numerical or functional deficiency (e.g., in autoimmune diseases) is associated with clinical symptoms and may predict outcome. For these reasons, measurements of Treg frequency and function in the circulation, and especially in tissues, are of great importance.

Human Treg, as opposed to murine Treg, are difficult to study. This is in part because Treg are a minor subset of $CD4^+$ T cells, but mainly because no marker specific for human Treg has been defined so far. FOXP3, a transcription factor, is a reliable biomarker of murine Treg; however, in humans, FOXP3 may be transiently expressed in activated conventional $CD4^+$ T cells, may be absent in some inducible Treg, and may be found in tumor cells (4, 5). For these reasons, it is not considered to be "specific" for human Treg. Thus, the only reliable identification of human Treg depends on their functional ability to suppress activities of other lymphocytes. While initially, Treg were considered to be a distinct subset of functionally defined suppressor cells, more recent data point to the existence of distinct Treg subsets responsible for specifically targeted regulatory activities (4). This functional heterogeneity of human Treg as well as their phenotypic plasticity have created considerable confusion in the field, and the definition of Treg subsets remains controversial, as reflected by recent attempts to update their nomenclature (6).

CURRENT NOMENCLATURE OF Treg

The recently adapted nomenclature for Treg renames natural (n)Treg to "thymic-derived (t)Treg," while the former inducible (i)Treg are now referred to as "peripheral (p)Treg" to reflect their differentiation in the periphery as opposed to the thymus. *In vitro*-induced Treg, which simulate pTreg, are now called Tr1 cells (6). This revised nomenclature correctly emphasizes the distinct origin of various Treg subsets. It also acknowledges the fact that pTreg can and, in fact do, differentiate in the periphery from the conventional $CD4^+$ Treg under conditions of antigenic stimulation and an appropriate cytokine milieu (7). In this chapter, I have selected to use the older terminology of iTreg rather than pTreg because, in my view, it better defines the inducible versus naturally acquired character of the Treg subsets detectable in the human peripheral circulation.

PHENOTYPING OF HUMAN Treg

There is currently no agreement as to the best phenotypic assay for human Treg. A 2013 international canvas resulted in a list of 21 markers used for flow-based phenotyping of Treg. Of these, only 4 (CD3, CD4, CD25, and FOXP3) were used by 95 to 100% of the canvas participants. Negative expression of CD127 was used by 77%, and of CD45RA by only 27%, of participants. These six markers were considered the "backbone" markers. All other markers, including CTLA-4, CD39, CCR7, HELIOS, or CD69, were considered "optional."

It has been suggested that, in the absence of a well-defined and stable marker for all human Treg, it might be useful to consider a combination of markers that could help define distinct Treg subsets, allowing, for example, for discrimination of circulating Treg from those preferentially recruited to lymph nodes or to other tissue sites. Indeed, a

TABLE 1 Phenotypic characteristics of human nTreg, iTreg, and CD4+T conventional[a]

Markers	nTreg	iTreg	$CD4^+$conv	Comment
CD3	+	+	+	
CD4	+	+	+	
CD25	High	±	Int/low	Activation marker
CD122/CD132	±	++	±	
FOXP3*	+	±	±	Transient expression in activated T cells
SATIB1	−	±	±	Transcription factor regulated by FOXP3 negative Treg marker
CD45RA	+	−	+ or −	iTreg are $CD45RO^+$
CTLA-4	+	+	+	Upregulated on Treg
CD127	−	−	+	Used for negative selection of Treg
HELIOS[b]*	+	−[b]	±	Transient expression in activated T cells
ICOS#	±	+	+	iTreg in melanoma TIL upregulate its expression
NRP1#	±	+	±	Restricted expression
CD39#	+	++	−	Ectonucleotidase; hydrolyzes eATP to 5AMP; upregulated on Treg in TIL
CD73*#	+	±[c]	±[d]	Ectonucleotidase; when coexpressed with CD39 on cell surface in activated Treg, it hydrolyzes 5′ AMP to adenosine
CD26[e]	−	±	+	Peptidase linked to ADA1; used as a negative Treg marker
GITR#	+	+	+	
CD134	±	++	±	Upregulated on Treg
CD137#	+	++	±	Upregulated on iTreg in TIL
PD-1#	±	++	±	As above
PD-L1#	±	++	±	As above
TIM-3#	+	++	?	As above
LAG-3#	+	++	+	As above
CCR-4#	+	++	±	As above
CCR6#	+	++	±	As above
CCR7#	+	++	±	As above
GARP/LAP[f]#	+	++	−	Upregulated on the surface of circulating Treg in cancer
TGF-β*#	+	++	−	
IL-10*#	+	+	−	
GrB/perforin#	±	++	−	
COX-2#	−	+	−	
Ki67*#	±	+	±	Treg proliferate *in vivo*

[a]The list is not comprehensive and includes most commonly studied Treg markers. The iTreg column includes data for *ex vivo*-evaluated cells and/or for *in vitro*-generated cells. For a more in-depth commentary on expression of the listed markers on nTreg and iTreg, see reference 9. Symbols: * indicates intracytoplasmic/intranuclear expression; # indicates that expression levels are variable and dependent on the state of Treg activation. Table reproduced with permission from reference 9.

[b]Expression of HELIOS in nTreg versus iTreg has been debated and its usefulness for discriminating between nTreg and iTreg is not entirely clear.

[c]CD73 is abundantly present in the cytoplasm of Treg but appears to be readily downregulated (probably enzymatically cleaved) from their cell surface; it is seen on the cell surface in highly variable proportions of iTreg and only <1% of nTreg.

[d]CD73 is expressed on the cell surface of a small subset (8 to 18%) of $CD4^+CD73^+$ T cells in the peripheral blood of normal donors.

[e]ADA1 is an enzyme (adenosine deaminase 1).

[f]GARP (glycoprotein A repetitions predominant) or garpin and LAP (latency-associated peptide) are TGF-β^- associated membrane-bound molecules.

combination of $CD4^+FOXP3^+CD25^{high}CD39^+$ Treg characterizes a subset of Treg capable of suppressing functions of autologous Teff cells, and the presence of CCR4, CCR6, or CCR7 chemokine receptors might suggest the ability of these cells to migrate to tissues in response to their respective ligands (8). Also, marker combinations could better discriminate activated Treg from their precursors or serve to distinguish iTreg from nTreg. Table 1 provides a list of phenotypic markers that are being used alone or in various combinations with other markers for flow cytometry assessments of Treg frequency and the functional attributes that can be evaluated by the use of flow cytometry. The list (reproduced with permission from reference 9) is not comprehensive, but it includes markers that have been most commonly used to study human Treg.

An alternative approach to a study of human Treg may be to focus on a Treg subset that is known to be biologically important and selectively defined by expression of a stable surface marker. For example, the subset of Treg and iTreg expressing CD39, an ectoenzyme that catalyzes hydrolysis of exogenous ATP to ADP and then to 5′ AMP is of considerable interest because $CD39^+$ Treg have been shown to produce extracellular adenosine (ADO), which exerts potent immunosuppressive activity (10). CD39 is present on the surface of Treg but not other $CD4^+$ T cells, and it defines a functionally active Treg subset that appears to be expanded in disease (9). This subset of Treg was first described in the seminal papers by Borsellino et al. and Deaglio et al. (11, 12). Our own studies have contributed to defining the role of $CD39^+$ Treg in cancer and HIV (9, 13) and have suggested that the adenosinergic pathway is one of the major components of tumor-induced or HIV-I-induced immune suppression.

Suppressor Assays for Human Treg

In view of the lack of Treg-specific markers in humans and the phenotypic profile combining multiple markers (Table 1), Treg suppressive activity remains the only reliable means of their identification regardless of the phenotypic subtype. Conventionally, inhibition of responder T-cell proliferation or of T-cell activation has been considered a useful functional assay for Treg (9). More recently, Ki67, the universal proliferation marker, proved to be useful as a functional Treg marker but only *in vivo* and only in mice, whereas Treg were shown to proliferate vigorously and express Ki67 (14).

Human Treg proliferate poorly *in vitro*. Table 2 lists *in vitro* suppressor assays commonly used to evaluate functions of human Treg. In addition, expression of certain phenotypic markers by Treg could be taken as evidence of their suppressor function. For example, markers such as CD39 and CD73 ectonucleotidases, expressed on the Treg subset that produces immunosuppressive adenosine (10), have readily measurable enzymatic activity and can be used to differentiate iTreg from nTreg (15). Expression of other markers such as the latency-associated peptide (LAP) and/or glycoprotein A repetitions predominant (GARP) on iTreg suggests the involvement of the TGF-β pathway in iTreg-mediated suppression (9). Intracellular expression of granzyme B and/or perforin granules in Treg, as well as surface expression of FasL in activated Treg (9), has been associated with suppressive functions of these cells; although none of these markers are specific for Treg, their flow cytometry-based detection in combination with the constellation of phenotypic Treg markers, such as $CD25^{high}$ and FOXP3, for example, are quite useful. They allow for estimations of Treg suppressor function without isolation of Treg from body fluids. The process of Treg isolation by immune capture on antibody-coated beads is complex, and it is dependent either on negative selection (e.g., the absence of CD127 or CD26 expression on Treg) or on positive selection (e.g., a high expression level of CD25 or the presence of CD39 on Treg) to differentiate these cells from conventional $CD4^+$ T cells. The recovery of purified Treg by this process in numbers sufficient for the performance of the conventional carboxyfluorescein succinimidyl ester (CFSE)-based suppressor assays (Table 2) represents a frequently encountered difficulty (9). Often, either the number or the purity of isolated Treg is insufficient for reliable performance or adequate interpretation of suppressor assays. For these reasons, flow cytometry-based assays incorporating the detection and measurements of levels of expression of biologically active markers in human Treg without cell isolation are useful. They allow for correlations of the Treg phenotype with Treg suppressor functions in selected tissue locations such as the tumor microenvironment or an inflammatory site of interest. For example, studying by flow cytometry expression levels of the checkpoint inhibitory molecules such as CTLA-4, PD-1, LAG-3, or TIM-3 on Treg found in tumor-infiltrating lymphocytes (TIL), we have observed increased surface expression of these molecules on Treg *in situ* (16). The implication of this finding

TABLE 2 Functional assays for human nTreg and iTreg[a]

Assay type	Suppressor cell (Ts)	Responder cell (Tr)	Measurement
Multiparameter flow cytometry	*Ex vivo*-activated T cells (6–12 h)	–	Intracellular expression of 1–5 cytokines
As above	nTreg or iTreg	–	GARP/LAP expression
As above	nTreg or iTreg	CD4+T conv *ex vivo* activated, 7–20 h	Downregulation of CD69 or CD154 expression on Tr
Supernatants	nTreg or iTreg ± activation	–	Adenosine, PGE2, TGF-β, IL-10 production
Cocultures[b]	nTreg or iTreg	CFSE-labeled CD4+T conv	Proliferation inhibition
FOXP3 demethylation (MS-QPCR)	nTreg	–	Detects T-reg specific demethylation region (TSDR)

[a]Table reproduced with permission from reference 9. Abbreviations: CFSE, carboxyfluorescein; MS-QPCR, mass spectrometry-quantitative PCR. Other abbreviations as listed in Table 1.
[b]Cocultures of suppressor with responder cells require assays set up at different Ts/TR ratios.

is that Treg-mediated suppression of antitumor immune responses *in situ* involves signaling via these regulatory molecules (16). These flow cytometry-based assessments make it possible to simultaneously estimate the frequency of human Treg and of their functional attributes *in situ*.

CORRELATIONS OF Treg MEASURES WITH DISEASE

Although considerable progress in understanding the role of Treg in human health and disease has been made, reports correlating the Treg frequency, and especially their suppressive activity, with disease progression are not always consistent or reliable. For example, elimination or downregulation of Treg activity has long been considered to be a desirable strategy in cancer immunotherapy, and various agents, including cyclophosphamide, daclizumab (anti-CD25 Ab), and denileukin diftitox (ONTAC), or tyrosine kinase inhibitors such as sunitinib, have been utilized in preclinical and clinical studies to deplete Treg (reviewed in reference 9). However, it has not been possible to convincingly correlate Treg depletion by these agents with clinical benefits in patients with cancer (17). This is likely to be a reflection of Treg diversity as much as of difficulties associated with reliable assessments of this small, phenotypically and functionally heterogenous lymphocyte subset. Nevertheless, the excessive accumulations of Treg (e.g., at tumor sites in some human cancers) and, conversely, the reduction/depletion of Treg in autoimmune diseases have been linked to cancer progression or to improvement of clinical manifestations, respectively (9). Furthermore, newer data on the effects of immune therapies on the Treg suggest that modulating the frequency and/or regulatory functions of these cells may be beneficial to patients (9). Therefore, accurate measurements of the changes in Treg before, during, and after therapy are critically important, and the development of reliable, readily applicable monitoring tools for Treg subsets in the peripheral circulation and tissues of patients remains a priority.

SUMMARY

Treg play an important role in homeostasis of antitumor, antiviral, and autoreactive immunity. For this reason, Treg remain an attractive target for immunotherapy. Measurements of their frequency and functions in health or disease and the understanding of mechanisms Treg utilize for mediating immune suppression are critical for the development of therapeutic strategies for autoimmune diseases, cancer, and chronic viral infections such as HIV-1. Treg may be beneficial to the host by containing excessive immune activation such as occurs in HIV-1 or in cancers associated with chronic local inflammation. They could also serve as biomarkers for disease progression/regression if more solid correlations between their presence/activity and disease outcome or response to therapy are established in the future. For either of these reasons, assessments of Treg in the circulation and tissues are an essential component of comprehensive immune monitoring of patients with dysfunctions of the immune system.

This work is in part supported by NIH grant R0-1 CA168628 to TLW.

Measurement of NK Cell Phenotype and Activity in Humans

SAMUEL C. C. CHIANG AND YENAN T. BRYCESON

32

Natural killer (NK) cells are a subset of innate lymphocytes initially identified for their ability to specifically kill virally infected and transformed cells without prior antigen sensitization. NK cells efficiently kill target cells through directed release of perforin-containing secretory lysosomes, a feature shared with cytotoxic T lymphocytes (CTLs) (1). Despite similarities in effector mechanisms, the strategies employed by NK cells and CTLs for target cell recognition are distinct yet complementary with respect to immune defense. Whereas CTLs express recombined, clonally distributed antigen receptors that dictate their activation and are selected for recognition of cells presenting nonself peptides in the context of major histocompatibility (MHC) class I molecules, NK cells rely on dynamic integration of signals from various germ line-encoded receptors for target cell discrimination. NK cells express numerous inhibitory receptors to detect normal expression of MHC class I and can selectively kill target cells that downregulate these molecules (2). NK cell activation by target cells with low MHC class I levels does not occur by default, but rather is mediated through engagement of different activating receptors (3). Representing an effector arm of humoral immunity, NK cells express the low-affinity Fc receptor CD16, which facilitates antibody-dependent cellular cytotoxicity (4). Moreover, supporting first-line defense against virally infected or stressed cells, a multiplicity of activating receptors that participate in natural cytotoxicity have been identified. In general, engagement of each such receptor alone is not sufficient to induce NK cell cytotoxicity. However, certain combinations of receptor signals can synergistically activate NK cell effector functions (5). Reflecting the expression of several activating receptors on NK cells that bind ligands exclusively expressed on hematopoietic cells, the ability of NK cells to kill autologous, activated immune cells is increasingly appreciated as an important immunoregulatory mechanism to control and shape adaptive immune responses (6). Upon activation, NK cells not only release granules but also abundantly produce chemokines and cytokines (7).

In humans, NK cells are commonly defined as $CD3^-$ $CD56^+$ cells and typically constitute 5 to 15% of peripheral blood lymphocytes (8). NK cells are also abundant in certain tissues such as the liver and uterus. During pregnancy, NK cells are attributed an important role in vascularization of the placenta (9). Increasingly, various NK cell subsets with differing functional properties are being described (10). A major distinction has been made between $CD3^-$ $CD56^{bright}$ and $CD3^-CD56^{dim}$ NK cells, in which the former is considered a precursor of the latter (11). $CD3^-CD56^{bright}$ NK cells all express NKG2A, an inhibitory receptor for HLA-E, as well as CD62L, a selectin that mediates homing to secondary lymphoid tissues, and produce abundant gamma interferon (IFN-γ) in response to combinations of exogenous cytokines including interleukin-2 (IL-2), IL-15, IL-12, and IL-18. Comparatively, $CD3^-CD56^{dim}$ NK cells are more cytotoxic and produce higher levels of tumor necrosis factor (TNF) and IFN-γ upon target cell recognition relative to $CD3^-CD56^{bright}$ NK cells (7). $CD3^-CD56^{dim}$ NK cells can also be divided into subsets based on variegated expression of inhibitory NKG2A and KIR receptors for HLA. Generally, levels of KIR increase while NKG2A and CD62L decrease upon differentiation. Compared with adaptive lymphocyte subsets, NK cells are generally considered to be relatively short-lived. However, upon infection with certain viruses such as cytomegalovirus, longer-lived NK cell subsets have been characterized in mice (12, 13). The nature and requirements for differentiation of similar, adaptive NK cells in humans is a topic of current research.

In humans, a few isolated primary NK cell deficiencies have been characterized (14, 15). Heterozygous mutations in *GATA2* may present as isolated NK cell deficiency, which has been designated classical NK cell deficiency (CNKD) 1 (16). GATA2 is a transcription factor implicated in development of multiple hematopoietic lineages. Remarkably, *GATA2* haploinsufficiency is associated with selective deficiency in monocytes, B cells, and NK cells and clinically associated with severe papilloma and herpesvirus infections as well as development of myelodysplastic syndromes that may progress to acute myeloid leukemia (17–20). Furthermore, autosomal recessive missense mutations in *MCM4*, encoding a protein involved in DNA replication, have been associated with NK cell deficiency and termed CNKD2 (21). MCM4 deficiency is associated with an absence of $CD56^{dim}$ NK cells and severe viral infections as well as adrenal insufficiency. Furthermore, a rare autosomal missense mutation in *FCGR3A*, leading to an L66H amino acid substitution in the extracellular domain of CD16, has been associated with severe herpesvirus infections in three unrelated families and so far represents the only described isolated functional NK cell deficiency (FNKD1) (14). Surprisingly, patients with CD16 L66H mutations displayed decreased natural

doi:10.1128/9781555818722.ch32

cytotoxicity but normal antibody-dependent cellular cytotoxicity, which might be attributed to abrogated biochemical interactions between CD16 and CD2 receptors (22).

Several primary immunodeficiencies have revealed genes required for development of NK cells as well as other lymphocyte subsets, for example, SCID caused by mutations in *ADA*, *AK2*, *IL2RG*, and *JAK3* (14, 15). In addition, patients with autosomal recessive *STAT5B* mutations manifest with a growth hormone insensitivity syndrome that is immunologically associated with low T-cell numbers and NK cell deficiency (23). Furthermore, autosomal recessive mutations in multiple genes required for NK cell- and CTL-mediated cytotoxicity have been associated with disease (1). Clinically, congenital impairments in lymphocyte cytotoxic function are associated with hyperinflammatory syndromes such as hemophagocytic lymphohistiocytosis (HLH) (24). Autosomal recessive mutations in *PRF1*, encoding perforin, abrogate lymphocyte cytotoxicity (25). In patients with *PRF1* mutations, typically perforin expression is absent while degranulation is normal (26). In other patients presenting with HLH, degranulation is defective, a feature that has been linked to autosomal recessive mutations in *UNC13D*, *STXBP2*, *STX11*, *RAB27A*, and *LYST* (mutations in the two latter genes also cause hypopigmentation) (26). Finally, autosomal recessive mutations in *ORAI1* and *STIM1*, required for store-operated Ca^{2+} entry, are associated with combined immunodeficiency and result in defective NK cell degranulation and cytokine production (27). Other genes have been associated with reduced NK cell numbers or impaired NK cell function. For a more comprehensive review of genes that have been associated with abnormalities in NK cell development and function, see reference 14.

In clinical diagnostic settings, cellular assays can offer rapid answers and, in some cases, identify defects that may not be revealed by conventional genetic screening approaches (28). Thus, cellular assays complement genetic screening approaches. Strategies to identify patients with primary defects in lymphocyte cytotoxicity based on laboratory assays have been developed and rely to a large extent on evaluation of NK cell cytotoxic activity (24, 26). Assays quantifying ^{51}Cr release from radioactively labeled K562 cells, an erythroleukemia-derived target cell line devoid of MHC class I expression, have represented a gold standard with respect to clinical evaluation of NK cell activity (29). Although widely used, ^{51}Cr release assays in particular and cytotoxicity assays in general have some limitations. First, the protocols used to study NK cell cytotoxicity are labor-intensive, usually involve radioactivity, and are thus not widely available. Second, the cytotoxicity assays using bulk peripheral blood mononuclear cells (PBMCs) do not discriminate between individuals with a reduced frequency rather than reduced function of NK cells. Thus, defects in NK cell development versus function are not revealed. Third, with respect to functional NK cell defects, cytotoxicity assays do not differentiate between defects in expression of granule constituents or granule release. Thus, with the advent of multiparameter flow cytometry, current procedures for the diagnosis of primary defects in lymphocyte cytotoxicity rather rely on flow cytometric assays, which may offer more-robust means of assessing NK cell activity and indicate defects in NK cell development or function (26). It should be noted that assays measuring NK cell cytotoxicity are not obsolete. NK cell cytotoxicity relies on a multifactorial process, while NK cell degranulation does not necessarily equate to target cell cytotoxicity (5, 30). In practical terms, however, the assessment of NK cell granule constituents, combined with quantification of the degranulative capacity of NK cells, typically provides a good estimate of NK cell cytotoxic activity.

Here we provide detailed protocols for the flow cytometric measurements of NK cell frequency, phenotype, and function. An NK cell phenotypic assay, including intracellular assessment of the expression levels of the lytic granule constituents perforin, granzyme A, granzyme B, and CD107a, is detailed. In addition, a functional assay for quantification of the ability of NK cells to degranulate (estimated by assessment of CD107a surface expression), produce the chemokine macrophage inflammatory protein 1β (MIP-1β) and the cytokine TNF, as well as upregulate the activation marker CD69 is also detailed. The assays are of value for the diagnosis of diseases associated with congenital defects in NK cell development and function. Moreover, they may also be useful for gaining further understanding of how NK cells are regulated by different physiological conditions and how their function correlates with the pathophysiology of other, more common diseases.

PROCEDURES

Sample Requirements

NK cells from peripheral blood or suspensions of cells isolated from body fluids or tissues can be used for assessment of NK cell phenotype and function. The flow cytometric assays do not require any specific isolation of NK cells. However, the outlined assays are optimized for cells subjected to density gradient centrifugations for purification of PBMCs according to standard procedures. When evaluating PBMC preparations, a minimum of 2×10^6 PBMCs are needed from each subject (translating to ~2×10^5 NK cells). Besides samples collected in sodium or lithium heparin vials, the outlined assays can be reproduced with cells collected in citrate vials, whereas samples collected in EDTA vials display diminished functional responses. Unless subjects are severely lymphopenic, 3 ml of heparinized venous blood should provide sufficient cells for the outlined assays. Importantly, quantification of NK cells in peripheral blood is recommended in order to determine necessary volumes for cell isolation and aid diagnostics in patients with suspected deficiencies in NK cell development. Absolute numbers of $CD3^-CD56^+$ NK cells in peripheral blood can be determined by flow cytometry using commercial kits that include fluorospheres. When analyzing the phenotype and function of NK cells from other fluids or tissues, it is important to make sure sufficient NK cells are present in the samples to allow flow cytometric analyses.

Ideally, when examining peripheral blood NK cell phenotype and function, blood should be drawn in the morning to avoid diurnal variation and be processed as soon after phlebotomy as possible. Blood samples that require transport to a reference laboratory should be shipped at ambient (~25°C) temperature and be processed within 24 h of collection. For analyses of cells from other fluids or tissues, it is equally important to process and isolate cells in a timely manner.

For assessment of the function of freshly isolated NK cells, at least 8 h of incubation in medium in a 37°C humidified incubator is recommended. Whereas assessment of NK cell cytotoxicity is best performed with fresh, not cryopreserved, samples, flow cytometric assessment of NK cell phenotype and function is less sensitive to cryopreservation. Thus, in studies comparing NK cell phenotype and function in cohorts of samples collected at different times, cryopreservation and subsequent collective analyses of samples may reduce interassay variability. In diagnostic settings in which

assays are run on a routine basis, good quality control procedures are imperative.

Materials and Reagents

Effector cells: PBMCs or NK cells separated from heparinized body fluids or tissue

Target cells: K562 cells (ATCC CCL-243) and P815 cells (ATCC TIB-64)

Complete medium (RPMI 1640 supplemented with 10% heat-inactivated fetal bovine serum and 2 mM L-glutamine)

Extracellular staining solution (phosphate-buffered saline supplemented with 2% fetal bovine serum and 2 mM EDTA)

Fixation solution, formaldehyde based (e.g., BD Biosciences' Cytofix/Cytoperm)

Permeabilization solution, saponin based (e.g., working concentration of BD Biosciences' Perm/Wash buffer)

Titrated, fluorochrome-conjugated antibodies to CD3 (clone S4.1), CD14 (clone M5E2), CD16 (clone 3G8), CD19 (clone HIB19), CD56 (clone NCAM16.2), CD69 (clone TP1.55.3), CD107a (clone H4A3), perforin (clone δG9), granzyme A (clone CB9), granzyme B (clone GB11), MIP-1β (clone D21-1351), and TNF (clone MAb11)

Dead cell marker (DCM) for flow cytometry (e.g., Molecular Probes' LIVE/DEAD Fixable Dead Cell Stain Kits)

Brefeldin A-containing solution (e.g., BD Biosciences' GolgiPlug diluted in complete medium as per manufacturer's recommendations)

15-ml conical polypropylene tubes

96-well V-bottom plates and plate covers

Equipment and Instrumentation

Multichannel micropipettor capable of delivering 100 μl

Centrifuge for 15-ml tubes and 96-well plates

Flow cytometer capable of measuring at least eight parameters (a BD Fortessa [BD Biosciences] instrument with four lasers was used in the design of the sample panels)

Experimental Procedure

Assessment of Lytic Granule Content

Experimental Protocol 1

1. For effector cell suspensions from each subject/sample, determine the number of viable cells by trypan blue exclusion or by other viability assay. Transfer the cells to 15-ml conical polypropylene tubes, centrifuge at 300 × *g* for 10 min, and resuspend the cells in complete medium (For PBMCs, the recommendation is 4×10^5 PBMCs, resuspended at 2.0×10^6 live cells/ml, approximately equivalent to a total of 4×10^4 NK cells.
2. Aliquot 150 μl of effector cell suspensions from each subject into single wells on consecutive rows of a V-bottom 96-well plate.
3. Centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
4. Prepare a surface stain master mix consisting of ice-cold extracellular staining solution supplemented with fluorochrome-conjugated antibodies to CD3, CD14, CD16, CD19, and CD56, as well as DCM. Refer to Table 1 for a suggested staining panel. Optimal concentrations of antibodies for flow cytometric analysis should be titrated beforehand.

TABLE 1 Suggested antibody panels

Laser	Fluorochrome[a]	Antibody	Master mix
Protocol 1: Phenotypic assay			
Blue	FITC	IgG/Perforin	**Internal**
Red	APC	IgG/Granzyme B	**Internal**
Red	APC-AF700	CD3	External
Violet	Pacific Blue		
	Violet 500	DCM, CD14, CD19	External
	Brilliant Violet 711	CD16	External
Yellow-green	PE	IgG/Granzyme B	**Internal**
	ECD	IgG/CD107a	**Internal**
	PE-Cy7	CD56	External
Protocol 2: Functional assay			
Blue	FITC	CD107a	External
Red	APC	TNF	**Internal**
Red	APC-Cy7	CD3	External
Violet	Pacific Blue	(CD57)	(Optional External Master Mix)
	Violet 500	DCM, CD14, CD19	External
	Qdot 705	(CD8)	(Optional External Master Mix)
Yellow-green	PE	MIP-1β	**Internal**
	ECD	CD69	**Internal**
	PE-Cy7	CD56	External

[a]Abbreviations: APC, allophycocyanin; Cy, cyanine; ECD, electron-coupled dye; FITC, fluorescein isothiocyanate; PE, phycoerythrin.

5. Resuspend cells in 50 μl of ice-cold surface stain master mix and incubate at 4°C for 20 min in the dark.
6. Top up each well with ice-cold staining solution. Centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
7. Resuspend the cells in 100 μl of fixation solution and fix the cells at room temperature for 10 min in the dark.
8. Resuspend the cells by gentle pipetting and transfer 50 μl of cell suspension to the adjacent well. Thus, there should be two wells of cells from each subject divided into two columns.
9. Top up wells with staining solution and centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
10. Prepare master mixes for intracellular staining as follows:
    a. Prepare intracellular staining master mix A of ice-cold permeabilization solution supplemented with fluorochrome-conjugated antibodies to perforin, granzyme A, granzyme B, and CD107a.
    b. Prepare intracellular staining master mix B of ice-cold permeabilization solution supplemented with fluorochrome-conjugated isotype control antibodies at equal concentrations to the antibodies used in the intracellular staining master mix A.
11. Resuspend cells in the first row with 50 μl of ice-cold intracellular stain master mix A and cells in the second row with 50 μl of ice-cold intracellular stain master mix B. Incubate the plate at 4°C for 30 min in the dark.
12. Top up each well with staining solution. Centrifuge the plate at 400 × *g* for 4 min. Flick off supernatant.
13. Resuspend cells in 200 μl of ice-cold staining solution. Acquire data on a calibrated flow cytometer.

Analysis of Flow Cytometric Data

1. Perform proper compensation for all parameters measured.
2. First analyze the isotype control sample from a healthy control. Consecutively gate as outlined (Fig. 1):
    a. Lymphocytes on a forward-scatter height versus side-scatter height plot.
    b. Single cells on a forward-scatter height versus forward-scatter area plot.
    c. Viable (DCM^-), $CD14^-$, and $CD19^-$ cells on a histogram plot.
    d. $CD3^-CD56^{dim}$ NK cells on a CD3 versus CD56 plot.
3. Calculate the median fluorescence intensity (MFI) of isotype controls.
4. Copy the outlined gating strategy to samples stained with antibodies to granule constituents. Subtract the MFI values of isotype control stainings from those of the granule constituents.
5. Compare the MFI levels for the various granule constituents among subjects.

Assessment of NK Cell Function

Experimental Protocol 2

1. Preparation of effector cells:
    a. For effector cell suspensions from each subject/sample, determine the number of viable cells by trypan blue exclusion or by other viability assay. Transfer the cells to 15-ml conical polypropylene tubes, centrifuge at 300 × *g* for 10 min, and resuspend the cells in complete medium (For PBMCs, the recommendation is 2×10^5 PBMCs, resuspended at 2.0×10^6 live cells/ml, approximately equivalent to a total of 2×10^4 NK cells.).
    b. Aliquot 100 μl of effector cell suspensions into 4 wells of a 96-well plate, with consecutive rows for each subject.
    c. Centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
    d. Resuspend cells in 100 μl of complete media containing brefeldin A (e.g., use 1:500 final dilution of GolgiPlug).
2. Preparation of target cells:
    a. Culture K562 and P815 cell lines in complete media. Maintain and use cell lines in logarithmic growth phase.
    b. Determine target cell viability by trypan blue exclusion or by other viability assay. For each subject/sample, 2×10^5 K562 cells and 4×10^5 P815 cells are needed. Transfer the K562 cells to one 15-ml conical polypropylene tube and the P815 cells to two 15-ml conical polypropylene tubes. Centrifuge

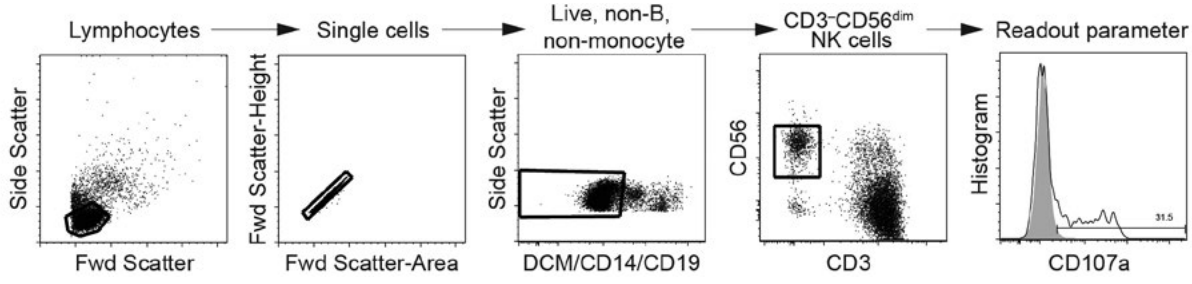

FIGURE 1 Gating strategy for flow cytometric analysis of NK cells. The strategy for consecutive gating of $CD3^-CD56^{dim}$ NK cells is depicted. First, lymphocytes are gated on forward-scatter versus side-scatter characteristics. Second, single cells are gated on forward-scatter height versus forward-scatter area characteristics. Third, a histogram representing a dump channel with staining for dead cells, $CD14^+$ monocytes, and $CD19^+$ B cells. Viable, nonmonocyte, non-B cells are gated. Fourth, $CD3^-CD56^{dim}$ NK cells are gated on a CD3 versus CD56 plot. Finally, phenotypic or functional readouts can be assessed in histograms.

the cells at 300 × *g* for 10 min and resuspend cell pellets at 2×10^6 cells/ml in complete medium.
   c. To one of the tubes of P815 cells, add unconjugated anti-CD16 antibody to a final concentration of 1 μg/ml. Vortex to mix.
3. To the plates with effector cells, add 100 μl of complete medium to each well with effector cells in the first column (acting as unstimulated controls), 100 μl of K562 cells to each well in the second column, 100 μl of P815 cells to each well in the third column, and 100 μl of P815 cells supplemented with anti-CD16 antibody to each well in the fourth column. Every well should hereafter have a total volume of 200 μl.
4. Resuspend all wells and incubate the plate in a humidified incubator for 3 h at 37°C.
5. Centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
6. Prepare a surface stain master mix consisting of ice-cold extracellular staining solution supplemented with fluorochrome-conjugated antibodies to CD3, CD14, CD19, CD56, and CD107a, as well as DCM. Refer to Table 1 for a suggested staining panel. Optimal concentrations of antibodies for flow cytometric analysis should be titrated beforehand.
7. Resuspend cells in 50 μl of ice-cold surface stain master mix and incubate at 4°C for 20 min in the dark.
8. Top up each well with staining solution. Centrifuge the plate at 300 × *g* for 4 min. Flick off supernatant.
9. Resuspend the cells in 50 μl of fixation solution and fix the cells at room temperature for 10 min in the dark.
10. Top up each well with staining solution. Centrifuge the plate at 400 × *g* for 4 min. Flick off supernatant.
11. Resuspend cells with 50 μl of ice-cold intracellular stain master mix and incubate the plate at 4°C for 30 min in the dark. Add in the appropriate fluorochrome-conjugated antibodies to CD69, MIP-1β, and TNF.
12. Top up each well with staining solution. Centrifuge the plate at 400 × *g* for 4 min. Flick off supernatant.
13. Resuspend cells in 200 μl of ice-cold staining solution. Acquire data on a calibrated flow cytometer.

Analysis of Flow Cytometric Data

1. Perform proper compensation for all parameters measured.
2. First analyze the unstimulated sample from a healthy control. Consecutively gate as outlined (Fig. 1):
   a. Lymphocytes on a forward-scatter height versus side-scatter height plot.
   b. Single cells on a forward-scatter height versus forward-scatter area plot.
   c. Viable (DCM^-), $CD14^-$, and $CD19^-$ cells on a histogram plot.
   d. $CD3^-CD56^{dim}$ NK cells on a CD3 versus CD56 plot.
3. Gate for percentage of NK cells expressing CD107a, CD69, MIP-1β, and TNF. Typically at a resting stage, there should be <1% positive-staining cells for CD107a and TNF, whereas the percentages of cells positive for CD69 and MIP-1β may be higher.
4. Copy the outlined gating strategy to samples stimulated with various target cells.
5. Examine the percentage of positive cells for readouts of activation in unstimulated samples and calculate the induced responses by subtracting values for unstimulated samples from those for samples with various target cells. Background percentages of CD107a, CD69, MIP-1β, and TNF from the stimulated samples should also be examined. Compare the results of the various markers in patients and healthy controls.

Controls

The NK cell assay should include several different types of controls, as follows:

Instrument controls: Fluorescent bead controls for calibration of instrument sensitivity and generation of compensation matrices.

Intra-assay controls: Replicates of PBMCs from a single healthy donor are tested with different plate layouts to control for inherent variability in pipetting as well as variability potentially caused by varying positioning on plate.

Interassay controls: Cryopreserved, thawed, and pretested PBMCs from different selected healthy donors, ideally with high and low levels of NK cell functional responses, are tested every time the assay is performed. Thus, these samples are included in assays over weeks and months, providing a measure of the assay's reproducibility.

Transport controls: When assessing patient samples that are shipped to a reference laboratory, samples from healthy donors from the patient sample origin should always be included, in addition to healthy donors recruited locally at the reference laboratory, to control for deterioration of NK cell activity during transport due to long transportation times or suboptimal handling.

Biological variability controls: At various time intervals, fresh PBMCs from the same healthy donors are repeatedly obtained and used to chart the biological variability in NK cell numbers, phenotype, and functional responses over time.

Quality Control and Assurance

Assay reproducibility needs to be established and monitored in each individual laboratory. Criteria for acceptable NK cell assays are defined on the basis of intra- and interassay variability. A quality control program needs to be in effect, accepting or rejecting NK cell assay results based on strict criteria. The following components should be included in a quality control program:

A formulated standard operating procedure (SOP) and strict definition of acceptable assay results based on continuous monitoring of fresh as well as standard, cryopreserved cells.

Strict adherence to the SOP and written documentation of any changes that may be introduced.

Regular maintenance and quality control of the flow cytometer.

Titration and control of new batches of antibodies to ensure optimal stainings.

Routine thawing of new target cells from a large batch of cryopreserved cells with low passage number.

Continued maintenance and frequent (at least every 6 months) cumulative analyses of the control cell performances to confirm the reproducibility of the assay.

Pitfalls and Troubleshooting

Phenotypic assays with intracellular staining as well as functional assays require considerable effort to reproducibly

perform and reliably interpret. Many sources of variability exist. Antibodies should be carefully titrated and tested. New target cells should be thawed every 2 to 3 months to ensure reproducibility in stimulations. Target cells can be avoided entirely, with stimulation based on antibodies to activating receptors alone. However, we find that NK cell functional assays are less consistent when target cells are omitted. To control interassay variability, inclusion of cryopreserved controls in repeated assays is useful to ensure consistent assay performance and enable comparisons across assays. We recommend using samples from three donors with high, intermediate, and low NK cell responses.

With respect to assessing multiple readouts of NK cell activation, each readout displays distinct kinetics. CD107a surface expression, acting as a readout of cytotoxic lymphocyte degranulation, occurs rapidly following engagement of activating receptors (30). Production of the chemokine MIP-1β and induction of CD69 expression can be measured at later time points, followed by TNF and IFN-γ production (7). If longer time points are necessary to reliably quantify expression of cytokines, addition of monensin to the assay may be useful to prevent reinternalization of CD107a and underestimation of NK cell degranulation (31).

Specimen handling is a major concern, particularly when samples require shipment and the time and conditions from phlebotomy to cell isolation cannot be controlled. In such settings, transport controls are imperative for interpretation of results. Notably, samples that have endured long or poor transport conditions can display reduced responses to K562 cells, whereas Fc receptor engagement may still mediate strong activation (32).

In some samples, including those from patients with infections or hyperinflammatory conditions, NK cell frequencies may be reduced. The outlined assays require a minimal number of NK cells for reliable assessment of phenotype and function. Interpretation of phenotypic and functional results is recommended only if data on a minimum of 100 NK cells are acquired. With respect to possible defects in cytotoxic lymphocyte degranulation, NK cell assays may be complemented with assays for the evaluation of cytotoxic effector T-cell degranulation (33). For examining T-cell degranulation, PBMCs are incubated for 3 h with P815 cells supplemented with a final concentration of 2.5 μg/ml of fluorescent conjugated anti-CD3 antibody (clone S4.1). The analysis strategy is similar to that described in the method above, but degranulation is evaluated in the $CD3^+CD8^+$ $CD57^{bright}$ population rather than $CD3^-CD56^{dim}$ NK cells. To this end, the inclusion of CD8 (clone 3B5) and CD57 (HCD57) surface staining is required in protocol 2, step 10. The same applies for T-cell granule staining in protocol 1, step 6.

Interpretation

With respect to NK cell development, NK cell numbers and frequencies vary considerably among individuals. Among a population of 200 healthy adult volunteers, we quantified $CD3^-CD56^+$ NK cell numbers in peripheral blood to 208 ± 110 cells/μl (mean ± standard deviation; range, 30 to 565 cells/μl), with a frequency of 11.0% ± 5.8% (mean ± standard deviation; range, 1.5 to 31.3%) among peripheral blood lymphocytes, consistent with other reports from smaller cohorts (34, 35). On average, the numbers of NK cells in peripheral blood are somewhat higher in children, particularly in infancy (34, 35). Specific guidelines for the diagnosis of NK cell deficiency have not been established. For CNKD1 with mutations in *GATA2*, patients have been reported to display a $CD3^-CD56^{bright}$ NK cell population

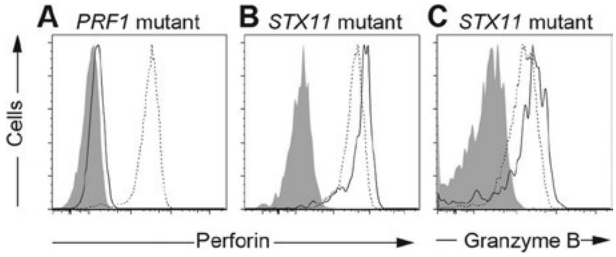

FIGURE 2 Lytic granule expression in $CD3^-CD56^{dim}$ NK cells from patients and healthy controls. PBMCs were stained and assessed according to protocol 1. Histograms depict expression of perforin (A, B) or granzyme B (C) in a patient with biallelic *PRF1* mutations (solid line) relative to a healthy control (dashed line) (A) or a patient with biallelic *STX11* mutations (solid line) relative to a healthy control (dashed line) (B, C).

that is <0.5% of the total $CD3^-CD56^+$ peripheral blood NK cells (16). For CNKD2 with mutations in *MCM4*, patients have been reported to display $CD3^-CD56^+$ NK cell numbers in peripheral blood of <200 cells/μl and frequencies of <4% among lymphocytes, with an absence of $CD3^-CD56^{dim}$ NK cells (21). When primary deficiencies in NK cell development are suspected, genetic tests are recommended to confirm a possible diagnosis.

A prerequisite for lymphocyte cytotoxicity is the intracellular expression of lytic granule constituents. Low or absent perforin expression is usually observed in patients with biallelic mutations in *PRF1* (as exemplified in Fig. 2A), which typically present with familial HLH or hematologic malignancies. Of note, individuals may display increased expression of perforin and granzymes (Fig. 2B), which is a feature of familial HLH patients and other patients with hyperinflammatory disease activity (36, 37).

With respect to functional responses, simultaneously probing several readouts of NK cell activation is useful for determining the overall responsiveness of cells and identifying possible defects in signaling pathways and effector functions. Healthy individuals normally display between 10 and 30% $CD107a^+$ degranulating $CD3^-CD56^{dim}$ NK cells following K562 stimulation, with stronger responses following engagement of CD16 (26, 33). Notably, upon stimulation with K562 cells, $CD3^-CD56^{dim}$ NK cell degranulation of <5% offers a 96% sensitivity and 88% specificity for the identification of patients with mutations in genes required for cytotoxic lymphocyte degranulation (26). Patients with primary defects in lymphocyte degranulation often also manifest constitutively high CD69 expression but poor induction of TNF upon stimulation with target cells (Fig. 3). Notably, more-general defects in lymphocyte activation, such as those caused by mutations in *ORAI1* and *STIM1*, required for store-operated Ca^{2+} entry, significantly reduce NK cell degranulation and cytokine production but only partially impair induction of MIP-1β (27).

In certain cases in which resting NK cell degranulation is absent and familial HLH is suspected, there is a noticeable recovery of function after activation with IL-2 (36, 38), which can direct genetic analyses and may be explained by redundancies among soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (SNARE proteins) for lytic granule exocytosis (26, 39). To determine possible gain

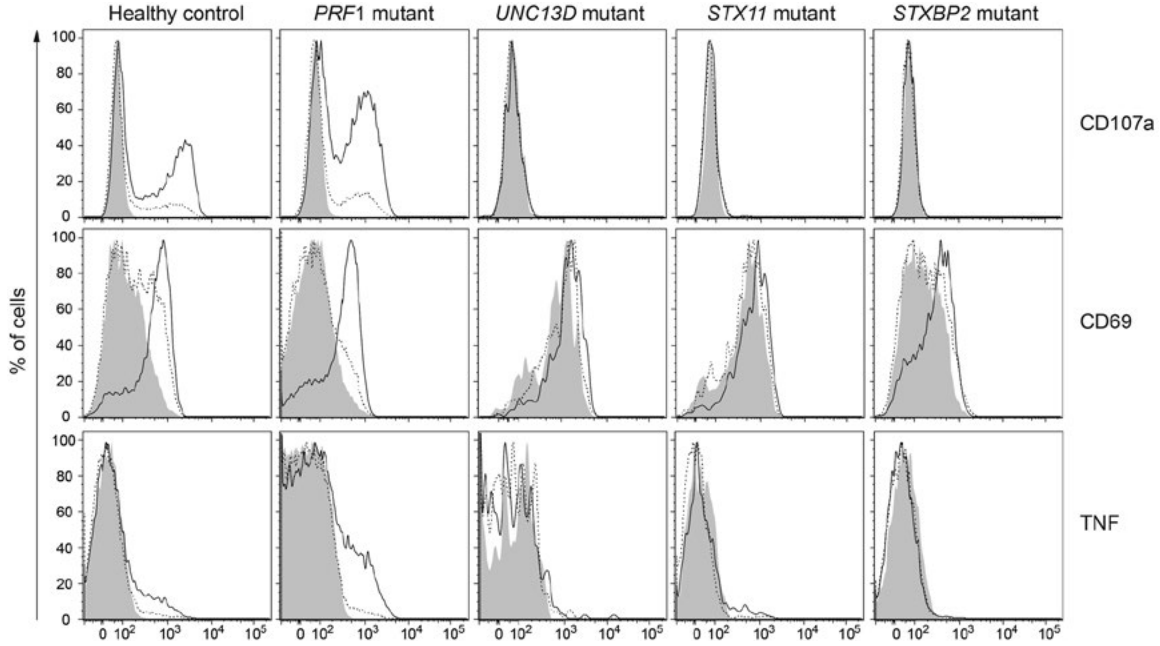

FIGURE 3 Functional responses by $CD3^{-}CD56^{dim}$ NK cells from patients and healthy controls. PBMCs were mixed with target cells and assessed according to protocol 2. Histograms depict expression of CD107a, CD69, and TNF, as indicated, on NK cells from a healthy control or patients with biallelic mutations in *PRF1*, *UNC13D*, *STX11*, or *STXBP2*. Expression in unstimulated cells (filled histograms), cells incubated with K562 cells (dashed lines), or P815 cells with added anti-CD16 mAb (solid lines) is depicted.

of degranulation upon NK cell activation, protocol 2 is repeated on PBMCs preactivated for 36 to 48 h in complete media containing 500 IU/ml of IL-2.

An explanation of selective defects in NK cell activation following incubation with K562 cells may be mutations in *FCGR3A* consistent with FNKD1. Remarkably, the CD16 L66H variant destroys an epitope recognized by the anti-CD16 mAb B73.1, whereas recognition of the anti-CD16 mAb 3G8 is unperturbed. However, loss of the anti-CD16 mAb B73.1 epitope does not necessarily imply FNKD1 (40). Thus, genetic analyses are necessary to confirm a diagnosis of FNKD1.

Table 2 summarizes the primary immunodeficiencies that may be detected with the outlined assays. Additional primary immunodeficiencies affecting NK cell development and function may be considered (14).

TABLE 2 Genes associated with strong defects in NK cell development or function[a]

Gene	Syndrome	Inheritance	Protein	Peripheral blood NK cells	Cytotoxicity defect	Partial albinism	Cellular diagnostic evaluation[b]
GATA2	CNKD1	AD	GATA2	Low ($CD56^{dim}$)	Yes	No	NK cell phenotype
MCM4	CNKD2	AR		Low ($CD56^{bright}$)	Yes	No	NK cell phenotype
ADA	SCID	AR	Adenosine deaminase	$B^{-}T^{-}NK^{-}$	Likely	No	
IL2RG	SCID	XL	IL-2 receptor γ chain	$B^{+}T^{-}NK^{-}$	Likely	No	
JAK3	SCID	AR	JAK3	$B^{+}T^{-}NK^{-}$	Likely	No	
STAT5B		AR	STAT5b	$B^{+}T^{low}NK^{-}$	Likely	No	
CD16	FNKD1	AR	CD16	Present	Natural cytotoxicity	No	Absent activity toward K562 cells

(Continued on next page)

TABLE 2 *(Continued)*

Gene	Syndrome	Inheritance	Protein	Peripheral blood NK cells	Cytotoxicity defect	Partial albinism	Cellular diagnostic evaluation[b]
PRF1	FHL2	AR	Perforin	Present	Yes	No	Absent intracellular perforin expression
UNC13D	FHL3	AR	Munc13-4	Present	Yes	No	Defective degranulation
STX11	FHL4	AR	Syntaxin-11	Present	Yes	No	Defective degranulation
STXBP2	FHL5	AR	Munc18-2	Present	Yes	No	Defective degranulation
RAB27A	GS2	AR	RAB27A	Present	Yes	Yes	Defective degranulation
LYST	CHS1	AR	LYST	Present	Yes	Yes	Defective degranulation
ORAI1	CID	AR	ORAI1	Present	Yes	No	Defective target cell activation
STIM1	CID	AR	STIM1	Present	Yes	No	Defective target cell activation

[a]Abbreviations: AD, autosomal dominant; AR, autosomal recessive; CHS, Chediak-Higashi syndrome; CID, combined immunodeficiency; FHL, familial hemophagocytic lymphohistiocytosis; GS, Griscelli syndrome; XL, X linked.
[b]Cellular phenotypic assays may fail to diagnose disease caused by coding mutations that impair protein function without affecting protein expression.

CONCLUSIONS

Herein we have detailed two flow cytometric assays that require small amounts of cells, facilitating analysis in many settings, including samples from infants or from small tissue samples. The assay measuring NK cell maturation and granule content can be useful for ascertaining normal NK cell development and detecting patients with primary immunodeficiencies with defective NK cell development. Moreover, evaluation of intracellular granule contents may reveal patients with primary immunodeficiency caused by biallelic *PRF1* mutations or indicate a hyperinflammatory state. The second assay, quantifying NK cell responses, can reveal primary immunodeficiency patients with defects in lytic granule exocytosis or general NK cell activation. The assays can easily be modified to probe function downstream of specific NK cell receptors or more generally assess lymphocyte function. They may also be modified to incorporate evaluation of target cell killing by flow cytometry. Not only are these assays useful for the diagnosis of primary immunodeficiency syndromes, they can also contribute to improving our understanding of NK cell function in various settings including tumor surveillance, organ development, and immune homeostasis.

Functional Assays for the Diagnosis of Chronic Granulomatous Disease

DEBRA LONG PRIEL AND DOUGLAS B. KUHNS

33

Chronic granulomatous disease (CGD) is a rare genetic disease (~1 in 200,000 in the U.S.) first described in the 1950s (1). It is characterized by a failure of phagocytes (polymorphonuclear neutrophils [PMN], monocytes, macrophages, and eosinophils) to generate superoxide ($O_2^{\cdot-}$) and other related reactive oxygen species (ROS), leading to recurrent infections, granulomatous complications, and premature death. Generation of $O_2^{\cdot-}$ requires the assembly and activation of a multicomponent enzyme, NADPH oxidase (NOX2) or phagocyte oxidase (phox), a complex consisting of numerous cytosolic proteins, including $p47^{phox}$ (2), $p67^{phox}$ (2), and $p40^{phox}$ (3), and two membrane proteins, $p22^{phox}$ and $gp91^{phox}$, that constitute cytochrome b_{558} (4, 5). NOX2 catalyzes the reduction of molecular O_2 to $O_2^{\cdot-}$ using NADPH generated by the oxidation of glucose through the pentose-phosphate pathway. $O_2^{\cdot-}$ is converted to H_2O_2 either spontaneously or enzymatically. H_2O_2 and $O_2^{\cdot-}$ can react to form the highly reactive hydroxyl radical, OH·. The molecular defect in CGD results from mutations in any one of 5 protein subunits of NOX2, that include $gp91^{phox}$ (~70% of patients), $p47^{phox}$ (~25%), $p22^{phox}$ (<5%), $p67^{phox}$ (<5%), and $p40^{phox}$ (one case identified). Because the molecular defect in CGD is the inability to generate ROS, most of the assays used in the diagnosis of CGD that are described below are based on assessments of ROS production using different probes and different detection platforms. The last two assays—flow cytometric analysis of NOX2 expression and immunoblot analysis of phox subunits—focus on identifying the specific protein defect and defining the target for genetic sequencing.

ANALYSIS OF PMN H_2O_2 PRODUCTION BY FLOW CYTOMETRY OF DIHYDRORHODAMINE 123 STAINING

Principle

Activation of the NOX2 complex of phagocytic cells results in the generation of $O_2^{\cdot-}$ as well as other ROS. The products of NOX2 activation can be measured in individual cells by flow cytometry using dihydrorhodamine 123 (DHR) (6), a weakly fluorescent probe that greatly increases its fluorescence upon oxidation to rhodamine in the presence of H_2O_2. Leukocytes are loaded with DHR by passive diffusion, and then stimulated with phorbol 12-myristate 13-acetate (PMA) for 15 min at 37°C. Using the NOX2-derived H_2O_2, endogenous cellular peroxidases (e.g., myeloperoxidase in PMN) convert DHR to rhodamine. Catalase is added to the medium to prevent cell-to-cell diffusion of H_2O_2.

PMN can be easily segregated from other leukocyte populations by flow cytometry using forward light scattering (FS) and right-angle light scattering (SS). However, stimulation of PMN with PMA results in a relocalization of the PMN population within the FS × SS plot, with a shift to the left and overall reduction in the variance of the forward light scattering (compare the Basal FS × SS plot with the PMA FS × SS plot in Fig. 1). Moreover, the distribution of PMN within the FS × SS region is not symmetric; the DHR^+ PMN, indicated in red, cluster along the lower left region of the gated population (note the back-gated FS × SS dot plot from an X-linked carrier in Fig. 1C).

The major advantages of the flow cytometric analysis of DHR assay are its sensitivity, signal-to-noise ratio, and ease of counting a large number of cells. Moreover, it has been shown that the DHR assay yields reliable results on EDTA- or heparin-treated blood samples that have been stored overnight.

Reagents

Lysis buffer

100 ml sterile distilled water

0.83 g ammonium chloride

0.2 ml of 0.5 M EDTA, pH 8.0 (51234, Lonza, Walkersville, MD)

0.2 g potassium bicarbonate

Add 0.83 g ammonium chloride, 0.2 ml EDTA, and 0.2 g potassium bicarbonate to water and sterilize through a 0.2-μm filter.

Flow buffer

0.5 g albumin (from human serum, fraction V, A9511, Sigma-Aldrich, St. Louis, MO)

500 ml Hanks' balanced salt solution without Ca^{2+}, Mg^{2+}, or phenol red (HBSS, 10-547F, Lonza)

1 ml of 0.5 M EDTA, pH 8.0 (51234, Lonza)

Mix reagents well and sterilize through a 0.2-μm filter.

doi:10.1128/9781555818722.ch33

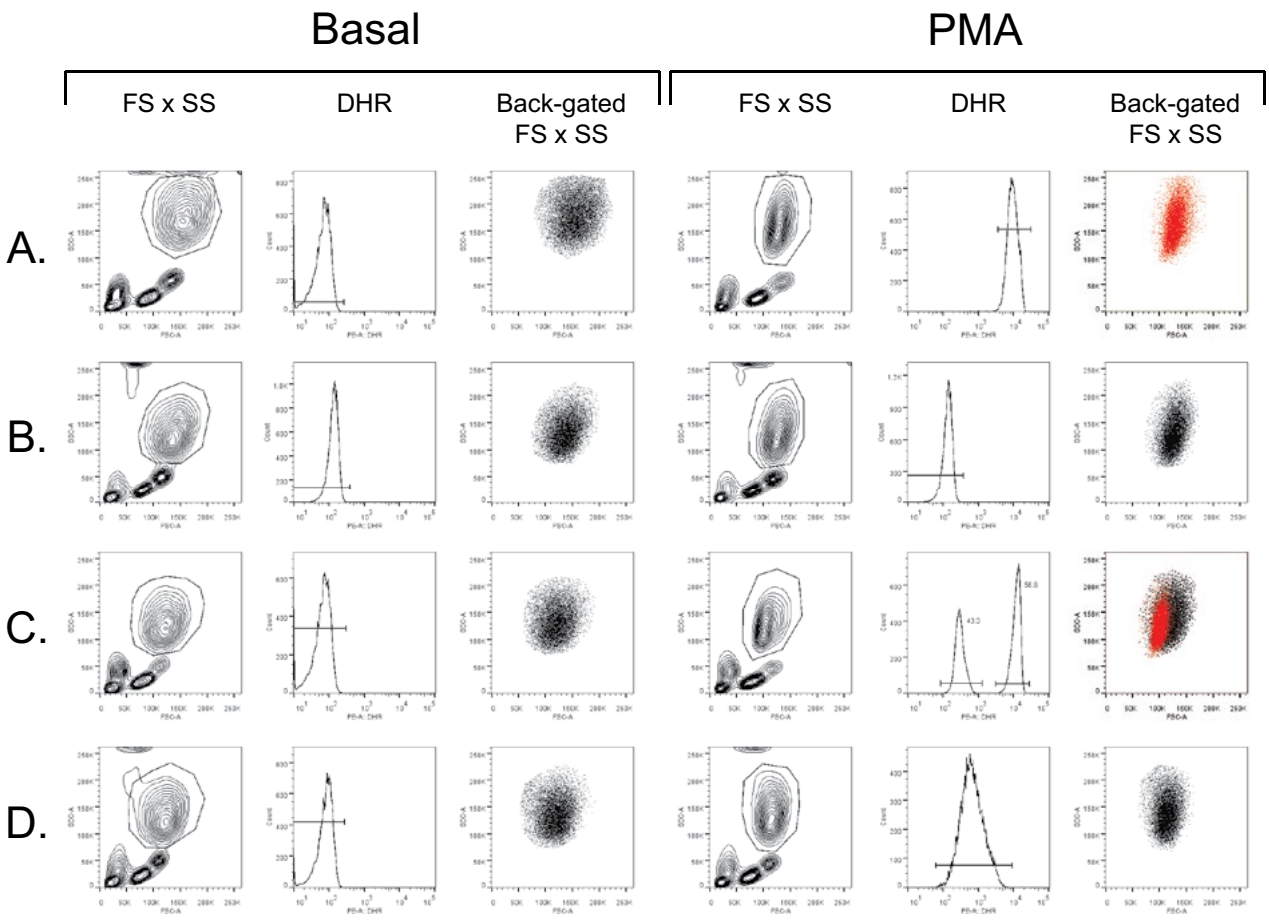

FIGURE 1 Analysis of H_2O_2 production by dihydrorhodamine-123 staining. PMN populations of buffer-treated (Basal) and PMA-treated (PMA) samples were gated using FS × SS shown in the contour plots on the left panel for each condition. The middle panel for each condition represents the DHR histogram which is presented on a log scale. The right panel for each condition represents a dot plot of the back-gated region of the DHR histogram to identify the nature of the population analyzed. Stimulation with PMA induces a shift in the FS × SS pattern of the PMN population in all subjects tested: a normal subject (A), a patient with $gp91^{phox}$ CGD (B), an X-linked carrier of CGD (C), and a patient with $p47^{phox}$ CGD (D). DHR^+ cells are indicated in red in back-gated FS × SS dot plots.

Catalase (10 mg/ml)

100 mg catalase (C-40, Sigma-Aldrich)

10 ml phosphate-buffered saline (PBS, 17-512F, Lonza)

Dissolve 10 mg catalase in 10 ml PBS. Store at −85°C in 100-μl aliquots.

Dihydrorhodamine 123 (DHR, 25 mM)

10 mg DHR (D-632, Molecular Probes, Life Technology, Grand Island, NY)

1.156 ml dimethyl sulfoxide (DMSO, D2650, Sigma-Aldrich)

Prepare solution by dissolving 10 mg DHR in 1.156 ml DMSO. Store at −85°C in 25-μl aliquots wrapped with foil to protect from light.

PMA (phorbol 12-myristate 13-acetate, 2 μg/ml)

PMA (P8139, Sigma-Aldrich)

DMSO

Prepare a stock solution of PMA (2 mg/ml) by dissolving 5.0 mg PMA in 2.5 ml DMSO. Store at −85°C in 100-μl aliquots. Dilute stock PMA solution to a 2-μg/ml working concentration in flow buffer.

Procedure

1. Collect patient blood samples in K_2EDTA blood-collection tubes (36661; Becton Dickinson, Franklin Lakes, NJ). A blood sample from a normal subject is also needed to serve as a control to validate the assay.
2. Warm the lysis buffer in a 37°C water bath.
3. Add 12 ml warm lysis buffer to a 15-ml polypropylene conical centrifuge tube.
4. Add 1.2 ml whole blood to the 12 ml lysis buffer. Cap the tube and invert several times to mix the blood.
5. Incubate at 37°C for 5 min.
6. Spin at 600 × *g* for 5 min, aspirate supernatant fluid, and wash the cells by adding 12 ml of flow-HBSS buffer, then repeat spin.
7. Aspirate the supernatant. If there is evidence of red blood cells in the leukocyte pellet (which can interfere with the DHR analysis), repeat steps 6 and 7.
8. Resuspend the cells in flow buffer to a cell concentration of 2×10^6 cells/ml.

9. Transfer 400 μl of cells to two 12 × 75 mm polypropylene tubes labeled "Basal" and "PMA-stimulated."
10. Add 2 μl of 25 mM DHR to each tube.
11. Add 2.5 μl of 10 mg/ml catalase to each tube and mix by vortexing.
12. Incubate at 37°C in a shaking water bath for 5 min.
13. Add 100 μl PMA to the "PMA-stimulated" tube. Add 100 μl flow buffer to the "Basal" tube.
14. Incubate at 37°C in a shaking water bath for 15 min.
15. Analyze the samples on a flow cytometer within 25 min of adding DHR to the tubes, using FS × SS to gate on the PMN population (Fig. 1). Collect at least 5,000 events within the PMN gate. When the number of DHR^+ cells is expected to be <1%, the number of events collected in the PMN gate should be increased to 200,000 to obtain an accurate determination of a minor population.

Results and Normal Range

Treatment of PMN from a normal subject with PMA results in a 2-log shift in the mean fluorescence intensity (MFI) in more than 90% of the PMN (Fig. 1A). In our laboratory, the expected MFI for PMN with buffer alone is 90 ± 34 arbitrary units (AU) (mean ± standard deviation); after stimulation with PMA, the expected MFI for PMN is 11,367 ± 2,719 AU. In general, PMN from patients with CGD exhibit less than a 1-log shift in fluorescence after stimulation with PMA (Fig. 1B). PMN from a female X-linked carrier of CGD exhibit two populations, an abnormal DHR^- population expressing the mutant allele and a brightly stained DHR^+ population expressing the normal allele (Fig. 1C). PMN from patients with $p47^{phox}$ CGD (Fig. 1D) and some CGD patients with missense mutations in $gp91^{phox}$, $p22^{phox}$, or $p67^{phox}$ can exhibit significant increases (up to a log) in the MFI, but still much less than observed in PMN from a normal subject.

Interpretation and Limitations

The DHR assay is probably the most commonly used assay to establish a diagnosis of CGD. However, subjects with myeloperoxidase deficiency (7), found in 1 per 2,000 individuals, as well as several other disease states (8) can give a false-negative DHR response, depending on the extent of their deficiency. Therefore, a negative DHR should be confirmed with a negative nitroblue tetrazolium (NBT) test and/or abnormal $O_2^{-\cdot}$ generation using superoxide dismutase-inhibitable ferricytochrome *c* reduction. Analysis of $O_2^{-\cdot}$ production by cytochrome *c* reduction in PMN from a patient with myeloperoxidase deficiency will yield normal/supranormal production of $O_2^{-\cdot}$. The myeloperoxidase deficiency can be confirmed by either histochemical staining or quantitation of myeloperoxidase by enzyme-linked immunosorbent assay (ELISA).

CGD patients with mutations in the PU.1 binding domain of the promoter region of *CYBB* may express DHR^+ eosinophils, while PMN are DHR^- (9). In addition, in two CGD patients, we have noted small populations (2% and 7%) of DHR^+ PMN that may result from genetic reversion. It is often necessary to increase the number of events in the PMN gate to accurately assess these minor populations of cells.

Blood samples older than 24 h can be analyzed by the DHR assay, but the results may become difficult to interpret because of decreased viability. Nonviable PMN in the analysis region are interpreted as DHR^- cells. Hence, a normal subject can be misread as an X-linked CGD carrier. For the same reason, overnight samples should not be used to definitively rule out X-linked heterozygosity, since a highly lyonized CGD carrier (>90% DHR^+) could yield a DHR similar to an aged sample from a normal subject. In these cases, sequence analysis of *CYBB* is needed to substantiate the final diagnosis.

ISOLATION AND CHARACTERIZATION OF PMN

Principle

For some assays, PMN must be purified from erythrocytes and other leukocytes to obtain an accurate estimation of ROS production. PMN isolation protocols use differences in the cell density as the primary basis for cell separation. The relative densities of blood cells are as follows: erythrocytes > PMN and eosinophils > monocytes, lymphocytes, and basophils > platelets. Ficoll-Paque has a density (1.077 g/ml) that falls between that of PMN and that of the mononuclear cells. To isolate PMN, whole blood is diluted with saline and underlayered with Ficoll-Paque. After centrifugation for 30 min at 500 × *g*, the less-dense monocytes, lymphocytes, basophils, and platelets remain at the upper interface of the Ficoll-Paque, while the denser erythrocytes and PMN pass through the Ficoll-Paque and pellet at the bottom. The plasma, mononuclear cells, and Ficoll-Paque are aspirated carefully without disturbing the erythrocyte/PMN interface. The erythrocyte/PMN pellet is resuspended with saline and mixed with 3% dextran. Dextran promotes the formation of rouleaux by the erythrocytes, causing them to sediment rapidly at 1 × *g*. The PMN-enriched supernatant fluid is harvested from the bulk of the erythrocytes. Contaminating erythrocytes are removed by a brief (30 s) hypotonic lysis. The isotonicity is quickly restored with an equal volume of re-equilibration buffer. A second hypotonic lysis removes many of the residual erythrocyte ghosts.

Alternatively, a PMN-isolation protocol that uses a discontinuous gradient of plasma/Percoll minimizes exposure of PMN to trace contamination by bacterial lipopolysaccharide (LPS) and reduces PMN priming (10).

In our laboratory, isolated PMN are routinely frozen in pellets containing 5 × 10^6 PMN. For immunoblot studies, PMN resuspended in HBSS (1 × 10^6 cells/ml) are pretreated for 20 min with the cell-permeant, irreversible serine-protease inhibitor diisopropylfluorophosphate (DFP, 5 mM). This treatment prevents proteolytic cleavage of PMN proteins after detergent solubilization of protease-rich granules in PMN prior to electrophoresis. The cells are then spun at 400 × g for 10 min and the supernatant fluid is removed prior to freezing. These frozen PMN, though not viable, can be used as a source of PMN proteins for immunoblot analysis and DNA for genetic analysis.

Reagents

Ficoll-Paque Premium (17-5442-02, GE Healthcare, Piscataway, NJ)

3% Dextran

15 g dextran (200,000–300,000 MW, 101514, MP Biomedicals, Solon, OH)

500 ml 1× PBS (17-512F, Lonza, Walkersville, MD)

Add 15 g dextran to 500 ml PBS. Mix well and sterilize through a 0.2-μm filter.

Hypotonic Lysis Buffer

13.6 ml 10× PBS (17-515F, Lonza)

600 ml sterile, distilled H_2O (17-724F, Lonza)

Add 13.6 ml 10× PBS to 600 ml sterile, distilled H_2O.

PBS Re-Equilibration Buffer

108.1 ml 10× PBS

500 ml sterile distilled H_2O

Add 108.1 ml 10× PBS to 500 ml sterile distilled H_2O.

HBSS without Mg^{2+}, Ca^{2+}, or Phenol Red

Procedure

1. Collect patient blood in sodium-heparin (5–10 U/ml whole blood, final concentration) or acid-citrate-dextrose (ACD-A) blood-collection tubes (BD Vacutainer 367874 or 364606, Becton Dickinson).
2. Dispense 15 ml HBSS to a 50-ml conical centrifuge tube.
3. Transfer 15 to 20 ml heparinized blood to tube.
4. Carefully underlay blood mixture with 12 ml Ficoll-Paque Premium.
5. Spin for 30 min at 500 × *g*, with brake off.
6. Aspirate mononuclear cells, remaining plasma, and Ficoll-Paque Premium from the tube, leaving the PMN and erythrocyte-rich pellet.
7. Dilute with HBSS for a final volume of 20 ml.
8. Add 20 ml of 3% dextran. Invert the tube several times to mix. Allow erythrocytes to sediment at 1 × *g* for 20 min at room temperature.
9. Transfer the PMN-rich supernatant fluid to a new tube. Dilute with HBSS.
10. Spin at 300 × *g* for 10 min. Remove the supernatant fluid.
11. Lyse the remaining erythrocytes with 10 ml hypotonic lysis buffer, followed by the quick addition (within 30 s) of 10 ml PBS re-equilibration buffer to restore the isotonicity. Dilute further with 20 ml HBSS.
12. Spin at 300 × *g* for 10 min, aspirate the supernatant fluid, wash, and repeat process twice. Repeat lysis if there is significant erythrocyte contamination.
13. Resuspend PMN in HBSS. Count the cells using an automated cell counter.

Results and Normal Range

In general, 1×10^6 to 2×10^6 PMN can be isolated per ml of whole blood from a normal subject, with a purity and viability of >95%.

Interpretation and Limitations

The most common cell contaminants of the PMN preparation are eosinophils; however, some lymphocytes and monocytes may also be present. Some PMN studies require a purity higher than >95%. Further purification of the PMN preparation with anti-CD16 magnetic immunobeads (130-045-701; Miltenyi Biotec Inc., Auburn, CA) eliminates contaminating eosinophils and results in a PMN preparation that is >99%.

PMN from patients with specific granule deficiency have decreased density because of their lack of specific granules and fail to penetrate the Ficoll-Paque density cushion, instead colocalizing with the peripheral blood mononuclear cells atop the density cushion.

HISTOCHEMICAL STAINING OF PMN WITH NBT

Principle

The NBT test is a qualitative histochemical assay used to detect the production of ROS by oxidation-reduction reactions in phagocytes. NBT, yellow in solution, is an electron acceptor and is reduced in the presence of $O_2^{\cdot-}$ to formazan, an insoluble blue-black precipitate. Either whole blood or isolated PMN are added to the NBT solution in a chamber slide and stimulated with PMA for 15 to 30 min at 37°C. The PMN are allowed to adhere to the slide. The slide is air dried, counterstained with 0.6% safranin, and examined using a 100× objective of a microscope. The NBT test yields a visual record of ROS generation by individual cells. Under basal conditions, PMN from a normal subject do not generate ROS and cannot convert NBT to formazan; the cytosol and nucleus of the PMN appear pink because of the safranin counterstain (Fig. 2A). Treatment of PMN from a normal subject with PMA results in the production of ROS and the appearance of blue-black formazan deposits in the cytosol of the PMN (Fig, 2B). Treatment of PMN from a CGD patient with PMA does not induce ROS production (Fig. 2C), leading to an appearance similar to normal PMN under basal conditions. As observed with the DHR assay, treatment of PMN from a female X-linked carrier of CGD will exhibit both NBT^+ and NBT^- PMN because of random inactivation of the X chromosome (Fig. 2D).

Reagents

HBSS with Ca^{2+} and Mg^{2+} with 10 mM HEPES (HBSS/HEPES), pH 7.35–7.40

500 ml HBSS with Ca^{2+} and Mg^{2+} (10-527F, Lonza)

5.0 ml of 1.0 M HEPES buffer (15630-080, Life Technologies)

Add 5.0 ml 1.0 M HEPES to 500 ml HBSS. Adjust the pH within the range of 7.35 to 7.40. Prepare on day of use.

HBSS/HEPES with 1% Bovine Serum Albumin

1 g bovine serum albumin (BSA, A-2153, Sigma Aldrich)

100 ml HBSS/HEPES

Add 1 g BSA to 100 ml HBSS/HEPES. Mix well and sterilize through a 0.2-μm filter. Store at 4°C.

NBT (0.2%, N5514, Sigma-Aldrich)

1 tablet (10 mg) NBT

5.0 ml HBSS/HEPES

Add 1 NBT tablet to 5.0 ml HBSS/HEPES. Mix well and sterilize through a 0.2-μm filter. Prepare fresh on day of use.

PMA (20 μg/ml)

Prepare a working solution of PMA (20 μg/ml) by adding 10 μl stock PMA (2 mg/ml) to 990 μl 50% DMSO.

Safranin O (0.6%, 65092B-95; Harleco, EMD Millipore, Gibbstown, NJ)

Procedure

1. Transfer 0.1 ml isolated PMN (1×10^7 cells/ml) into a labeled conical tube.
2. Add 0.4 ml of 1% BSA in HBSS/HEPES.
3. Add 0.5 ml of 0.2% NBT solution.
4. Add 5 μl of 20 μg/ml PMA and mix well.

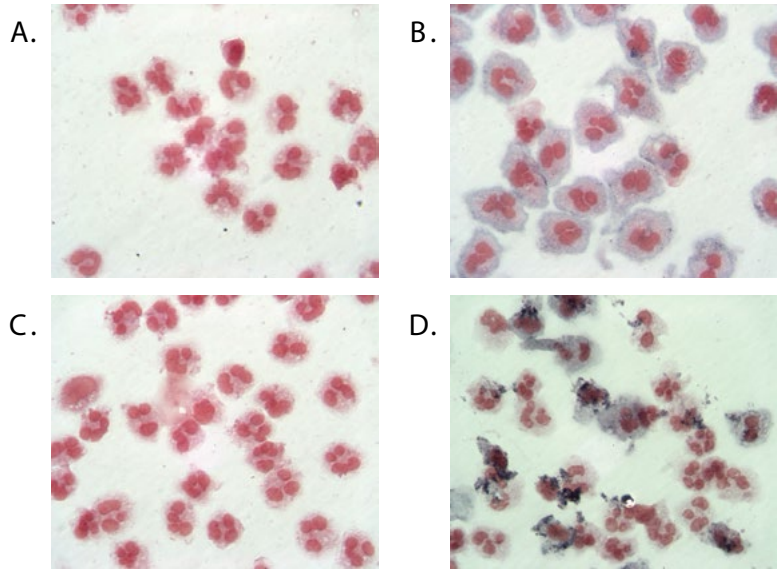

FIGURE 2 Histochemical staining of PMN with NBT. (A) PMN from a normal subject under basal condition exhibit only the safranin counterstain of the cytosol and nucleus. (B) PMN from a normal subject stimulated with PMA exhibit blue-black formazan deposits in the cytosol and the safranin counterstain in the nucleus. (C) PMN from a patient with gp91^{phox} CGD stimulated with PMA fail to generate ROS and exhibit only the safranin counterstain of the cytosol and nucleus. (D) PMN from an X-linked carrier of CGD stimulated with PMA exhibit both an NBT^- population and an NBT^+ population of PMN. In this case, the X-linked carrier was 52% NBT^+.

5. Transfer 500 μl (in duplicate) to a well of a chamber slide (177445, Nunc Lab-Tek; Thermo Fisher Scientific, Inc., Waltham, MA).
6. Incubate the slide for 15 min at 37°C.
7. Wash the slide with HBSS/HEPES.
8. Fix the slide with methanol.
9. Counterstain with 0.6% safranin for 5 min.
10. Allow the slide to dry before viewing the cells on the microscope.
11. Enumerate the % NBT^+ cells by counting 200 PMN, differentiating between NBT^+ and NBT^-.

Results and Normal Range

Treatment of PMN from a normal subject with PMA in the presence of NBT results in the formation of blue-black formazan in the cytosol and a pink counterstained nucleus in 98 to 100% of the cells (Fig. 2B).

Interpretation and Limitations

PMN that fail to reduce NBT include those that have little or no oxidase activity. This can include patients with CGD or glucose-6-phosphate dehydrogenase deficiency. In general, an NBT test on PMN from a patient with CGD exhibits only the safranin-counterstained nucleus with no formazan precipitate in the cytosol (Fig. 2C). Very few, if any, cells are NBT^+, although some patients with p47^{phox} CGD can stain weakly. Hence, the ability to reduce NBT does not exclude the diagnosis of CGD.

The NBT test can also be used to diagnose X-linked carriers of CGD (Fig. 2D) but cannot differentiate autosomal carriers from normal subjects. Because of inactivation of one of the X chromosomes, an NBT test on PMN from a carrier of CGD reveals two populations of PMN: PMN that are functioning correctly and able to generate ROS contain blue-black precipitate in the cytosol from the reduction of NBT to insoluble formazan, whereas PMN that do not generate ROS contain only pink-counterstained cytosol. The NBT test has a wide distribution in X-linked carriers of CGD, from as little as 5% NBT^+ to as much as 95% NBT^+.

The drawback of the NBT test is the time required to view sufficient individual cells and the subjectivity of the technician interpreting the response in each cell.

QUANTITATIVE ANALYSIS OF $O_2^{\cdot-}$ GENERATION USING SOD-INHIBITABLE FERRICYTOCHROME *c* REDUCTION

Principle

The release of ROS such as $O_2^{\cdot-}$ and H_2O_2 is an important component of the bactericidal machinery of PMN. The production of $O_2^{\cdot-}$ can be detected using the reduction of cytochrome *c*. $O_2^{\cdot-}$ causes a one-to-one stoichiometric reduction of ferricytochrome *c* to ferrocytochrome *c*, with a resultant increase in the absorption spectrum at 549.5 nM. Superoxide dismutase (SOD) is added to an identical tube to act as a blank by removing the substrate, thereby validating $O_2^{\cdot-}$ production. Resultant supernatants are analyzed by spectrophotometry using an analytical wavelength of 549.5 nm for peak absorbance and background wavelengths of 541 nm and 556 nm. The amount of $O_2^{\cdot-}$ generated is calculated from the optical density (OD) of reduced cytochrome *c* to nanomoles of $O_2^{\cdot-}$ released using the micromolar extinction coefficient of 0.0211. However, since cytochrome *c* is not permeable to the cells, the detection of $O_2^{\cdot-}$ is limited to that released into the extracellular milieu. An estimate of normal $O_2^{\cdot-}$ generated in 60 min can be obtained by reducing the number of PMN in the assay to 2×10^5 cells. PMN isolated from most patients with CGD fail to generate significant $O_2^{\cdot-}$ in response to PMA in 60 min. However,

some patients with autosomal forms of CGD have low but detectable $O_2^{-\cdot}$ production in 60 min. PMN isolated from X-linked heterozygous carriers of CGD can yield a full spectrum of $O_2^{-\cdot}$ production. Since the data represent the average $O_2^{-\cdot}$ generation of both functional and dysfunctional cells, a highly lyonized X-linked carrier with few DHR^+ or NBT^+ cells can exhibit less total $O_2^{-\cdot}$ generation than a CGD patient with some residual NOX2 activity. These data suggest that it is more immunologically advantageous to express a small population of PMN with normal NOX2 activity than the entire population of PMN with reduced NOX2 activity. Although the detection of $O_2^{-\cdot}$ by reduction of cytochrome *c* is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result from the degree of X-chromosome lyonization.

Recent studies have shown that $O_2^{-\cdot}$ determinations on PMN isolated from whole blood stored overnight are sufficiently reliable to diagnose CGD. By 48 h of storage, however, there are marked reductions in the PMA response and the data are no longer valid. Hence, analyses can be performed on blood samples shipped by overnight express. A normal control blood sample should accompany the sample to ensure proper shipment conditions and handling.

Reagents

HBSS/HEPES

Cytochrome *c* (200 μM)

26 mg cytochrome *c* (C7752, Sigma-Aldrich)
10 ml HBSS/HEPES

Dissolve 26 mg cytochrome *c* in 10 ml HBSS/HEPES.

Catalase (10 mg/ml)

SOD (10 mg/ml)

20 mg SOD (S2515, Sigma-Aldrich)
2.0 ml PBS without Ca^{2+} and Mg^{2+}

Dissolve 20 mg SOD in 2.0 ml PBS. Store at −85°C in 100-μl aliquots.

PMA (20 μg/ml)

Procedure

1. Add 200 μl catalase to 10 ml cytochrome *c* solution.
2. Resuspend PMN at 2×10^6 cells/ml in HBSS with Ca^{2+} and Mg^{2+}.
3. Label 6 × 1-ml polypropylene microtubes (#1 through 6) and prepare tubes as described in Table 1. It is important that PMN be added last.
4. After addition of PMN, immediately place tubes on an end-over-end rotator (12 rpm) in a 37°C incubator and incubate for either 10 min or 60 min (note: in a 60-min incubation, PMN from normal subjects, or carriers of CGD with DHR^+ PMN >20%, should be diluted 1:5 for tubes #4 through 6).
5. At the end of the incubation, immediately place tubes on ice and spin at 500 × *g* for 15 min at 4°C.
6. Transfer supernatants to cuvettes and read on spectrophotometer, using an analytical wavelength of 549.5 nm and background isosbestic (equivalent absorbance for both oxidized and reduced cytochrome *c*) wavelengths of 541 nm and 556 nm. The background wavelengths represent the intersections of the spectral scans of oxidized and reduced (determined after the addition of a few grains of dithionite) cytochrome c.
7. The net absorbance of each sample is determined using the following formula:

$$OD_{549.5\ nm} - \{[(OD_{556.0\ nm} - OD_{541.0\ nm}) \times (8.5/15)] + OD_{541.0\ nm}\}$$

8. The basal production of $O_2^{-\cdot}$ generated (nanomoles/10^6 cells) is calculated by subtracting the net absorbance of the SOD-containing sample (tube #3) from the mean of net absorbance of tubes #1 and 2 and dividing the difference by 0.0211, the micromolar extinction coefficient for reduced cytochrome *c*. Repeat the calculations for tubes #4 through 6. For 60-min samples with reduced cell numbers (20%), multiply by 5 to normalize to 10^6 cells.

TABLE 1 Experimental design for quantitative analysis of $O_2^{-\cdot}$ generation using superoxide dismutase-inhibitable ferricytochrome c reduction[a]

Conditions	Tube no.	Vol (μl)			
		Cytochrome *c*/ catalase soln	SOD	PMA	PMN
Resting	1,2	500	—	—	500
Resting-SOD	3	500	10	—	500
PMA	4,5	500	—	5	500
PMA-SOD	6	500	10	5	500

[a]SOD, superoxide dismutase; PMA, phorbol 12-myristate 13-acetate

Results and Normal Range

PMN isolated from normal subjects produce 0.41 ± 0.32 nmol/10^6 PMN/10 min and 2.15 ± 1.60 nmol/10^6 PMN/60 min under basal conditions. Treatment of normal PMN with PMA results in 43.53 ± 12.61 nmol/10^6 PMN/10 min and 235.38 ± 55.69 nmol/10^6 PMN/60 min.

Interpretation and Limitations

Since cytochrome *c* is not cell-permeant, the data obtained using this assay represent only a portion of the total ROS production, i.e., that $O_2^{-\cdot}$ released from the cell and detected in the extracellular milieu. In addition, $O_2^{-\cdot}$ generation using ferricytochrome *c* reduction reflects the average response of all the cells in the population. For example, a CGD patient with 100% of cells functioning at 10% cannot be distinguished from an X-linked CGD carrier with 10% of cells functioning at 100% capacity. Hence, detection of $O_2^{-\cdot}$ generation by ferricytochrome *c* reduction alone is insufficient to diagnose X-linked carriers, and it should be used in conjunction with the DHR or NBT assay.

The $O_2^{-\cdot}$ generated by PMN isolated from CGD patients ranges from 0.50 to as much as 60 nmol/10^6 cell/60 min. Although NOX2 function is impaired in all patients with CGD, there is variability (0.1 to 27% of normal) in residual ROS production by patient PMN. Analysis of this residual ROS production allowed discrimination of CGD into subgroups with different rates of mortality (11). The production of ROS has become an important tool to perform risk assessment in patients with CGD. Patients with the lowest ROS generation (<1% of normal generation) have lower predicted survival than patients with higher ROS generation (3 to 10% of normal).

ANALYSIS OF PMN ROS GENERATION BY LUMINOL-ENHANCED CHEMILUMINESCENCE

Principle

While the analysis of $O_2^{\cdot-}$ generation using ferricytochrome *c* reduction is a reasonable approach to quantitate extracellular ROS production, it does not provide an estimate of intracellular ROS production. An estimate of both intracellular and extracellular ROS production can be determined using ROS-mediated, luminol-enhanced chemiluminescence. It should be noted that the kinetics of PMA-induced chemiluminescence are different from the kinetics of PMA-induced $O_2^{\cdot-}$ generation using ferricytochrome *c* reduction.

Reagents

HBSS/HEPES

Luminol (50 mM)

35.44 mg luminol (A8511, Sigma-Aldrich)

4.0 ml DMSO

Add 35.4 mg luminol to 4.0 ml DMSO. Store at −85°C in 50-μl aliquots wrapped with foil to protect from light. On the day of analysis, prepare a working solution of 400 μM.

PMA (400 ng/ml)

Prepare a 400 ng/ml working concentration of PMA by adding 20 μl PMA (20 μg/ml) to 980 μl HBSS/HEPES buffer.

Procedure

1. Isolate PMN from whole blood as described previously. Resuspend PMN in HBSS/HEPES at 1×10^6 cells/ml.
2. Transfer 10^5 PMN/100 μl in triplicate for each condition to a 96-well, white analysis microplate (655207; Greiner Bio-One, Monroe, NC).
3. Add 50 μl luminol to each well of the microplate containing PMN. Incubate for 10 min at 37°C.
4. Transfer 50 μl buffer or PMA to the proscribed wells of the analysis microplate using an 8-channel pipettor. Immediately place the plate into a luminometer, thermally regulated at 37°C.
5. Measure the luminescence of each well every 2 min for up to 120 min, shaking the plate at medium speed prior to each reading.

Results and Normal Range

Luminol-enhanced chemiluminescence is a measure of both intracellular and extracellular ROS production, specifically $O_2^{\cdot-}$ production. Addition of SOD causes significant reduction in both the peak height and area under the curve after stimulation with PMA, whereas addition of catalase has much less impact. The luminescence signal is in photons/second and is expressed as relative light units (RLU). The kinetics of the response varies with the activator used. Stimulation of PMN from a normal subject leads to a rapid peak of luminescence with a prolonged decay that persists for almost 2 h (Fig. 3). PMN from a patient with gp91^{phox} CGD exhibits little detectable luminescence. PMN from an gp91^{phox} X-linked carrier CGD exhibits an intermediate signal that is consistent with the percentage of DHR$^+$ cells within the population. PMN from a patient with p47^{phox} CGD, as observed with other assays of ROS production, exhibit low but detectable luminescence, particularly at longer incubation times. Comparing the responses from different subjects is typically performed by comparing the area under the curves.

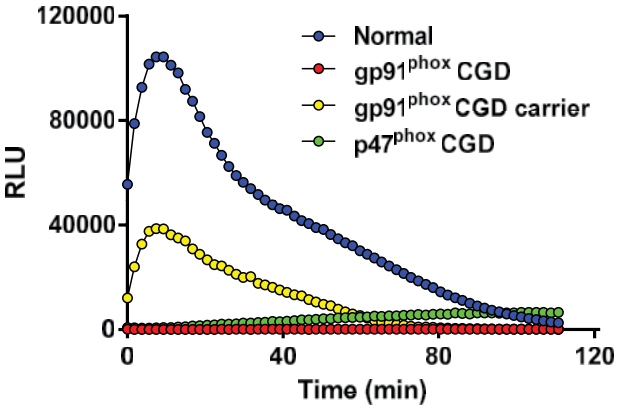

FIGURE 3 Analysis of PMN ROS generation by luminol-enhanced chemiluminescence. PMN (1×10^5 cells/200 μl HBSS/HEPES with 100 μM luminol) were incubated for 120 min in the presence of PMA (100 ng/ml). Luminescence of each well was determined every 2 min. The data from each subject were performed in triplicate. Blue circles represent the mean response of normal subjects ($n = 20$); yellow circles, an X-linked carrier of gp91^{phox} CGD; green circles, a patient with p47^{phox} CGD; red circles, a patient with gp91^{phox} CGD.

The primary advantage of the luminol-enhanced chemiluminescence is the increased sensitivity with reduced cell numbers. In addition, PMN from several different subjects can be stimulated with several different stimuli on the same plate.

Interpretation and Limitations

Similar to detection of $O_2^{\cdot-}$ generation by ferricytochrome *c* reduction, luminol-enhanced chemiluminescence reflects the average response of all the cells in the population; alone is insufficient to diagnose X-linked carriers; and should be used in conjunction with the DHR or NBT assay. In addition, luminol-enhanced chemiluminescence is not directly quantifiable. Instead, comparison of responses of cells from normal subjects and patients is usually based on a comparison of the area under the curves for each subject.

ANALYSIS OF gp91^{phox} SURFACE EXPRESSION BY FLOW CYTOMETRY

Principle

The NADPH oxidase is a multicomponent enzyme that transfers electrons from NADPH to O_2 to generate superoxide anion radical ($O_2^{\cdot-}$), a key part of the phagocytic or PMN respiratory burst response. Flavocytochrome b_{558} is the catalytic component of the phagocyte NADPH oxidase and consists of a transmembrane heterodimer composed of a large glycoprotein, gp91^{phox}, and a smaller protein, p22^{phox}. The expression of flavocytochrome b_{558} on the cell surface antigens can be determined by flow cytometric analysis of PMN stained with fluorescently labeled monoclonal antibody 7D5, which recognizes a specific extracellular epitope (12, 13). PMN stained with nonspecific isotype antibodies are used to determine the nonspecific background staining. To determine the expression of circulating PMN and avoid artifacts induced by PMN isolation, an aliquot of whole

blood can be stained with the appropriate antibody prior to lysis of the erythrocytes. During flow cytometric analysis, the PMN are generally easy to identify using FS × SS gating.

Reagents

Fluorescein Isothiocyanate (FITC)-Labeled Anti-Flavocytochrome *b*558 Monoclonal Antibody 7D5 (500 μg/ml, D162-4; MBL International Corporation, Woburn, MA)

Mouse IgG_1 FITC Isotype Control (50 μg/ml, 349041, BD Biosciences)

OptiLyse C, No-Wash Lysing Solution (A11895, Beckman Coulter, Indianapolis, IN)

PBS with 2% BSA

2 g BSA (A-9543, Sigma-Aldrich)

PBS

Dissolve 2 g BSA in 100 ml PBS. Mix well and sterilize through a 0.2-μm filter.

Procedure

1. Label 12 × 75 mm polypropylene tubes with the designations "IgG_1" or "7D5" and add either 20 μl IgG_1 isotype or 4 μl monoclonal antibody 7D5 to designated tubes.
2. Add 100 μl whole blood to each tube and vortex.
3. Cover samples with foil and incubate at 4°C for 30 min.
4. Add 500 μl Optilyse C to each tube and vortex immediately. Cover tubes with foil and incubate at 4°C for 30 min.
5. Add 2.0 ml PBS with 2% BSA to each tube.
6. Spin tubes at 400 × *g* for 5 min, decant and repeat wash.

Resuspend PMN in 0.2 ml of PBS with 2% BSA and analyze by flow cytometry.

Results and Normal Range

The expression of Ab 7D5 on PMN from normal subjects is typically 830 ± 442 compared to the IgG_1 isotype (95.1 ± 25.4). Activation of isolated PMN with formyl-methionyl-leucyl phenylalanine (fMLF) or LPS can lead to mobilization of latent $gp91^{phox}$ stored in specific granules.

Interpretation and Limitation

PMN from CGD patients with either defects in $p22^{phox}$ or $gp91^{phox}$ generally exhibit abnormal expression of Ab 7D5. However, often patients with missense mutations in $gp91^{phox}$ in the nucleotide-binding domains can exhibit normal expression of $gp91^{phox}$.

IMMUNOBLOT ANALYSIS OF phox SUBUNITS OF NOX2

Principle

NOX2 consists of two membrane components, $p22^{phox}$ and $gp91^{phox}$; three cytosolic components, $p47^{phox}$, $p67^{phox}$, and $p40^{phox}$; and several GTP-binding proteins. The severity of CGD may be related to the specific protein defect. Determination of the specific protein defect in CGD by immunoblot analysis also provides direction for determination of the specific genetic defect as well as enabling appropriate genetic counseling for the extended family. A validated normal control is included on each gel for band identification and intensity comparisons. A typical phox protein immunoblot of a PMN lysate from a normal subject is presented in Fig. 4, lane 1. Patients with mutations in $gp91^{phox}$ can exhibit different protein expression. Some CGD patients with missense mutations in $gp91^{phox}$ can express detectable mutant protein (Fig. 4, lanes 2 and 3). Because $p22^{phox}$ and $gp91^{phox}$ exist as a membrane complex, increased $gp91^{phox}$ protein expression is accompanied by a proportionately higher expression of $p22^{phox}$. CGD patients with nonsense mutations in $gp91^{phox}$ exhibit undetectable expression of $gp91^{phox}$; however, there is low but detectable expression of $p22^{phox}$ (Fig. 4, lane 4). In our laboratory, we typically include a PMN lysate from known $gp91^{phox}$ CGD on each blot to ensure adequate development of $p22^{phox}$. CGD patients with mutations in $p22^{phox}$ are immunoblot-negative for both $p22^{phox}$ and $gp91^{phox}$ (Fig. 4, lane 5). CGD patients with mutations in $p47^{phox}$ CGD exhibit no detectable protein expression (Fig. 4, lane 6). Similarly, CGD patients with mutations in $p67^{phox}$ CGD generally exhibit undetectable protein expression (Fig. 4, lane 7); however, we have analyzed one patient with a missense mutation in $p67^{phox}$ who exhibits detectable protein expression.

PMN isolated from overnight samples can be used to diagnose $p47^{phox}$ deficiency because of the stability of the protein. However, detection of defects in other phox protein in overnight samples can be more problematic because of proteolysis of $p67^{phox}$ and the $gp91^{phox}$:$p22^{phox}$ complex.

Reagents

3-(*N*-Morpholino)propanesulfonic acid (MOPS)–sodium dodecyl sulfate (SDS) running buffer (2.0 liters, 1×)

100 ml NuPAGE MOPS-SDS running buffer (20X, NP0001; Novex Life Technologies)

1,900 ml distilled H_2O

Add 100 ml 20× running buffer to 1,900 ml H_2O.

Antioxidant Solution (NP0005, Novex Life Technologies)

Protease-Inhibitor Solution (10×)

1 Complete Mini Protease-Inhibitor tablet (68196820; Boehringer Mannheim, Gaithersburg, MD)

1 ml distilled H_2O

Dissolve one Complete Mini Protease-Inhibitor tablet in 1 ml H_2O.

Sample Buffer (1×)

250 μl 4× sample buffer (NP0003, Novex Life Technologies)

100 μl 10× protease inhibitor solution

650 μl distilled H_2O

Add 250 μl 4× sample buffer and 100 μl 10× protease inhibitor solution to 650 μl dH_2O.

Reducing Agent (NP0004, Novex Life Technologies)

SeeBlue Plus2 Prestained Standards (LC5625, Novex Life Technologies)

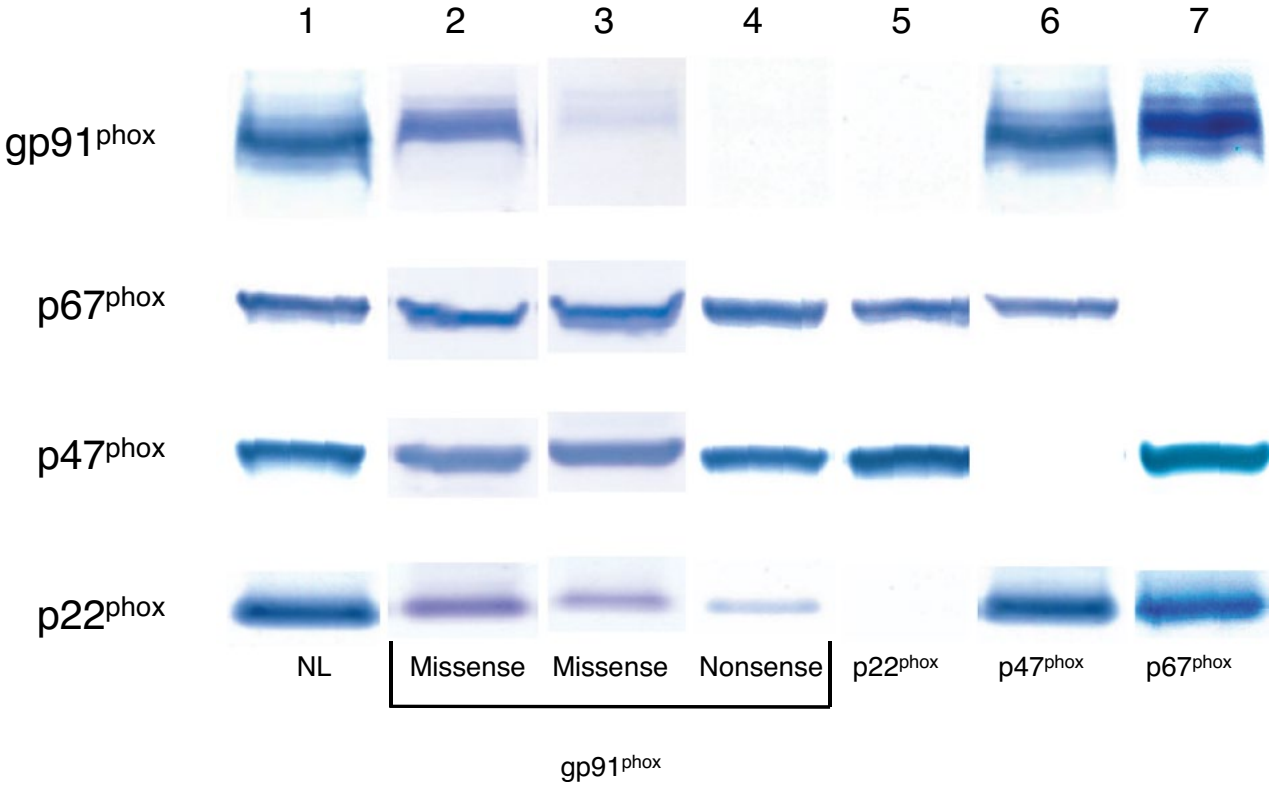

FIGURE 4 Immunoblot analysis of phox subunits of NOX2. DFP-treated PMN (5×10^6 cells) were sonicated in 100 μl of sample buffer. For each subject, an aliquot (20 μl or 1×10^6 cell equivalents) of PMN lysate was loaded into a well of the precast BisTris SDS-PAGE gel. In this composite figure, the bands corresponding to each phox subunit from each subject have been aligned. Lane 1 represents PMN from a normal subject and defines the position and the expression of each phox subunit. Lanes 2 and 3 represent CGD patients with missense mutations in $gp91^{phox}$ and illustrate the proportional expression observed with $gp91^{phox}$ and $p22^{phox}$. Lane 4 represents a CGD patient with a nonsense mutation in $gp91^{phox}$ with undetectable expression of $gp91^{phox}$ but faint expression of $p22^{phox}$. Lane 5 represents a CGD patient with $p22^{phox}$ deficiency with undetectable expression of both $p22^{phox}$ and $gp91^{phox}$. Lane 6 represents a CGD patient with undetectable $p47^{phox}$. Lane 7 represents a CGD patient with undetectable expression of $p67^{phox}$.

NuPAGE Novex Bis-Tris Gels

NuPAGE Novex 10% Bis-Tris Gel 1.0 mm, 10 well (NP0301, Novex Life Technologies) for detection of $p47^{phox}$ and $p67^{phox}$ and NuPAGE Novex 4 to 12% Bis-Tris Gel 1.0 mm, 10 well (NP0321, Novex Life Technologies) for detection of $p22^{phox}$ and $gp91^{phox}$.

Tris-Buffered Saline (TBS)

80 ml 1.0 M Tris, pH 7.4 (16-014F, Lonza)
116.8 g NaCl (S9625, Sigma-Aldrich)
3,920 ml H_2O

Add 80 ml 1.0 M Tris and 116.8 g NaCl to 3.920 ml H_2O.

TBS/0.5% Tween

1.0 liter TBS
5 ml Tween 20 (P1379, Sigma-Aldrich)

Add 5 ml Tween 20 to 1.0 liter TBS.

Transfer Buffer (3.0 liters, 1×)

150 ml NuPAGE Transfer buffer (20×, NP0006, Novex Life Technologies)
3.0 ml antioxidant solution (NP0005, Novex Life Technologies)
300 ml methanol
2,547 ml distilled H_2O

Add 150 ml 20× transfer buffer, 3.0 ml antioxidant solution, and 300 ml methanol to 2,547 ml H_2O.

Immobilon-P Transfer Membrane (IPVH 00010; EMD Millipore, Billerica, MA)

Sodium Azide (1.0 M)

0.65 g sodium azide
10 ml H_2O

Add 0.65 g sodium azide to 10 ml of H_2O.

Membrane-Blocking Solution

10 g nonfat dry milk
100 μl Tween 20
200 ml TBS
200 μl 1.0 M sodium azide

Add 10 g dry milk and 100 μl Tween 20 to 200 ml TBS. Add 200 μl 1.0 M sodium azide as a preservative.

Primary Goat Antibodies against $p22^{phox}$, $p47^{phox}$, $p67^{phox}$, and $gp91^{phox}$
Obtained from Harry Malech and Tom Leto (National Institute of Allergy and Infectious Diseases, National Institutes of Health).

50 μl antibody
50 μl 1.0 M sodium azide
2.5 g nonfat dry milk
25 μl Tween 20
50 ml TBS

Add 50 μl of the desired antibody to solution containing 50 ml TBS with 2.5 g nonfat milk and 25 μl Tween 20. Add 50 μl 1.0 M sodium azide as a preservative (shelf life: 6 months).

Goat IgG, Whole Molecule, Peroxidase-Labeled (A5420, Sigma-Aldrich)
20.0 μl peroxidase anti-goat IgG
10 g nonfat milk
100 μl Tween 20
200 ml TBS

Dilute peroxidase-labeled anti-goat IgG antibody (1:10,000) by adding 20.0 μl anti-goat IgG to a solution containing 200 ml TBS, 10 g nonfat milk, and 100 μl Tween 20.

TMB One Component Horseradish Peroxidase (HRP) Membrane Substrate (TMBM-0100-01; SurModics IVD, Eden Prairie, MN)
Warm to room temperature before use.

Procedure

1. Add 90 μl 1× sample buffer and 10 μl reducing agent to DFP-treated PMN pellet (5×10^6 cells/pellet). Sonicate the PMN pellet for 80 short (<1-s) pulses at low setting to prevent sample loss. Cool on ice and repeat sonication for an additional 80 pulses.
2. Spin at 10,600 × *g* for 5 min.
3. Repeat sonication for 40 pulses at low setting, if necessary.
4. Place gel in electrophoresis apparatus according to manufacturer's instruction.
5. Fill the upper chamber with 1× running buffer (600 ml) + antioxidant (1.5 ml) and check for leakage. Fill the lower chamber with ~350 ml of buffer (without antioxidant). Add sufficient buffer until each chamber is full.
6. Load 10 μl of the SeeBlue Plus2 prestained molecular weight standards in lane 1 of each gel—two 10% gels for detection of $p47^{phox}$ and $p67^{phox}$ and two 4–12% gels for detection of $p22^{phox}$ and $gp91^{phox}$.
7. Load 20 μl of a normal PMN lysate in lane 2 and load 20 μl of PMN lysate from each patient in lanes 3 through 10 of all four gels.
8. Run the gels at 4°C using constant voltage (125 V) until the dye front reaches the bottom of the gel.
9. Turn off the power supply and disconnect the gel apparatus from the power supply.
10. Remove the precast gel(s) from the gel chamber and remove the gels from the cassette according to the manufacturer's instruction.
11. Transfer the gels to the Immobilon-P membrane according to the instructions supplied with blotting apparatus.

    To ensure adequate protein transfer to the membrane, check the gels for residual prestained standards. Using a pen, mark the membrane at the leading edge of each of the prestained molecular weight standards.
12. Place the membrane in the membrane-blocking solution and incubate for at least 6 h at 4°C with gentle rocking.
13. Remove the membrane from the blocking solution and wash the membrane 3× for 5 min with TBS/0.5% Tween 20.
14. Add the appropriate primary antibody solution to blot and incubate overnight at 4°C with gentle rocking.
15. Remove the membrane from the primary antibody solutions, reserving the primary antibody.
16. Wash the membrane 3× for 5 min with TBS/0.5% Tween 20.
17. Add the secondary antibody solution to the membrane and incubate with gentle rocking for 2 h at room temperature.
18. Wash the membrane 3× for 5 min with TBS/0.5% Tween 20.
19. Add the membrane peroxidase substrate to the membrane.
20. Carefully monitor development of the membrane to ensure adequate staining, particularly for detection of $p22^{phox}$. A faint $p22^{phox}$ band is generally observed in patients with $gp91^{phox}$ -deficient CGD.
21. To stop the development, quickly wash the membrane twice with distilled H_2O.

Results and Normal Range

For each immunoblot analysis, a PMN lysate from at least one normal subject should be included on each gel for comparison. The expression of each phox protein can be determined by densitometric scanning. Alternatively, the expression of each protein can be assigned a value based on a semiquantitative scale, comparing the expression of each protein to the expression observed in a normal subject, e.g., "0," lack or absence of expression; "1," trace expression; "2," intermediate expression; and "3," normal expression. The primary goal of the immunoblot analysis is the identification of the protein defect in patients with CGD, targeting the gene for sequence analysis.

Interpretation and Limitations

The membrane components $gp91^{phox}$ and $p22^{phox}$ are expressed as a complex. Absence of $gp91^{phox}$ results in faint expression of $p22^{phox}$. However, absence of $p22^{phox}$ results in absence of bands for both $p22^{phox}$ and $gp91^{phox}$. Missense mutations in $gp91^{phox}$ often result in decreased expression of $gp91^{phox}$ as well as a parallel decrease in expression of $p22^{phox}$. Reduced or absent expression of $p47^{phox}$ or $p67^{phox}$ has little or no impact on the expression of the other phox proteins.

CONCLUSION

Although the DHR assay is probably the single most used assay for diagnosis of CGD, other assays used can complement the findings of the DHR. Since there are conditions which can give a false-negative DHR response (as in myeloperoxidase deficiency), the $O_2^{\cdot-}$ dependent ferricytochrome *c* reduction assay can confirm the DHR finding. Similarly, X-linked carriers of CGD can exhibit a very low value in the $O_2^{\cdot-}$ dependent ferricytochrome *c* reduction assay. However, the DHR may indicate that the patient has very few DHR^+ cells. Hence, a final diagnosis of CGD or carrier of CGD

should not be based on a single assay, but rather it should be based on several assays with results that agree among them.

Cytokines and Chemokines

section F

VOLUME EDITOR: BARBARA DETRICK
SECTION EDITOR: JOHN J. HOOKS

Introduction

JOHN J. HOOKS

34

Nearly 60 years ago, the first cytokine was described. Today, >300 cytokines, chemokines, and adhesion molecules have been identified. We have witnessed an explosion in knowledge about cytokine biology. This can be highlighted by reviewing the interferon (IFN) molecules as an example. IFN was first identified in 1957 as a potent antiviral molecule. We now know that there are four major types of IFNs (alpha, beta, gamma, and lambda). Although IFN was first identified as an antiviral protein, IFNs are now recognized as critical immunoregulatory proteins capable of altering various cellular processes, including cell growth, differentiation, gene transcription, and translation. The advent of innate immunity and Toll-like receptors revealed the intimate role of IFNs in innate immune responses. The presence of IFN-α is a critical component of the autoimmune disease systemic lupus erythematosus. Advances in biotechnology and molecular biology have generated highly specific reagents with clinical relevance. In fact, the IFNs have been approved by the Food and Drug Administration for the treatment of infections, malignancies, autoimmunity, and immunodeficiency. IFN-α treatment is efficacious for hepatitis C infection, IFN-β for multiple sclerosis, and IFN-γ for chronic granulomatous disease. The examples outlined for the IFNs can be replayed throughout the cytokine kingdom.

The key element throughout this section is the measurement of cytokines. We need to know what to measure, how to measure, and the utility of this measurement. The five chapters in this section provide us with this knowledge and much more.

Chapter 35, by Duffy and Remick, provides a critical review of reasons and ways to measure cytokines. They identify ways to monitor the proteins, beginning with the standard enzyme-linked immunosorbent assay, and then present insight into multiplex assays. It is of interest to note that they include a cost comparison of these assay systems. Molecular methods to measure cytokine mRNA are then presented, with an analysis of *in situ* hybridization and PCR assays. The authors keenly note that cytokines are critical from birth (gestation) to death (apoptosis).

Chapter 36, written by Maecker, expands on cytokine measurement with a focus on flow cytometry. This assay method allows for the measurement of these proteins on a single-cell basis. In fact, multiparameter flow cytometry provides the investigator with a detailed characterization of the cytokine-producing cells.

The next chapter, prepared by Islam, Medoff, and Luster, is a detailed description of the chemokine and chemokine receptor system. This critical topic highlights the concept that the movement of leukocytes toward a site of antigen challenge, infection, or tissue damage is a central component in establishing inflammation. These chemokine experts offer an overview of basic principles of chemokines and chemokine receptors and their role in several disease states. Finally, they identify ways to measure chemokines and the clinical applications for this analysis.

The final two chapters are new additions for the section in the 8th edition of the *Manual* that deliver insight into advances in cytokine biology. Vashisht and Niewold provide us with a concise description of the newer diagnostic and clinical applications of cytokines. They stress the concept that cytokine measurements are helpful in the diagnosis and prognosis of autoimmune diseases and discuss how cytokine patterns provide insights into the causes of diseases. In particular, they highlight the role of IFN-α in systemic lupus erythematosus and interleukin-1 in juvenile idiopathic arthritis. They also discuss the key concept of cytokine inhibitors and recombinant cytokines in the treatment of human disease.

Chapter 39, by Browne, identifies the key role of anticytokine autoantibodies in human diseases. This is a rapidly expanding field of study that cuts across several medical disciplines. The reason for this diversity lies in the various cytokine pathways inhibited and the resulting diverse manifestations of disease. Browne highlights examples, such as antierythropoietin autoantibodies and pure red cell aplasia, anti-IFN-γ autoantibodies and severe opportunistic infection, and anti-granulocyte-macrophage colony-stimulating factor autoantibodies and pulmonary alveolar proteinosis. The author characterizes methods of measurement and notes that diagnosis can directly influence clinical management because therapy can focus on the autoantibody.

The primary function of this section is to identify ways to monitor cytokines and chemokines in a laboratory setting. Beyond this mission, the authors of this section have also provided us with a greater understanding of the role of cytokines, chemokines, and their receptors in human diseases. Moreover, they provide insight into how this knowledge can lead to the development of novel therapeutic approaches to combat these diseases.

Multiplex Cytokine Assays

ELIZABETH R. DUFFY AND DANIEL G. REMICK

35

Cytokines are low-molecular-weight proteins representing important components of inflammatory and immune reactions (1). In response to multiple stimuli (2), cytokines are rapidly induced and secreted into the extracellular milieu. However, in some situations, cytokines are constitutively present. Cytokines exert numerous biological activities which are critical for host defense, physiologic responses to stress, and immune surveillance. Cytokines, along with complement, are considered to be part of the innate immune system. The world of cytokine biology has exploded in the past decades. It can be said without hyperbole that cytokines are critical from birth (gestation) (3) to death (apoptosis) (4).

Given the wide range of activities induced by cytokines, there is great interest in accurate measurement of these critical mediators. It is important to know if the cytokines are present during a particular disease process since they may potentially serve as a target for therapy (5). Conversely, there may be value in documenting that cytokines are depressed during a disease state such that the appropriate therapy is administration of exogenous cytokines, e.g., granulocyte colony-stimulating factor. Clear evidence of the interest in measuring cytokines is demonstrated by the numerous companies which prepare and market kits for quantifying levels of cytokines.

Since there are numerous cytokines, a final biological outcome may not be dependent upon a single cytokine. Indeed, it has been reported that the ratio of cytokines to cytokine inhibitors provides the best predictor for progression of disease (6, 7). The best insights into the disease state will probably be achieved when multiple parameters are analyzed and assessed. As in making a clinical diagnosis, as much information as possible is needed in order to arrive at the correct determination for the precise disease process.

As a result of these issues, multiplex cytokine assays have been developed which will allow measurement of several cytokines simultaneously. While some of these assays were described several years ago, they have mushroomed in the commercial sector. As will be discussed further below, flow cytometric bead array assays are now marketed by numerous vendors. The technology has developed to the point that papers are now being written which directly compare the different kits from different vendors (8, 9).

While this chapter will examine measurement of cytokines, it should be borne in mind that the technology is not limited to measuring only these inflammatory mediators. Indeed, virtually any molecule that exhibits a specific interaction with another molecule may be measured by either a traditional enzyme-linked immunosorbent assay (ELISA) or a multiplex assay. Whether the interaction is a ligand-receptor interaction, a nucleic acid-protein interaction (10), or the traditional antibody-antigen interaction, the multiplex technology may be adapted to allow measurement (11). The principal consideration is the specificity of the interaction, such that the results are specific for measuring the analyte in question.

This chapter will explore both traditional ELISAs and the newer multiplexed assays. The methods, technology, instrumentation, and data analysis will be examined. Pitfalls that may arise with the assay will be explored to provide a better understanding of the limitations of the technique in question. We will also briefly describe the principles of nucleic acid detection by *in situ* hybridization and PCR.

TRADITIONAL ELISA

The traditional ELISA serves as an appropriate starting point. This is done because most of the newer assays are still based on the same antibody-antigen interaction that is most easily understood through examination of a single ELISA for a single cytokine. Virtually all ELISAs are based on the concept that a specific antibody will recognize a specific antigen. This concept dates back to the pioneering work of Yalow and Berson, who discovered that an antibody could recognize insulin (12). This single finding revolutionized the process for the detection and quantification of specific analytes.

Most commercially available ELISAs are based on a sandwich, or two-antibody, technique. A simpler method is the direct ELISA. For this assay, the antigen is bound directly to the surface of the microtiter well in the plate (Fig. 1). An antibody which specifically detects the cytokine in question is then added. For purposes of illustration, the cytokine interleukin 6 (IL-6) will be used in the schematic figures. There are multiple methods for detecting the antibody bound to the antigen. The antibody may be directly conjugated to an enzyme such as horseradish peroxidase, and the enzymatic reaction will occur within the well of the microtiter plate, as illustrated in Fig. 1. Alternatively, the antibody may be detected by a second antibody.

doi:10.1128/9781555818722.ch35

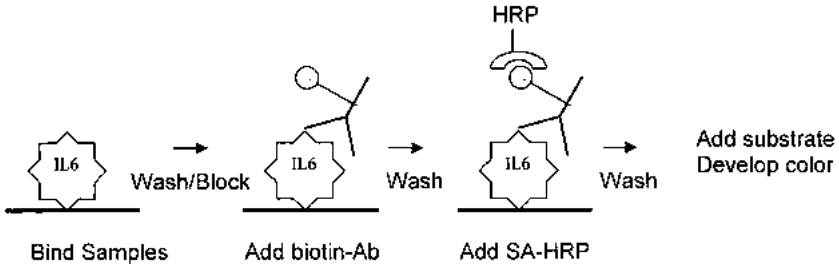

FIGURE 1 Direct ELISA. In the direct ELISA, the analyte is first bound to the bottom of the microtiter well. In this example, the analyte is IL-6. Unbound IL-6 is washed away, and excess protein binding sites are blocked in order to reduce background. In the next step, biotin-labeled antibody directed against IL-6 is added; the small circle represents the biotin moiety directly attached to the antibody. After washing, streptavidin (SA) conjugated to horseradish peroxidase (HRP) is added and a final wash is performed. Following addition of a colorimetric substrate, the color develops. The intensity of the color development is directly proportional to the amount of IL-6 in the first step.

For example, the first antibody may be a mouse monoclonal antibody which recognizes human IL-6. The second antibody may then be a goat anti-mouse antibody which has been labeled with horseradish peroxidase. An alternative method for detecting the primary antibody is to attach a biotin moiety to the antibody. Streptavidin conjugated to horseradish peroxidase is applied next, since the streptavidin will bind to the biotinylated antibody bound to IL-6. For all of these assays, the enzyme conjugated to the detection moiety produces the color. The process follows a fairly simple equation in which more antigen present results in more antibody binding, which results in greater concentrations of the enzyme, which results in stronger color development.

A slight modification is used for the sandwich ELISA. First, an antibody is bound to the surface of the microtiter well (Fig. 2). This antibody has specificity for the cytokine which will be detected, in this case IL-6. The sample is then applied to the well, and the IL-6 binds to the antibody. During washing, all the proteins which are not IL-6 should be washed away. The only entity remaining in the well should be the IL-6 bound to the antibody. Subsequent development steps are similar to those for the direct ELISA described above. Typically, the sandwich ELISA is more sensitive than the direct ELISA.

There are several critical elements in developing a sensitive and specific ELISA. These same critical elements apply to multiplexing assays, but again the concepts are more easily understood when a single cytokine is considered. First and foremost, the primary factor driving the sensitivity and specificity is the quality of the antibodies (13, 14). There is simply no substitute for having high-quality antibodies for the assay. As a specific example, antibodies are available which detect the precursor form of IL-1β but not the mature, processed form (15, 16). This may result in gross underestimation of the total amount of IL-1β present in cell lysates, because the antibodies selected for detection may not be appropriate. In many situations, the antibodies have already been matched for the development of a sandwich ELISA. With a few simple techniques, it is possible to buy these antibodies and establish ELISAs for the detection of cytokines (17). In this regard, the commercial vendors are excellent sources of good-quality reagents.

Another important aspect is the selection of the proper blocking reagent. Blocking reagents are added to the wells to prevent nonspecific binding. After the antigen (direct ELISA, Fig. 1) or the antibody (sandwich ELISA, Fig. 2) has been applied to the plate, it is important that nonspecific binding sites on the plate are blocked. Frequently, it is

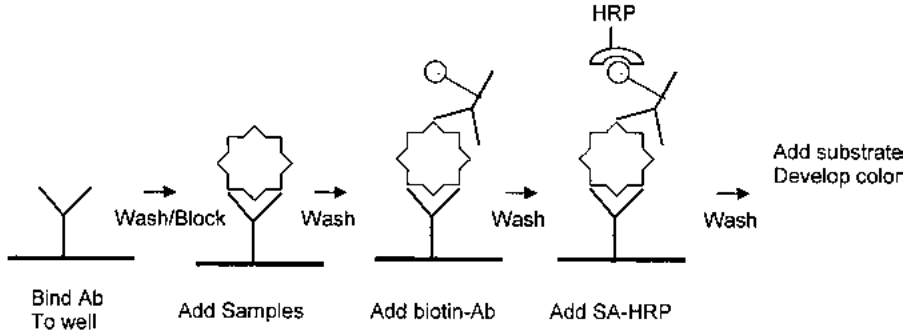

FIGURE 2 Indirect or sandwich ELISA. This ELISA shares many features with the assay described in the legend to Fig. 1. The major difference is in the first step, in which an antibody (Ab) directed against the analyte is bound to the bottom of the microtiter well. This antibody is termed the capture or coating antibody. Following addition of the analyte, the biotin-labeled detection antibody (biotin-Ab) is applied, followed by horseradish peroxidase (HRP)-conjugated streptavidin (SA-HRP). Color development proceeds, and the intensity of the color is directly related to the amount of the analyte. This is termed a sandwich ELISA because the analyte is sandwiched between two antibodies.

not possible to predict the optimal blocking reagent, and testing needs to be done in order to determine which reagent will work the best. The "matrix" of the sample may also affect the best blocking reagent. For example, in tissue culture supernatants, the protein content is extremely low compared to that in organ homogenates or plasma. A blocking reagent such as bovine serum albumin which works quite well for tissue culture supernatants may be suboptimal for measuring cytokines in human plasma. Testing different blocking reagents, which are available from the commercial vendors, will generally produce a low background.

Different enzymes may be conjugated to the detection moiety, whether it is an antibody or streptavidin. Horseradish peroxidase is the most commonly used enzyme, but alkaline phosphatase may also be used.

A number of substrates may be used in the assay; the substrate will depend upon the enzyme used for detection. The color development reagents are available from a number of commercial vendors, and they may be purchased already prepared. It is also possible to buy the individual reagents necessary for the substrate preparation and assemble one's own color detection components. This results in significant cost savings compared to purchasing already prepared material and usually results in similar sensitivity and specificity (17). Several authors have reported that the use of chemiluminescent reagents results in greater sensitivity (18–21). However, if careful attention to detail is used in the development of a colorimetric ELISA, better sensitivity than the chemiluminescent assay can be achieved, as well as significant cost savings (22).

Once the assay has been completed, it is necessary to calculate the results. Typically, the readout from an ELISA reader is the absorbance measured at a specific wavelength. If a fluorescent or chemiluminescent detection reagent has been used, then relative light units are the output. Regardless of the output, the actual concentrations of the cytokine in the sample are determined by comparison to a standard curve. There are several commercial software programs available which will perform these calculations. These programs may come bundled with the plate reader, or one may purchase separate, stand-alone software. Examples of data analysis are presented later in this chapter.

This has been a brief overview of the traditional ELISA, an assay that is run in hundreds of labs thousands of times every week. This assay is robust and relatively straightforward and has exquisite sensitivity and specificity. Given the tremendous utility of measuring a single cytokine, a natural extension is to measure multiple cytokines. Each of the steps in a traditional ELISA have been detailed (23).

SEQUENTIAL ELISA

The sequential ELISA is an easy method for measuring multiple cytokines in a single sample. In most biological samples, multiple cytokines are present simultaneously. The antibody directed against the cytokine which is present on the plate should react only with its specific cytokine. When the sample containing multiple cytokines is added to the microtiter well, only the cytokine recognized by the antibody will remain bound on the plate (Fig. 3). Therefore, when the sample is removed, all of the other cytokines will be taken away and will be available for detection by another ELISA. Thus, it is possible to measure the cytokines in sequence, which allows use of the sample to detect multiple cytokines. A basic description of this technique has been published previously (24). Others have also reported on the ability of sequential ELISAs to detect several cytokines simultaneously (25, 26).

The sequential ELISA still has several pitfalls. First, the sample volume necessary is still greater than that used in most multiplex assays. Second, the amount of time required to measure each one of the cytokines is not reduced in the sequential ELISA, so there is no cost savings with regards to time. Third, if there is potential cross-reactivity of the antibodies, then measurement of the first cytokine will result in an overestimate of the amount of that cytokine present, and measurement of the next cytokine in the sequence will result in an underestimate of the amount of that cytokine

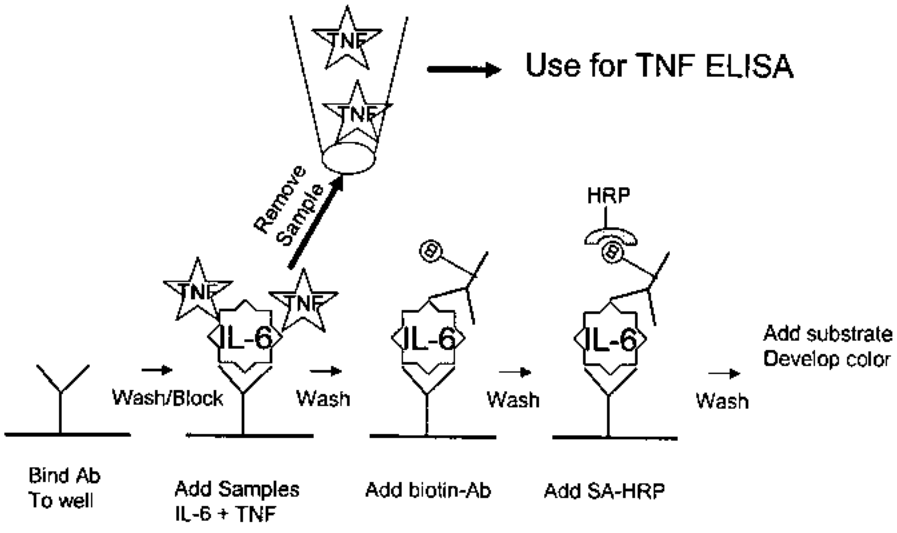

FIGURE 3 Sequential ELISA. A sample containing a mixture of cytokines is applied to an IL-6 ELISA. IL-6 binds to the anti-IL-6 antibody attached to the bottom of the well. When the sample is removed, cytokines which are not IL-6, such as tumor necrosis factor (TNF), may be used in a subsequent ELISA. Ab, antibody; B, biotin moiety; biotin-Ab, biotin-labeled antibody; HRP, horseradish peroxidase; SA-HRP, horseradish peroxidase-conjugated streptavidin.

present. Despite these caveats, the sequential ELISA is a method that is available to anyone presently running traditional ELISAs.

MICROARRAYS

Glass Slides

Glass slides have been used extensively for gene chip analysis. For traditional gene chips, portions of nucleic acid are spotted onto the slide. Each bit of nucleic acid codes for a specific gene (27), similar to what is described in the section on *in situ* hybridization. A similar format is used for the protein microarrays; however, instead of placing nucleic acid sequences onto slides and performing DNA hybridization, a compound which will interact with a specific protein is placed onto the slide. Typically, this means that an antibody directed against cytokines is placed on the individual slide.

The antibodies used for the protein microarrays are usually those which have already been demonstrated to be effectively employed in an ELISA format. These antibodies usually have been screened to determine that they have appropriate sensitivity. Additionally, when the antibodies are purchased from commercial vendors, they have frequently been tested against multiple different cytokines to ensure appropriate specificity. A careful examination of the antibody description supplied by the company will allow one to determine if cross-reactivity may represent a potential problem.

For protein microarrays, the capture antibody is placed onto the slide. The surface of the glass slide may be altered to enhance the binding of the antibody. Alternatively, a matrix may be applied to the surface to enhance the antibody binding. A number of different coatings are available for this purpose, although one of the simpler solutions is to affix nitrocellulose membranes to the surface of the slide. Nitrocellulose has a high protein binding affinity and will avidly capture the antibody (28). However, appropriate blocking reagents must be used in order to prevent a high background resulting from nonspecific binding of other proteins. Several different blocking reagents are available, but there is frequently a trade-off with these reagents. The trade-off arises because although one blocking reagent may be optimal for one antibody pair, a different blocking reagent is optimal for another antibody pair. In other words, the best blocking reagent for detecting tumor necrosis factor may be bovine

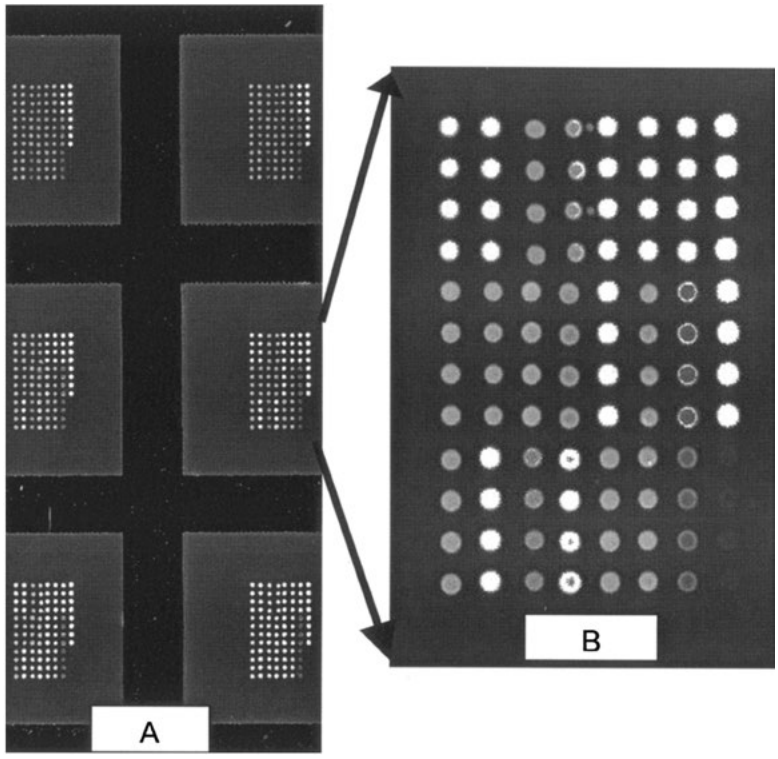

FIGURE 4 Example of a microarray. Panel A shows six individual nitrocellulose pads arranged on a glass slide. Each pad has been spotted in an 8-by-12 format. The black area between the pads is the place where a silicon gasket was adhered to the surface to allow each of the wells to function individually, similar to the way in which an individual well in a 96-well plate is independent from its neighbors. The antibodies have been spotted in an identical manner onto each of the nitrocellulose pads. Panel B is an enlarged picture of one of the individual pads and highlights the detail of the spots. The antibodies have been spotted in quadruplicate. Each individual spot has a diameter of 150 μm, and the distance between the spots is 300 μm. The total volume delivered to each spot was 350 to 367 pl. In the far right column of spots, those in the top eight positions are extremely bright and the lower four have virtually no signal. This line of eight plus four spots may be used for alignment of the image from the protein chip. The intensity of the individual spots may be quantified and used to determine the cytokine concentration in the sample. This image shows excellent reproducibility of the quadruple spots.

serum albumin, and the best blocking reagent for the antibodies detecting IL-6 may be casein. As in the traditional ELISA, a significant amount of trial and error is necessary in order to arrive at the appropriate combination of reagents.

Once the slide has been blocked, the detection antibodies are added. Because the assay is in a multiplex format, all of the detecting antibodies are added at once in a cocktail of cytokine detection antibodies. Usually these antibodies have a biotin moiety attached to them in order to improve the sensitivity of the signal. Each of the individual antibodies needs to be appropriately titered in order to achieve a strong signal with low background. It is also important to keep the antibodies at the correct concentrations in order to prevent cross-reactivity. If an antibody is present in too high a concentration, it is possible that there will be a loss of specificity.

Many of the slide microarray formats detect the antibodies through the use of fluorescent tags. These fluorescent reagents are directly attached to streptavidin, which binds to the biotin attached to the detection antibody. The slide is then read in a glass slide reader by using the same equipment used for the gene chip array work. Similar software is also employed in order to properly align the individual spots and quantitate the intensity of the signal. An example of a spotted microarray is shown in Fig. 4, which was directly obtained from the image obtained from a glass slide reader.

The fluorescent tags commonly used to determine the intensity of the spots are the cyanine (Cy) dyes. These dyes are extremely stable and emit with a bright intensity. Two principal dyes are used: Cy3, which has an emission maximum at 563 nm, and Cy5, which has an emission maximum at 662 nm. These dyes may be used together since the spectra essentially do not overlap.

When the cytokines are detected in the multiplex format, antibody specificity becomes an even more critical issue. Even slight cross-reactivity between individual antibodies may result in false-positive signals. Rigorous testing must be performed in order to document that the antibodies detect only that against which they are directed. This testing may be accomplished in the multiplex format by running the entire assay and detecting the presence of a cocktail of cytokines. In this cocktail of cytokines, one of the cytokines will be left out. In the multiplex assay which detects 18 different cytokines, 19 different cocktails will need to be prepared. One of these will have all of the cytokines present, and the fluorescence intensity for each individual cytokine will be determined. The remaining 18 cocktails will each have one of the cytokines intentionally left out. When these cocktails are run on the microarray, the intensity should be virtually nonexistent for the cytokines which are missing. Figure 5 represents an example of this type of study for examining cross-reactivity. In this example, the cocktail was prepared with 17 different cytokines, although the microarray was designed to detect 18 cytokines. The missing cytokine for this assay was IL-12. As can be observed, no signal was detected from any of the spots that were arrayed with the antibodies detecting IL-12. This demonstrates that this assay has the appropriate level of specificity. Similar results were obtained in the other studies in which the individual cytokines were deleted.

After the intensity of the individual spots has been quantified, data analysis becomes the next critical issue. In order to efficiently manage the information, the software needs to generate a mathematical model of the standard curve. The concentrations of the cytokines in the unknown samples are then calculated by referring back to the model of the standard curve.

Multiple mathematical models may be used to generate the appropriate fit for the standard curve. The same set of data may be analyzed by different iterations of the standard curve. For example, the data may be analyzed by plotting the number of relative light units (i.e., fluorescence intensity) versus the concentration of the cytokine. A simple linear expression may then be used to draw a straight line

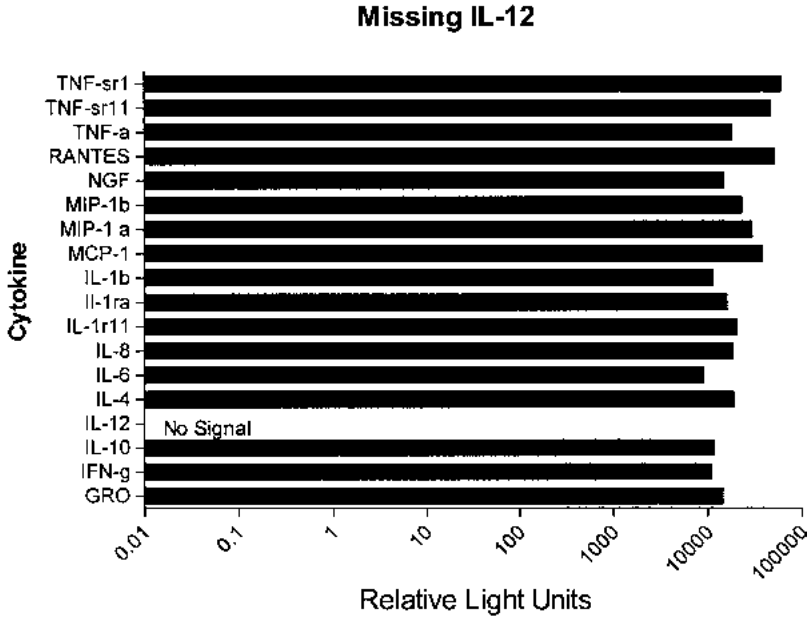

FIGURE 5 Specificity of the microarray. For this microarray, 18 different cytokines were tested. A cocktail containing recombinant cytokines was prepared, but IL-12 was not added to the cocktail. There is a strong signal from all the other cytokines, but no fluorescence was observed on the array for IL-12. This demonstrates the specificity for the array.

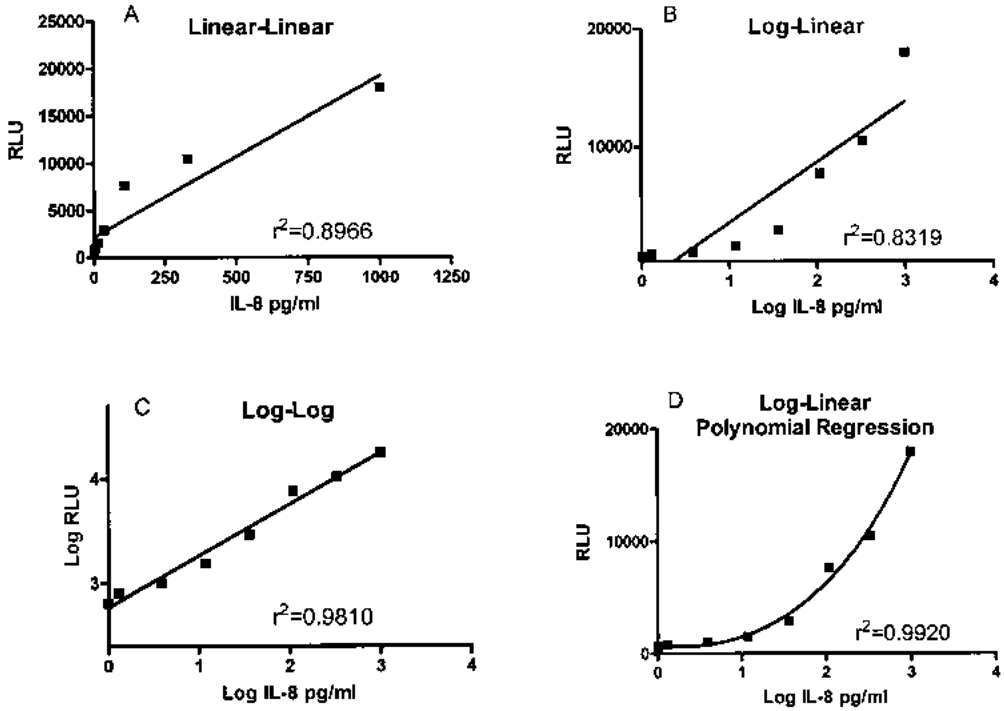

FIGURE 6 Mathematical modeling of the standard curve. Data from a microarray standard curve were used to generate a mathematical model for calculations for unknown samples. In panel A, the number of relative light units (RLU) and the concentration of the cytokine (IL-8) were plotted on a linear-linear scale. The correlation coefficient (r^2) was not very precise. In panel B, the concentration of the IL-8 was plotted on a log scale and the number of RLU was plotted on a linear scale. This resulted in even worse correlation. In panel C, both the number of RLU and the IL-8 concentration were plotted on a log scale and a very good linear regression could be fitted. However, the optimal modeling of the curve was obtained when the number of RLU was plotted on a linear scale, the IL-8 concentration was plotted on a log scale, and a fourth-order polynomial regression line was used. The results for all four panels were obtained using the same data from the IL-8 standard curve, but similar results are observed with most other cytokines.

through the points. Alternatively, the data may be graphed on a log-log scale, and again, a straight line may be fitted to the points. Software is available which automates and reduces the time necessary for data analysis (Fig. 6).

Examples of a standard curve prepared from the multiplex assay for the cytokine IL-8 are shown in Fig. 7. The exact same standard curve was subjected to different mathematical models to determine the one which would yield the optimum performance. As can be observed, plotting the information on a log-linear scale and using polynomial regression result in the highest correlation between the standard curve and the actual data.

Another level of data analysis is needed when substantial amounts of information are collected: analysis of the biological significance of the findings. In contrast to gene chip data, where only the relative abundances of different genes are determined, the actual levels of the cytokines have been measured. The levels may be important, because previous publications have indicated that the levels of some cytokines are associated with worse prognosis. For example, plasma IL-6 concentrations predict outcome in mouse models of infection (29, 30).

There are circumstances in which the standard curve is not appropriate due to a technical error, but where all of the samples have been run appropriately. It is possible to back calculate the concentrations of these samples using a different standard curve (31, 32). Using this approach, it is not necessary to rerun all of the samples, which may be important if there are limited volumes.

A modification of the slide-based microarray method has been developed which allows amplification of the signal (33). The same sandwich-type ELISA is used, but the detection antibody contains a small fragment of a DNA primer. A circular piece of DNA hybridizes to the primer conjugated to the antibody, and the circular piece of DNA is used for the amplification step. Amplification occurs when DNA polymerase is incubated with the sample in the presence of labeled nucleotides. As the DNA polymerase works on the circular piece of nucleic acid, an elongated string of labeled nucleic acid is generated. With this method, researchers were able to measure up to 75 cytokines. However, because of antibody cross-reactivity, it was necessary to separate the samples into two separate reaction mixtures. This helps to illustrate the point, raised previously, that the major limitation for many of these methods is specificity of the antibodies.

There is another variation that is used with the glass slides, a method that compares normal to abnormal samples but does not quantify the amount of protein present. For this type of assay, samples are obtained from healthy sources and also from those in altered states. Altered-state sources may be patients who have disease, or may be tissue or stimulated cells. All of the proteins from one sample are labeled with one color; for example, the normal samples may be

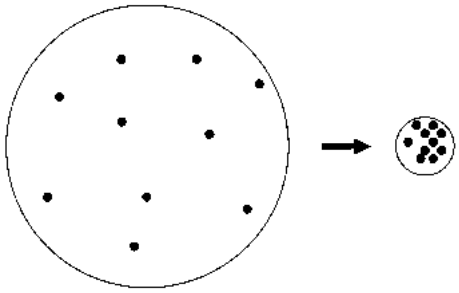

FIGURE 7 Increase in signal intensity with smaller spot size. On the left, each black dot represents the analyte bound to an antibody, which spreads across the entire well. On the right, the same number of antibodies are bound to the analyte, but they now occupy a smaller space, with a resulting increase in signal intensity.

labeled in green. All of the diseased or altered-state samples are labeled with a second color, such as red. The proteins from the normal and the diseased or altered-state samples are then mixed together. In this situation, there is a mixture of red and green molecules in the same tube.

As a specific example, one could take tissue culture supernatants from endotoxin-stimulated macrophages to represent the altered state and label these in red. Among these proteins would be IL-6. Tissue culture supernatant from unstimulated cells would represent the control state and in this situation would be labeled in green. Both of these protein samples would compete for binding to the antibodies which had been placed on the slide. In this example, there would be a large amount of IL-6 labeled red because the stimulated cells would secrete a large amount of IL-6. Normal, unstimulated cells would have very low concentrations of IL-6, and there would be virtually no IL-6 labeled green. When the samples were placed on the slide, the IL-6-specific antibodies would be occupied mostly by red IL-6. Looking at the ratio between the red and green proteins would reveal the relative increase or decrease in the disease or altered state. For this example, the results would predict that lipopolysaccharide upregulates IL-6. This approach has been used successfully in several experiments and has been used specifically to demonstrate that certain proteins become upregulated following radiation treatment (34). A pitfall to this technique is that the number of samples is typically limited to 16.

Special Equipment Required

Spotter. A high-quality spotter is required in order to prepare the microarrays. It is possible to obtain acceptable results using the same type of equipment used to prepare slides for gene chip studies. However, for spotting of proteins, noncontact printing generally results in better quality arrays. Commercial companies presently produce prespotted slides with the capture antibodies already spotted onto the slides. Custom arrays may also be prepared by commercial vendors.

Detection equipment. The glass slide may be read in a glass slide reader, or there are commercial services that will read the slides.

PLATE-BASED MICRO-ELISAS

None of the previously described techniques using traditional ELISA plates measure multiple cytokines at once. The breakthrough in technology comes about when several cytokines may be detected simultaneously from a small sample volume. The first report demonstrating the feasibility of this approach was published in 1999 (35). This publication documented the ability to detect up to eight different analytes simultaneously in a single well. The analytes that the researchers detected were immunoglobulins derived from different species, such as rabbit, guinea pig, and human. The detection was achieved by placing very small amounts of these immunoglobulins in the bottom of a 96-well glass-bottom plate. The amount of immunoglobulin that was placed on the bottom of a well was approximately 200 pl. This is in contrast to a typical ELISA, in which the bottom of the entire well is coated with a single antibody directed against a single cytokine, with a volume of approximately 100 µl. Therefore, the amount of antibody used for detection is 500,000 times smaller in the microarray assay than in the traditional ELISA. As will be discussed in greater detail below, the use of a smaller volume of antibody does not result in lower signal intensity.

An individual spot of the immunoglobulin was designated as an element, and six-by-six arrays of these elements were printed onto the bottom of each well. Four identical arrays could be printed, resulting in the deposition of up to 144 elements. Precise control of the locations of the individual elements is necessary so that the locations can be appropriately mapped to the later images.

Each one of the immunoglobulins affixed to the glass bottoms of the wells was then detected with the appropriate biotinylated secondary antibody. For this assay, alkaline phosphatase was used as the detection enzyme. This enzyme results in color development in the region of the spot. A charge-coupled device (CCD) camera was used to record the image. Typically, special modifications to the CCD camera are made, including the addition of specialized hardware and cooling to improve the optical image. Additionally, a black Teflon mask is usually applied around the individual wells to prevent scatter of the light from one well to the next.

Once the image has been captured, the intensity of the individual spot is mapped back to its precise location. Since each element detects a single cytokine, the intensity of an element is directly proportional to the concentration of the cytokine. Similar to the method in traditional ELISA, a standard curve is prepared with a separate set of wells. The intensity of the color, or the number of relative light units if fluorescence or chemiluminescence has been utilized, is compared back to the standard curve to determine the concentration of the analyte in question.

Although the technique described in this initial publication was used only to measure immunoglobulins, which are present in high concentrations and relatively easy to detect, the next innovation was the simultaneous measurement of multiple discrete molecules within the same well (35). This served as a launching point for the development of other assays.

Shortly after this report was published, another study used a 96-well plate to detect three separate molecules simultaneously (36). In this study, prostate-specific antigen, prostate-specific antigen bound to 1-antitrypsin, and IL-6 were measured at the same time. The report carefully compared the results of the protein microarray with the results obtained from a traditional ELISA. The results were surprisingly consistent, especially when one considers that the researchers included serum samples from patients. However, the sensitivity of the individual determinations was not exceptional.

Another report published in the same year from a commercial vendor showed that this technology could be used

to detect multiple human cytokines (37). In this study, the sensitivity was very close to that observed in a traditional ELISA. This initial study had three-by-three arrays of the monoclonal antibodies detecting seven different cytokines. More recent iterations of this technology have detected far more cytokines.

As one can imagine, when one is working with extremely small sample volumes the printing of the arrays is a critical issue. The deposition of the small sample volumes must be uniform, and the alignment must be extremely precise (38). There are several manufacturers of spotters used to accurately place the proteins. In many situations, spotters that have been used for the preparation of DNA microarrays may be successfully used for protein applications. These are typically contact type printers, where a quill tip is dipped into the protein solution and the solution is dotted onto the substrate. While these work quite well for nucleic acid microarrays, better results are typically obtained with noncontact printers. In one extremely novel and low-cost approach, a standard ink jet printer was used for depositing the antibodies (39).

The substrate onto which the antibodies are spotted is also important. Nucleic acids spot quite well onto glass slides, but antibodies are not optimally placed onto glass. The surface of the glass slide may be derivatized in order to improve binding of the antibodies (38). Alternatively, the antibodies may be spotted onto other substrates such as nitrocellulose that have a high protein-binding capacity. Other membranes are also suitable. For 96-well plates, traditional ELISA plates may be used since these have already been developed and tested for binding of antibodies. A potential disadvantage is that it may be difficult to spot onto the bottom of the 96-well plate.

Since only a small amount of antibody is spotted and the spot is extremely small, the immediate concern is that the signal intensity would be extremely weak. In fact, the signal intensity may be greater with the smaller amounts of antibody. In a traditional ELISA, the antibodies spread across the bottom of the entire plate. Once the analyte binds to the antibody, the signals also spread across the entire plate. In contrast, with the microarrays, the antibodies are usually at higher concentrations. This is shown schematically in Fig. 7. In this figure, each of the black dots represents an antibody to IL-6 that has been coupled with IL-6 and subsequently detected. If the same amount of one analyte (IL-6) is bound to the same number of antibodies but the antibodies are now more closely spaced, the resulting signal intensity will be higher.

Special Equipment Required

Spotting device. Accurately placing each of the individual spots into the well of the microtiter plate requires a high-quality spotting device. This device must be capable of accurately and reproducibly placing the capture antibody in a precise location. Additionally, because of the depth of the microtiter plate, the robotic arm doing the plating must have pipette tips able to clear the tops of the wells. This problem does not occur with the glass slide-based arrays, yet the number of samples that can be done on the plate versus the slide does make up for the extra time required during the spotting process. Noncontact printers provide the most uniform arrays when working with proteins. This is a rapidly changing market, and the investigator should carefully research the spotters available on the market before purchase.

Detection equipment. Microarray assays are run using a colorimetric reagent, and a CCD camera is used to record the image. This is a high-quality camera which is specially modified in order to reduce background and provide a greater range of sensitivity and specificity. Other methods have been used using near-infrared dyes coupled to the secondary antibodies and then scanned on a special scanner that can detect near-infrared.

MEMBRANE-BOUND ANTIBODY ARRAYS

A series of recent papers have been published which describe technology capable of detecting multiple cytokines in a relatively simple format (40–43). The authors have manually arrayed antibodies to several cytokines on a membrane. Simplicity of design represents an attractive feature of this methodology. In the initial study, several important steps were evaluated to arrive at the optimal conditions for the assay. Some of the parameters that were studied include the concentrations of antibodies and the best membranes for use.

For this type of assay, there are multiple antibodies directed against specific cytokines bound to a membrane. Each antibody is spotted onto the membrane in a different location, and the location is determined by the map. Diluted samples are placed onto the membrane, which is then incubated for 1 h. Following washing, a cocktail of detection antibodies is placed onto the membrane. After washing again, the detection reagent is added and the spots representing the individual cytokines are detected by chemiluminescence. X-ray film or a phosphorimager may be used to determine the intensity of the individual spots. These arrays may be used for screening in a semiquantitative manner or for actual quantification.

Advantages to this technology are that it is easily performed in virtually any laboratory. The incubation may be done in a simple six-well tissue culture dish, and the cytokines are arrayed on a membrane about the size of a postage stamp.

An important disadvantage to this technology is reduced sensitivity. Published results have shown that the sensitivity of the membranes is at least 2 logs lower than that of the traditional ELISA for several cytokines (44).

Special Equipment Required

X-ray film processor or phosphorimager. X-ray film may be used to capture the relative intensities of the individual spots, or this step may be done more quantitatively using the phosphorimager. Most institutions have an X-ray film processor available from molecular biology experiments in which older style Northern blots were developed, so it may not be accurate to consider this as special equipment.

CAPILLARY ELECTROPHORESIS

A recent paper has described a novel method for rapidly detecting cytokines. In a special apparatus, antibodies directed to specific analytes were placed in the injection ports, where they were permanently bound (45). The samples containing the cytokines were then added, and all the bound proteins were labeled with Alexa Fluor 633. Electrophoresis was performed by lowering the pH, which dissociated the labeled cytokine from the antibody. The retention time determined the cytokine, and the intensity of the label correlated with the concentration. The entire process was very rapid and

could be completed in just a few minutes. Additionally, the sample volume required for the assay was only a few microliters. By using this technology, six cytokines could be quantitated in less than 2 min. However, the chemistry of coupling the antibodies and performing the electrophoresis and detection presently are beyond the capabilities of most laboratories.

BEAD ARRAY ASSAYS

Bead array assays have become standard for cytokine measurement. They have become sufficiently routine that papers are now being written comparing multiplex bead assays to traditional ELISAs (46). The first papers hinting at the capabilities of using a flow cytometer to measure cytokines were published more than 20 years ago (47, 48). There are several commercial vendors marketing the bead array assays. The assays may generally be divided into two groups, and the differences between these two types of assays will be described in greater detail below. The bead array assays may be used to measure proteins such as cytokines and immunoglobulins. Additionally, they have been used extensively for the development of assays for examining polymorphisms in genetic material (49, 50). HLA typing has been revolutionized by the adaptation of this technology (51). Bead array assays for the measurement of cytokines are all based on the standard antibody-cytokine interactions already described. They are represented schematically in Fig. 8. The first and most important step in the bead array assay is finding a specific antibody that may be conjugated to the bead. The quality of the antibody drives the sensitivity and specificity of the assay, as with virtually all immunoassays. The steps are similar to the basic steps shown in Fig. 2 for a sandwich ELISA. As the first step, the capture antibody is conjugated to the bead. This bead mixture is then incubated with the samples containing the cytokines. After the cytokines are bound to the capture antibody, a biotinylated detection antibody is added, followed by streptavidin which is coupled to a fluorescent probe. The entire mixture is then run on a flow cytometer. Although this is a simple description of the overall assay, several features allow the assay to be performed rapidly and in a multiplexed manner.

The beads are an important part of the overall assay since they are the component that allows the samples to be run in a multiplexed manner (52). There are variations on the way the individual beads are detected. In the first version, a single fluorescent molecule is incorporated into the beads (53). The beads are distinguished by the various amounts of fluorescent probe inside the beads. Careful manufacturing allows the individual groups of beads to be distinguished from one another. For this example, the antibodies to IL-6 would be conjugated to bead set 1, and the antibodies to tumor necrosis factor would be conjugated to bead set 2. When these beads are mixed together, the fluorescence intensity of the fluorochrome inside each bead indicates whether one is analyzing tumor necrosis factor or IL-6. Multiple sets of beads may be distinguished with this method.

Another method for discriminating among the individual bead sets involves mixing two different fluorescent dyes in various mixtures. The individual groups of beads are then differentiated based on two-color analysis. The groups of beads may be clumped according to the relative intensities of the two separate fluorochromes. Similar to the method for the assay previously described, one group of beads is conjugated to antibodies to tumor necrosis factor, and a separate group of beads is conjugated to antibodies to IL-6. Up to 100 different discrete sets of beads may be differentiated on the basis of the various concentrations of the two fluorescent dyes. There are several commercial vendors who manufacture the beads conjugated to the antibodies. An example of an assay run using the Luminex platform is shown in Fig. 9.

We have described how the individual beads are grouped, but how does the quantification of the cytokines occur? Quantification takes place through measurement of the intensity of the fluorescent tag attached to streptavidin. As in the traditional ELISA, the intensity of the signal is directly related to the amount of detection antibody that is attached to the cytokine. A standard curve with several concentrations of cytokines is prepared and run in the assay. Figure 10 shows an example of the standard curve with mouse IL-1β. The steps that are involved with the precise measurement of the cytokine include, first, the detection of the groups of the beads. The intensity of the streptavidin fluorescent tag for each group of beads is then assayed and compared to the standard curve in order to determine the concentrations of the cytokines within the sample. In Fig. 9, there are 22 individual groups of beads that may be assayed, which indicates that there are 22 individual groups or individual cytokines that may be measured in this multiplexed assay.

There are several advantages to the bead array assays. First, it is possible to perform the assays without washing the beads, limiting many of the time-consuming and tedious steps in a traditional ELISA (52, 54). It is possible to do these assays without washing because the fluorescence intensity of only the molecules bound to the beads is measured, not the intensity of everything in the solution. In a traditional ELISA, the fluorescence intensity or color is measured in the well. Unless unbound antibodies are washed away, the background will be extremely high. In the bead array assay,

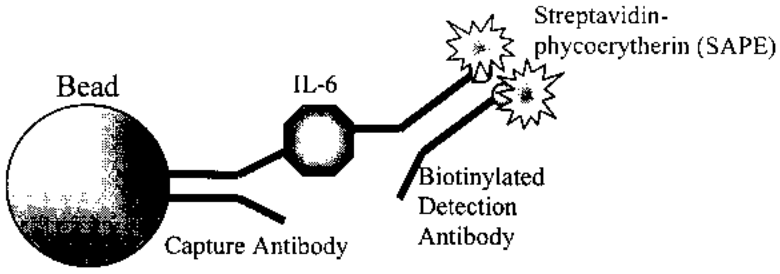

FIGURE 8 Schematic representation of the principle of a flow cytometric bead-based assay. The capture antibody specific for the analyte, in this example IL-6, is attached to a bead. The IL-6 binds to this antibody, which is then followed by a detection antibody which is biotinylated. Streptavidin conjugated to phycoerythrin is then added, and the entire complex is analyzed with the flow cytometer.

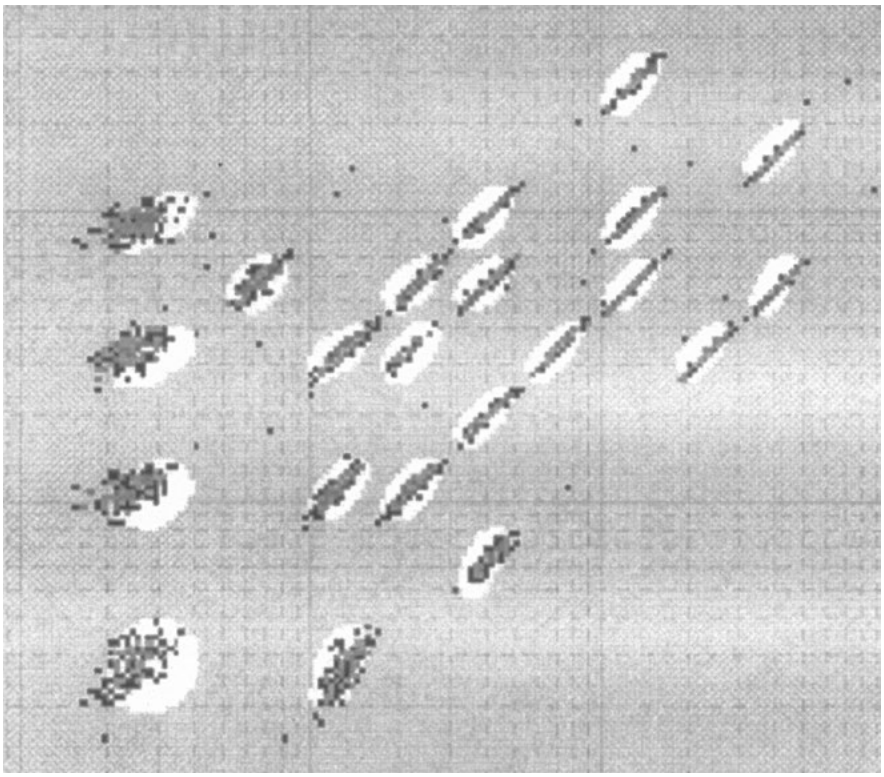

FIGURE 9 Example of the readout from a bead-based flow cytometry assay. In this example, the individual beads have different concentrations of two fluorescent dyes. The groups of beads are detected on the basis of the fluorescence intensities. The individual dots represent individual beads, and the darker-colored dots are doublets. The clear areas around collections of beads indicate those areas used for analysis. In this example, 22 individual cytokines have been detected. The intensity of the fluorescence of each individual bead is captured in a third fluorescent channel and compared to the standard curve in order to determine the concentration of the cytokine.

the flow cytometer will analyze the group of beads to determine the specific fluorescence intensity and not the overall fluorescence intensity.

A second significant advantage is that up to 100 discrete groups of beads may be analyzed; thus, up to 100 different cytokines may be measured in a multiplexed assay. The major limitation is obtaining an antibody with sufficient specificity in order to prevent cross-reactivity.

Many of the steps for the bead array assays may be automated, which is a third distinct advantage of this methodology. Automated sampling of each of the discrete wells used for an individual sample may be done, allowing walk-away ease of use. Finally, the volume of sample required to measure multiple cytokines is extremely small. This is an advantage of any of the multiplexed assays, which generally require smaller sample volumes than the traditional ELISA. Even use of the sequential ELISA requires a larger sample volume than that typically used in a bead array assay.

At the present time, there are at least 75 different identified cytokines that may be measured by using this platform. The cytokines include those of human, rat, and mouse. Additionally, this technology may be used for allergy testing, tissue typing, detection of cardiac markers and cancer markers, and diagnosis of infectious diseases. The bead array assays have been successfully used to measure cytokines in human plasma (55), though appropriate caution must be used when working with plasma or serum samples (56). Additionally, there may be false positives using human samples if rheumatoid factor is present (57).

Special Equipment Required

Preparation of Beads

While it is possible to conjugate the antibodies to the purchased beads, in reality this is technically difficult to do. Fortunately, there are several vendors in the marketplace at the present time. This is encouraging news for investigators, since it is not likely that all of the vendors would terminate manufacturing of beads at the same time. Inevitably as the market matures, there will be fewer vendors, but the strong should survive such that those companies with excellent technical assistance, range of reagents, and ease of use will continue to sell products. The fact that several companies are marketing their products for the bead array assays also indicates that business analysts have determined that there is a robust market available for their wares. Again, this increases enthusiasm among investigators since the technology is more likely to persist. Additionally, the technology has been used to detect more than just cytokines. As a result, the flow cytometry apparatus is more widely available since it can be used for multiple applications. Vendors are also beginning to produce kits that allow antibody conjugation to beads, so that investigators can make their own reagents; this can both reduce cost and allow for a very custom array.

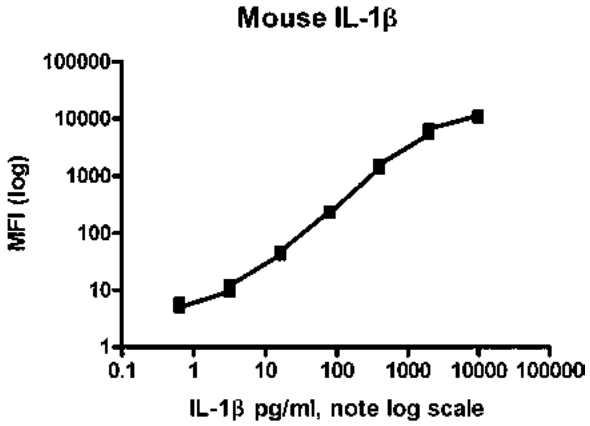

FIGURE 10 Example of a standard curve generated from the bead-based flow cytometry assay. In this example, a standard curve using recombinant mouse IL-1β is displayed. MFI, mean fluorescence intensity.

By working with the vendors, it is possible to have custom-prepared sets of beads. The companies are pleased to conjugate specific antibodies to the beads and then multiplex the reagents into kits for the customer. Provided that there is an appropriate antibody available, there is really no limitation on what is available.

Flow Cytometry

For some of the commercial kits, it is not necessary to have a special, dedicated instrument. Any standard flow cytometer may be used for measuring cytokines provided that the appropriate software has been employed. Since many institutions already have flow cytometers which have been used for routine cell work, there is no real additional expense for running the assays.

COST COMPARISON

A true comparison of different multiplexed formats requires a delineation of the costs involved. A cost comparison was made using a bead array assay compared to a conventional ELISA performed in the sequential format. For the ELISA, the cost remains essentially the same for each cytokine that is measured. However, in the bead array the cost decreases with the number of cytokines that are measured. This savings comes about as the cost of the kits decreases as the number of cytokines multiplexed increases. The cost analysis is carefully delineated in Table 1. The analysis was carefully constructed to include the time of a skilled technician as well as the cost of reagents. When the ELISA is performed, the major component of the cost is the salary of the person who actually performs the assay. The cost analysis was based on a single technician being able to process five plates of samples per day. Five plates of samples would amount to measuring approximately 200 samples for a single cytokine per day. The calculated cost of the beads was based on using only a single well of the 96-well plate for each sample. Many investigators would use two individual wells to measure a sample, and the cost would proportionally increase. As can be observed in Table 1, the total cost for measuring a single cytokine by ELISA is about $11, whereas the same sample run in a multiplexed assay would cost about $59. These cost estimates will vary depending on the ability to obtain competitive pricing from the antibody vendors.

TABLE 1 Cost analysis for cytokine measurements[a]

Parameter	Assay	
	ELISA	Bead array
No. of cytokines	1	17
Vol (μl)	50	50
Cost per sample (U.S. dollars)	1.95	59
Cost per cytokine (U.S. dollars)	1.95	1.87–3.31
Lower limit of detection	1–10	1–10
Range (logs)	3	3
Expandability	Not expandable	Expandable

[a]The cost of measuring cytokines by traditional ELISA, used in the sequential format, is directly compared to the cost of doing a bead array assay. Included in these costs are the necessary reagents, including buffers, antibodies, and kits purchased from the manufacturer. Also included is the time of a technician, assuming that the technician could test up to five full plates (about 200 samples) per day. The cost of this time is also included in cost analysis for the bead assays.

However, the cost decreases as the number of cytokines that are measured increases. This is delineated in Table 2, demonstrating that there is a sliding scale for the cost of measuring cytokines in a single sample. When approximately 17 cytokines are measured, it is less expensive to use the bead array assay than to perform multiple ELISAs. Again, it must be borne in mind that the cost of doing the ELISA principally involves the time of a technician, and that has been included in the cost calculation.

There is one significant cost which has not been included in these analyses, that of the capital equipment necessary to perform some of these assays. Specifically, these analyses did not include the cost of a plate reader or a flow cytometer. Typically, these large pieces of equipment are purchased through capital funds and may be considered a fixed cost for the assays. In other words, if one cytokine is measured there is still the cost of buying a flow cytometer, and this cost is the same if one runs 100,000 cytokines.

Issues concerning the sample volumes necessary to run the individual assays also become important. These are especially critical when dealing with rodents such as mice from which only a small volume of plasma may be obtained (58). Since only a single sample is required to run the multiplexed assay, the bead array assays or the spotted arrays consume significantly less sample volume than even a sequential ELISA. The amounts of sample necessary to run several different cytokines are listed in Table 3.

While this cost analysis was performed for measuring cytokines in a bead array assay, similar comments may be made regarding an alternative multiplexed format such as the spotted arrays on glass slides or spotted arrays in a 96-well plate. Additionally, analysis of issues such as the purchase

TABLE 2 Sliding-scale cost of measuring cytokines[a]

No. of cytokines	Cost (U.S. dollars) for:	
	ELISA	Bead array assay
4	7.80	13.25
6	11.70	19.28
14	27.30	27.95
17	33.15	31.79

[a]As the number of cytokines measured in a multiplexed assay increases, the cost decreases. The cost per cytokine per assay remains relatively fixed in the ELISA format, but as more antibodies are multiplexed to different sets of beads, the bead array assay decreases in cost. At about 17 cytokines, the bead array assay becomes more cost-effective than the ELISA.

TABLE 3 Sample volumes required for performing assays[a]

No. of cytokines	Vol (μl) needed for:	
	ELISA	Bead array
1	50	25
6	75	25
20	145	25

[a]As the number of cytokines measured increases, the sample volume necessary for the ELISA increases while that for the bead array assays remains static. The calculation of the sample volumes for the ELISA assumes that the assay is being performed in sequential manner.

of capital equipment and the amount of a technician's time necessary to perform the assays would probably give similar results. Specifically, as more cytokines are measured, the cost per cytokine would go down for the multiplexed assay and would remain the same, of course, for the sequential ELISA. Additionally, the sample volume would remain static for a spotted microarray.

MOLECULAR METHODS FOR MEASURING CYTOKINES

The standard molecular approach to measuring cytokines quantifies the amount of mRNA coding for the cytokine protein. There are many methods for measuring mRNA, including some which are primarily of historical interest such as Northern blots. In current practice, most cytokine mRNA is detected by either *in situ* hybridization or PCR.

In Situ Hybridization

In situ hybridization detects the cytokine mRNA typically on a tissue section fixed to a glass slide. The advantage of this method is that it allows one to determine exactly which cell is making the cytokine, which may be of biological relevance. For example, it may be important to know whether the endothelial cells or the epithelial cells are producing cytokine mRNA in the lung. For this methodology, a piece of labeled nucleic acid is incubated with a tissue section. The sequence of nucleotides in the nucleic acid should be specific for the mRNA that one wishes to detect. If one wants to determine whether mRNA for TNF is present, the nucleic acid sequence would be specific for the mRNA coding for TNF. Any cells that were expressing mRNA for TNF would show positive staining.

In situ hybridization is built on the basic concept that a defined sequence of nucleotides will hybridize or bind to complementary nucleic acid. This follows the typical tenets of molecular biology with base pairs joining to each other. The piece of nucleic acid is specifically designed using appropriate software so that it will only bind to mRNA coding for the cytokine in question. This piece of nucleic acid should only bind to TNF, and not to IL-6 or other cytokines. The nucleic acid sequence is labeled such that it may be detected after it is firmly bound or hybridized to the mRNA. The label may be either an enzyme, such as horseradish peroxidase, or biotin. If the nucleic acid is labeled with biotin, then streptavidin conjugated to horseradish peroxidase or another enzyme is used for detection. Substrates are added to the slide, and positive cells are typically stained brown if they contain the appropriate mRNA.

The sequence of nucleotides that will be used as detection probes may be either DNA or RNA. The most important element is that the nucleic acid has specificity for the mRNA. DNA:RNA binding interactions are usually stronger than RNA:RNA interactions, which allows more stringent washes to clear away any unbound nucleic acid probe.

PCR

PCR is the most commonly used method for the detection of cytokine mRNAs. This technology was developed based on the discovery of a DNA polymerase which remained active even after exposure to high temperatures (59). The Nobel Prize was awarded for the discovery of this enzyme, highlighting the contribution to science. There are several steps that need to be performed carefully and in the correct order to produce a positive result. The first step is the extraction of the mRNA from the sample. This sample may be cells isolated from blood, cells from a tissue culture flask, or a sample isolated from a paraffin block used to make glass slides. Extraction of the mRNA must be done carefully since this nucleic acid is highly labile and easily degraded. The second step is to create a DNA strand complementary to the mRNA, the cDNA. This is done using the enzyme reverse transcriptase, which will bind to double-stranded nucleic acid and create a reverse transcript. Two approaches may be used to create the cDNA. One approach is to generate cDNA for any mRNA present in the sample by using a poly(T) nucleic acid which will bind to any mRNA containing a poly(A) tail. The second approach is to use a small sequence of nucleic acid which binds specifically to the mRNA that will be amplified. Creating cDNAs from all the mRNA has the advantage of creating a pool of cDNAs that may then be amplified, if there is an interest in detecting several cytokines. Using a probe specific for the cytokine that will be detected increases the specificity of the reaction.

Once the cDNA has been created, PCR will substantially amplify the final product. To understand how this amplification occurs, one must know the steps involved. Two nucleic acid primers are created specific for the cytokine you wish to detect, called the forward and reverse primers. The PCR goes through a series of reactions or cycles. In the first cycle, the double-stranded nucleic acid is denatured into two separate single strands by raising the temperature. These single strands are then incubated with both primers, which will bind to their individual strands when the temperature is lowered. Once the primers have annealed, the DNA polymerase will adhere to the double-stranded DNA (created by the primer binding to the denatured DNA) and proceed to create a new piece of nucleic acid which is complementary to the original piece. The second cycle then starts again, by denaturing the newly created double-stranded DNA.

There are several considerations in this relatively simple sequence of events. First, the DNA polymerase must remain active when the temperature is raised to allow the DNA to denature. The discovery of the thermostable DNA polymerase was the significant achievement that allowed this to occur. Second, all of the necessary components are in a single tube so that raising and lowering the temperature is all that is required for the reaction cycles to take place. There is no need to open the tube to add additional reagents. Third, each cycle amplifies the products from the previous reaction. This allows a geometric increase in the number of amplified sequences ($1 \rightarrow 2 \rightarrow 4 \rightarrow 8 \rightarrow 16$, etc.), which provides unparalleled sensitivity. PCR has been used to detect virtually any nucleic acid, in addition to cytokines. For example, it may be used to detect cytokine mRNA (60) in addition to pathogens (61).

CONCLUSIONS

Multiplex assays for measuring cytokines are rapidly becoming standard across the world. A clear indicator of the enthusiasm for these assays may be found in the large number of companies which are presently producing and manufacturing multiplex cytokine kits. There are several platforms that are available for measuring the cytokines, and the market is not yet sufficiently mature to conclusively address which of these offers the best speed, sensitivity, and specificity, and the lowest cost. Molecular techniques are also used to detect cytokine mRNAs.

This work has been supported in part by NIH grants GM 97320 and T32 GM86308.

Cytokine Measurement by Flow Cytometry

HOLDEN T. MAECKER

36

In the years since intracellular cytokine staining (ICS) was first developed (1), this method has become a standard way to analyze the functions of immune cells by flow cytometry. It has been used with specific antigen stimulation (2, 3) to read out T cell populations responsive to vaccines (4–6), pathogens (7, 8), cancer (9–11), or allergens (12), in both human and animal models. The technique has been combined with MHC-peptide multimer staining (11, 13), including combinatorial tetramer staining that allows the interrogation of many epitope specificities at once (14, 15). Combined assays with tetramers can be done by first staining with tetramer(s), then stimulating with a nonspecific agent such as PMA+ionomycin, which bypasses the tetramer-occupied T cell receptors. ICS has also increasingly been used with detection of CD154 (16, 17) or CD107a (18) induction, as markers of activation and degranulation, respectively. When used with cell surface and other intracellular phenotyping markers, such multiparameter ICS assays are a tool of choice for functional characterization of T cells and other cytokine-producing cell populations. ICS has also successfully been converted to the mass cytometry platform (19) allowing the use of many more simultaneous markers without significant spillover between readouts.

Alternatives for assessing cytokines at the cellular level include enzyme-linked immunospot (ELISPOT) (20) and cytokine capture technology (21). While ELISPOT assays provide a relatively low-cost and high-throughput method for quantitating cytokine-producing cells, they do not offer the additional dimensions of cellular phenotyping possible with flow cytometry. They have been adapted in recent years to the detection of multiple cytokines, most effectively done with a fluorescence readout (so-called fluorospot assays [22, 23]). Conversely, the cytokine capture assay allows for multiparameter flow cytometry analysis and even sorting of live cells (21). It has not been widely used, however, beyond the experimental situations in which live cell sorting for downstream assays is employed. A comparison of the various types of antigen-specific T cell assays and their features is shown in Table 1.

SPECIMEN TYPES

In order to assess the population of antigen- or mitogen-responsive cells by ICS or cytokine capture assays, short-term *in vitro* stimulation is used. This can be done either in whole blood (3) or isolated peripheral blood mononuclear cells (PBMC) (2) or other sources of mononuclear cells. Addition of exogenous antigen-presenting cells (APC) is not required, though purified autologous APC such as dendritic cells can be used when stimulating APC-depleted or deficient cell samples. For whole blood, heparin is the preferred anticoagulant, as EDTA or acid citrate dextrose (ACD) will block the cytokine stimulation pathways. For PBMC, the anticoagulant is not critical, as the cells are washed free of it prior to stimulation.

STIMULATION VESSELS

Either tubes or multiwell plates can be used for stimulation (24). At least 200 μl of whole blood is advised for detection of antigen-specific responses, or at least 5×10^5 PBMC, per sample. Up to 2×10^6 cells can be accommodated in a 96-well plate, for typical stimulation periods of 6 to 8 h. Round- or V-bottom plates are preferred, both for promoting cell-cell contact and for best performance when pelleting and washing the cells poststimulation.

RESTING PRIOR TO STIMULATION

Particularly with cryopreserved and thawed PBMC, resting of the cells at 37°C prior to stimulation is helpful, increasing both the number of responsive cells and the cytokine staining intensity per cell (24). Resting for at least 2 h, and up to 24 h, is advised.

COSTIMULATION

With the use of whole-protein antigens, stimulation in the presence of costimulatory antibodies, such as anti-CD28 and anti-CD49d, has been shown to increase the frequency of responsive T cells (25). This effect is less dramatic when using peptide stimulation, particularly optimal-length peptides (e.g., 9-amino-acid residues for CD8+ T cell responses) at saturating concentrations (around 1 μg/ml). Costimulatory antibodies can also increase the background of cytokine-producing cells in the unstimulated condition (for some donors), so their use should be carefully considered and tested in the system of interest.

doi:10.1128/9781555818722.ch36

TABLE 1 Comparison of antigen-specific T cell assay features

Cell recovery	Cytokine readout only	Cytokines + phenotypes	
		Without epitope specificity	With multiple epitope specificities
No live cell recovery	ELISPOT	ICS (protein or peptide pool stimulation)	ICS with tetramers (PMA+ionomycin stimulation)
Live cell recovery		Cytokine capture assay (protein or peptide pool stimulation)	Cytokine capture assay with tetramers (PMA+ionomycin stimulation)

STIMULATION ANTIGENS

Either peptides or protein antigens can be used for stimulation, and most assays rely on endogenous host antigen-presenting cells (APC). There is no need to preload a population of autologous APC unless one wishes to study such a system. While intact proteins can be processed and the resulting major histocompatibility complex (MHC) class II-restricted peptides can be presented to CD4+ T cells, exogenous proteins are inefficiently presented via MHC class I for stimulation of CD8+ T cells (26). Therefore, a common strategy has been to use mixtures of overlapping peptides, spanning a protein sequence, to stimulate both CD4+ and CD8+ T cell responses (27). The use of 15-amino-acid peptides with 11-amino-acid overlap has been most popular and provides a reasonable balance of cost and efficiency for both CD4+ and CD8+ T cell stimulation (27, 28). While mixtures of several hundred peptides can be used in this fashion, there is some evidence for gradual reduction of responses when using more than 100 peptides per mix (29).

SECRETION INHIBITORS

For ICS, the *in vitro* stimulation must be accompanied by addition of a secretion inhibitor, usually brefeldin A or monensin. The choice of optimal secretion inhibitor(s) depends on the readouts of interest. Most proinflammatory cytokines are best retained intracellularly using brefeldin A (30, 31), while monensin is best for detection of IL-10 and TGFβ (our unpublished data). Monensin is also useful for the detection of CD107 (18) and CD154 (17), because it prevents the acidification of internalized vesicles that recycle these molecules. In these assays, the CD107 and/or CD154 antibody conjugate(s) are usually added during the stimulation, so that even target proteins that are transiently expressed can be stained and the fluorochrome is not degraded upon internalization. Monensin and brefeldin A can be combined (e.g., 5 μg/ml each) for applications where both proinflammatory cytokines and CD107/CD154 are targeted.

STIMULATION KINETICS

The optimal time course of *in vitro* stimulation will depend upon the stimulating antigen(s) and the targeted cytokines and/or activation markers. When antigen processing is required, a 2-h incubation prior to addition of secretion inhibitors is helpful; when using peptides or mitogens that do not require antigen processing, the secretion inhibitor can be added simultaneously with the stimulus. Six- to 8-h stimulation is sufficient for detecting most cytokines (32), although interleukin-10 (IL-10) production does not peak until 12 to 24 h. Additional incubation time, with secretion inhibitor present, is not detrimental until it becomes toxic to the cells; a maximum of 12 h in 10 μg/ml of brefeldin A is advised (32). For CD107 and CD154 detection, incubation times of not more than 5 to 6 h are optimal (17, 33).

These kinetics obviously place some constraints on the readouts that can be feasibly combined without loss of signal. For example, combining IL-10 detection with CD107 or CD154 would be unadvised, since their kinetics are so different. However, combination of CD107/CD154 with proinflammatory cytokines is easily accomplished, using a 6-h stimulation time in a combination of brefeldin A and monensin (5 μg/ml each). Similarly, combination of proinflammatory cytokine and IL-10 detection is possible using a stimulation time of around 12 h, with brefeldin A and monensin present for most if not all of this time.

If needed, stimulations can be automated using a programmable heat block, incubator, or water bath. The device is set for the desired incubation period at 37°C, followed by cooling and holding of samples at 4 to 18°C until further processing. Temperatures of 15 to 18°C are preferred for whole blood to avoid excessive platelet activation; 4°C is fine for PBMC (our unpublished data). Ideally, a CO_2 incubator should be used, but we have also obtained good results using *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES)-buffered media in a non-CO_2-enriched environment.

CELL PROCESSING

Important variables in the processing of stimulated cells include the choice of fixation and permeabilization buffers, centrifugation speeds, and choice of staining antibodies and conditions.

Commercial systems for fixation and permeabilization are available and are usually based on formaldehyde-based fixation and permeabilization with either saponin or other detergents. Of note, saponin-based permeabilization is reversible, so the detergent needs to be maintained during the intracellular staining steps and washes. There are some trends towards better performance of certain systems with certain cytokines, e.g., a saponin-based system such as Cytofix/Cytoperm (BD Biosciences, San Diego, CA) is superior for detection of IL-10 and transforming growth factor-beta (TGF-β) (34). However, for most cytokines and other targets, the differences are small. An exception is staining for transcription factors, such as FoxP3, for which specialized (harsher) permeabilization systems should be used. In these cases, it is safest to use the permeabilization system of the vendor producing the transcription factor antibody.

Initial centrifugation of live cells should be done at relatively low speed (250 to 300 × *g*) to preserve cell integrity.

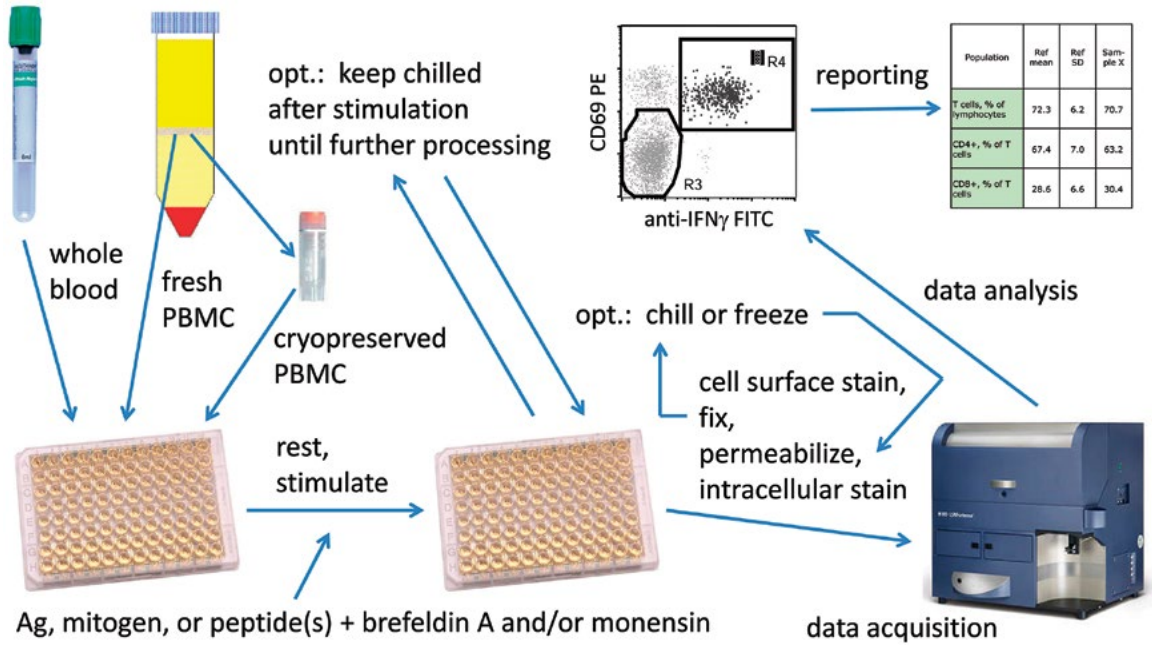

FIGURE 1 Workflow of ICS assays. Steps in the ICS assay, with variations and optional stopping points as shown.

However, fixed cells are much more buoyant, and centrifugation should be harder (at least 500 × *g*) to avoid loss of cells during washing. When using multiwell plates, a fixed-length vacuum manifold is helpful for aspiration of supernatants after washing, for both speed and consistency of residual volumes. Efficient washing, particularly after the intracellular staining step, is critical to reduce nonspecific staining.

Considerations for multicolor antibody panels have been published (35, 36) and will not be repeated here. Suggestions for 8- to 10-color panels combining intracellular cytokines and T-cell markers are also available (29, 34). One specific consideration is the staining of CD3, CD4, and/or CD8 before or after fixation/permeabilization. These antigens are specifically internalized during stimulation with antigen or T cell mitogens. Thus, while antibodies will have generally higher binding to live versus fixed epitopes, the ability to stain already internalized antigen may improve the ability to detect activated T cells in ICS assays, particularly with strong stimuli, such as phorbol-myristate-acetate (PMA)+ionomycin, or high concentrations of optimal-length peptides (27).

DATA ANALYSIS

Recently, a proficiency panel was conducted to test the reproducibility of gating intracellular cytokine data across laboratories (37). The results showed that differential gating strategies were rampant and greatly affected the results. Previous studies have also highlighted the importance of standardized gating to achieve reproducible results with ICS (38, 39). An important variable is the inclusion of cells that are dim in CD3, CD4, and CD8, since these are often activated cells (see previous paragraph). Also important is the relative placement of the cytokine-positive gate, to minimize background in unstimulated samples while maximizing the detection of rare positive events. Placement of the lymphocyte gate, inclusion/exclusion of CD4+CD8+ T cell populations, gate uniformity, and adjustment of biexponential scaling are also important (37).

In order to draw conclusions about whether ICS results are significantly above background, it is important to collect enough events. Statistical significance of results can be determined using a power calculation (see reference 40), which takes into account the number of relevant cells (e.g., CD4+ or CD8+ T cells) in both the unstimulated and test samples, as well as the proportion of positive events in each. As a practical benchmark, one can distinguish a response of 0.1% from an unstimulated background of 0.03%, with 99% power and $P < 0.005$, by collecting a minimum of 45,000 relevant (CD4+ or CD8+) cells.

It is helpful for large studies to apply batch analysis routines, which can be combined with automated cluster finding if desired. Such options are available within traditional flow cytometry software packages, as well as through R packages such as Bioconductor (http://www.bioconductor.org) and new algorithms such as those tested in the FlowCAP workshops (41). It is important to stress, however, that close manual oversight of these processes is still important, to avoid spurious results.

DETAILED PROTOCOLS AND ADDITIONAL INFORMATION

A detailed ICS protocol, which also discusses many of the above technical variables, has been published relatively recently (34). Concise general protocols for activation and cell surface and intracellular staining, with notes on key variables, are also available on the Web (http://maeckerlab.typepad.com/maeckerlab_weblog/maeckerlab_protocols_and_tools). Figure 1 shows the general workflow of ICS assays, with potential variables and stopping points that can be employed. Finally, information on validation of ICS assays has also been published (29, 42).

Chemokine and Chemokine Receptor Analysis

SABINA A. ISLAM, BENJAMIN D. MEDOFF, AND ANDREW D. LUSTER

37

The active movement of leukocytes towards a site of antigen challenge, infection, or tissue damage represents a central aspect of the establishment of both inflammatory and immune responses (1–4). The movement of cells towards a chemical gradient of a particular stimulus or chemotactic factor is called chemotaxis. Chemotactic factors that induce the directional movement of leukocytes include the chemokines, a super family of proteins 8 to 10 kDa in size that signal chemotaxis through seven transmembrane G protein-coupled cell surface receptors (GPCRs) (1, 2). In this chapter, the methodological approaches to studying the role of chemokines and chemokine receptors in the physiology of immune and inflammatory responses are described. Although assays of chemokines or chemokine receptors have yet to be used for widespread clinical applications, this chapter briefly reviews the role of these proteins in the pathophysiology of several inflammatory diseases and illustrates potential clinical settings in which measuring these proteins or studying their functional activity may be of useful.

CHEMOKINE AND CHEMOKINE RECEPTORS: BASIC PRINCIPLES

Chemokines

Comprehensive analyses of the human and mouse genomes have identified more than 50 chemokines that share 20 to 70% homology in amino acid sequence identity (1, 2) (Table 1). Chemokines share the common function of attracting leukocytes to sites of an inflammatory or immune response. A standardized nomenclature in which chemokines were given numerical names, like the interleukins and the chemokine receptors, was proposed more than a decade ago and is now widely used (2). In this nomenclature, CC chemokines are named CCL*n*, for CC chemokine ligand since they have two adjacent cysteines near the N terminus, where *n* is the number that corresponds to the gene symbol number given to each chemokine when they were called SCY "n" for small secreted cytokine, followed by a number. Likewise, the CXC chemokines are named CXCL*n*, for CXC chemokine ligands, since the two N-terminal cysteines are separated by one amino acid represented in this name with an "X."

As mentioned, chemokine families are defined on the basis of the spacing of the first two cysteine amino acids in the mature protein. Based on this, four families of chemokines exist. In α or CXC chemokines, the cysteine residues are separated by a single amino acid. A further subdivision of CXC chemokines relates to the presence or absence of the sequence glutamic acid-lysine-arginine (ELR) near the N terminus of the protein. In general, ELR CXC chemokines chemoattract neutrophils, whereas non-ELR-containing CXC chemokines attract lymphocytes. In β or CC chemokines, the cysteine residues are adjacent to each other. The first and third cysteine are missing in the (X) C family of chemokines, which includes the chemokine XCL1. CX3CL1 is a single member of the CXXXC chemokine family, with three intervening amino acids between the proximal two cysteine residues. CX3CL1 and CXCL16 are also unique in that they exist in both soluble and membrane-anchored forms; the membrane-anchored form is expressed as a cell surface glycoprotein, with the "chemokine domain" sitting on top of a mucin-like stalk, and has both transmembrane and cytoplasmic domains.

Chemokine Receptors

All chemokines signal via seven transmembrane-spanning GPCRs (1), which are named by a numbering system based on the type of chemokine to which they bind (CC, CXC, CX3C, C) (Tables 1 and 2). GPCRs are a highly versatile group of proteins that have evolved to sense subtle changes in concentration gradients and are involved in signal transduction for vision, olfaction, hormone reception, and neurotransmission in addition to directional cell movement (1). As signal transducers of chemotaxis, the GPCRs appear to be highly conserved in evolution, being present on amoebae and slime molds, and are involved in the signaling of chemotaxis in these simple eukaryotes.

GPCRs consist of an extracellular N terminus, an intracellular C terminus, and seven transmembrane-spanning regions (1). Chemokine binding to the extracellular portion of the receptor results in intracytoplasmic signaling, which is mediated in part through heterotrimeric G proteins of the $G\alpha_i$ subclass. Chemokines may present to chemokine receptors in both the liquid and solid phases (5). Chemokine receptor binding occurs between both the chemokine in solution and the chemokine bound to matrix and cell surface glycosaminoglycans (1). The binding of chemokine to receptor results in a complex signaling cascade that may result in directed cell movement, cell activation, differentiation, and/or cell proliferation (1–4). The activation of chemokine

doi:10.1128/9781555818722.ch37

TABLE 1 Chemokines

Chemokine	Other names	Receptor	Key/main immune function
CXCL1	GROα, MGSA, mouse KC	CXCR2	
CXCL2	GROβ, MIP-2α, mouse MIP2	CXCR2	Neutrophil trafficking
CXCL3	GROγ, MIP-2β	CXCR2	
CXCL4	PF4	?	Procoagulant
CXCL5	ENA-78, mouse LIX	CXCR2	
CXCL6	GCP-2	CXCR1, CXCR2	Neutrophil trafficking
CXCL7	NAP-2	CXCR2	
CXCL8	IL-8 (no mouse)	CXCR1, CXCR2	
CXCL9	Mig	CXCR3	
CXCL10	IP-10	CXCR3	Th1 response; Th1, CD8, NK trafficking
CXCL11	I-TAC	CXCR3	
CXCL12	SDF-1	CXCR4	Bone marrow homing
CXCL13	BLC, BCA-1	CXCR5	B-cell and Tfh positioning LN
CXCL14	BRAK	?	Macrophage skin homing (human)
CXCL15	Lungkine (mouse only)	?	?
CXCL16		CXCR6	NKT and iLC migration and survival
CCL1	I-309, mouse TCA3	CCR8	Th2 cell and Treg trafficking
CCL2	MCP-1, mouse JE	CCR2	Inflammatory monocyte trafficking
CCL3	MIP-1α	CCR1, CCR5	Macrophage and NK cell migration; T-cell–DC interactions
CCL4	MIP-1β	CCR5	
CCL5	RANTES	CCR1, CCR3, CCR5	
CCL6	C-10, MRP-1 (mouse only)	Unknown	?
CCL7	MCP-3, mouse Fic or MARC	CCR2, CCR3	Monocyte mobilization
CCL8	MCP-2	CCR1, CCR2, CCR3, CCR5 (human); CCR8 (mouse)	Th2 response; skin-homing mouse
CCL9/10	MIP-1γ, MRP-2 (mouse only)	Unknown	?
CCL11	Eotaxin-1	CCR3	Eosinophil and basophil migration
CCL12	MCP-5 (mouse only)	CCR2	Inflammatory monocyte trafficking
CCL13	MCP-4	CCR2, CCR3, CCR5	Th2 responses
CCL14	HCC-1	CCR1	?
CCL15	Leukotactin-1, HCC-2, MIP-5	CCR1, CCR3	?
CCL16	HCC-4, NCC-4, LEC	CCR1, CCR2, CCR5	?
CCL17	TARC	CCR4	Th2 responses, Th2 cell migration, Treg, lung and skin homing
CCL18	PARC, DC-CK1	CCR8	Th2 response; marker AAM, skin homing
CCL19	ELC, MIP-3β	CCR7	T-cell and DC homing to LN
CCL20	MIP-3α, LARC	CCR6	Th17 responses; B and DC homing to gut-associated lymphoid tissue
CCL21	SLC, 6CKine	CCR6, CCR7	T-cell and DC homing to LN
CCL22	MDC	CCR4	Th2 response, Th2 cell migration, Treg migration
CCL23	MPIF-1, MIP-3	Unknown	?
CCL24	Eotaxin-2, MPIF-2	CCR3	Eosinophil and basophil migration
CCL25	TECK	CCR9	T-cell homing to gut; thymocyte migration
CCL26	Eotaxin-3	CCR3, CX3CR1	Eosinophil and basophil migration
CCL27	CTAK	CCR10	T-cell homing to skin
CCL28	MEC	CCR3, CCR10	T-cell and IgA plasma cell homing to mucosa
XCL1	Lymphotactin, SCM-1α	XCR1	Cross-presentation by CD8+ DCs
XCL2	SCM-1β	XCR1	
CX3CL1	Fractalkine	CX3CR1	NK, monocyte, and T-cell migration

TABLE 2 Chemokine receptors[a]

Receptor	Immune cell expression	Key immune function
G protein-coupled receptors		
CXCR1	N > Mo, NK, MC, Ba, CD8 T_{EFF}	Neutrophil trafficking
CXCR2	N > Mo, NK, MC, Ba, CD8 T	B-cell lymphopoiesis Neutrophil egress from bone marrow Neutrophil trafficking
CXCR3	Th1, CD8 T_{CM} and T_{EM}, NK, NKT, pDC, B, Treg, T_{FH}	Th1-type adaptive immunity
CXCR4	Most (if not all) leukocytes	Hematopoiesis Organogenesis Bone marrow homing
CXCR5	B, T_{FH}, T_{FR}, CD8 T_{EM}	B-cell and T-cell trafficking in lymphoid tissue to B-cell zone/follicles
CXCR6	Th1, Th17, γδ T, iLC, NKT, NK, PC	Innate lymphoid cell function Adaptive immunity
CCR1	Mo, MΦ, N, Th1, Ba, DC	Innate immunity Adaptive immunity
CCR2	Mo, MΦ, Th1, iDC, Ba, NK	Monocyte trafficking Th1-type adaptive immunity
CCR3	Eo > Ba, MC	Th2-type adaptive immunity Eosinophil distribution and trafficking
CCR4	Th2, skin- and lung-homing T, Treg, > Th17, CD8 T, Mo, B, iDC	Homing of T cells to skin and lung Th2-type immune response
CCR5	Mo, MΦ, Th1, NK, Treg, CD8 T, DC, N	Type 1 adaptive immunity
CCR6	Th17 > iDC, γδ T, NKT, NK, Treg, T_{FH}	iDC trafficking; GALT development Th17 adaptive immune responses
CCR7	T_N, T_{CM}, T_{RCM}, mDC, B	mDC and B-cell and T-cell trafficking in lymphoid tissue to T cell zone Egress of DC and T cells from tissue
CCR8	Th2, Treg, skin T_{RM}, γδ T, Mo, MΦ	Immune surveillance in skin Type 2 adaptive immunity thymopoiesis
CCR9	Gut homing T, thymocytes, B, DC, pDC	Homing of T-cells to gut GALT development and function thymopoiesis
CCR10	Skin-homing T, IgA-plasmablasts	Humoral immunity at mucosal sites Immune surveillance in skin
XCR1	Cross-presenting CD8+ DC, thymic DC	Ag cross-presentation by $CD8^+$ DCs
CX3CR1	Resident Mo, MΦ, MG, Th1, CD8 T_{EM}, NK, γδ T, DC	Patrolling monocytes in innate immunity Microglial cell and NK cell migration Type 1 adaptive immunity
Atypical (nonsignaling) receptors		
ACKR1 (DARC; Duffy)	RBC, LEC	Chemokine transcytosis Chemokine scavenging
ACKR2 (D6)	LEC, DC, B	Chemokine scavenging
ACKR3 (CXCR7)	Stromal cells, B	Shaping chemokine gradients for CXCR4
ACKR4 (CCRL1; CCX-CKR)	Thymic epithelium	Chemokine scavenging

[a]This table was adapted from reference 1. Abbreviations: B, B-cell; Ba, basophil; Eo, eosinophils; GALT, gut-associated lymphoid tissue; iDC, immature DC; LEC, lymphatic endothelium; MΦ, macrophage; MG, microglia; Mo, monocyte; N, neutrophil; pDC, plasmacytoid DC; PC, plasma cell; RBC, red blood cell; T_{CM}, central memory T cell; T_{EFF}, effector T cell; T_{FH}, follicular helper T cell; T_{FR}, follicular regulatory T cell; T_N, naive T cell; T_{RCM}, recirculating memory T cell.

receptors is usually accompanied by a transient rise in intracellular calcium. The G protein is itself coupled to a number of downstream intracytoplasmic signal transduction pathways, including those involving protein kinase C, tyrosine kinases, and PI-3 kinase (1–4) (Fig. 1). The direct link between these signal transduction pathways and the activation of the cytoskeletal machinery involved in cell motility has become better understood in recent years. Rho proteins, which are known to mediate actin-dependent processes, are thought to be involved in linking chemokine receptor activation to activation of the cytoskeletal machinery (6, 7). It is now understood that the synaptotagmin family of proteins, which are known to regulate calcium-dependent lysosomal vesicle transport and fusion, link chemokine-induced elevated intracellular calcium to activation of the cytoskeletal machinery and directed cell migration (8).

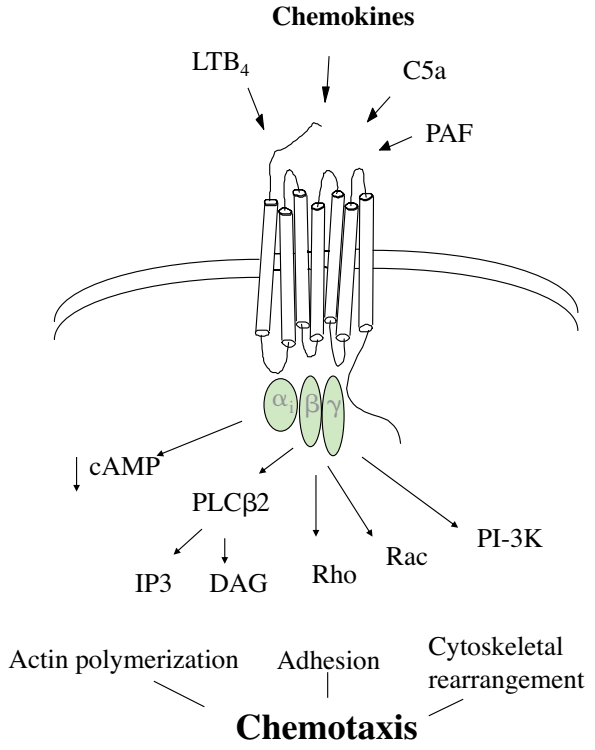

FIGURE 1 Chemokine receptor signal transduction. Chemokine receptors are a subfamily of G protein-coupled seven transmembrane-spanning cell surface receptors. They are coupled to heterotrimeric G proteins of the Gi subclass, which are distinguished by their pertussis toxin sensitivity. Chemokine receptor activation leads to the stimulation of multiple signal transduction pathways, including the activation of phosphatidylinositol 3-kinase (PI3K) and phospholipase C (PLC), leading to generation of inositol triphosphates, intracellular calcium release, and protein kinase C (PKC) activation. Chemokine signaling also induces the upregulation of integrin affinity and the activation of Rho, leading to cytoskeletal reorganization. Agonist-stimulated receptors also activate G protein receptor kinases, which leads to receptor phosphorylation, arrestin binding, G protein uncoupling (desensitization), and clathrin-mediated receptor endocytosis (internalization).

ROLE OF CHEMOKINES AND CHEMOKINE RECEPTORS IN DISEASE

The attraction of leukocytes to sites of inflammation and infection is an essential component of the host response to disease. Chemokines and chemokine receptors have been shown to be an integral part of this process and have been implicated in the pathophysiology of many infectious diseases and inflammatory disorders (1–4). Although chemokines are clearly important for the ability of the host to control infections, they can also be detrimental in certain inflammatory diseases, such as asthma, atherosclerosis, and rheumatoid arthritis (RA), and transplant rejection, in which inflammatory cells are recruited to tissue sites of inflammation and produce tissue damage (1, 9–12). For example, inflammation is a critical component of atherosclerosis, and the expression of multiple chemokines has been shown to be upregulated in human atherosclerotic lesions (10, 13). Prominent leukocyte recruitment occurs in almost every stage of lesion development, and the recruited monocytes and T lymphocytes are thought to play a key role in the pathogenesis of atherosclerotic plaque; thus, the molecular signals that attract these cells into the lesions are likely important for their formation (10, 14, 15). Mouse models of atherosclerosis have implicated the CC chemokine receptors (CCR) CCR2 and CCR5 as well as the CX3C chemokine receptor CX3CR1, which are important for monocyte trafficking and mobilization in the formation of atherosclerotic lesions, and highlight the importance of monocytes in the pathogenesis of atherosclerotic inflammation (16–18).

In contrast, the underlying pathology of RA is notable for very prominent infiltration of the synovial tissue of the joints by neutrophils in addition to mononuclear leukocytes, which presumably helps propagate the inflammation and joint destruction. Neutrophil (CXCL8, CXCL5, CXCL1), monocyte (i.e., CCL3, CCL5, CCL2), and T-cell (i.e., CXCL10, CXCL9, CCL3, CCL5, CCL17)-attracting chemokines are expressed by fibroblasts and macrophages in the synovium of RA patients (12, 19). Consistent with this chemokine expression, synovial fluid T cells recovered from patients with active RA express high levels of the chemokine receptors CCR5 and CXCR3 (20). Confirming the importance of neutrophils in the pathogenesis of RA, in a serum-transfer mouse model of RA, inflamed synovial tissue cells produced different neutrophil-active CCR1 and CXCR2 ligand chemokines, which are absolutely required for the induction of arthritis in this model (21). Initially, CCR1 ligands and, later, CXCR2 ligands in the joint amplify the recruitment of neutrophils which, by releasing multiple mediators such as LTB_4, IL-1β, and CXCL2, orchestrate inflammation in the joint. This mouse model of arthritis also highlights an important principle of chemokine-mediated inflammation *in vivo*, in that the generation of full-blown arthritis requires that this sequential cascade must run its course; otherwise, inflammation is dampened.

As another example, asthma is a disease characterized by chronic inflammation of the airways; studies in animal models and humans suggest that allergen inhalation initiates a cascade of events that leads to the recruitment of eosinophils, neutrophils, lymphocytes, and mast cells into the airways (22–24). Chemokines have been implicated as important mediators of this cellular recruitment and are likely crucial for the development of allergic inflammation in the airways (23, 24). Data from bronchoalveolar lavage (BAL) and lung biopsy studies have demonstrated the upregulation of the chemokines CCL11, CCL24, CCL7, CCL13, CCL5, CCL17, CCL22, and CXCL10 in patients with asthma attacks or after an allergen challenge (24, 25). Some of these chemokines recruit eosinophils and others affect T-cell trafficking. Analogous to RA, animal models of asthma, however, suggest that no single chemokine controls all aspects of cell trafficking into the airway; rather, multiple chemokines likely work in a sequential and redundant manner to orchestrate the inflammation (24).

Chemokines also have been implicated in the organ transplant setting. Although a transplant is often life-saving therapy for the large number of patients with end-stage kidney, liver, heart, or lung disease, it ushers in a new set of problems and diseases for the organ recipient. These include increased risk of infection, organ ischemia-reperfusion injury, acute rejection, and chronic organ dysfunction from chronic rejection. These processes involve recruitment of leukocytes into the transplanted organs, with neutrophil recruitment dominating infections and ischemia-reperfusion injury and lymphocytes and monocyte recruitment involved in rejection. Infections of organs, organ ischemia-reperfusion injury, acute rejection, and chronic rejection

lead to increased expression of multiple chemokines. These chemokines are surprisingly similar in all organs after transplantation, although organ-specific differences do exist (26, 27). In studies looking at chemokine expression following human organ transplantation, the expression of CXCL8/IL-8 has been associated with ischemia-reperfusion injury (28), while CCL5, CCL2, CCL3, CCL4, CXCL9, CXCL10, and CXCL11 have been associated with acute rejection (26, 28–32). In chronic rejection of lungs, CXCL8, CCL5, CXCL9, CXCL10, CXCL11, and CCL2 are upregulated and may be predictive of the development of this complication (29, 33).

In conclusion, as illustrated above, different leukocyte subsets bear signature combinations of chemokine receptors (Table 2), and the chemokine-chemokine receptor axis likely promotes pathologic accumulation of specific leukocyte subsets, which in turn facilitate different types of inflammation in affected tissues (34). In such disorders, it has been suggested that the chemokine-chemokine receptor axis could be used as a diagnostic tool for characterizing the type of inflammation and the functional phenotype of the leukocytes that provoke the inflammation; this information could then be used to develop targeted therapeutics for controlling inflammation (1, 35). Tailored therapeutics directed against the chemokine-chemokine receptor axis in diseases such as asthma, RA, and transplant rejection may provide a means of avoiding the adverse side effects of the broad immunesuppressive therapies that are currently used to treat these diseases in clinical practice.

Clinical Applications for Analyzing Chemokine Expression in Disease

In the past decade, validated assays for measuring chemokine mRNA and protein have become widely available. In particular, more than a few commercial kits routinely allow for the simultaneous multiplexed measurement of many inflammatory cytokine and chemokine proteins from small amounts of sample. Assays that measure chemokines in serum and affected tissue could provide a noninvasive and relatively inexpensive adjunct diagnostic tool for diagnosis as well as phenotypic classification and provide a means of quantifying disease severity for the purposes of stratification, prognostication, and treatment. These assays may thus be useful in guiding the initiation of therapy and aid in monitoring the subsequent response to therapy. For instance, a clinical setting in which such a strategy might be usefully employed is in the management of refractory asthma. Currently, clinicians monitor the effectiveness of therapy in people with asthma based on symptom reporting and crude measures of lung function. Acute exacerbations of asthma are life-threatening complications of this disorder that often occur rapidly. In addition, it is hypothesized that long-term low-grade inflammation, which can be missed with routine monitoring, may lead to scarring of the airways and permanent changes in lung function. Importantly, it is now appreciated that human asthma is a heterogeneous disease, and therapeutic strategies directed at a single allergic inflammation-promoting cytokine may be successful only in subpopulations of patients with asthma in whom the therapy is matched to the underlying pathophysiology (36, 37). Unfortunately, available technology does not allow us to easily measure the degree of asthmatic airway inflammation and thus predict a patient's risk for an exacerbation or airway scarring/remodeling. Nor does it allow for the characterization of the type of inflammation driving the particular subtype of asthmatic airway inflammation to predict the most effective targeted therapy. Chemokine expression in the lung or blood could be used as a reliable noninvasive marker of inflammation in the airways and thus would be of great value in the management of asthma. The technology to measure chemokine levels in exhaled breath condensates is available and has been used in limited studies for measurements in children with asthma (38). In addition, expectorated sputum or serum has been used in assays to measure chemokine levels and predict exacerbations in patients (39). Finally, allergic asthma can often be confused with related disorders such as emphysema, bronchiolitis, and eosinophilic bronchitis. These disorders have different forms of airway inflammation and thus may have a different profile of chemokines expressed. Thus, it may be possible to use the chemokine or chemokine receptor profiles of samples from the lung or serum to accurately diagnose a patient with airway inflammation. The use of measurements of markers of inflammation such as chemokines could have a large impact in the diagnosis and management of asthmatics.

Another disease in which monitoring chemokines in serum or affected tissue may have implications for disease prognosis and management is RA, as suggested by some recent supportive data. In a nested case-control study, a Scandinavian study monitored 30 chemokines and cytokines by multiplex analysis in banked blood samples of 69 individuals prior to the onset of symptoms of joint disease and subsequent to the diagnosis of RA (12). After anticyclic citrullinated peptide (anti-CCP) antibodies, the most important elevated factors that differentiated asymptomatic patients who went on to develop RA from control subjects included the chemokines CCL11, CCL2, CXCL10, and CCL3 and the cytokines IL-13, IL-10, IL-9, and IL-1Ra. The factors that best discriminated between patients after the onset of RA and control subjects included anti-CCP antibodies, the chemokines CCL4, CXCL9, and CCL11, and the cytokines IL-6, IL-10, and G-CSF. A second study measured chemokines and cytokines in synovial fluid by multiplex analysis and found that the chemokines CCL11, CXCL11, CCL8, CXCL9, CCL5, CCL17, and CXCL8 were elevated in synovial fluid from RA compared with those in osteoarthritis (19). The finding of CCL11, a chemokine associated with eosinophil migration and allergic inflammation, in both of these studies, and elevated serum Th2 cytokines in the first study, is surprising and provides potential new insights for investigation to understand the pathophysiology of RA. Finally, monitoring serum chemokines and cytokines in association with anti-CCP antibodies may provide better sensitivity and specificity in at-risk asymptomatic individuals than anti-CCP antibodies alone in predicting the risk of developing RA, to possibly aid in preventing disease progression.

In solid organ transplant, frequent episodes of acute rejection and untreated low-grade rejection are thought to lead to chronic organ dysfunction, which is the major limiting factor in long-term graft survival. Thus, the ability to better detect these processes could have a major impact in the management of posttransplant patients. The expression of specific chemokines during episodes of acute rejection or in low-grade chronic rejection may be a biomarker of inflammation and could allow better detection of these processes. In the renal transplant setting, the finding that chemokines were important mediators of allograft injury in animal studies (40) prompted investigators to develop assays to monitor chemokines in the urine of human kidney transplant recipients. These studies led to the finding that urine CXCL9, CXCL10, and CXCL11 mRNA are elevated in patients with acute rejection, acute tubular injury, or BK

virus nephropathy compared with individuals with chronic rejection or stable renal function and healthy individuals, suggesting their potential utility as biomarkers (32, 41). Urine chemokine measurements may also have a role in predicting late graft failure, as urine CCL2 levels 6 months posttransplant were associated with the development of interstitial fibrosis, tubular atrophy, and graft dysfunction at 24 months (42). Thus, measuring urinary chemokine biomarkers could be a cost-effective noninvasive graft-sparing alternative to allograft biopsy that may limit long-term allograft injury, particularly in high-risk patients. Ongoing prospective multicenter validations of these assays and clinical trials, to test whether urinary chemokine levels can guide immunosuppressant withdrawal in low-risk patients and direct specific therapeutic strategies to limit graft injury for better individualized treatment strategies, will help to determine better the clinical utility of urinary chemokines as biomarkers. In conclusion, the ability to measure chemokine levels in serum or sputum suggests that noninvasive, reliable, cost-effective chemokine biomarkers may also have a useful role in the setting of other organ transplants to assess the risk of graft injury to prolong graft survival.

METHODOLOGICAL APPROACHES

Overview

Since inflammatory and immune cell localization appears to be central to the pathogenesis of a wide variety of diseases, numerous avenues for studying the role of chemokines and chemokine receptors have emerged. These techniques follow a logical progression from the characterization of the inflammatory or immune cell infiltrate through the measurement of chemokine and chemokine receptor distribution in diseased tissues, the establishment of *in vitro* models of chemotaxis, and *in vivo* dissection of the role of chemokines in animal models of the disease process. This series of approaches has enabled the definition of the role of chemokine and chemokine receptor-driven immune and inflammatory cell localization in a variety of diseases.

Analysis of the Cellular Infiltrate and Chemokine/Chemokine Receptor Milieu

The first step toward understanding whether localization of immune or inflammatory cells influences a disease process is to define the cellular composition of the infiltrate seen in sites in the body that are affected by the disease. This may be best done by one of two methods: immunohistochemistry of tissue sections or staining of cellular preparations obtained from disaggregated pathological specimens. There are a large number of monoclonal antibodies that enable the definition of subpopulations of immune and inflammatory cells and the characterization and quantitation of chemokine and chemokine receptor expression (43, 44). Monoclonal antibodies that are reactive to specific antigens expressed on T cells, B cells, monocytes, macrophages, dendritic cells, neutrophils, eosinophils, and basophils/mast cells can be utilized to detect these cells or specific subsets of these cells in frozen sections using immunohistochemical techniques. The immunoperoxidase technique using the avidin-biotin complex has enhanced sensitivity, and stained slides can be mounted and stored permanently. In addition, sections can be counterstained with hematoxylin and eosin, for example, to provide additional morphologic information. Serial sectioning allows the assessment of three-dimensional (3D) relationships between subsets of immune and inflammatory cells in tissue specimens. Appropriate isotype controls should be run with experimental immunostaining to establish levels of background nonspecific staining.

Fluorescent conjugated monoclonal antibodies targeting specific cell surface molecules can be similarly used to establish the cellular makeup of a tissue infiltrate (43). Tissue samples can be physically disaggregated and then passed through a sterile sieve. Mononuclear cell preparations can then be stained with monoclonal antibodies and the immunophenotype of cell populations can be determined by fluorescence-activated cell sorting–based flow cytometry. As many as 18 different fluorochromes can be used, depending on the number of available lasers, to define cell subpopulations. Again, appropriate isotype antibody controls should be used to establish background and nonspecific staining.

Another aspect of the analysis of cellular infiltrates is the determination of levels of chemokine or chemokine receptor expression. A combination of methods can be used, including RNA *in situ* hybridization, immunohistochemistry, quantitative reverse transcriptase PCR (QPCR), ELISA or protein multiplexing technology, and flow cytometry. Monoclonal antibodies directed against a number of chemokines suitable for use in staining tissue sections, ELISA, or protein multiplexing have been defined and validated over the past decade. These antibodies can be used as a basis for measuring chemokine protein concentrations from tissue lysates and fluid collections. A number of different chemokines can be detected by sandwich ELISAs, which are commercially available as kits. Initially, microtiter plates are coated with the capture antibody and nonspecific protein binding is adsorbed with goat serum or bovine serum albumin. Chemokine-containing samples are then added to the wells of the plate and this is followed by exposure to a second enzyme-conjugated antibody. A caveat, when using ELISAs for the measurement of proteins in serum and tissue such as synovial fluid from individuals with autoimmune disorders, is the presence of heterophilic human anti-animal antibodies such as anti-mouse antibodies, which can cause false-positive and false-negative results (19). Use of appropriate blocking reagents and diluents can obviate these technical issues (19).

Multiplex microwell protein array kits are now widely available and can also be manufactured to detect custom combinations of proteins. Similarly, these chemokine-specific monoclonal antibodies are also available conjugated to a fluorochrome or to fluorescent bead arrays, which allows them to be used to assess intracellular chemokine levels in permeablized cells or to assess the levels of multiple chemokines simultaneously in various biologic samples using flow cytometry technology. Monoclonal antibodies specific for individual chemokine receptors are also commercially available and are used to determine the expression of chemokine receptors on individual cells *in situ* or those isolated from inflammatory tissue or fluid via immunohistochemistry or flow cytometry.

Analysis of Chemotactic Responses: *In Vitro* Assays

Having defined the chemokine and chemokine receptor expression in the diseased tissue, one can examine the chemotactic responses of the specific leukocyte subpopulations to chemokines. A variety of transmigration assays exist which exploit the ability of migratory cells to polarize and migrate in response to a chemotactic gradient. The *in vivo* correlate of *in vitro* transmigration is thought to be the migration of cells towards sites of tissue injury, pathogen invasion, and/or immune challenge. Cells to be used in the transmigration assays can be derived from a number of sources, including the diseased tissue itself or purified subpopulations of inflammatory and immune cells isolated from the peripheral blood.

Boyden Chamber

The Boyden chamber, designed in 1962, represents the original system by which the chemotactic responses of cells can be quantitated (45). The assembly consists of two chambers, an upper and a lower, separated by a polycarbonate filter of standard pore sizes. Disposable Boyden chambers containing polycarbonate membranes with defined pore sizes for different cell types are commercially available. Membranes with a pore size of 3 μm for neutrophils; 5 μm for lymphocytes, monocytes, and eosinophils; and 8 μm for fibroblasts, endothelial cells, and tumor cells are used to assay migration. The chemokine, dissolved in medium containing a low percentage of serum or 0.5% bovine serum albumin, is loaded into the lower chamber. A fixed number of indicator cells in suspension at cell concentrations of 10^6 to 10^7/ml are loaded in an identical medium into the upper chamber. The unit is then sealed and incubated at 37°C for 30 min to 1 h for granulocytes, 1 to 2 h for monocytes, and 2 to 4 h for lymphocytes.

Transmigration is then assessed in a number of ways. The polycarbonate membrane is carefully removed from the assembly, and the cells that are adherent to the underside of the filter are stained with Giemsa and quantitated. Alternatively, the cells that have transmigrated into the lower chamber are counted using a hemocytometer and the proportion of migrating cells is determined. If the migration index is low and cells are adherent to the bottom chamber, an inverted light microscope may be used to count multiple fields within the chamber after the experiment or after fixation with 10% buffered formalin. Ultimately, a so-called checkerboard analysis of chemotaxis can be performed in which every combination of chemokine concentration in the lower chamber is combined with every tested concentration of chemokine in the upper chamber. Chemotaxis is defined as cell movement toward increasing chemokine concentration. Chemokinesis refers to random or nondirectional cell movement in response to a stimulus. In the checkerboard analysis, chemotaxis is measured when there is a greater concentration of chemokine in the lower chamber, and chemokinesis is measured when the concentration of chemokine is equivalent on both sides of the membrane (Fig. 2). Chemotactic index is calculated by normalizing the number of cells that migrate at a concentration of chemokine to the number of cells that migrate in response to medium alone.

Automated quantitation of transmigration can also be achieved by loading cells to be tested with a vital fluorescent dye such as 5-chloromethylfluorescein diacetate (CMFDA), acridine orange, or Calcein AM and then using a fluorescent plate reader to quantitate the number of cells in the lower chamber (46). Alternatively, migrated cells can be lysed and labeled with a DNA-binding dye such as Cyquant and quantitated with a fluorescent plate reader. A further modification of the fluorescent plate reader includes the ability to read the kinetic changes of transmigration into the lower chamber over time.

Transwell Assays

More recently, transmigration assays have been performed in a transwell system (47). In this assembly, each lower chamber is associated with an independently removable upper chamber containing the polycarbonate membrane of fixed pore size. A checkerboard analysis of chemotaxis can be similarly performed in the transwell system. The Boyden chamber appears to be markedly better for analyzing granulocyte movement with a polycarbonate membrane of 3 μm pore size, whereas transwells containing membranes with a 5-μm or 8-μm pore size have proven useful for quantitating mononuclear cell migration. Several modifications of transmigration have been designed. These include the assessment of transmigration through a layer of cells grown on the transwell membrane. Transmigration of lymphocytes, eosinophils, or monocytes through an endothelial cell layer has been assessed by this means. Transmigration systems allow further phenotypic characterization of responding cell subpopulations from a complex mixture of input cells. Using flow cytometry, cells that transmigrate can be phenotypically compared with those that do not.

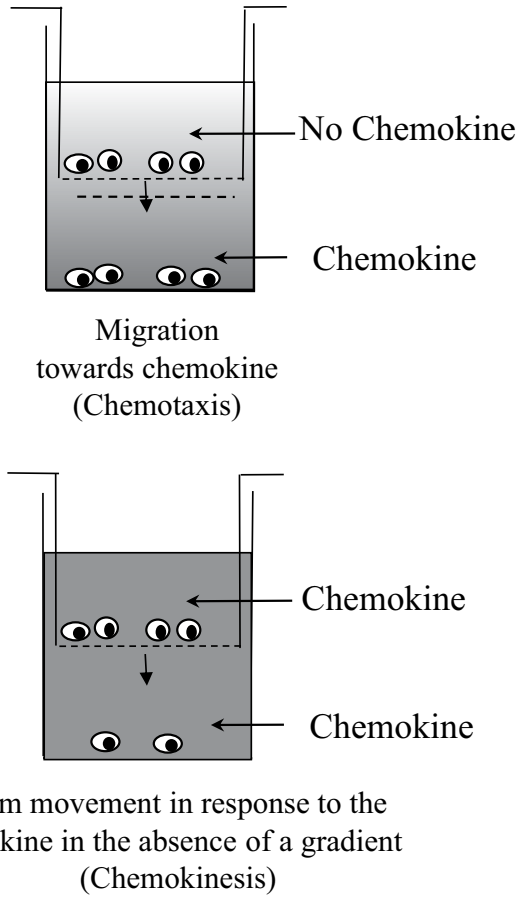

FIGURE 2 Transmigration assay system. Positive, negative, and absent gradients of a chemokine are established in order to assess chemotaxis (movement towards a chemokine) and chemokinesis (random movement of cells in response to a chemokine in the absence of a gradient). Cells are plated into the upper chamber of the transwell system or Boyden chamber and the proportion of migrating cells determined by accurate counting of cells that migrate to the lower chamber. The upper and lower chambers are separated by a polycarbonate membrane of standard pore size (3 μm to 8 μm), depending on the migrating cell type.

Direct Visualization

Additional modifications of the Boyden chamber have been made, including the use of an image analyzer to quantitate the number of labeled cells that migrate in response to a chemokinetic agent (48). Transmigration with a Boyden chamber or transwell assay can also be confirmed using time-lapse video microscopy with a direct-viewing approach in which cells migrate on a horizontal surface (Fig. 3) (49). The active movement of cells is viewed with a video camera

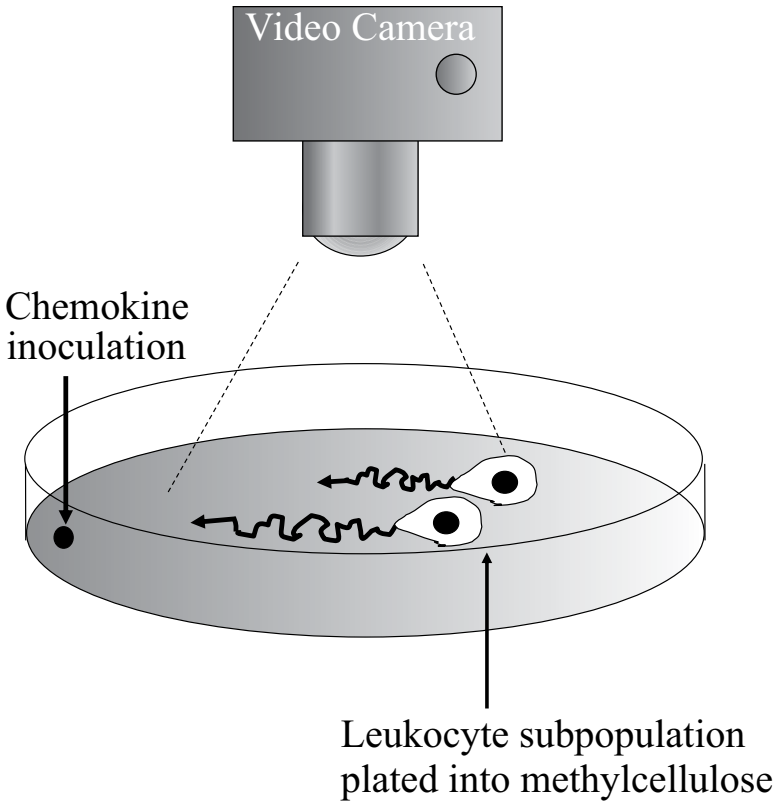

FIGURE 3 Digitized time-lapse photography of cells moving in the presence of a gradient of chemokine. Positive and negative gradients of a chemokine can be established in methylcellulose, as previously described (49). Cells are plated into methylcellulose and a gradient is established by inoculating the methylcellulose at a fixed point with the chemokine. Cells are then visualized migrating in response to the gradient using time-lapse video microscopy.

as they respond to gradients of a chemokinetic agent. A continuous gradient of chemokine or a point source of chemokine can be used to manipulate the directional movement of cells. Cell movement can also be tracked using digital video and images analyzed for cell polarization and speed of movement towards a chemokine source, using leukocytes or other organisms such as *Dictyostelium* (50, 51). These modalities allow the measurement of many parameters such as cell morphology, area, and location during chemotaxis. Automated chemotaxis and cell morphology assays in a 96-unit direct-viewing plate in a high-throughput format can also now be achieved (52). In recent years, the EZ-Taxiscan has become commercially available (53, 54). The EZ-Taxiscan is a horizontal viewable chemotaxis chamber in which a microchannel connects a compartment containing ligand and another compartment containing cells. A stable chemoattractant concentration gradient is formed and maintained through the channel without the flow of medium. The migration of cells in the chambers can be traced with time-lapse intervals using a charge-coupled device camera.

Adhesion Assays

The migratory response of immune cells *in vivo* involves a rapid adhesive event in which the circulating cell is stimulated to adhere firmly to the endothelial surface over which it flows and rolls; this event is necessary for a cell to undergo diapedesis into an immune organ or an inflammatory site (1–4). This event is triggered by chemokines and involves the upregulation of integrin affinity on leukocytes. This aspect of cell migration can be studied *in vitro* in a static adhesion assay or dynamically using a flow chamber to visualize the adhesion of leukocytes to endothelial cell monolayers. In these latter systems, endothelial cell layers are established on cover slips, and fluorescently labeled leukocytes are passed over these monolayers at controlled flow rates; the number of cells rolling or sticking to the endothelial layer is determined using image analysis and digitized time-lapse video microscopy. *In vivo* flow systems have been designed that use intravital microscopy (IVM) to visualize and quantitate the adhesion and transmigration of fluorescently labeled leukocytes in the vasculature of living animals (55).

Assays To Measure Integrin Conformation Change

In the steady state, leukocytes express integrins, which are in an inactive conformation that does not mediate adhesion. Chemokines activate integrin function by inducing a change in integrin conformation that increases the affinity and/or avidity of the integrin for its ligand, which leads to inside-out integrin activation. This chemokine-mediated conformational change that transiently results in high-affinity integrins can be measured with monoclonal antibody (MAb)-based flow cytometry assays (56). Chemokine-induced integrin conformational changes in activated integrins result in exposure of previously masked epitopes, which can be detected with monoclonal antibodies that detect high-affinity integrins. Detection of high-affinity β2 integrins can be achieved using the antibody MAb24 (57). Binding of this antibody occurs only at 37°C. Leukocytes are stimulated with chemokines in

the presence of MAb24, rapidly cooled on ice to terminate any additional MAb24 binding, and fixed with paraformaldehyde (58). Likewise, a high-affinity β1 integrin can be detected by flow cytometry after stimulation with chemokine with the HUTS-21 MAb (59).

Analysis of Signal Transduction Associated with Active Cell Movement

The signal transduction events activated by ligand binding controlling leukocyte migration are not entirely defined and involve many different signaling pathways. A dramatic polarization of the cell occurs in response to a chemotactic gradient which is the result of asymmetric signal transduction and the establishment of intracellular molecular gradients. While all of the molecular details remain to be elucidated, certain signaling molecules appear to play important roles in chemokine-induced cell movement. Chemokine receptors are coupled to the Gi subfamily of G proteins and pertussis toxin (PTX), which ADP-ribosylates and irreversibly inactivates the Gα subunits of the αi class and inhibits the majority of chemokine-induced effects on leukocytes, including chemotaxis, calcium flux, and integrin activation (1). Other signaling events activated by the majority of chemokine receptors include the activation of phospholipase C (PLC), leading to generation of inositol triphosphates, intracellular calcium release, and protein kinase C (PKC) activation. Inhibition of chemokine-induced chemotaxis by wortmannin implicates phosphatidylinositol 3-kinase (PI3K) in chemokine receptor signal transduction. Mouse strains engineered with a null mutation of the p110 subunit of PI3Kγ have defects in chemokine-induced neutrophil and macrophage migration, confirming the importance of this enzyme in directed leukocyte movement (60). PMA activation of integrins implicates PKC as a potential mediator by which chemokines activate integrins. Chemokine signaling also leads to guanine nucleotide exchange on Rho, indicating the activation of Rho (7). Rac and Rho are small GTP-binding proteins involved in controlling cell locomotion through regulation of actin cytoskeletal rearrangement, leading to membrane ruffling and pseudopod formation.

The first and most immediate indication of a signal being transduced in relation to chemokine-induced signaling is a measurable rise in intracellular calcium concentration. The calcium flux is transient and may be detected using several methods (61). Cells are examined within cuvette-based techniques that assess calcium flux in populations of cells and flow cytometry-based systems, which assess individual cell calcium flux responses to chemokine. Emission ratio dyes such as Indo-1 and Fura-2 are commonly used for flow cytometry-based and cuvette-based methods, respectively. Cells to be tested, including monocytes and lymphocytes, are loaded with ionic calcium-binding dyes. Cells are then exposed to sequential pulses of chemokine, and the change in intracytoplasmic fluorescence is monitored. Control substances include ionomycin, which selectively causes a large calcium flux because it serves as a calcium ion channel in the membrane. EDTA can be used to deplete all calcium from the medium and hence eradicate any cell-related calcium flux. Modifications have been made in order to determine the calcium flux in single cells. Adherent cells on a single slide can be visualized, and loading of calcium dyes and intracytoplasmic changes in calcium concentrations can be monitored directly under a fluorescent microscope with an associated image analyzer. The GTPγS exchange assay can also be used in both cell membranes and permeabilized peripheral blood lymphocytes to assess the first step of G protein-coupled receptor activation (62).

Activation of additional signal transduction pathways can be measured in cells in response to activation by chemokines (1). Adenylate cyclase assays, phosphoinositide turnover, protein kinase activation, and assays of protein tyrosine kinase activity have all been used to measure chemokine receptor activation.

Although the precise mechanistic link between chemokine receptor activation and the activation of the cytoskeletal machinery, which induces cellular migration, remains unknown, the polymerization of filamentous F-actin has been used as a measure of chemokine-induced functional signaling (63). Intracellular F-actin polymerization can be quantitated using FITC-labeled phalloidin and flow cytometry (63). This technique has been especially useful for assaying small numbers of responding cells. Polymerized F-actin can also be visualized in cells by using confocal microscopy in conjunction with a fluorescently labeled MAb directed against F-actin. These studies have revealed that signal transduction occurring after exposure to a chemokinetic gradient results in the polarization of the cell's cytoskeletal elements and polymerization of activated actin at the leading edge of a cell's newly formed pseudopodia. The Arp2/3 complex has recently been shown to colocalize with and nucleate sites of actin polymerization. An engineered GFP-Arp2/3 fusion protein has been used to visualize sites of actin polymerization in the advancing pseudopods of migrating cells by using phase contrast fluorescent time-lapse photography (64). A time-lapse fluorescent microscope with a digital spot camera can be used to visualize the polarization of actin polymerization and pseudopod formation in cells transduced with the GFP-Arp2/3 construct and exposed to gradients of chemokines.

In Vivo Analysis of Chemotactic Responses

In Vivo Recruitment Assays

Several systems have been developed to assess leukocyte infiltration into specific anatomical sites *in vivo*. Chemokines can be injected intradermally, subcutaneously, or intratracheally or into the intraperitoneal space, and leukocyte infiltration can thus be quantified (65). Recruitment of endogenous leukocytes or adoptively transferred leukocytes can be assessed in this manner. Leukocytes can be labeled *ex vivo* with radiolabels such as indium-111 or with fluorescent dyes such as green fluorescent protein (GFP) or CMFDA (5-chloromethylfluorescein diacetate-green). In addition, MAbs exist that can recognize adoptively transferred antigen-specific T cells or congenic allelic markers. A transgenic mouse has been engineered in which the vast majority of T cells express a T-cell receptor (TCR) which binds ovalbumin (OVA) (66). This specific TCR chain can itself be detected using an MAb (66). T cells reactive to a specific antigen can be quantitated, and the localization of adoptively transferred OVA-specific T cells in specific anatomic sites can be detected by immunostaining for OVA-specific TCR.

In vivo Imaging

More recent technology, known as molecular imaging, allows scientists to assay several different aspects of chemokine biology in intact organisms. It is now possible to evaluate, with imaging, the distribution of injected chemokines as well as to track the movement of cells in response to chemokines or inflammation (67). This is a rapidly developing field that uses techniques of molecular and cell biology, advanced imaging technology, and highly specific probes

that serve as sources for the imaging signal. Specifically, whole-body imaging of animals or humans after injection of radiolabeled chemokines or bioluminescent cells allows localization of the labeled material to specific organs and areas of the body. Whole-body imaging of radioactive material or light generated deep within the body is now feasible in laboratory animals and, potentially, in humans, representing an exciting new tool for studying chemokine biology.

Multiphoton IVM

For almost 2 decades, intravital microscopy (IVM) enabled the two-dimensional imaging of leukocyte adhesion to endothelial cells, as well as leukocyte migration and extravasation from blood into tissue *in vivo* and in models of organ systems *in vitro* through bright-field transillumination and epifluorescence videomicroscopy (55). The advent of two-photon microscopy (2-PM) for *in vivo* live-cell imaging a decade ago revolutionized IVM because it provided an unprecedented live 3D window into leukocyte migration, cellular interactions, and the dynamics of innate and adaptive immune responses in lymphoid and peripheral tissues (Fig. 4) (68–71). Conventional single-photon fluorescence microscopy uses excitation wavelengths within the visible spectrum; 2-PM uses very brief laser pulses of excitation wavelengths in the infrared spectrum to generate optical sections of fluorescent signals hundreds of micrometers below the surface of solid tissues.

In 2-PM microscopy, a single fluorochrome molecule has to be hit nearly simultaneously by two infrared photons that are double the wavelength but half the energy of visible light (68–71). Infrared excitation light is scattered less because of its longer wavelength and, as such, has a

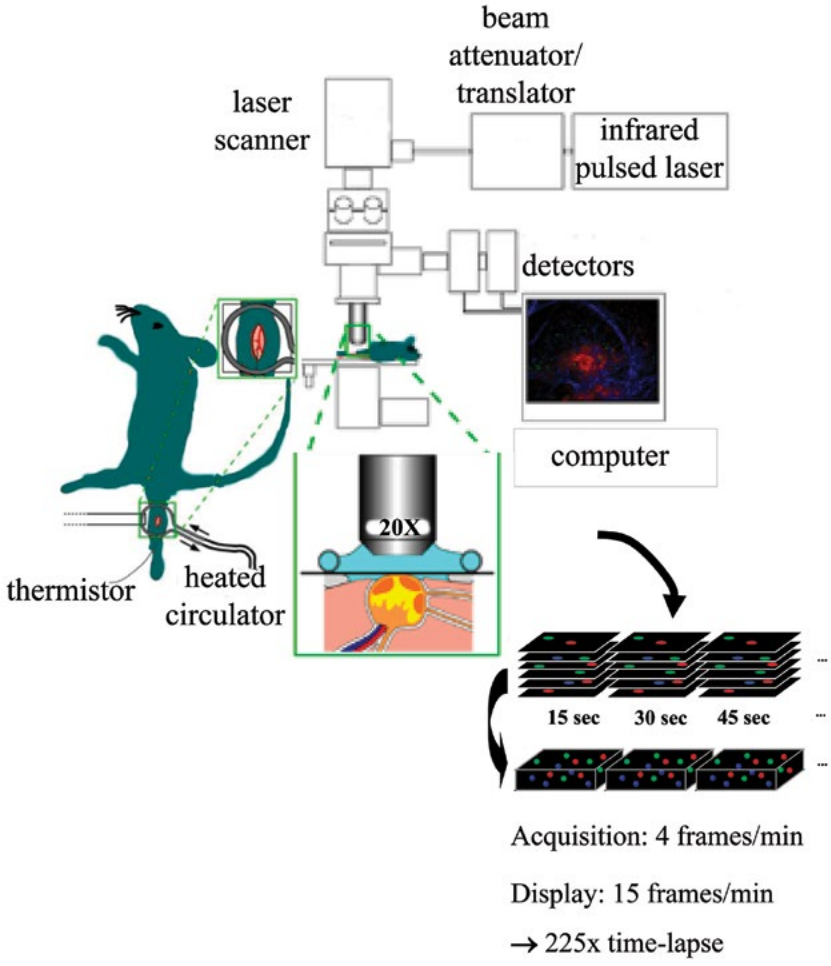

FIGURE 4 *In vivo* analysis of cell motility by multiphoton IVM in popliteal lymph node. The basic multiphoton microscope system consists of an infrared laser to deliver two-photon excitation; a laser intensity adjuster to decrease the laser power; a beam translation optical system to convey the laser beam to the back aperture of the objective; a laser scan head to raster scan the field of view with the microscope objective by rapid synchronized movement of dichroic steering mirrors; a low-magnification high-numerical-aperture water immersion objective; and external nondescanned detectors to concurrently acquire multiple fluorescent channels. The popliteal lymph node is visualized by making a skin incision in the knee, which is immersed in saline and sealed with a cover slip and vacuum grease after percutaneous clamps are used to prevent tissue movement. A thermistor is used to monitor temperature close to the lymph nodes, and the temperature is adjusted with a heating coil. Fluorescence is induced only in the focal plane; vertical image stacks are repetitively acquired that are then transformed into 3D images. Figure adapted from Mempel et al. (73).

higher penetration depth. Ultrashort laser pulses elicit the near-simultaneous excitation of two infrared photons with identical fluorochrome molecules; this occurs only within a very small volume of the focal point of the optical system. Consequently, as light scatter and fluorochrome bleaching outside of the focal plane are eliminated, tissue photodamage is minimized and fluorescent properties of the specimen are conserved to allow continuous imaging of the same area of tissue for several hours. In contrast to single-photon excitation microscopy, multiphoton microscopy also allows several fluorescent dyes or proteins with distinct emission and excitation characteristics to be visualized concurrently with two-photon excitation. Thus, the behavior and movement of different cell subsets labeled with different fluorescent dyes or proteins can be captured in deep tissue simultaneously with the rapid acquisition of 3D image stacks. The combination of MPM technology with IVM (MP-IVM) enables the investigation of the dynamic nature of cell behavior and migration deep within living tissue through time-lapse movies of 3D tissue reconstructions (Fig. 4) (68).

The utility of MP-IVM can be harnessed only if cells and tissue structures are fluorescently labeled (69, 70). In this respect, blood vessels can be labeled as structural landmarks with fluorescent high-molecular-weight dextran or with fluorescent semiconductor nanocrystals (quantum dots), which leak less into the interstitium than dextran (69, 70). *In vivo* labeling of nonhematopoietic cells with fluorescently conjugated antibodies is also possible (72). *Ex vivo* labeling of leukocytes with cell-permeable vital fluorescent dyes like CMAC (blue), CFSE (green), CMTMR (orange), CMPTX (red), or SNARF (far red) and adoptively transferring them into syngeneic recipients allow tracking until the dyes are diluted out in dividing cell populations. Besides these dyes, infrared fluorescent dyes have recently been developed that will allow imaging of deeper tissues (69).

Fluorescent cells from reporter mice that express the GFP-derived proteins eGFP, eCFP, and eYFP, and dsRed-derived proteins tdTomato and mCherry can also be used because they are less susceptible to phototoxicity at high laser intensities. Cells from these mice can be adoptively transferred or used to generate mosaic mice with mixed-radiation bone marrow chimeras. Mice with lineage-specific expression of fluorescent proteins have also been created. These mouse strains can be used to evaluate radiation-resistant cells that are difficult to isolate and adoptively transfer. Alternatively, inducible lineage-specific fluorescent reporter gene expression can be used to obtain information about functional proteins. This has been used to label cells based on the expression of transcription factors Blimp1 and Foxp3; the production of cytokines such as IL-2, IL-4, IFNγ, IL-17, and IL-10; and the production of chemokines such as CXCL12, CCL17, CXCL9, and CXCL10 as well as chemokine receptors such as CX3CR1 and CXCR6 (69, 70). Increasingly, fluorescent reporter expression of targeted genes in transgenic mice, partnered with advances in multiphoton imaging, are tools that are becoming more widely used and are enabling scientists to understand the *in vivo* dynamics and cellular interactions of immune cells at a molecular level.

Animal Models To Assess the Role of Chemokines and Chemokine Receptors in Development and Disease

The above-mentioned techniques provide data that suggest how chemokines and their receptors may play a role in immune/inflammatory cell function in health and disease. Genetically modified mice in which the gene for a specific chemokine or chemokine receptor has been deleted or is overexpressed in a tissue-specific manner have been used to study both physiological and pathological processes. The effect of neutralization of a specific chemokine or chemokine receptor by specific antibodies on disease processes has also been utilized. These animal models currently provide the cornerstone for determining functional roles of chemokines and chemokine receptors *in vivo* (1–4).

The role of chemokines and their receptors *in vivo* is complex. In an attempt to correlate *in vitro* determinations of chemokine activities and chemokine receptor expression with *in vivo* physiology and pathology, gene-targeted mice have been created by selective homologous recombination, which fails to express a chemokine or chemokine receptor (1–4). The phenotype of the so-called "knockout" is then compared under physiological and pathological conditions. The generation of knockout mice involves the introduction of a mutant gene into embryonic stem cells *in vitro* and the selection for homologous recombination at the desired locus, which results in the deletion of a specific gene. Animals are then produced that are homozygous for the deleted gene. Embryonic, fetal, and neonatal development is then examined in these mice with a targeted disruption of both wild-type alleles in order to determine whether the gene deletion affects embryogenesis, hematopoiesis, or immunologic abnormalities such as thymic development. In the adult mouse, inflammatory and immune responses can be examined. Knockout mice for over 10 of the chemokines and for all of the chemokine receptors have been developed (1, 2). So far, only the deletions of the CXCL12 and CXCR4 genes have been shown to be embryonically lethal and are associated with severe neurological, cardiological, and hematological abnormalities (1, 2). In contrast, fetal development is not affected in other chemokine and chemokine receptor knockouts such as CCL11, CCL2, and CCR2 (1, 2).

Many important roles for chemokines and their receptors have been elucidated in experiments using knockouts and inhibitory antibodies. Different aspects of the host response to infectious pathogens have been shown to be dependent on neutrophil-active chemokines and their receptors, such as CXCL1 and CXCR2; monocyte-active chemokines and their receptors, such as CCL2 and CCR2; T-cell active chemokines and their receptors, such as CXCL10; and natural killer cell-active chemokines such as CCL3 (1–4, 34). Likewise, individual chemokine receptor knockouts have revealed an important role for this family of molecules in inflammatory and autoimmune diseases and allograft transplantation. For example, attenuated immunopathology has been noted in CCL2 knockout and CCR2 knockout mice in models of atherosclerosis and glomerulonephritis (1). Decreased inflammatory responses and increased allograft survival have been noted in CCR1 and CXCR3 (1). CCR1 and CXCR2 are absolutely required for arthritis in a serum transfer model of RA (21). CCR4 and CCR8 have been found to be essential in different models of allergic inflammation (1). These *in vivo* experiments have revealed the significant role of individual chemokine and chemokine receptors in the immune and inflammatory response that could not be appreciated by *in vitro* assays that implicated apparent functional redundancy.

CONCLUSIONS

The Boyden chamber stood for more than 20 years as the singular system for quantitating leukocyte migration in response to chemokinetic agents. However, in the past 20 years, and since the discovery of the chemokine and chemokine receptor

superfamilies, there has been a considerable expansion in the number of methodological approaches available to scientists for quantitation and analysis of cell migration. These techniques vary widely, from phase contrast fluorescent digital video microscopy to examine individual cell movement in response to chemokines, to the use of knockout or fluorescent reporter mice with multiphoton IVM to delineate the effects of specific chemokines and chemokine receptors *in vivo*. These diverse methodological approaches have revealed an intricate world of immune and inflammatory cell localization that appears critical to the pathophysiology of a wide variety of disease processes ranging from allergic lung inflammation, through atherosclerosis, to the way in which the immune system handles infectious agents such as *Toxoplasma gondii*.

During the next 10 years, we should expect to see a further expansion in the methodological approaches to studying the roles of chemokines and chemokine receptors, which should itself lead to a greater understanding of human diseases and the development of novel therapeutic approaches in order to combat them.

Cytokines: Diagnostic and Clinical Applications

PRIYANKA VASHISHT AND TIMOTHY B. NIEWOLD

38

Many cytokines can be measured in the circulation via antibody-based detection protocols such as enzyme-linked immunosorbent assays and multianalyte bead systems. These measurement systems are robust and adaptable to many different analytes, and thus the large-scale measurement of cytokines in the circulation in human populations and disease states is possible. The measurement of cytokines in the circulation may provide a unique window into the immune response and the biology of human immune-related diseases. Cytokines represent messages sent between cells of the immune system, and thus confer a great deal information about ongoing immune processes. It is attractive to think that by intercepting these messages, we may be able to gain valuable insights regarding human disease diagnosis, prognosis, and potential therapeutic avenues. In this chapter, we review some of the ways in which cytokines are applied to clinical medicine. While cytokines can also be detected in tissue, this requires a biopsy, and for the purpose of this chapter we focus our discussion on circulating cytokines.

In the realm of diagnosis, we discuss how cytokine profiles may be applied to the diagnosis of autoimmune disease. While most of these efforts are still in the research arena, this is a promising area that may be implemented in the diagnostic algorithms in the near future. We also discuss the role of cytokines in the etiology of immune-related diseases. This is a broad area, and we focus on a few illustrative stories. For example, in some settings, genetic background can lead to the alteration of cytokine profiles or signaling, which subsequently leads to the development of disease. Another example demonstrates the use of modern gene expression profiling techniques to implicate cytokine pathways in human disease, which can enable novel therapeutic strategies. Circulating cytokines may also provide prognostic information. In autoimmune disease, differences in cytokine profile may indicate differences in disease severity and clinical manifestations between different patients. In this way, the measurement of cytokines in circulation may predict disease outcome. Additionally, baseline cytokine profiles may be useful in predicting therapeutic outcomes, indicating which patients may be appropriate for a particular therapy.

Cytokines and cytokine inhibitors have also been used in the treatment of human diseases. In the last section of this chapter, we summarize some of the major uses of recombinant human cytokines as well as cytokine inhibitors in the treatment of human disease. For example, in rheumatoid arthritis (RA), a number of cytokine inhibitors have been approved by the Food and Drug Administration (FDA) for treatment. Therapeutic algorithms in inflammatory bowel disease also include the use of cytokine inhibitors. In other cases, recombinant human cytokines have been used as therapeutics in human disease. In chronic viral hepatitis C, alpha interferon (IFN-α) has been used as a therapeutic with great success, augmenting the subject's own viral immunity. Additionally, IFN-β has been used with great success in the treatment of multiple sclerosis. It is not possible to summarize all possible ways in which the measurement of circulating cytokines may prove useful in human disease, but in this chapter we provide some illustrative examples that span multiple fields of clinical medicine.

DIAGNOSIS

Profiles of circulating cytokines may be useful in the diagnosis of autoimmune conditions. Autoimmune conditions are caused by primary disturbances in the immune system, characterized by immune system activation and the loss of self/nonself discrimination, resulting in chronic inflammation in characteristic tissue sites that differ among diseases. The use of cytokines to aid in the diagnosis of autoimmune diseases aims to leverage the information that can be gained by measuring immune system response modifiers and the between-cell communications in the circulation. We will discuss two examples in which work examining circulating cytokines may be applicable to diagnosis in autoimmune disease: RA and systemic lupus erythematosus (SLE).

In RA, a number of studies have examined profiles of circulating cytokines. Cytokines that are elevated include tumor necrosis factor alpha (TNF-α), interleukin-6 (IL-6), IFN-γ, and others (1). Interestingly, studies have also assessed cytokine profiles in samples taken from individuals before they developed RA (2). This study design leverages existing blood banks that have a sample stored from a date prior to the time that an individual developed RA. In these samples that predate the clinical onset of disease, an increasing prevalence of elevations in a number of inflammatory cytokines can be observed, which intensifies as the subject approaches the date of diagnosis (2). This would suggest that elevations in circulating cytokines and activation of the immune system predate disease by many years. While this information is not yet used clinically, it is possible that

doi:10.1128/9781555818722.ch38

circulating cytokines could be useful in early diagnosis or in the prediction of disease. While this is not currently possible, it seems that the feasibility of this approach could be enhanced by including other data such as family history, genetic markers, and environmental risk factors.

Cytokines may not be sufficient for the complete diagnosis of autoimmune conditions, but they are an important parameter. One approach has been to incorporate cytokines in the circulation along with autoantibodies and other disease manifestations and attempt to make a multimodal biomarker composite score (3). These are currently being developed, and one is now available for practicing physicians for RA. It will be interesting to see how these evolve over time, as our knowledge of the pathogenesis of disease is still incomplete and it is likely that additional marker sets will be developed in the future. For example, despite brisk progress in genetics, much of the genetic variation underlying autoimmune diseases remains to be discovered. Additionally, most autoimmune diseases demonstrate both clinical and biological heterogeneity—differences between patients who are diagnosed with the same condition. While clinicians have long appreciated this idea, new studies are identifying some of the biological and immune system parameters that underlie this clinical heterogeneity (4); incorporating these features into diagnostic algorithms would be useful and improve our diagnostic capacity.

In SLE, elevated cytokines include IFN-α, TNF-α, as well as IL-6, and interestingly, IL-2 cytokine levels are low (5). With regard to the elevation of IFN-α, this is one of the most impressive abnormalities when examining peripheral blood gene expression profiles. The remarkable elevation of IFN-α-induced transcripts in the peripheral blood has led to use of the term "interferon signature" to describe this finding. The coordinate upregulation of such a large number of IFN-induced transcripts strongly supports that IFN-α is present in the circulation and signaling through the receptors on the cells. Not all patients with lupus exhibit the IFN signature, but it is a major discriminator between cases and controls in those cases that have the signature. This is not yet being used as a diagnostic test but holds promise for future diagnostics.

ETIOLOGY: GENETICS AND GENOMICS OF HUMAN CYTOKINE RESPONSES

IFN-α in SLE

IFN-α is an antiviral cytokine in the type I IFN family. It is classically induced following activation of viral pattern recognition receptors like endosomal Toll-like receptors (TLRs) and cytosolic nucleic acid sensors (6). IFN-α signaling causes a spectrum of effects upon the immune system, including upregulation of the major histocompatibility complex molecules and activation of antigen-presenting cells (6). IFN-α is in a critical position bridging the innate and adaptive immune responses and thereby could be instrumental in setting thresholds for autoimmunity (7). There are many reports in the literature to support the involvement of IFN-α as a primary pathogenic factor in the human autoimmune syndrome SLE (7). Major lines of evidence that support a primary role of IFN-α in the pathogenesis of human lupus are as follows.

1. Serum IFN-α levels are high in human SLE.
2. Therapeutic IFN-α can induce SLE in humans.
3. High serum IFN-α is a heritable risk factor for SLE.
4. SLE-associated autoantibodies are strongly associated with serum IFN-α in SLE patients.
5. SLE-associated genetic variations in the IFN-α pathway are gain-of-function.
6. Novel genetic loci are associated with IFN-α and autoantibodies in SLE.

Serum IFN-α Levels Are High in Human SLE

As early as the 1970s, many investigators detected elevated levels of type I IFNs in SLE patient sera (8, 9). Subsequent gene expression microarray studies in peripheral blood cells revealed that overexpression of type I IFN-induced genes is a common pattern in SLE (10, 11). Because large-scale measurement using either microarray or real-time PCR of freshly isolated circulating blood cells was limiting, and enzyme-linked immunosorbent assay has been characterized by poor sensitivity and specificity in human sera, a method of assessing serum IFN-α was developed using human cell lines (12, 13). WISH cells were chosen based on their known sensitivity to type I IFNs and their use in the initial viral inhibition assays employed to detect type I IFNs. In this assay:

1. The WISH cells are incubated with serum for 6 h, and then the cells are lysed.
2. Total mRNA is purified from the cells, and then this mRNA is converted to cDNA.
3. Three classical IFN-induced genes are quantified using real-time PCR (*IFIT1*, *MX1*, and *PKR*) (13), and expression of these genes is compared to housekeeping gene expression in the same sample.
4. The level of induction of IFN-induced gene expression caused by the patient sera is then normalized to the mean and standard deviation of the induction of the same genes by healthy donor sera in WISH cells. This step accounts for the fact that different transcripts are induced to different degrees after stimulation with the same amount of IFN-α. If gene expression values are summed directly, then the most highly induced transcripts tend to dominate the overall score.
5. After the genes are normalized in this way, the various levels of induction are summed, and a standardized IFN-induced gene score is generated.

Standard curves can be run with known amounts of IFN-α, and if desired, the IFN-induced gene score could be converted back to a picograms-per-milliliter measurement. One important benefit of this assay is that frozen serum banks can be studied, and the need for live or fresh cells is obviated. Additionally, the WISH cell line is clonal and stable, and the response to a given amount of IFN is reliable from experiment to experiment. Patient cells are more heterogeneous, likely due to differences in genetic background between people and differences in cellular activation states and the proportional composition of the various immune cells in either whole blood or mononuclear cell fractions. This heterogeneity can be interesting but also likely makes the interpretation of the IFN signature more complicated and less direct as a measurement of IFN in the circulation. WISH cell assays for circulating type I IFN activity are correlated with microarray IFN signatures run on the same sample, but as expected, the correlation is not perfect, likely due to the issues raised above. The WISH cells are epithelial-type cells, and while they express the type I IFN receptor, they do not express many other immune receptors such as TLRs, etc., and cycloheximide does not reduce the amount of IFN detected, suggesting that autocrine and paracrine IFN-related signaling is not contributing to the WISH cell output.

Therapeutic IFN-α Can Induce SLE in Humans

There are a number of published reports describing IFN-α-induced SLE in patients receiving recombinant human IFN-α to treat malignancy and chronic viral infection (14, 15). These patients show the highly specific and characteristic manifestations typical of idiopathic SLE. When IFN-α was withdrawn, many of these cases improved or resolved, supporting the idea that the IFN-α was causal (15). This human experience provides a proof of principle that IFN-α can break tolerance (16) and that this IFN-α-induced tolerance break in some individuals results in the very specific autoimmune phenotype of SLE. Importantly, not all patients who receive exogenous IFN-α develop SLE, which indicates that signaling through this pathway is polymorphic in nature and is dependent on other host factors.

High Serum IFN-α Is a Heritable Risk Factor for SLE

Abnormally high levels of IFN-α are present in healthy first-degree relatives of SLE patients as compared with healthy unrelated subjects (13), suggesting that high serum IFN-α is an inherited risk factor for SLE. A number of genetic variants have now been associated with increased IFN-α in SLE (17, 18), which further supports the concept of heritability. The familial nature of the high-IFN-α trait is common across SLE patients of all ancestral backgrounds, suggesting that high serum IFN-α is a common shared pathway to SLE susceptibility.

SLE-Associated Autoantibodies Are Strongly Associated With Serum IFN-α in SLE Patients

SLE patients produce autoantibodies that bind to double-stranded DNA or small RNA-binding proteins such as Ro, La, Sm, and RNP. Immune complexes formed by these autoantibodies can activate normal antiviral immunity through the endosomal TLRs and generate IFN-α. *In vitro* experiments have supported this idea, showing that SLE-associated immune complexes can induce IFN-α production in human peripheral blood mononuclear cell (PBMC) and dendritic cell cultures (19). In SLE patients, autoantibody profiles provide the strongest correlation with serum IFN-α as compared with other clinical features (13, 20), supporting the idea that the *in vitro* model is relevant in humans *in vivo*. A two-hit model may apply, in which the formation of SLE-associated autoantibodies exacerbates an underlying genetic tendency toward greater IFN-α production or greater IFN-α sensitivity, resulting in clinical development of lupus.

SLE-Associated Genetic Variations in the IFN-α Pathway Are Gain-of-Function

A number of the genetic polymorphisms that contribute to susceptibility to SLE are found in the genes that function in the IFN-α pathway. These polymorphisms have been linked to greater IFN-α activity or greater sensitivity to IFN, and hence are gain-of-function in nature. For example, genetic variations in both interferon regulatory factor 5 (IRF5) and IRF7 have been associated with lupus (21). These transcription factors work downstream of the endosomal TLRs and can induce the transcription of IFN-α. Interestingly, these genetic variations are linked to higher IFN-α levels only in those SLE patients who have specific autoantibodies (22). This suggests an induced model, in which the chronic stimulation of the TLR system by autoantibody immune complexes results in dysregulation of circulating IFN in the presence of these gain-of-function variants in IRF5 and IRF7 (23). Other gene polymorphisms reported include polymorphisms in STAT4 (24), IRF8 (25), IFIH1 (IFN induced with helicase C domain 1) (26), and PTPN22 (protein tyrosine phosphatase N22) (17), among others. See Fig. 1 for an illustration of these genes positioned in their proposed cellular pathways. Additionally, through genetic mapping of high IFN levels in SLE, a number of novel loci have been discovered that have an impact on IFN levels in SLE (18). This further supports the idea that IFN levels are influenced by genetics and that activation of this pathway is heterogeneous among SLE patients. In conclusion, multiple lines of evidence support the involvement of IFN-α in the primary pathogenesis of human SLE. There is intriguing genetic evidence that signaling through this pathway is highly polymorphic in humans, and this may explain the heterogeneity in response to exogenous IFN-α. This same heterogeneity in IFN-α signaling seems to underlie idiopathic SLE as well.

IL-1 in Juvenile Idiopathic Arthritis

Systemic-onset juvenile idiopathic arthritis (SoJIA) contributes to ~10% of cases of arthritis with onset in childhood (27). This disease is characterized by prolonged and severe clinical manifestations, severity of joint involvement, and lack of response to TNF blockade (27, 28). Due to frequent poor outcomes and long-term disability, this disease represents a serious challenge to pediatric rheumatologists. Patients frequently need prolonged courses of steroids and/or methotrexate to control their disease. Anti-TNF therapy works in some types of juvenile idiopathic arthritis; however, most SoJIA patients do not respond.

The exact molecular pathogenesis of SoJIA remains an enigma, but treatment has been significantly advanced by the use of IL-1 inhibitors. A seminal gene expression study by Pascual et al. (29) supported the idea that IL-1 is a major mediator of the inflammatory cascade that underlies SoJIA and that an IL-1 receptor antagonist (IL-1Ra) would be effective as a treatment for this disease. The key results that indicate the role of IL-1 in SoJIA are as follows. The incubation of healthy PBMCs with SoJIA serum upregulated transcription of innate immunity genes, including several members of the IL-1 cytokine/cytokine receptor family, specifically IL-1a and IL-1b as well as their receptors, IL-1R1 and IL-1R2 (29). Additionally, SoJIA sera induced healthy PBMCs to produce multifold-increased levels of IL-1b, and sera from febrile patients were more efficient in inducing the secretion in comparison with afebrile sera. High levels of IL-1b were also produced by activated SoJIA PBMCs. Dramatic responses have been observed with the use of IL-1 antagonism in this disease, including resolution of fever and systemic symptoms, even in highly refractory cases not responding to conventional treatment (29, 30). Parallel improvements in inflammatory markers and blood counts are typically observed. To summarize, the central role of IL-1 in SoJIA is supported by gene expression studies in the disease and illustrated by the remarkable clinical response of patients to IL-1Ra.

TREATMENT: CYTOKINE INHIBITORS AND RECOMBINANT CYTOKINES AS THERAPY

Treatment with Cytokine Inhibitors

RA

Joint inflammation results from an imbalance in the cytokine cascade. The clinical management of RA has been revolutionized by the introduction of "biological agents," including monoclonal antibodies (MAbs), fusion proteins, and Fab (fragment antigen-binding) portions of MAbs (Table 1). The

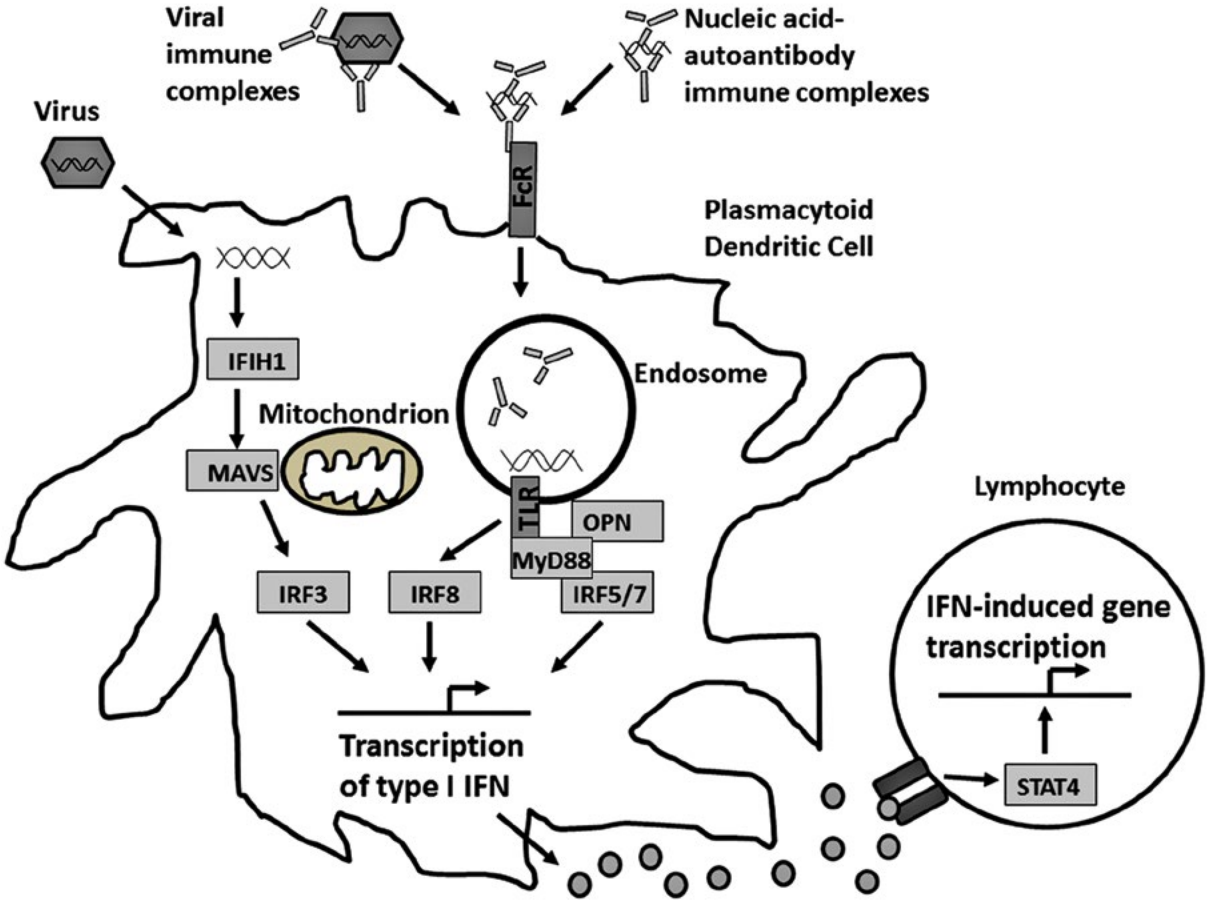

FIGURE 1 Diagram illustrating the proposed cascade of IFN production in SLE, with SLE risk genes demonstrated in boxes within the cells. Viruses and immune complexes made from SLE-associated autoantibodies can stimulate both the TLR and cytosolic nucleic acid recognition systems. Multiple SLE risk genes are found in these pathways, resulting in augmented type I IFN production in plasmacytoid dendritic cells. IFN is recognized by other cells in the immune system via the type I IFN receptor, and some SLE risk genes such as STAT4 are associated with greater IFN-induced gene expression. MAVS, mitochondrial antiviral signaling protein; MyD88, myeloid differentiation primary response gene 88; OPN, osteopontin.

biological therapeutics approved for use in RA target the proinflammatory cytokines TNF-α, IL-1, and IL-6, which are key players in the pathogenesis of RA (31). We will focus our discussion on each of these three mechanisms of action. Of note, there are two additional biologic agents that target the B-cell-specific antigen CD20 and T-cell antigen CD28, respectively, and these will not be dealt with in detail as their mechanisms are not direct cytokine inhibition.

TNF-α Inhibition

Beginning in the late 1990s, TNF-α-inhibiting drugs have received regulatory approval for use in RA. Currently available drugs include MAbs directed at TNF-α (either chimeric mouse-human or fully human antibodies), antibody fragments that target TNF-α, and soluble decoy receptors that can bind TNF-α but do not result in any signaling, effectively neutralizing the biological effect of TNF-α. TNF-α inhibitors have been used in combination with methotrexate or alone in the treatment of RA.

Mechanism of action. MAbs that target TNF-α bind to both soluble and membrane-bound TNF-α with high affinity, forming stable nondissociating immune complexes. This binding neutralizes the biological activity of TNF-α by inhibiting its binding to receptor. The TNF-α receptor decoy can bind to both soluble TNF-α and soluble TNF-β (lymphotoxin-α). Blocking TNF-α inhibits the release of proinflammatory cytokines (IL-1, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor) and acute-phase reactants. This alteration of cytokine profiles in the disease results in inhibition of the activation of eosinophils and neutrophils, as well as inhibition of leukocyte migration (32). Through the binding of MAbs to membrane-bound TNF-α, cells expressing TNF-α can be lysed in the presence of complement.

Adverse events. Several side effects have been noted in patients taking anti-TNF-α agents. The chances of tuberculosis (TB) are increased in patients receiving TNF-α inhibitors, and therefore testing for latent TB is recommended prior to initiating therapy. If latent TB is suspected, then treatment of latent TB infection is recommended before starting TNF-α inhibition (33). It seems likely that TNF-α inhibition may destabilize old granulomas containing latent

TABLE 1 Anticytokine therapy in RA

Name of biologic (commercial name)	Approval year (FDA)	Class	Type	Target
Infliximab (Remicade)	1998	Chimeric MAb	IgG1	TNF-α

Tocilizumab (RoActemra)	2009	Humanized MAb	IgG1	IL-6R
Anakinra (Kineret)	2001	Human IL-1ra	Receptor antagonist	IL-1

TB, allowing the infection to become active. Worsening of chronic hepatitis B infection is also a concern, and testing for hepatitis B is recommended prior to beginning therapy. Other common adverse events are headache, vertigo, viral infection, flushing, upper and lower respiratory tract infection, dyspnea, sinusitis, nausea, infusion-related reactions, diarrhea, dyspepsia, urticaria, abdominal pain, and elevated liver enzymes. Because rates of bacterial infection are increased, careful observation of patients is important for the early awareness of development of signs and symptoms of infection during and after therapy. The production of antibodies directed at the therapeutic protein has been observed in patients with RA (34), and it seems possible that some of these antibodies are able to neutralize the efficacy of the drug, although in many cases no decrease in efficacy is observed. Additionally, new onset or increase in titer of antinuclear autoantibodies, similar to those detected in SLE and connective tissue diseases, has been reported in patients taking anti-TNF-α agents (35). Additionally, some patients have developed a multiple sclerosis-like syndrome that typically improves when the drug is stopped. A risk of lymphoma had been suggested in early data sets and resulted in a package label warning, although many recent studies have not supported the association between TNF-α inhibition in RA and the development of lymphoma (36).

Clinical efficacy. A number of large double-blind, randomized trials have been conducted examining the use of TNF-α inhibitors in RA patients. Some have examined the addition of a TNF-α inhibitor to standard therapy with methotrexate, and others have included study arms examining use of the anti-TNF-α agent alone (37–39). These trials have demonstrated that anti-TNF-α therapies can reduce signs and symptoms of active RA, inhibit radiographic progression of structural damage, and improve physical function. These studies have included thousands of patients in both early and later stages of disease (35).

IL-6 Inhibition

A MAb targeting the IL-6 receptor (IL-6R) was approved by the FDA in 2010 for the treatment of RA patients with moderate to severe active RA who do not respond to one or more conventional RA drugs such as methotrexate or TNF antagonist therapies. This humanized anti-IL-6R antibody is engineered by grafting the complementarity-determining regions of a mouse anti-human IL-6R antibody into human IgG1κ to create a humanized MAb with specificity to human IL-6R.

Mechanism of action. The anti-IL-6 therapy binds to the IL-6 binding site of human IL-6R and competitively inhibits IL-6 signaling, neutralizing the action of IL-6. Tocilizumab binds specifically to both soluble and membrane-bound IL-6Rs and has been shown to inhibit soluble and membrane-bound IL-6R-mediated signaling. IL-6 is a pleiotropic proinflammatory cytokine that has widespread effects on acute-phase reactants and hematopoietic lineages, such as induction of Ig production in B cells, T-cell proliferation, and differentiation into cytotoxic T cells (40).

Adverse events. As with all immunosuppressive treatments for RA, careful observation of patients is important for the early awareness of signs and symptoms of infection during and after therapy. Common adverse reactions may include lung infection (pneumonia), abnormal liver function tests, conjunctivitis, headache, hypertension, and serious hypersensitivity reactions. Regular monitoring of liver enzymes, blood counts, and serum lipids is required with IL-6 signaling blockade. In particular, both neutropenia and thrombocytopenia have been observed with IL-6 signaling blockade.

Clinical efficacy. Several multicenter, double-blind, placebo-controlled, phase 3 trials were conducted to evaluate the efficacy of IL-6 signaling blockade. These studies have documented significant improvement in standardized disease outcome measures in thousands of RA patients (41). These studies compared patients taking standard therapy with methotrexate to those receiving both methotrexate and IL-6 signaling blockade, and demonstrated a nonredundant effect of IL-6 blockade in addition to standard therapy on RA disease features, similar to that seen with the anti-TNF-α agents outlined above.

IL-1 Inhibition

A recombinant human IL-1Ra was approved by the FDA in November 2001 for use in RA patients who have failed one or more traditional RA drugs. It is the first selective blocker of IL-1, a cytokine that plays an important role in RA pathogenesis. This molecule is a recombinant,

nonglycosylated form of the human IL-1Ra, which is produced in *Escherichia coli* expression systems. Anakinra differs from native human IL-1Ra in that it has the addition of a single methionine residue at its amino terminus (31).

Mechanism of action. The recombinant IL-1Ra molecule blocks the biologic activity of IL-1a and IL-1b by competitively inhibiting their binding to the IL-1R. IL-1 is an inflammatory mediator that binds to the IL-1R and triggers the inflammatory response. The presence of IL-1 in the synovial tissue of the affected joints induces production of osteoclasts that further exacerbate the inflammation. Anakinra neutralizes responses elicited by IL-1 *in vitro*, including the induction of nitric oxide and prostaglandin E_2 and/or collagenase production by synovial cells, chondrocytes, and fibroblasts.

Adverse events. The most common and frequently reported side effect is injection-site reaction, which is usually mild, characterized by erythema, ecchymosis, inflammation, and pain, and lasts for 15 days to 1 month. Other frequent side effects may include bacterial infection such as cellulitis, bone and joint infections, and pneumonia, similar to those reported with other biological agents used in RA. Patients are also prone to develop neutropenia, which can increase the infection risk (31).

Clinical efficacy. Double-blind clinical trials have been performed using recombinant IL-1Ra to treat patients with RA. These studies have suggested some clinical efficacy of IL-1 antagonism, generally concluding modest efficacy and relative safety (42). Because many consider the other approved therapies in RA to have greater efficacy, the use of IL-1 antagonists in RA has been somewhat limited, but as noted in the section above, they have been highly effective in a particular form of juvenile-onset RA.

Inflammatory Bowel Disease

Inflammatory bowel disease is a group of chronic disorders of the gastrointestinal tract comprising Crohn's disease (CD) and ulcerative colitis (UC). Their etiologies are unknown, but they are characterized by an imbalanced production of proinflammatory mediators, e.g., TNF-α, as well as increased recruitment of leukocytes to the site of inflammation. Increased understanding of the role of the inflammatory pathways in inflammatory bowel disease has led to new therapies, including the TNF-α inhibitors outlined above. TNF inhibitors have been shown to be effective in treating moderate to severe CD and UC (43).

Several double-blind, placebo-controlled trials have demonstrated that TNF inhibitors are efficacious in moderate to severe CD, as both first- and second-line therapy, and in maintenance of response and remission (44, 45). TNF inhibitors also allowed tapering of glucocorticoid therapy and mucosal healing in CD patients (44, 45).

Similar results have been observed in UC, with randomized, controlled trials demonstrating benefit from TNF inhibitors (46, 47) in inducing and maintaining clinical remission. Interestingly, the TNF decoy receptor has not been effective in CD and UC, suggesting that there is some mechanistic difference in the way these drugs work between RA and inflammatory bowel disease. One main difference is the ability of the MAbs and antibody fragments to bind membrane-bound TNF-α and possibly induce cell death or otherwise alter cellular signaling via membrane-bound TNF-α, while the decoy receptor binds to soluble TNF-α.

Treatment with Recombinant Cytokines

Chronic Viral Hepatitis C Treated with IFN-α

Recombinant human IFN-α has been a major therapeutic option in the treatment of chronic viral hepatitis C. While some newer antiviral therapies are currently revolutionizing treatment of hepatitis C, combination regimens that include recombinant human IFN-α are still common (48). The rationale for IFN-α in the treatment of hepatitis C is directly related to its properties as an antiviral protein, which are summarized above in the section on SLE. The common side effects are largely related to the action of the drug on the immune system, including flu-like symptoms on the day of injection, injection-site reactions, and in some cases features of autoimmune disease such as antinuclear antibodies and SLE (15).

Multiple Sclerosis Treated with IFN-β

Multiple sclerosis has been treated effectively with recombinant human IFN-β (49). This is somewhat surprising at first glance, given that multiple sclerosis is an autoimmune disease and the related cytokine IFN-α has been associated with the development of autoimmune disease, as noted above. While we do not know the exact reasons why different highly related members of the same cytokine family can induce or treat different autoimmune diseases, there are interesting theories currently. Circulating levels of IFN are low in multiple sclerosis, the opposite of SLE, and it is possible that the decrease in IFN levels present in multiple sclerosis is pathogenic in the disease (50). This would suggest that either too much or too little type I IFN may predispose to autoimmune disease. It is likely that this story will become more complex as more is understood about IFNs in autoimmunity. Side effects of IFN-β are similar to those of IFN-α, although interestingly, reports of new-onset connective tissue disease seem to be uncommon in multiple sclerosis patients treated with IFN-β.

Detection of Anticytokine Autoantibodies and Clinical Applications

SARAH K. BROWNE

39

Anticytokine autoantibodies are an emerging mechanism of disease pathogenesis that have been shown to elicit a broad range of clinical phenotypes. Some anticytokine autoantibodies can lead to immune susceptibility, with examples including nontuberculous mycobacteria, salmonellae, or fungi due to autoantibodies against gamma interferon (IFN-γ) (1); staphylococcal infection due to anti-interleukin-6 (IL-6) autoantibodies (2); *Burkholderia gladioli* infection due to anti-IL-12p70 autoantibodies (3); chronic mucocutaneous candidiasis due to anti-IL-17 and anti-IL-22 autoantibodies (4, 5); and cryptococcal meningitis (6) or *Nocardia* infection due to anti-granulocyte-macrophage colony-stimulating factor (GM-CSF) autoantibodies (7). Other diseases in which immunodeficiency is not the primary presentation include the severe lung disease pulmonary alveolar proteinosis (PAP) caused by anti-GM-CSF autoantibodies; pure red cell aplasia (8); pure red-cell aplasia due to antierythropoietin autoantibodies (9); and severe osteoporosis associated with antiosteoprotegerin autoantibodies (10). For other anticytokine autoantibodies, such as anti-IFN-α autoantibodies detected in thymoma or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome, their biological effect is not immediately apparent (11). Diagnosis has important implications for management because therapies can be used to directly target the underlying mechanism, i.e., a neutralizing antibody, and not just their ultimate clinical consequences, with approaches such as B-cell depletion (12–14) or receptor agonists (15).

The diagnosis of anticytokine autoantibody syndromes must be specifically considered and carefully sought, particularly in the context of idiopathic disease in previously healthy adults, because clues to their presence may not be readily apparent on routine laboratory testing. PAP remained idiopathic for 40 years (16) before anti-GM-CSF autoantibodies were recognized as causal in ~90% of cases (17, 18). Understandably, it was not immediately apparent how a focal lung disease would result from blocking hematopoietic growth factors. In fact, it was the observation that GM-CSF cytokine-null (19) and receptor-null (20) mice both developed lung pathology strongly reminiscent of human PAP that gave clues as to the mechanism. The story continues to evolve: while even the initial report described opportunistic infection in the context of PAP (16), it has only recently been appreciated that anti-GM-CSF autoantibodies could lead to infection in the absence of PAP altogether (6, 7). It remains unknown how tightly autoantibody titers correlate with disease activity or response to therapy, but the ability to quantitate antibody levels over time may have implications for monitoring and managing disease beyond initial diagnosis.

Once an autoantibody is identified, evaluation for biological activity is paramount, given that anticytokine autoantibodies have been identified extensively in health and disease but without clear pathogenic consequences (21). Analogous to this phenomenon is the observation that only a small subset of patients who have antiphospholipid autoantibodies actually carry an increased risk of thrombosis (22). In addition to demonstrating that the autoantibody is both present and neutralizing, there should also be a biological rationale that supports a direct pathogenic role. The fact that many of the currently appreciated anticytokine autoantibody syndromes share phenotypic similarities with genetic defects in the same pathway supports the hypothesis that the autoantibody is producing a clinical "phenocopy" of the corresponding genetic deficiency. For example, anti-IFN-γ autoantibodies and mutations to the IFN-γ receptor both result in disseminated mycobacterial infection (Table 1). Assessing the functional activity of the autoantibody and considering what a deficiency in that pathway might induce can help determine if the underlying mechanism of disease has been identified or, conversely, if an alternative diagnosis must still be sought.

DETECTION STRATEGIES

Many approaches have been used to evaluate for the presence and activity of anticytokine autoantibodies, often conducted in independent laboratories on a research basis. The techniques themselves as well as the interpretation of these data (including normal ranges) remain largely unstandardized. Further, the relative values produced by each technique are difficult, if not impossible, to compare. Each technique has unique features such as cost, requirement for specialized technology, types of reagents, and amount of plasma needed. These relative attributes may have more or less import depending on the diagnostic circumstances.

Enzyme-Linked Immunosorbent Assay

In an enzyme-linked immunosorbent assay (ELISA), the cytokine of interest is bound to the surface of a 96-well plate

doi:10.1128/9781555818722.ch39

TABLE 1 Anticytokine autoantibody-associated syndromes[a]

Cytokine target	Clinical manifestations	Laboratory and radiologic manifestations	Functional assays	Infections	Biological rationale
GM-CSF	PAP; insidious and progressive respiratory failure (8); newly described cases of isolated cryptococcal meningitis and CNS nocardiosis in HIV-uninfected individuals (6, 7)	BAL fluid contains large foamy macrophages or monocyte-like macrophages (41, 42) and elevated levels of surfactant proteins; characteristic CT of chest demonstrates ground-glass opacities with thickening of intralobular septae, "crazy paving." PFTs demonstrate restrictive and diffusion defects.	Anti-GM-CSF autoantibodies inhibit pSTAT5 production (6), PU.1 expression (43), and MIP-1α protein production (6).	Pulmonary and extrapulmonary infections with *Nocardia* (44–54), *Aspergillus* (55), and *Proteus* (54, 56) spp.; histoplasmosis (57); and cryptococcosis (6, 16)	Mutations in GM-CSF receptor α or β subunits lead to early-onset (often neonatal) and severe PAP (8). GM-CSF receptor-null (20) and cytokine-null (19) mice develop PAP.
IFN-γ	Chronic infections with intracellular pathogens, particularly lymphadenitis, skin, soft tissue, and bone infections; can be multiple organisms simultaneously or sequentially; reactive dermatoses; constitutional symptoms common	Elevated erythrocyte sedimentation rate, CRP, and β_2-microglobulin; anemia; hypergammaglobulinemia. CT imaging may demonstrate abscess formation or osteomyelitis.	Anti-IFN-γ autoantibodies inhibit pSTAT1 production (1, 29), IFN-γ-inducible gene expression (32), and IL-12p70 and TNF-α protein production (1, 29).	Nontuberculous mycobacteria, tuberculosis, nontyphoidal *Salmonella*, *Histoplasma*, *Penicillium*, *Cryptococcus*, *Burkholderia pseudomallei*, and varicella-zoster virus	Mutations in *IFNgR1*, *IFNgR2*, *STAT1*, *IL-12Rβ1*, *IL-12Rβ2*, and *IL-12p40*, all directly within the *IFN-γ–IL-12* axis, lead to similar infections (58).
IL-17A, IL-17F, and IL-22	Recurrent candidal infections of mucosal surfaces, nails, and skin; infection may become resistant to antifungals.	None	Anti-IL-17 autoantibodies inhibit IL-17-induced IL-6 (4).	*Candida* spp.	Mutations in *IL-17RA*, *IL-17F* (59), and other genetic diseases with impairment in Th17 cells (59) lead to mucocutaneous candidiasis.
IL-6	Recurrent staphylococcal skin infections	Undetectable CRP	Anti-IL-6 autoantibodies prevent IL-6-induced CRP mRNA (2, 60).	*Staphylococcus aureus* (two cases) and empyema with *Streptococcus intermedius* and *Escherichia coli* (one case)	Mutations in *STAT3*, immediately downstream of the IL-6 receptor, cause Job's syndrome, which predisposes to *S. aureus* skin infections (61).
OPG	Severe, high-turnover osteoporosis (10) with pathologic fractures	Elevated alkaline phosphatase level	Anti-OPG autoantibodies prevent OPG inhibition of RANKL-induced NF-κB.	NA	Mutation in *TNFRSF11B*, the gene encoding OPG, results in childhood hyperphosphatemia, rapid bone turnover, and pathologic fractures (62).
EPO	Pure red cell aplasia	Low hemoglobin and hematocrit levels with absence of erythroid cells on bone marrow biopsy and absence of circulating erythrocytes; low or inappropriately normal endogenous EPO levels (9, 33)	Serum prevents formation of erythroid colonies from erythroid progenitor cells.	NA	NA

[a]Abbreviations: ABC, adenosine triphosphate-binding cassette; BAL, bronchoalveolar lavage; CNS, central nervous system; CT, computed tomography; EPO, erythropoietin; IRF, interferon regulatory factor; MIP, macrophage inflammatory protein; NA, not applicable; NEMO, NF-κB essential modulator; OPG, osteoprotegerin; PFT, pulmonary function test; RANKL, receptor activator of NF-κB ligand; SP, surfactant protein; TNF, tumor necrosis factor.

(Fig. 1A) (23) and patient plasma or serum is applied to the well containing the protein. The plate is washed, and if an autoantibody is present that recognizes the cytokine, it remains bound to the plate while the remaining material, including all nonspecific antibody, is removed. A secondary anti-human IgG detection antibody linked to an enzyme is added, which binds the IgG remaining on the plate. After washing, a substrate for the enzyme is added that changes color. Thus, only if detection antibody is present will the well change color, with an intensity that is a function of how much antibody is bound to the plate. This can be compared to a standard curve in which known amounts of an anticytokine antibody are added to the plate to determine the relationship between quantity and enzyme-related color shift.

A variation on the direct ELISA uses a plate that quantifies a given cytokine rather than the autoantibody. In this case, a known concentration of cytokine is mixed with patient plasma and the amount of cytokine detected by ELISA is less than the input amount if a neutralizing antibody is present in the plasma. This method is indirect, because it assumes but does not prove that the neutralizing "factor" is an antibody. However, because the factor blocks detection of the cytokine, it provides some additional evidence not only that the (presumed) autoantibody is present but also that it may indeed have neutralizing activity *in vivo*.

The benefits are that these assays are relatively inexpensive assays that do not require sophisticated technology and thus can be performed in most laboratories, including resource-limited settings. The disadvantages are the risk of high, nonspecific signal background and poor resolution between different concentrations, making them less quantitative than other approaches.

Luminex

Luminex is essentially a liquid-phase ELISA whereby the cytokine is coupled to a bead in suspension rather than to the surface of a plate (Fig. 1B). In this system, the beads themselves fluoresce, each at a different wavelength, so that they can be distinguished from each other when combined in the same well. Each unique set of beads can be coupled to a different cytokine so that multiple autoantibodies can be measured simultaneously with minimal plasma requirements. The beads are mixed with plasma, and after washing, a fluorescently labeled anti-human IgG binds any autoantibody that recognizes a particular cytokine-coupled bead. When run on a Luminex instrument, the bead fluorescence indicates what cytokine the autoantibody recognizes and the magnitude of fluorescence from the detection antibody quantifies the amount of each autoantibody that is present.

The Luminex technology requires a specific instrument for running this assay as well as availability of purified recombinant cytokines. However, if the instrument is available, the test is rapid, inexpensive, sensitive, specific, and reproducible (24). The ability to test for multiple cytokines in one assay minimizes plasma requirements to less than a microliter per test and allows for high-throughput screening of dozens of targets simultaneously.

Luciferase Immunoprecipitation Systems

In this technique, the cytokine is made to fluoresce by inserting the gene for the cytokine of interest into an expression vector next to the *Renilla* luciferase gene (Fig. 1C). A mammalian cell line is transfected with the expression vector, leading the cells to generate large amounts of the fluorescing cytokine (25, 26). The crude extracts from this cell line containing fluorescent protein are incubated with patient plasma, and subsequently the IgG from the plasma is captured with protein A/G-Sepharose beads (Fig. 1C). Whereas in the ELISA and Luminex assays only the specific autoantibody binds the surface, in this case total IgG is captured, but only that which binds the fluorescent protein is detected. The values are measured in arbitrary light units and are a function of autoantibody titer.

This is a sensitive and specific technique for which virtually any fusion protein can be synthesized, hence alleviating the need for purified recombinant proteins. Because the protein is expressed in a mammalian cell line, both conformation and posttranslational modifications should remain largely intact, which can improve epitope recognition.

Radioimmunoassays

Radioimmunoassays are similar to luciferase immunoprecipitation systems in that the cytokine "bait" is the labeled moiety that is incubated with serum (Fig. 1C). Either recombinant protein is synthesized with incorporation of radioactive [^{35}S]methionine into the protein (27), or recombinant protein is coupled to radioactive iodine (^{125}I) (28). A fixed amount of radioactivity (protein), measured in counts per minute, is combined with plasma (27). Total IgG is captured on protein A/G-Sepharose beads, and the degree of radioactivity compared with a negative control is a function of how much specific antibody is present that is binding the radioactive "bait." The main limitation of this assay is the need to work with radioactive reagents.

Immunoblotting

In immunoblotting, also known as Western blotting, denatured recombinant cytokine is run by agarose gel electophoresis and migrates based on its intrinsic size and charge (29) (Fig. 1D). The protein is transferred from the gel to a membrane (typically polyvinylidene difluoride or nitrocellulose) that is subsequently "blotted" using diluted plasma. As in ELISA, the detection antibody detects human IgG and is enzyme bound. If there is an autoantibody to the cytokine, the detection antibody remains bound to the autoantibody-cytokine complex after washing of the membrane. Addition of substrate causes light emission that can be used to develop light-sensitive film, revealing a band. The amount of light produced is a function of how much autoantibody there is, as indicated by the width and darkness of the band produced on the film.

The benefits of this assay are that it can be performed in most labs given that the technology is commonly used for many applications and has been available for decades. However, it is less sensitive than other approaches, more technically cumbersome, and requires more plasma compared with other diagnostic strategies. Furthermore, because it is usually performed with denatured protein, conformational epitopes may be lost.

Protein Array

Recently, investigators have used a protein array to screen for anticytokine autoantibodies (30). The concept is similar to ELISA, Luminex, and immunoblotting in that plasma is incubated with known protein that has been attached to a surface and the amount of antibody in the plasma binding the cytokine is quantified with a secondary antibody that recognizes human IgG. It is similar to microarray except that cytokines and not RNA are printed on a nitrocellulose-surface glass slide. The slide is incubated with plasma and subsequently quantified with a fluorescently labeled anti-human IgG that detects any human antibody that binds a cytokine present on the slide. Microarray software analyzes the degree of binding to each target, and heat maps can be

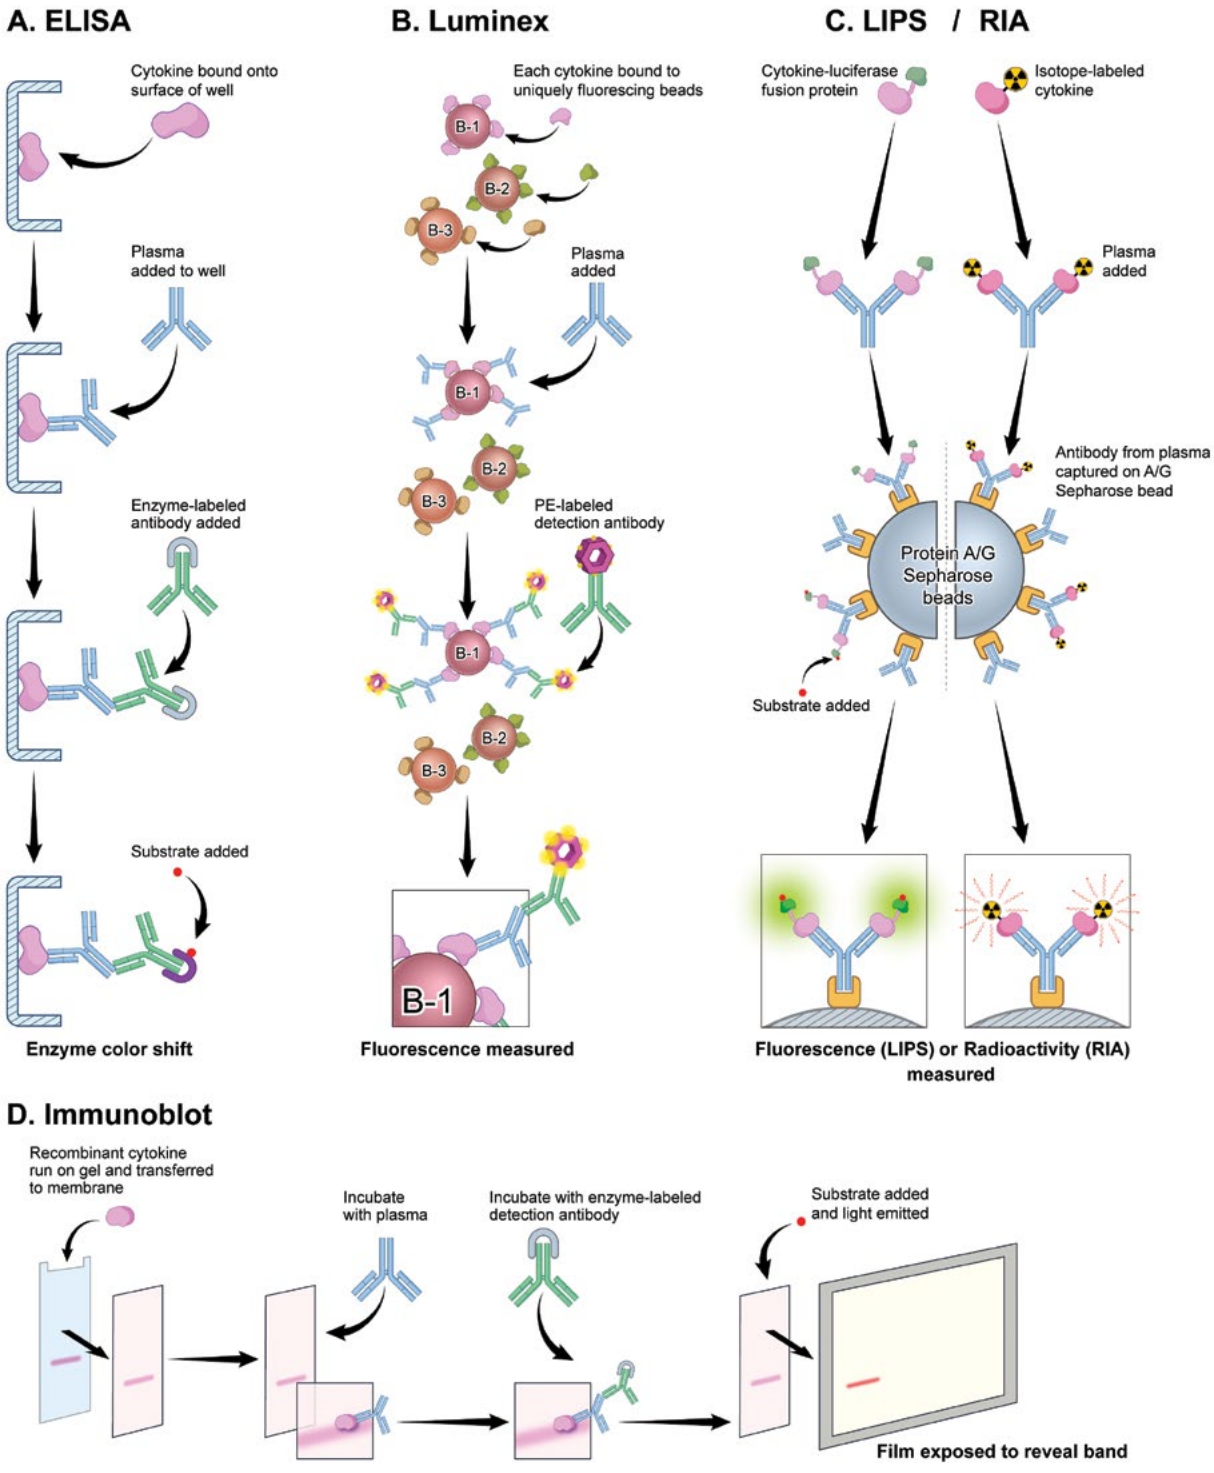

FIGURE 1 Summary of anticytokine autoantibody detection assays. LIPS, luciferase immunoprecipitation system; PE, phycoerythrin; RIA, radioimmunoassay.

generated that show relative binding to each of dozens to potentially hundreds of targets. This assay requires technical expertise regarding microarray platforms and data analysis. It has the capacity to simultaneously screen for the largest number of proteins. One patient can be screened per array, so this approach may be better for discovering novel autoantibodies or searching for patterns in autoantibody profiles within certain diseases rather than diagnosing specific anticytokine autoantibodies, for which a narrower panel may be sufficient and more cost-effective.

FUNCTIONAL ASSAYS

Upon identification of an anticytokine autoantibody, biological activity should be assessed. This is an important aspect of evaluating autoantibodies to cytokines, particularly when the phenotype is not clear-cut, as many anticytokine autoantibodies have been identified in both health and disease (31) without apparent physiological consequences. In general, when autoantibodies are causal, they are high-titer and neutralizing and have a clear clinical phenotype. This does not necessarily mean lower-titer or nonneutralizing autoantibodies do not have significant biological relevance; it may just be more difficult to detect or prove, and the effects may be physiologic rather than pathogenic. Nonneutralizing autoantibodies might alternatively represent an epiphenomenon devoid of immunomodulatory effects. A variety of assays have been used to evaluate the functionality of anticytokine autoantibodies with the common goal being to determine if the autoantibody prevents the ability of the cytokine to induce its normal inflammatory response (Table 1). Ideally, the patient cells are washed of autologous plasma and also evaluated for their ability to both elaborate and respond to cytokines appropriately, hence excluding cell-intrinsic defects.

The general strategy for functional assays is to use primary human cells (or cell lines) that are known to express a receptor for the cytokine of interest. The cells are stimulated with the cytokine in the presence of subject or control plasma. Finally, techniques such as flow cytometry, quantitative real-time PCR, microarray, immunoblotting, or cytokine detection assays evaluate if the normal cells respond appropriately to the cytokine in the presence of plasma. Each of these assays detects the downstream effects of the cytokine, such as activation/phosphorylation of signaling molecules, cytokine-induced RNA expression, or cytokine-induced protein production. For example, intracellular phosphorylation of STAT1 occurs when normal monocytes are stimulated with IFN-γ. Thus, monocytes can be stimulated with IFN-γ in the presence of subject plasma and the amount of phosphorylated STAT1 (pSTAT1) produced can be quantified by flow cytometry or immunoblotting. If the plasma contains an autoantibody that blocks IFN-γ, then the cells will appear as if they have not been stimulated; i.e., no additional pSTAT1 will be detected. Similarly, these neutralizing autoantibodies have been shown to prevent IFN-γ-induced RNA expression (13, 32) and protein production (29). Functional assays have been developed for many of the anticytokine autoantibodies reported in association with disease. Examples include GM-CSF-induced pSTAT5 production, PU.1 gene expression, or macrophage inflammatory protein 1α production in monocytes or alveolar macrophages; IL-6-induced pSTAT3, as well as IL-6-induced C-reactive protein (CRP) mRNA and protein expression (2); IL-12-induced IFN-γ; IL-17A-induced IL-6; osteoprotegerin (4) inhibition of RANKL-induced NF-κB (10) (Table 1); and erythropoietin-induced erythroid colony formation (33). In each of these cases, plasma from patients with biologically active autoantibodies prevents the cytokine from exerting normal effects on a specific cell population. These assays are essential in the assessment of anticytokine autoantibodies because many of these autoantibodies have been reported in healthy controls or outside of their specific disease associations.

ISOTYPE AND SUBCLASS ANALYSIS

So far, all the reported syndromes associated with anticytokine autoantibodies have been reported as IgG. Assays such as Luminex and ELISA can assess isotype and subclass by varying the detection antibody to detect total IgG, specific IgG subclasses, or different isotypes altogether. It has been demonstrated that in PAP, anti-GM-CSF autoantibodies tend to be IgG1 and IgG2 (34), whereas in immunodeficiency due to anti-IFN-γ autoantibodies, they tend to be IgG3 or IgG4 (1), possibly suggesting syndrome-specific mechanisms underlying autoantibody production. In PAP, it has also been suggested that the IgG κ/λ ratios predict disease severity (35). In pemphigus vulgaris, a blistering skin condition caused by anti-desmoglein 3 autoantibodies, it was shown that anti-desmoglein 3 IgG4 titers track with disease activity, whereas anti-desmoglein 3 IgG1 levels are seen in quiescent disease or unaffected relatives. Thus, in the future, evaluation and monitoring of the IgG subclass of certain autoantibodies might have clinically important implications for prognosis and disease activity (36, 37).

TITER

The titer of a specific anticytokine autoantibody may play a role in disease activity. This has not been thoroughly studied in any of these conditions, and reports vary across diseases in the instances in which it has been evaluated. Studies have demonstrated efficacy of inhaled GM-CSF for patients with PAP despite no predictable change in autoantibody levels relative to disease activity (38, 39). In contrast, we have found that the titer of anti-IFN-γ autoantibodies does appear to track closely with disease activity and may even predict relapse (13; unpublished data). Research is needed to evaluate the relationship between titer and disease activity as this could eventually be used to guide preemptive therapy or heightened surveillance for relapse.

OTHER DIAGNOSTIC CONSIDERATIONS

Although titer may vary dramatically between patients, antibody levels for a given patient tend to remain relatively stable over time (39). Given the potential for interassay variability within one technique and the difficulty in translating results between assays, it can be helpful to store banked samples for a patient. Over time, autoantibody levels can be tested in parallel to eliminate differences in assays and tracked for a given patient with regard to disease activity and clinical interventions. Ideally, the samples should be stored in aliquots to avoid repeated freeze-thaw cycles.

SUMMARY

Although anticytokine autoantibodies have been recognized for decades, appreciation for their direct role in disease pathogenesis is more recent and rapidly evolving. If we look to known autoantibody-mediated syndromes, other idiopathic diseases may someday find their origins in a neutralizing autoantibody. They may extend beyond cytokines to other soluble factors (as seen in diabetes associated with anti-insulin autoantibodies), receptors (as seen in myasthenia gravis and anti-acetylcholine receptor autoantibodies), or other extracellular elements (as seen in pemphigus vulgaris associated with autoantibodies against the basement membrane protein desmoglein 3). While many autoantibodies are inhibitory, some may be stimulatory, akin to anti-thyroid receptor autoantibodies in Graves' disease or recombinant anti-IL-2 autoantibodies (40). Despite broad disparities in clinical phenotype, the principles and diagnostic strategies (along with their pitfalls) for autoantibody-mediated conditions overlap. Because anticytokine autoantibodies, like other autoantibodies, may

be found in the absence of overt clinical consequences, it is helpful to evaluate the functionality of the antibody and establish a biological rationale that links the autoantibody and the clinical phenotype. Understanding the natural history and pathogenesis of anticytokine autoantibody-associated syndromes will inform the management of these unique diseases. Ultimately, these syndromes may help define critical pathways of immune homeostasis and dysregulation, autoimmunity, and immunodeficiency.

Immunohistology and Immunopathology

section G

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: R. NEAL SMITH

Introduction

ROBERT G. HAMILTON

40

Immunohistochemistry techniques are integral to the practice of anatomic pathology. In contrast to the 7th edition of this *Manual*, in which a separate chapter discusses the principles and advances of immunohistochemistry, these techniques have been directly incorporated in two chapters along with figures illustrating the detection of antibodies involved in renal and cardiac diseases. In the first chapter, Collins et al. provide a brief history of immunofluorescence. Methods for the handling, freezing, and storage of tissue specimens, typically obtained by biopsy, are discussed. While most immunofluorescence studies are performed with unfixed frozen tissue, tissue fixation and tissue sectioning are detailed. Direct immunofluorescence is illustrated for the detection of immunoglobulin G (IgG), IgA, IgM, C3, C1q, fibrinogen, and kappa and lambda light chain deposition in renal tissue. A brief discussion of dual fluorescence and microscope instrumentation is followed by an overview of interpretation. In the second chapter, Collins and Smith discuss Western blot analysis for the detection of antibodies specific for glomerular basement membrane and phospholipase A2 receptors. Special requirements are highlighted for antigen presentation, enzymatic digestion of glomeruli, and transfer onto nitrocellulose paper. Section G provides an overview of immunohistology and immunopathology measurements in present-day clinical practice.

Immunofluorescence Methods in the Diagnosis of Renal and Cardiac Diseases

A. BERNARD COLLINS, JAMES R. STONE, AND R. NEAL SMITH

41

Immunofluorescence is a well-established technique for the detection of antigens in tissue sections or cell suspensions (1, 2). The technique was developed in 1941 by Albert Coons to demonstrate the presence of pneumococcal antigens in tissue (3). Since then, immunofluorescence has become a crucial tool in the diagnosis and determination of prognoses of immunologically mediated disease (4). Direct immunofluorescence (defined as the application of specific antibodies to detect specific antigens in tissue) is a sensitive and well-established technique for the detection of tissue-bound immunoglobulins, their subclasses, complement components (C3, C1q, and C4d), amyloidogenic proteins, and fibrin-fibrinogen. In the kidney, many forms of primary glomerulonephritis are characterized by deposition of immunoreactants in distinctive diagnostic patterns. The primary renal targets are the glomerulus, the proximal tubules, and the interstitium. In the heart or open fat pad biopsy specimens, direct immunofluorescence is useful to speciate the type of amyloid identified on specimens with positive Congo red staining in paraffin-embedded tissue (5). The diagnosis of antibody-mediated rejections in heart and kidney allografts is facilitated by the detection of C4d (6–8). This chapter will also emphasize the common immunofluorescence techniques used for diagnosis and interpretation with kidney and skin biopsy specimens.

TISSUES FOR IMMUNOFLUORESCENCE

Tissue submitted for immunofluorescence studies is usually obtained by biopsy, nephrectomy, or heart explantation. For biopsy specimens, a hand lens or dissecting microscope is useful to determine if the tissue is adequate and not just fibrofatty tissue. For needle renal biopsy specimens, a 1-mm portion is cut from each end of the two cores and placed immediately in Karnovsky's fixative for electron microscopy studies. One core is frozen for direct immunofluorescence studies, and the second core is placed into 10% buffered formalin for light microscopic studies. Renal or cardiac tissue at autopsy is usually suitable for immunofluorescence. In the case of endomyocardial biopsy specimens, multiple separate fragments are received. One should be frozen, one should be placed in Karnovsky's fixative, and the remaining fragments should be fixed in formalin. Ultrastructural review of cardiac tissue is useful to confirm the presence of amyloid, especially if the immunofluorescence pattern is negative, if storage disorders are noted in the differential, or if the immunofluorescence analysis identifies immunoglobulin/complement deposition, which is Congo red negative. Open fat pad biopsy specimens are useful for the detection of amyloid. A section of the fat pad biopsy specimen should be frozen for amyloid subtyping. If the Congo red is positive on the formalin-fixed and paraffin-embedded tissue, the type of amyloid (usually kappa versus lambda) can be determined. Fine-needle aspiration of fat pad biopsy specimens for Congo red is not optimal because Congo red staining can often be indeterminate due to artifact. Renal or cardiac tissue at autopsy is usually suitable for immunofluorescence. Amyloid that cannot be subtyped can be speciated by proteomic analysis (9).

TISSUE HANDLING AND FREEZING PROCEDURE

Tissue for immunofluorescence studies should be obtained fresh and kept moist until it is rapidly frozen or snap-frozen. Freezing should be performed within 20 to 30 min if possible. However, the tissue can be kept on a saline-moistened piece of gauze or filter paper in a closed vial or small petri dish. For longer delay times (due to transport) or as an alternative to freezing, the specimen can be put into Michel's immunofluorescence transport medium. The medium is composed of an 85% saturated solution of ammonium sulfate, the protease inhibitor *N*-ethylmaleimide, and magnesium sulfate, in citrate buffer, pH 7.25 (available commercially from Zeus Scientific, Inc., Raritan, NJ). The solution is stable at room temperature but must be kept in a tightly capped container to prevent absorption of CO_2 and acidification. The ammonium sulfate reversibly denatures all proteins in the biopsy specimen. Specimens stored in the transport medium are stable for at least 2 to 4 weeks at room temperature. Specimens in transport media often show increased background. When the specimen is received in the laboratory, the ammonium sulfate is removed by placing the tissue into the wash solution (three 10-min washes; Zeus Scientific, Inc.).

Tissue is frozen by immersing properly oriented tissue into a small amount of OCT compound, a water-soluble resin (Miles Laboratories, Inc., Naperville, IL), on a precooled metal chuck in a cryostat and applying the heat extractor until the OCT is opaque and the tissue frozen. Tissue is then ready for sectioning in less than 3 min.

doi:10.1128/9781555818722.ch41

Many of the difficulties in immunofluorescence studies are related to tissue-handling techniques, suboptimal freezing procedures, drying, or inappropriate frozen storage conditions. If tissue is allowed to freeze too slowly, ice crystal formation can occur, causing structural disruption.

STORAGE CONDITIONS FOR FROZEN SPECIMENS

Frozen specimens should be stored frozen at −70°C in a small plastic bag with as little air as possible. At −70°C, it is possible to store tissue blocks for long periods, often for years, and still obtain adequate results. Tissue can be stored at −20°C, but at this temperature, the duration of satisfactory preservation usually does not exceed several months. Frozen tissue deteriorates during storage, usually from ice crystal formation or desiccation.

FIXATION

Most diagnostic studies using direct immunofluorescence techniques are performed with unfixed frozen tissue sections, since many antigens can be altered or destroyed by fixation. However, demonstration of the presence of some cytoplasmic antigens, such as viral antigens, for diagnostic purposes may require fixation. The optimal fixation conditions must be empirically determined for each antigen of interest. Fixation may also cause the physical redistribution of some antigens. For example, in anti-neutrophil cytoplasmic antibody assays, alcohol fixation of the neutrophil slide preparation causes the myeloperoxidase contained in the primary azurophilic granules in the cytoplasm of neutrophils to redistribute to a perinuclear or nuclear location.

FROZEN-TISSUE SECTIONING

Frozen sections for direct immunofluorescence should be cut in a cryostat at a thickness of 2 to 4 mm. The frozen blocks of tissue should be equilibrated in the cryostat at −25 to −20°C before frozen sectioning. The tissue sections are picked up on single-end SuperFrost/Plus glass slides (Fisher Scientific, Pittsburgh, PA) to facilitate labeling and decrease the chance that tissue will be lost by wiping it off the wrong side. The tissue attaches because the slides are at a higher temperature than the tissue and are positively charged, reducing the likelihood of washing off the tissue. Furthermore, the Plus slide pretreatment eliminates the time-consuming need for coating slides with tissue adhesive solutions (albumin, poly-L-lysine, or 3-aminopropyltriethoxysilane). If necessary to determine if the tissue is adequate, an initial frozen tissue section can be stained using a 1% toluidine blue solution. If the specimen is small, a circle is marked around the tissue with a diamond or aqueous insoluble pencil because it can be difficult to find the tissue on the slide after coverslips are placed on the tissue sections.

Three sections are placed on each slide and either air dried and stained immediately or stored frozen at −20°C in a slide box covered with aluminum foil or plastic wrap. Storing slides overnight allows more effective organization of technical time.

DIRECT IMMUNOFLUORESCENCE

Principle

In the direct immunofluorescence technique, frozen tissue sections are incubated at room temperature in a moist chamber using well-characterized fluorochrome-conjugated antibodies. After incubation, the unbound labeled antibody is washed from the tissue sections, the slides are placed on coverslips, and the bound, labeled antibody is detected by examination and interpretation using a fluorescence microscope. For large workloads, automated stainers enhance technical uniformity and efficiency.

Staining Procedure

Kidney specimens are routinely stained with a panel of immunoglobulin G (IgG) fractions of fluorescein-labeled monospecific antisera to IgG, IgA, IgM, C3, C1q, fibrin-fibrinogen, kappa and lambda light chains, and, in the case of renal biopsy specimens, albumin as a negative control. For genetic renal diseases of the glomerular basement membrane, antibodies to the alpha 1, 3, and 5 chains of type IV collagen can be used to distinguish thin basement membrane disease from an Alport's type of hereditary nephritis. If amyloid is suspected for cardiac specimens or non-light-chain amyloid for renal specimens, antibodies to IgA, IgG, IgM, fibrin-fibrinogen, kappa, lambda, amyloid A, apolipoprotein A1, transthyretin, and β2-microglobulin are used.

1. Prior to staining, cryostat sections (2 to 5 μm) are air dried for 30 min at room temperature to maximize adherence. Afterward, slides are washed for 5 min in 0.01 M sodium phosphate-buffered saline (PBS)–0.15 M NaC1 (pH 7.3) to remove unbound serum proteins which contribute to background staining. The slides are loaded into a staining rack of a Tissue-Tek II (Miles Laboratories) slide-staining unit, which is placed on a clinical rotator adjusted to give gentle stirring.
2. After washing, one slide at a time is removed, the excess PBS is blotted from around the tissue section, and 50 to 100 μl of appropriately diluted fluorescein conjugate is applied to the tissue section while it is still moist. A drop of conjugate should be added just above the tissue section, and to ensure that the conjugate covers the entire specimen, the slide should be gently tipped to one side and then the other. The slides are then incubated for 30 min at room temperature in a moist, level chamber or in petri dishes containing a moistened piece of filter paper. It is essential that tissue remain moistened after being hydrated to avoid problems with background staining.
3. After incubation, the slides are tipped to one side to allow the excess conjugate to run off and the slides are washed as in step 1 in PBS four times for 5 to 10 min each time to remove unbound fluorochrome-labeled conjugate from the section.
4. The excess PBS is blotted from around the specimen, and the moistened tissue is placed on a coverslip with mounting medium. Aqua-Mount (Lerner Labs, Pittsburgh, PA) is used as a mounting medium.
5. The slides are examined using a fluorescence microscope with epi-illumination equipment, which consists of barrier and excitation filters contained in a dichroic mirror package, to allow the visualization of fluorescein.

The above steps are adequate for small laboratories with small workloads. Automated stainers are a better choice because of their technical uniformity and efficiency.

C4d Staining of Renal Allografts

In addition to being stained with the routine direct immunofluorescence panel, allograft kidney or allograft cardiac biopsy specimens are stained for C4d as a marker of

antibody-mediated rejection by using a three-step immunofluorescence technique (6). Diffuse staining of C4d in peritubular renal capillaries or cardiac capillaries has been shown to be associated with circulating antibodies to donor HLA class I and class II antigens in alloantibody-mediated rejections (7–9).

TWO-COLOR IMMUNOFLUORESCENCE

Two-color immunofluorescence can be used to colocalize immunoglobulin deposits with a known antigen. This is a most useful technique used clinically to show that the membranous deposits of IgG4 colocalize with the phospholipase A2 receptor (PLA2R), the antigen of idiopathic/primary membranous nephropathy (10). In this technique, a single slide is air dried for 30 min at room temperature, preblocked first with avidin and then D-biotin, and then incubated sequentially first with anti-human IgG4 fluorescein isothiocyanate (FITC)-labeled (green) subclass antibody, then rabbit anti-PLA2R antibody, biotinylated goat anti-rabbit IgG(H+L), and finally, Cy3 streptavidin. Between each incubation step, the slides are washed in PBS 3 times for 2 to 3 min. Colocalization is identified as yellow when examined under fluorescence microscope using dual excitation filters for FITC and Cy3. Alternatively, separate green and red pictures can be photographed and merged using a camera or, alternatively, software (11).

MOUNTING MEDIUM

A polyvinyl alcohol-glycerol-PBS solution is a common mounting medium. It immobilizes the coverslip by forming a semisolid gel when it sets and allows storage for several weeks at 4°C without significant loss of fluorochrome intensity. Polyvinyl alcohol (Monsanto, St. Louis, MO) is a water-soluble resin available commercially under the name of Aqua-Mount (Lerner Laboratories). For most purposes, the pH of mounting medium should be neutral. However, the pH of mounting medium can be adjusted to achieve more intense fluorescence or to emphasize one color over another, which is particularly helpful in performing double staining. The green fluorescence of fluorescein is quenched at lower pHs, which accents the visualization of the red fluorescence of rhodamine; at high alkaline pHs, both fluorochromes fluoresce yellow. If slides are mounted in Aqua-Mount and stored without light exposure at 4°C or frozen, the fluorescence can be preserved for at least 4 to 8 weeks and longer if the staining is intense.

Rapid fading of fluorescence after excitation is a serious limitation of immunofluorescence preparations, since it restricts reexamination of slides for further evaluation. To ensure that sufficient sections are available for interpretation and reevaluation, several can be placed on the same slide or staining can be done in duplicate. Photography can also be used to document results.

The fading of immunofluorescence slides is related to a combination of factors, including photochemical reactions, fluorochrome oxidation, and the physical and chemical properties of the FITC conjugate. As mentioned previously, it may be necessary to mount the specimens with a medium containing compounds to reduce fluorescence burnout, such as Permafluor (Shandon Lipshaw). Alternatively, newer green fluorochromes are commercially available that are resistant to fading.

QUALITY CONTROL AND ANTIBODY SPECIFICITY

Fluorescein-conjugated antibodies are available from commercial sources. The conjugate should be diluted according to the manufacturer's recommendations. Optimal dilutions of the fluorochrome conjugates are determined empirically using known positive and negative control specimens. The range of working dilutions for direct immunofluorescence studies using fluorochrome-labeled conjugates is usually 1:5 to 1:40 (or about 50 to 150 mg of protein/ml). The range of working dilutions for direct immunofluorescence is usually lower than that for indirect immunofluorescence because of the amplification effect. The appropriate dilution should be determined empirically.

Specificity is an important prerequisite for labeled antibodies used in immunofluorescence studies. Many commercial suppliers sell monospecific fluorochrome-labeled reagents that produce satisfactory results. Relative monospecificity is achieved by absorption, usually non-human immunoglobulins. However, confirmation of specificity and sensitivity is the core responsibility of the user. Commercial suppliers of antibodies usually provide information about the specificity and sensitivity of the fluorochrome-labeled antisera. However, if specificity is defined from Ouchterlony immunodiffusion studies or immunoelectrophoresis, results may be insufficiently sensitive to detect minor contaminating antibodies.

The best method for determining the specificities of labeled antibodies used in diagnostic immunofluorescence studies is to assess their reactivities with known positive and negative tissue controls. For example, a renal biopsy specimen from a patient with membranous glomerulonephritis that has previously been shown to contain only IgG but not IgA is very helpful in defining the specificity of a new lot of labeled anti-human IgA. When in doubt, specificity can be established by blocking or absorption studies. To block staining, the tissue is incubated with unlabeled specific antibody prior to being incubated with the specific fluorochrome-labeled antibody. Although this sometimes results in diminished fluorescence, complete prevention of staining is rarely seen. If specificity is in question, alternative techniques may be required to confirm specificity. Useful positive controls for immunoglobulins can include touch preparations and frozen tissue sections of tonsil or small intestine. Another useful approach is to compare old lots of antisera to new ones with respect to their abilities to detect a known antigen in archival positive cases.

Polyclonal antibody preparations may contain extraneous antibodies, such as antinuclear antibodies, because the antigenic preparation used for immunization can be contaminated with nuclear fragments. Unwanted antibodies can be removed by incubation of the antiserum with appropriate insoluble preparations, such as tissue homogenates or washed red blood cells. It is necessary to use insoluble antigens, since soluble complexes cannot be removed effectively by centrifugation and may bind to the tissue. One method of insolubilizing proteins is to conjugate cross-reactive antigens to CNBr-activated Sepharose beads (Pharmacia, Uppsala, Sweden). These methods should be unnecessary because most commercial sources of antibodies have already absorbed undesirable specificities from the antibodies.

Analytical specificity is more easily ascertained than analytical sensitivity. It is quite possible that a paraprotein or amyloidogenic light chain might have sequence abnormalities that cause loss of epitopes detected by conventionally anti-heavy or -light chain antibodies. So with new lots of antibodies, in addition to specificity studies on samples with readily detectable deposits or amyloid, analytical sensitivity studies should also be done on samples with marginal reactivity. Assessing analytical sensitivity is also problematic for C4d deposition. Both two-step

and three-step indirect immunofluorescence techniques are used to improve sensitivity. Testing a new lot of C4d antibody initially on a known acute antibody-mediated rejection specimen or on a membranous or lupus glomerulonephritis specimen is usually satisfactory and adequate. However, the intensity of C4d staining can vary from faint and segmental to diffuse and intense on both renal and cardiac allograft specimens (6, 8, 12, 13). However, for optimal laboratory quality, testing on a variety of samples is optimal to ensure adequate sensitivity. Because C4d staining correlates with anti-donor alloantibody, multiple samples from patients with known alloantibodies should be tested to adjust the sensitivity of the C4d assay to capture as many of the alloantibody-positive samples as possible while minimizing excess background staining. This is important for cardiac samples. In negative allograft renal biopsy specimens (no peritubular capillary staining), glomeruli invariably show a weak-to-moderate smooth linear staining, which is helpful to assess the strength of staining and the reliability of a negative result. In cardiac allografts, no such internal positive control exists, so the adequacy of the positive control is important.

FLUORESCENCE MICROSCOPES

Fluorescence microscopy depends on the principle that fluorochromes have electrons that are readily excited to unstable higher energy states by absorbing photons of light of specific energies. They then release stored energy as light but at a lower energy level and a longer wavelength.

This loss of energy is emitted as fluorescent light. An excitation filter is chosen to provide incident photons of optical energy at the correct wavelength, and a barrier filter is chosen to block most of the photons of excitation energy and allow only those with lower energies (the fluorescent or emitted photons) to pass through. For example, fluorescein is maximally excited at around 490 nm and has a peak emission at around 510 to 517 nm. FITC interference and excitation filters take advantage of the strong absorption of fluorescein at 490 nm, and when combined with a barrier filter, they block energy with a wavelength of less than 500 nm. This combination of filters results in an apple green color with fluorescein-labeled antibodies.

Tissues or cells stained with fluorescein conjugates can be examined with fluorescence microscopes equipped with appropriate excitation and barrier filters. The most commonly used system is that of epi-illumination, composed of a vertical illuminator and dichroic mirrors. The dichroic mirrors serve as both excitation and barrier filters, since they allow the passage of excitation energy in one direction and emission energy in the other. One limitation of epi-illumination is that the intensity of light at lower magnifications is considerably less than with a dark-field condenser. Another problem is that fluorescence signals of structures above or below the plane of focus result in a background glow or halo effect. This can interfere with interpretation and is frequently more of a concern with cell suspension preparations than with tissue sections. Reduction of these out-of-focus signals can be accomplished by using laser confocal microscopy, usually not necessary for diagnostic applications but more useful for research purposes. Despite these disadvantages, there are several advantages of epi-illumination: (i) no oil is needed; (ii) the intensity of illumination is constant, once the objective is focused so that the brightnesses of staining of different specimens can be more reliably compared; and (iii) viewing can be combined with standard-phase microscopy, which is important for cell suspension studies and for definition of morphological detail in tissue sections, and examination in double-staining studies is easier because of interchangeable FITC and rhodamine dichroic filter systems.

The light source for most fluorescence microscopes is a high-pressure mercury lamp. Illumination is very important, since the brightness of fluorescence depends on the light source, the efficiency of the fluorochrome in converting incident light into fluorescent light, and the concentration of the fluorochrome in the specimen.

EXAMINATION OF SLIDES AND EVALUATION AND RECORDING OF STAINING RESULTS

Preferably, slides should be examined on the day of staining, and a detailed record of the results should be kept on worksheets. Positive and negative controls should be run with each biopsy specimen until one gains confidence in the specificity of staining with a given fluorochrome-labeled reagent. Unexpected findings should always be confirmed before results are reported.

The fluorescence staining of kidney specimens should be described according to location, extent, pattern, and intensity in the glomerular basement membrane (GBM), mesangium, arterioles, tubules, capillaries, interstitium, and casts. For cardiac specimens, descriptions of the staining should include myocytes, capillaries, arterioles, and interstitium.

PHOTOGRAPHY

Photography is the only permanent record one has of the immunofluorescence findings. Laboratories now use digital cameras interfaced with a computer to capture fluorescence images for documentation of results. For routine digital photography, an automated exposure is satisfactory. However, for issues of clonality of light chains, amyloid, or collagen stains, fixed-exposure comparisons are better. This is because automated exposures will intensify weaker staining with longer exposures, thereby making the resultant images appear more similar. It is better to start with a short exposure that just outlines the tissue with faint fluorescence on the most negative reactant and then use that exposure for the other positive or more-positive reactants.

The appendix shows illustrative examples of how immunofluorescence is used on frozen tissues for the identification of immune complexes and speciation of types of amyloid.

Figure 1 shows examples of positive capillary staining for C4d in patients with anti-HLA alloantibodies and acute antibody-mediated rejections of the heart (Fig. 1, left panel) and kidney (Fig. 1, right panel). Figure 1, left panel, shows a cardiac allograft with diffuse capillary staining for C4d. Figure 1, right panel, shows a renal allograft with diffuse peritubular capillary staining for C4d.

Figure 2 shows an example of how immunofluorescence is used to identify cardiac kappa light chain amyloidosis. Figure 2, left panel, shows excess amyloid stain for kappa light chain. Figure 2, right panel, shows negative staining for lambda light chain. Other reactants are also negative.

Figure 3 identifies cardiac lambda light chain amyloidosis. Figure 3, left panel, shows excessive anti-lambda light chain staining of the amyloid deposits. Figure 3, middle panel, shows negative kappa light chain staining. Figure 3, right panel, shows a weak blush of transthyretin staining, which is negative and is background staining when compared to a positive control for transthyretin amyloid (see Fig. 5, right panel). Some reactants, most commonly transthyretin and IgG, show weak background staining within

amyloids. Only a single dominant stain can be called positive. Otherwise, the assay is indeterminate.

Figure 4 shows IgM kappa pseudothrombi (large intraglomerular capillary subendothelial deposits) in a patient with hepatitis C-related cryoglobulinemia. Figure 4, left panel, identifies IgM pseudothrombi within glomerular capillary loops. Figure 4, right panel, identifies kappa light chain staining of the pseudothrombi.

The image shown in Fig. 5 allows diagnosis of the cardiac amyloid as transthyretin, and in this case, it can be called cardiac or senile systemic amyloidosis due to amyloid deposition containing native transthyretin. Figure 5, left panel, shows a negative anti-IgG with background staining. Figure 5, right panel, shows intense positive anti-transthyretin staining.

Figure 6 shows characteristic granular mesangial IgA staining diagnostic of IgA nephropathy. C3, kappa, and lambda staining are similar. IgG can be do-dominant with IgA or less intense. C1q is usually sparse.

Figures 7A and 7B show fluorescent images characteristic of proliferative lupus nephritis, classes III and IV. Figure 7A, left panel, shows strong granular IgG within the GBM and mesangium; kappa and lambda light chain staining are similar. Figure 7A, middle panel, shows segmental granular IgM in the GBM with wire loops (intense coalescing deposits within the GBM). Figure 7A, right panel, shows segmental granular IgA within the GBM with a wire loop. Figure 7B, left panel, shows strong granular C3 within the GBM and mesangium. Figure 7B, middle panel, shows granular C1q within the GBM and mesangium. Figure 7B, right panel, shows granular IgG in the tubular basement membranes with tissue antinuclear antibody (ANA). Granular IgG in the tubular basement membranes (green granular staining within green rings, which are tubules) and tissue ANA (intense green ovals in cells, which are nuclei) are very commonly seen in active lupus glomerulonephritis.

Figure 8 shows colocalization of membranous deposits, which contain IgG (often IgG4 dominant) and the antigen PLA2R of podocytes in idiopathic/primary membranous nephropathy. Figure 8, left panel, shows finely granular IgG4 within the GBM (green, FITC). Figure 8, middle panel, shows finely granular anti-PLA2R staining within the GBM and staining of the podocytes (both red, Cy3). Figure 8, right panel, shows colocalization of the granular IgG4 deposits with the PLA2R antigen (yellow). Colocalization can be done with appropriate filters or by overlaying the green and red images using image software.

Western Blot Analysis for the Detection of Anti-Glomerular Basement Membrane Antibodies and Anti-Phospholipase A2 Receptor Antibodies

A. BERNARD COLLINS AND R. NEAL SMITH

42

Anti-basement membrane antibodies and diffuse alveolar hemorrhage (Goodpasture's syndrome) receives its eponym from Ernest Goodpasture. While studying the influenza pandemic after World War I, Goodpasture studied an 18-year-old male, who died of pulmonary hemorrhage, and diagnosed his pathological findings as systemic vasculitis (1). Although the disease that Goodpasture described is probably different from the disease that now carries his eponym (2), Goodpasture's disease is now well recognized as one of the causes of pulmonary hemorrhage and/or acute renal failure. Immunofluorescence later identified that some cases of pulmonary hemorrhage and renal failure were associated with the linear deposition of immunoglobulins deposited along the pulmonary and glomerular basement membranes (GBM) (3–5). The term Goodpasture's is now generally reserved for the diseases of pulmonary hemorrhage and renal failure with anti-basement membrane antibodies (6, 7).

Animals immunized to basement membranes first established the immunological basis of this disease (8–10), and human anti-basement membrane antibodies passively transfer the disease to monkeys (11). Additional confirmation occurred when Alport's patients lost their allografts to anti-GBM nephritis (12–15). The disease is complement dependent (7, 16). Animal models of pulmonary and glomerular anti-basement membrane disease strongly support the pathogenic nature of these autoantibodies (17–20). The autoantibodies are immunoglobulin G (IgG), predominantly IgG1 (21), and complement fixing (16). Plasmapheresis removes autoantibodies and complement and mitigates the disease (6, 22, 23). Recurrence of antibodies can cause relapse (24, 25). Why some patients develop only pulmonary or renal disease is unknown.

The antigenic sites identified by autoantibodies in anti-basement membrane disease are within the type IV basement membrane collagen (26–28), specifically and most commonly the antigenic target is the non-collagenous globular domain (NC1) of the alpha 3 chain of type IV collagen (29–31). The antigen in the alveolar basement membrane is thought to be the same as that of the GBM (32, 33). Fine specificity analysis identifies two binding sites for pathological autoantibodies within the NC1 domain that are normally sequestered within the alpha 3 chain (34, 35). Autoantibodies against these two epitopes correlate with disease severity as compared to autoantibodies against other basement membrane antigens (36–38). Patients with anti-basement membrane disease have two normal alpha 3 collagen genes (COL4A3) (39). Studies of the molecular architecture of basement membrane identify that the quaternary structure of the alpha 345 NC1 hexamer must be perturbed to expose the cryptic autoantigenic epitopes within the alpha 345 NC1 hexamer. These epitopes elicit autoantibodies because anti-GBM autoantibodies are nonreactive to the native intact hexamer (40). In contrast, in posttransplantation anti-GBM nephritis in Alport's, these anti-GBM antibodies bind to intact hexamers (40). This seminal study also showed that titers to the alpha 3 NC1 correlated with disease activity, as did the presence of alpha 5 NC1 autoantibodies, likely developing through epitope spreading.

There is a strong association of class II genes and human anti-basement membrane disease, which is consistent with genetic immune response gene control within the major histocompatibility complex (39, 41–43). Similar findings are found in mice (44). Additional non-major histocompatibility complex genetic variation in disease susceptibility is found in mice (18, 45). The mere presence of anti-basement membrane antibodies does not necessarily lead to disease. In spite of the normal clonal selection against B cells with reactivity to alpha 3(IV) NC1 epitopes (46), some human immunodeficiency virus patients, possibly due to B-cell dysregulation, have anti-basement membrane antibodies without Goodpasture's disease (47, 48). Anti-alpha 3(IV) NC1 antibodies are found in normal sera (49) with much lower titers and avidity than in sera from patients with Goodpasture's. In addition, the subclass distribution was different, with IgG1 present in the sera of a patient with disease compared to IgG2 in normal sera, suggesting the importance of complement. T-cell tolerance may be broken by T-cell priming to bacterial antigens which cross-react on alpha 3(IV) NC1 epitopes (epitope mimicry) (50). Variation in host natural killer T cells, transforming growth factor β, Fc receptor, and kallikrein esterase activity may exacerbate or mitigate disease activity (18, 51, 52). Because the alpha 3(IV) NC1 pathogenic epitopes are sequestered within the normal hexamer, pathogenic antibodies may still be excluded from binding (40, 53). In a mouse model of anti-basement membrane disease, mice resistant to anti-basement membrane disease became susceptible with injections of interleukin-2 or gamma interferon (54),

doi:10.1128/9781555818722.ch42

suggesting that inflammation or other pulmonary injury can promote disease by making the pathogenic epitopes available for antibody binding. This is an intriguing hypothesis because many reports of anti-basement membrane disease were temporarily associated with viral infection, smoking, or inhalation injury (55–62). An additional complexity in the pathophysiology of anti-basement membrane disease is that 20 to 30% of patients with anti-alpha 3(IV) NC1 autoantibodies also have anti-neutrophil cytoplasmic antibodies (ANCA) to myeloperoxidase or proteinase 3 (44, 63–67). A detailed serological analysis suggested that double-positive patients had fewer antibodies to the two pathogenic epitopes of alpha 3(IV) NC1 than patients with only anti-basement membrane antibodies. This suggests that some double-positive patients should have a disease pattern more closely resembling ANCA disease. However, some double-positive patients have fulminant disease, more closely resembling anti-basement membrane disease, so it is impossible to distinguish which autoimmune process is more pathogenic. It is possible that the ANCA disease in anti-GBM susceptible patients causes sufficient basement membrane injury to unmask the cryptic alpha 3(IV) NC1 epitopes and allow T-cell epitope spreading, permitting an anti-alpha 3(IV) NC1 antibody response (35–37).

Pathologically, there is diffuse alveolar hemorrhage and/or crescentic glomerulonephritis. By immunofluorescence, there is strong linear staining for IgG, which exceeds albumin (anti-GBM immunofluorescence). The staining must be linear and not granular. The presence of granular IgG GBM staining indicates the presence of immune complexes, which would most likely exclude anti-GBM disease in most cases. Confirmation of anti-basement membrane disease requires a positive Western blot, the most sensitive assay for anti-basement membrane disease, confirming bands at 28 and 48 to 50 kDa (67). Monitoring of anti-alpha 3(IV) NC1 titers guides therapy and can identify early relapse (68). Determination of anti-GBM antibodies by Western blotting is the most critically important test in the differentiation of acute pulmonary hemorrhage because negative enzyme immunoassays may miss low titers, which are readily detected as positive by Western blotting.

WESTERN BLOT ANALYSIS

Our laboratory uses a sensitive and specific assay developed for the detection of circulating anti-GBM antibodies using Western blot analysis. This assay is advantageous because the exact molecular weight of the antigen recognized by the autoantibody is determined and compared to the reactivity of a known Goodpasture serum to the α3(IV) chain. The antigenic preparation used is a collagenase digest of isolated human GBM prepared by the enzymatic digestion of the GBM, which releases the NC1 domains of the type IV collagen, including the α3(IV) NC1, the Goodpasture antigen. Separation of the soluble proteins by polyacrylamide gel electrophoresis (PAGE), followed by transfer to nitrocellulose paper for immunoblotting, allows discrimination between antibody reacting to the Goodpasture antigen and those reacting with other components of the GBM.

ANTIGEN PREPARATION FOR ANTI-GBM ANTIBODIES

GBM is prepared from normal human kidneys obtained at autopsy or from nephrectomy specimens. Use of autopsy specimens is limited to no more than 10 to 12 h after death, and in the case of surgical specimens, only the normal portion at least 1 to 2 cm distal from any tumor is taken. The kidneys are then stored frozen at −70°C for glomerular isolation.

The tissue is thawed in 0.01 M phosphate-buffered saline (PBS), pH 7.2, containing 10 mM phenylmethylsulfonyl fluoride as a protease inhibitor. All subsequent isolation steps are carried out in the presence of phenylmethylsulfonyl fluoride. The cortical portion of the kidneys is cut away from the medulla and placed in ice-cold PBS. Glomeruli are isolated from the cortical tissue using differential sieving. The glomeruli are washed two or three times with PBS. After the final wash with PBS, the glomeruli are washed twice with distilled water to rupture the cell membranes. To further remove cellular material, the glomeruli are sonicated by pulsation using a W200 P Sonifier cell disrupter (Heat Systems-Ultrasonics, Inc., Plainview, NY) equipped with a microtip at a 40% duty cycle. After the initial sonication, the preparation is examined using phase microscopy and the sonication step is repeated until only refractile GBM remains. The GBM is dialyzed against distilled water overnight at 4°C, lyophilized, and stored in a desiccator at 4°C.

ENZYMATIC DIGESTION OF GLOMERULI

The GBM is digested using chromatographically purified collagenase type VII prepared from *Clostridium histolyticum* (Sigma, St. Louis, MO). The collagenase preparation is substantially free of nonspecific protease, clostripain, and tryptic activities. Ten milligrams of lyophilized GBM is suspended in 2 ml of 0.1 M Tris-HCl (pH 7.5) in a 15-ml centrifuge tube with 5 mM $CaCl_2$ added to facilitate digestion. The mixture is sonicated for 30 min in a Bransonic 220 water bath sonicator (Branson Co., Shelton, CT). Collagenase type VII (1,000 U/mg of GBM) is added, and the GBM is digested at 37°C in a shaking water bath for 48 h. The pH is monitored at 30, 60, and 120 min and adjusted to 7.5 if necessary using 1 N Tris-HCl or 1 N Trizma base. After digestion, 1 ml of 0.1 M Tris-HCl, pH 7.5, containing 2 mM EDTA is added to chelate free Ca^{2+} and thus quench the reaction. The particulate solution is centrifuged at 1,500 × *g* for 30 min at 4°C. The clear supernatant is recovered and assayed for protein concentration. The solubilized antigen is then stored frozen at −70°C in 50-μl aliquots.

In initial studies, the GBM was subjected to various durations of enzymatic digestion, from 24 to 96 h, to maximize the degradation of the collagenous portions of the membrane. Protein determinations by the Lowry method were performed, and the results obtained showed that approximately 50 to 60% (wt/wt) of the membrane was solubilized in the first 24 h. The solubilization occurred less rapidly after that but continued for up to 72 to 96 h.

PAGE AND TRANSFER TO NITROCELLULOSE PAPER

An aliquot of the soluble antigen preparation obtained from the collagenase digestion of the GBM is thawed, and 200 μg is added to each precast gel (Jule, Inc., Milford, CT) and then separated by sodium dodecyl sulfate-PAGE in 12% unreduced gels using a Mighty Small II gel apparatus (Hoefer Scientific, San Francisco, CA) at a constant current of 40 mA for 1 h. Included as a marker is a low-molecular-weight standard (Bio-Rad, Richmond, CA). After PAGE, the separated proteins are transferred to nitrocellulose paper (GE Healthcare Amersham Hybond-ECL Fisher Scientific, Agawam, MA) using a TE series Transphor electrophoresis unit (Hoefer Scientific) and a PS 500X direct current power

supply. The transfer electrophoresis is carried out using a constant current of 200 mA for 1 h with a circulating water cooling system. To verify and visualize the separated transferred proteins, the nitrocellulose paper is cut from one side of the paper to include the molecular weight standard and the soluble GBM antigen digest and placed into 0.1% India ink on a slow rotator for 30 to 60 min, followed by a PBS wash. The remainder of the nitrocellulose paper is stored dry between two pieces of Whatman filter paper at room temperature. Storing paper in this manner allows sera to be tested quickly and efficiently. Paper can be stored dry for up to 2 months.

WESTERN BLOTTING

An appropriate piece of the dried nitrocellulose paper is cut for the number of serum samples to be tested and placed into 5% skim milk buffer for 1 h, with agitation, for blocking. After blocking, the nitrocellulose paper is cut into 3- to 4-mm-wide strips and placed into the wells of a Mighty Small incubation tray (Hoefer Scientific). The strips are incubated in 1 ml of test serum diluted 1:10 in 0.5% skim milk buffer for a minimum of 1 h. After incubation, the excess serum is aspirated and the strips are washed three times for 5 min each time with 0.5% skim milk buffer. They are then incubated with 1 ml of biotin-conjugated goat anti-human IgG (heavy and light chains; Vector Labs, Burlingame, CA) at 1:250 for 1 h, with agitation. After incubation, excess conjugate is aspirated and the strips are washed with 0.5% skim milk buffer. To detect bound labeled antibody, the strips are incubated in 1 ml of avidin biotin complex (Vector Labs) for 60 min, the excess reagent is aspirated, and the nitrocellulose strips are washed in the 0.5% skim milk buffer as described above. The last incubation is with 3-amino-9-ethyl carbazole (1 ml per well), a chromogen for horseradish peroxidase. Finally, the strips are washed in distilled water for 5 to 10 min and blotted dry between two pieces of Whatman filter paper, so the strips can be examined for reactivity to the α3(IV) NC1 (the Goodpasture antigen) or reactivities to other NC1 domains of type IV collagen. The total time for performance of the test is 4 to 5 h.

Figure 1 shows a positive and negative Western blot for anti-GBM antibodies.

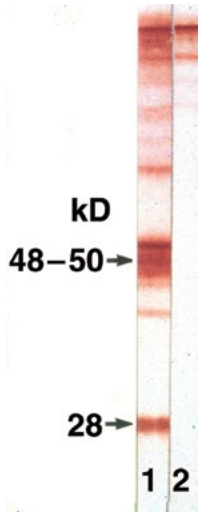

FIGURE 1 Lane 1 shows a Western blot of known positive anti-GBM (1:20) identifying the required bands of 28 and 48 to 50 kDa. Lane 2 shows a negative serum sample. Note the higher-molecular-mass bands in both the positive and negative sera.

ELISA FOR α3(IV) NC1

Western blot analysis is a sensitive and specific assay for detecting anti-GBM antibodies, but for monitoring disease activity, quantitation is required. A satisfactory monitoring commercial enzyme-linked immunosorbent assay (ELISA) kit (Scimedx Corp., Denville, NJ) uses microtiter strips coated with the monomer of the α3(IV) NC1 subunit. The value, in ELISA units (EU), for each unknown serum is determined from a standard curve constructed from analysis of known positive sera containing assigned values of 5, 20, 80, and 320 EU/ml. A positive serum and a negative serum are also included in each determination. The level of antibody is expressed as EU per milliliter. A value equal to or greater than 15 EU/ml is considered positive. A value equal to 5.1 to 14.9 EU/ml is considered equivocal, and a value equal to or less than 5 EU/ml is considered negative. Differences in sensitivity and specificity were observed when the results of ELISA and Western blot analysis were compared using the same serum. The differences in results were evident for treated patients, particularly when plasmapheresis was part of the treatment regimen. However, the ELISA is clearly less sensitive than Western blotting. Often after treatment, the ELISA will become negative, while the Western blot analysis remains positive. False positives are also a problem in this ELISA; we have obtained positive ELISA results with sera from nine patients with no evidence of anti-GBM disease by biopsy or Western blot analysis. Therefore, the most sensitive and specific current method for detecting circulating anti-GBM antibodies is Western blot analysis. In our laboratory, positive anti-GBM antibody results obtained by ELISA are never reported without confirmation by Western blot analysis. It is also important to note that the antibody titer obtained in the ELISA for different patients cannot be used as a measure of the disease severity, since the antibodies may have different affinities and biological activities. The test is most useful for monitoring an individual patient, comparing subsequent samples with the initial sample.

ANTIGEN PREPARATION FOR ANTI-PHOSPHOLIPASE A2 RECEPTOR ANTIBODIES

The antigen preparation for the detection of anti-phospholipase A2 receptor antibodies is identical to the methods of Beck et al. (69) in their supplementary appendix. Cortical sections are snap-frozen and stored at −70°C from deceased human kidneys not used for transplantation. Cortical sections are pressed through a gradient of sieves (Fisher Scientific) with cold PBS to enrich for glomeruli. Pellets of glomeruli with an equal volume of 100 mM Tris, pH 8.1, 1 mM $MgCl_2$ are freeze-thawed at −80°C. An equal volume (twice the glomerular pellet volume) of radioimmunoprecipitation assay buffer (50 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1% NP-40, 0.5% sodium deoxycholate, 0.1% sodium dodecyl sulfate; Boston BioProducts, Ashland, MA) is added with 1× protease inhibitor cocktail set I (Calbiochem/EMD Chemicals, Inc., San Diego, CA), and the glomeruli are manually Dounce homogenized while on ice. Glomerular proteins are extracted on ice for 40 min, with intermittent vortexing. Radioimmunoprecipitation assay-insoluble debris is removed by a 10-min centrifugation at 14,000 rpm at 4°C. Due to the presence of contaminating human IgG in this preparation, the human glomerular extract was incubated for 4 h (or overnight) at 4°C with

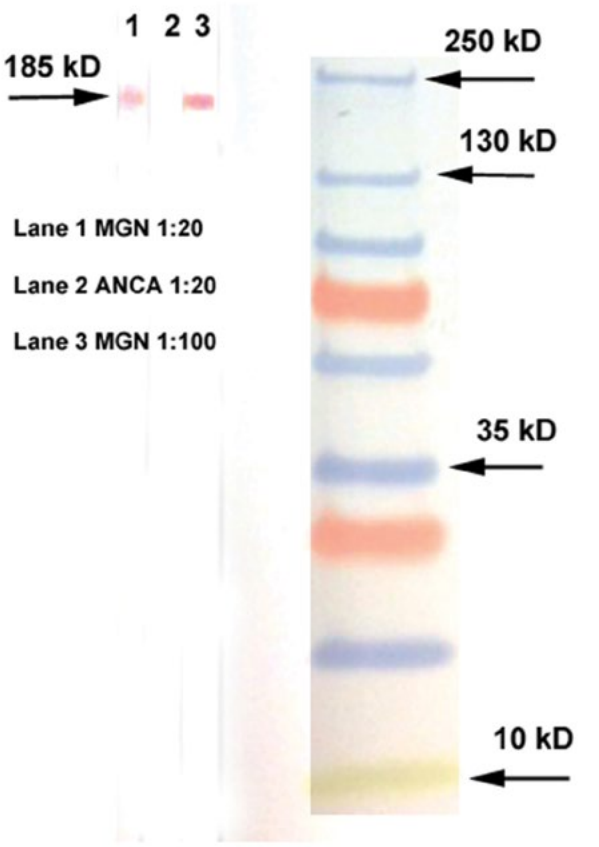

FIGURE 2 Example of a Western blot for anti-phospholipase A2 receptor antibodies. Lanes 1 and 3 show positive serum samples at 1:20 (lane 1) and 1:100 (lane 3) dilutions from a patient with primary/idiopathic membranous nephropathy (MGN) of the anti-phospholipase A2 receptor type. Lane 2 shows a negative control at 1:20 dilution from an ANCA-positive patient. On the right are molecular mass markers.

immobilized Protein G Plus (Thermo Fisher) and the beads discarded. Human glomerular extract was tested by Western blotting with anti-human IgG to ensure that all detectable IgG had been removed.

WESTERN BLOT FOR ANTI-PHOSPHOLIPASE A2 RECEPTOR ANTIBODIES

The Western blot procedure for anti-phospholipase A2 receptor antibodies is the same as described above for anti-GBM antibodies, except that electrophoresis is performed with 7.5% nonreducing gels and transfer is done using Immobilon polyvinylidene difluoride paper (Millipore Corp, San Diego, CA). See Fig. 2.

Infectious Diseases Caused by Bacteria, Mycoplasmas, Chlamydiae, and Rickettsiae

section H

VOLUME EDITOR: JOHN L. SCHMITZ
SECTION EDITOR: CHRISTINE LITWIN

Introduction

CHRISTINE M. LITWIN

43

This section contains chapters describing methods for the immunologic diagnosis of acute, chronic, or latent infections and nonsuppurative sequelae caused by bacteria, rickettsiae, mycoplasmas, bartonellae, and borreliae. The majority of the methods described in these chapters measure antibodies. In situations where it is difficult to culture the infectious agent, antibody detection is one of the only effective ways to identify the infecting organism. The described methods cover a wide range of antibody assays, including hemagglutination, indirect fluorescence, complement fixation, and enzyme-linked immunosorbent assays.

The newer cellular immune response assays for *Mycobacterium tuberculosis* (e.g., skin testing and gamma interferon release assays) are described. These assays are used for the detection of latent disease, as opposed to the case for assays for other organisms, in which antibody serology is used for the assessment of active or recent infection.

Also described in this section are antigen detection assays which use organism-specific polyclonal or monoclonal antibodies as capture and/or indicator reagents. Such assays include assays of urinary lipoarabinomannan for the detection of active tuberculosis and assays of *Helicobacter pylori* antigens in stool.

Molecular methods for diagnosing infectious diseases are presented in chapters where appropriate, since these methods are often performed in combination with serologic testing in clinical immunology laboratories.

Notable changes to section H from the previous edition of this *Manual* include moving the assessment of vaccine efficacy to the more relevant section E, which addresses functional cellular assays. Syphilis serology is now covered in a separate chapter from that for Lyme disease, borrelliosis, and leptospirosis. In addition, a new chapter has been added which addresses tests for diagnosing infections with *Francisella tularensis*, *Brucella* species, and *Bartonella* species.

Diagnostic Methods for Group A Streptococcal Infections

CHRISTINE M. LITWIN, SHELDON E. LITWIN, AND HARRY R. HILL

44

Group A streptococcus, also known as *Streptococcus pyogenes*, is an important bacterial pathogen that is the most frequent bacterial cause of acute pharyngitis. It also causes a multitude of other cutaneous and systemic infections, including impetigo, scarlet fever, necrotizing fasciitis, and streptococcal toxic shock syndrome. The pathogen has a unique tendency to initiate autoimmunity after acute infection, resulting in the nonsuppurative sequelae acute rheumatic fever (ARF) and poststreptococcal acute glomerulonephritis (AGN). The heart disease resulting from ARF has been responsible for substantial morbidity and mortality in all parts of the world.

Group A streptococci are Gram-positive, nonmotile, non-spore-forming, catalase-negative, and facultatively anaerobic bacteria belonging to the genus *Streptococcus*. The initial classification of streptococci dates back to 1903, from the description by Schötmuller of the blood agar method of differentiating hemolytic from nonhemolytic streptococci. Further classification by patterns of hemolysis was made in 1919 by Brown, who introduced the terms alpha, beta, and gamma hemolysis. In 1933, the beta-hemolytic streptococci were classified by Lancefield into distinct serogroups (20 in all; groups A to H and K to V) based on immunologic and biochemical characteristics (1). Most strains found to be pathogenic to humans were found to belong to serogroup A (*S. pyogenes*). Lancefield further established the important role of the M protein of streptococcus as a virulence factor. The ability to differentiate serotypes of the M protein of group A streptococcus (and later *emm* types) has allowed epidemiologic associations of ARF and AGN with certain M serotypes. Over 100 different M proteins have been identified in the group A streptococci, but there are specific M types that are identified most often with ARF, pharyngitis-associated AGN, and pyoderma-associated AGN in the United States (Table 1).

Sizeable epidemics of scarlet fever have been reported since the 12th and 13th centuries, in association with consumption of nonpasteurized milk, in surgery wards, obstetric wards, schools, and day care centers, and among families. Transmission of group A streptococci is usually by the oral route, from aerosolized droplets or from ingestion of contaminated milk or other foods. The incidences of group A streptococcus infections, ARF, and rheumatic heart disease decreased over the course of the 20th century in many parts of the world. The decline in infection rate was particularly steep during the 1960s and 1970s. One notable outbreak, however, occurred in 1968, when a sudden and abrupt epidemic of group A streptococcal pharyngitis developed in over 1,000 cadets at the U.S. Air Force Academy in Colorado during a 7-day period. An epidemiologic investigation implicated hard-boiled eggs in tuna salad as the source of the outbreak (2). Careful observation and follow-up of the cadets did not identify any nonsuppurative sequelae.

A resurgence of ARF occurred in the United States in the mid-1980s, in multiple regions. In early 1985, an epidemic of ARF occurred in Salt Lake City, UT, and the surrounding intermountain area (3, 4). During the years 1985 through 1992, patients who sought medical treatment for ARF at Primary Children's Medical Center in Salt Lake City, UT, came predominantly from middle class families (84%), with carditis as the major manifestation (68%) (5). The resurgence continued, and by 2000, more than 500 cases had been diagnosed. The striking and sudden reappearance of ARF in Salt Lake City was likely due to the rheumatogenicity of the prevalent group A streptococci in the area at that time. A study of the isolates from these patients demonstrated that specific strains of a mucoid group A streptococcus, primarily M protein type 18, were associated with the two periods with the highest incidences of rheumatic fever in Salt Lake City, i.e., 1985–1986 and 12 years later, 1997–1998. During these outbreaks, there was a statistically significant association between the percentage of mucoid strains and the number of cases of ARF (6–8). At around the same time, small clusters of epidemics, ranging from 15 to 40 cases each, were also reported in Kansas City, MO, Dallas, TX, Columbus and Akron, OH, Nashville and Memphis, TN, Morgantown and Charleston, WV, Pittsburgh, PA, and New York City, NY (9). And for the first time since the 1960s, outbreaks were again occurring in navy and army training camps (10). This unexplained resurgence ultimately resulted in a heightened public health concern for the accurate diagnosis of group A streptococcal infections, thus allowing prevention of ARF and, ultimately, rheumatic heart disease.

ARF is a delayed, nonsuppurative sequela of a group A streptococcal upper respiratory infection, usually pharyngitis. ARF occurs in 0.1 to 2.5% of individuals after untreated group A pharyngitis. Table 2 describes the acute manifestations of acute group A streptococcal infection versus ARF. ARF is an inflammatory disease with lesions primarily

[b]M types 49 and 55 have occasionally caused pharyngitis-associated AGN.

involving the joints, heart, central nervous system, and subcutaneous tissues. The classic form of ARF is acute, febrile, and predominantly self-limited. Studies of ARF have shown that the disease occurs only after an immunologically significant streptococcal infection, with elevated serum levels of antistreptococcal antibodies almost always documenting a recent streptococcal infection (11, 12). An unexplained but intriguing aspect of ARF is that cutaneous infections do not initiate ARF but, rather, poststreptococcal AGN. ARF may require the lymphoid tissue of the pharyngeal site for initiation of the disease, or the pyoderma strains that cause AGN may not be rheumatogenic.

The signs and symptoms of ARF can occur singly or with multiple symptoms. The most important signs and symptoms are termed the major manifestations and include carditis, polyarthritis, chorea, subcutaneous nodules, and erythema marginatum. Additional findings that are often present in ARF but are nonspecific are called the minor manifestations, and these include fever, arthralgia, heart block, and elevated levels of acute-phase reactants in the blood.

The latent period between pharyngitis and the onset of ARF is 19 days, on average. Arthritis is usually the first manifestation, although this may be preceded by abdominal pain (13). Overall, the arthritis occurs in about 75% of initial attacks with ARF. Carditis, if it appears, also does so early in the course of disease, approximately 20 days after the pharyngitis, with a frequency of about 50% of ARF patients (14). Carditis is the one manifestation of ARF that can cause long-term residual morbidity or mortality. Chorea occurs in 15% of cases, and subcutaneous nodules and erythema marginatum occur in fewer than 10% of cases (15).

Poststreptococcal AGN is a delayed nonsuppurative sequela of either pharyngeal or cutaneous infection with certain nephritogenic group A streptococcal strains. It is characterized by diffuse proliferative glomerular lesions and by clinical manifestations of renal disease, such as edema, hypertension, hematuria, and proteinuria (16). Patients may also complain of lethargy, weakness, anorexia, headache, and dull back pain. Fever is not a usual feature. About 5 to 10% of patients develop severe hypertension complicated by encephalopathy, ranging from headache and vomiting to confusion and convulsions. Conversely, many cases of AGN can be quite mild.

The long-term sequela of ARF is rheumatic heart disease. The prognosis of ARF is usually related to the severity of cardiac involvement during the acute phase of the disease. In a large comprehensive study performed in the United Kingdom and the United States, only 6% of patients with no carditis or with questionable carditis were found to have heart murmurs 10 years later. Heart disease was present at the 10-year follow-up in 30% of patients initially found to have only apical systolic murmurs, 40% of those with basal diastolic murmurs, and 68% of those who initially suffered from congestive heart failure and/or pericarditis (17). While ARF is usually associated with mitral valve regurgitation, recurrent bouts of ARF with carditis are the main cause of later development of mitral valve stenosis.

Laboratory findings of poststreptococcal AGN include an elevated erythrocyte sedimentation rate, mild normocytic normochromic anemia, slight hypoproteinemia, and elevations of the BUN and serum creatinine concentrations. Hypercholesterolemia and hyperlipemia may also be present. Total hemolytic complement and C3 complement levels are reduced in a majority of patients. As discussed later, anti-streptolysin O (ASO) responses are weak in pyoderma-associated (cutaneous infection) AGN, and it is frequently necessary to perform an anti-DNase B measurement to provide evidence of poststreptococcal sequelae.

This chapter focuses primarily on different laboratory methods for diagnosing acute group A infections and the nonsuppurative sequelae ARF and AGN. The different laboratory methods discussed include the "gold standard" (culture and identification), rapid antigen detection, molecular detection, and serological tests to measure the human response to group A streptococcal antigens for the diagnosis of nonsuppurative sequelae.

CULTURE AND IDENTIFICATION

Detailed throat culture procedures have been published by the American Heart Association (18). Culture of the throat or wound remains the gold standard for establishing

TABLE 2 Clinical manifestations of group A streptococcal infection and ARF

Acute group A streptococcal infection	ARF[a]	
	Major	Minor
Beefy, swollen, red uvula	Carditis	Arthralgias and fever
Fever	Polyarthritis	Elevated acute-phase reactants (erythrocyte sedimentation rate or C-reactive protein)
Headache	Chorea	Prolonged PR interval
Nausea, vomiting, and abdominal pain	Erythema marginatum	
Pain with swallowing	Subcutaneous nodules	

[a]Two major manifestations or one major and two minor manifestations must be present for diagnosis.

the presence of group A streptococci. Sheep blood agar is preferred because unambiguous patterns of hemolysis are observed with this medium. Group A colonies grown in 5% sheep blood agar at 35°C to 37°C overnight are typically surrounded by a clear zone of hemolysis (beta-hemolytic). Plates that are initially negative should be kept and reexamined after another 24 h. There have been some discussions in the literature with regard to variations of this culture procedure. Some publications suggest that the addition of trimethoprim-sulfamethoxazole to the blood agar helps to suppress the competing normal pharyngeal biota. There has also been debate over the optimal atmosphere for incubation—aerobic, aerobic in the presence of 5 to 10% CO_2, or anaerobic. A presumptive identification can be made by demonstrating a zone of growth inhibition around bacitracin disks (0.04 IU) placed on the surface of the blood agar. Serologic grouping and identification may be performed using commercially available kits.

Definitive identification is made by cell wall carbohydrate grouping. This involves extraction of the carbohydrate by use of hydrochloric acid or formamide followed by incubating the streptococcal antigen with group-specific antisera. Rapid grouping methods that involve latex agglutination (LA) (Streptex; Wellcome Diagnostics) have generally replaced traditional grouping techniques in the modern laboratory. Because no group A streptococci resistant to penicillin or cephalosporin have yet to be detected, antibiotic testing for resistance to these drugs is unnecessary. The same holds true for macrolides in the United States.

M Protein Serotyping

The classification of group A streptococcal strains by M protein serotyping is used primarily for epidemiological studies, basic laboratory research, and, potentially, vaccine development. The identification of M types is performed using type-specific antisera. Over 80 different M types of strains have been characterized using this method. The M protein antigen is extracted from streptococci by using a hot hydrochloric acid method and then incubated with type-specific antisera (19). M type identification uses a precipitation reaction between the M protein and the corresponding type-specific antiserum.

A protein antigen very closely associated with the M protein molecule of group A streptococci is the serum opacity factor. Streptococcal serum opacity factor is a type-specific strain marker produced by certain serotypes of group A streptococci. In 1946, Lancefield described the serologic classification of group A streptococci based on their surface T antigens. Four of the 20 T antigens have been revealed to be pili. Both T-antigen serotyping and opacity factor type determination are alternative methods that can be used to characterize group A streptococcal strains (20).

Molecular Approaches to Characterization of Group A Streptococci

emm Typing

Prior to molecular approaches to strain typing, many group A streptococcal strains were nontypeable because of a lack of expression of the M protein or a lack of reactivity with the antisera or, most often, because they expressed previously unidentified M proteins. The introduction of *emm* gene sequence typing permitted M type determination of nearly all strains of group A streptococci by any laboratory with DNA sequencing capability. The molecular technique of *emm* typing consists of sequencing the 5′ end of the group A streptococcal *emm* gene (which encodes the M protein) by rapid PCR analyses using nucleotide primer pairs. The molecular procedure is detailed at the CDC website (http://www.cdc.gov/streplab/protocol-emm-type.html). In large-scale epidemiologic investigations of group A streptococcus isolates, restriction digests of *emm* amplicons can be electrophoresed and the resulting restriction patterns compared. Strains with common patterns can be grouped and sequencing performed on representatives from the group. There are now 124 recognized M genotypes based on this technique (21).

PFGE

Pulsed-field gel electrophoresis (PFGE) has been employed widely for epidemiologic typing of many species of bacteria. When PFGE is used for group A streptococcal epidemiological studies, the DNA is typically treated with the restriction enzyme SmaI. The DNA fragments are then separated by pulsed electrical fields on agarose gels to obtain restriction enzyme patterns. The restriction patterns of the different isolates are compared to identify relatedness or clonality. PFGE typing of group A streptococcus, however, does not have a standardized nomenclature (22).

RAPID STREPTOCOCCAL ANTIGEN AND MOLECULAR DETECTION TESTS

One of the major disadvantages of throat culture is the delay in obtaining a diagnostic result. To overcome this delay, commercial rapid antigen detection tests (RADTs) were developed in the 1980s for the immediate identification of group A streptococcus from the throat. These RADTs allow for expedited diagnosis and management shortly after seeing patients in the clinic or emergency department. The tests involve an acid extraction step to solubilize the cell wall carbohydrate, followed by an antigen-antibody immunologic reaction. The early RADTs used the principle of LA, which is a relatively insensitive technique with unclear endpoints. Newer tests based on enzyme immunoassay have increased the sensitivity and have much more clearly defined endpoints. Some tests, such as the QuickVue In-Line Strep A test (Quidel, San Diego, CA), have been given a Clinical Laboratory Improvement Amendments (CLIA)-waived status. An alternative antigen detection technique that has been developed is optical immunoassay, which has been reported to be as sensitive as culture. The overall sensitivity and specificity of the newer optical immunoassay methods are 84% and 93%, respectively (23).

Molecular RADTs

The most recent advances in antigen detection use molecular biologic techniques. One commercial method uses a nucleic acid hybridization test based on a chemiluminescent single-stranded DNA probe that detects specific rRNA sequences unique to group A streptococci (Group A Streptococcus Direct test; Gen-Probe, Inc., San Diego, CA). A study comparing the DNA test with conventional culture showed sensitivity and specificity values of 86 and 95%, respectively (24). Another available method is a test that combines rapid PCR and real-time detection of amplified DNA (LightCycler Strep-A assay; Roche Applied Science, Indianapolis, IN). Compared to routine culture, the LightCycler PCR showed 93 and 98% sensitivity and specificity, respectively (25). The recently FDA-approved *illumi*gene group A streptococcus DNA amplification assay (Meridian Bioscience Inc., Cincinnati, OH) uses loop-mediated isothermal amplification technology in a process by which designed primers allow specific isothermal amplification of DNA. A recent study applied this approach to test 796

deidentified remnant throat swabs, using a routine culture method as the gold standard. The loop-mediated isothermal amplification technology demonstrated sensitivity and specificity values of 100% (95% confidence interval, 95% to 100%) and 94.2% (95% confidence interval, 92% to 95%), respectively (26).

Recommendations on Use of RADTs from National Advisory Groups

A number of advisory groups have made recommendations regarding the use of RADTs for the diagnosis of group A pharyngitis. The Committee on Infectious Diseases of the American Academy of Pediatrics recommends that when a patient suspected of having group A streptococcus pharyngitis has a negative RADT, a culture should be performed to confirm the results of the RADT (27). A positive test, however, does not require confirmation with a culture because of the high specificity of the RADT. Rapid antigen detection tests using DNA probes or PCR may be more sensitive than the earlier RADTs, and some experts think that these newer tests may be sufficiently sensitive to be used without culture backup.

The Infectious Diseases Society of America also states that positive RADT results do not require culture confirmation (28). For children and adolescents, a negative result should be confirmed with a culture unless the physician has determined in his/her practice that the RADT performs comparably to culture. However, the Infectious Diseases Society of America suggests that because adults have a lower incidence of group A streptococcal pharyngitis than children and are at a low risk of acquiring ARF, negative RADT results do not need to be confirmed with cultures. Providers should keep in mind that the risk of streptococcal pharyngitis may be higher in certain adults, such as teachers, whose occupation brings them into close association with children, or parents of young school-aged children.

Pathogenesis of ARF and AGN

A number of theories have been proposed regarding the mechanism by which group A streptococcus induces rheumatic fever, including a serum sickness-like reaction caused by antigen-antibody complexes, toxic effects of streptococcal products, such as streptolysin O or S, and an autoimmune response induced by molecular mimicry (29). The most currently accepted theory on the pathogenesis of ARF is that of molecular mimicry, or the sharing of a number of epitopes between streptococcal bacterial antigens and the tissues of the human host. Much of the interest in this theory has been supported by the identification of antibodies in the sera of patients with ARF that react with the human heart. For example, epitopes of the M proteins have been found to share epitopes with articular cartilage, synovium, cardiac myosin, and sarcolemmal membrane proteins (12, 29). Cross-reactions have also been described between group A polysaccharide and a structural glycoprotein isolated from human heart valves (30). Children with Sydenham's chorea have been found to have circulating antibodies that react both with neurons of the caudate and subthalamic nuclei and with group A streptococcal cell membranes (31). In conclusion, there is much cumulative evidence that indicates that the production of streptococcal antibodies cross-reactive to various human tissues provides a plausible autoimmune explanation for many of the individual manifestations of ARF.

Antibody Responses to Group A Streptococcus

In response to infection with group A streptococci, the host mounts specific antibody responses to both extracellular and cellular antigenic components of the organism (Table 3). The extracellular antigens streptolysin O and DNase B are classified as nonspecific markers of group A infection yet are the most useful biomarkers used clinically for the diagnosis of a previous streptococcal infection. The cellular components of the streptococcus elicit antibody responses specific for streptococcus infections. In general, these types of antibodies are not used for clinical assessment of poststreptococcal sequelae but rather are used in clinical research related to acute rheumatic heart disease.

Figure 1 depicts the overall structure of the cell envelope of group A streptococci and the locations of the streptococcal components. The structure can be divided into four parts: the cell surface, capsule, cell wall, and cytoplasmic membrane. The cell surface of group A streptococcus contains the fimbrial portion of the M protein, lipoteichoic acids, and fibronectin-binding proteins. The capsule is largely composed of hyaluronic acid and is similar in structure to human connective tissue. The cell wall contains the group A carbohydrate as well as peptidoglycan. The cytoplasmic membrane is composed of highly complex lipoproteins and contains antigens similar in structure to human cardiac, skeletal, and smooth muscle, heart valve fibroblasts, and neuronal tissues (12).

TABLE 3 Host immune response to group A streptococcal infection

Streptococcal serological test	Antigen
Test for extracellular streptococcal antigen response	
Tests for nonspecific immunogenic antigens (extracellular antigens)	
Anti-streptolysin O (ASO)	Streptolysin O
Anti-DNase B	DNase B
Anti-streptokinase[a]	Streptokinase
Anti-streptococcal hyaluronidase[a]	Hyaluronidase
Anti-NADase[a]	NADase
Tests for specific immunogenic antigens (cellular components)	
Anti-streptococcal C5a peptidase[a] (anti-SCPA)	Streptococcal C5a peptidase (group A)
M protein antibody[a]	Type-specific M protein
Anti-A-carbohydrate[a]	Group A carbohydrate

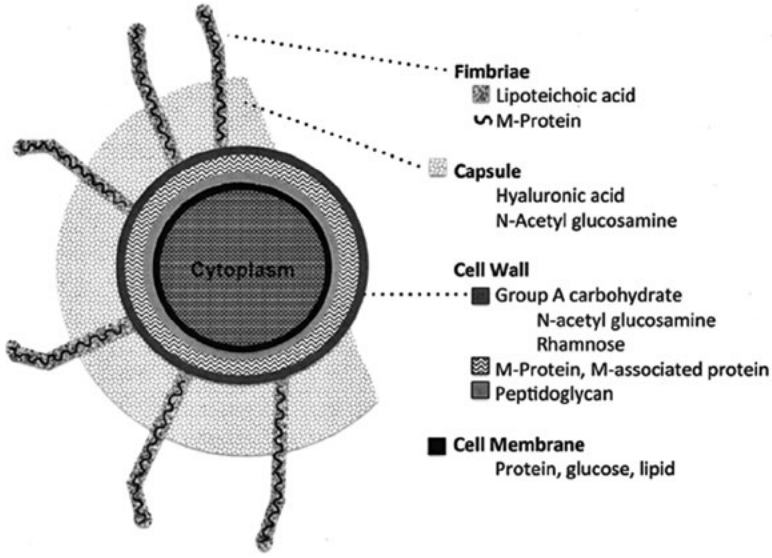

FIGURE 1 Schematic diagram of cellular and extracellular antigens of group A streptococci.

DETECTION OF ANTIBODIES TO EXTRACELLULAR ANTIGENS

Streptozyme Screening Test

The Streptozyme test (Wampole Laboratories, Cranbury, NJ) is a screening test for the detection of antibodies to several of the extracellular antigens, including NADase, DNase, hyaluronidase, streptokinase, and streptolysin. The test is rapid and simple to perform but is much less reliable than the ASO and anti-DNase B tests, which are the preferred tests. Sheep red blood cells are coated with the antigens. The reagent is mixed with a 1:100 dilution of patient serum. The methodology is hemagglutination, with agglutination of the red blood cells representing a positive result. Positive samples are titrated to the endpoint. Values of [mt]100 streptozyme units are considered positive.

Golubjatnikov et al. found both false-positive and false-negative results when the Streptozyme test was compared to the ASO and anti-DNase B assays. The Streptozyme test fails to detect up to 25% of elevated anti-DNase B titers (32). Therefore, if the test is to be used at all, it should be used in conjunction with the ASO and anti-DNase B tests when the sequelae of group A streptococcal infection are suspected.

ASO Test

Group A streptococcus produces two extracellular hemolysins: streptolysin S and streptolysin O. Only streptolysin O is antigenic and induces naturally occurring antibodies. It is a member of a family of pore-forming cytolysins that hemolyze erythrocytes and lyse polymorphonuclear leukocytes. The antibody against streptolysin O, ASO, has been well characterized. Identification of ASO is one of the main tests in use for the serodiagnosis of a previous streptococcal infection. The ASO antibody is thought to be composed of IgG, IgA, and IgM isotypes (33). Usually ASO is measured concurrently with anti-DNase B.

The ASO test provides serological evidence of preceding group A streptococcal infections and is used primarily for patients suspected of having rheumatic fever or AGN. Finding ASO antibodies following skin infections is uncommon. Therefore, anti-DNase B antibodies should also be measured to support the diagnosis in these cases. ASO titers are not used for the diagnosis of acute group A streptococcal infections. Culture or rapid antigen detection is a more appropriate test in these circumstances.

More than 80% of patients with ARF following streptococcus pharyngitis will develop a positive ASO titer of [mt]200 Todd units/ml if the serum sample is obtained within 2 months of onset. The antibody response rises 7 to 10 days after infection and reaches a peak about 3 to 6 weeks later. Antibody levels decline after about 6 to 8 weeks in uncomplicated cases, but they can remain elevated for indefinite periods in some individuals. The ASO antibody, however, has not been shown to have a protective role against repeat infections. Antibiotic therapy may decrease the antibody response.

A few limitations of the ASO test should be mentioned. About 20% of infected individuals do not respond to infection by having elevated ASO titers (34). A negative ASO titer should prompt testing for other antibodies, such as anti-DNase B (detectable for 6 to 9 months following infection), if such tests were not already ordered in tandem. False-positive ASO titers can be due to increased levels of serum beta-lipoprotein produced in liver disease and by "contamination" of serum by *Bacillus cereus* and *Pseudomonas* species. Group C and G streptococcal infections may result in elevated ASO titers, since these groups also produce streptolysin O. False-negative results or low titers may occur if the serum sample has undergone multiple freeze-thaw cycles.

The classic method of measurement of ASO is based on neutralization of the hemolytic activity of streptolysin O by ASO antibodies. The classic protocol is detailed in the 7th edition of this *Manual* (35) and is summarized here. Dilutions of serum from the patient are added to streptolysin O reagent. After a brief incubation at room temperature, a 5% red blood cell suspension is added. If the patient serum contains ASO antibodies and neutralizes the streptolysin O reagent, there will be no hemolysis. If there is hemolysis, no ASO antibodies are present. The reciprocal of the highest dilution of serum without hemolysis is expressed as Todd

units or international units (depending on whether the streptolysin reagent used is the Todd standard or the World Health Organization international standard, respectively).

LA is a much simpler procedure that has also been used for the measurement of ASO antibodies and requires no special equipment or expertise. With LA, latex particles coated with streptolysin O can react with ASO antibodies in the serum. Agglutination occurs when the level of antibody in serum is higher than 200 IU/ml. Compared to the standard neutralization test, the LA procedure shows a sensitivity of 91% and a specificity of 86% (36).

Nephelometry has replaced the classic hemolytic method for streptococcal antibody determination in most clinical and reference laboratories. Nephelometry has been shown to be more sensitive than the standard hemolytic inhibition assay, is simpler to perform on automated nephelometric instruments, and can detect antibody within the range of 25 to 28,800 IU/ml (37). The sensitivities and specificities of single antibody titers with standard ASO and anti-DNase B methods range from 70.5 to 72.7% and 86.4 to 93.2%, respectively (38). A study of 114 patients with or without evidence of streptococcal infection was performed using the Beckman Coulter IMMAGE rate nephelometry system. This analysis showed an increased sensitivity (88%) and a decreased specificity (68%) (39). Combining the nephelometric ASO assay with the anti-DNase B assay increased the sensitivity of diagnosis to 96%, with a specificity of 63%.

The nephelometric ASO test measures the rate of increase in light scattered from particles suspended in solution as a result of complexes formed during an antigen-antibody reaction of ASO in the serum sample with particle-bound streptolysin O (antigen) provided as the reagent. Following calibration, the signal is converted to international units by the analyzer (37). Results are reported in ASO international units (per milliliter). Each laboratory establishes its own reference levels based on the patient population. In general, for babies and children aged 0 to 1 year, the normal reference range is <200 IU/ml; for children of 2 to 12 years, the range is <240 IU/ml; and for patients aged 13 years and older, the range is <330 IU/ml (40). Measurements of acute- and convalescent-phase sera taken 2 weeks apart are recommended to detect a significant rise in antibody titer.

Nephelometric Method

Specimens

Serum samples are recommended. Plasma samples can be used.

Equipment

Nephelometer

Centrifuge capable of 90,000 × *g*

Reagents

Standard kit components: ASO cartridge containing ASO antigen (purified recombinant protein attached to polystyrene particles) and evaporation caps

Calibrators and at least two levels of control material

Wash solution, buffer, and diluent provided by the nephelometer manufacturer

Quality Control and Calibration

Perform calibration with calibrators provided by the nephelometer manufacturer. It is recommended that at least two levels of control material, normal and abnormal, be analyzed daily. Controls should also be run with each new calibration, with a new lot of reagent or buffer, and after maintenance. Calibrations are automatically checked by the nephelometer and will produce a calibration report. Using the reagents made specifically for the instrument, the instrument performs a single-point calibration.

Procedure

Most clinical instruments designed for nephelometric assays are highly automated. Series of sixfold dilutions of calibrator and test samples are performed automatically. Using a preprogrammed curve-fitting program, light-scattering signals are converted to concentrations. The instrument automatically checks for antigen excess and out-of-range specimens and gives instructions for dilutions and reassays.

Interpretation

Results of the ASO test are reported in international units per milliliter. The test is designed to detect concentrations of this analyte by using an initial 1:6 sample dilution. The initial analytical range is 25 to 800 IU/ml and can be extended to 25 to 28,800 IU/ml with dilution. The upper limit of normal is defined as the highest titer that is exceeded by only 20% of a population. Expected values are typically lower than 100 IU/ml. A twofold increase in the ASO value for serial analysis of samples obtained 1 to 2 weeks apart is supportive of a prior streptococcal infection. A single ASO analysis may not be meaningful due to the variability of ASO values within the healthy population.

Limitations

1. False-positive results may be associated with liver disease or bacterial contamination of specimens.
2. Streptococcal infections already treated with antibiotics may not produce increased values.
3. Abnormally high ASO results should not be used as a single diagnostic indicator but should be correlated with other clinical findings. Serial measurements at 1- to 2-week intervals are recommended.

Interferences

Quantitation of ASO in lipemic specimens may produce inaccurate results. Grossly lipemic specimens should be delipidated by ultracentrifugation prior to determination of ASO concentrations. Bilirubin (5 to 30 mg/dl), lipid (50 to 400 mg/dl), and hemoglobin (200 to 1,000 mg/dl) will not interfere with test results. Dust particles or other particulate matter in the reaction solution may result in extraneous light-scattering signals.

Anti-DNase B Test

DNase B is the most immunogenic of the four DNases (A, B, C, and D) produced by group A streptococci following infection (34). DNase B antibody concentrations usually begin to rise within 1 to 2 weeks of the initial pharyngitis or skin infection. DNase B antibodies usually peak 6 to 8 weeks after initial infection, in contrast to ASO, which tends to peak 3 to 6 weeks after initial infection. DNase B antibodies also remain in the serum longer (2 to 3 months) than ASO (6 to 8 weeks). Thus, the anti-DNase B test is a more reliable test for establishing a diagnosis for patients with suspected Sydenham's chorea, in whom symptoms may not be observed for several months.

DNase B is usually used along with the ASO titer to diagnose ARF or AGN following group A streptococcal infections. Unlike in the ASO test, infections of the skin will produce a strong response in the anti-DNase B test, and

this test is more reliable for providing evidence of a recent streptococcal infection in patients with sequelae following pyoderma (41). Anti-DNase B antibodies should also be measured in patients with suspected sequelae following pharyngeal infection when ASO titers are negative. Failure to demonstrate positive antistreptococcal antibody titers by using either the ASO or anti-DNase B test makes the diagnosis of ARF or AGN unlikely. The exception is in the case of a patient with isolated symptoms of chorea. In this particular circumstance, antibody titers may have decreased to the normal range because of the long latent period between the acute streptococcal infection and the onset of chorea. Also, if the diagnosis of carditis has been delayed significantly, antibody titers may have dropped into the normal reference range.

Similar to the classic ASO test, the classic methyl green anti-DNase B test is also a neutralization test. Antibodies in the patient's serum will neutralize the enzyme DNase B, preventing it from depolymerizing DNA. The classic protocol is detailed in the literature (42) and summarized briefly here. Dilutions of patient serum are incubated at 37°C with DNase B to allow the antibodies, if present, to neutralize the enzyme. The substrate is then added to each tube. After an overnight incubation at 37°C, the tubes are observed for color formation. Methyl green is green when complexed with DNA. When DNase B hydrolyzes DNA, the methyl green is unbound from the hydrolyzed DNA and becomes colorless. The reciprocal of the highest dilution of serum that shows definite inhibition of enzyme activity represents the antibody titer for that serum. The test should be performed on acute- and convalescent-phase sera, with a fourfold rise considered evidence of a recent group A streptococcal infection. Normal reference ranges for the classic methyl green dye test quoted in the literature are titers of <120 for preschoolers and <1,360 for older children.

As with ASO titers, nephelometry has largely replaced the classic methyl green dye anti-DNase B test in most clinical and reference laboratories. Nephelometry has been shown to be more sensitive than the reference test and is simpler to perform on automated nephelometric instruments (39). In the same study of patients described above, the Beckman Coulter IMMAGE system demonstrated 84% sensitivity for anti-DNase B. This improves upon the 70.5 to 72.7% sensitivity often seen with standard methods. The specificity of measuring anti-DNase B levels in that study was 49%. The low specificity was attributed to the small number of positively diagnosed cases in the study. Therefore, to increase the sensitivity and specificity, it is recommended that both ASO and DNase B antibodies be measured. An abnormally high anti-DNase B test result should not be used as a single diagnostic indicator. It is important to use serial analysis of samples taken 1 to 2 weeks apart to detect rising values in anti-DNase B levels as evidence of streptococcal disease.

The method for measuring anti-DNase B levels is the same as that described above for ASO, except that particle-bound DNase B is added to patient serum to form immune complexes. The rate of light scatter as the complexes are formed is extrapolated from values from the classic method and reported in units per milliliter. As for ASO titers measured by nephelometry, each laboratory establishes its own reference levels based on the patient population. In general, for babies and children aged 0 to 6 years, the normal reference range is <250 U/ml; for children aged 7 to 17 years, the range is <310 U/ml; and for adults 18 years and older, the range is <260 U/ml. The limitations and interferences are the same as those of the ASO nephelometric test.

RESEARCH USE ONLY TESTS

Anti-DNase B and ASO are the most useful biomarkers used clinically for the diagnosis of a previous streptococcal infection. Measurements of antibodies to other streptococcal cellular components are used for research purposes, or they were used in the past for the diagnosis of streptococcal disease and are now used only for research purposes. These antibody tests are summarized in Table 4 and are briefly discussed below.

Anti-Hyaluronidase Test

The pattern of human antibody responses to hyaluronidase is very similar to that for ASO. The number of patients who develop antibodies to the hyaluronidase following a group A streptococcal infection is somewhat smaller than the number of patients who develop ASO antibodies (34). Before the introduction of anti-DNase B testing, the anti-hyaluronidase test was the most widely used streptococcal antibody test other than the ASO test. However, because of difficulty in standardization, wide differences in titers reported between healthy and rheumatic fever patients, and a number of technical difficulties encountered with the test, the anti-hyaluronidase test is no longer commercially available and is now usually performed only in research laboratories (43).

TABLE 4 Research Use Only tests for detection of antibodies to extracellular antigens

Test	Overall characteristic
Anti-hyaluronidase test	Follows same pattern as that for ASO antibodies, but with a lower incidence
Anti-streptokinase test	Follows same pattern as that for ASO antibodies, but with a lower incidence
Anti-NADase test	Tends to produce higher titers following AGN initiated by pharyngitis and inconsistent titers for AGN initiated by pyoderma
Anti-SCPA test	Highly immunogenic in children after pharyngitis, antibody remains through adulthood
Anti-A-carbohydrate test	Higher antibody responses in patients with rheumatic carditis and rheumatic mitral valve disease
Anti-M-protein test	Antibodies take months to appear after acute streptococcal infection

Anti-Streptokinase Test

The rise in anti-streptokinase titer following a streptococcal infection follows the same general pattern as that for the ASO titer (34). Several studies indicate that the antibody response occurs less frequently, which may be explained by differences in production of streptokinase by different infecting strains. A quantitative method for assaying anti-streptokinase levels, involving a neutralization test, was developed by Kaplan in 1946. Because of the low reproducibility of the test and the relative infrequency of the antibody response in ARF patients, the test is available only in research laboratories.

Anti-NADase Test

NAD-hydrolyzing enzyme (NADase; previously known as DPNase) is an extracellular enzyme and toxin produced not only by group A hemolytic streptococci but also by group C and group G strains of streptococci. There is significant strain variation in regard to the production of NADase by group A streptococcus, with serotype M12 and other nephritogenic strains expressing more protein. The NADase enzyme of group A streptococcus elicits inconsistent antibody responses following AGN previously initiated by pyoderma, but it tends to produce high antibody titers following AGN initiated by pharyngitis (44). The NADase test is based on the ability of antibodies in the sera to neutralize the NADase enzyme. The test is now usually performed only in research laboratories.

DETECTION OF ANTIBODIES TO CELLULAR ANTIGENS

Anti-C5a Peptidase Antibodies (Anti-SCPA)

Streptococcal C5a peptidase (SCPA) is a highly specific surface endopeptidase that cleaves C5a. C5a is important for leukocyte activation and chemotaxis. Cleavage of C5a therefore inhibits chemotaxis of phagocytes, preventing clearance of the streptococci and allowing colonization, invasion, and infection. SCPA is highly immunogenic in children after recent pharyngitis. Shet et al. (45) examined acute- and convalescent-phase sera from 202 children with group A pharyngitis and found parallel anti-ASO and anti-DNase B antibody responses in both acute- and convalescent-phase samples. The antibodies in response to SCPA following infection remain through adulthood. O'Connor et al. (46) developed an enzyme-linked immunosorbent assay (ELISA) to detect human IgG and IgA antibodies against SCPA. The ELISA, however, is used only in research laboratories.

Anti-A-Carbohydrate Test

The group A carbohydrate is the basis for the Lancefield classification of the 20 serologic groups of streptococci. Although it is not a virulence factor, it does elicit antibodies after infection. Antibody levels usually peak 1 to 3 weeks after the initial pharyngitis and may remain for a prolonged period in patients with rheumatic heart disease. Todome et al. (47) developed an ELISA for anti-A-carbohydrate antibodies to study 45 patients with rheumatic fever and found significantly higher antibody responses in patients with rheumatic fever. Appleton et al. (48) similarly found an association between the persistence of group A carbohydrate antibodies and the presence of rheumatic carditis and rheumatic mitral valve disease. The anti-A-carbohydrate test is only available at a few research laboratories.

Anti-M-Protein Antibodies

The M proteins are the basis for the Lancefield classification of over 100 group A serotypes. M protein antibodies appear very slowly, over several months. Both IgA and IgG antibodies against M proteins are produced in response to infection. IgA M protein antibodies have been found to inhibit streptococcal adherence to pharyngeal cells. IgG M protein antibodies, in turn, prevent internalization of the streptococci into epithelial cells. These antibodies have opsonic properties and have been shown to protect against group A streptococcal infection (49). Tests to detect M protein antibodies are available only in research laboratories and are used mainly for vaccine research.

CONCLUSIONS

Group A streptococcus is an important bacterial pathogen that is the most frequent bacterial cause of acute pharyngitis. The organism has the ability to initiate autoimmunity after acute infection, resulting in the nonsuppurative sequelae ARF and AGN. Several diagnostic tests are available for the diagnosis of acute group A streptococcal infection. Although culture and identification remain the gold standard for diagnosing acute group A streptococcal infections, rapid antigen detection methods are now used in most clinical settings due to their efficiency, ease of use, and immediate results. Streptococcal culture is still recommended as a backup for negative rapid antigen test results for children. Streptococcal antibody tests (i.e., ASO and anti-DNase B tests) should not be used for the diagnosis of an acute group A streptococcal infection but rather to provide evidence of prior infection in the past 2 to 12 weeks. Newer molecular antigen detection methods may be sufficiently sensitive to not need a backup culture, especially for adults.

Both the ASO and anti-DNase B antibody tests provide evidence of a preceding group A streptococcal infection and support the diagnosis of sequelae to group A streptococcal infection in combination with clinical findings. ASO antibodies are not useful in cases of AGN following a pyodermal infection, since ASO antibodies are not often found in these cases. Unlike in the ASO test, infections of the skin will produce a strong response in the anti-DNase B test. Therefore, anti-DNase B testing is more reliable in clinical circumstances where poststreptococcal sequelae of skin infection are suspected. Anti-DNase B antibodies should also be measured in patients with suspected sequelae following pharyngeal infection when ASO titers are negative. The anti-DNase B test is a more reliable test for establishing a diagnosis for patients with suspected Sydenham's chorea, since antibody titers remain for longer periods. Failure to demonstrate positive antistreptococcal antibody titers by using either the ASO or anti-DNase B test makes the diagnosis of ARF or AGN unlikely, unless a late diagnosis of chorea or carditis has been made.

Tests for anti-hyaluronidase, anti-streptokinase, and anti-NADase antibodies are no longer being offered commercially for the diagnosis of preceding group A streptococcal infections. They are now used only for research purposes. Tests for antibodies against the cellular antigens C5a peptidase, group A carbohydrate, and M proteins are actively used in research.

Diagnosis of *Helicobacter pylori* Infection and Assessment of Eradication

BRUCE E. DUNN AND SUHAS H. PHADNIS

45

CLINICAL PRESENTATION AND OUTCOMES OF INFECTION WITH *HELICOBACTER PYLORI*

Helicobacter pylori is a Gram-negative, microaerophilic spiral bacterium which is recognized as the primary cause of chronic gastritis in humans. Untreated *H. pylori* infection precedes and is required for the development of most cases of gastric and duodenal ulcers (1, 2). Further, *H. pylori* infection substantially increases the risk of development of gastric cancer in some populations. Following the discovery and identification of *H. pylori* as a significant human pathogen, it is now recognized as probably the most common bacterial infection of humankind, infecting approximately 50% of the world's population. Specific antibiotics combined with proton pump inhibitors are now routinely used to treat and eliminate previously chronic gastroduodenal diseases. For their novel work in helping us to understand the critical role played by *H. pylori* in peptic ulcer disease, Robin Warren and Barry Marshall were awarded the Nobel Prize in Physiology or Medicine in 2005.

H. pylori infection occurs in all human populations; the observed incidence of infection ranges from about 30% in developed countries to more than 90% in some developing countries. In general, *H. pylori* infection occurs in childhood in developing countries, and unless specifically treated, the infection persists throughout the lifespan of the individual (1, 2). In developed countries, a higher rate of infection is generally observed in older individuals. It has been suggested that improvements in hygiene in developed countries since the 1950s have resulted in a reduction of *H. pylori* infection rates within younger populations. Chronic infection with *H. pylori* is now recognized as a significant risk factor for gastric carcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma. The prevalence of *H. pylori* infection, gastritis, and gastric carcinoma increases with age and is associated with low socioeconomic status (1, 2).
