
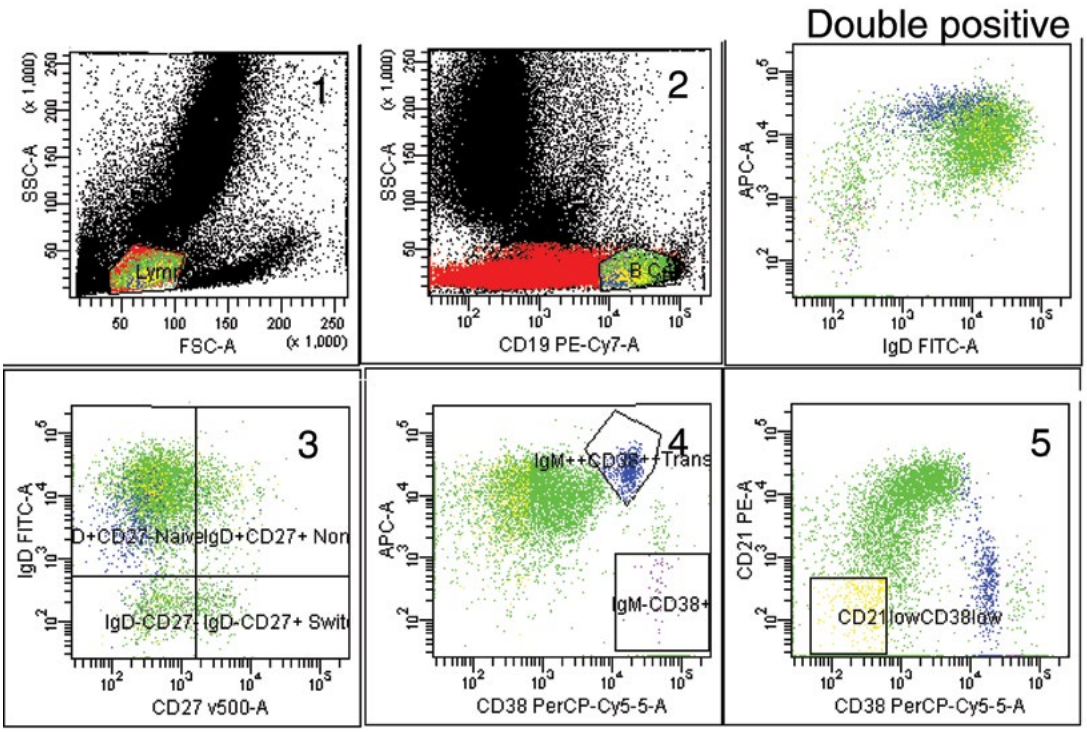

FIGURE 2 Extended B-cell immunophenotyping. The FACS plots demonstrate the gating strategy for B-cell immunophenotyping. Lymphocytes are gated based on forward (FSC) versus side scatter (SSC) (panel 1). The lymphocyte population is then used to gate B cells (CD19 versus side scatter) (panel 2). Using quadrants, naive B cells are defined as $IgD^+/CD27^-$, $IgD^+/CD27^+$ are non-switched memory B cells, and $IgD^-/CD27^+$ are switched memory B cells (panel 3). Transitional B cells are defined as $IgM^{++}CD38^+$ and IgM-$CD38^+$ B cells and plasmablasts as IgM-$CD38^+$ (panel 4). CD21low/CD38low B cells are indicated in panel 5. The presence of double-positive B cells greatly decreases the possibility of mutations in the AID gene, and they are used for back gating to confirm the IgM status of naive, switched, and non-switched memory B cells.

7. Dilute the CD154 with Cell Wash according to the manufacturer's instructions, usually 1:50. Add 80 μl of this dilution to the appropriate tubes.
8. Add 200 μl of blood/culture media to the bottom of each FACS tube. Mix thoroughly and leave to incubate at room temperature for 10 minutes.
9. Add 1 ml of 1× FACS lysing solution. Mix thoroughly (important) and leave to incubate at room temperature for 10 minutes.
10. Centrifuge on high for 45 s (1,000 rpm), tip the supernatant off, and blot the tubes on tissue.
11. Mix to resuspend. Add 1 ml of Cell Wash.
12. Centrifuge on high for 45 s, tip the supernatant off, and blot the tubes on tissue.
13. Resuspend in 500 μl of Cell Fix.
14. Acquire using a FACS that can detect four or more colors.

To analyze, compare unstimulated with stimulated scattergrams and set the quads using the unstimulated tubes. Check that cells have activated using CD25 and CD4 expression as a guide. A good stimulation should produce over 70% CD25-positive cells. Weak and absent expression with less than 70% activation should be interpreted with caution. (See Fig. 3 for examples of normal and absent CD154 expression.)

Diagnosis of X-Linked Lymphoproliferative Syndrome 1 (XLP1), X-Linked Lymphoproliferative Syndrome 2 (XLP2), and X-Linked Antibody Deficiency (XLA)

Intracellular FACS is a rapid and reliable technique for screening patients suspected of having XLP1, XLP2, or XLA. If the protein is absent or abnormal, then genetic analysis can focus on analyzing that single gene. In addition, many carriers of these X-linked conditions may be detected using this technique.

Materials

FACS capped Tubes (VWR, catalog no. 734-0443)
Anti-SLAM-associated protein (Anti-SAP) (Stratech Scientific, catalog no. H00004068-MO1)
Anti-mouse IgG1 FITC (Dako, catalog no. F0479)
Anti-BTK (gift of Toshio Miyakawi, clone 48-2H)
Anti-CD14 PE (Becton Dickinson, catalog no. 345785)
Anti-XIAP (Becton Dickinson, catalog no. 610763)
IgG1 isotype control (Becton Dickinson, catalog no. 349040)
Anti-CD56 PE (Becton Dickinson, catalog no. 345810)
Anti-CD8 PerCP (Becton Dickinson, catalog no. 345774)

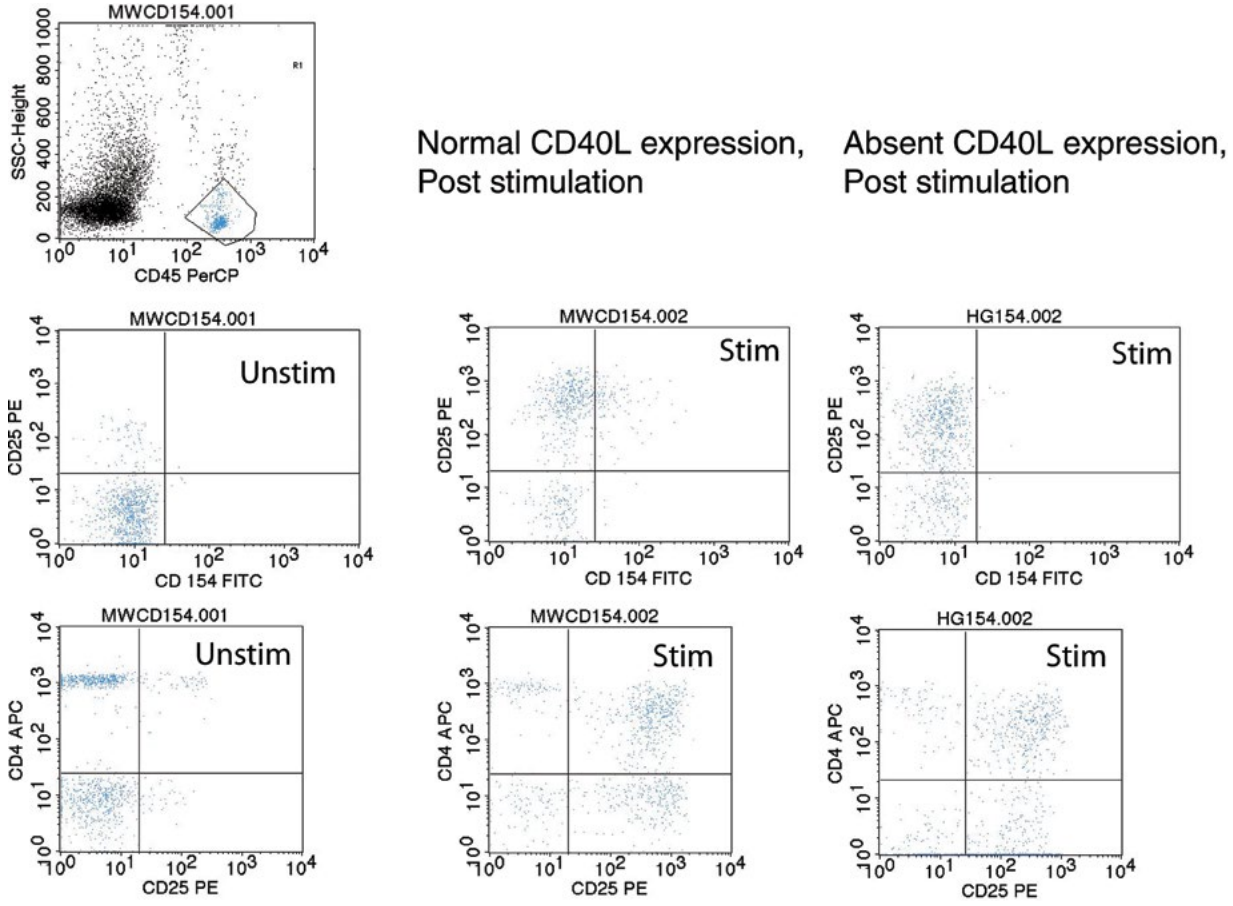

FIGURE 3 CD40L expression. Lymphocytes are defined by CD45 versus SSC. Prior to stimulation, there is limited CD25 and CD40L (CD154) expression ("Unstim" panels). Post stimulation in healthy individuals, there is an increase in both CD40L and CD25 expression (middle "Stim" panels). In patients with XHIM, although there is significant upregulation of CD25 (bottom right "Stim" panel), there is no increase in CD40L expression (top right "Stim" panel).

Anti-CD3 APC (Becton Dickinson, catalog no. 345767)
Intraprep Perm/Fix (Beckman Coulter, catalog no. A07802)
PBS/0.5% BSA/0.1 μM EDTA (SAP wash)
Cell Fix (Becton Dickinson, catalog no.340181)
DMEM/10% FCS (block)
SAP wash: phosphate-buffered saline plus 0.2 mM EDTA plus 1.0% bovine serum albumin
0.6 ml EDTA patient blood
0.6 ml EDTA control blood

Procedure

1. Label each tube with control (C) or the patient's initials and isotype (I), BTK (B), SAP (S), or XIAP (X). Add 50 μl of blood to the bottom of each tube. If BTK and SAP/XIAP expression are analyzed for the same patient, set up two isotype tubes labeled I-S/X and I-B.
2. Add 100 μl of Intraprep solution 1 to each tube and mix immediately upon addition. Incubate at room temperature for 15 minutes.
3. Add 1 ml of SAP wash, mix, add a further 2 ml of SAP wash, spin for 45 seconds in the bench top centrifuge (1,000 rpm), decant, and drain well.
4. Add 100 μl of Intraprep solution 2. Do NOT mix, but let diffuse naturally into cell pellet. Incubate at room temperature for 5 minutes.
5. Disperse the cell pellet and add 1 μl of BTK antibody, 0.5 μl of SAP antibody, 1 μL of XIAP antibody or 6 μl mouse isotype control antibody to the bottom of appropriate tubes. Incubate at room temperature for 15 minutes. Make up secondary solution during this incubation.
6. Wash two times with 2 ml of SAP wash per wash.
7. Add 100 μl of secondary solution (anti-mouse IgG FITC/SAP block/SAP wash [1 μl/10 μl/90 μl]) and incubate for 15 minutes.
8. Wash two times with 2 ml of SAP wash.
9. Add 5 μl of CD56-PE, CD8-PerCP, and CD3-APC to each tube except for the BTK and isotype tube I-B, into which 5 μl CD14 should be added instead.
10. Incubate at room temperature for 10 minutes.
11. Wash two times with 1 ml of SAP wash per wash.
12. Add 250 μl Cell Fix.
13. On a four-color FACS, acquire 20,000 $CD3^+$ events for the SAP/XIAP/isotype tubes or 20,000 $CD14^+$ events for the BTK/isotype tubes. Once fixed, samples are stable for 72 hours.

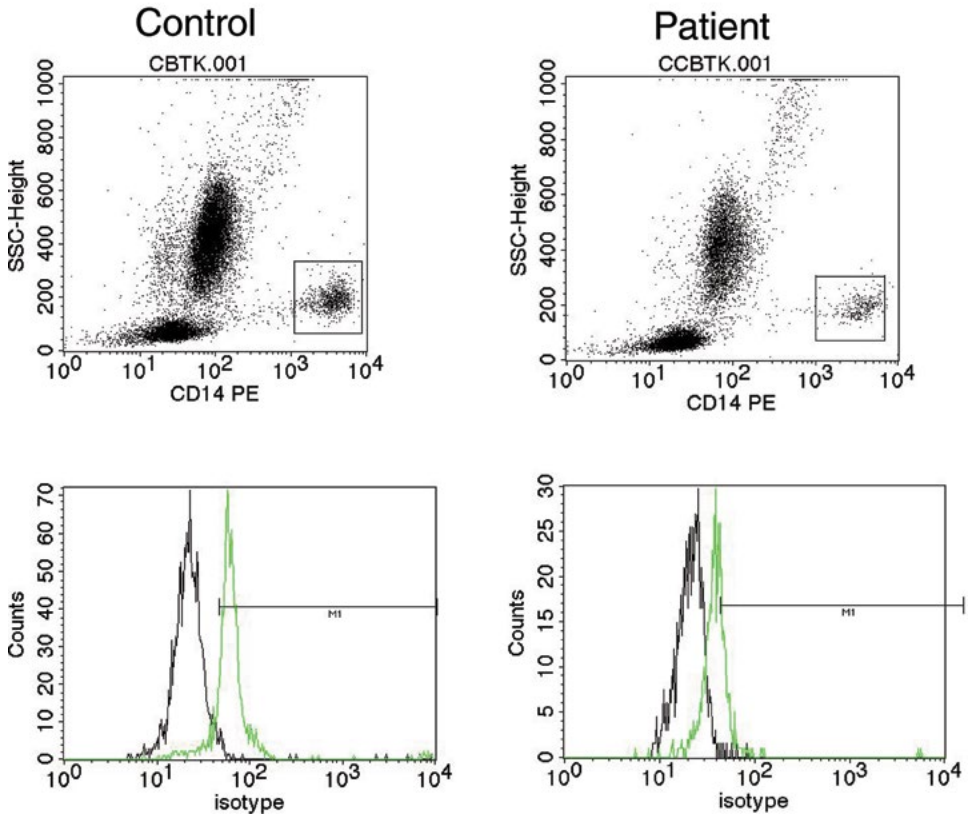

FIGURE 4 BTK analysis by FACs. Monocytes are gated by $CD14^+$ versus SSC. Histograms showing isotype staining and BTK staining are then overlaid. Many hypomorphic mutations in BTK show a partial overlay as shown in the patient sample.

14. For BTK, gate on monocytes as defined by CD14 versus SSC and then compare isotype against BTK by overlaid histograms (see Fig. 4). For the SAP/XIAP, gate on lymphocyte followed by CD8 T cells and then analyze using overlaid histogram (see Fig. 5).

GENETIC ANALYSIS

For many PIDs, a genetic diagnosis enables optimal management of the condition as well as offering carrier testing and prenatal screening. Until recently, direct sequencing (also known as Sanger sequencing) of exons and exon/intron boundaries was the method of choice.

Direct Sequencing

In direct sequencing, the exons or other regions of interest are amplified by PCR using fluorescently labeled oligonucleotides as primers. The primers bind to specific regions of DNA and enable those regions to be amplified many times. The amplified product is then separated by size and an automated reader identifies each nucleotide, resulting in a trace that shows each nucleotide in sequence order. Direct sequencing is rapid for smaller genes and detects not only nucleotide changes but also small deletions. It is a recommended method of genetic analysis for single genes (14). However, if multiple genes need to be sequenced, direct sequencing can be costly and time consuming. Direct sequencing cannot detect single chromosomal deletions, duplications, or inversions.

MPLA and aCGH

Multiplex ligation-dependent probe amplification (MLPA) is a new technique used to detect copy number variation (deletions or extra copies of a gene) (15). It is ideal for examining gene deletions in targeted genes. Like direct sequencing, the gene to be analyzed must be known. MPLA is based on denaturing the DNA and oligonucleotides, letting the oligonucleotides bind the DNA, ligating (joining) the oligonucleotides together, amplifying the product by PCR, and running and analyzing the products on a gel. MPLA can also be used to detect point mutations (single nucleotide changes), by designing the probe so that it will only bind with a normal sequence. This is useful for detecting common point mutations. MPLA is routinely used to detect deletions in the SH2DAI (XLP1) gene where exon 2 and other deletions are common.

Although relatively few antibody deficiencies are due to large deletions and duplications, array comparative genomic hybridization (aCGH) is a useful screening tool to detect copy number variation in the entire genome. Patients with chromosomal abnormalities including Down syndrome may have abnormal B cells and/or impaired antibody production (16). aCGH can detect changes in copy number where the deletion or additional copy is 100 kilobases or greater and is unbalanced. It is particularly useful for detecting deletions and duplications. There is a consensus group (the International Standards for Cytogenomic Arrays Consortium) that provides guidance as to best practice for running and interpreting this technique (www.iscaconsortium.org). The

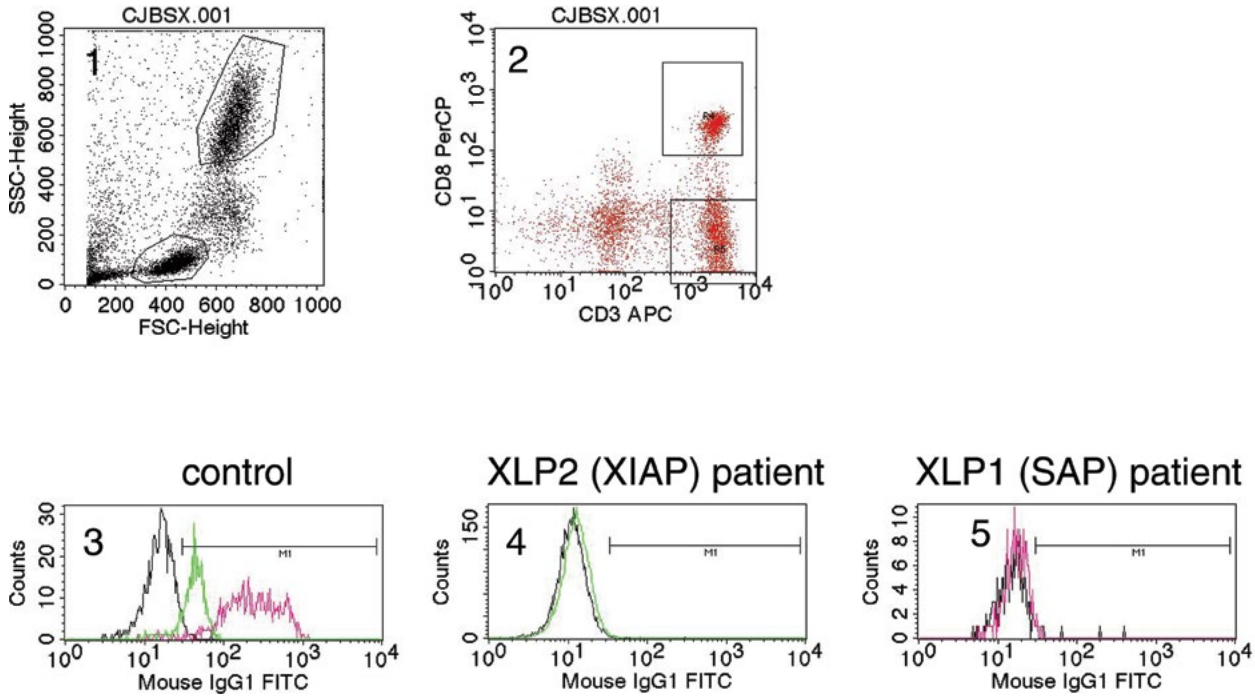

FIGURE 5 XIAP and SAP by FACs. Lymphocytes are defined based on FSC vs. SSC (panel 1). $CD8^+$ T cells are then gated based on $CD3^+/CD8^+$ (panel 2). Isotype, XIAP (green), and SAP (pink) are analyzed as overlaid histograms (panel 3), where the XIAP shift about 1 log and the SAP about 2 logs. An XLP2 patient lacks XIAP (panel 4). An XLP1 patient lacks SAP (panel 5).

basis of aCGH is that it compares the patient's genome to a reference genome and any differences are identified. Both genomes are labeled with different fluorescent probes, hybridized to normal sequence probes spanning the genome, and then measured. If the patient's sample shows decreased fluorescence in a particular area, it indicates a deletion; if the patient's sample shows an increased signal, then a duplication is identified.

NEXT-GENERATION SEQUENCING

(See reference 17 for a fuller discussion of this topic.)

Next-generation sequencing (NGS), also known as high-throughput sequencing, is a method for rapidly sequencing a large number of genes from a number of patients. The advantage of NGS is the amount of data that are rapidly generated. The entire human genome can be sequenced in less than three weeks. The main disadvantages are the analysis and storage of the data as well as the ethical considerations regarding incidental findings (also known as unsolicited information). These are the discovery of a mutation in a gene that the clinician was not expecting (e.g., finding a breast cancer mutation in a PID patient). For NGS, DNA is isolated, fragmented, and then hybridized to a library of interest. This library contains fragments of a defined list of genes or might represent the entire human exome. The hybridized fragments are then selected, and nonselected DNA is washed away. The selected DNA is then sequenced, the data generated are checked for quality and aligned to a defined human genome, and then sequence variants can be identified. Once these variants are identified, they can be compared to known databases to eliminate known variants; unknown variants can then be assessed for likely pathogenicity *in silico* and based on known gene function. The variants are then confirmed by direct sequencing, and functional assays can be performed to demonstrate that a variant is the likely cause of the disease of interest. To speed up analysis, provide better coverage, and avoid the possibility of incidental findings, a number of groups are using targeted NGS where only a subset of genes is analyzed. This is less expensive than exome sequencing, the analysis time is much more rapid, and it meets the guidelines of the European Society of Human Genetics (14). For PIDs, several groups are using the targeted approach and have identified a number of patients with mutations in rare PID genes (Dury et al., manuscript in preparation). The current approach is to use targeted NGS to rapidly screen known PID genes, and where no mutation is identified, to then undertake whole-exome sequencing.

Hereditary and Acquired Complement Deficiencies

PATRICIA C. GICLAS

77

Complement deficiencies comprise a small but important category of primary immune deficiency diseases. Complement deficiency states can also be acquired from *in vivo* activation or inhibition of the complement system, temporarily depleting components faster than they can be replaced or causing changes in control of the system. Complement plays an important role in the host's response to infection by directly killing bacteria, neutralizing viruses, or coating microbial surfaces with complement fragments that enhance uptake and killing by phagocytes, a process called opsonization that ensures that objects identified as foreign by complement are dealt with quickly and efficiently. Complement serves as a link between many of the activities of acquired immunity, with ties to diverse cell signal responses and other defense mechanisms, as an ever-increasing number of related conditions are identified (1).

Activation of the complement enzyme cascade produces fragments that exhibit proinflammatory properties, including chemotactic activity and the ability to regulate local blood flow and vascular permeability and cause smooth muscle contraction or relaxation. These properties are species and tissue dependent. Complement also has "housekeeping" activities, such as clearance of immune complexes, effete and apoptotic cells, and cellular debris. Deficiencies or mutations of complement components, whether inherited or acquired, create a predisposition to infections, autoimmune diseases, impaired immune responses, and diverse conditions such as acute and chronic renal disease, vasculitis, allergic reactions, hereditary angioedema (HAE), and age-related macular degeneration (AMD). The discussion that follows touches on examples of these and other complement-related functions that go awry when one or more of the proteins in a pathway is missing or functions abnormally. Figure 1 depicts the complement pathways for review of the steps and proteins involved.

Measurement of most of the complement components in the circulation can be done by standard immunochemical techniques. If the protein concentration is relatively high (milligrams per milliliter), then nephelometry or turbidimetry can be used, but when the concentrations are lower (micrograms per milliliter down to nanograms or picograms per milliliter), radial immunodiffusion, radioimmunoassay, and enzyme-linked immunosorbent assay are the methods of choice. Newer variations on the latter include bead-based multiplex tests that allow the measurement of several different proteins at a time. Flow cytometry is used to evaluate the cell-bound complement control proteins such as membrane cofactor protein (MCP; CD46) and decay accelerating factor (CD55), as well as receptors for C3 and C4 fragments such as CR1 (CD35) and CR3 (CD11b/CD18).

Measuring the functions of the complement pathways and their individual components presents challenges for the clinical laboratory. Except for a few tests, the methods and reagents used are, for the most part, not sold commercially, and the procedures are done manually. The temperature sensitivity of the proteins makes it difficult to maintain the serum samples at 0°C during the time required for the test setup.

The first functional assay for complement was done by bactericidal measurements, either *in vivo* in guinea pigs or *in vitro* using serum from guinea pigs, humans, or other species. The CH50 was developed around 1900 as an easy method using available supplies (2–5). The AH50 was built on the model of the CH50 except that it required a different target cell. For human serum, either guinea pig or rabbit red blood cells have been used for the AH50. The two tests, described below, cover the function of complement except for the lectin pathways (LPs), which are described in chapter 14.

HEMOLYTIC ASSAYS FOR COMPLEMENT FUNCTION

The CH50 assay (name derived from "CP hemolytic 50%") depends on the sequential activation of each of the 11 classical pathway (CP) components: C1q, C1r, C1s, C4, C2, C3, C5, C6, C7, C8, and C9, in that order, ending in lysis of sensitized sheep erythrocytes (E) that have been coated with polyclonal rabbit IgM or IgG anti-sheep E antibodies (A). The antibody-treated cells are referred to as "sensitized," and the abbreviation EA is used in the following description of the assay.

The AH50 assay (name derived from "AP hemolytic 50%") relies on lysis of rabbit red blood cells (E_{rab}) that have a natural charge on their surface that promotes antibody-independent activation of the human alternative pathway (AP). The AH50 relies on the same terminal pathway components (C3, and C5 through C9) as those of the CP, but there are unique components in the initiation phase: preformed C3b, factor D (FD), and factor B (FB) are necessary to generate the C3bBb enzyme complex that cleaves C3, and properdin (P) has a unique role in stabilizing the C3bBb

doi:10.1128/9781555818722.ch77

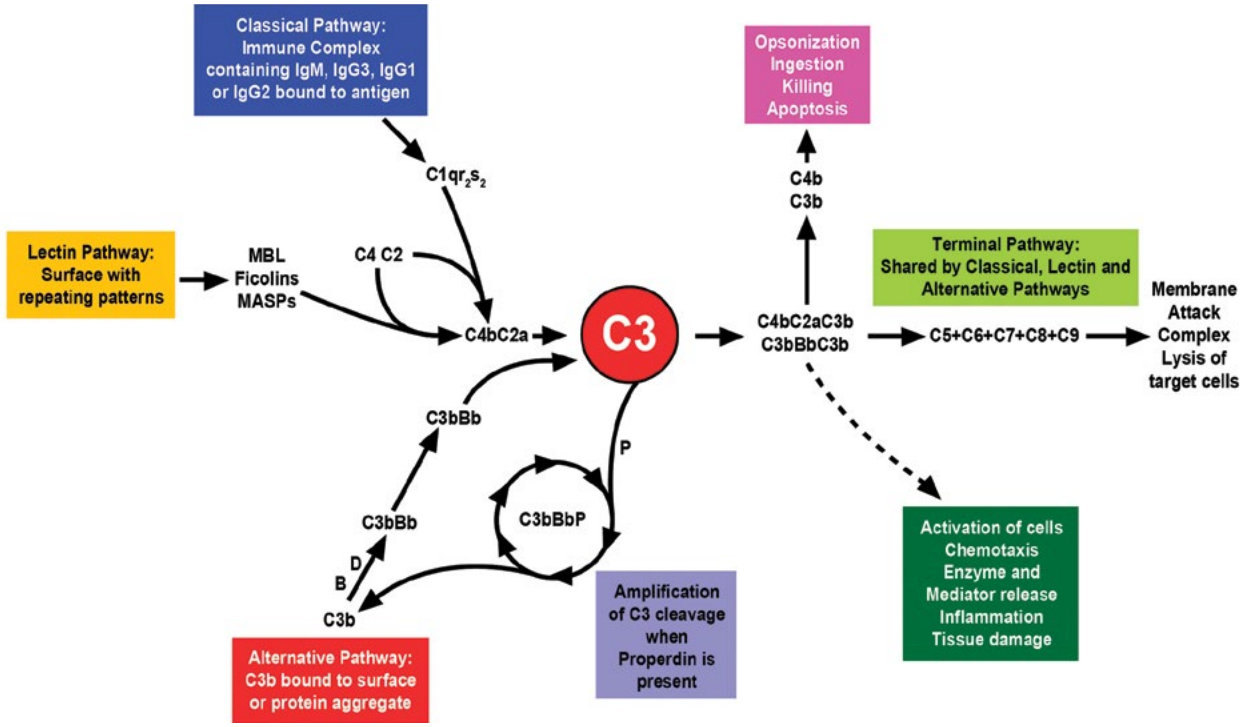

FIGURE 1 Complement was one of the earliest members of the innate immune system to evolve, and, as such, different forms of pattern recognition allowed it to become active against a variety of organisms and substances without the need for prior exposure. The three boxes to the left (classical pathway [CP], blue; lectin pathway [LP], orange; alternative pathway [AP], red) indicate examples of one of the triggers for activation of each pathway. As drawn, the C3 molecule is the central target for all three pathways. Activation of the CP by immune complexes, or the LP by a recognized target pattern, results in cleavage of C3, C4, and C2. Clearance of the complex or LP target from the circulation occurs through interaction of the phagocytes in the liver and spleen with the C4b and C3b bound to the complex. The alternative pathway is different. In the AP, the unique protein properdin allows the formation of an amplification process (shown as circle of arrows) in which a very large amount of C3 but not C4 becomes rapidly cleaved. The resulting C3b from this process becomes covalently bound to the surface of nearby proteins, microbes, and cells and flags them as targets for destruction by the immune system. The fragments of C3 and C4 form the major opsonins that are used by cells such as phagocytes and lymphocytes to clear the C3 and C4 fragments. Note that complement fragments can be useful in the laboratory to identify the pathway involved in a reaction. Note also that a large decrease in serum C3 but not C4 is indicative of AP activation. The majority of the physiological effects of complement activation are due to the inflammatory properties of the fragments. These include opsonization, chemotaxis, mediator release, priming of phagocytes and lymphocytes, apoptosis, and direct killing of microbes by lysis.

to prolong its half-life and promote the amplification of the C3 cleavage process.

The AH50 assay described below depends on AP-dependent lysis of unsensitized (i.e., no antibody) E_{rab} by human serum complement. Activation of the calcium-dependent CP or LP is prevented by adding a calcium chelator, EGTA, to the AH50 buffer along with magnesium, necessary for the AP activity. In an endpoint titration of the patient's serum using serial dilutions, complement activity is quantitated by determining the dilution of serum it takes to lyse 50% of the EA in the assay mixture, and the results are expressed as the reciprocal of this dilution, in CH50 units (U) per milliliter. Thus, if a dilution of 1/20 lyses half the cells, the CH50 reported would be 20 units. There are some commercially available reagents such as buffers for performing the CH50 assay, or you can prepare your own.

The CH50 and AH50 are dose-response methods. The test article (serum) is tested at different concentrations until the amount that gives a 50% effect is found.

CH50 Assay

Sample Requirements

The CH50 assay requires 0.5 ml of serum from blood collected in a red-top Vacutainer tube or serum separator tube, allowed to clot for 30 to 60 min at 37°C or room temperature, and centrifuged to separate the serum from the clot. The minimum serum requirement from an infant or to allow for repeat of the assay is 50 μl. The serum should be transferred without cellular contamination to a clean plastic tube, capped tightly, and frozen at −70°C until the assay is performed. Transportation of the serum to another location for CH50 or AH50 analysis should use a box containing enough dry ice to keep it frozen until it reaches its destination.

Both the CP and AP contain factors that are heat labile, so care must be taken that the specimen to be tested has been collected and stored properly. Repeated freeze-thaw cycles or allowing specimens to stand at room temperature

for long periods of time (>30 min) can cause erroneously low results. Patients with low CH50 may have immune complexes, cryoglobulins, bacteria, or other complement activators in their serum that continue to activate the complement after the blood is drawn, so in the case of a low CH50, the assay should be repeated with a fresh specimen from the patient for confirmation at a later date.

Materials

Chipped or crushed ice: essential for keeping buffers, dilution tubes, and sera cold while the assay is being set up. A tube will stay upright if pushed down in chipped ice, but not if ice cubes are used. A mixture of ice and water will stay at 0°C as long as there is still ice present.

Container for ice such as ice bucket, Styrofoam box, or other insulated container

Plastic dishpans about 10 by 14 in. and at least 4 in. deep, or other similar-sized trays to hold racks for dilution tubes

Disposable borosilicate glass or clear plastic culture tubes (12 by 75 mm) for preparing the dilutions of serum: 10 tubes to run each specimen in duplicate, including standard and controls

Racks to hold tubes (12 by 75 mm): separate racks for making dilutions and for incubating serum dilutions with EA

2 conical-bottom 50-ml plastic tubes with screw caps

Equipment and Instruments

Pipettors with volume ranges covering 10 μl to 1 ml

37°C water bath

Centrifuge

Spectrophotometer capable of reading visible light

Buffers, Sera, and Other Reagents

Human serum complement standard (available at Quidel Corp., San Diego, CA). Normal human serum, pooled and standardized for hemolytic assays: need 50 μl per test run. Store in 60-μl aliquots so you can recover 50 μl and discard the rest. Do not refreeze after thawing.

Normal human serum controls: 50 μl of high, medium, and low controls. Prepare these sera from individual or pool of donors, making enough individual aliquots as above to last for a few months at −70°C. Aliquots of serum at 60 μl each can be prepared and stored safely in small Eppendorf tubes at −70°C for up to 1 year. The same sera should be used each time the assay is run for control of interassay variability. The run-to-run coefficient of variation should be 10% or less.

Test sera: 50 μl each; sera from patients to be tested should be run in duplicate

Ice-cold saline: 0.15 M NaCl, 12 ml per sample

Sheep's whole blood in Alsever's solution (Colorado Serum Co., Denver, CO)

Buffer (gelatin-Veronal buffer with metal ions; GVB^{2+}): 200 ml of ice-cold Veronal-buffered saline with gelatin, calcium, and magnesium (Veronal is another name for barbital)

Hemolysin: rabbit anti-sheep E antiserum (Colorado Serum Co.). This is usually whole rabbit serum, so it must be heat-inactivated before being used: incubate it at 56°C for 30 min to inactivate the rabbit complement. The heat-treated hemolysin can be stored for months at −20°C.

Buffer Preparation

1. For 2 liters of 5× stock GVB^{2+}, dissolve 83.0 g of NaCl and 10.19 g of Na-5,5′-diethyl barbiturate in about 1.5 liters of warm (75 to 85°C) distilled water, add 10 g of gelatin, and continue to stir until it is dissolved. Add 2 ml of calcium chloride (0.3 M) and 2 ml of magnesium chloride (2.0 M), followed by 4 ml of 10% (wt/vol) sodium azide.

2. Mix well, and bring the pH to 7.35 ± 0.05 with a small amount of 1 N HCl or NaOH, as needed. Bring the volume to 2.0 liters with distilled water. Store at room temperature for up to 1 month. Discard buffer stock if it becomes cloudy or develops a strong odor. Aliquots of 40 ml can be frozen at −20°C in 50-ml conical-bottom centrifuge tubes if the assay is not done frequently.

3. For 1× working buffer, mix 1 part stock with 4 parts distilled water.

Sensitized Sheep Cells (EA)

1. Wash the cells. To obtain about 20 ml of EA at 2×10^8 cells per ml, gently mix the bottle of sheep's blood (Colorado Serum Co.) and take out 4 ml with a syringe. Put it into a 50-ml conical-bottom plastic centrifuge tube and add enough GVB^{2+} to bring the volume to 40 ml. Invert the tube a few times to mix, and then centrifuge the cells for 5 to 10 min at 1,250 × *g*. Remove the supernatant and buffy coat cells. Add more GVB^{2+} to bring the volume to 40 ml and centrifuge again. Repeat wash three or four times until the supernatant is clear.

2. Make 5% suspension. Measure the volume of packed E after the last centrifugation, and add enough GVB^{2+} to give a 5% cell suspension, by volume. To determine the actual concentration of cells, remove 100 μl of the 5% cell suspension and add it to 1.4 ml of distilled water and mix to lyse the cells. Read the optical density (OD) of the lysate at 541 nm (OD_{541}). If the cells are at 1×10^9 per ml, the OD_{541} should be 0.700. Adjust the cell suspension by adding more buffer if the OD_{541} is >0.700, or spin the E down and resuspend them in less buffer if the OD_{541} is <0.700.

3. Once the cells are at 1×10^9 cells per ml, put 4 ml of the E into a conical-bottom plastic tube. In another tube, put 4 ml of GVB^{2+} and add enough hemolysin to obtain the optimum dilution for sensitizing the E (1). Prewarm the E and the diluted hemolysin to 37°C; then add the hemolysin all at once to the E and quickly mix thoroughly. Incubate at 37°C for 20 min. Centrifuge as described above, decant the supernatant, and resuspend the E to 20 ml with ice-cold GVB^{2+}. At this point, the E should be at 2×10^8 per ml and ready to use for the CH50. Keep cells on ice or in refrigerator or cold room (temperature maintained at 2 to 8°C until needed for assay). If kept cold, the E should be stable for 1 to 2 weeks. Discard if the background lysis exceeds 10% of the total lysis.

Procedure for CH50 Assay

Once starting the assay, proceed quickly. Thaw serum tubes rapidly at 37°C; then put them on ice once they are thawed. Keep the cells and buffer on ice.

1. Prepare two test tube racks, one for making the serum dilutions and one for the assay tubes. For each sample you will need five tubes in the dilution rack and duplicate rows of five tubes in the assay rack. Label each tube with its dilution and a code for the sample to be tested. Add four additional control tubes to the assay rack: two for 0% (background lysis) and two for 100% (total lysis) controls. Place both racks into a slushy ice bath so that the bottom inch or so of each tube is below the ice-water level.

2. Put 150 μl of GVB^{2+} into each of the tubes in the dilution rack and add an extra 135 μl to the first tube in each series. Add 15 μl of the appropriate undiluted test, control, or standard serum to the first tube of its series and vortex to mix well. To make doubling dilutions, transfer 150 μl from the first tube to the second, vortex to mix well, transfer 150 μl from the second tube to the third, etc. The final dilutions will be 1/20, 1/40, 1/80, 1/160, and 1/320.

3. When all the serum samples have been diluted, quickly transfer 50 μl of each dilution into the duplicate tubes in the assay rack, starting from the most dilute and ending with the least dilute. Put 50 μl of GVB^{2+} into the 0% tubes and 50 μl of distilled water into the 100% tubes. Once all the samples have been transferred, add 50 μl of EA at 2×10^8 cells per ml to each tube. A repeating pipettor works well for this purpose. Remove the rack from the ice bath, cover with Parafilm, and shake it vigorously to mix the cells with the serum dilutions.

4. Place the rack in the 37°C water bath and incubate for 30 min at 37°C, with shaking two or three times during that time to keep the EA suspended (a shaking water bath can be used). Add 1.2 ml of ice-cold saline to each of the tubes except the 100% lysis controls, to which 1.2 ml of distilled water should be added. Centrifuge all tubes at $1{,}250 \times g$ for 5 min to pellet the unlysed EA and read the OD_{412} of the supernatants. Use distilled water or GVB^{2+} as the blank to zero the spectrophotometer. Calculate the percent lysis for each tube (divide its OD_{412} by the OD_{412} of the 100% lysis control tube and multiply by 100). *Note: lysis of the background (0%) tube should be <10% of total lysis*. Average the results of the duplicate tubes for calculations. Some spectrophotometers can be programmed to do this step.

5. Data calculations: Manual method: Plot the data on 3 log-cycle probability paper (Keuffel & Esser, Morristown, NJ). Plot the reciprocal serum dilutions on the logarithmic *y* axis, using the percentage scale at the top of the page. Draw the best-fit line through the points and locate the corresponding *y* value where it crosses the line at 50% lysis. The reciprocal of the dilution at this point is the CH50 value (5). Note that lysis of >85% or <15% of the cells tends to fall off the straight line formed by the points between these values, so use only the points that fall within this linear range for calculations. If a computer or calculator with linear regression capability is available, the data can be calculated using the natural logarithm of the reciprocal dilution as the independent variable (x) and the percent lysis as the dependent variable (y). Once the best-fit line [$y = m * \ln(x) + b$] is determined, the 50% lysis point can be calculated from its slope (m) and intercept (b). For the CH50, the value of $y = 50\%$, so $x =$ the anti-ln of $[(50 - b)/m]$. The correlation coefficient, R^2, for the line should be >0.95.

6. The results are reported as the number of CH50 units per milliliter, where the CH50 unit (U) is defined as the reciprocal of the dilution of serum. Thus, a sample that lyses 50% of the EA at a dilution of 1:150 will be reported as 150 CH50 U/ml. Because different laboratories do CH50 assays using different cell concentrations and conditions, the ranges for normal sera vary from one laboratory to the next, and when you are setting the test up, you must establish your own normal range. Interassay variability can be controlled by using a calibrated serum standard each time you do the test. The experimental CH50 value obtained for the standard in the current run is divided by its established value, and the resulting factor is used to correct the CH50 values of the other samples in the run. This allows comparisons to be made between tests run over a long period of time. The corrected values for the controls should not vary by more than ±10% from run to run for the data to be acceptable.

AH50 Assay

Materials and Reagents (Sources)

Materials and reagents are the same as for the CH50 procedures except as follows.

Buffer ($GVB\text{-}Mg^{2+}$–EGTA): prepare stock GVB as described above for the CH50 procedure, except leave out the calcium and add 160 ml of 0.1 M EGTA solution and 10 ml of 2.0 M $MgCl_2$ before bringing to 2 liters with distilled water

Calibrated standard serum: same as for CH50 except use the AH50 value assigned to it

Control sera: normal serum pool or sera from individual donors with normal AH50 values. As above, high, middle, and low controls should be collected and aliquoted for one-time use.

Starting with rabbit whole blood in Alsever's solution (Colorado Serum Co.), prepare E_{rab} at 2×10^8/ml as for the CH50 procedure preparation of sheep E. Use the $GVB\text{-}Mg^{2+}$–EGTA buffer for washing the cells.

Equipment and Instruments

Equipment and instruments are the same as for the CH50 procedure.

Procedure for AH50 Assay

Apart from the difference in the target cells and the buffer, the main difference between the CH50 and the AH50 is that the latter is more sensitive to dilution. For this reason, the volumes and dilutions are different for the AH50. Activity is lost at higher dilutions than those given.

1. Use disposable glass tubes (12 by 75 mm) for the test and dilutions. Set up two racks of tubes, one for making the dilutions and one for the assay itself. In the dilution rack, put five tubes for each serum sample you want to test (plus serum pool or other controls). In the assay rack, put duplicate rows of the five tubes each for the sera. Label each row with the name of its sample and dilution. Place the rack of dilution tubes into a slushy ice bath. Put 600 μl of $GVB\text{-}Mg^{2+}$–EGTA in the first tube of each series and 200 μl into each of the remaining four tubes. Make 1.5-fold dilutions in each row beginning with 1/4 dilution: add 200 μl of serum to the first tube, and transfer 400 μl from tube 1 to tube 2, etc., for the serial dilutions. Transfer 50 μl of each dilution into the duplicate tubes for the appropriate sample in the assay rack. Also include the following controls for each assay: two tubes for 100% cell lysis (substitute 100 μl of distilled H_2O for buffer and serum) and two tubes for background lysis (100 μl of buffer only but no serum). Background should not exceed 10% of the total lysis.

2. Add 50 μl of the E_{rab} suspension to each of the serum dilution tubes and transfer the rack to a water bath at 37°C.

3. Incubate for 60 min, with occasional shaking to keep the cells in suspension.

4. Add 1.2 ml of ice-cold saline to each tube to stop the reaction and spin the cells down ($1{,}000 \times g$ for 5 to 10 min). Read the OD_{412} of each supernatant. If the spectrophotometer you are using has the ability to calculate concentration of samples versus a standard, enter 100 as the value of the standard and read the OD of the 100% lysis tubes. Next, read the OD of the background tubes and rezero the machine so

that this background will be subtracted from each of the test samples to follow.

Calculate Results

1. Using probability paper, plot the percent lysis on the *x* axis (use the percentage scale at the top of the page) versus the log of the dilution on the *y* axis. Draw the best-fit straight line between the points, excluding those for percent lysis >85% or <15%, since the curve is nonlinear at the ends. The AH50 is the corresponding point on the *y* axis where the line crosses 50% and is the reciprocal of the dilution that caused 50% lysis in the test. Since the volumes used were 50 μl, the result can be converted to units per milliliter by multiplying the answer by 20.

2. An alternative method for calculating results is as follows. Calculate $y/(1-y)$ and graph the results on log paper, using the reciprocal of the serum dilution on the *y* axis and the value of $y/(1-y)$ on the *x* axis, where *y* is the fraction of cells lysed (3). The AH50 value is then read off the graph as the reciprocal of the dilution where $y/(1-y) = 1$ (50% of the cells lysed). Use a linear regression program to determine the best-fit line for the data [*x* = percent lysis and *y* = ln(dilution)] as described for the CH50 method.

Standardizing the Results

To minimize the variability of the test from one batch of cells and reagents to the next, use a correction factor based on your calibrator serum or serum pool so that interassay comparisons can be made. Determine the average value for your serum pool (from 10 or more assays) or use the given value for the calibrated standard or other serum with known AH50 titer. Divide the answer obtained in your assay for the standard by the value of the standard obtained as described above, and use the resulting factor to multiply all other results in that run. This will bring the amount of interassay variability to within the desired limits of ±10%.

Controls

A control serum with predetermined (from 10 to 20 tests) CH50 or AH50 units per milliliter should be included with each batch of test sera. Ideally, sera with high and low activities should be used to control for variability at each end of the CH50 or AH50 range. The background lysis (0%) and total lysis (100%) controls define the OD range that is acceptable for the assay. The 0% control should be <10% of the total lysis.

Standardization, Quality Control, and Quality Assurance

A calibrated standard serum must be included with each run. This can be a serum that is obtained from another laboratory that is using a similar method or prepared in-house. To obtain enough to last for a reasonable length of time, prepare a pool of sera from 10 or more donors and store it in aliquots of 50 to 100 μl each at −70°C. Perform the CH50 or AH50 assay on this standard pool of serum at least 10 times and calculate the average CH50 or AH50 value. The coefficient of variation should be within 10% for these values if the assay is working well. The average is then defined as the CH50 or AH50 value for the serum pool. Quality control should include Levy-Jennings plots of the control sera for each assay run, and Westgard rules should be followed. A normal range should be established from 50 to 120 serum samples obtained from healthy individuals. The range to be used for the assay is the mean ± 2 standard deviations, and any abnormal test results that are >3 standard deviations from the mean should be verified by repeat assay.

Preanalytical Concerns

Proper collection of samples is critical for the CH50 and AH50 assays. Serum should be collected and frozen at −70°C or placed on dry ice within 1 to 2 h from the time the blood is drawn. If the assay is to be done in-house on the same day, the serum can be kept on wet ice until the assay, or it may be frozen overnight at −20°C in a non-frost-free freezer. Prolonged storage at temperatures above −70°C will result in loss of complement activity, whereas sera stored at −70°C or below are stable for years. Ship specimens for CH50 and AH50 assay by overnight mail in a well-insulated package with enough dry ice to last 48 h. *Note: if the patient has cryoglobulinemia, the serum must be kept at 37°C and the testing must be done with cells and buffers at that temperature within a few hours.*

Analytical Concerns

These assays work best when all reagents and serum dilutions are kept on ice. The control sera and the standard serum must be stored at −70°C in small aliquots that can be thawed once for the assay and discarded afterward. *Do not refreeze and reuse the sera more than one time.* Patients' sera to be tested should be stored at −70°C and thawed just before the test is to be performed. If the test needs to be repeated, make a few small aliquots of the patient's serum, so that the main tube does not undergo repeated freeze-thaw cycles. Do not reuse diluted sera, but prepare new dilutions for repeat assays.

The sheep blood and rabbit blood in Alsever's solution are stable for 4 to 6 weeks in the cold (2 to 8°C). If the cells continue to lyse during the washing process, discard them and obtain a fresh supply. Hemolysin can be stored at −20°C for several years in a non-frost-free freezer.

Postanalytical Concerns

Test results should be analyzed as described earlier. If only a few specimens are to be tested, the probability paper plotting method is the simplest way to obtain the results. For larger runs, use the linear regression program on a personal computer.

Normal ranges can be established from 30 to 50 serum samples obtained from healthy individuals. The distribution should be normal for this population.

Quality control for these assays includes the high (top 10% of reference range) and low (lowest 20% of reference range) serum controls and the background lysis (0%). The total lysis (100%) should be within the interassay variability range as well. Because there is no established proficiency testing available from the College of American Pathologists or other organizations, in-house proficiency testing should be performed on a regular basis. Specimens for this could include repeated testing of a patient's sample, especially if abnormal, or varied proficiency test samples prepared in-house. For example, serum from a healthy individual, treated by dilution (1/2 or 1/5), by heat inactivation (56°C, 30 min), or by activation with a known complement activator such as zymosan (1 to 10 mg/ml, 20 min, 37°C), will have low or completely blocked CH50 or AH50 values. Specimens with elevated CH50 or AH50 results can be obtained by testing acute-phase sera or by gently concentrating normal sera.

Pitfalls and Troubleshooting

The most common problem encountered with functional complement tests is improper sample collection and handling. This occurs often when the blood is collected off-site and is allowed to stand for hours with the cells and clot present or when the serum is collected and then put into a

TABLE 1 Testing for complement deficiency or dysfunction[a]

First order of testing	CH50 and AH50			MBL
Results	CH50 low or absent; AH50 normal	AH50 low or absent; CH50 normal	Both CH50 and AH50 low or absent	MBL low or absent; CH50 normal; AH50 normal
	▼	▼	▼	▼
Interpretation	Likely classical component deficiency	Likely alternative component deficiency	Likely terminal component deficiency	Likely lectin component deficiency
	▼	▼	▼	
Next steps	C1, C2, and C4 function and level	Factor B and factor D level or function	C3, C5, C6, C7, C8, C9 levels or functions	
	C1-INH level or function	Properdin level or function	Factor H, factor I levels and H function	
Final step	Genetic analysis of complement components in pathway identified			

[a]Because genetic mutations alter the function but not the level of the protein, testing for both the level and the function can reveal a defect that the level alone does not pick up. If these tests are inconclusive, consider testing for complement autoantibodies against C1q, C1-INH, Factor H, FB, C3NeF, FI, and others.

refrigerator where it may be kept for days before it reaches the laboratory. The major problem with running the CH50 assay is failure to sensitize the E correctly. The hemolysin should be titrated before it is used, but once the titer of a given hemolysin is known, the titration does not need to be repeated for each test (5). Buffers should be made up fresh for each assay and discarded after 24 h.

Interpretation

The CH50 and AH50 assays reflect the sequential interaction of all of the components of the CP and AP, respectively. If any single component is missing, the resulting CH50 or AH50 value will be 0 U/ml. Because the pathways share the same terminal components (C3, C5, C6, C7, C8, and C9), a deficiency of one of these will lead to the loss of both CH50 and AH50 activity. Using the algorithm in Table 1, the physician can decide on the best set of assays to use for a patient with a suspected complement deficiency. Thus, if only the CP is 0, there is no need to look at late components or AP components. If both pathways are blocked, then one of the late components is likely to be missing. When the CH50 and/or AH50 value is between 0 and the low end of the normal range, the most likely cause is *in vivo* activation. This can be verified in two ways: (i) assays of individual components will show that more than one is decreased, or (ii) results obtained with assays of complement split products will be elevated (see chapter 15). The primary pathway that has been activated can be determined by which component levels are decreased or which split product levels are elevated.

The CH50 and AH50 assays are excellent screens for total complement activity but are relatively insensitive to small changes that may occur because of complement activation. Much more sensitive assays exist to look at ongoing inflammatory processes or involvement of complement in disease states, as described in chapter 15 of this volume.

The basic screening tests should include hemolytic CH50 and AH50 tests that measure total CP and AP activity, respectively, or their equivalents that have been developed for CP and AP function by enzyme-linked immunosorbent assay, liposome lysis, or other methods. Additional tests for LP function are available for mannose-binding lectin (MBL) (chapter 14), and tests for other LP proteins are in development that will further narrow the search for abnormal proteins in this important system (6). Since all three initiating pathways, CP, AP, and LP, feed into the same terminal pathway, a missing component unique to any one of the pathways blocks progression of the reaction of the affected pathway and thus no lysis occurs when that pathway is activated. The other pathways are unaffected. A block in the late components that make up the terminal pathway affects all of the others.

An algorithm depicting a useful sequence for testing is given in Table 1. Exceptions to this might be for a patient with HAE due to C1-INH deficiency, for whom the testing should include C4 level and C1-INH level and function, or a patient with one of the C3 glomerulopathies due to AP dysregulation, for whom testing might also include C3, factor H (FH), factor I (FI), CD46, C3 nephritic factor, or antibodies to FH.

As with other laboratory tests, care must be taken with specimen collection, handling, and shipping. The best policy to follow is to minimize the amount of time that a given specimen spends at room temperature, from the time it is collected from the patient to the time it is processed and safely stored (e.g., frozen at −70°C). Because specimens from patients may contain bacteria, immune complexes, cryoglobulins, drugs, and other potential activators of complement, the reaction can continue long after the blood has been drawn and result in misleading results when tested in the laboratory. It is strongly advised to contact the

laboratory to which the specimen will be sent for instructions for specific assays.

DEFICIENCIES OF CP PROTEINS: C1q, C1r, C1s, C2, AND C4

The CP is critical for the clearance of immune complexes, the removal of apoptotic cells, and the defense against certain bacterial and viral infections. The phenotype of CP component deficiencies is closely linked to diseases in which these processes are impaired, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, anaphylactoid purpura, vasculitis, and infections with encapsulated bacteria (7). SLE patients with C1q or C4 deficiencies have characteristic features such as earlier age of onset, prominent photosensitivity, lower frequency of renal disease, variable antinuclear antibody titers, and a nearly equal male-to-female ratio. In addition to SLE and other immune complex diseases, CP deficiencies also lead to recurrent infections with streptococcal, staphylococcal, and other common encapsulated bacteria and should not be overlooked in the workup for immune dysfunction. Infections with Gram-negative organisms, especially *Neisseria*, are associated with the terminal pathway, and the CH50 or equivalent assays are the best initial screens for these deficiencies, followed by tests for individual components, since the absence of any one of the CP proteins prevents lysis by CP activity (8).

The gene for human C1q is located on chromosome 1, at 1p34-1p36.3 (9). The protein is related to the collectin family, possessing both collagen-like and globular pattern recognition structures. There are six each of three different polypeptide chains, A, B, and C, in the intact 460-kDa molecule. These chains are combined to form six triple-chain helices that make up the collagen-like "stalk" of the molecule. The stalks branch at flexible hinge regions midway along their length, and their ends are capped with globular protein head regions. The molecule has been described as a bunch of six tulips, based on electron micrographs. This complex structure is highly labile and becomes denatured if subjected to temperatures above 56°C or to repeated freeze-thaw cycles.

Cells of monocyte/macrophage lineage are responsible for most of the circulating C1q that is produced, while follicular dendritic cells provide a secondary site of synthesis. C1q deficiency is an autosomal recessive condition, with deficient patients having little or no detectable protein or C1q function in the circulation. Mutations have been identified in the genes for each of the three chains. Almost all patients with documented C1q deficiency have developed SLE-like disease, and linkage studies demonstrate that the C1q gene is close to that for other proposed SLE susceptibility genes on chromosome 1 in humans (10, 11). Acquired C1q deficiency occurs when autoantibodies are produced against the collagen-like region of the C1q molecule. These anti-C1q antibodies are associated with SLE and also with hypocomplementemic urticarial vasculitis syndrome (12). C1q can also be temporarily reduced in the circulation by ongoing CP activation *in vivo*, as well as activation in the specimen after blood is drawn if the patient has an immune complex burden, cryoglobulinemia, bacteremia, or other condition likely to activate complement.

The genes for C1r and C1s are located on chromosome 12, at 12p13, where the two genes lie in tandem (13). C1r and C1s are synthesized as single-chain proenzyme molecules that, with C1q, form a calcium-dependent complex: $C1q_1C1r_2C1s_2$. During activation of the CP, each proenzyme is activated by cleavage of a single bond that produces two disulfide-linked peptides, the smaller of which has esterase activity. C1r has very limited trypsin-like activity and undergoes autoactivation followed by cleavage of C1s. C1s has trypsin-like activity against C4 and C2, each of which it cleaves into two fragments: C4a and C4b, and C2a and C2b.

C1r and C1s are synthesized primarily by hepatocytes, but monocytes, macrophages, epithelial and endothelial cells, and some cells of the central nervous system provide secondary synthesis sites. Deficiencies of C1r and C1s are very rare and may be partial or combined. They predispose the patient to recurrent pyogenic infections as well as immune complex disease and are associated with SLE and other autoimmune disorders (14). Without C1r and C1s, the CP cannot be activated.

The proteins C4 and C2 are required for formation of the C3 convertase of the CP (C4bC2a). C4b has cofactor activity required for the enzyme function of C2a. The absence of either protein leads to a complete block of CP activity and is associated with recurrent infections and immune complex disease as described above. In spite of this, many patients with C2 deficiency remain asymptomatic for long periods, if not for life. A bypass mechanism is provided by the LP that allows direct C3 cleavage by the MBL-associated serine proteases (MASPs), generating C3b for AP activation without the need for C2 or C4, and explaining why some patients have milder disease. Those who do have recurrent severe infections may have undetected LP or other defects as well. The wider availability of functional assays for the lectins and their enzymes will help to answer this question (15, 16).

The genes for C4 and C2, along with those for FB, are found in the major histocompatibility complex (MHC) on chromosome 6, in the class III MHC genes. The null allele for C2 deficiency is linked to HLA-A25, B18 haplotype (17, 18).

C4 is produced primarily by hepatocytes but can also be made by other cells. It is synthesized as a single chain that undergoes posttranslational modification to three chains, α, β, and γ, that are disulfide linked. The α chain contains an internal thioester linkage that is transiently exposed and forms a covalent bond with nearby substances when C4a is clipped off the N-terminal end during activation. This bond provides a means for attachment of C4b to the nearest protein or carbohydrate group when activation occurs, and results in long-lasting deposition of C4b and its breakdown fragment, C4d, on the activator or nearby cells.

Human C4 exists in two forms called C4A and C4B, coded for by different genes. Approximately 75% of the Caucasian population has two alleles for each C4 haplotype (19). The differences between the two forms of C4 are in a few amino acids near the thioester group, and they alter the ability of the C4b fragment to bind covalently to nearby surfaces when C4 is cleaved during activation. C4A binds best to amino groups on proteins such as antibodies, and C4B binds to carbohydrate on cell surfaces. The naming of these haplotypes is unfortunate, since the uppercase A and B are confused with the lowercase in C4a and C4b. Standard assays for C4 do not distinguish between these forms. Variation in C4 gene copy number is not uncommon, and the number can range from none to eight or more copies, giving this protein a wide range of concentrations in the general population (19, 20). More than 100 different polymorphisms in the C4 protein make it one of the most variable proteins in the circulation.

Most of the partial C4 deficiencies are without consequence, but some individuals have a total deficiency of one haplotype and not the other. C4A deficiency is increased (8 to 12%) in Caucasian lupus patients compared to control individuals (1 to 3%), resulting in decreased binding of C4b to protein antigens and antibodies and consequently

difficulty with immune complex clearance. An increased incidence of C4B null alleles was recently reported for patients with Henoch-Schönlein purpura (21). A report in 2010 described two siblings who developed membranoproliferative glomerulonephritis type III. The brother was diagnosed with Henoch-Schönlein purpura with proliferative glomerulonephritis at age 14 and died on dialysis at age 28. The lab results and biopsy were not available. The sister, age 28, presented with proliferative glomerulitis with confirmed C4B deficiency. The biopsy showed 3+ staining for C4 and IgG, 2+ for C1 and IgM, and weak IgA and C3 (22). This case illustrates the need for both protein and genetic analysis to arrive at the diagnosis.

Many cell types produce C2, including hepatocytes, monocytes, macrophages, fibroblasts, astroglioma cells, and alveolar type II cells. It is synthesized as a single-chain proenzyme that expresses its esterase activity only after it has been cleaved. This activity is very weak in the fluid phase but becomes efficient when, in the presence of magnesium, the C2a fragment binds to C4b that is fixed on a surface. C2a that has been dissociated from C4b is rapidly inactivated in the fluid phase, and native C2 protein, like C1q, is rapidly degraded at temperatures near or above 50°C.

Children and infants with C2 deficiency have increased susceptibility to infections such as streptococcal pneumonia and other encapsulated bacteria, as well as the previously mentioned association with immune complex diseases. In Caucasian patients with rheumatologic disorders such as SLE, the incidence of C2 deficiency approaches 1/100, as opposed to the general population, where the incidence is estimated to be 1/10,000 (23, 24). There are two forms of C2 deficiency. Type I C2 deficiency, which affects >90% of patients, results from a complete lack of protein in the circulation, while type II C2 deficiency comes from the production of protein that is incapable of normal function but that can be detected in the circulation by immunochemical assays. The former deficiency is caused by a 28-base-pair deletion that stops production of the protein, while the latter occurs from single nucleotide polymorphisms or point mutations identified by sequencing. Because some of the latter mutations result in production of normal levels of dysfunctional protein that reacts with the antibodies used in C2 analysis, similar to the situation in type II C1-INH deficiency, C2 should also be tested by a functional assay. With the increased availability of genetic tests, it is likely that the percentage of cases identified as type II C2 deficiency will increase in the next few years.

DEFICIENCIES OF THE LP: MBL, FICOLINS, AND MASPs

The family of proteins that make up the LP are ancient conserved pattern recognition molecules that recognize danger signals such as microbes as well as altered self surfaces. They are involved in clearance of infectious organisms, damaged tissues, and inflammatory responses. MBL was the first characterized, and the pathway was initially called the MBL pathway. Similar in structure to C1q, it is made up of trimers of single polypeptide subunits, two to six of which combine to form oligomers. The head group of each trimer has specificity for sugars and binds with high affinity to mannose, peptidoglycan, and *N*-acetylglucosamine residues that are found on the surfaces of bacteria, yeasts, and fungi (25). Like C1q, it is associated with serine proteases called MASPs that become active when MBL is bound to a surface (26). In addition to activating complement, MBL may be able to act as an opsonin by interacting directly with cell surface receptors.

The gene for MBL is found on chromosome 10, at 10q11.2-q21, with another gene that encodes a truncated protein at 10q22.2-22.3. There is a wide range of serum concentrations of MBL, due in part to the presence of gene variants that produce different amounts of the protein. Approximately 5 to 10% of individuals studied to date are MBL deficient (27). Because complement activation by the LP is antibody and C1 independent, it is thought to play an important role in innate immunity during infancy at the time when maternal antibodies are disappearing and before the infant's own adaptive immune responses are mature (28, 29). Deficiency of MBL has been linked to an increased frequency of pyogenic infections and sepsis, particularly in neonates and young children. It has been implicated as a risk factor in ischemia-reperfusion injury, Behçet's disease, cystic fibrosis, severe acute respiratory syndrome, and other respiratory infections (30–34). There is a 2- to 3-fold increase in MBL deficiency in those lupus patients who tend to have more frequent and severe infections. Worse outcomes are also observed in rheumatoid arthritis patients with MBL deficiency. Autoantibodies that reacted with MBL were found in a Japanese study of patients with SLE, but the significance of the antibodies was not evident from the disease characteristics of the patients (35). A recent report from Denmark linked deficiency of MBL (<100 ng/ml) and low levels of MASP-2 along with the *MBL2* YA two-marker haplotype in a group of patients with panic disorder, and the *MBL2* LXPA haplotype and low MASP-2 levels in patients with bipolar disorder. Both disorders are associated with infections and inflammation (36).

The ficolins are also similar to C1q and MBL, with four or more trimers bound together in a collagen-like tail region and a C-terminal fibrinogen domain that is thought to be the ligand-binding site for *N*-acetylglucosamine (37). Three ficolins have been described: ficolin-1 (previously M-ficolin), ficolin-2 (previously L-ficolin), and ficolin 3 (previously H-ficolin, also known as Hakata antigen). The genes for ficolin-1 and ficolin-2 are at chromosome 9q34 and are similar, suggesting gene duplication in their past. The gene for ficolin-3 is found at 1p36.11. The ficolin-1 and ficolin-2 proteins are 80% homologous with each other, while the ficolin-3 protein is only 48% homologous with ficolin-1 and ficolin-2. The carbohydrate binding sites differ in that ficolin-1 and ficolin-3 have a single domain but ficolin-2 has four distinct binding sites. Ficolin-1 is expressed in monocytes and is present in the spleen and type II alveolar cells. Ficolin-2 is expressed primarily in the liver, but low levels of mRNA can be found in the bone marrow, tonsils, intestine, and the fetal lung. It is not known if these represent synthesis sites. Ficolin-3 is produced in the liver and the lung, with low levels found also in the heart, kidney, spleen, pancreas, and placenta. Low levels of mRNA have been seen in the brain and in a human glioma cell line. The levels in the lung exceed those in the liver, suggesting a role for ficolin-3 in lung defense. Hereditary deficiencies of the ficolins are extremely rare, but polymorphisms that affect the level and concentration of ficolin-2 are relatively common. A frameshift mutation was found in ficolin-3, resulting in a truncated protein. The patient had recurrent lower respiratory infections since childhood. He later developed cerebral abscesses (38).

The MASP enzymes also associate with the ficolins, with MASP-2 being the primary initiator for activation. MASP-1 and MASP-2 are also capable of cleaving prothrombin and fibrinogen and generating a fibrin clot (39, 40).

All forms have similar opsonizing capacities for pathogens and are associated with the MASP enzymes found with MBL. Although the ficolins were first described as opsonins

in 1996, little is known of the prevalence or phenotype of ficolin deficiencies.

The four MASP proteins, MASP-1, MASP-2, MASP-3, and Map19, are encoded by two genes. Structurally they are similar to C1r and C1s, with a serine protease domain in the B chain. MASP-1 and MASP-3 are alternative splice products of one gene (*MASP-1/3*) that have the same A chain but different B chains. A different gene encodes MASP-2 and Map19, the latter of which has only the first two domains of MASP-2 plus an additional four amino acids. MASP-2 is responsible for the cleavage of C4 and C2, making it analogous to C1s in function. Although there have been mutations found in the genes for the MASP proteins, the mutations in MBL that prevent the assembly of the complete complex are the major known cause of functional deficiency of these proteins (29, 41).

DEFICIENCIES OF THE CP AND LP CONTROL PROTEINS: C1-INH AND C4BP

The active enzyme forms of C1r and C1s are regulated solely by C1-INH, a member of the SERPIN family of serine protease inhibitors. C1-INH also contributes to the control of other enzymes, including coagulation factors XIa, XIIa, plasmin, and plasma kallikrein. When the enzyme and inhibitor interact, the enzyme binds to and cleaves a "bait-sequence" on the inhibitor and the resulting change in conformation forms a tight complex, rendering the enzyme inactive. The enzyme-inhibitor complexes formed in these reactions are cleared from the circulation by cells of the reticuloendothelial system. If the inhibitor is present in low levels, if it has a defect that makes it nonfunctional, or if there is an autoantibody that binds to and inactivates the C1-INH, then symptoms of angioedema are likely to occur.

C1-INH deficiency can be of hereditary origin (HAE) or acquired (AAE). Clearance of inhibitor-enzyme complexes that result from complement activation or action of autoantibodies that react with the inhibitor and result in its inappropriate cleavage can decrease the available amount of C1-INH present at a given time. Symptoms are similar regardless of the cause of the deficiency, so careful evaluation is required to distinguish between HAE and AAE. In the past few years, other forms of HAE have been recognized that are not associated with C1-INH deficiency. Konrad Bork, working in Germany, found numerous patients, most of whom were women, with HAE but normal levels and function of C1-INH. A subgroup of these patients was shown to have a mutation in factor XII of the contact coagulation pathway. Since his publication, other families with the same mutation have been identified (42, 43). The biochemical mediator of C1-INH deficiency-related HAE, as well as the factor XII-related form, has been identified as bradykinin. C1-INH is also involved in the coagulation pathway as an inhibitor of factor XIIa, kallikrein, plasmin, and other enzymes, so decreased amounts of the C-INH would allow increased production of bradykinin. The mutation in factor XII makes it less susceptible to control by C1-INH, which can also lead to more bradykinin. The fact that both kinds of patients respond to inhibition of bradykinin or its receptor supports this assumption.

C1-INH is inherited in an autosomal codominant pattern in which each allele produces approximately half of the protein in the circulation, although increased catabolism often causes decreases of the normal gene product to below the predicted 50% level. To date, very few patients with homozygous deficiency of C1-INH (both alleles defective) have been reported, and the heterozygous state determines the dominant phenotype (44). Patients with C1-INH deficiency suffer various degrees of intermittent angioedema characterized by nonpainful, nonpruritic, and nonerythematous subcutaneous and submucosal swelling that spontaneously subsides within 72 h (45, 46). Swelling may arise sporadically and spontaneously, or it may be triggered by mild trauma or psychological stress. It is not accompanied by urticaria and is not responsive to antihistamines, steroids, or β agonists. Symptoms usually begin in adolescence and range in severity from mild edema of the extremities to life-threatening laryngeal edema. Edema of the bowel wall results in severe colicky abdominal pain, nausea, and vomiting that can be distinguished from acute abdominal syndromes by the absence of fever, peritoneal signs, and elevated white blood cell count. Angiotensin inhibitors may increase attack frequency and severity. In one case report, an underlying autoantibody to the C1-INH was "unmasked" by an angiotensin-converting enzyme inhibitor, greatly enhancing the patient's symptoms.

Genetic defects in C1-INH range from single nucleotide polymorphisms that may alter the function of the protein produced to inappropriate stop codons resulting in large deletions and no protein production. Since most patients are heterozygous for the deficiency, each patient has one normal allele and one abnormal allele, and he or she will have variable amounts of C1-INH protein in the circulation, from very low to elevated, depending on the particular mutation in the affected gene. In the majority of patients, low levels of C1-INH are indicative of the defect, but final diagnosis of HAE should be based on the functional activity of C1-INH protein in conjunction with decreased levels of C4, the clinical presentation, and family history. Spontaneous mutations in C1-INH genes have been documented in about 20% of cases, so the lack of family history does not rule out the defect (47, 48). The prevalence of C1-INH deficiency is 1/10,000 in Caucasian populations. MASP-1 and MASP-2 are controlled in a 1:1 manner by C1-INH, in the same way that C1r and C1s are controlled. The control of MASP-3 is not known at this time.

The classification of HAE is undergoing scrutiny by several consensus groups that are trying to define the disease based on its genetics, symptoms, and response to treatment. The two "classical" forms of HAE appear the same clinically. Type I HAE (80% of patients) is defined by a reduction of C1-INH to less than half of normal antigenic and functional levels. Type II patients have normal or elevated C1-INH antigenic levels but synthesize a dysfunctional protein that results in reduced C1-INH function. Recent studies have identified other forms in which the patients, all women, have clinical findings consistent with HAE but normal C1-INH level and function (49, 50). The underlying estrogen-dependent defect has not been identified. In some families, a gain-of-function mutation in coagulation factor XII has been associated with the HAE (28).

Several forms of AAE have been described, depending on the underlying cause. Patients with B-cell lymphoproliferative diseases that produce circulating anti-idiotype antibodies generate immune complexes that cause a persistent activation of complement and result in profound C1-INH depletion as the enzyme-inhibitor complexes are cleared (51, 52). In this form of AAE, the C1q level is decreased due to the activation, whereas in the hereditary forms it is not, making the measurement of the C1q protein a method for identifying these patients. Another form of AAE results from inactivation of C1-INH caused by autoantibodies to the C1-INH protein (53). In these patients, the C1-INH level can be normal by immunoassay but the protein's function is blocked, similar to type II HAE. The autoantibody can be detected by enzyme-linked immunosorbent assay,

and a cleaved form of the C1-INH molecule can be detected by Western blotting.

The good news about HAE is the availability of new treatments for patients, and more rapid diagnosis so that they can get help sooner. Human plasma-derived purified C1-INH and recombinant human C1-INH protein preparations are now available for infusion or subcutaneous administration. There is also a drug that blocks the receptor for bradykinin and another that acts on the bradykinin itself. The interest that the pharmaceutical industry has shown in orphan diseases has increased greatly in the past 10 years and resulted in benefits for other complement-related diseases as well.

The fluid-phase control of C4aC2b, the C3 convertase of the CP and LP, is accomplished through the combined effects of C4b-binding protein (C4BP) and FI. Also known as proline-rich protein, human C4BP is a member of the gene family called regulators of complement activation (RCA). Characterized by multiple short consensus repeat motifs, also referred to as complement control protein (CCP) units, the RCA proteins bind C3b and C4b fragments and possess various control properties that are critical for regulation of complement activity. These small globular CCP units are typically connected in linear fashion like beads on a string. They occur in all of the RCA and many other complement proteins in various numbers.

C4BP has several isomers made up of two types of subunits: six or seven α chains and zero or one β chain. These are connected at a central joining region and radiate outward, giving the molecule a spider-like appearance in electron micrographs. The α chains bind to C4b and accelerate the dissociation of C4bC2a to form free C2a and C4b-C4BP. C2a is unable to bind to newly formed C4b and becomes inactivated, while C4b undergoes degradation by FI (with C4BP as a cofactor) to form C4c and C4d (54). C3 convertase activity by the CP enzyme is short-lived due in part to the efficiency of C4BP. For this reason, activation of the CP does not produce a large amount of C3 fragments and activation often stops at this point in the cascade unless enough C3b is generated to allow the AP to be activated. In autoimmune diseases such as SLE and rheumatoid arthritis, the ratio of C4 to C3 is used to determine the state of complement activation in the patient: low C4 but normal C3 implies low-level CP activity. Another method of looking at the amount of activation is to measure the amounts of C4d and C3d that are deposited on platelets, erythrocytes, and other cells that are in the vicinity of complement activation. Flow cytometry is used for evaluation of these markers for complement activation (55, 56).

In the absence of C1-INH, it is the control of C4bC2a activity by C4BP and FI that accounts for the stability of C3 in HAE patients in spite of decreased C4 and C2 (57). The β chain has a binding site for the anticoagulant protein S and plays a role in control of coagulation (58).

C4BP is synthesized by hepatocytes. The genes for the C4BP α and β chains are located in the RCA gene cluster on chromosome 1, at 1q32. Circulating concentrations of C4BP vary according to genetic determinants as well as fluctuations due to consumption during disease states. Deficiencies of C4BP are very rare and would logically be associated with uncontrolled activation of C3 through the CP. The only documented case was a patient with an atypical form of Behçet's disease and angioedema (59).

DEFICIENCIES OF THE AP: FD, FB, AND P

FD is the smallest of the complement proteins and is the only serine protease of the system that does not require enzymatic cleavage in order to become active. Instead, its enzyme activity is a function of its conformational state, and it can flip between the active and inactive forms depending on its proximity to its substrate: C3b-bound FB (60). Monocytes and their lineage synthesize some of the FD found in the circulation, but the major source is in adipose tissue. FD has another role apart from its complement duties, in that it is known as adipsin and acts as a regulator of fat metabolism. Likewise, C3a is known as acylation-stimulating protein, or ACP (61). FD is the only initiating enzyme for the AP. It binds to and cleaves FB only when the FB is bound to C3b. The resulting complex, C3bBb, is the AP C3 convertase.

The gene for FD is located on chromosome 19. FD deficiency is extremely rare. One family with FD deficiency has been described to date. In five generations of family members, the propositus was a 23-year-old woman who presented with meningococcemia from *Neisseria meningitidis*. Three relatives had FD deficiency with no health problems, and a deceased family member had a history of meningitis in his twenties and died from pneumonia and meningitis caused by *Streptococcus pneumoniae* at age 81 (62). Complement studies for the patient and family members included C3 and C4 levels and CH50 (normal in all). The AH50 was <10% of normal in homozygous deficient individuals but was normal in all others, including those heterozygous for the deficiency. When FD was analyzed, it was found to be slightly elevated in those members who were homozygous for the wild-type FD gene, about half the normal level in those heterozygous for the mutation, and undetectable in the four patients homozygous for the mutation.

In addition to its participation in the AP of complement, FD plays a role in fatty acid metabolism, and the $C3a_{desArg}$ fragment produced by FD-mediated cleavage of C3 has been identified as the autocrine mediator of hyperapobetalipoproteinemia (61, 63). It is tempting to speculate that this involvement with lipid metabolism may be impaired or dysregulated somehow in those rare patients with partial lipodystrophy who have increased cleavage of C3 due to the presence of autoantibodies to the C3bBb complex (C3 nephritic factors) (64). Another question that is receiving attention in this regard is the role of complement in cardiometabolic disease or type 2 diabetes (121).

FB has been known variably as glycine-rich β-glycoprotein, properdin factor B, and C3 proactivator. The gene for FB is in the MHC complex on chromosome 6, at 6p21.1-6p21.3, 3′ to the C2 gene (65). It is synthesized primarily in the liver, with additional protein produced by cells of monocyte/macrophage lineage, fibroblasts, endothelial cells, and alveolar type II epithelial cells. Secreted as a single polypeptide chain proenzyme, FB is activated only when it is bound to C3b and cleaved by FD. Its activity is specific for C3 and C5, but it requires C3b as a cofactor to cleave the former and an additional C3b to cleave the latter. The hydrolyzed form of C3 known as $C3(H_2O)$ can also serve as the first ligand for FB binding.

FB is an acute-phase protein and increases during inflammation. There are two polymorphic forms of FB, FB*F and FB*S, based on their electrophoretic mobilities on immunoelectrophoresis. The amount of FB in the circulation is higher in individuals homozygous for the former and lower in individuals homozygous for the latter, with heterozygous individuals intermediate (66). A recent letter to the *New England Journal of Medicine* described an FB deficiency due to a nonsense mutation inherited from the patient's father and a frameshift mutation from the mother. The patient had normal CH50 and no AH50 activity, while the parents both

had normal activity for both assays. The patient had recurrent pneumococcal and meningococcal infections, starting at age 2 years (67).

P is a unique protein that acts as a stabilizer for the AP C3 convertase and makes possible the amplification loop that very efficiently cleaves C3 when the AP is activated. This unique property makes it the only positive regulator in the complement system. P is a single-chain linear molecule with no enzyme activity, but it forms head-to-tail polymers, about half of which are trimers, with dimers and tetramers making up the remainder. P binds to C3b with increasing avidity depending on the number of C3b molecules in a cluster, and its affinity increases when Bb is present (68, 69). In some cases, P binds to the activator surface before any other complement proteins, providing a nucleus on which the C3bBbP complex can form and start the amplification loop for deposition of C3b (70, 71).

P is the only complement protein that is X-linked, with its gene at Xp11.3-Xp11.23 (72, 73). The protein is synthesized by monocytes, granulocytic cells, and T cells. Three types of P deficiency have been described. Type I deficiency is associated with fulminant meningococcal infections, with little or no P detectable in the circulation. Partial P deficiency found in another family with neisserial septicemia was characterized by about 10% of normal levels of P in the serum (74). Several dysfunctional mutant forms of the protein have been identified that result in decreased AP function, making this type III deficiency (75). P deficiency increases the susceptibility to bacterial infections, including *Neisseria* infections. Carriers of a defective or absent P gene cannot be reliably identified from the protein's level in the circulation or by other lab tests, and genetic typing is necessary to provide evidence of the carrier state (76).

CONTROL PROTEINS OF THE AP: FH, FI, MCP (CD46), AND CR1 (CD35)

The amplification, or feedback, loop of the AP makes it one of the most efficient enzyme systems in the circulation (77). As long as P can continue to stabilize the C3 convertase (C3bBbP), C3 cleavage continues unchecked. This leads to deposits of C3 clusters on the surface of nearby cells, close to where the C3bBb is bound, and greatly enhances opsonization and other inflammatory cell interactions with the C3-coated particles due to the increased avidity provided by multiple closely spaced C3 fragments for C3 receptor interaction. The two major controls of the fluid-phase activation of the AP are FH and FI. The former is a member of the RCA family with the ability to bind C3b, and the latter is a serine protease with specificity for cleaving C3b. When C3bBb is formed, FH can bind to the C3b, displacing the Bb. FI can then cleave the C3b in two places on the α chain to create the fragments: iC3b and C3f (78). FI can then further degrade the fragments to C3c, C3dg, and C3d. C3 degradation prevents the reuse of the C3b in forming another C3bBb enzyme. On cell surfaces, two membrane proteins act in a manner similar to FH. CR1 (CD36) and MCP (CD46) are found on the surface of most cells in the body and possess cofactor activity for FI in degradation of C3b and C4b. While decay accelerating factor (CD55) can dissociate the C3 convertases of the CP and AP, it does not provide cofactor function for FI, so the dissociated C4b and C3b can reenter the activation process with a new partner (79).

FH binds to many anions including those on endothelial and other cell surfaces. Thus it can provide local backup control on a surface where complement activation is causing tissue damage, such as in the kidney or the eye. When the FH is compromised by a genetic defect that prevents it from binding to the surface, there is less help provided and the damage proceeds unchecked. The same result is seen when one of the other proteins in the pathway is not fully functional or has a gain-of-function defect that allows it to evade control. This has been shown to be true for mutations in FB and C3, and the resulting loss of regulation of the AP is seen in the development of uncontrolled deposition of C3b in sites such as the macula of the eye, contributing to AMD, or in the kidney, generating damage that impairs kidney function. The list of complement-related risk factors for developing these diseases includes mutations in factors H, I, B, C3, and thrombomodulin.

The important complement control protein FH is synthesized as a single chain comprising 20 CCP modules. The gene for FH is located in the RCA cluster of genes on chromosome 1, at 1q32 (80). FH is produced primarily in the liver, but monocytes, macrophages, fibroblasts, endothelial cells, and myoblasts can also produce it. There are several variant forms of FH, referred to as FH-like (FHL1) or FH-related (FHR1 to -5) proteins, that differ in size and function from FH. In humans, these different forms of FH appear to represent products of alternative splicing of the FH gene rather than separate genes (81).

FH has multiple binding sites that interact with C3b, heparin, chondroitin sulfate and other polyanions, bacterial surface components, DNA and other nucleotides, and endothelial cells. Its mode of action as a control protein is to bind to C3b and displace the Bb enzyme component of the AP C3 convertase. If additional C3b fragments are bound to or near the convertase, the avidity of this binding is increased. Once Bb has been removed, FI can use FH as a cofactor in cleaving C3b to form iC3b, C3dg, and C3c, thus preventing the C3b from interacting with B to form a new convertase. The fragments iC3b and C3dg can interact with CR3 receptors on phagocytic cells and with CR2 receptors on B cells and dendritic cells, respectively. In addition to its function as a fluid-phase control protein, FH has been reported to have chemotactic activity for monocytes (82, 83). It also functions as an adhesion protein for neutrophils, possibly through the RGD sequence in the fourth CCP module. FH binds to many cell types, including endothelial cells, through its polyanion binding regions and can serve as a cell surface control protein in this capacity.

FH deficiency involves compromise of the complement regulatory action, which can be severe in patients who lack FH protein completely. These patients have varied presentations, including recurrent infections, membranoproliferative glomerulonephritis, SLE, and atypical hemolytic-uremic syndrome (aHUS) (84–86). Initial lab results may identify them as C3 deficient, since without functional FH, the C3 in their circulation is diminished or absent. More-subtle deficiencies stem from point mutations in the *CFH* gene and result in decreased ability of the FH to control complement on cell surfaces, particularly in the kidney (aHUS) and in the eye (AMD) (87–92). In the latter case, the Y402H mutation is strongly associated with the susceptibility to AMD. In a recent study by Hageman and colleagues (88), the result of combining the genetic information with the fundus phenotype, age, and smoking history provided better ability to predict geographic atrophy or choroidal neovascularization as the endpoint. The genes analyzed included *ARMS2*, *CFH*, *C3*, *C2*, *FB*, *CFHR4*, *CFHR5*, and *F13B*.

An acquired form of aHUS is associated with anti-FH autoantibodies (93, 94). The list of complement gene mutations that are risk factors for AMD and renal disease includes *FI*, *MCP* (*CD46*), as well as missense mutations in

C3 and *FB* that make them unable to allow FH binding and thus evade control (95).

Another disease-related property of FH is the prevalence of bacterial or viral binding surface proteins that have evolved to bind it and thus wrap the microbe in a protective coating that prevents complement activation on their surfaces. Among the microbes that use this scheme to escape complement attack are strains of *Borrelia*, *Streptococcus*, *Yersinia*, and *Neisseria* (96–98). This method of acquiring serum resistance also includes binding of other regulatory proteins (C4BP and MCP) as well as RCA-like proteins encoded by the microbial DNA and expressed on the surface.

FI, also known in the older literature as C3b-inactivator and KAF (conglutinogen-activating factor), is a single-chain serine protease that cleaves two sites on the α chains of both C4b and C3b: one on either side of the thioester bond region. This stops further participation of these molecules in complement activation and creates first iC4b or iC3b, followed by the final breakdown fragments C4c and C4d, and C3c and C3dg. FI requires C4BP (for C4b cleavage) or FH (for C3b cleavage) for cofactor activity in the fluid phase. On cell surfaces, the complement receptors CR1 and CR3 and MCP can fill this role as cofactors (99). FI production occurs in many different cell types: hepatocytes, monocytes, fibroblasts, endothelial cells, myoblasts, glial cells, and Raji cells. The gene for FI is on chromosome 4, at 4q25. FI deficiency was first identified in a patient with little or no C3 in the circulation (100, 101). FI deficiencies, like those of FH, are characterized by low or absent C3 in the circulation. FI deficiency is associated with recurrent severe pyogenic infections, vasculitis, glomerulonephritis, and aHUS (54, 102, 103).

DEFICIENCIES OF THE TERMINAL PATHWAY COMPONENTS: C3, C5, C6, C7, C8, AND C9

Because C3 occupies the central position where the three initiating pathways merge with the terminal pathway, it is critical in the functioning of the system as a whole. C3 is an acute-phase reactant, increasing as much as 2-fold during inflammation. This increase may mask decreases due to activation, making it difficult to determine what is actually happening *in vivo*. Cleavage of C3 during complement activation produces a sequence of fragments, most of which have biological activities associated with opsonization, phagocytosis, immune adherence, effects on local vasodilation, smooth muscle contraction, and induction of mediator release, including histamine from inflammatory cells. The absence of C3, due to either an inherited defect or an acquired condition, renders the individual highly susceptible to bacterial infections, membranoproliferative glomerulonephritis, and immune complex-mediated diseases such as lupus. The internal thioester bond in C3 is like that described earlier for C4 and leads to permanent attachment of the C3b and C3d fragments to the surface of the activating particle or molecule.

Most of the C3 in the circulation comes from hepatocytes, but many other cells can produce C3 and contribute to the local supply. The gene for human C3 is located on chromosome 19, at 19p13.3-p13.2 (104). Inheritance follows an autosomal recessive pattern in which the C3 protein is undetectable in the homozygous state and is approximately half the normal level in heterozygous individuals. The acquired forms of C3 deficiency can be profound and have been mistaken for genetic C3 deficiency on occasion. The usual causes of acquired C3 deficiency are secondary to deficiencies of FI or FH, or the presence of autoantibodies to either of the C3 convertases, C3 or C4 nephritic factors, resulting in uncontrolled C3 cleavage in the circulation. In these cases, C3 fragments (iC3b, C3c, or C3a) can usually be detected in the circulation, and incubation of the patient's serum with normal serum or with purified C3 leads to C3 cleavage in the normal serum.

C5 is structurally similar to C3 but lacks the internal thioester bond that characterizes C3 and C4. When cleaved during activation, C5 also gives rise to similar fragments, but their activities are different from those for C3 and C4: C5b participates in the initiation and formation of the lytic complex (C5b-9) that inserts into the membrane of the target cells, and C5a is one of the most potent chemoattractants for neutrophils and other inflammatory cells. As anaphylatoxins, C5a and C3a induce changes in vascular permeability; smooth muscle contraction; cell activation; upregulation of adherence molecules; and release of enzymes, mediators such as histamine, and cytokines.

Like C3, C5 is produced mainly in the liver but can also be synthesized by cells in the lung, spleen, and intestine, as well as by monocytes, macrophages, and alveolar type II cells. The gene for C5 is located on the ninth chromosome, at 9q33. Several strains of mice have spontaneously occurring C5 deficiency. Homozygous deficiency of C5 is associated with severe infections, often from *N. meningitidis* or *Neisseria gonorrhoeae*. C5-deficient individuals lack bactericidal activity and are unable to mobilize their neutrophils and other inflammatory cells to respond to bacterial infections. Other presentations have included discoid lupus and Sjögren's syndrome (105–107).

An interesting phenomenon is occurring in laboratories measuring C5 levels and function. The number of patients with little or no C5 function is increasing due to the increased use of the humanized anti-C5 antibody eculizumab for treatment of paroxysmal nocturnal hemoglobinuria and aHUS. Other conditions that are being considered for eculizumab treatment include phospholipid antibody syndrome, lupus nephritis, and kidney transplantation, so the frequency of low C5 results will probably continue to increase (108).

C6 and C7 are similar proteins that are encoded by genes on the fifth chromosome, at 5p12-14. Another complement gene, C9, is close to this locus as well. Unlike the previously discussed complement proteins up through C5 in the activation pathways, none of the late components (C6, C7, C8, and C9) is cleaved during activation, but all are critical for the formation of C5b-9, the membrane attack complex (MAC), also called the terminal complement complex. When C5 is cleaved by the C5 convertase (C4bC2aC3b), a neoepitope is exposed on C5b, allowing C6 to bind to it and form a C5b6 complex that is rapidly expanded to C5b-7 by the addition of C7. The final complex formation occurs on a membrane surface when C8 binds and multiple C9 molecules polymerize to form the membranolytic complement lesion, C5b-9, on the cell surface, leading to osmotic lysis of the cell.

Deficiencies of C6 and C7 are associated with recurrent severe neisserial infections as well as infections caused by other pyogenic bacteria, although there have been reports of lupus in individuals with these deficiencies as well. A number of cases of combined deficiency of C6 and C7 have been reported, as well as the influence of one gene upon the synthesis rate of the other, leading to decreased production of one of the proteins from an otherwise normal gene. Subtotal deficiencies of both proteins were accompanied in one patient by a lower-molecular-weight form of C6 that was associated with a defect in the 5′ splice donor site of intron 15 of the C6 gene. The same patient had low C7 as well, with the C7 protein containing an Arg→Ser substitution that altered the protein's isoelectric point. Patients with complete

deficiency of C6 or C7 lack measurable protein and have little or no hemolytic activity in the CH50 or AH50 assays. Subtotal deficiencies of C6 or C7 are similar, although loss of hemolytic function is not complete (109).

C8 is a complex protein made up of three nonidentical polypeptide chains: a disulfide-linked α-γ pair and a non-covalently linked β chain. Each one of the chains is coded for by a separate gene and the protein is assembled intracellularly, although there is evidence from deficiencies that C8α-γ and C8β may be produced and secreted independently. The intact molecule is required for function in the lysis of the target cell (110).

The genes for the C8 subunits are located on the first (C8α and C8β at 1p32) and ninth (C8γ at 9q34.4) chromosomes. The three chains of C8 are interesting in that C8α and C8β are similar to C6, C7, and C9 in their structure, while C8γ is more closely related to the lipocalin family of proteins that bind and transport small hydrophobic ligands (111). Because C8 deficiency is due to decreased or no synthesis of only part of the complex molecule (C8α chain or C8β chain), the part of the molecule that is produced is still recognized by the antisera used for measuring C8 levels in serum, giving, in effect, a false-positive result. This makes it necessary to use caution in diagnosing C8 deficiency from protein levels alone, and a functional test should be done as well. C8 deficiency, like that of other MAC proteins, is characterized by recurrent infections, most often caused by neisserial species. C8 is synthesized primarily by hepatocytes, although it can also be produced by cells of monocyte/macrophage lineage, astrocytes, oligodendrocytes, fibroblasts, and endothelial cells.

As the MAC is assembled on the cell surface, the C5 to C8 proteins are joined by C9, the final protein in the terminal complement pathway. The C9 protein unfolds to form polymers that penetrate the membrane and create perturbations that lead to osmotic lysis of the target cells. Estimates of the number of C9 molecules required to form a lytic pore range from 6 to 18 (112). C9 is produced primarily by hepatocytes and secondarily by monocytes, glial cells, fibroblasts, and other local cells at sites of inflammation. It is an acute-phase protein and is coded for by a gene at 5p13, close to the genes for C5 and C6.

Many cases of C9 deficiency have been reported, and the remarkable thing is the lack of strong association of disease phenotypes with this complement deficiency. Although there have been scattered reports of neisserial infections, most C9-deficient patients appear to be healthy. This is most likely because C9 is not absolutely required for lysis of the target cell. C9 is the most common complement component deficiency in Japan and other Asian populations as well (113, 114).

CONTROL PROTEINS OF THE TERMINAL PATHWAY: VN, CN, AND CD59

Protection of host cells from "bystander lysis" caused by insertion of fluid-phase C5b-9 (MAC) complexes is accomplished by several mechanisms. Two proteins, Vn (vitronectin; formerly S-protein) and Cn (formerly clusterin, SP 40,40, or apolipoprotein J), act as solubilizing factors to bind the MAC and block its hydrophobic insertion into the membranes of nearby cells. These proteins can bind to C5b-7 and C5b-8 in the fluid phase, preventing membrane interaction and C9 polymerization, although at least one C9 molecule is associated with the final sC5b-9 complexes detected in the circulation. This complex is relatively long-lived and serves as a marker for complement activation when most other complement fragments (C3a, C5a, etc.) have been cleared from the circulation. No deficiency of either of these proteins has been identified to date.

CD59 is a membrane-bound glycoprotein that inhibits the polymerization of C9 and the lytic activity of the MAC. It is expressed on a wide variety of cell types, including erythrocytes. Because it is species specific, it is the primary cell surface protector against lysis mediated by homologous complement. CD59 is linked to the cell membrane by a glycophosphatidylinositol anchor that is variably lost from cells in patients with paroxysmal nocturnal hemoglobinuria; loss of CD59 provides one of the mechanisms for hemolysis in these patients. Inherited CD59 deficiency is rare and is associated with chronic hemolysis and infections (115).

THERAPY FOR COMPLEMENT DEFICIENCIES

Treatment of patients with complement deficiencies has been limited to prophylactic antibiotics, vaccination for relevant organisms, and treatment of infection and autoimmunity. Replacement of the missing component with fresh frozen plasma at this point in time, or the use of recombinant components for a completely deficient patient, is possible, but the hurdles of economics and potential for immune responses to the recombinant proteins make this tactic unlikely to succeed. Blood transfusion to replace C2 has been used with some success in two SLE patients and early in aHUS patients with FH deficiency (84, 116). Purified plasma C1-INH has been successful at the time of attacks, but other possible drugs are currently available or in the pipeline, including recombinant C1-INH and a specific inhibitor of the bradykinin receptor BK2.

Recombinant or monoclonal antibody complement inhibitors have been used in ischemia-reperfusion injury, cardiopulmonary bypass surgery, and autoimmune disorders. Soluble CR1 acts against the C3 and C5 convertases of both the AP and CP (117, 118). The humanized anti-C5 monoclonal antibody eculizumab prevents cleavage of C5 to C5a and C5b and has been effective in treatment of paroxysmal nocturnal hemoglobinuria and aHUS as well as other complement-mediated kidney disease. As seen with the expanding uses of eculizumab and C1-INH drugs in patients with diverse conditions, there will be continued production and modification of the current inhibitors as well as development of novel solutions for treating patients with deficiencies as well as dysfunctional complement pathways (119, 120). Given this beginning, it seems only a matter of time until most patients with complement deficiencies can be helped by compounds that will reverse the acute symptoms as well as provide long-term prevention of the often devastating diseases associated with malfunction of this important immune pathway.

Neutropenia and Neutrophil Defects

STEVEN M. HOLLAND

78

Concern about the neutrophil status of a patient is usually raised on the basis of the frequency, severity, and distribution of a specific infectious agent(s) involved in one or more episodes that are, or are thought to be, infectious. The clinical presentations of patients with neutrophil disorders usually share a few common features: gingivitis, periodontal disease, and oral ulceration. Cutaneous infections with *Staphylococcus aureus* are often recurrent and can be severe. In neutrophil disorders characterized by inadequate inflammation (neutropenia, leukocyte adhesion deficiency [LAD], Chédiak-Higashi syndrome, and specific granule deficiency), infections can extend locally and subcutaneously with little reaction until marked destruction has taken place. Clinically relevant neutrophil abnormalities fall into several broad categories: neutropenia, abnormalities of neutrophil adherence and locomotion, abnormalities of neutrophil granule formation or content, and abnormalities of killing. With the widespread use of therapies which modulate the immune system either by design (e.g., steroids and monoclonal antibodies) or incidentally (e.g., cytotoxic chemotherapy), the most common causes of immunodeficiency are iatrogenic. The recognition, characterization, identification, and cloning of disease-related genes and, in some cases, genetic correction of immune defects are progressing rapidly. As specific and genetic treatments become available, making the correct diagnosis early takes on greater therapeutic importance (1).

The clinical history should include type, location, microbiology, severity, and frequency of infections; family history with specific questioning as to consanguinity; and physical examination of the oral mucosa and any lesions or scars. A complete peripheral blood count with differential and examination of the peripheral smear are necessary initial studies to determine whether the patient has a quantitative, qualitative, or combined abnormality of neutrophils.

NEUTROPENIA

The normal neutrophil count in peripheral blood is about 4,000/mm^3, with a large variation among racial and ethnic groups, especially certain West Indian and African blacks and Yemeni Jews, who may have much lower neutrophil counts. Neutropenia is determined by the presence of fewer than 1,500 neutrophils/mm^3. Increased risk of infections does not occur until the absolute neutrophil count (the sum of mature and band-form neutrophils) falls below 1,000/mm^3; risk of serious infections occurs below 500 neutrophils/mm^3. Since about 90% of the body's neutrophils are kept in reserve in the bone marrow, neutropenias with impaired marrow stores are associated with greater infection risk than neutropenias with normal marrow stores. Thus, acute neutropenias associated with a lack of marrow reserves, such as those induced by cancer chemotherapy, are usually associated with greater infectious complications than chronic neutropenias (2).

There are three basic mechanisms by which neutropenia can occur: decreased neutrophil production, increased neutrophil destruction, or abnormal neutrophil trafficking (either defective release of neutrophils from the bone marrow or an abnormal increase in the marginated or tissue pools). Recently, an autosomal dominant disorder with mild neutropenia due to neutrophil retention in the bone marrow (myelokathexis) has been molecularly characterized. The syndrome of warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) is due to mutations in the chemokine receptor CXCR4 which lead to retention of mature neutrophils on their marrow-expressed ligand stromal cell-derived factor 1 (SDF1; CXCL12). Major causes of intrinsic, acquired, and apparent neutropenia are listed in Table 1. An acquired cause of neutrophil destruction is antineutrophil antibodies. These antibodies can be detected in the clinical laboratory by either immunofluorescence or agglutination, procedures which are readily available in most laboratories (2).

Methods of neutrophil preparation and isolation are reviewed in chapter 33 of this volume.

Antineutrophil Antibodies

Principle

Antineutrophil antibodies may cause neutrophils to be more susceptible to complement-mediated lysis, enhance neutrophil sequestration via Fc receptors on tissue macrophages, or affect the maturation and development of myeloid precursors. Detection of these antibodies in a flow cytometer relies upon demonstration of specific binding of patient immunoglobulin G (IgG) and IgM to neutrophils (3). Many of these antibodies are directed against Fcγ RIII (CD16). Techniques which are not dependent on flow cytometry are more difficult to interpret.

doi:10.1128/9781555818722.ch78

Specimen Collection

Patient serum, stored at −70°C, 1 ml

Pooled normal sera from several donors, stored at −70°C, 200-μl aliquots

Neutrophils isolated from three healthy donors, prepared as described above (≥10^7 neutrophils per serum sample to be assayed)

Reagents and Equipment

Phosphate-buffered saline, pH 7.2 (PBS), 1×

Bovine serum albumin (BSA), 0.22% (1 ml of 22% BSA plus 99 ml of PBS; make it fresh and keep it stable for 1 week at 4°C)

Paraformaldehyde, 4% stock solution (2 g of paraformaldehyde in 45 ml of 0.85% normal saline; warm to 70°C with dropwise addition of 1 N NaOH solution, adjust final pH to 7.2 with dropwise addition of 1 N HCl, bring volume to 50 ml, and store in the dark at 4°C) and 1% working solution (1 volume of 4% stock solution in 3 volumes of PBS; can be stored for 1 week at 4°C)

Fluorescein isothiocyanate-conjugated goat anti-human IgG and IgM, diluted 1:10 with PBS

Microcentrifuge

Flow cytometer

Procedure

1. Label triplicate pairs of microcentrifuge tubes for each serum sample to be assayed (i.e., assays for antineutrophil IgG and IgM with each of three normal donor neutrophil preparations).
2. Dilute the patient and control sera 1:1 with PBS.
3. Resuspend the healthy-donor neutrophils in PBS and sediment them at 300 × *g* for 7 min.
4. Remove and discard the supernatants and resuspend the neutrophils in 2 ml of 1% paraformaldehyde; allow this to stand for 5 min at room temperature.
5. Resuspend the neutrophils in 20 ml of PBS and sediment them at 300 × *g* for 7 min.
6. Resuspend treated cells in PBS to 3 × 10^7 neutrophils/ml.
7. Transfer 50 μl of each diluted serum sample to the appropriate microcentrifuge tube.
8. Add 50 μl of the neutrophil suspension to the appropriate microcentrifuge tube and incubate it at 4°C for 30 min.
9. Wash the suspension twice with ice-cold 0.22% BSA, sedimenting the cells for 10 s in a microcentrifuge.
10. Remove and discard the supernatants, add 50 μl of the diluted conjugated anti-human IgG or IgM to the appropriate tube, and incubate the tube at 4°C for 30 min.
11. Wash the cells once with ice-cold 0.22% BSA, sedimenting them for 10 s in a microcentrifuge.
12. Remove and discard the supernatants, resuspend the pellets in 1 ml of PBS, and transfer the suspension to tubes appropriate for analysis in the flow cytometer (usually 12 by 75 mm).

Interpretation

Patient sera are examined for a distinct shift in the peak fluorescence relative to that of the control samples run the same day. Modest and great shifts of fluorescence should be noted through both the histograms and the determinations of channel fluorescence. Increased binding of IgG or IgM over that in the normal control sera is considered abnormal and is reported. The report should be descriptive, including the antibody subclass implicated and the number of normal donors (out of the day's controls) to which it bound.

NEUTROPHIL DYSFUNCTION

The determination of a qualitative defect of neutrophil function is more complex than the simple determination of neutropenia, since it requires the demonstration of a dysfunctional phenotype. Methods for diagnosis of these abnormalities range from inspection of the peripheral blood smear to fluorescence-activated cell sorting (FACS). Some of these diseases simultaneously affect several limbs of neutrophil function, making prior determination of the single-best diagnostic test in a given case important. The clinical history, peripheral blood neutrophil count, and inspection of the peripheral smear readily indicate the direction of further evaluation of a possible neutrophil functional abnormality.

The major classes of neutrophil defects highlight the major neutrophil functions: adhesion, chemotaxis, phagocytosis, degranulation, and killing (Table 2). General features which suggest clinically relevant neutrophil disorders include recurrent, severe infections often requiring intravenous antibiotics, hospitalization, or surgery. Cutaneous and oral infections are common. The microbiology of specific infectious episodes may be quite informative: infections with *Burkholderia* (*Pseudomonas*) *cepacia*, *Serratia marcescens*, *Chromobacterium violaceum*, *Nocardia* species, *Aspergillus* species, or *Paecilomyces* species, or hepatic abscesses with *S. aureus*, suggest the diagnosis of chronic granulomatous disease (CGD) (4).

Adhesion Disorders

A normal neutrophil exits the bone marrow and remains in the circulation for about 7 h before entering the tissue, the intestinal lumen, or the oral cavity. During its time in the peripheral circulation, it is frequently "rolling" along and sampling the endothelium for evidence of infection or tissue damage. The low-affinity rolling of the neutrophil along the postcapillary endothelium is mediated by interacting glycoproteins on the endothelial surface (endothelial selectin [E-selectin] and platelet selectin [P-selectin]) and the neutrophil surface (sialyl-Lewis^x, CD15s). When the neutrophil encounters endothelium activated by chemokines or other stimuli, it adheres to specific molecules (intercellular adhesion molecules 1 and 2 [ICAM 1 and 2]) by way of the heterodimeric leukocyte integrins (leukocyte functional antigen 1 [LFA-1] and Mac-1 or complement receptor 3 [CR3]), which contain CD18 as their common β chain. Disorders in both of these critical pathways have been described as LADs. LAD type 1 (LAD1) is due to loss of leukocyte integrin function secondary to CD18 deficiency (5); LAD2 is due to loss of neutrophil selectin binding due to loss of CD15s. LAD3 is quite rare and due to mutations in *FERMT3*, which encodes the protein KINDLIN-3 (6). These diseases lead to profound impairment of the ability of neutrophils to exit the circulation to sites of infection. One of the CD18-containing molecules (CD18/CD11b, Mac-1, or CR3) also serves as the receptor for the cleaved, inactivated third component of complement (C3bi). Therefore, the absence of CD18-containing leukocyte integrins leads to the inability of neutrophils to perform complement-mediated phagocytosis as well. The cellular signal from CD18 ligation leads to adherence and movement toward the ligand. Rac2 is the G protein that tethers CD18 to cytoskeletal actin. In Rac2 deficiency, CD18 expression is

TABLE 1 Causes of neutropenia[a]

Disease	Clinical features	Mechanism(s)	Diagnosis	Treatment
Intrinsic				
Severe chronic neutropenia (Kostmann syndrome)	Neutropenia (<200 PMN/mm^3) at birth; recurrent, severe infections, autosomal dominant and recessive	Mutations in neutrophil elastase gene (*ELANE*), *HAX-1*, and GFI1	Bone marrow aspiration shows maturation defect at promyelocyte/myelocyte stage	G-CSF
Cyclic neutropenia (cyclic hematopoiesis)	Severe neutropenia ca. every 21 days for about 4–5 days; fever, cutaneous oral infections; autosomal dominant, spontaneous, and acquired forms	Mutations in neutrophil elastase gene (*ELANE*)	Serial blood counts (6 wk) at least every 3 days; mutation detection	G-CSF
Warts, hypogammaglobulinemia, infections, myelokathexis (WHIM)	Neutropenia; hypogammaglobulinemia, warts; familial cases reported	Mutations in *CXCR4*	Bone marrow aspiration, no evidence of peripheral destruction, abnormal marrow release on steroid challenge	G-CSF
Shwachman-Diamond syndrome	Moderate to severe neutropenia, anemia, growth retardation, exocrine pancreatic insufficiency, bone abnormalities; some patients may develop aplastic anemia or malignancy	Mutations in *SDBS*	Demonstration of fatty infiltration of the pancreas	G-CSF
Benign chronic neutropenia	Infantile severe neutropenia (<200 PMN/mm^3) without serious infections; can last for years	Unknown	Bone marrow aspiration shows normal morphology and development of myeloid series	None
Chédiak-Higashi syndrome	Mild to moderate neutropenia, partial oculocutaneous albinism, recurrent cutaneous, pulmonary infections; fatal lymphoproliferative syndrome in some cases; autosomal recessive	Mutations in *CHS1*	Demonstration of giant primary granules in peripheral blood neutrophils and in other lysosome-containing cells	Supportive; bone marrow transplantation
Reticular dysgenesis	Neonatal neutropenia, hypogammaglobulinemia, thymic abnormalities, lymphopenia, deafness; fatal without bone marrow transplantation	Mutations in *AK2*	Absent myeloid development in bone marrow; other lines may be normal	Supportive; bone marrow transplantation
GATA2 deficiency	Neutropenia, warts, lymphedema, mycobacterial diseases	Mutations in *GATA2*	Hypoplastic marrow, dysplastic megakaryocytes	Supportive; bone marrow transplantation
Acquired				
Cytotoxic chemotherapy	Severity of neutropenia depends on dose and specific agent, commonly profound; neutropenia onset variable after treatment; fevers, oral ulcers, bacteremia (e.g., cyclophosphamide)	Reduction of dividing cells	Clinical history	Supportive; G- or GM-CSF in some cases

Drug induced				
Immune	Requires sensitization of neutrophils to antibody (e.g., β-lactams); antibodies may cross placenta	Peripheral destruction of neutrophils	Demonstration of antineutrophil antibodies	Discontinuation of drug, supportive, G-CSF in some cases
Nonimmune	Dose-related or idiopathic reaction to drug, may cause profound neutropenia (e.g., chloramphenicol or clozapine)	Suppression of bone marrow precursors	Clinical history	Supportive; G-CSF in some cases
Isoimmune	Neonatal neutropenia due to maternal alloimmunization; lasts for several weeks; may be moderate to severe; predominantly cutaneous infections	Antibody-mediated peripheral destruction of neutrophils; against FcγRIII (CD16)	Clinical history, demonstration of antineutrophil antibodies epitopes	Supportive; G-CSF in some cases
Autoimmune	Antibody-mediated neutropenia during collagen vascular diseases (e.g., rheumatoid arthritis with splenomegaly, Felty syndrome; systemic lupus erythematosus)	Sequestration, peripheral destruction of neutrophils	Clinical history, demonstration of antineutrophil antibodies	Treatment of underlying disease; splenectomy in Felty syndrome; steroids in some cases; G-CSF in some cases
Splenomegaly	Mild to moderate neutropenia with moderate to massive splenomegaly due to mechanical (e.g., portal hypertension), infectious (e.g., chronic malaria), or neoplastic causes; often accompanied by anemia and thrombocytopenia	Sequestration with or without destruction of neutrophils	Clinical history and exam, normal bone marrow examination	Treatment of underlying disease; no specific therapy usually required
LGL induced	Moderate to severe acquired cyclic neutropenia; onset usually in adulthood	Clonal proliferation of T cells; probably acts on stem cells	LGL, serial blood sampling, demonstration of LGL proliferation	Treatment of underlying disease; supportive; G-CSF, steroids, or immunosuppression in some cases
Nutritional deficiency	Mild to severe neutropenia associated with vitamin B_{12}, folate, or copper deficiency; protein energy malnutrition (marasmus)	Ineffective myelopoiesis	Clinical history, determination of specific nutrient levels	Treatment of underlying disease; supportive
AIDS	Moderate to severe neutropenia in AIDS; pyomyositis and aspergillosis seen	HIV related; treatment related (e.g., zidovudine and ganciclovir)	Demonstration of HIV infection; drug history	Discontinuation of drug if possible; G-CSF
Apparent				
Severe infections	Mild neutropenia seen early in severe infections; resolves relatively rapidly	Increase in marginated tissue neutrophil pools	Demonstration of acute infection (e.g., Gram-negative sepsis)	Treatment of underlying infection
Hemodialysis	Mild to moderate neutropenia seen during hemodialysis; resolves off dialyzer	C5a-induced stiffening of neutrophils leads to transient trapping in lung	Clinical history, no evidence of acute infection	None

[a]G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; LGL, large granular lymphocyte; PMN, polymorphonuclear leukocytes.

TABLE 2 Neutrophil defects[a]

Disease	Clinical features	Mechanism(s)	Diagnosis	Treatment
Adhesion disorders				
LAD1	Neutrophilia (>15,000 PMN/mm^3), delayed umbilical stump separation; recurrent, severe infections; autosomal recessive	Defective leukocyte integrin expression; neutrophils unable to exit circulation to sites of infection	FACS analysis for CD18 and the integrins it constitutes: LFA-1 (CD18/CD11a), Mac-1/CR3 (CD18/CD11b), and p150,95 (CD18/CD11c); abnormal complement-mediated phagocytosis; impaired chemotaxis	Supportive; bone marrow transplantation
LAD2	Neutrophilia, short stature, abnormal facies, mental retardation, recurrent infections; autosomal recessive	Defective neutrophil selectin ligand (CD15s)	FACS analysis for sialyl-Lewis^x (CD15s) on neutrophils	Supportive
LAD3	Neutrophilia, recurrent infections, recurrent bleeding	Defective KINDLIN-3 due to mutations in *FERMT3*	Demonstration of absent KINDLIN-3 or mutation in *FERMT3*	Supportive; bone marrow transplantation
Rac2 deficiency	Neutrophilia, recurrent infections	*RAC2* defect	Defective adhesion; defective chemotaxis; absence of Rac2 on immunoblot	Supportive; bone marrow transplantation
Granule disorders				
Chédiak-Higashi syndrome	Mild to moderate neutropenia, partial oculocutaneous albinism, recurrent cutaneous or pulmonary infections, fatal lymphoproliferative syndrome in some cases; autosomal recessive	LYST defect due to mutations in *CHS1*	Demonstration of giant primary granules in peripheral blood neutrophils and in other lysosome-containing cells; delayed staphylococcal killing	Supportive; bone marrow transplantation
Specific granule deficiency	Recurrent infections, poor inflammatory response; rare; autosomal recessive	C/EBPε mutation; absence of neutrophil secondary granules and defensins	Absent secondary granules; bi- and trilobed neutrophil nuclei; absence of neutrophil lactoferrin defensins; impaired chemotaxis	Supportive; bone marrow transplantation
Chemotactic disorder				
Actin dysfunction	Recurrent infections, poor inflammatory response; rare; autosomal recessive	Defective actin polymerization	Impaired chemotaxis and staphylococcal killing; absence of 47-kDa protein	Supportive; bone marrow transplantation
Oxidative metabolism disorders				
MPO deficiency	No clinical phenotype except in diabetics, in whom severe *Candida* infections occur; most common neutrophil abnormality; autosomal recessive	Abnormalities in MPO gene	Absence of peroxidase staining of peripheral blood neutrophils; impaired candidacidal activity	No treatment needed in most cases
CGD	Recurrent life-threatening infections with catalase-positive organisms; tissue granuloma formation; X-linked and autosomal recessive forms	Defective superoxide formation	Impaired superoxide production: abnormal NBT test, chemiluminescence, DHR oxidation, or cytochrome *c* reduction; impaired staphylococcal killing	Supportive; antibiotic, antifungal and interferon gamma prophylaxis; bone marrow transplantation

[a]PMN, polymorphonuclear leukocytes; LYST, lysosomal transporter.

intact, but adherence is reduced and the clinical presentation is like that of LAD1.

Diagnosis of LAD1 should be made by FACS staining for CD18 and its associated alpha chains, CD11a, CD11b, and CD11c. The functional assays below can help to suggest the diagnosis. LAD2 is rarer and clinically distinct; it can be definitively diagnosed by FACS staining for sialyl-Lewis^x (CD15s). The diagnosis of Rac2 deficiency requires specialized research laboratory resources (6).

Neutrophil Adherence to Nylon Wool

Principle

Normal neutrophils adhere to several synthetic surfaces, including glass, plastic, and nylon wool, in addition to the endothelium. This adherence is impaired in LAD1 and by aspirin, ethanol, and prednisone.

Specimen Collection

Heparinized blood, 5 ml each from the patient and three healthy subjects, is used.

Reagents and equipment

Analytical balance

Apparatus for counting leukocytes and performing differential counts

Scrubbed nylon fiber (3 denier, 4 cm, type 200; Fenwal Laboratories, Morton Grove, IL)

Tuberculin syringes, 1 ml, without needle (three per sample)

Small collecting tubes (polypropylene is preferred)

Procedure

1. Weigh out 40 mg of nylon wool/column to be used.
2. Using a plunger, pack each column with the 40 mg of nylon wool to the 0.4-ml mark on the syringe.
3. Aliquot and reserve 1 ml of blood from each sample for total leukocyte and differential counts ("precolumn" sample).
4. Place the packed syringes in a rack with their tips inside but not touching the sides or bottom of the small tubes.
5. Add 1.0 ml of heparinized blood to the column and allow it to filter by gravity for 10 min at room temperature.
6. Discard the columns.
7. Determine complete and differential leukocyte counts of the pre- and postcolumn samples.

Interpretation

The percent neutrophils adherent to the nylon wool is calculated as follows: 100% – ([cells per milliliter postcolumn/cells per milliliter precolumn] × 100) = percent cells adherent. Normally, 68% ± 7% neutrophils adhere in this assay. Adherence of a significantly lower percentage of neutrophils is suggestive of an adherence defect. Neutrophil adherence to plastic or glass requires more-specialized techniques and is described elsewhere (5).

Flow Cytometric Determination of LAD

FACS analysis (chapter 33) of peripheral blood or isolated neutrophils is required for definitive diagnosis of LAD1 or LAD2. In LAD1, levels of CD18 are profoundly reduced on neutrophils and monocytes, leading to low levels of the associated molecules CD11a, CD11b, and CD11c (the method is given in chapter 33). Levels of CD18 expression below 0.5% of normal are seen in the "severe" phenotype and are associated with more devastating disease and earlier mortality in the absence of bone marrow transplantation than with other phenotypes. Levels of CD18 expression between 0.5 and 10% of normal are associated with the "moderate" phenotype of LAD1 and are associated with a better rate of survival. The display of CD18/CD11 complexes, which are stored in secondary granules, is upregulated by neutrophil activation.

Demonstration of sialyl-Lewis^x (CD15s) deficiency on neutrophils confirms the diagnosis of LAD2. These patients also have the relatively rare Bombay (Hh) blood type, another manifestation of the underlying genetic defect in fucosylation caused by mutations in the GDP-fucosyl transferase. This disease is also now named congenital disorder of glycosylation IIc. LAD3 is confirmed by reduced levels of KINDLIN-3 when blotted or by mutations in *FERMT3*. Rac2 deficiency should be suspected in cases in which the surface display of CD18 and CD15s is normal but adherence is impaired, as is superoxide production (6).

Granule Disorders

In the normal course of neutrophil ontogeny, the large (about 0.8 μm in diameter) azurophilic or primary granules, containing myeloperoxidase (MPO), lysozyme, β-glucuronidase, and defensins, among others, appear at the promyelocyte stage; the smaller (about 0.5 μm in diameter) specific or secondary granules, containing lactoferrin, vitamin B_{12}-binding protein, cytochrome b_{558}, and CR3, among others, appear during the myelocyte stage.

In Chédiak-Higashi syndrome, neutrophil primary granulogenesis is initially normal, but the primary granules readily fuse to each other and subsequently to some secondary granules as well, resulting in giant primary granules that are easily appreciated under a light microscope. Chédiak-Higashi syndrome is due to autosomal recessive mutations in the gene lysosomal transporter (*LYST* or *CHS1*). Neutrophils from Chédiak-Higashi syndrome patients show delayed bactericidal activity against *S. aureus*. Other clinical features include partial oculocutaneous albinism, irregular melanization of hair, peripheral neuropathy later in life, and an eventual lymphoma-like "accelerated phase" in most patients.

In specific granule deficiency, the secondary granules are rare or absent, as are secondary granule proteins, such as lactoferrin. One form of secondary (specific) granule deficiency is due to an autosomal recessive mutation in the CCAAT/enhancer binding protein C/EBPε. Since lactoferrin is present in other secretions, it appears to be a tissue-specific phenomenon. Levels of defensins, a primary granule product, are also low to absent, because the defect is in a transcription factor important in neutrophil ontogeny and granule protein expression. Careful inspection of the peripheral smear suggests the diagnosis, as these neutrophils are larger and paler than normal. The diagnosis is confirmed by electron microscopy, showing an absence of secondary granules, or demonstration of the absence of lactoferrin in patient neutrophils by direct immunofluorescence or enzyme-linked immunosorbent assay. Methods for the detection of lactoferrin and other secondary and primary granule proteins are detailed elsewhere (5).

Chemotaxis

The neutrophil's ability to locomote up a chemoattractant gradient is chemotaxis, whereas the stimulation of shape change and random locomotion induced by a uniform concentration of a chemoattractant is chemokinesis. These properties are critical for the neutrophil response to

infection. Disorders involving chemotaxis are found in only a few diseases; secondary causes of depressed chemotaxis are more common (e.g., aspirin, prednisone, and ethanol). Actin dysfunction, Chédiak-Higashi syndrome, LAD1, Rac2 deficiency, secondary granule deficiency, and Job's syndrome (intermittently) all show decreased chemotaxis, although the mechanisms are quite disparate. In none of these disorders is the demonstration of a chemotactic defect diagnostic. The several assays of chemotaxis all require fresh neutrophils and an experienced laboratory technician. The sensitive techniques (Boyden chamber migration or the multiwell chamber) require highly specialized equipment, radioactivity, or both (5). In view of the complexity of the current chemotactic assays and their extremely limited diagnostic value, I recommend that for cases in which chemotactic determination appears to be appropriate, specialty reference or research laboratories be contacted. Chemotaxis assays are discussed in reference 6.

Oxidative Metabolism Disorders

Neutrophils, eosinophils, and macrophages use the NADPH oxidase enzyme complex to augment molecular oxygen by one electron, yielding superoxide (O_2^-). This in turn is converted to hydrogen peroxide (H_2O_2) by superoxide dismutase. H_2O_2 is combined with halide (X^-) by MPO to produce hypohalous acid (HOX); in the neutrophil, which uses chloride for its halide, this is bleach (HOCl). Defects in the proximal portion of this pathway, at the level of the NADPH oxidase, lead to life-threatening infections in CGD; defects in the latter portion of the pathway caused by MPO deficiency are clinically quite inapparent and lead to infectious problems only when coupled to other diseases, such as diabetes mellitus.

CGD is a genetic disorder estimated to occur in about 1/250,000 persons and is characterized by severe, recurrent life-threatening infections with catalase-producing bacteria and fungi and tissue granuloma formation (7). Five separate genotypes (one X chromosome linked, gp91^{phox}; four autosomal recessive, p22^{phox}, p47^{phox}, p67^{phox}, and p40^{phox}) can give rise to the phenotype of CGD, but there are slight differences in clinical phenotype and obvious differences in genetic transmission and associated counseling. Since all of the relevant genes have been cloned and characterized, a definitive molecular diagnosis can be made. Molecular diagnoses can be performed by reference and commercial laboratories. All patients with CGD should be referred for definitive molecular characterization of their CGD to help with genetic counseling and prognosis (8).

Several methods are available for diagnosis of CGD. Nitroblue tetrazolium (NBT) reduction and dihydrorhodamine (DHR) oxidation are the simplest tests available and are discussed here. Chemiluminescence and staphylococcal killing are also discussed since they not only are used in the demonstration of CGD functional defects but also occasionally may help in diagnosis (4). Superoxide production, hydrogen peroxide production, and cytochrome *c* reduction are other techniques which bear on the integrity of oxidative metabolism covered elsewhere in this text (chapter 33).

NBT Test

Principle

Superoxide produced by neutrophils reduces NBT from a soluble yellow dye to blue-black formazan, which is readily apparent as a cytoplasmic precipitate. Neutrophils unable to produce superoxide fail to reduce NBT and are therefore free of precipitate. Because this assay is read by light microscopy, individual cells reducing or not reducing NBT can be recognized. Mothers of patients with X chromosome-linked CGD show mosaicism of peripheral blood neutrophil NBT reduction, since X chromosome inactivation (lyonization) occurs randomly in hematopoietic precursors.

Interpretation

More than 95% of normal neutrophils will reduce NBT, showing orange nuclei with clumps of blue-black precipitate in the cytoplasm. In a patient with CGD, there is usually no NBT reduction. Since X chromosome inactivation is thought to be random in females, there should be two populations of neutrophils in the peripheral blood of X-linked carriers, NBT reducing (normal) and non-NBT reducing (CGD). This mosaic pattern can range anywhere from 0.001 to 97% of neutrophils, although most carriers will fall within a range of about 20 to 80% NBT-reducing neutrophils. At the extremes of lyonization, these X-linked carriers are indistinguishable from CGD patients or healthy subjects, respectively. It is best to report the results as percent NBT-reducing neutrophils to avoid the confusion surrounding the terms positive and negative in this setting. The drug D-penicillamine can act as a superoxide-generating source when oxidized and therefore can cause unreliable NBT results.

The X-linked form of CGD is the most common (about 65% of cases in outbred populations). One can often rapidly determine whether a male patient is X linked or autosomal recessive by analysis of the mother's blood at the time of the initial NBT test. In this way, the genotype can be approximated at the same time as the phenotype in most cases.

There are several reports of patients with variant forms of X-linked CGD in whom a dysfunctional gp91^{phox} protein is normally expressed. These patients may have apparently normal NBT reduction. In cases in which the clinical suspicion is high, testing by DHR oxidation, quantitative superoxide generation, or bactericidal activity should be pursued.

DHR Oxidation

Principle

DHR 123 is oxidized to rhodamine 123 by H_2O_2 and O_2^-, with the emission of bright fluorescence upon stimulation by blue light (488 nm). This dye is freely able to permeate cells and can be used in whole blood to determine whether granulocytes produce H_2O_2 and O_2^-, upon stimulation with phorbol myristate acetate (PMA), a potent stimulus of NADPH oxidase activity.

This technique is simple, sensitive, and quantitative and can be performed on whole blood shipped overnight. PMA-stimulated and unstimulated samples are run simultaneously.

Specimen Collection

Collect 1 ml of heparin-anticoagulated peripheral blood in plastic, endotoxin-free tubes.

Reagents

Lysis buffer (store at room temperature)

Ammonium chloride	4.15	g
Sodium bicarbonate	0.84	g
0.5 M EDTA (pH 8.0)	1	ml
Distilled water	500	ml

Suspension buffer (store at room temperature)

Hanks' balanced salt solution (HBSS) (without Ca^{2+}, Mg^{2+}, or phenol red)	500	ml

Albumin (human fraction V)	0.5	g
0.5 M EDTA, pH 8.0	1	ml

Catalase stock solution (1,400 U/μl)

Catalase (C40; Sigma)	28	mg
Suspension buffer	400	μl

Store 10-μl aliquots at −70°C. For catalase working solution, dilute 10 μl of stock with 130 μl of suspension buffer immediately before use. Use 5 liters for each 500-μl tube (final concentration, 1,000 U/ml).

PMA stock (2 μg/μl)

PMA (P8139; Sigma)	1	mg
Dimethyl sulfoxide (DMSO) (D2650; Sigma)	500	μl

Store 10-μl aliquots at −70°C. PMA working solution (1:1,000 dilution) consists of 2 μl of PMA stock solution combined with 1,998 μl of suspension buffer immediately before use. Add 100 μl to tubes for a final concentration of 400 ng/ml.

DHR stock (29 mM)

DHR 123 (catalog no. D-632; Molecular Probes, Eugene, OR)	10	mg
DMSO	1	ml

Store 25-μl aliquots at −70°C. Add 1.8 μl of stock to each reaction tube.

Procedure

The procedure for DHR oxidation is as follows.

1. Add 4 ml of prewarmed, 37°C lysis buffer to polypropylene tubes.
2. Add 100 to 300 μl of whole blood to each of two tubes for each sample to be assayed, mix by inversion, and let stand for 5 min at room temperature.
3. Centrifuge at 800 × *g* at room temperature for 5 min to pellet leukocytes.
4. Discard the supernatant and blot the tubes.
5. Resuspend the leukocyte pellet in 4 ml of suspension buffer and centrifuge as described above.
6. Discard the supernatant, blot the tubes, and resuspend the pellet in 400 μl of suspension buffer.
7. Add 5 μl of the catalase working solution.
8. Add 1.8 μl of DHR 123 stock solution and incubate the tubes for 5 min in a 37°C shaking water bath.
9. Add 100 μl of PMA working solution to one tube and 100 μl of suspension buffer to the other (unstimulated) tube.
10. Incubate for 15 min in a 37°C shaking water bath.
11. Analyze by flow cytometry, collecting forward and side scatter.

Interpretation

Histograms are compared for unstimulated and PMA-stimulated tubes. In normal neutrophils, PMA-stimulated DHR oxidation yields between 50- and 200-fold more mean channel fluorescence than unstimulated DHR oxidation. CGD neutrophils usually show less than 10-fold augmentation of DHR oxidation by PMA. X-linked carriers show two distinct populations of neutrophils, those which oxidize normally in the presence of PMA and those which do not. This technique is sensitive to at least 0.01% normal cells among 99.99% CGD cells and is therefore able to identify highly lyonized carriers (4). Given the general availability of FACS machines and the ease, sensitivity, and reproducibility of this assay, this test should be widely applied for the diagnosis of CGD. It is important to recognize some diagnostic overlap in the DHR assay with myeloperoxidase deficiency (7).

Chemiluminescence

Principle

In the normal neutrophil, stimulation of the NADPH oxidase leads to the generation of H_2O_2, which couples with hypochlorite (OCL^-) to produce singlet oxygen ($^1O_2$), water, and chloride (Cl^-). Singlet oxygen is molecular oxygen with an electron lifted to a higher orbit with inversion of spin. The return of this electron to its ground state is associated with light emission, which can be measured as chemiluminescence with several different reagents (9).

Specimen Collection

Isolated neutrophils, 2×10^4/ml, are used.

Reagents and Equipment

Chemiluminometer or fluorometer with only one photomultiplier tube or a beta counter that can be shifted to only one photomultiplier tube, since the coincidence sum cannot be used. Use the ^3H channel; background is usually 25,000 to 50,000 cpm.

Twenty-milliliter glass scintillation vials (keep in the dark) or microtiter plates

37°C incubator with rotator

Luminol stock solution (A8511; Sigma) (275 μM in DMSO stored at room temperature in the dark; the final concentration for the assay is 1 μM) or lucigenin stock solution (M8010; Sigma) (6.88 μM in distilled water stored at room temperature in the dark; the final concentration for the assay is 25 μM)

PMA stock solution (P8139; Sigma) (200 μg/ml in DMSO, aliquot and store at −70°C)

Zymosan stock solution (Z4250)

Zymosan	500	mg
PBS	50	ml

Boil for 1 h and then cool. Centrifuge at 500 × *g* for 10 min and discard the supernatant. Resuspend the pellet in 10 ml of PBS and keep at 4°C in the dark.

Opsonized zymosan: on the day of use, suspend 1 part zymosan stock in 9 parts pooled human serum. Rotate for 15 min at 37°C. Centrifuge at 500 × *g* for 10 min and discard the supernatant. Resuspend to 1.25 mg/ml in $HBSS^+$ HBSS (with $Ca^{2+}$and Mg^{2+}).

Procedure

1. To each vial add 400 μl of opsonized zymosan or 55 μl of PMA, 20 μl of luminol solution, and $HBSS^+$ to 4.5 ml.
2. Place scintillation vials in a counter in the dark for at least 20 min before adding the cells.
3. Arrange control vials as follows:
   HBSS plus luminol
   HBSS plus luminol plus zymosan or PMA
   HBSS plus luminol plus cells
4. Record the background chemiluminescence of the vials.

5. At 1-min intervals, add 1 ml of cells to each vial sequentially, swirling each vial for 30 s before replacing the vial in the counter.
6. Count vials sequentially for 1-min periods continuously for 1 h.
7. Plot the counts per minute versus time.

Interpretation

The normal range of chemiluminescence values is 300,000 to 600,000 cpm, with peak values obtained between 8 and 12 min. Chemiluminescence is not entirely specific for singlet oxygen, but it is a sensitive technique for detecting abnormalities in oxidative metabolism. Very low chemiluminescence is consistent with CGD. Heterozygotes can be detected as intermediate between those of normal subjects and CGD patients. If performed with opsonized zymosan instead of PMA, this assay can detect abnormalities of phagocytosis, such as in LAD1, in which the receptor for C3bi (CR3 or CD18/CD11b) is deficient (5).

The assay given here is adaptable to laboratories without highly specialized equipment. These procedures are now routinely performed in many laboratories with microtiter plates on specialized chemiluminometers. Recently, an enhancer of chemiluminescence has been marketed (Diogenes, order no. CL-202; National Diagnostics, Atlanta, GA), which allows ≥100-fold amplification of the chemiluminescent signal using essentially the same protocol. For experiments using B cells or cell lines which produce small amounts of superoxide or very low numbers of neutrophils, the Diogenes system should be considered.

Myeloperoxidase

MPO is the enzyme that makes pus green and catalyzes the conversion of hydrogen peroxide to bleach in the neutrophil. Deficiency of MPO is the most common neutrophil disorder, occurring in about 1/2,000 persons. Despite the important role of MPO in neutrophils, clinical disease from MPO deficiency is quite rare and has been reported mostly for diabetics with disseminated *Candida* infections. MPO is an important marker of myeloid maturation, appearing at the promyelocyte stage of development. This procedure will stain peroxidase-containing granules in neutrophils, eosinophils, and monocytes.

Specimen Collection

Cytocentrifuged neutrophils on glass slides are preferred, but peripheral blood can be used.

Reagents and Equipment

Fixative, 10% formyl ethanol

Ethanol (absolute)	90	ml
Formaldehyde (37%)	10	ml

Stain, pH 5.8 to 6.5

Ethanol (30%)	100	ml
Benzidine hydrochloride (carcinogen)	0.3	g
Zinc sulfate · $7H_2O$ (3.6%)	1.0	ml
Sodium acetate	1.0	g
Hydrogen peroxide (30%)	70	μl
Safranin O	0.2	g

Mix reagents well in the order listed. The benzidine hydrochloride may leave a slight residue, which will not dissolve. A precipitate forms upon the addition of the zinc sulfate, which will dissolve with addition of the remaining reagents. Filter and store the solution capped at room temperature. This solution is good for 6 months.

Procedure

1. Fix the slide in formyl ethanol for 60 s.
2. Rinse the slide thoroughly to remove residual formyl ethanol, since this can inactivate the benzidine hydrochloride stain.
3. Place the slide in the stain for 45 s.
4. Rinse the slide thoroughly, and allow it to air dry.

Interpretation

Neutrophils show a blue cytoplasm with discrete blue granules, monocytes stain more weakly but still display discrete granules, and eosinophils stain most intensely, often tinged brown-black or green-black. Lymphocytes, basophils, and platelets do not stain. Cells from patients with MPO deficiency do not stain (7).

Other techniques related to neutrophil function and measurement are reviewed by Metcalf et al. (10).

This research was supported by the Intramural Research Program of the National Institute of Allergy and Infectious Diseases, National Institutes of Health.

Evaluation of Natural Killer (NK) Cell Defects

KIMBERLY RISMA AND REBECCA MARSH

79

CLINICAL INDICATIONS FOR EVALUATION OF NK CELL FUNCTION

Genetic defects in natural killer (NK) cell and cytotoxic T lymphocyte (CTL) function generally lead to one of two outcomes: (i) life-threatening and/or severe chronic infections with viruses, particularly from the *Herpesviridae* family member viruses Epstein-Barr virus, cytomegalovirus, herpes simplex viruses, and varicella-zoster virus but also other viruses such as human papillomaviruses; or (ii) a life-threatening hyperinflammatory disorder called hemophagocytic lymphohistiocytosis (HLH).

The first clinical indication to measure cytotoxic function is in the patient presenting with severe herpesviral infections. Such infections are noted in many primary immunodeficiencies in which the gene defect disrupts both NK and CTL interaction with target cells. An extensive list of gene defects associated with abnormal cytotoxic function in NK and CTL has recently been compiled (1). Recently, NK-specific disorders have been described (Table 1). The typical starting point for evaluation of NK cell function in children or adults with severe or persistent herpesviral infections includes NK cell enumeration and an NK cell functional assay. Conditions associated with a specific deficiency of NK cell numbers are sometimes referred to as "classical NK cell deficiency," whereas "functional NK cell deficiency" implies the presence of NK cells but abnormal function.

The second clinical indication for evaluation of NK cell function is the development of HLH. HLH is a systemic hyperinflammatory disorder that arises when CTL and NK function is severely impaired and/or absent due to genetic defects in the perforin-mediated cytotoxic pathway (Table 2) (2). HLH may be triggered by viral infections, especially herpes virus family members; however, the pathophysiology of the disease is distinct. Patients have uncontrolled T cell and macrophage activation due to a failure of elimination of antigen-presenting cells. Patients presenting with symptoms of HLH (fever, rash, pancytopenia, lymphoproliferation [lymphadenopathy and splenomegaly], and multisystem organ failure) require prompt diagnosis and recognition, as the disease is fatal if immunosuppressive therapy is not urgently initiated (3).

The first tests performed for the rapid evaluation of patients with HLH also include enumeration of NK cells and one or more NK cell functional assays but, uniquely, should also include measurement of intracellular perforin. These tests can be performed on even limited blood samples from patients with suspected disease. Additional testing (generally from a second blood draw due to limitations of volume in young children) should include genetic testing which can be guided by the initial immune findings. Of note, males with X-linked lymphoproliferative disease (XLP) may present with HLH despite normal NK numbers and preserved NK function (against K562 cells) due to X-linked inheritance of gene mutations in *SH2D1A* (XLP type 1) or *XIAP/BIRC4* (XLP type 2). Therefore, flow cytometric evaluation of signaling lymphocyte activation molecule-associated protein (SAP) and XIAP protein is recommended for boys to rule out either form of XLP as a cause of HLH (4, 5). The cytotoxic defect associated with SAP deficiency appears to be restricted to Epstein-Barr virus-infected B cells (6), whereas no cytotoxic defect has been described in boys with XIAP deficiency (7–9).

DEFECTS IN NK CELLS ASSESSED BY ENUMERATION

Patients may be noted to have quantitative defects in NK cell number (if the NK number is <1% of all lymphocytes) due to a primary disorder in NK generation or from secondary etiologies. Primary defects in the number of NK cells are rare and have been described thus far only in relationship to two genes, *GATA2* and *MCM4*, as recently reviewed (1). NK cell lymphopenia is also described in numerous other primary immune deficiencies, including severe combined immunodeficiency due to a failure in interleukin-15 signaling (common gamma chain or JAK3 deficiency) or adenosine deaminase deficiency, and for unknown reasons in common variable immunodeficiency (10, 11). Patients with primary quantitative disorders present largely with recurrent and/or severe viral infections rather than HLH. Quantitative defects in NK cells (generally transient) can also be observed at the time of presentation with HLH (12), unfortunately delaying diagnosis due to the inadequacy of NK function and protein expression testing when numbers are limited.

Secondary defects in NK cell number may also be noted incidentally upon evaluation of lymphocyte subpopulations in children with lymphopenia unrelated to NK functional defects. For example, reduced or absent peripheral and lung NK cells may be a transient phenomenon during viral infections, as described in infants with life-threatening varicella-zoster virus (13) and respiratory viral infections, including respiratory syncytial virus (RSV) (14, 15). The mechanism for

CD16	Functional NK defect type 1	CD16 flow cytometry (with antibody clone B73.1) Cr^{51} release (K562)

quantitative deficiency may be related to abnormal trafficking to inflamed organs or apoptosis, as theorized to occur upon influenza virus infection of human NK cells (described *in vitro* only in human cells) (16). Shown in Fig. 1 is a 2.5-year-old child with life-threatening RSV who was initially noted to be mildly lymphopenic. Lymphocyte subpopulation analysis revealed absent NK cells and normal T cells. Repeat testing revealed that this was a transient phenomenon, with reappearance of NK in the blood (at reduced numbers) at 2 days, coincident with improvement in clinical symptoms. It is unknown whether the low NK cells played any role in his primary disease; however, it illuminates the need for serial testing when abnormal NK cell quantification is noted.

DEFECTS IN NK CELL FUNCTION ASSESSED BY PERFORIN STAINING

When patients present with HLH, an immediate diagnosis of perforin deficiency may be made by flow cytometric evaluation of intracellular perforin in NK and CTL. Perforin is required for cytotoxic granule contents from NK cells and CTL to penetrate the outer cell membrane of target cells (17). Blood samples are stained to identify CTL (CD3 and CD8 positive) and NK cells (CD3 negative and CD56 and/or CD16 positive), and perforin is assessed on both populations. $CD8^+$ T cells express perforin and granzymes only after they have differentiated into CTL effectors and/or memory cells (18, 19). This is an age-dependent phenomenon due to exposure to antigen followed by acquisition of secretory granules that store perforin and granzymes. Therefore, in young babies, the amount of perforin in $CD8^+$ cells may be nearly zero physiologically. In contrast, at birth, essentially all NK cells are perforin positive in healthy individuals. Therefore, this population is the easiest in which to diagnose perforin deficiency (biallelic mutations) as well as detect heterozygous carriers of *PRF1* defects. As shown in Fig. 2A, when biallelic *PRF1* mutations are present, perforin staining is absent. Heterozygous carriers of defective alleles often have one-half of the normal or reduced expression. For a detailed description of lytic granule content procedure, refer to chapter 32 of this volume.

As intracellular perforin staining is dependent upon the presence of secretory granules, an internal control protein such as granzyme B is also typically stained when assessing patients for perforin expression. Interestingly, in patients with active HLH, this protein is markedly upregulated in both CTL and NK cells (19), suggesting that the cytotoxic lymphocytes are chronically activated by the presence of ongoing antigenic stimulation. In fact, in patients with HLH related to inherited defects in degranulation (*UNC13D* and *STXBP2*), both granzyme B and perforin are detected at higher levels in NK and CTL during active disease. These levels normalize with immunosuppressive therapy.

DEFECTS IN NK CELL FUNCTION ASSESSED BY Cr^{51} RELEASE ASSAY

Historically, the first-line test for assessing NK cell cytotoxic function in patients with suspected immunodeficiency has been the Cr^{51} release assay. Briefly, peripheral blood mononuclear cells (PBMC) are prepared from a blood sample and coincubated at various ratios with tumor cell line target cells preincubated with Cr^{51}. After 4 hours, the supernatant is assayed for the amount of Cr^{51} released due to cell death. The result is reported as a percentage

TABLE 2 Primary immunodeficiency presenting with development of HLH

Gene	Clinical disorder	Abnormal immunologic assays
PRF1	Familial HLH type 2	Perforin protein (flow cytometry) Cr^{51} release (K562)
UNC13D	Familial HLH type 3	Cr^{51} release (K562) CD107 degranulation assay (K562)
STX11	Familial HLH type 4	Cr^{51} release (K562) CD107 degranulation assay (K562)

XIAP/BIRC4[a]	X-linked lymphoproliferative syndrome type 2	XIAP protein (flow cytometry)

[a]Cytotoxic function against K562 target cells is preserved.

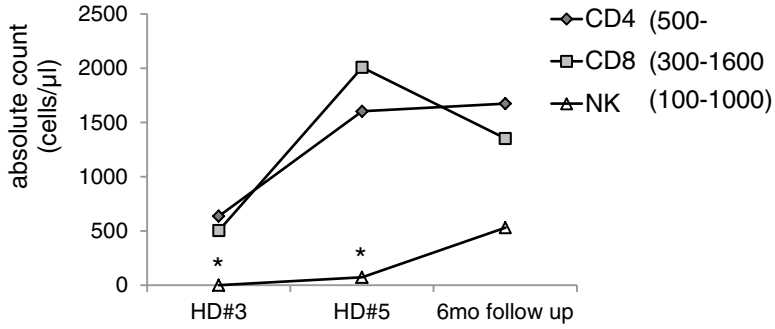

FIGURE 1 Transient NK lymphopenia. A two-and-a-half-year-old child with life-threatening RSV infection was evaluated for low lymphocyte counts on hospital days (HD) 3 and 5. No detectable NK cells in the peripheral blood were seen in the first sample, and a reduced number was noted (<1%) 2 days later. In contrast, CD8 and CD4 T cells were in the normal range. NK cell numbers were normal at follow-up (age-appropriate normal ranges are shown in parentheses).

of maximum release from a detergent-treated, target cell, typically K562 cells.

As shown in Fig. 2B, when patients have biallelic *PRF1* mutations, cytotoxic function is absent. Carriers of a single *PRF1* mutation have one-half of the normal function but do not develop HLH and are not known to be at any increased risk of cancer, autoimmunity, or viral disease. Absent cytotoxicity is also observed in patients with profound defects in NK degranulation (Table 2) leading to HLH. The development of HLH is dependent upon a fundamental defect

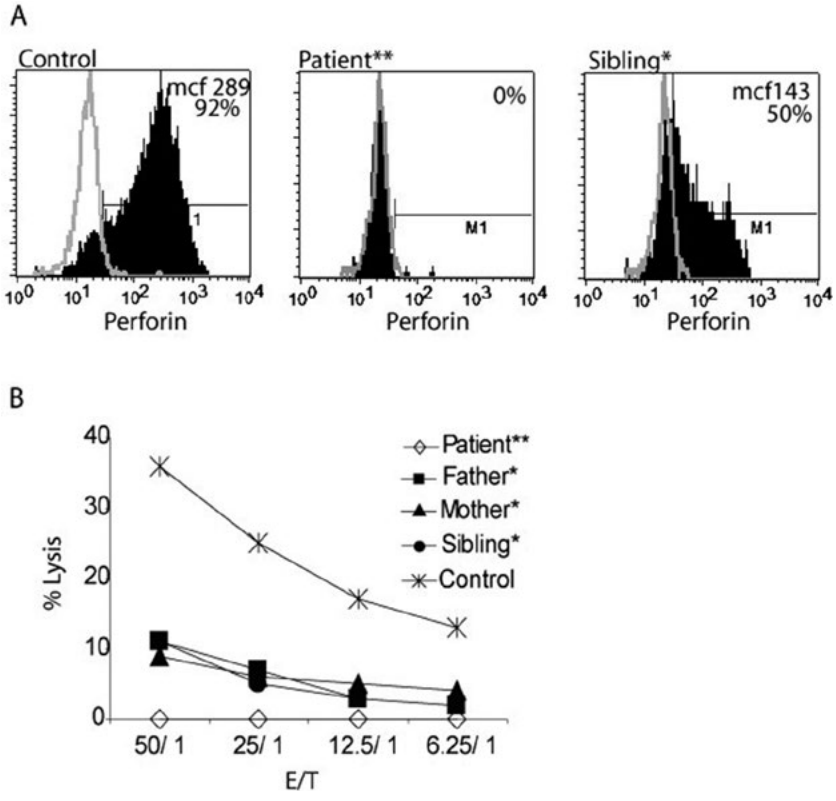

FIGURE 2 Example of assessment of perforin staining and NK cell functional testing by Cr^{51} release assay. (A) Intracellular perforin staining on NK cells is performed by flow cytometry using whole-blood samples. Gating on $CD56^+$ lymphocytes, histograms from a healthy control, a patient with biallelic *PRF1* mutations, and a representative, heterozygous carrier (family member) of *PRF1* mutations are shown. The patient's perforin is not detectable, whereas the sibling has one-half the normal perforin detection. (B) NK function against K562 target cells as measured by Cr^{51} release is measured by preparing peripheral blood mononuclear cells (PBMC) from the patient and family members as described for panel A. PBMC were diluted at ratios of 50:1 down to 6.25:1 target cells. K562 target cells release Cr^{51} to the supernatant upon death in a 4-h assay. Family members with one-half the normal perforin protein have reduced function compared to healthy controls but are not at risk for developing HLH. E/T, effector/target cell ratio.

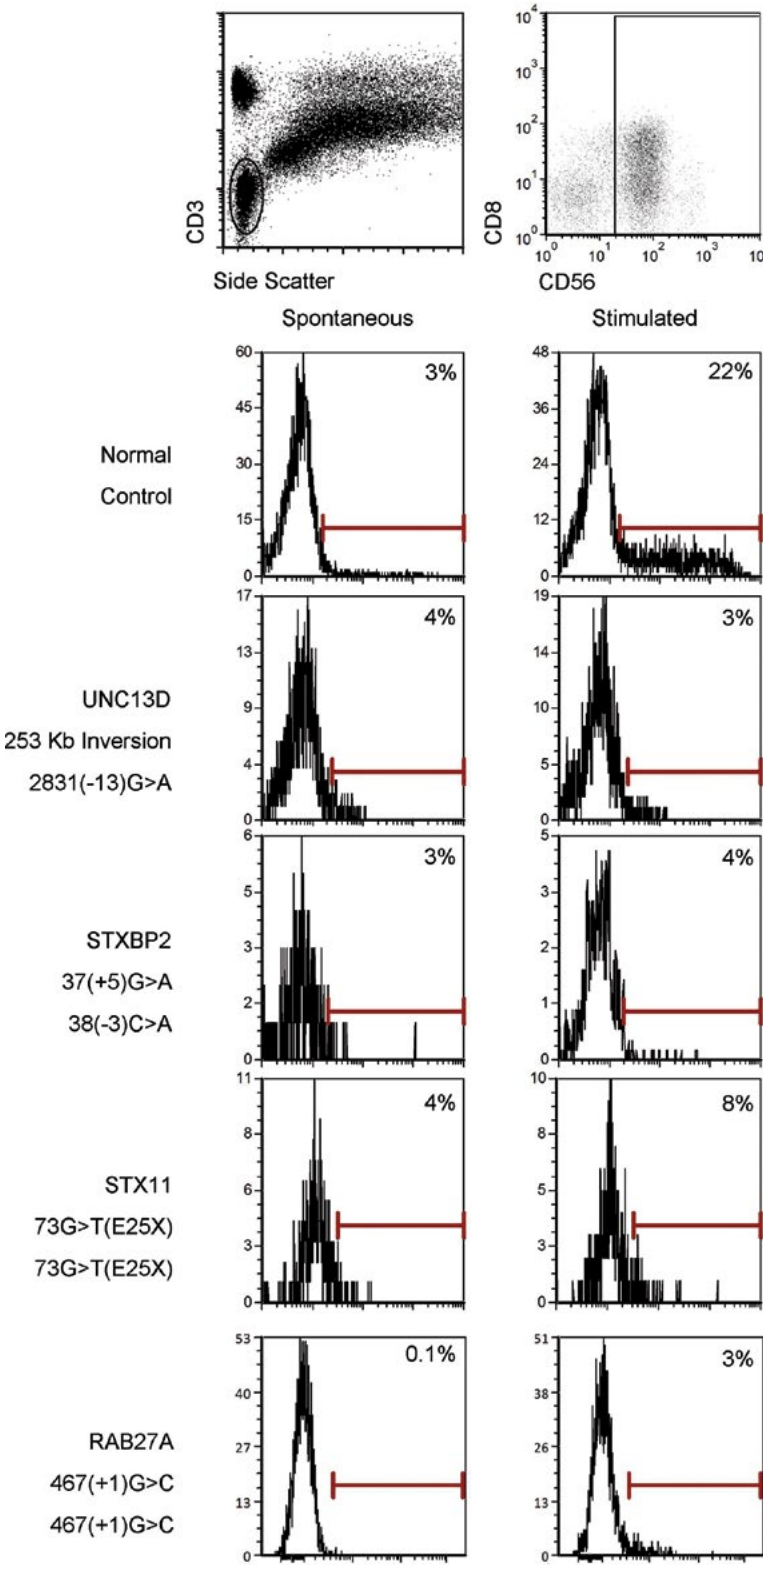

FIGURE 3 Examples of assessment of NK cell degranulation in a representative control and in patients with genetic forms of HLH. Peripheral blood mononuclear cells from a representative control and patients with UNC13D, STXBP2, STX11, and RAB27A mutations were incubated with target cells in medium containing a fluorochrome-labeled antibody directed against CD107a in the presence of monensin. Following that, cells were surface stained for CD3 and CD56. NK cells were identified as CD3-negative, CD56-positive lymphocytes. CD107a detection following incubation (Stimulated) was quantified in the NK cells by flow cytometric analysis in comparison to baseline CD107a expression (Spontaneous) and isotype control staining (not shown). Examples courtesy of the Diagnostic Immunology Laboratory, Cincinnati Children's Hospital.

in CTL and NK function. Therefore, reduced NK function as an isolated finding does not lead to HLH. A mutation in CD16 that impairs costimulation through CD2 has been described as an exclusive NK defect (20). The phenotype is not associated with HLH, as CTL do not express CD16.

The Cr^{51} assay is also impacted by cell number and the type of NK cells circulating in the peripheral blood, as the sample typically measures lysis from a total PBMC sample, not isolated NK cells. Human circulating NK cells are distinguished by cell surface markers CD56 and CD16. There are two subtypes, CD56dim and CD56bright. The former population is thought to possess the cytotoxic function required for removal of tumor or virally infected cells. A pitfall in assessing function may occur if the total number of NK cells (bright and dim) is not determined at the same time as testing for cytotoxic function by Cr^{51} release assay. NK function may be low or absent if CD56dim cells are low in the patient sample at the time of testing, as seen in patients with functional defects in NK development (Table 1) (1).

A major obstacle to assessing NK function for most clinical labs is the use of radioactivity. Therefore, the development of flow-based assays represents an alternative method for testing. For a detailed description of NK cell procedure, refer to chapter 32.

In research labs, a variety of methods are available to assess markers of apoptosis and death (annexin staining, propidium iodide, or 7-aminoactinomycin D uptake); however, these approaches have not been readily adapted to the clinical lab. One of the major difficulties is in timing: measurements at early time periods (15 to 45 minutes after coincubation) capture apoptotic events but are not sensitive enough for quantification. Late measurements (90 to 240 minutes) are problematic, as cells are routinely "lost" upon death. Commercially available reagents can assess granzyme B delivery to the target cells using a fluorescent probe that is cleaved by granzyme B. This method is effective to detect NK function defects (data not shown); however, the number of samples required for replicate testing at multiple effector/target ratios has prevented routine use in the clinical lab, where the 96-well Cr^{51} assay is straightforward. A nonradioactive 96-well microplate assay would be desirable but has not yet been described. Additionally, patients may have cytotoxic defects that are not detected against the tumor target cell in routine usage in the diagnostic immunology lab (K562), such as those observed in boys with SAP deficiency.

DEFECTS IN NK CELL FUNCTION ASSESSED BY DEGRANULATION ASSAY

The measurement of degranulation of NK cells is an attractive method to evaluate NK function when perforin detection is normal and Cr^{51} release is abnormal, or in addition to or in place of traditional Cr^{51} release studies. According to this method, patient PBMC are coincubated with tumor target cells and CD107a is detected by flow cytometry on the cell surface. CD107a is normally detected on the inner aspect of the cytotoxic granule and therefore detected on the cell surface only when NK have recognized a target cell and degranulated in response to immune synapse formation. This method is sensitive to detect defects in the machinery required for NK degranulation, such as MUNC 13-4 (21), STXBP2 (22), STX11 (23), or RAB27A (24), and offers greater than 85% sensitivity for identifying patients with the various genetic causes of HLH due to degranulation defects (25). Shown in Fig. 3 are examples of patients with genetic forms of HLH.

CONCLUSION

Assessment of NK phenotype and function in humans relies on flow cytometry and radioactive assays in the diagnostic immunology lab. In the setting of recurrent or severe viral infections, these assays may be repeated to ensure that the findings are not transient. In the clinical setting of HLH, these assays may be reported within 24 hours, facilitating rapid diagnosis and treatment. It is often difficult to assess the results of functional assays if enumeration and phenotyping of NK cells are not performed at the same time. The development of nonradioactive, microplate assays is desirable to evaluate NK function, and additional information may be obtained if future clinical assays were to include more than one type of target cell for testing function.

Allergic Diseases *section L*

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITOR: PAMELA A. GUERRERIO

Introduction

PAMELA GUERRERIO

80

The prevalence of allergic diseases has risen dramatically throughout the world in recent years, creating a major health care burden. While immunoglobulin E (IgE) has been recognized to play a central role in the pathogenesis of human allergic conditions since 1967, a multitude of inflammatory mediators and cells are now known to contribute to these common phenotypes. Section L covers laboratory investigations useful in the diagnosis and management of allergic disorders. Important topics covered include the allergen, *in vivo* and *in vitro* assays to screen for the presence of allergen-specific IgE and other mediators of allergic inflammation, and analytic approaches to diagnosing food allergy, hypereosinophilic syndromes, and mast cell disorders.

Chapter 81, by Rabin et al., examines the quantification and standardization of allergens. Although hundreds of allergen extracts are commonly used clinically for both diagnosis and treatment (immunotherapy) of allergic diseases, only 19 allergen extracts are currently standardized for allergen potency in the United States. This chapter describes the major *in vivo* and *in vitro* assays used to assess the potency of manufactured allergen products. These include quantitation of erythema size following serial intradermal skin testing of highly allergic individuals, quantitation of total protein content or specific major allergens within the extract, and inhibition of IgE binding from pooled allergic sera to a reference allergen extract. The potential utility of research-based assays, including basophil histamine release and expression of basophil activation markers by flow cytometry, for characterizing allergen extracts is also discussed.

Chapter 82, by Hamilton, describes the immunoassays performed by clinical immunology laboratories that can aid in the diagnosis, management, and research of allergic conditions. This chapter details the methods used to quantify serum levels of total IgE and allergen-specific IgE, including the use of allergenic components that can be used to identify cross-reactivity among different allergens. Methods to quantify the levels of antigen-specific IgG and IgG4, which may have utility as a biomarker for successful immunotherapy, are also discussed.

Chapter 83, by Schroeder et al., examines the major cells and mediators of allergic inflammation. The most recent approaches for measuring histamine, leukotriene C4, prostaglandin D2, tryptase, and Th2 cytokines (interleukins 4 and 13) are covered, as well as flow-based assays used to monitor basophil activation. Cellular assays utilized to study the role of basophils and dendritic cells in allergic responses are described. This chapter also includes a detailed discussion of the procedures and allergen reagents needed for prick/puncture and intradermal skin testing, both of which are commonly used by clinicians to identify allergens to which a patient is sensitized. However, the diagnosis of an allergic disorder additionally requires a clinical history that supports a causal relationship between exposure to the allergen and the development of allergic symptoms. Chapter 83 concludes with a discussion of *in vivo* provocation tests, focusing primarily on airway challenges, which can be used to further define the relationship between a patient's allergen sensitivities and their development of clinical respiratory symptoms.

Chapter 84, by Santos et al., examines the diagnostic tools used in the evaluation of patients with food allergy. Topics that are examined include prick/puncture and intradermal skin testing, fresh-food skin prick testing, atopy patch testing, food-specific IgE serology testing, elimination diets, and the double-blind placebo-controlled food challenge, which remains the gold standard for diagnosing food allergy. The performance, interpretation, advantages, and limitations of each approach are discussed. The authors discuss component-resolved diagnostic testing that may improve the accuracy of food allergy testing, as well as highlighting the lack of utility of total IgE and food-specific IgG testing in food allergy diagnosis. Chapter 84 concludes with a discussion of research-based assays and their potential role in the diagnosis and management of food allergy, including specific epitope analysis, serum tryptase, and basophil histamine release assays.

Chapter 85, by Akin et al., overviews the laboratory analyses used in the evaluation of patients with suspected hypereosinophilic syndromes (HES). The authors present the clinical features and diagnostic criteria for the HES variants, as well as the controversies surrounding the diagnosis of HES and its classification into subtypes. Eosinophilic gastrointestinal diseases (EGID) are a family of disorders characterized by excessive eosinophilic inflammation in the gastrointestinal tract. The prevalence of EGID appears to be increasing in recent years in both children and adults. The authors detail the major clinical and pathologic features of EGID and current treatment approaches. Chapter 85 concludes with a discussion of the clinical presentation, classification, diagnostic approach, and treatment of mast cell disorders.

Quantitation and Standardization of Allergens

RONALD L. RABIN, LYNNSEY RENN, AND JAY E. SLATER

81

Allergic reactions and allergic diseases are the most common human disorders of immune regulation. Diseases may include localized responses in the skin and various portions of the airway, or systemic responses characterized by extensive skin involvement, severe airway compromise, or cardiovascular collapse. Mechanisms include mast cell or basophil activation by the cross-linking of allergen-specific homocytotropic IgE, cellular infiltration following mast cell or basophil mediator release, complement activation, the deposition of immune complexes in susceptible tissues, or the infiltration of activated T-lymphocytes. The degree of impairment from allergic disease varies widely, with most reactions posing minor inconvenience, but with rare episodes requiring intensive—and sometimes unsuccessful—interventions to prevent death.

While the treatment of allergic diseases often includes highly effective and specific pharmacotherapy, for many allergic disorders allergen avoidance and allergen immunotherapy remain the best and safest options. Specific *allergen diagnosis*, which is a prerequisite for effective avoidance or immunotherapy, may be achieved by confirmation of a suggestive clinical history using a controlled *in vivo* allergen challenge (skin testing or, less often, ocular or respiratory challenge) or using *in vitro* methods such as serological assays for IgE antibody, basophil histamine release assays, or lymphocyte stimulation analysis. Specific *allergen immunotherapy* involves a graded administration of the identified allergen specificities to which the individual is sensitized. The goal of immunotherapy is to achieve a temporary reduction in the individual's allergic response, either through receptor saturation, antibody depletion, the formation of blocking antibodies, or T-cell tolerance. Remarkably, the purity of the allergen being tested is not essential for diagnostic or therapeutic efficacy. In fact, purity has not been achieved for any commercially available allergen preparations. However, for each of these evaluations or treatments, it is critical that the allergen used be correctly identified and that it is present in a sufficient bioactive form to achieve the expected diagnostic or therapeutic performance. Thus, for the successful use of allergens in allergy diagnosis or immunotherapy, it is important that we are able to *identify* and *measure* the allergen being used.

Allergens are molecules that elicit allergic reactions in susceptible individuals. Typically, allergens are naturally occurring proteins or glycoproteins derived from plants or animals, but biomolecules derived from single-cell organisms, synthetic compounds, metals, and small molecules may elicit significant allergic reactions as well. In this chapter, we limit our discussion to *natural or recombinant proteins or glycoproteins used in the diagnosis and/or treatment of IgE-mediated allergic disease*.

Allergen extracts are manufactured and sold worldwide for the diagnosis and treatment of IgE-mediated allergic disease. Crude extracts are composed of natural animal or plant source materials, and they are complex mixtures of natural biomaterials. Each extract contains proteins, carbohydrates, enzymes, and pigments of which the allergens—presumably the active ingredients—may constitute only a small proportion (1).

All current U.S. allergenic products were licensed prior to the efficacy requirements that were established for biologics in 1972. The safety, efficacy, and labeling of these products were evaluated by a Review Panel in the 1970s, which considered all of the products available at that time and made separate recommendations for the diagnosis and therapy indications of these products (2). Although some allergenic products have been removed from the market following the Panel's deliberations, most have been deemed presumptively safe and effective for therapy and/or diagnosis (3).

Traditionally, allergen extracts have been labeled either with a designation of extraction ratio (wt/vol) or with a protein unit designation (protein nitrogen units/milliliter) that is determined using the Kjeldahl method. However, little correlation has been detected between these two designations and biological measures of allergen potency (4, 5). In the absence of a concerted effort to maintain product consistency, lot-to-lot variations in allergen content may be considerable. Product consistency may be enhanced by the inherent nature of the raw materials. For example, pollen and pure mite extracts (6) generally have greater lot-to-lot consistency than mold, house dust, and insect extracts (7). In addition, manufacturers can increase the consistency of their products by controlled collection, storage, and processing of the raw materials; by reproducible and optimized extraction and manufacturing techniques; and by setting expiration dates based on real-time stability data. However, consistency can only be assured by measuring the potency of each lot of extract, and by marketing only those lots whose potency falls within a pre-defined acceptable range. When such additional tests and specifications are applied to similar products from more than one manufacturer, those products are said to be *standardized*.

doi:10.1128/9781555818722.ch81

FDA's allergen standardization regulation (21 CFR 680.3(e)) mandates that when an appropriate potency test exists, manufacturers must test each lot of an allergen extract for potency prior to distribution. In practice, the FDA has provided manufacturers with a U.S. reference standard for 19 products to which each new lot of allergen extract may be compared. The purpose of allergen standardization is to ensure that the allergen extracts are consistent in terms of allergen content and that variation between lots is minimized, even among different manufacturers (8). Since standardized allergenic extracts are compared to a single, national potency standard, patients and their physicians can switch from one manufacturer's product to another with minimized risk of adverse reaction.

The 19 standardized allergen extracts currently available in the U.S. are presented in Table 1. For each of these products, there is a U.S. standard of potency to which each lot is compared prior to release for sale to the public. The potency measures, and the assays used to determine these measures, are specified in the approved product-license applications submitted by each manufacturer for each product.

Overview of *In Vivo* Assessments of Allergen Potency

Allergen standardization in the U.S. comprises two important components: the selection of a reference allergenic extract and the selection of the procedures to compare manufactured products to the reference extract (9–11). In the U.S., the use of a biological model of allergen standardization has permitted the assignment of "bioequivalent allergen units" or BAUs for most standardized allergens (10). Once a specific unitage is assigned to a reference, then all allergenic extracts from the same allergenic source can be assigned units based on the relative potency (RP) with respect to the reference, using an established quantitative *in vitro* potency method (12).

In theory, standardizing an allergenic extract might involve purifying each allergenic component in the extract and establishing with precision the importance of these allergens. However, most allergenic extracts are complex mixtures of several relevant allergens of as yet uncertain immunodominance. In addition, an individual allergen in a particular lot may be less likely to elicit an allergic or immunotherapeutic response due to instability or denaturation.

The choice of the best potency test depends on the extract that is being standardized. In the absence of data supporting the safety of potency designations based on single allergen content, a measure of overall allergenicity may be a better predictor of safe dosing. For two allergenic extracts (short ragweed and cat hair), data have supported the use of single allergen determinations (Amb a 1 and Fel d 1, respectively). For extracts of cat pelt and hymenoptera venoms, the presence of two allergens (Fel d 1 and albumin for cat pelt; hyaluronidase and phospholipase A2 for hymenoptera venoms) is verified for each lot. For extracts of dust mites and grass pollens, overall allergenicity is determined.

For initial overall allergenicity assessment, the Center for Biologics Evaluation and Research (CBER) developed a method using erythema size following serial intradermal testing of highly allergic individuals. Intradermal testing was chosen over prick/puncture testing to achieve greater dosing accuracy. The erythema size was chosen over wheal size to achieve greater accuracy in reaction measurements (12). This method is called IntraDermal dilution for 50 mm sum of Erythema determines the bioequivalent ALlergy units ($ID_{50}EAL$), and it can be used to compare the allergenicity of extracts regardless of their source. Subsequent comparisons of extracts from the same source material are made by a variant analysis called the parallel line bioassay. Both of these methods are described in CBER's Methods of the Allergenic Products Testing Laboratory (13).

In the $ID_{50}EAL$ method, allergenic extracts are evaluated in subjects maximally reactive to the respective reference concentrates. Each subject is tested with serial 3-fold dilutions of the reference extract. After 15 minutes, the sum of the longest and midpoint orthogonal diameters of erythema (ΣE) is determined at each dilution, and the log dose producing a 50-mm ΣE response (D_{50}) is calculated (12) (Fig. 1).

Extracts that produce similar D_{50} responses can be considered bioequivalent and are assigned similar units, the bioequivalent-allergy unit (BAU). Because the modal D_{50} of a series of allergen extracts was 14 (a 3^{-14} or 1:4.8 million dilution), extracts with a mean D_{50} of 14 were arbitrarily assigned the value of 100,000 BAU/ml (10). Thus, the formula for the determination of potency from the D_{50} is:

$$\text{Potency} = 3^{-(14-\text{ mean D50})} * 100{,}000 \text{ BAU/ml.}$$

By a similar technique and analysis, bioequivalent doses of test extracts from the same source as the reference extract can be determined by the parallel-line bioassay (14). The inverse ratio of the doses of test extract required to produce identical D_{50} responses to a reference extract is the RP of that extract. This analysis requires that the log dose-response curves of the test extract and the reference extract be parallel. If the two dose-response lines are not parallel, then the ratio of skin test doses for identical responses and the reference preparation will vary with the dose. In this situation, which strongly suggests compositional differences between the two extracts, the distance between the two lines is different at each dose and a meaningful RP cannot be determined (9, 15) (Fig. 2).

In the original 1994 protocol, the mean D_{50} for 15 highly allergic individuals was used to determine the D_{50} for the extract. In a later re-analysis of the statistical considerations underlying such potency studies, Rabin et al. (16) applied the following formula for the number of study subjects, n, that would be required:

$$n = 2\left(\frac{\sigma}{\delta}\right)^2 (z_{1-\alpha} + z_{1-\beta/2})^2$$

where σ is the standard deviation of the measurement, δ is the acceptable difference in D_{50}s of two equivalent products, and the z values are the critical values from the cumulative normal distribution table for a significance level α and a power of $1 - \beta$ (17). From this formula, n is a function of the *squares* of σ and δ. The value of n will depend on the particular allergen to be tested, but, for typical values of σ and δ, n will usually be larger than 15.

In Europe, the Committee for Proprietary Medicinal Products issued a Guideline on Allergen Products: Production and Quality Issues that was revised in 2009 (18). The European system for standardizing allergens and determining allergenic extract potency is different from the system used in the U.S. The differences are as follows:

1. Manufacturers ensure batch-to-batch consistency using an in-house standard. The in-house standard may be characterized by a number of physico-chemical and immunologic assays, with demonstration of the presence of individual allergens preferred.

2. There are no external reference standards to ensure consistency among manufacturers.

TABLE 1 Allergenic extracts currently standardized in the U.S.

Allergen extract	Current lot-release tests	Labeled unitage	Current standard (date placed in service)	Method to establish equivalence to previous standard
Dust mite (*Dermatophagoides farinae*)	Competition ELISA Protein	AU/ml (equivalent to BAU/ml)	E11-Df (2012)	Competition ELISA
Dust mite (*Dermatophagoides pteronyssinus*)			E11-Dp (2011)	Competition ELISA
Cat pelt (*Felis domesticus*)	Fel d 1 (RID)	BAU/ml	E6-cat pelt (2012)	RID, IEF
Cat hair (*Felis domesticus*)	IEF Protein	5-9.9 Fel d I U/ml = 5,000 BAU/ml 10-19.9 Fel d I U/ml = 10,000 BAU/ml	E8-cat hair (2015) C13-cat (calibration set, 2012)	RID, IEF
Bermuda grass (*Cynodon dactylon*)	Competition ELISA	BAU/ml	E12-Ber (2016)	Competition ELISA
Red-top grass (*Agrostis alba*)	IEF Protein		E7-Rt (2016)	
June (Kentucky blue) grass (*Poa pratensis*)			E8-Jkb (2016)	
Perennial ryegrass (*Lolium perenne*)			E15-Rye (2015)	
Orchard grass (*Dactylis glomerata*)			E6-Or (2013)	
Timothy grass (*Phleum pretense*)			E10-Ti (2014)	
Meadow-fescue grass (*Festuca elatior*)			E6-Mf (2014)	
Sweet vernal grass (*Anthoxanthum odoratum*)			E7-Sv (2015)	
Short ragweed (*Ambrosia artemisiifolia*)	Amb a 1 (RID)	Amb a 1 units	E15-Ras C14-Ras (calibration set, 2011)	RID
Yellow hornet (*Vespa* spp.)	Hyaluronidase and phospholipase activity	μg protein	V4-HB (2015)	
Wasp (*Polistes* spp.)				
Honey bee (*Apis mellifera*)				
White-faced hornet (*Vespa* spp.)				
Yellow jacket (*Vespula* spp.)				
Mixed vespid (*Vespa* + *Vespula* spp.)				

ELISA, enzyme-linked immunosorbent assay; AU/ml, absorbance units/milliliter; BAU/ml, Bioequivalency Allergy Units/milliliter; RID, radial immunodiffusion assay; IEF, isoelectric focusing

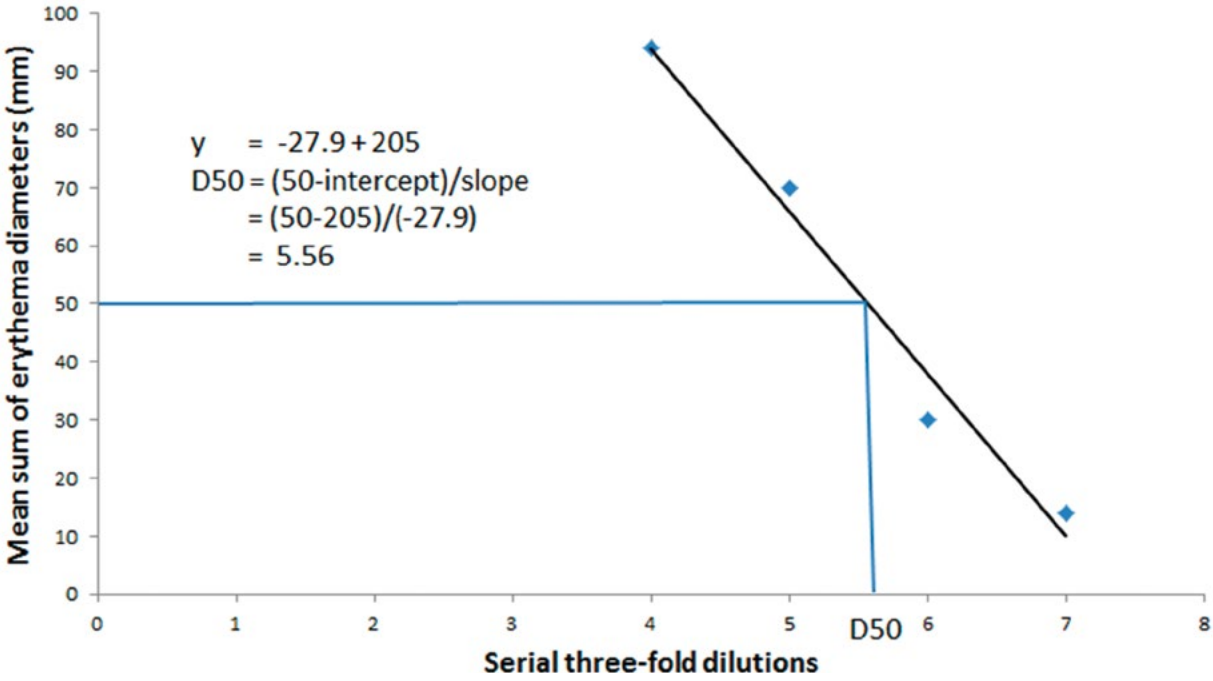

FIGURE 1 Sample calculation of D_{50}. Serial 3-fold dilutions of test material—in this example, histamine base—were injected and the ΣE responses were plotted against the negative log dilutions. The D_{50} is determined from the best-fit line using the formula: D_{50} = (50 - Intercept)/slope. The calculated D_{50} of 5.56 corresponds to a value of $-3^{-(14-5.56)}$ * 100,000 BAU/ml = 9.4 BAU/ml.

3. Potency may be determined by any validated measure of *in vitro* IgE binding or other immunoassay. The potency of the in-house standard may also be tested by a skin test technique.

4. An *in vivo* method by which European products may be tested is called the Nordic technique (19). This skin test method differs from the U.S. FDA CBER $IDE_{50}AL$ method in its use of prick skin tests rather than intradermal tests; its focus on wheal size rather than erythema; its choice of study subjects; and its use of a histamine dose-response curve to determine unitage. The method likely provides a reasonable estimate of extract potency. In theory, the comparison of the skin test reactivity of all allergens to a single standard (histamine dihydrochloride 10 mg/ml) allows the assignment of universal unitage without the development or maintenance of specific allergen reference standards. However, the European guideline does not prescribe the skin test technique to be used, and manufacturers are free to modify it as needed as long as the test is validated. Thus, as applied in Europe, this method cannot provide a level of standardization among the different manufacturers that market products in the European Union.

$ID_{50}EAL$ Test (12, 20)

Study Sequence

1. Identify three to four testing sites to achieve geographic and ethnic diversity of study populations.
2. Recruit 6 to 10 subjects per tester for proficiency testing (subjects need not be atopic). In order to generate useful data, the $ID_{50}EAL$ and parallel line bioassay methods must be performed by individuals proficient in the accurate and reproducible delivery of intradermal skin test doses, and the precise measurement of the skin test responses. Hence, a proficiency program has been developed to qualify personnel. This program, which is not described in detail here, involves puncture skin testing with histamine at 0.1 mg/ml and intradermal testing with eight serial 3-fold dilutions of histamine. The tester then analyzes the data and compares the results with normative data. Thus, the proficiency program examines the tester's ability to prepare accurate dilutions, administer the skin tests with precision, and record and analyze the data properly.
3. Recruit 10 to 20 study subjects for initial allergen skin testing.
4. Skin-test subjects and analyze the intradermal skin test data. Analysis will include determination of σ for intradermal testing.
5. Based upon initial data, determine the final study size.
6. Recruit study subjects, skin-test subjects, and analyze skin test data.
7. Prepare final study report.

Selection of subjects. Select individuals within the target-age range with a history of allergic disease relevant to the allergen being tested. Subjects must have a puncture sum of erythema diameter responses (ΣE) to the allergen concentrate of at least 30 mm. Exclude individuals with asthma whose peak flow is less than 75% of predicted at the time of testing; whose skin coloring or skin condition would preclude the measurement of erythema responses; who are dermographic; or who are currently using antihistamines, tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, and beta-blockers.

Dilution of allergens for skin testing. Starting with the undiluted or reconstituted lyophilized extract, prepare serial 3-fold dilutions using sterile technique, down to a dilution

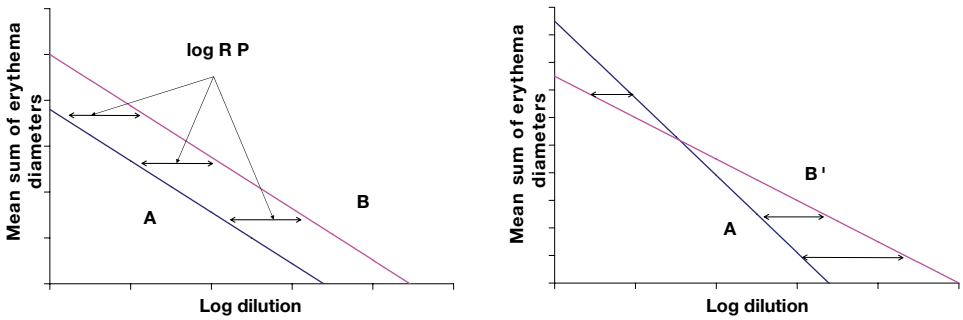

FIGURE 2 Hypothetical parallel line bioassay curves. In panel A, the bioassay curves are parallel, and the difference of log dilutions resulting in the same diameters is constant at all diameters. The log relative potency (log RP) of test sample B compared to reference A is represented by the difference. In panel B, the curves are not parallel, and the differences vary with the strength of the reaction. Thus, the log RP of B′ compared to A cannot be calculated.

of 3^{-17}. For convenience, label the dilution by the $\log_3$ doses: undiluted extract is labeled "0" and the 3^{-17} dose is labeled "17".

Preparation of subject. Skin tests may be placed on the back or the glabrous skin of the volar surface of the arms, avoiding a 1-inch area above and below the antecubital fossa and a 1-inch area above the wrist. For consistency, the back should be used for final titrations.

Injection technique. The volume of solution to be injected is 0.05 ml. Insert the needle of a 27-gauge 0.5 ml syringe at a 30° angle, bevel down. A distinct injection bleb should be observed. Injections in which gross leakage of extract around the needle, an indistinct bleb, or a subcutaneous injection occur should be repeated at a different site.

Measurement of skin tests. THIS IS A TIME-DEPENDENT ASSAY. Exactly 15 minutes following injection, the wheal and erythema margins are outlined using a fine, roller-tip pen with washable ink. In order to make a permanent record of the skin test reaction, transparent surgical tape is placed on the skin over the skin test outline. Lifting of the tape from the skin results in transfer of the outline to the tape. The tape is then placed in a notebook for future reference.

The size of the skin response is obtained by measuring and recording the longest diameter of erythema and the orthogonal erythema diameter measured at one-half the longest erythema diameter (Fig. 3). The sum of the longest and orthogonal erythema diameters (ΣE) (or wheal [ΣW]) constitutes the skin response at that site. Measurements are made from the inner edge of the skin test outlines.

Skin test procedure. The dose-response line for each product is generated using four serial 3-fold dilutions with graded erythema responses that bracket ΣE = 50 mm and includes the endpoint where ΣE = 0 or ΣE ~ ΣW. The skin response (ΣE) should fall within the limits of ≤0 to <125 mm. Each more concentrated dilution should produce a graded erythema response. The four dilutions selected should span a wide range of ΣE (for example from 0–20 mm to 80–125 mm) and bracket ΣE of 50 mm.

Inject the test and reference extracts beginning with dilution #15. The expected change in ΣE going from one dilution to the next dilution is about 20 mm. Therefore, if dilution #15 is negative, proceeding to dilution #12 would not be expected to exceed a ΣE response of 60 mm. Similarly, if dilution #12 is negative, proceed to dilution #9. Do not inject reference extract dilutions more concentrated than #5 unless the extract is known to be of low potency. Apply each dilution in singlicate for each product and reference. Always include an intradermal diluent control test.

Overview of *In Vitro* Assays of Allergen Potency

Although skin testing is an essential component of the allergen standardization program, it is not intended for routine use in the testing of manufactured lots of extracts prior to release. *In vitro* potency assays that accurately predict the *in vivo* activity of extracts have been developed (15). Once an *in vivo* assay has been utilized to assign unitage to a reference extract, then an appropriate surrogate *in vitro* assay can be used to assign units to test extracts from the same sources. These methods can be based on quantitation of the *total protein* content (Hymenoptera venoms), the *specific allergen* content within the allergenic extract (short ragweed and cat), or the *inhibition of the binding of IgE* from pooled allergic sera to reference allergen (grasses, mites) (17). For the Hymenoptera venom allergens, the potency determination is also based on the content of the known principal allergens within the extract, hyaluronidase and phospholipase, which is determined by enzyme activity (see Table 1).

The potency units for short ragweed extracts were originally assigned based on their Amb a 1 content. Subsequent data suggested that 1 unit of Amb a 1 is equivalent to 1 μg of Amb a 1, and 350 Amb a 1 units/ml is equivalent to 100,000 BAU/ml. However, the original unitage has been retained.

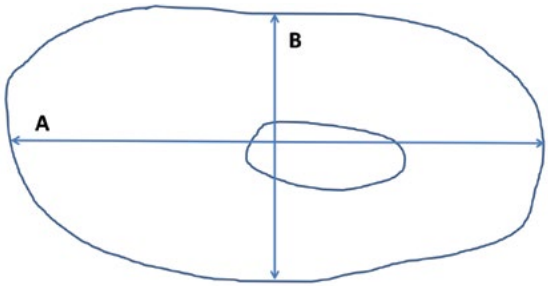

FIGURE 3 Diameters are measured from the inner margins of the penned outline. Longest (A) plus midpoint orthogonal diameters (B) and summed (A + B).

Grass pollen extracts are labeled in BAU/ml, based on ID_{50}EAL testing. In some cases, the assignment of potency units to standardized allergenic extracts in the U.S. has changed as better bioequivalence data have become available (12). Cat extracts were originally standardized based on their Fel d 1 content, with arbitrary unitage (AU/ml) tied to the Fel d 1 determinations. Subsequent ID_{50}EAL testing suggested that the 100,000 AU/ml cat extracts, which contained 10–19.9 Fel d 1 U/ml, should be relabeled as 10,000 BAU/ml (21). In addition, 20% of individuals allergic to cat were found to have antibody to non-Fel d 1 proteins (22), and the identification of a cat albumin band on isoelectric focusing (IEF) gel was added as a requirement for cat pelt extracts. Dust mite extracts were originally standardized (in AU/ml) based on IgE antibody-based inhibition assays. Subsequent ID_{50}EAL testing has indicated that the arbitrary unitage is statistically bioequivalent to BAU/ml (21, 23). Thus, in this case, the original unitage was retained (24).

Tests for Individual Allergens

Individual allergens may be measured and detected by various approaches using monospecific antisera or antibodies. Assay designs using these antisera include the radial immunodiffusion assay (RID), crossed immunoelectrophoresis/crossed radioimmunoelectrophoresis (CIE/CRIE), and enzyme-linked immunosorbent assay (ELISA) variants (direct, two-site, competition). Each of the assays utilizes monospecific antisera or antibodies to detect and quantify the specified allergen. The RID assay is currently applied to two standardized allergenic extracts, short ragweed and cat, in which the immunodominant allergens (Amb a 1 and Fel d 1, respectively) have been identified and defined. Sheep antisera are used for the RID performed at CBER/FDA, but polyclonal and monoclonal antibodies from several species have been used with success for many of these assays. Specifications for the antibodies vary with the assay system. For example, antibodies for the RID must form a discrete precipitin ring; the two antibodies for the two-site ELISA must recognize different epitopes on the allergen molecule; and, in all cases, the epitope(s) recognized must be present on the allergen and reflective of its bioactivity.

Antibodies

Monospecific antisera that recognize the allergen of interest may be purchased or, alternatively, obtained by inoculating an animal with the appropriate amounts of recombinant or purified allergen. Monoclonal antibodies or recombinant antibodies (such as scFv or Fabs) can also be generated for these assays.

RID

This assay is currently used by CBER and most U.S. allergen manufacturers to measure the allergen content of short ragweed and cat allergen extracts. Monospecific antiserum is added to an agar solution which is allowed to solidify. Wells are then cut into the agar and test allergen is placed in the wells. As the specific allergen diffuses out into the agar a precipitin ring forms. The precipitin area delineates the equivalence zone for antigen-antibody binding. The radius of the precipitin ring can then be measured. Since the antibody concentration in the agar is constant, the antigen concentration decreases with increasing distance from the well and is proportional to the log of the concentration of the applied test allergen in comparison to the reference extract (25).

1. Prepare a solution consisting of 1% Noble agar (Difco, Becton, Dickinson and Company, Franklin Lakes, NJ) and 1% sodium azide in water. Heat in a boiling water bath until the solution is clear. Allow the temperature to equilibrate in a 55°C water bath.

2. Once the solution has cooled to 55°C, add 0.2 ml monospecific antiserum to 2 ml of agar solution. Mix thoroughly but gently and pour onto a microscope slide that has been pre-coated with 0.01% Noble agar. Allow agar to solidify at room temperature (RT).

3. After the agar has hardened, place the slide on a sheet of graph paper that contains a template with five evenly spaced dots, approximately 1.5 mm apart. Cut wells into the agar over each dot with a gel cutter; and carefully pipette 8 μl of allergen test solutions into each well. Incubate the slides in a sealed humidified chamber at RT for 72 hours.

4. Fix the slides by soaking them in 10% acetic acid for 2 minutes, followed by a brief rinse in deionized water. The diameters of the precipitin rings can be measured to the nearest 0.1 mm using a calibrating viewer (Transidyne General Corporation, Ann Arbor, MI).

5. After measuring the diameter of the precipitin rings, the reference standard data are graphed on a semilog scale. The average ring size of the unknown can then be used to determine the amount of allergen by interpolation.

Troubleshooting the RID. Prior to performing this assay on an unknown, a dose-response curve should be performed to determine the antiserum concentration at which the ring diameter plateaus. If multiple RID assays are going to be compared, person-to-person variability should be established by direct comparison of an identical test profile. Likely sources of person-to-person variability may include 1) pipetting errors leading to spillover of samples applied to the wells, and 2) measurement errors using the calibrating viewer.

Sandwich ELISA

While CBER has been using the RID assay for over 20 years, individual variability, technical challenges, reagent consumption, and the difficulty in obtaining replacement calibrating viewers have led to recent efforts by CBER (26) to replace the RID with ELISA-based methods of specific-allergen measurement.

Antibody-sandwich ELISAs (sELISAs) are 2- to 5-fold more sensitive than ELISAs in which the antigen is bound directly to the plate. sELISAs use capture antibodies, such as recombinant single-chain variable fragments (scFvs), attached to a plate surface to detect sample antigens. sELISAs can be developed to quantify major allergens in test samples using allergen-specific antibodies.

sELISA Procedure

1. Avian scFv antibodies against Fel d 1 and Amb a 1 were generated and purified as described previously (27). scFv antibodies are stored at −20°C.

2. Prepare a coating solution consisting of 10 μg/ml purified monospecific scFv antibody diluted in 1X phosphate-buffered saline (PBS). Add 50 μl of the diluted coating solution to each well of a 96-well polystyrene plate and incubate overnight at 4°C.

3. Wash the plate with 1X PBS with 0.05% Tween (PBS-T) buffer using a Dynex Ultra Wash Plus (Dynex Technologies, Chantilly, VA) plate washer. Block the plate with 200 μl Pierce StartingBlock blocking buffer (Thermo Scientific, Middletown, VA) per well for 1–2 hours at RT.

4. Prepare a standard antigen dilution series in duplicate with an initial 1:3 dilution followed by serial 1:3 dilutions of

the antigen in PBS-T buffer. Positive displacement pipettes are used for diluting glycerinated allergenic extracts. Wash the plate with PBS-T, add 50 μl of the dilution series and incubate the plates for 1 hour at RT.

5. Prepare a 1:1,000 dilution of the sheep antiserum (containing the antigen-specific antibody) in StartingBlock. Wash the plate with PBS-T, add 50 μl diluted antiserum to each well and incubate for 1 hour at RT.

6. Prepare a 1:1,000 dilution of the rabbit anti-sheep horseradish peroxidase (HRP)-labeled antibody-enzyme conjugate (KPL; SeraCare Life Sciences, Gaithersburg, MD) in StartingBlock. Wash the plate with PBS-T, add 50 μl conjugate to each well, and incubate for 45 minutes at RT.

7. To develop the reaction, prepare a mix (1:1) of the peroxidase solution B and 3,3′,5,5′-tetramethylbenzidine (TMB)-peroxidase substrate from the microwell TMB Substrate System (KPL) and incubate the working substrate solution for 5 minutes at RT. Wash the plate with PBS-T, add 100 μl of substrate to each well and incubate for 5 minutes. Add 100 μl of 1 M phosphoric acid (H_3PO_4) stop solution to each well and measure the absorbance values (Abs_{450}) within 30 minutes using a Dynex MR 5000 plate reader or other microplate reader capable of measuring absorbance at 450 nm.

To analyze the data, the values obtained from the test samples are compared to the standard antigen dilution. Statistical tests, such as the Grubb's test, are used to mathematically remove outlier points from data sets prior to analysis. The four-parameter logistic regression (4PL) and associated statistical analysis is a commonly used analysis method for immunoassays. It provides an unbiased modeling method to determine testing parameters. The four parameters assessed in the analysis are the upper and lower asymptotes, hillslope, and inflection point.

ELISA results rely on the interpolation of data based on a standard curve. Methods for purification of natural allergens have made it possible to develop assays to quantify antigens using major allergens as reference standards. Therefore, natural allergens are useful as a reference reagent of known starting concentration to use to determine the concentration of a particular antigen in test extracts.

CIE/CRIE

In CIE, allergen extract is typically separated by electrophoresis on a 1% agarose gel, and a narrow strip of gel containing the separated antigen is then transferred to a clean glass plate. The remaining area of the plate is then filled with agarose containing poly-specific antisera against the antigen. A second electrophoresis is performed at right angles to the first one (hence "crossed" electrophoresis). Immune complexes form precipitin arcs that can be visualized by Coomassie blue staining (28, 29).

In CRIE, the unstained CIE preparation is incubated in the presence of appropriately diluted patient sera containing specific IgE, which is detected by overnight incubation in ^{125}I-labeled anti-IgE (30).

Enzyme Activity Assays

Hymenoptera venoms contain multiple glycoprotein enzymes, the most important of which are hyaluronidase and phospholipases A1 and A2. Venom allergenic extracts are standardized using enzymatic assays, which estimate hyaluronidase and phospholipase content based on their enzymatic activity. In these assays, an agar solution is prepared with the appropriate enzymatic substrate and test samples are then added to cut wells. As the enzyme present in the sample diffuses into the agar, it digests the substrate, forming clearing zones around the wells. The radius of the clear zones is then measured and calculated as the log of the concentration of the enzyme present in the sample (31).

Tests of Overall Potency

The potency of those standardized allergen extracts for which the immunodominant components have not been identified with certainty may be estimated using assays for IgE-antigen binding. These assays compare the overall IgE-binding properties of test and reference extracts, using pooled allergic sera. Initially, a radioallergosorbent test (RAST) inhibition assay was used for this purpose; CBER adopted the competition ELISA as its alternative standard assay because of its greater precision and convenience. After coating the wells of the polystyrene microtiter plate with the reference allergen and blocking the wells with bovine albumin, a mixture of the extract to be tested and a reference serum pool is added to the wells. The greater the amount of immunoreactive allergen in the mix, the less free IgE antibody will be available from the serum pool to bind to the immobilized allergen on the plate. The concentration of the allergens in the extract is determined by comparison to the reference allergen extract. However, since this assay does not explicitly measure a specific allergen, the allergen concentration is expressed as relative potency (RP), with the reference extract assigned an arbitrary RP of 1.0. Early studies showed an excellent correlation between RP assigned by titration skin testing and RP determined by RAST inhibition (10); subsequent studies showed the competition ELISA to be equivalent as well (32).

Method Summary: Inhibition Immunoassays

The inhibition immunoassays for the determination of overall allergen potency share basic design features:

1. Known allergens are bound to a solid-phase support.
2. The solid support is then exposed to serum containing IgE antibodies from an allergic individual, mixed with dilutions of unknown competing allergen.
3. IgE binds to the allergens on the solid phase forming antigen-allergen complexes. The competing (soluble) unknown allergen reduces the binding of specific IgE to the solid-phase allergen.
4. The unbound IgE is washed away. Labeled anti-IgE is allowed to bind to the antigen-IgE complexes. After a final wash, the label remaining bound to the antigen-allergen complex is related to the quantity of the IgE antibody present in the serum of the patient.
5. The results are then plotted and the 50% binding value determined is proportional to the potency of the extract. In addition to finding the 50% binding value, the slopes of different extracts can be compared; those extracts with similar slopes have similar antigen composition. The relative potency may then be determined as illustrated in Fig. 2, above.

RAST was first described in 1967 (33). In this assay, which is intended to determine the presence of specific IgE in a serum sample, allergen is bound to cyanogen bromide-activated paper disks, followed by incubation with patient serum. After unbound antibody is washed away, ^{125}I-radiolabeled anti-IgE is used to detect the bound IgE. Following the approach outlined above, RAST inhibition is used to establish the overall allergen content of an unknown extract.

Several IgE-antibody autoanalyzers have replaced the original paper disk-based RAST assay. These are the

ImmunoCAP (Thermofisher Scientific/Phadia division), and the Immulite (Siemens Healthcare). The ImmunoCAP system, which was introduced in 1990, has been used by CBER for allergen extract qualification. In place of the paper disk, it employs a sponge cellulose material to which allergen is covalently bound. The secondary antibody is an anti-human IgE-β-galactosidase conjugate. Substrate 4-methylumbelliferyl-β-D-galactoside is cleaved by the β-galactosidase, which generates a detectable fluorogen. The ImmunoCAP system has reported increased analytical sensitivity for some allergen specificities such as the Hymenoptera venoms (34, 35), cat (35–37), *Dermatophagoides pteronyssinus* (35–37), and *Alternaria alternata* (36, 37). Other studies failed to show a significant improvement in analytical sensitivity (38, 39). This assay can be used to measure overall allergen content in a manner similar to the past RAST assay.

Overview of ELISA Inhibition, or Competition ELISA

The competition ELISA is the one assay used by CBER and most U.S. allergen manufacturers to determine the relative potency of standardized grass pollen and dust mite allergenic extracts. In this assay, serial dilutions of an extract to be tested are placed in their respective wells that have been precoated with a known amount of reference extract. Optimal concentrations of the reference extract and the detecting antibody conjugate must be determined by checkerboard titration for each new set of reagents.

The detection antibody is a critical component of the assay. It is essential that the antibodies used reflect the broadest range of allergens considered relevant to the overall allergenicity of the allergenic extract being tested and should be evaluated by Western blot or a comparable technique. IgE is biologically relevant for allergic disease, but each batch of IgE-containing sera is likely to vary in the specificity profile of the IgE. Since most atopic donors will be multi-allergic, their sera may contain IgE molecules that recognize irrelevant allergens as well. Such extraneous IgE will only interfere in the assay to the degree that the coating allergen contains cognate irrelevant allergens. Human sera containing IgE antibodies should be collected from as many allergic individuals as possible, with a minimum of six, but preferably 10 to 20 (40). Other polyspecific antisera can also be utilized for these assays and are discussed above.

ELISA inhibition procedure (41, 42).

1. Coat the microplate wells with 100 μl/well of the reference extract and allow to bind at 4°C overnight. Wash the plates in 0.05% Tween in PBS (PBS-T).
2. Block at RT for 1 hour 30 minutes in blocking buffer (1% BSA in PBS-T), and wash in PBS-T.
3. Into duplicate wells, pipette 1:3 serial dilutions of the reference extract. Into the remaining wells, pipette 1:3 serial dilutions of the test extracts in duplicate.
4. Immediately add 50 μl of the detecting antibody at the appropriate concentration.
5. Incubate overnight at 4°C.
6. Wash the plate with PBS-T, develop, and read as appropriate.
7. The results are plotted with the values of the optical density along the *y*-axis and the log of the dilution factor along the *x*-axis. The 50%-binding value that is determined is proportional to the potency of the extract; the RP is estimated by comparing the *x*-intercepts of the test and reference extracts. The slopes of the different extracts can also be compared; those extracts with identical slopes as determined by the *t*-test are presumed to have similar antigen composition.

Basophil Activation

Basophil histamine release is an *in vitro* surrogate for skin testing. As with other assays based upon interactions between allergen and specific IgE, the release of histamine from sensitized human basophils may be used to measure the allergen content of an unknown solution. Histamine release assays have been performed on heparinized whole blood (43, 44), crude leukocyte preparations (45), purified basophils (46–48), cell lines (49, 50), and using RBL SX-38, a rat basophil cell line that expresses human FcεR1 (51). The drawbacks of this assay are that histamine release assays from whole or fractionated blood require large amounts of recently drawn blood, and specialized cell lines are not readily available. In addition, basophils from 20% or more of skin test-positive patients do not release histamine *in vitro* (52), even in the presence of cross-linking anti-IgE. However, these same individuals' serum IgE may still be used in histamine release experiments by passively sensitizing basophils from other donors with the heterologous IgE (53). In all variants of this assay, released histamine may be quantified by radioimmunoassay, fluorimetry (54), or measurement of radioactivity after pretreatment with tritiated 5-hydroxytryptamine. Although this technique and its variants have been used to assess allergen potency (55–57), it does not appear to have any advantage over other assays that depend upon specific allergen-antibody interactions (58). Basophil histamine release assays are discussed further in chapter 83 of this volume (Schroeder et al.).

Flow Cytometry

In the past 20 years, the discovery of basophil activation markers CD63, CD45, CD69, and CD203c have led to a flow cytometric approach that assesses the *in vitro* activation of basophils (59). Most commonly, CD63 and CD203c are used (60). CD63 is located on the membrane of intracellular secretory granules that fuse with the plasma membrane upon stimulation through high-affinity IgE receptor FcεRI. CD203c is weakly expressed on the plasma membrane of resting basophils, and is rapidly increased upon stimulation through FcεRI. While both of these surface antigens measure basophil activation, they may represent the end point of different molecular pathways, and the best choice appears to be dependent on the context of activation (59).

Identity Testing

The identity of an allergen extract may be verified by visualizing the separated allergen proteins based on their size and isoelectric points (1). The IEF assay is an important safety test in the lot release of grass pollen and cat extracts. The patterns produced by the crude allergen mixtures are reproducible enough to consistently indicate the presence of known allergens, to identify possible contaminants present in the extracts, and to check lot-to-lot variation (61). In addition, IEF is used to verify the presence of cat albumin in cat pelt extracts.

Method Summary: Identity Testing

IEF

Polyacrylamide gels IEF pH 3-10, Anode (Upper) and Cathode (Lower) Buffers, IEF pH 3-10 Sample Buffer,

cellophane-preserving sheets, and the electrophoresis unit are available from Invitrogen by ThermoFisher (Life Technologies Corporation, Carlsbad, CA).

1. Prepare Anode and Cathode buffers. Refrigerate for at least 6 hours.
2. Remove IEF pH 3-10 polyacrylamide gel from pouch and rinse with deionized water. Rinse the electrophoresis unit with deionized water and assemble the apparatus.
3. Mix equal volumes of extract and Sample Buffer and load into the appropriate wells on the gel. (Note that for cat pelt 0.6–0.8 Fel d 1 units must be used, and more may be needed for cat hair extracts.)
4. For each sample, a reference extract and an IEF pH 3-10 marker (Serva Electrophoresis GmbH) should also be run on the gel. For best results, the gel should be run initially for 60 minutes at 100 volts constant, then 60 minutes at 200 volts constant, and finally at 500 volts constant for 30 minutes. The expected current is 5 mA (start) and 6 mA (end). IEF is typically performed by increasing the voltage gradually and maintaining the final focusing voltage for 30 minutes. During IEF, proteins migrate in an electric field until a stable pH gradient is formed and proteins reach their isoelectric point (pI). At that point, a high finishing voltage is applied to focus the proteins into narrow zones. High voltage cannot be applied during the initial stages of IEF due to excessive heat generated by the movement of carrier ampholytes.
5. After the gel has been run, the gel is immediately fixed for 30 minutes in 12% trichloroacetic acid, washed with deionized water, and stained for 1 to 3 hours in SimplyBlue SafeStain (Invitrogen, Carlsbad, CA). Destain over a period of 16 to 24 hours with several exchanges of deionized water until the background is clear.
6. An image of the gel may be captured using a G-Box Gel Imaging and Analysis System (Syngene, Frederick, MD) and exported as a joint photographic experts group (JPEG) file or a tagged-image file (TIF). Alternatively, the gel may be photographed with high-contrast film and a yellow filter. To preserve the gel, incubate it in Gel-Dry gel drying solution (Novex ThermoFisher Scientific, Carlsbad, CA) for 10 to 20 minutes at room temperature. Place the gel on a gel drying frame (Novex ThermoFisher Scientific) between cellophane preserving sheets previously soaked in the Gel-Dry drying solution for 10 to 20 seconds. Allow the gel and cellophane to dry for 24 to 48 hours and store away from bright light.
7. The pI of the sample proteins can be determined by interpolation on a calibration curve utilizing the IEF marker that was resolved along with the sample.

Immunological Methods in the Diagnostic Allergy Clinical and Research Laboratory

ROBERT G. HAMILTON

82

Nearly 50 years have passed since IgE was identified as the reagin or serum antibody that sensitizes skin mast cells and circulating basophils and mediates immediate-type hypersensitivity reactions in humans (1, 2). Since IgE's identification, the clinical immunology laboratory has provided the clinician with analytical measurements that aid in the diagnosis, management, and research of the natural history and epidemiology of IgE-mediated diseases. Total and allergen-specific IgE antibody are the primary analytes measured clinically to support the diagnosis of human allergic disease. Antigen-specific IgG antibodies are measured as a research analyte to identify chronic allergen exposure and to monitor potential blocking antibody activity following immunotherapy.

The goal of this chapter is to overview the status of immunological methods that are used in the quantification of total and allergen-specific IgE and research investigation of IgG antibodies. Other analytes that will not be discussed but that are occasionally measured in allergy and asthma patients include mast cell tryptase (see chapter 85 of this volume), cotenine (a metabolite of nicotine and indicator of passive smoke exposure), and the levels of indoor indicator aeroallergens from dust mites, house pets (cats and dogs), rodents (mice and rats), insects (cockroaches), and molds in surface dust, which help target avoidance therapy.

ANALYTES RELEVANT TO THE EVALUATION OF PATIENTS FOR ALLERGIC DISEASE

As discussed in chapters 83 and 84, immediate-type hypersensitivity manifests as a spectrum of symptoms that involve respiratory responses (asthma or rhinitis), ocular symptoms (conjunctivitis), skin reactions (urticaria, dermatitis), gastrointestinal symptoms, and/or life-threatening anaphylactic shock. These symptoms are produced as a result of the re-exposure of a previously sensitized (IgE antibody positive) individual to one or more sensitizing allergen(s). These allergens are ubiquitous proteins that are abundant in nature. They are released from pollens of grasses, weeds and trees, or antigenic proteins released from mites, rodents, domestic animals, insects, and mold spores and present in some drugs and generally well-tolerated foods. Allergenic proteins tend to form aggregates and vary in the symptoms that they induce based on their degree of stability to processing (heat) and enzymatic digestion. The more stable the allergenic molecule, the more likely it is able to evade destruction by the body's defenses (mucosal enzymatic digestion, gastrointestional pH denaturation) and induce serious allergic reactions.

IgE mediates allergic reactions by binding onto high-affinity epsilon Fc receptors on mast cells and basophils and initiating the release of vasoactive mediators following allergen binding and cell surface IgE antibody cross-linking (see chapter 83 of this volume) (2). Total serum IgE levels are used clinically by some immunologists as a diagnostic analyte because a moderately elevated total serum IgE reinforces the clinical diagnosis of atopic disorders, including allergic rhinitis, allergic asthma, and atopic dermatitis (3, 4). Moreover, high IgE levels are commonly observed in parasite infections (see chapter 54 of this volume) and are necessary in the definitive diagnosis of bronchopulmonary aspergillosis, Wiskott-Aldrich syndrome, and hyper-gammaglobulinemia E syndrome (Table 1). Serial total serum IgE levels can confirm an expected seasonal boost in serum IgE antibodies that is commonly seen after environmental exposure to the allergen to which the patient has become sensitized. However, the wide overlap in total serum IgE levels among atopic and non-atopic individuals and the age dependency diminishes its general diagnostic utility (3, 4). Thus, the clinician must refrain from discounting allergy when total IgE levels are low or from automatically inferring an allergic etiology when the total serum IgE level is high. Since the therapeutic Omalizumab (anti-IgE) was licensed in 2003 for the treatment of allergic asthma and, most recently, for idiopathic urticaria, total serum IgE measurements are needed to ensure that the patient is a candidate for anti-IgE therapy and to select the proper anti-IgE dose, which is based on the pre-treatment total serum IgE level (5). The required total serum IgE range for Omalizumab treatment is 30 and 700 kIU/liter (where 1 IU = 2.4 ng of IgE).

Allergen-specific IgE antibody has remained the primary analyte that is used to support the clinical history based diagnosis of IgE-mediated allergic disease (Table 1). IgE antibody can be detected *in vivo* using a puncture or an intradermal skin test that provokes IgE-mediated skin mast cell release and elicits a visible wheal and erythema, if positive, larger than the skin reaction produced by a saline control. Because skin testing is extensively discussed in chapter 81 in this volume, it will not be discussed further here. While skin testing is a biologically relevant response

doi:10.1128/9781555818722.ch82

TABLE 1 Clinical conditions in which serological determination of IgE and IgG antibodies may be useful in the differential diagnosis

Clinical condition	Total serum IgE	Allergen-specific IgE	Allergen-specific IgG
Atopic disorders: allergic rhinitis, allergic asthma, atopic dermatitis	Moderately elevated levels positively reinforce clinical diagnosis; however, low or normal IgE level is not incompatible with diagnosis	Positive allergen-specific IgE antibody level supports the diagnosis of IgE-mediated atopic disorders	In the absence of allergen immunotherapy, the allergen-specific IgG antibody can be low or undetectable
Intrinsic (non-allergic) asthma	Normal or low levels suggest that IgE mechanisms play only a minor role in the pathogenesis of asthma	Negative IgE antibody levels support the diagnosis of intrinsic asthma	Not useful in the definitive diagnosis of intrinsic asthma
Allergic bronchopulmonary Aspergillosis (ABPA)	Normal serum IgE levels virtually exclude diagnosis	Positive *Aspergillus*-specific IgE antibody is required for the definitive diagnosis of ABPA	Precipitating IgG antibodies are required for the definitive diagnosis of ABPA
Wiskott-Aldrich syndrome	Elevated levels are commonly found in patients who exhibit eczema		
Hypergammaglobulinemia E syndrome (elevated IgE, increased susceptibility to infection and dermatitis)	Very high serum IgE levels are necessary for the definitive diagnosis of hyper-IgE syndrome		
Parasitism	Many parasitic infections produce extreme elevations in serum IgE; a very high IgE in the absence of other explanations strongly suggests the possibility of parasitism	The presence of parasite-specific IgE antibodies confirms the diagnosis of parasitism	Parasite-specific IgG antibodies confirm a present or recent parasite infection
Eosinophilia	A normal IgE level makes the diagnosis of parasitism less likely as a cause of eosinophilia; eosinophilia with normal serum IgE is a common feature of non-allergic asthma		
Allergen immunotherapy	Same as atopic disorders (above)	Specific IgE antibodies are not helpful in monitoring patients on immunotherapy and assessing its clinical efficacy	Used in *Hymenoptera* venom immunotherapy to confirm adequate immunotherapy dosages and assess relative risk for reactions on resting

in the patient's skin, some generalized skin conditions such as eczema, dermagraphism, psoriasis, and urticaria make skin testing problematic. Moreover, skin testing of children younger than 10 can be difficult. There are also occasions when skin reactivity has been suppressed by prolonged use of antihistamines and other medications that cannot be stopped prior to skin testing. In all these cases or when a characterized allergen extract is not available for *in vivo* use, *in vitro* analysis of a serum specimen for allergen-specific IgE antibody may be preferred over skin testing in the diagnostic work-up of a suspected allergic patient (6).

The immunological methods used to quantify IgE antibody levels in serum have reached an elevated state in which highly quality-controlled reagents and computer-driven autoanalyzers are widely employed for clinical testing (7). There are, however, several recent trends in IgE antibody serology analyses. First, there is an increasing use of allergenic components to detect IgE antibodies that allow identification of cross-reactivity, especially among pollen and food allergens (8). This has had a particular impact on the evaluation of patients with suspected food allergies (see chapter 84). Microarrays have been introduced into the research laboratory that semi-quantitatively detect IgE antibody in more than 100 individual allergenic components from more than 70 allergen specificities. For select food allergen specificities such as peanut, the presence and level of IgE antibody specific for signature allergic components may aid in defining the relative risk of a patient experiencing a

mild versus severe systemic reaction. As discussed earlier, the presence of IgE antibody in serum is known to be a "risk factor" for, but not a guarantee of, allergic disease manifestation (9). The use of quantitative IgE antibody measurements has expanded the use of select food-specific IgE antibody levels in making predictions about the need for a food challenge to verify an allergic versus tolerant state (10).

One area in which the laboratory has limited useful analytes involves biomarkers for identifying successful immunotherapy treatment of allergic patients that leads to tolerance. Antigen-specific IgG and IgG4 antibody levels in serum have been historically considered markers of intentional or inadvertent chronic exposure in an individual exposed to potent antigens (11). They increase following repetitive antigenic exposure in parallel with a concomitant decrease in allergen-specific IgE antibody-facilitated binding to B cells (12, 13). IgG antibodies are known to bind circulating antigen and thus block allergen from binding cell-bound IgE antibody. Unfortunately, changing levels of allergen-specific IgG and IgG4 antibodies as well as the degree of inhibition of CD23-dependent facilitated IgE antibody binding to B-cells have each failed to correlate with improved clinical symptoms following immunotherapy (14). Thus, allergen-specific-IgG and IgG4 antibody and the degree of inhibition of facilitated IgE antibody binding to B cells are not routinely assayed clinically because of the lack of a clinical indication for these measurements (Table 1).

TOTAL SERUM IgE

Of the assays historically used to measure the total level of IgE in human serum, the two-site (sandwich) immunometric (labeled antibody) assays and nephelometric assays have emerged as the principal methods of choice for clinical immunology laboratories. Of these assays, the two-site immunometric assay has become the most widely used clinical and research assay for the quantification of total serum IgE (6). The first reported noncompetitive solid-phase two-site immunometric assay used polyclonal anti-human IgE covalently bound to a solid phase (paper disks) to bind IgE from unknown and calibrated reference and control sera (15). Following a buffer wash, radioiodinated anti-IgE detected bound IgE. The amount of radiolabeled anti-IgE bound was directly related to the IgE content in the original serum. The assay displayed excellent sensitivity (as low as 0.2 ng of IgE per ml) and precision (coefficients of variation [CV] $\leq$5%), and it was minimally affected by nonspecific serum factors. Clinical laboratories currently perform one of several U.S. FDA-cleared assays for measuring total serum IgE, and all display exceptional analytical sensitivity and reproducibility, as discussed elsewhere (6, 16).

Occasionally, researchers need to measure total serum IgE using a less expensive and more flexible assay design that can accommodate unusual specimens and varying dilutions. A research monoclonal antibody-based noncompetitive solid-phase two-site immunoenzymetric assay (IEMA) is one option for investigation of total IgE levels in serum. In this assay, monoclonal anti-human IgE that has been adsorbed onto plastic wells of a microtiter plate binds IgE from the specimen, and a second monoclonal anti-human IgE clone that is labeled detects bound IgE (6). More specifically, use of murine IgM monoclonal anti-human IgE Fc capture antibody (clone HP6061) and biotinylated murine IgG monoclonal anti-human IgE Fc detection antibody (clone HP6029; EMD-Millipore, La Jolla, CA) optimizes both assay sensitivity and specificity. The assay performs best with serum, but IgE levels can also be measured in plasma, tear fluid, bronchial alveolar lavage fluid, saliva, nasal washings, and peripheral blood cell culture supernatants. Appendix A describes the generic microtiter plate-based IEMA protocol in more detail.

The World Health Organization international reference preparation for human IgE 75/502 is nearly depleted, and its replacement 11/234 is currently being validated (17). Secondary total IgE standards can be cross-calibrated against these primary standards and used in routine clinical assays. The assay regularly achieves a working range from 1 to 200 IU/ml. The analytical sensitivity of 0.5 IU/ml (1.2 μg/liter) can be achieved, and agreement among replicates and between assays is usually excellent (CV $<$ 5% and CV $<$ 15%, respectively). Parallelism is also maintained with interdilutional CVs of $<$15%. The total serum IgE IEMA can be quality controlled by inclusion of two or three well-studied sera within each assay. The quality control sera should, minimally, have a low ($<$10 IU/ml), moderate (100 to 250 IU/ml), and high level of IgE ($>$1,000 IU/ml).

When interpreting the total serum IgE levels, non-atopic percentiles are known to be age-dependent. The level of IgE in cord serum is usually less than 2 IU/ml, since IgE does not cross the placental barrier in significant amounts. Mean serum IgE levels progressively increase in healthy children until 10 to 15 years of age (3, 4). Atopic infants have an earlier and steeper rise in serum IgE levels during the early years of life compared with non-atopic controls. An age-dependent decline in total serum IgE typically occurs from the second to eighth decade of life. Individuals with total serum IgE levels above the upper 95% confidence limit often have atopic disorders such as allergic rhinitis, extrinsic or allergic asthma, and atopic dermatitis (Table 1).

ALLERGEN-SPECIFIC IgE ANTIBODY

Historically, the first-generation assay for allergen-specific IgE antibody in human serum was the radioallergosorbent test (RAST) (15). This assay employed allergen extracts immobilized on paper disks to bind specific antibody of any immunoglobulin class from serum. The solid phase was then washed with buffer and radiolabeled anti-human IgE antibody detected bound IgE. The quantity of bound radioactivity directly correlated with the quantity of specific IgE antibody in the original serum. IgE antibody results were compared with a calibrated standard reference serum, and insolubilized allergen and radiolabeled anti-IgE antibody were used in molar excess.

Over the past 50 years or so, there have been major improvements in the design and performance of allergen-specific IgE assays. Commercially available allergen-specific IgE antibody autoanalyzers are now widely used in hospital and private clinical immunology laboratories. An overview of these commercial IgE antibody assays is presented elsewhere (6, 16). These assays have in common an allergen-containing reagent (typically a solid-phase allergosorbent); a panel of reference, control, and test human sera; and a labeled anti-human IgE reagent. As of this writing, the Thermofisher Scientific/Phadia ImmunoCAP system and the Siemens Healthcare Corporation Immulite 2000 have achieved the widest use throughout the world. Tight precision around the positive/negative threshold and a more rapid, robust chemistry have been achieved with computer-controlled automation. A third assay system called HyTech-288 by Hycor Biomedical is being replaced by a new instrument that is currently in development. With clinical use comes the need to analyze quality-control sera with IgE antibody levels across the measured dose-response curve range, from 1 to 100 kUa/

liter. As many as 15 quality-control sera containing different specificities and levels of IgE antibody are randomly sprinkled throughout the assay run to investigate quality. Daily monitoring of results from these positive control sera in the form of Levey-Jennings plots verifies that the instrument is performing accurately (16).

In the United States, the FDA regulates the sale of clinically used *in vitro* diagnostic products under regulation 21 CFR 809. This includes allergen-specific IgE antibody assay reagents that are intended for human use. Some allergen extracts that have been insolubilized on allergosorbents for use in allergen-specific IgE assays have not yet been cleared by the FDA. These are currently analyzed by clinical laboratories as research reagents under an "analyte-specific reagent" classification. These allergosorbents can be used by laboratories that are qualified to perform high-complexity testing; however, a disclaimer must be stated on the report indicating that a measurement was performed with an "analyte-specific reagent." The FDA now requires that manufacturers phase out ASRs from their reagent inventory, so all allergosorbents used in the future will be FDA-cleared.

Among the newest of the IgE antibody commercial assays is the ImmunoSorbent Allergen Chip or ISAC from Thermofisher Scientific/Phadia that uses a glass slide on which more than 100 purified allergenic components from more than 70 allergen specificities are spotted in triplicate in four separate matrices (18). Serum (35 μl) is incubated on the chip for 2 hours. Following a buffer wash, IgE (IgG or IgG4) antibodies are detected using a fluorescent-labeled anti-human IgE (IgG or IgG4) reagent. This is a remarkably sophisticated technology that involves inserting the completed chip into a fluoresecent scanner and obtaining antibody results within minutes that have been interpolated from an antibody reference curve. Depending on the allergen specificity, this multiplex chip has a more limited analytical sensitivity for IgE antibody than the singleplex autoanalyzers. It also reports in semiquantitative ISU units and has the disadvantage of not containing all the relevant allergen specificities for any given allergen source material.

Researchers sometimes have need of a more versatile immunoassay to measure allergen-specific IgE antibody than is available with the principal commercial autoanalyzers. A number of polymers have been used for allergen insolubilization, including carbohydrate matrices (Sephadex, agarose, and cellulose) and polystyrene test tubes and microtiter plates. Each of these polymers differs with respect to its allergen-binding capacity, nonspecific binding properties, stability, and ease of washing. The use of a solid phase with the highest allergen-binding capacity is often needed when maximum sensitivity is required or when sera from hyperimmunized patients with high levels of allergen-specific IgG blocking antibodies are being analyzed. For suitably equipped clinical laboratories with adequate facilities for centrifugation, aspiration, and pipetting, a carbohydrate particle matrix is preferred because of its high antigen-binding capacity. Alternatively, polystyrene microtiter plates can be satisfactory with allergens that are purified proteins. Plastic solid phases, however, display selectivity and variability with limited binding capacity, which make them less than ideal for use in IgE antibody immunoassays that involve crude allergen extracts with multiple protein antigens.

One versatile research assay has been effectively used for the measurement of both IgE and IgG antibodies that are specific for crude allergen mixtures. It is a noncompetitive radioallergosorbent test that uses an agarose carbohydrate solid phase (16, 19). In this assay, protein that is present in allergenic extracts is covalently coupled to agarose using CNBr chemistry. The immobilized allergen then binds specific antibody from the human specimen. Radiolabeled anti-human IgE is then used to detect bound IgE. An alternative assay uses a microtiter plate-based enzyme immunoassay to measure IgE antibodies that are specific for purified allergenic components. IgE antibodies can be detected using the assay format in Appendix A by replacing the immobilized anti-IgE with purified allergen that has been adsorbed onto the plate. This microtiter plate-based assay is not useful for detecting antibodies to complex allergen extracts that contain multiple proteins with different pIs and molecular weights. In this enzyme immunoassay, serum (neat to 1:5) is added to allergen-coated plates, and biotin-conjugated murine anti-human IgE detection antibody is used to detect bound allergen-specific IgE antibody. As in the total IgE assay, serum is the optimal specimen. IgE anti-allergen assay responses are interpolated from a total IgE reference curve by "heterologous interpolation" (20).

In terms of quality control, the most important region of the IgE antibody assay dose-response curve, from a clinical point of view, is its minimal detectable dose. Positive thresholds can differ according to the blank subtraction and reporting methods used. Therefore, each allergen-specific IgE antibody assay should contain one or more positive and negative serum controls that span the entire working range of the reference curve. All samples should be analyzed in duplicate to document reproducibility and minimize random errors. Since the quality of each antibody measurement depends on parallelism between the dilution curves of the reference serum and test sera under study, 2 or 3 dilutions of IgE antibody-positive test serum should be periodically analyzed to confirm assay parallelism.

Federally licensed clinical laboratories that perform allergen-specific IgE antibody assays are required to participate in an external proficiency testing program. The College of American Pathologists conducts the Diagnostic Allergy "SE" Survey, which submits five sera in each of three cycles per year to participating laboratories (7). The laboratory is required to analyze each serum, for a total serum IgE and IgE antibody to five allergen specificities that cycle among the weed, grass, and tree pollens; pet epidermals; molds; occupational allergens; and food allergens. Results are submitted to the survey's coordinating center, and performance of a participating laboratory is judged in relation to its peers that use the same assay.

The presence of allergen-specific IgE antibody in serum does not directly indicate allergic disease without a positive history (9). A positive IgE antibody result does indicate that the individual is sensitized to that allergen specificity and has an increased probability (or risk) of experiencing allergic symptoms if exposed to that allergen. The relative quantity of IgE antibody in serum may, but does not always, correlate with the relative risk of severe symptoms. The association between antibody quantity and allergic symptoms can be confounded by many variables, including the IgE antibody's affinity, the presence of IgG-blocking antibodies, and most important, the relative biochemical sensitivity, or "releasibility," of the subject's IgE-laden effector cells. Thus, IgE antibody is necessary but not sufficient for expression of allergic disease symptoms. For many food-, drug-, and insect venom-related allergies, only about half of individuals with IgE antibody react clinically when challenged. IgE results must therefore be carefully integrated with clinical history-based information for proper diagnostic interpretation.

ALLERGEN-SPECIFIC SERUM IgG AND IgG4 ANTIBODIES

Allergen-specific IgG and IgG4 antibodies are measured as research analytes to assess the status of the individual's humoral immune response to systematic exposure through immunotherapy or inadvertent accidental natural exposure. The levels of specific IgG antibodies are generally low (e.g., <1 ng/ml) or non-detectable in an unimmunized individual who has been naturally exposed to clinically important antigens (e.g., aeroallergens from weeds, grass, and tree pollens; dust mite, mold; and animal epidermal antigens). The analytical sensitivity and specificity of an IgG antibody assay that is used to assess these sera therefore becomes important because nanogram-per-milliliter levels of specific IgG must be measured in the presence of mg/ml levels of nonspecific IgG. In contrast, individuals who have received injections of an antigen, either by accidental exposure (e.g., bee sting, drug injection) or by active allergen immunotherapy, can produce high microgram-per-milliliter levels of specific IgG. At these levels, nonspecific binding and assay sensitivity become less critical, and assay parallelism, precision, and accuracy and human antibody standards become the focus of assay design.

The non-isotopic microtiter plate and monoclonal antibody-based enzyme immunoassay that has been described in Appendix A for total and allergen-specific IgE can be used to detect IgG antibodies specific for purified allergens. Although a crude aqueous extract can also be used as an antigen source, it contains many irrelevant proteins that readily adsorb onto plastic surfaces. In doing so, these occupy limited sites on the plastic surface that can be used to bind more relevant protein antigens. While serum is the specimen of choice for this assay, plasma and other body fluids (e.g., bronchial alveolar lavage, tears, nasal secretions) can be tested if the appropriate negative controls are analyzed in the same assay to identify the level of nonspecific binding.

The IgE ELISA procedure in Appendix A must be modified to allow the detection of IgG antibodies. This is accomplished by adsorbing purified antigen at 10 ug/ml in phosphate-buffered saline (PBS) (10 μg/ml, 0.1 ml/well) on the plate instead of anti-human IgE. After the buffer wash and blocking, 0.1 ml of antigen-specific IgG-containing reference, control, and test sera (diluted at least 1:50 in PBS-1% bovine serum albumin [BSA]) is added to their respective wells. Following a PBS-Tween buffer wash, horseradish peroxidase-conjugated/conjugated mouse anti-human IgG Fc (HP6043-HRP; EMD Millipore Corp., La Jolla, CA) is added (0.1 ml per well, 1 μg/ml in PBS-1% BSA). The plates are then processed in a similar manner, and response data is interpolated from the IgG anti-antigen reference curve.

The typical working range of the IgG antibody assays is 10 to 2,000 ng of specific IgG per ml. Both the sensitivity and working range of these assays are dependent on the density of the antigen on the solid phase, the dilution and affinity of the detection antibody, duration of the serum, conjugate and substrate incubations, and the relative amount of specific antibody of other isotypes (e.g., IgE, IgA, IgM) that compete for available solid-phase antigen epitopes. Parallelism between the reference and test serum dilution curves remains good over the working range of both assays, with interdilutional CVs typically <20%. The CV for within-experiment replicates typically averages 5%, and the CV for results between assays when all reagents remain constant should be 10% to 15%.

In terms of quality control, the minimum detectable concentration of the assay varies as a function of the negative serum subtraction and reporting methods used. Therefore, each assay should contain one or more positive and negative serum controls in addition to the reference serum dilution curve. All samples should be analyzed in duplicate to minimize systematic (procedural) and random errors. At present, there are no external proficiency surveys for assays that monitor allergen-specific human IgG antibody assays.

An IgG antibody measurement is commonly performed to document an exposure of an individual to an immunizing dose of antigen and to follow changes in antibody levels with long-term exposure. In select cases, it can serve as an indicator of the effectiveness of various antigen doses that are used to induce a specific IgG antibody response during immunotherapy. In research applications, specific IgG antibody levels are used to quantitatively monitor humoral immune response to an antigen to which a patient has been accidentally or intentionally exposed.

In the 1930s, allergen-specific IgG antibodies were identified as "blocking antibodies" that could block transfer of reaginic activity in the Prausnitz-Kustner reaction and basophil leukocyte histamine release assays. Presently, the only cited clinical application for IgG antibody measurements in the field of allergy is their use in the evaluation of Hymenoptera venom-allergic patients who are initiating venom immunotherapy or who have been receiving maintenance injections for a number of years. In a 1992 study (11), 211 insect sting challenges were performed in 109 patients over a 4-year period to investigate the clinical significance of venom-specific IgG levels. In individuals on immunotherapy for fewer than 4 years, systemic symptoms occurred in only 1.6% of individuals with venom-specific IgG levels greater than 3.5 μg/ml but 16% of individuals with levels lower than 3.5 μg/ml. The venom-specific IgG level had no predictive value for risk in patients who received therapy for more than 4 years. This study concluded that venom-specific IgG levels of <3.5 μg/ml were associated with an increased risk of allergic reactions upon resting during the first 4 years of immunotherapy with yellow jacket or mixed-vespid venoms. Other published studies of IgG antibody levels in patients receiving ragweed, grass, and dust mite immunotherapy have remained research observations that relate the antigen exposure to IgG (humoral) immune responses.

CONCLUDING THOUGHTS

In summary, the diagnostic allergy laboratory employs a number of immunoassay methods to quantify the levels of IgE and IgG antibodies in serum that can aid the clinician in the diagnosis and management of individuals with allergic disease. At present, there are no molecular biology techniques explicitly used by allergy laboratories to facilitate the diagnosis of allergic disease. Recombinant DNA technology to date has only been used in the generation of recombinant allergenic proteins that have become incorporated as component reagents in both the singleplex assays and multiplex microarray ISAC assay for IgE and IgG antibody. The laboratory analyses of allergen-specific IgE antibodies in serum identify a state of sensitization in support of a clinical history-based diagnosis of allergic disease, while allergen-specific IgG antibodies indicate antigenic exposure.

APPENDIX A

Total serum IgE IEMA procedure

The IEMA has been designed to balance good performance with a reasonable turnaround time.

1. Plastic 96-well microtiter plates are coated for 1 hour at room temperature (RT; ~23°C) and then overnight at 4°C with mouse

IgM monoclonal anti-human IgE Fc (clone HP6061, 100 μl/well) that has been diluted in PBS to 10 μg/ml just prior to use.

2. Each plate is washed once with PBS-Tween, and 0.3 ml of PBS-1% BSA is added to each well to block unreacted sites.

3. After a second wash (4x) with PBS-Tween 20, 0.1 ml of reference, control, or test serum is added to their respective wells. The standard curve is composed of 8 to 10 two-fold dilutions in duplicate of a reference serum, beginning with a concentration of 100 kIU/liter (1 IU of IgE = 2.4 ng). The plates are then incubated for 2 hours at 23°C. Two or three dilutions of high, medium, and low serum controls are analyzed in different regions of the plate to demonstrate that the assay is in control. The total IgE levels in the reference serum should be calibrated against the second WHO human IgE international reference preparation (IRP) 75/502 or the new third IgE IRP 11/234, which is currently being validated.

4. Following a PBS-Tween buffer wash (4x), biotin-conjugated mouse IgG anti-human IgE Fc (clone HP6029) is added (0.1 ml per well, 1 μg/ml in PBS-1% BSA), and the plates are incubated for 1 hour at 23°C.

5. The plates are washed with PBS-T buffer, strepavidin-horseradish peroxidase (avidin HRP) is added (0.1 ml per well, 1 μg/ml in PBS-1% BSA), and the plates are incubated for 1 hour at 23°C.

6. Plates are washed, and 0.1 ml of substrate is added. For routine analysis of human sera, 1 mM ABTS is prepared in 70 mM citrate-phosphate buffer. Immediately prior to use, 1 μl of 30% hydrogen peroxide is added per ml of ABTS required. The substrate is immediately pipetted into the plate (0.1 ml/well).

7. The peroxidase enzymatic reaction is stopped by adding 0.1 ml/well of 2 mM sodium azide when the top point on the standard curve reaches 1.5 to 2.0 OD. The plate is read on a microtiter plate reader at 410 nm, and optical densities of the unknown sera are interpolated from the standard curve in kIU/liter.

Note: This assay can be converted into an allergen-specific IgE, IgG, or IgG4 antibody assay by replacing the capture anti-human IgE reagent adsorbed to the microtiter plate with allergenic protein. Second, a monoclonal detection antibody with specificity for human IgE (HP6029-biotin), human IgG (HP6043-biotin), or human IgG4 (clone HP6023-biotin) needs to be used to detect IgE, IgG, or IgG4 antibodies, respectively. These monoclonal antibody reagents are available from EMD-Millipore, La Jolla, CA.

Assay Methods for Measurement of Mediators and Markers of Allergic Inflammation

JOHN T. SCHROEDER, R. STOKES PEEBLES, JR., AND PAMELA A. GUERRERIO

83

Assays facilitating the measurement of mediators and markers of allergic inflammation have evolved during the past 40 years, arising from two primary discoveries: first, that immunoglobulin E (IgE) is the source of reaginic activity in serum, and second, that tissue mast cells and blood basophils—cells expressing the high-affinity receptor for IgE (FcεR1)—respond to allergen by releasing the most relevant mediators underlying immediate hypersensitivity reactions. Naturally, skin testing has long been used to assess the *in vivo* mast cell response to allergen. Basophils, however, by virtue of their accessibility and the fact that they are the sole source of many of these mediators among blood leukocytes, continue to dominate the performance of *in vitro* assays assessing IgE-mediated responses.

Histamine and leukotriene C_4 (LTC4) have potent vaso- and bronchoconstrictive properties and represent two classes of mediators released by mast cells and basophils that have long been at the core of assays used to assess allergic inflammation. Cytokines represent a third class of mediator released from cells expressing FcεR1, but unlike histamine and LTC4, they are generated *de novo* (1). In particular, human basophils secrete copious amounts of interleukin-4 (IL-4) and IL-13—arguably the two most important cytokines in allergic disease, given the primary role of these cytokines in regulating IgE synthesis from B cells. The importance of this has only recently been appreciated, with evidence that basophils *in vivo* are, indeed, a major source of this cytokine (2). Also, the activation-linked markers CD63 and CD203c continue to be popular as flow cytometry-based assays used as surrogate indicators of basophil degranulation and mediator release. Therefore, it has been the objective of this chapter during the last three editions of this manual to focus on the laboratory procedures commonly performed for measuring the release of these inflammatory mediators, both *in vitro* and in biological fluids. Rather than concentrating in detail on procedures that have changed little during the course of three decades, this chapter instead focuses more on recent approaches for measuring, for example, histamine, LTC4, cytokines, and markers but refers to previous editions when specific details are deemed necessary. Likewise, the assays used for the detection of tryptase (a mast cell product) and major basic protein (MBP, a product of eosinophils) have also changed little during the past 15 years or so and therefore are mentioned only briefly. Instead, some discussion of more novel cellular assays utilizing dendritic cells (DC) to assess the allergic condition is included. Of note, while several technical advances have made these *in vitro* detection assays more applicable for clinical use, some of these methods remain time-consuming and are presently useful only in specialized clinical situations or for research purposes.

While these types of *in vitro* assays provide an important means to evaluate the mechanisms and pathways that regulate allergic inflammation, a number of complementary *in vivo* assays are routinely used to facilitate the diagnosis and management of patients with allergic disease. Most of these assays are based on the simple idea of challenging subjects with antigenic material to reproduce a biological response. Prick-puncture and intradermal skin testing represent the most common methods for diagnosing immediate hypersensitivity to aeroallergens, food, venom, and medications in the clinic, while intranasal and whole-lung challenges are often used in the research setting to evaluate end-organ allergen sensitivity as it relates to clinical symptoms.

HISTAMINE

Commercial and Laboratory Assays

Commercial assays for measuring histamine have become mainstream compared with other approaches, such as the automated fluorometric technique. However, this shift has been driven by availability rather than dependability and ease in performance. For instance, an enzyme immunoassay (EIA) and an enzyme-linked immunosorbent assay (ELISA) are offered by Cayman Chemicals and Immuno-Biological Laboratories, respectively, for the detection of histamine in a variety of biological specimens, including culture supernatant, urine, and plasma. These assays are sensitive, do not require specialized equipment, require small sample volumes (e.g., 0.050 to 0.100 ml), are less affected by high-protein contamination than automated fluorometry (see below), and are cost-effective for low-throughput needs. On the other hand, their dynamic range (~20–1.000 pg/ml) remains quite limited compared with the flurometric approach (~0.5–100 ng/ml), which is less appealing when measuring histamine released from leukocyte/basophil suspensions.

The fluorometric approach was first automated in the mid-1970s, making it possible to analyze 45 to 60 samples per hour with today's machines. The chemistry behind the assay is described elsewhere (3). Briefly, histamine is first

doi:10.1128/9781555818722.ch83

extracted from the specimen and is coupled with ophthalaldehyde (OPT) using *n*-butanol from a salt-saturated, alkalinized solution to form a fluorescent product. Samples tested must be relatively free of protein and other interfering compounds such as histidine. Before the condensation step with OPT, histamine is back extracted into an aqueous solution of diluted HCl by adding heptane. The histamine-OPT complex is stable at an acid pH, which increases the fluorescence intensity of the compound. The chemicals utilized require that proper ventilation be used to house the machine. Relatively larger sample volumes (0.6 to 1.0 ml) are also required. The major advantage of automated fluorometry over other systems is its ability to rapidly process, with reproducibility and ease, a large quantity of samples, making it the method of choice when assaying histamine released from basophil or mast cell suspensions. It has also been useful for determining levels of histamine released at sites of experimental allergen challenge in the nose, lung, and skin by assaying fluids from lavages performed with normal saline. Fluorometric measurement of histamine in whole blood and in serum at concentrations greater than 10% requires extensive acid precipitation and/or dialysis to remove protein, cumbersome manipulations that lead to a loss of assay sensitivity.

The radioenzymatic assay (REA), which involves the transfer of ^{3}H- or ^{14}C-labeled methyl groups from *S*-adenosylmethionine to histamine by using the enzyme histamine *N*-methyltransferase, is essentially no longer used in measuring histamine. While highly sensitive in detecting histamine (10 pg/ml) and not interfered by high protein, the assay is rather cumbersome, requiring a series of extractions and back extractions that are not automated as in the fluorometric approach. The assay also requires a source of histamine *N*-methyltransferase, which is typically derived from crude extracts of rat kidney (Pel-Freez, Rogers, AR). The assay is relatively time-consuming and lacks the reproducibility achieved with the automated fluorometric system. Presently, one must also establish this assay in-house, since greater appeal of the ELISA and EIA have diminished the commercial availability of the REA.

The standards used in the fluorometric assay are made from stock solutions prepared by accurately weighing an appropriate amount of histamine dihydrochloride (see Appendix). Standard solutions are stable at 4°C when diluted in water containing 2% $HClO_4$. Commercial EIA and ELISA kits come with standards and should use diluent best representing the samples to be tested but in the absence of $HClO_4$, which interferes with the assay.

Clinical Indications for Measuring *In Vitro* BHR

Measurement of *in vitro* basophil histamine release (BHR) continues to serve as a valuable test for evaluating IgE-mediated reactions. In fact, the indications for the use of this method remain more extensive than those for any other *in vitro* test described in this chapter. Yet, because the parameters involved in the histamine release assay are extensively described in previous editions of this book, they will be mentioned only briefly here.

Evaluation of Allergic Status

In vitro BHR can serve as a dependable and precise indicator of the allergic status of an individual, with few false positives compared with skin-testing techniques. Nonetheless, the presence of allergen-specific IgE is not sufficient and must be combined with the clinical history to indicate the presence of disease, given the widespread prevalence of IgE specific to insect venoms, latex, and food allergens. Since many dilutions of an antigen can be tested for reactivity, the BHR assay can also be more quantitative than skin testing, which often relies on a somewhat less precise endpoint. Basophil analyses can be performed safely using "crude" allergens and products not yet approved for *in vivo* use. However, any clinical applicability is limited to a positive assay result, since *in vitro* BHR does not necessarily predict a negative skin test reaction. Due to the complexities of the assay, direct measures of specific IgE rather than histamine release are more commonly used in clinical practice (see chapter 82, this volume).

Demonstration of IgE Antibody Activity

Measuring BHR from normal donor leukocyte suspensions passively sensitized with IgE is a useful technique for detecting allergen-specific antibody in the sera (or plasma) of patients presenting with clinical symptoms (6). In fact, BHR has some advantages over the more commonly used serological assays used in the detection of allergen-specific IgE. First, it gives a quick and precise assessment of whether serum contains biologically active IgE. The serological assays for IgE antibody, although more easily standardized, simply quantify the amount of IgE antibody in serum. Second, very little antigen is often required to induce BHR. In contrast, the serological assay reagents require relatively larger quantities of allergen in order to be successfully bound to an insoluble matrix for subsequent binding of allergen-specific IgE from serum. Third, the BHR assay is excellent for studies investigating, by direct analysis and after passive sensitization, whether a patient has become sensitized to an uncommon allergen for which serological assay methods are not available. A disadvantage of these assays is their requirement for fresh leukocytes from a nonallergic subject whose cells can withstand the rigors of passive sensitization (see below) and retain responsiveness.

Quality Control of Prepared Allergens

It is often desirable to check the quality of allergens, whether commercially prepared or made in-house, by testing their ability to induce histamine release from leukocytes obtained from allergic donors. This is becoming particularly useful for immunotherapy studies for which modified allergens can be evaluated for biological activity or cross-reactivity prior to being used *in vivo*.

Alternative for Skin Testing

In some instances, it is desirable to avoid skin testing and to use the *in vitro* BHR assay as an alternative approach for evaluating allergic status. However, given the wide use of serological methods for detecting allergen-specific IgE, this particular indication is rarely practiced.

Test Procedures

Induction of Histamine Release from Washed Human Leukocytes: General Method

While there are presently many variations of the protocol originally described for inducing histamine release from basophils *in vitro*, these relate primarily to the method used for histamine analysis. Otherwise, little has changed in the 40 years since its first description (4). The reader is therefore directed to previous editions of this book for specific details, as this section emphasizes only certain aspects of the assay. Also, the techniques described herein are, for the most part, used when histamine is analyzed by automated fluorometry.

Blood is drawn into a plastic syringe, preferably by using a butterfly infusion set with the needle size reflecting the

desired volume required for the assay. Usually, 1 ml of blood per reaction tube provides total histamine levels of approximately 20 ng, with some variation occurring among donors. Dextran sedimentation remains the method of choice for preparing washed leukocytes for histamine release, as it requires little technical expertise and is the least manipulative of the cells. These issues are necessary to consider when both preparation time and retention of cell function are of greatest importance. In this instance, whole blood is immediately transferred into disposable 50-ml polypropylene centrifuge tubes (catalog no. 25330; Corning Incorporated, Corning, NY), each containing 12.5 ml of dextran, 5.0 ml of 0.1 M EDTA, and 375 mg of dextrose, which allows proper mixing for up to 20 ml of blood. After sitting for 60 to 90 min at room temperature (23 to 25°C), the leukocyte-rich plasma layer is carefully removed and centrifuged and the cell pellet is washed two or three times in PIPES [piperazine-*N*,*N*′-bis(2-ethanesulfonic acid)]-albuminglucose (PAG) buffer (see Appendix) to remove platelets. It is sometimes useful to do one or more washes in PAG containing EDTA (~4 mM), since this reagent chelates calcium and prevents platelet clumping. However, it is important that the final wash be done in the absence of EDTA, since histamine release requires calcium, and residual EDTA may prevent the reaction cascade. After the final wash, the cell pellet is resuspended in PAG buffer containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$ (PAGCM) to a volume sufficient to allow the addition of the required amount of cells to each reaction tube, as per the protocol. Histamine release can be induced in almost any variety of test tube, but total reaction volumes usually range from 0.1 to 1.0 ml. The washed leukocytes in PAGCM and the reaction tubes are then warmed separately in a 37°C water bath before mixing with one another. The total histamine content (called "completes") is obtained by the lysis of cells in a duplicate set of reaction tubes using perchloric acid at a final concentration of 1.6%. The amount of histamine released spontaneously (usually less than 5% of the total) is determined by incubating cells in buffer alone. Reactions are allowed to proceed at 37°C for 30 to 45 min, at which time buffer is added to a 1-ml total volume, the cells are centrifuged, and the cell-free supernatants are decanted into 2-ml autoanalyzer cups (catalog no. 73.641; Sarstedt, Inc., Princeton, NJ) and stored at 4°C in plastic racks (Elkay Products Inc., Shrewsbury, MA). To prevent evaporation, samples should be frozen at −20°C if histamine cannot be analyzed within 2 weeks. Any samples requiring added protein during the reaction may require acid precipitation in order to prevent interference with histamine measurements using the automated fluorometric technique. In such instances, much of the protein can be precipitated prior to analysis by adding perchloric acid to the cell-free supernatant at a final concentration of 1.6%, incubating overnight at 4°C, and recentrifuging prior to analysis. Alternatively, histamine can be measured using either the REA or ELISA.

Inhibition of Histamine Release from Basophils

Inhibition of the standard BHR assay can be useful in monitoring whether a patient's serum contains an allergen-neutralizing blocking antibody (e.g., IgG antibody), as often happens during the course of immunotherapy (6). However, the assay has largely been replaced by immunoassays that directly measure specific IgG antibody. The reader is therefore directed to previous editions of this book for specific details of this assay. Although its clinical utility is somewhat limited, the inhibition of *in vitro* BHR is often used to determine the effectiveness of pharmacologic agents. This test also involves a modification of the standard release assay but differs slightly from that used in measuring IgG antibodies. In brief, washed leukocytes are mixed with PAGCM alone or with several concentrations of the drug diluted in buffer. Final drug concentrations of 10^{-4} M to 10^{-6} M are useful for initial screening. After preincubation (usually for 10 to 15 min) at 37°C, several concentrations of an allergen (or anti-IgE antibody) are added for an additional 45 min to induce BHR. Once again, it is best to use stimulus concentrations that cause roughly half of the maximal histamine release. In addition to the usual controls (completes and blanks), it is important to include cells incubated with drug alone to assess any lytic effects, as well as drugs diluted in buffer (no cells) to control for fluorescent compounds if the OPT-based assay is used.

Passive Sensitization of Basophils

The basophils isolated from some donors express sufficient numbers of unoccupied FcεR1 sites to enable these cells to be passively sensitized with IgE antibody from an unrelated source. Thus, the serum or plasma of an allergic individual can be tested for antigen-reactive IgE antibodies by sensitizing the basophils of a nonallergic donor and inducing BHR from these cells by using the antigen in question. The success of studies using this technique requires the use of nonallergic donors whose basophils normally release well in response to IgE-dependent stimulation and whose cells have naturally unoccupied FcεR1 sites that can be passively sensitized with IgE antibody. Since only an estimated 1 out of 20 nonallergic individuals has basophils that meet these criteria, lactic acid is often used to remove endogenous basophil-bound IgE, thereby increasing one's ability to passively sensitize cells. In fact, the details of performing this procedure are outlined elsewhere (6) and are also described in previous editions of this chapter. As a result, it seems appropriate to note here only a few considerations, since the reader can refer to the above-mentioned references for specific information. First, these assays are best done using mixed leukocytes containing basophils. The lactic acid solution (pH 3.9) can be used effectively at room temperature (25°C) or on ice (4°C) for as long as 5 min. However, only partial removal of IgE is expected when performed on ice and with shorter treatment times. Treated cells are immediately washed to remove unbound IgE before passive sensitization (30 min at 37°C) with an appropriate dilution of patient serum in PAG containing 10 U of heparin/ml and 4 mM EDTA. An important negative control includes acid-treated cells sensitized with an equal amount of irrelevant IgE in control serum. It is also important to leave a portion of cells untreated with acid solution in order to control for any effect this treatment may have on basophil responsiveness. After washing twice in PAG buffer, the leukocytes are tested for histamine release by using identical test conditions. The antigen-induced release of histamine by leukocytes passively sensitized with the patient's serum, but not with control serum, indicates positivity. Of course, non-passively sensitized cells should not react with the antigen, while cells subjected to all conditions of passive sensitization should still respond to anti-IgE used as a positive control.

LIPID MEDIATORS

Leukotriene C4

The secretion of LTC4 by basophils and mast cells is also rapid, nearly paralleling the release of histamine, and is essentially complete by 30 min after activation. IL-3 enhances LTC4 levels generated by basophils in response to

IgE-dependent activation by nearly 100-fold, and following IL-3 priming, release of LTC4 occurs with stimulation by C5a, a secretagogue that alone does not normally cause the release of this mediator. Essentially no release of prostaglandins from basophils occurs in response to activation, indicating that cyclooxygenase enzyme activity is not prominent in these cells. However, all human mast cells studied to date do produce prostaglandin D_2 (PGD2), and lung and mucosal cells secrete levels of LTC4 nearly identical to those secreted by basophils but usually only in response to IgE-dependent stimuli.

While competitive RIAs have long been used in detecting LTC4 (and PGD2), their requirement for radioactive isotopes and cumbersome protocols have given way to commercial ELISA kits (Assay Designs and Cayman Chemicals). These assays are also generally quite sensitive (~50 pg/ml) and exhibit only slight cross-reactivity with LTD4 and LTE4.

Clinical Indications

Evaluation of Allergic Status

LTC4 is generated from several cell types, including monocytes and eosinophils. However, the formation and secretion of this mediator from washed leukocytes can serve as an *in vitro* test of allergic status, since the basophil is the only cell in these preparations that responds to IgE-mediated stimulation. In practice, however, since histamine is released in parallel with LTC4 and the assays for measuring it are less cumbersome and more reliable, histamine is more often used as an index of allergen sensitivity. Nonetheless, measurements of LTC4 in biological specimens may be useful in assessing the inhibitory actions of the 5-lipoxygenase inhibitors, which do not affect histamine release.

Test Procedures

Washed leukocytes are prepared from peripheral blood using dextran sedimentation, as described above for BHR; LTC4 and histamine release are assessed simultaneously. However, the reactions are done in a total volume of 0.1 ml in PAGCM buffer. PAG buffer (0.2 ml) is added to all tubes at the end of the reaction, and after centrifugation, a portion of the supernatant (0.1 ml) is carefully removed for LTC4 analysis. An additional 0.5 to 0.8 ml of PAG buffer is then added to the reaction tubes, and following recentrifugation, the supernatant is obtained for histamine analysis by automated fluorometry, as described above. By measuring the release of these two mediators from the same aliquot of cells, the LTC4 levels can be normalized to the amount of histamine released (i.e., picograms of LTC4 per nanograms of histamine).

CYTOKINE GENERATION BY BASOPHILS

Evidence has emerged during the past 20 years showing basophils to be an important source of cytokines that are essential for allergic inflammation (1). In particular, basophils secrete IL-4 and IL-13—two cytokines critical in promoting IgE production from B-lymphocytes, activating endothelium for the selective adherence and transendothelial migration of eosinophils, and promoting development of the Th2 phenotype. The parameters important for the generation of these cytokines in basophils indicate that both proteins, much like histamine, are important correlates of immediate hypersensitivity. Both IL-4 and IL-13 are secreted following IgE cross-linking, and the concentration of a stimulus required for optimal release is nearly 10-fold less than that necessary for histamine release. IL-4 protein levels peak after 4 to 6 hours of activation, with IL-13 secretion being somewhat slower, beginning at about 4 hours and peaking after some 20 hours of incubation. The generation of both cytokines is inhibited by the addition of cycloheximide, suggesting that their production occurs *de novo* and that neither is stored and released during degranulation or produced minutes following stimulation, as is true for histamine and LTC4.

Clinical Indications for Measuring *In Vitro* Basophil IL-4 and IL-13 Secretion

The clinical indications for measuring IL-4 and IL-13 are much the same as those described for measuring BHR. Indeed, basophil cytokine production shows increased sensitivity to IgE-mediated stimulation and is somewhat specific for this type of activation: C5a and *N*-formyl-methionyl-leucyl phenylalanine (FMLP), which are potent stimuli for histamine release, do not normally induce IL-4 and IL-13. Basophils from allergic subjects have been shown to secrete greater levels of IL-13 in response to IL-3 compared with those from non-allergic individuals (7). This response is particularly evident following allergen exposure (8, 9). Overall, these findings suggest a novel indication for measuring basophil secretion of cytokines (particularly IL-13), since these cytokines are observed in the absence of BHR and may also be indicative of underlying systemic Th2-like responses occurring as a result of allergen exposure. Nonetheless, the clinical applicability of measuring IL-4 and IL-13 remains less than that of measuring BHR, since measuring these cytokines is time-consuming and requires multiple assay systems.

IL-4 and IL-13 Protein: Methods of Cytokine Detection

Measurements of IL-4 and IL-13 protein are most often done by ELISA, and many sources of commercial kits (or matched antibodies to make in-house plates) now exist with assay ranges of 1 pg/ml to 1 ng/ml. Since protocols described elsewhere in this manual are devoted to ELISA design, specific details will not be belabored here other than to make some general comments. First, when quantifying IL-4 and IL-13 protein by ELISA (as with any protein ELISA), problems may arise with inter-assay variation. This is particularly true since many assays, including commercially available kits, are supplied with standards that typically give different results among assays. It is important, therefore, to calibrate in-house standards against a variety of other available standards, ideally those set by World Health Organization specifications.

It has become increasingly popular to monitor cytokine generation at the single-cell level by using multicolor flow cytometry. The technique requires the inclusion of a protein transport inhibitor, such as brefeldin A (1–10 μg/ml), which is added to cell cultures during stimulation to prevent the secretion of cytokines from activated cells. Intracellular cytokines are subsequently detected in paraformaldehyde (4%)-fixed, detergent (e.g., saponin, 0.1%)-permeabilized cells using fluorescence-conjugated antibodies. With the use of a two-color staining protocol, basophils account for most of the IL-4 and IL-13 produced in peripheral blood mononuclear cell suspensions following *in vitro* stimulation with an allergen (10). While multicolor flow cytometry has significant potential as an analytical technique for monitoring cytokine generation in specific cell types, particularly those found in low frequencies, its success depends on antibodies

that are compatible with fixation and permeabilization. These steps are necessary in allowing intracellular access by fluorescence-conjugated antibodies. These procedures, however, can often affect antigenic binding sites, making cytokines unrecognizable by antibodies (particularly those monoclonal in nature) that would ordinarily detect native protein. When antibodies do stain, it is important to establish specificity by performing neutralization experiments with unlabeled antibody.

Preparation of Basophil Suspensions for Cytokine and/or Mediator Release

Enriched Suspensions

Basophil-enriched suspensions are prepared by density centrifugation on isotonic Percoll gradients to allow simultaneous assessment of cytokine secretion and histamine release. For IL-4 and IL-13 production, 5 ml of blood per reaction tube, approximately five times the amount required for histamine release, is anticoagulated with 10 mM EDTA. The plasma layer, obtained following centrifugation (300 × *g*; 15 min; 24°C), is aspirated without disturbing the leukocyte interface (buffy coat). The buffy coat interface is then removed and transferred into a tube containing an equal volume of PAG-EDTA buffer (approximately 20 ml of buffy coat per 50 ml of whole blood). Diluted buffy coat (20 ml) is then layered onto gradients consisting of 12.5 ml of 55% isotonic Percoll (approximate density, 1.072 g/ml) underlaid with 12.5 ml of 61% isotonic Percoll (d ≈ 1.082 g/ml), as illustrated in Fig. 1. Note that an alternative to performing this "double Percoll" approach is the simple use of the 61% Percoll solution for a "single Percoll" protocol. While this typically results in a basophil purity of less than 3%, it adequately removes excessive red cells, producing a leukocyte suspension suitable for investigating cytokine expression by flow cytometry. In any case, the gradients are centrifuged (700 × *g*; 20 min; 24°C). The cells banding at the 55% Percoll interface and penetrating the top half of this layer are removed and discarded. Basophils are present in the fraction consisting of the lower half of the 55% Percoll layer, the 61% interface, and the upper half of this layer. These leukocytes are immediately transferred into clean tubes containing 35 ml of PAG-EDTA buffer and centrifuged (150 × *g*; 10 min; 24°C). After combining and transferring the cells into 15-ml polypropylene tubes, the cells are washed twice in cold PAG (6 to 10 ml per wash). The mean percentage of basophils found in these fractions ranges from 5% to 50% (using the double Percoll approach), as determined by cell counts in Spiers-Levy chambers using alcian blue (11). Of note, these enriched suspensions allow concurrent analysis of multiple mediators within the same culture/tube simply because more total cells can be added without overcrowding, which is harder to do the more impure the suspension. When warranted, enriched suspensions also facilitate basophil purification by negative selection using commercial kits (e.g., Miltenyi Biotec, StemCell Technologies). And, while the need for pure basophil suspensions is often not necessary in assessing mediator release and cytokine secretion, having this technology enables testing of substances that potentially have a direct effect of function.

Culture Procedure

For cytokine protein secretion from basophils, leukocytes obtained directly or from Percoll gradients are resuspended in a culture medium such as Iscove's modified Dulbecco's medium, pH 7.4, supplemented with 5% heat-inactivated (56°C for 30 min) fetal bovine serum, nonessential amino acids, and 5 μg of gentamicin per ml (C-IMDM). For simultaneous analysis of histamine release and IL-4 protein secretion, basophil-enriched suspensions are prepared on Percoll gradients, and 100,000 to 200,000 basophils, accurately enumerated by counting of alcian blue-stained cells, are added per well in a 96-well microtiter plate. The cells are added in 125 μl of C-IMDM and are brought to 37°C in a CO_2 incubator (5% CO_2), after which 125 μl of C-IMDM with or without a stimulus (e.g., a specific antigen) at 37°C is added for a 4-hour incubation. The cultures are then centrifuged, and the cell-free supernatants are collected for analysis. A portion of the supernatant is obtained for histamine measurement by carefully removing the upper 25 to 50 μl of supernatant and adding this to 1 ml of PAG buffer containing 1.6% $HClO_4$. After precipitation of protein overnight at 4°C, the histamine in the samples is measured by automated fluorometry (note: histamine measurements

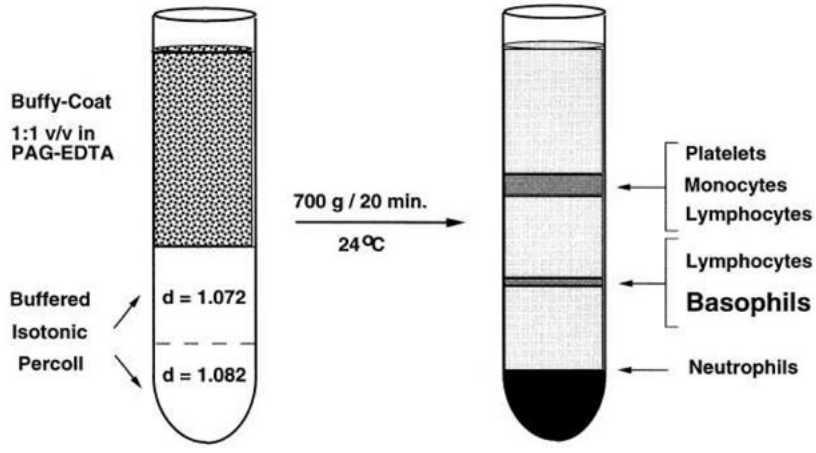

FIGURE 1 Diagrammatic representation of preparation of peripheral blood basophils by discontinuous Percoll density centrifugation. Leukocyte interface cells (buffy coat) are prepared from whole blood by centrifugation. Diluted buffy-coat cell suspensions are layered onto buffered isotonic gradients consisting of two Percoll densities (d) of 1.072 and 1.082 g/ml. Following centrifugation (700 × *g*, 20 min, at 24°C), basophils band on the 1.082-g/ml Percoll interface and range from 5 to 50% purity. v/v, vol/vol.

using ELISA must be free of $HClO_4$). Histamine release is reported as a percentage of the total histamine, which is measured by taking a portion of the starting leukocyte suspension, containing a number of basophils proportional to the amount of supernatant used for analysis, for direct lysis in 1 ml of acid solution. The supernatant remaining is then collected for IL-4 protein analysis by ELISA.

The conditions necessary for IgE-dependent secretion of IL-13 are essentially the same as those important for IL-4 secretion, with the only difference being that detection of the former cytokine requires an 8- to 20-hour incubation. Thus, the protocol described above for IL-4 also applies to IL-13 secretion, with the exception that longer incubation times are required.

BASOPHIL SURFACE ACTIVATION MARKERS: CLINICAL INDICATIONS

The so-called basophil activation markers (BAM), CD63, CD69, and CD203c have been put forward as surface markers that are sensitive to basophil activation after exposure to an allergen (CD63 and CD203c), exposure to IL-3 (CD69), or exposure to other degranulation stimuli such as FMLP and ionophores. In particular, the commercially available basophil activation test (BAT) reportedly assesses IgE-dependent activation of basophils *in vitro* by monitoring for the increased expression of CD63—a surrogate marker for BHR. This flow-based assay has become widely used, particularly in evaluating drug, food, and venom hypersensitivities. Likewise, CD203c (ectonucleotide pyrophosphatase/phosphodiesterase family member 3) is a marker of blood basophils in which increased expression was recently shown to associate both in food allergy and asthma (12, 13). The use of these activation markers as part of diagnostic evaluation of the presence of allergic reaction-specific IgE has been reported. However, several questions remain as to the specificity of these markers for diagnostic testing with specific allergens (14). As apparent from BHR assays, a broad range of allergen doses must be utilized to allow the use of these tests across a given population. Access to blood basophils for each individual allergen to be tested must be considered, as well as the potential that nearly 1 in 20 subjects may have non-responding basophils, which may hamper the ability to interpret the results. In addition, IL-3 is often added as an amplifier of IgE-dependent responses, yet this cytokine can often directly induce basophil responses, thus interfering with interpretations. The use of whole blood for assay of these surface markers is quite popular; however, the conditions used for the lysis of contaminating red cells (see below) may also deliver an activation stimulus to the basophils. Other isolation strategies such as Percoll isolation may be desirable, but negative selection procedures for highly purified basophil preparation may evoke nonspecific basophil activation due to prolonged handling of basophils. In addition, controls to monitor for false signals from other cell types that bear CD69 and CD63, such as adherent platelets, must be considered in these assays. Although some studies have shown expression of activation markers in parallel with histamine release from basophils, a very early study showed discordance between the elevation of activation marker expression and basophil histamine release in response to a polyclonal anti-IgE stimulus (15). Thus, concerns remain regarding the use of these surface markers as diagnostic tests in assessing allergic status.

Standard Assay Approach

BAM assays are often conducted using heparinized whole blood (0.1 ml/assay tube), which is added to reaction tubes (e.g., flow cytometry test tubes) containing negative controls (buffer alone), positive controls (e.g., anti-IgE, anti-FcεRI antibody), and several concentrations of the test antigen. Fluorescently labeled antibodies are then added for the detection of basophils and the BAM of interest. For example, phycoerythrin (PE)-labeled anti-CD123 (anti-CD123/PE) and fluorescein isothiocyanate (FITC)-labeled anti-CD303 (anti-CD303/FITC) readily identified basophils from other leukocytes (16). BAM are then detected using allophycocyanin (APC)-labeled antibodies (e.g., anti-CD63/APC). The presence or absence of other markers have also been useful in identifying basophils (e.g., $CCR3^+$, $CD203c^+$, MHC II^-), and may function equally as well depending on the application. Once labeling for the markers of choice is complete, red blood cells are lysed using commercially available reagents (e.g., PhosFlow, BD Biosciences), thus facilitating subsequent analysis by flow cytometry. BAM values are generally reported as the percent positive basophils above the negative control. Net mean fluorescence intensity (nMFI) is also often reported.

MAST CELL SPECIFIC MEDIATORS AND MARKERS

Tryptase

Tryptase is a neutral protease stored in large quantities in mast cells (roughly 10 pg per lung mast cell and up to 135 pg per skin mast cell). Several forms have been described (I, βII, III, α, and transmembrane tryptase), and all are found in mast cells. Only the mature form of tryptase, previously referred to as β-tryptase, and immature or protryptase, previously referred to as α-tryptase, are clinically relevant. Although tryptase is generally accepted as a mediator of immediate hypersensitivity, its biological role is not known. However, several *in vitro* activities of tryptase, such as its ability to sensitize smooth muscle to histamine and to stimulate fibroblast proliferation, have suggested a direct role for this enzyme in conditions ranging from asthma to wound healing.

Assessment of *In Vivo* Mast Cell Activation: Clinical Indications

The ability to detect tryptase in many types of biological specimens, such as serum, bronchial lavage fluid, nasal lavage fluid, skin blister fluid, and tears, has made this enzyme a valuable marker of *in vivo* mast cell activation. In conjunction with histamine measurements, the detection of tryptase is useful in determining the involvement of mast cells in immediate allergic responses occurring in many different reaction sites. Mature β-tryptase is released from mast cells within 15 min following *in vitro* degranulation and is the predominant form detected in the serum 1 to 2 hours following anaphylaxis (>1 μg/liter). However, immature α-protryptase is spontaneously secreted from mast cells and often elevated (>20 μg/liter) in mastocytosis patients, which reflects an increased mast cell burden. Quantifying ratios of the immature and mature forms of tryptase in serum provides the best indication of mast cell activation (16). Additional details regarding tryptase detection are found in chapter 85.

Test Procedures for Detection of Tryptase

Tryptase is often measured using ELISA, with anti-lung tryptase primary and biotinylated secondary antibodies in a two-site immunoenzymatic assay. Polyclonal antibodies are also useful for detecting tryptase by RIA, although nonspecific binding and protein interference are often problematic. Human lung mast cell tryptase is often used

as a standard in both the ELISA and RIA techniques and requires extensive purification protocols. Recombinant tryptase is available, but its usefulness as a standard has not been fully determined. It is also now possible to measure immature pro-tryptase using the commercially available ImmunoCAP assay (Thermofisher Scientific/Phadia, Uppsala, Sweden), which is designed as a sandwich immunoassay involving a cellulose-derivative solid-phase component. The assay is reported to be suitable for serum or nasal lavage specimens collected 15 min to 3 hours after mast cell activation.

Prostaglandin D2

PGD2 is a pro-inflammatory mediator released from mast cells (roughly 60 ng/10^6 cells) upon IgE-dependent activation and is capable of causing bronchoconstriction, dilation, and increased permeability of the microvasculature via binding to the DP1 receptor. Also, PGD2 is an important chemoattractant, selectively recruiting cells (e.g., eosinophils, basophils, Th2) expressing a second receptor, DP2, (also known as CRTH2). PGD2 assays should be performed as quickly as possible, especially when skin mast cells are involved, since this mediator is susceptible to degradation even when stored at –20°C. PGD2 is most often measured using a competitive RIA, either a commercially available or an in-house assay. Because of the technical problems observed, especially with high-protein-concentration fluids, some laboratories have developed gas chromatographic technology, which is considered the method of choice for detection of prostanoids in biologic fluids. Adding tetradeuterated standards overcomes problems of differential degradation, and chromatography of samples using Sep-Pak columns removes interfering proteins and other substances in biologic matrices. PGD2 is not regularly analyzed as a mediator of allergic inflammation, since tryptase is more readily detected in the same biological specimens and is generally accepted as a more specific marker of mast cell activation.

DENDRITIC CELLS: INNATE IMMUNE RESPONSES

Blood dendritic cell (DC) subtypes are gaining distinction in allergic disease for possessing impaired innate immune responses but also the capacity to induce Th2 responses. As a result, they are being increasingly used in cellular assays indicative of the allergic status (16). While the clinical applicability of these assays remains limited at this time, we discuss a few selected assays here because they are predicted to gain greater validation in the future.

IFN-α: Clinical Indication and Assay

Although plasmacytoid DCs (pDCs) constitute <0.5% of the PBMC isolated from blood, they are the predominant (if not sole) source of IFN-α and other type I IFNs upon stimulation with TLR7/9 agonists (18). Yet, there are now several reports indicating that this response is impaired among subjects suffering from allergic disease and that events occurring from the cross-linking of the IgE receptors expressed by these cells may account for this deficiency (19–22). Moreover, there is evidence suggesting that these responses improve in subjects undergoing allergen immunotherapy (IT) and therefore may become useful in monitoring one's course during this treatment (23). A straightforward assay to assess IFN-α production involves stimulating PBMCs (or the basophil-depleted cells on the 1.075-g/ml Percoll interface shown in Fig. 1) with DNA oligodeoxynucleotides (ODN) containing unmethylated CpG motifs, which activate pDC within the suspension via TLR9. In particular, ODN-2216 is a well-known type A ODN that induces potent IFN-α responses, especially when synthesized with a phosphothioated backbone to preserve its stability in culture. Its nucleotide sequence consists of two CpG motifs, and there are now several companies (e.g., TriLink Biotechnologies, San Diego, CA; IBA Inc., Göttingen, Germany; Coley Pharmaceutical-Pfizer, Wellesley, MA) that will synthesize various ODNs as stimuli of IFN-α production by pDC. We typically use ODN-2216 at 100 nM to activate PBMC (1.25 $\times$ 10^6 per 0.250 ml C-IMDM). After incubating cultures for 18 to 20 hours at 37°C, 5% CO_2, cell-free supernatants are harvested and assayed for IFN-α using commercial ELISAs. These IFN-α values are then normalized to picograms/10^6 pDCs by determining the frequency of $CD123^+BDCA2^+$ pDCs within an aliquot of the PBMC suspension using flow cytometry. TLR7-specific stimuli, including single-stranded RNA viruses (e.g., influenza A, rhinovirus) and synthetic compounds (e.g., R848), also induce potent IFN-α responses and have been used in assessing pDC responses. It is important to emphasize that there are now many (~20) different species of IFN-α. And while these potentially cross-react with detection antibodies, most ELISAs to date report specificity for IFNα2. Finally, both pDCs and myeloid DCs (mDCs) have been shown to support T-cell responses to allergen, suggesting that these adaptive immune responses may also function as assays to monitor allergic inflammation. Naturally, the requirement to purify these rare DC subtypes makes these assays technically challenging, thus lessening their clinical relevance at this time. As a result, the reader is referred elsewhere for an in-depth description of how these assays are performed (16), since they are beyond the scope of this chapter.

QUALITY ASSURANCE OF *IN VITRO* ASSAYS

The above assays are not regulated by the Clinical Laboratory Improvement Act of 1988. Therefore, inter-laboratory proficiency surveys are not available. However, there are critical steps that can be taken to ensure the validity of the analytical measurements. First, when the allergic status of an individual is evaluated, it is important to include controls to ensure basophil reactivity, especially when the challenging allergen does not induce the release of the mediator in question. For histamine and LTC4 release, but also BAM expression, this inclusion is most commonly achieved by stimulating basophils with anti-IgE antibody and/or with FMLP, which are both quite effective in inducing the release of these mediators from basophils obtained from most donors. For IL-4 and IL-13 protein, anti-IgE antibody alone is usually sufficient to induce the secretion of these cytokines from most donors' basophils. However, as noted above, a calcium ionophore (ionomycin or A23187) has been shown to be a potent and relatively specific stimulus for the secretion of both cytokines by basophils. The lack of reactivity with these stimuli could indicate that calcium is missing from the reaction buffer or that the temperature is not 37°C, but at ≥40°C. It is also important that IL-3 will often enhance the IgE-mediated release of all of the above-listed mediators and BAM and may be employed when basophils show marginal release in response to an antigen alone. In contrast, false-positive histamine release may occur as a result of cell lysis due to solvents found in allergen preparations. In this instance, it is important to include controls showing that, in the absence of allergen, the solvents cause no additional release above the spontaneous release (blanks). Similarly, in studies investigating substances that inhibit mediator release,

it is important to show that final concentrations of the solvent (e.g., dimethyl sulfoxide) have no effect on secretion.

There are several other factors to consider when performing the assays that directly measure mediators and markers of allergic inflammation. The first deals with the general use of standards for these assays. Stock solutions should always be prepared using established methodology to prevent inter-assay variability. Storing these in small aliquots avoids repeated freeze/thaw conditions that may result in loss of activity. It is also extremely important that the standards be prepared in diluent identical to or closely resembling that found in the test samples. For example, when culture supernatants are tested for IL-4 or IL-13 protein, it is important that the standards be diluted in medium identical to that used in the cultures, since medium-containing serum may produce different background levels compared with buffer containing little to no protein. Finally, data analysis for these assays is greatly facilitated by the use of computer application programs, which are often commercially available from equipment manufacturers. They are especially helpful for histamine measurements determined by automated fluorometry, in which many samples can be assayed at a given time and the data can be saved and stored for later access and rapid analysis.

IN VIVO DIAGNOSTIC ALLERGY TESTING: SKIN TESTING

Allergen skin testing is a convenient, rapid, and cost-effective screening modality for the detection of IgE-mediated conditions. A positive skin test indicates the presence of allergen-specific IgE bound to FcεRI on the surface of mast cells. Introduction of allergen into the skin either by prick-puncture or by needle injection crosslinks the allergen-specific IgE on the surface of local mast cells, leading to degranulation and mediator release, as described above, that produces a sharply demarcated area of edema (wheal) and an even larger area of erythema (flare). Some individuals also develop a late-phase reaction (LPR) at skin test sites, characterized by warmth, deep tissue edema, erythema, and pruritus that typically resolves over 24 to 48 hours. LPRs are instigated by mast cell-derived mediators but do not predict clinical symptoms and are therefore not useful in the diagnosis of allergic disease (24). Subjects harboring IgE specific to an allergen are said to be "sensitized" to that allergen. However, the diagnosis of an allergic disorder also requires a clinical history and/or allergen challenge that supports a causal relationship between exposure to the allergen and the development of allergic symptoms.

As noted above, alternatives to allergen skin testing are available, including serum assays that allow direct measurement of allergen-specific IgE antibodies (see chapter 82). Naturally, some situations mandate the use of in these *in vitro* assays over the use of skin testing, especially in individuals deemed to be at high risk for an anaphylactic reaction to testing, those with severe poorly controlled asthma, or patients who have experienced severe reactions following exposure to minute amounts of allergen. However, systemic reactions following prick-puncture testing are exceedingly rare (<0.001%), with only one case of fatal anaphylaxis ever reported (25, 26). Patients with extensive dermatitis or dermatographism as well as those who cannot withhold interfering medications (either those that interfere with interpretation of skin test results or those that inhibit treatment of anaphylaxis) may also not be candidates for skin testing. A recent episode of anaphylaxis can lead to false-negative results since skin mast cells can persist in a hypoactive state for at least 4 weeks following a severe allergic reaction. Assessment of basophil mediator release and expression of activation markers as described above is another strategy to investigate the role of IgE in clinical symptoms. The relative sensitivity of *in vivo* and *in vitro* testing varies, depending on the particular antigen being tested. Many early comparative studies suggested that skin testing is more sensitive than *in vitro* tests; however, most of these studies were performed with earlier generations of *in vitro* tests, and newer versions appear to give comparable diagnostic sensitivity and specificity (27).

Clinical Indications

Aeroallergen Assessment

Skin testing with a panel of aeroallergen extracts of clinical relevance to the geographical area where testing is performed or symptoms are experienced is a primary means of diagnosing allergic rhinitis, asthma, and conjunctivitis. Assessment using the prick-puncture method has excellent positive predictive value. A positive intradermal test for an aeroallergen in the setting of a negative prick-puncture test has low positive predictive value for predicting symptoms following allergen exposure (28).

Food Allergy Assessment

The use of *in vivo* tests for the diagnosis of food allergy are discussed in detail in chapter 84.

Stinging-Insect Assessment

The diagnosis of Hymenoptera venom allergy requires a clinical history of a sting that elicited a systemic allergic reaction, as well as evidence of venom-specific IgE. For *in vivo* testing, intradermal injection is required for definitive diagnosis when prick-puncture testing is negative. Initially, prick-puncture testing is started at 100 μg/ml. If negative, the protocol proceeds with intradermal testing with venom concentrations between 0.001–0.01 μg/ml, and injections are advanced in logarithmic increases to 1.0 μg/ml. Concentrations higher than 1.0 μg/ml may result in irritant reactions (29). If skin testing is negative in patients with a convincing history, *in vitro* testing should be performed and skin testing should be repeated in 6 to 12 weeks. These two methods of testing can provide complementary information, as up to 20% of skin test-positive patients have undetectable venom-specific IgE, and 10 to 20% of patients with negative skin tests have positive *in vitro* studies (30, 31). Together, skin testing and *in vitro* studies identify approximately 98% of patients who will develop a systemic allergic reaction to a subsequent sting.

Medications Adverse Reaction Assessment

Skin testing can be a helpful diagnostic tool when the adverse reaction to a medication is suspicious for an IgE-mediated mechanism. However, in many instances, the relevant antigen is not the parent compound and therefore is not commercially available for testing. Interpreters must keep in mind that the antigenic epitope responsible for the reaction may be a metabolized product of the parent compound. Currently, the only group of medications for which skin testing has been validated and standardized is beta-lactam antibiotics. Skin testing is the preferred method for identifying patients at risk for penicillin-induced anaphylactic reactions, because this method is more sensitive than *in vitro* assays for penicillin-specific IgE. The minimal reagents required for penicillin skin testing include the major determinant, penicilloyl-polylysine (Pre-Pen), and the minor determinant, penicillin G, although a minor determinant mixture that also includes

penicilloate and penilloate can be used if available. However, most studies have suggested that the negative predictive value of skin testing with Pre-Pen plus the minor determinant mixture was similar to Pre-Pen plus penicillin G alone (32, 33). Prick-puncture testing is usually performed first, followed by intradermal testing if the prick-puncture tests are negative. Approximately 50% of patients who have a positive skin test for penicillin develop an immediate-type allergic reaction following exposure to penicillin (33, 34–37). However, a negative test confers a 97 to 99% negative predictive value (32, 35, 37–39). While the availability of Pre-Pen had been plagued with manufacturing issues, this product became commercially available again in the United States in 2009.

Procedures

Several preparatory measures are required for successful testing outcomes. All interfering medications must be discontinued in order to achieve interpretable results. Second-generation H1 antihistamines (cetirizine, loratadine) should be discontinued for 7 days prior to testing, while 1 to 3 days is typically sufficient for first-generation nonselective antihistamines (diphenhydramine) (40). Hydroxyzine should be discontinued at least 96 hours prior to testing, H2 receptor antagonists (ranitidine, cimetidine) for 48 hours, and tricyclic antidepressants for 7 to 14 days (41). In general, systemic glucocorticoids, inhaled or intranasal glucocorticoids, decongestants, inhaled beta agonists, cromolyn, and leukotriene receptor antagonists do not affect skin test responses (42, 43). Topical steroids can transiently reduce the frequency of skin mast cells, and therefore, skin testing should be performed on non-treated areas of skin (44, 45). Finally, patients who received omalizumab, a humanized anti-IgE monoclonal antibody, may exhibit reduced skin test responses for as long as 6 months following discontinuation of the drug. *In vitro* assays should be considered an alternative in patients with dermatographism or active dermatitis, given the increased risk of obtaining false-positive results. Testing can be performed on pregnant patients but is not advisable unless the information gained from testing is deemed to outweigh the risk of adverse effects on the fetus if a systemic reaction occurs. Although systemic reactions are rare, a supervising physician and resuscitation materials should always be on hand. First-line treatment for a systemic reaction is 0.3 ml of 1:1000 aqueous epinephrine for adults and 0.01 ml/kg of body weight (up to 0.3 ml) for children, administered intramuscularly (46). Other resuscitative materials should include antihistamines, corticosteroids, oxygen, and normal saline for volume replacement. Patients with life-threatening reactions should be transported to the nearest emergency department. The risk of systemic reaction is higher with intradermal testing; therefore, a practical approach is to use prick-puncture testing for screening and intradermal testing for confirming equivocal or negative percutaneous tests (47). While intradermal testing does have much greater sensitivity, it also produces more false-positive results. Intradermal testing is primarily used in the diagnosis of venom allergy and is not recommended for diagnosing food or latex allergy due to an unacceptably high rate of systemic reactions to testing. The number of individual extracts tested is dependent on many variables, including the patient's clinical history, geographical area, age, and knowledge of antigen cross-reactivity. Skin testing can be performed at any age. Skin reactivity generally increases throughout childhood and then plateaus in the teenage years. Although both infants and older adults may exhibit smaller positive results, skin testing can still be clinically useful in these age groups (48, 49).

Testing sites are cleansed with 70% isopropyl alcohol and marked for identification. Using barrier precautions, allergen extracts of known composition are introduced into the skin, usually on the volar surface of the arm or the upper back. While the forearm may produce smaller wheals than the skin on the back, the difference is not thought to be clinically relevant (50). Individual tests should have sufficient spacing, usually 2.5 cm, and should not be placed within 5 cm of the wrist or 3 cm of the antecubital fossa. False-positive results from adjacent reactions are unlikely if there are at least 2 cm between individual test sites (50).

Controls

Positive and negative controls must be applied in the absence of interfering medications. Histamine as a positive control must be read at 10 to 15 min to achieve peak reactivity. Histamine dichloride (10 mg/ml for epicutaneous use and 0.001 mg/ml for intradermal use) is typically used as the positive control and the same diluent used for the allergen extracts (usually glycerinated saline) as the negative control.

Prick-Puncture Tests

Several devices and techniques can be used to perform the prick-puncture test. The purpose is to introduce a small quantity of allergen into the skin after interruption of the epidermal barrier. Disposable lancets on single or multi-tipped devices (which allow application of multiple allergens simultaneously) as well as various needles can be used for the prick-puncture technique. The type of testing device used can influence the results (51, 52). For example, multi-tipped devices generally produce more false-negative results than single-tipped devices, but can be useful for rapid testing of multiple allergens (51, 53, 54). Additional variables involved in testing include the angle and depth of penetration and the force applied by the applicator. Proper application should not cause excessive trauma or bleeding at the site. Single- and multi-tipped devices often simultaneously place a drop of allergen extract while puncturing the skin. If such devices are not used, a drop of extract is placed on the skin, and the needle or lancet is used to prick through the extract.

Intradermal Tests

Intradermal testing is usually performed on the volar aspect of the arm to allow application of a tourniquet in the event of a systemic reaction. The concentration used is usually 100- to 1,000-fold more dilute than the concentration used in the prick-puncture method. The skin test site is first cleansed and marked for allergen identification. Using a 26- or 27-gauge tuberculin needle, 0.01–0.05 ml of diluted extract is introduced into the skin. With the skin held taut, the needle is inserted bevel down at a 45-degree angle to the skin. After initial insertion, the syringe is lowered parallel to the skin and advanced only sufficiently to provide an intradermal injection. A small wheal about 3 mm in diameter is usually formed. A new needle is used for each injection.

Interpretation

Quality interpretation can depend on many variables, including skin color, testing site, skin reactivity, and reader skill. Histamine-positive controls are ideally read 10 min after application and allergen extracts after 15 to 20 min. Reporting in a standardized manner as recommended by the American College of Allergy, Asthma, and Immunology and the American Academy of Allergy, Asthma, and Immunology should include subject name and date of birth, longest diameter of wheal and flare in millimeters,

device used, time, date, reader, and extracts tested. A semi-quantitative manner of reporting using, for example, 1+, 2+, is not advised due to marked inter-physician variability in reporting results this way, other than for extreme positive results (55). A positive prick puncture test is defined as either a wheal equal to or larger in size than that elicited by the histamine control (which usually produces a wheal of at least 3 mm) or a wheal diameter of 3 mm or greater compared with the diluent control. For intradermal testing, a wheal of 5 mm or larger is considered positive; the clinical significance of smaller positive reactions has been debated (56). In general, prick-puncture testing is considered more specific but less sensitive than intradermal testing. False-positives with intradermal testing may be due to the presence of naturally occurring histamine or other vasoactive amines, endotoxin, or other skin irritants in the extracts, especially those for venom, molds, and food. Interpretation of all skin tests is dependent on clinical correlation and an understanding of testing limitations, since the presence of IgE antibodies does not always imply symptom culpability.

Reagents

Reconstitution, Stability, and Storage

The potency and quality of the allergen extracts used for testing can drastically alter the results. Currently, 19 allergens, including grass pollens, cat hair, dust mite, ragweed, and Hymenoptera venoms are standardized in potency units. However, the other extracts, including all commercially available food extracts, are not. Non-standardized extracts are supplied in weight per volume and, therefore, may have significant variation in lot-to-lot concentration (57). The thermal stability, compatibility, and cross-reactivity of allergen extracts are critical to consider when storing and mixing different reagents for testing and/or allergen immunotherapy. Allergen extract potency deteriorates with time, dilution, and increased temperature. Several studies have demonstrated extract degradation with higher temperatures, fungal and insect protease activity, and percent glycerin of diluent (58, 59). Glycerinated extracts protect unstable allergens from denaturation, inhibit protease degradation, and increase thermal stability. Diluted extracts need to be remixed every 2 to 3 months in buffered saline or normal saline diluent and every 6 months in 10% glycerin or human serum albumin diluent. Allergen extracts should be stored at 4°C.

A number of recombinant allergens are undergoing preclinical and clinical studies but are not yet licensed for use in skin testing or immunotherapy. Recombinant allergens may be advantageous since they can be produced with greater purity and stability, although critical antigen epitopes may be excluded when single recombinant allergens, versus their natural counterparts, are used. The diagnostic and therapeutic uses of recombinant allergens await further study (60, 61).

AIRWAY CHALLENGES

While both skin and serologic testing can provide insight into the antigens that elicit IgE-mediated reactions, these tests do not predict the nature or intensity of clinical symptoms in a given individual when exposed to those allergens. For this reason, allergen challenges of either the upper (intranasal) or lower (bronchial) airway can be done to further assess the relationship between a patient's allergen sensitivities and their development of rhinitis and/or asthma symptoms following allergen exposure.

Clinical Indications

Airway challenges, either intranasal or bronchial, can be used to determine whether a single allergen may be responsible for symptoms of either rhinitis or asthma or both conditions. In general, most allergists use a combination of patient-reported rhinitis symptoms and positive skin tests to identify the most likely culprit of allergic nasal symptoms. Intranasal challenges are more often used to determine the effect of anti-allergic drugs in an experimental setting. Bronchial challenge can be done to assess airway reactivity in the diagnosis of asthma but has also been utilized to determine the effectiveness of pharmacologic agents. Two bronchial challenge models that have been developed to mimic allergic asthma are the whole-lung and segmental antigen challenges. Segmental challenge involves installation of antigen solution through a bronchoscope into a sub-segment of the lung. Since it may be performed only by those trained in bronchoscopy and is used almost exclusively for research investigation, it will not be discussed further in this chapter. Whole-lung antigen challenge can be used both as a diagnostic and as a research tool and is useful in determining relevant environmental stimuli, including occupational exposures that may be provoking asthma symptoms in a patient who cannot define exacerbating factors. In addition to its diagnostic application, whole-lung antigen challenge is also used to determine the effects of treatment methods to block allergic physiologic changes and asthmatic symptoms. Bronchial challenge with nonspecific agents (e.g., methacholine, histamine) can also be used to assess bronchial reactivity and are discussed further in prior editions of this manual.

Both intranasal and whole-lung antigen challenges initiate allergic reactions and may precipitate bronchoconstriction. Therefore, these procedures should be performed only by trained personnel equipped to treat such emergencies. Neither intranasal nor whole-lung antigen challenges should be performed during asthma exacerbations, because doing so may make the flare worsen and may also lead to aberrant results due to the increase in nonspecific bronchial reactivity that can occur during asthma flares. In general, it is not recommended that whole-lung antigen challenge be performed if the forced expiratory volume in 1 s (FEV1) is <60% of predicted values (62). Other health problems such as underlying heart disease must also be considered, since whole-lung antigen challenge may result in prolonged bronchoconstriction and, potentially, hypoxia.

Test Procedures

Intranasal Challenge

Several methods have been developed to test the effect of antigen exposure on the nasal mucosal surface in allergic reactions. The decision of which allergens to test usually depends on the patient's clinical history and sensitivities as determined by skin testing and/or serologic testing. Nasal provocation tests using standardized allergens are usually started at an initial concentration of 1:1,000 and then increased at log or half-log intervals. For other allergens, 1/1,000 of the concentration that elicits a positive prick-puncture test can be used as the starting dose (63). Sequential dose increments are usually given in 10- to 15-min intervals, but this varies depending on the allergen and the patient's sensitivity. A diluent solution (in which the allergen is dissolved) is first applied to detect nonspecific responses, followed by application of the allergen. The allergen can be applied using several methods, but the most commonly used methods include a spray pump or nebulizer that instills allergen into the nares or a micropipette that

deposits the allergen solution directly on the inferior turbinate. The patient should be seated and hold his/her breath during application to prevent allergen from entering the lower respiratory tract. Several outcomes can be followed, including symptom scores (e.g., sneezes, itchiness, rhinorrhea, nasal obstruction, ocular symptoms), measurements of nasal patency by rhinometry, and inflammatory responses (e.g., cell differentials and inflammatory mediator concentrations in nasal lavage fluid, nasal brushings, or nasal biopsies) (64). The quantity and weight of nasal secretions can also be measured from paper disks placed on the nasal mucosa for a defined period of time. Alternatively, the weight and/or number of paper tissues into which a subject has blown his or her nose is determined (65). Generally, both a symptom score and an objective measure of nasal obstruction are recommended. Outcomes are typically assessed at baseline, following application of the inert diluent, and after each dose of allergen. Completion of the challenge protocol may be determined by a preordained level of symptoms or physiologic changes or by administration of a defined number of individual allergen concentrations.

Since there is no standardized protocol for intranasal challenge, and different investigators have used a wide variety of methods and doses of antigen instillation, the reproducibility of intranasal challenges is not well-established. To improve the reliability of results, the patient should be asymptomatic at the time of the challenge, the procedure should not be performed during the peak pollen season, and at least 1 week should be left between tests in order to reduce the "priming" effect, in which an exposure to an allergen augments the response to subsequent exposure to the same allergen.

Whole-Lung Antigen Challenge

Allergen inhalation challenges are invaluable to study the mechanisms of asthma and the potential of new asthma therapeutics but can induce severe bronchoconstriction. Therefore, the dose of allergen used must be chosen carefully so that it will induce a sufficient airway response but still be safe for the patient. The starting dose of allergen used is typically determined using end point dilution intradermal skin testing, in which 10-fold allergen dilutions are injected into a patient's skin, and the wheal measured 15 min later (66). The concentration given intradermally is then increased at 15-min intervals until a wheal response of 10 mm is obtained. One log higher than this concentration is used to initiate the inhaled challenge.

The choice of an apparatus to deliver aerosolized solutions is important for delivering test doses reliably. The Wright and DeVilbiss nebulizers are commonly used. The Wright nebulizer generates an aerosol that is inhaled by tidal breathing for 2 min for each dose. The flow rate on the nebulizer is adjusted to achieve an output of 0.13 ml/min. Optimal particle size from the nebulizer is 0.5 to 2 μm, which is ideal for allergen delivery to the small airways; larger particles are deposited in the mouthpiece and upper airway, and smaller particles are lost through exhalation (67). At the start of the procedure, baseline pulmonary function testing is performed, and the FEV1 is recorded. Next, the subject takes five breaths of sterile 10% phosphate-buffered saline solution used as a diluent via the nebulizer. Spirometry is performed 3 min later. If the FEV1 decreases by more than 10%, the study should be terminated since the specificity of the antigen challenge cannot be evaluated. Five breaths of the initial antigen concentration are then inhaled, and the FEV1 is measured 10 min later. Five breaths of half-log-increasing concentrations of antigen are inhaled at 10-min intervals until either a >20% decrease in FEV1 or the maximum dose is achieved. At this point, bronchodilators can be administered to immediately relieve the bronchoconstriction, or hourly pulmonary function measurements can be made to determine whether the subject experiences an asthmatic late-phase reaction. The presence of a late-phase reaction is defined as an FEV1 measurement 4 to 8 hours after the whole-lung antigen challenge that is <15% of the saline control FEV1 measurement. The physiologic mechanisms behind late-phase reactions are unclear but may involve smooth muscle constriction, airway edema, and mucus hyperproduction that causes airflow obstruction. Approximately 30% to 40% of subjects who have at least a 20% immediate decrease in FEV1 with whole-lung antigen challenge experience a late-phase reaction.

Whole-lung allergen challenges are considered to be the most definitive method to test the specificity of a particular antigen to cause bronchial reactions. False-positive reactions can occur when the antigen is given in high enough concentrations to cause asthma symptoms in allergic rhinitis patients or normal subjects who previously had never experienced asthma. The reproducibility of whole-lung allergen challenge from day to day is less than 2-fold in concentration and is improved if the prechallenge FEV1 is within 10% on the two challenges.

SUMMARY

It is now possible to measure a number of inflammatory mediators released from cells participating in allergic disease. Measurement of the release of preformed histamine from peripheral blood basophils challenged with a specific antigen is among several tests available, and histamine release remains a valuable *in vitro* correlate of immediate hypersensitivity reactions. However, other mediators that have a role in allergic inflammation, such as LTC4 and IL-4, are also generated by basophils upon IgE-dependent activation, and *in vitro* assays have recently been developed to measure these products. These assays, combined with those long used for *in vivo* assessment of immediate hypersensitivity reactions, have significantly added to our understanding of the parameters, mechanisms, and pharmacologic control of allergic inflammation.

APPENDIX

Special Reagents and Equipment

RFA 300 rapid flow analyzer for histamine measurement by fluorometry (Astoria-Pacific International, Clackamas, OR)

Filtered Reagents for Fluorometry

Phosphoric acid (0.73 M)

30% NaCl

5 N NaOH

1 N NaOH containing 1 mM EDTA

0.1 NHCl

Brij-saline-EDTA: 0.17 M NaCl, 1.5 mM EDTA, 0.015% Brij 35 (Perstorp Analytical, Silver Spring, MD)

Heptane

Butanol

OPT solution: 50 mg of OPT (Sigma, St. Louis, MO) recrystallized in ligroine solvent (Eastman Kodak Co., Rochester, NY), 1 ml of spectranalyzed methanol (Fisher Scientific, Pittsburgh, PA), and 99 ml of borate buffer (0.5 M)

Histamine Standards (for Fluorometry)

Histamine dihydrochloride (molecular weight, 184.1)

Histamine (molecular weight, 111.0)

Make a 1-mg/ml solution of histamine.

Note that 1 mg of histamine equals 1.66 mg of histamine dihydrochloride.

Dilute the 1-mg/ml solution 1/1,000 in 2% $HClO_4$ to give a 1-μg/ml stock and store at –20°C in 6-ml aliquots. Six milliliters of 1-μg/ml histamine added to 294 ml of 2% $HClO_4$ yields 20 ng/ml; 50 ml of 20-ng/ml standard added to 50 ml of 2% $HClO_4$ yields 10 ng/ml.

10× PIPES buffer, pH 7.4: 250 mM PIPES (Sigma Chemical Co.), 1.10 M NaCl, 50 mM KCl

PAG buffer: 10% 10× PIPES, 0.003% human serum albumin (Calbiochem-Behring Corp., La Jolla, CA), 0.1% D-glucose

PAG-EDTA buffer: PAG containing 4 mM EDTA

PAGCM buffer: PAG containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$

Isotonic Percoll: 9 parts Percoll (Pharmacia, Piscataway, NJ) plus 1 part 10× PIPES

Lactic acid buffer (pH 3.9): 90.1 mg of lactic acid (Calbiochem-Behring Corp.), 817.6 mg of NaCl, 37.28 mg of KCl, 100 ml of distilled water

Tests for Immunological Reactions to Foods

CARAH B. SANTOS, DAVID M. FLEISCHER, AND ROBERT A. WOOD

84

Food allergy is defined as an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food protein, and is distinguished from food intolerance (e.g. lactose intolerance), which is typically non-immunologic in origin (1). Food allergic disorders can be divided into those that are immunoglobulin E (IgE)-mediated and those that are non-IgE mediated. Disorders with acute onset of symptoms, defined typically as occurring within 2 hours after ingestion, are usually mediated by IgE antibodies, while subacute and chronic food allergic disorders may be cell mediated (primarily T cell) or of mixed origin with both cell-mediated and IgE-associated mechanisms. The subacute and chronic food allergic disorders primarily affect the gastrointestinal tract. Table 1 lists examples of IgE-, cell-, and mixed IgE- and cell-mediated disorders.

The diagnosis of food allergy must first begin with a detailed medical and reaction history. The information gathered should guide the best mode of diagnosis, or the history alone may rule out a diagnosis of food allergy. In some studies, only about 40% of suspected food-induced allergic reactions could be verified by double-blind, placebo-controlled food challenges (DBPCFCs) (2). In cases of acute reactions, such as anaphylaxis and urticaria following the ingestion of an isolated food, the medical history has a much higher predictive value than in reactions secondary to chronic disorders, such as atopic dermatitis and eosinophilic gastrointestinal disease. The history should focus on the type and quantity of food(s) suspected of provoking the reaction, the nature of the symptoms attributed to food ingestion (acute versus chronic), the timing between ingestion and onset of symptoms, the patterns of reactivity, the most recent reaction, and whether associated activities (e.g., exercise or alcohol ingestion) play a role in inducing symptoms. Once a reaction history is established (see Table 2 for a list of signs and symptoms of food-induced allergic reactions), the likelihood that a food is causative must be considered. For example, food-allergic reactions account for about 20% of acute urticaria, 2% of chronic urticaria, and approximately 35% of moderate to severe atopic dermatitis in children, while food allergy is not a common cause of atopic dermatitis in adults (3, 4). Also, the prevalence of food allergy is greatest in the first few years of life, affecting about 3 to 8% of children and then decreasing to a prevalence of 1 to 3% in adults (5).

Furthermore, although any food may theoretically cause an allergic reaction, only a small number of foods account for approximately 90% of verified food reactions. These foods include milk, egg, soy, wheat, peanut, tree nuts, and fish in children, and peanuts, tree nuts, fish, and shellfish in adults. Finally, the majority of patients outgrow their food allergy, usually in childhood. While the natural history of food allergy varies by food, approximately 50 to 80% of patients with milk, egg, soy, or wheat allergy acquire tolerance to these foods by their teenage years (5). However, sensitivity to peanut, tree nuts, fish, and shellfish usually persist into adulthood. Some of the tests that will be discussed in this chapter not only aid in the diagnosis of food allergies but also are useful in monitoring the natural history of patients' food allergies over time, from diagnosis to oral tolerance.

The physical examination should focus on detecting other atopic features, such as atopic dermatitis, which are more common in patients with IgE-mediated food allergy. Information gathered during the history and physical exam can indicate the likelihood that the patient has true food allergy and whether an IgE-mediated or non-IgE-mediated mechanism is most likely responsible. IgE-mediated reactions, such as urticaria, angioedema, and wheezing, typically have a rapid onset, often immediately but usually within two hours after ingestion, whereas other presentations, such as vomiting, diarrhea, and bloody stools, may not develop for hours to days after ingestion of the allergen in non-IgE-mediated disorders. Once food allergy has been identified as the likely cause of a patient's symptoms, confirmation of the diagnosis and identification of the implicated food(s) can begin. There are a number of tools that aid in the diagnosis of food allergy, some of which are more commonly used than others, and they vary in their ability to provide an accurate diagnosis. In general, laboratory tests are more useful in determining the specific foods responsible for IgE-mediated reactions, whereas they are of limited value in non-IgE-mediated disorders. Available studies include *in vivo* tests, such as skin prick tests (SPTs), oral food challenges (OFCs), elimination diets, and patch testing, and *in vitro* tests, such as quantification of food-specific IgE antibodies in serum and basophil histamine release (BHR). The utility of these and other test modalities will be discussed in detail.

TABLE 1 Food allergy disorders

IgE-mediated
Gastrointestinal: pollen-food allergy syndrome, gastrointestinal anaphylaxis
Cutaneous: urticaria, angioedema, morbilloform rashes and flushing
Respiratory: acute rhinoconjunctivitis, wheezing
Generalized: anaphylactic shock
Mixed IgE- and cell-mediated
Gastrointestinal: eosinophilic esophagitis/gastroenteritis/colitis
Cutaneous: atopic dermatitis
Respiratory: asthma
Cell-mediated
Gastrointestinal: food protein-induced enterocolitis, proctocolitis, and enteropathy syndromes; celiac disease
Cutaneous: contact dermatitis, dermatitis herpetiformis
Respiratory: food-induced pulmonary hemosiderosis (Heiner syndrome)

IN VIVO TESTS

Skin Prick Tests

Skin prick tests are commonly used to screen patients with suspected IgE-mediated food reactions. While the patient is off antihistamines for an appropriate amount of time (short acting, 72 h; long acting, 5 to 7 days), a device, such as a bifurcated needle, lancet, plastic probe, or the tip of a small-gauge needle, is used to puncture the skin through a glycerinated food extract (1:10 or 1:20, wt/vol) into the epidermis. Positive (histamine) controls are used to show that the skin response is not blocked, and negative (saline-glycerin) controls are used to rule out false-positive results, such as those due to dermatographism, irritant and contact reactions from the diluent used to preserve allergen extracts, or poor technique of the tester. Testing should be limited to the most common foods that are suspected of provoking symptoms gathered on history since false-positive results are common (6). If food-specific antibody is present, mast cells with food-specific IgE bound to their surface degranulate and release mediators, such as histamine, that result in a local wheal-and-flare reaction within 15 to 20 min.

SPTs are generally considered positive if the mean wheal diameter is ≥3 mm after subtraction of the negative-control wheal. The mean diameter of the wheal is calculated by measuring the greatest diameter of the wheal and the largest diameter perpendicular to it, then averaging the sum of these diameters. The positive predictive accuracies of SPTs are <50% compared to those of DBPCFCs. Thus, when an SPT is positive, it indicates only a possible association between the food tested and the patient's reactivity to that food, rather than confirmation of a clinically relevant food allergy (7). On the other hand, negative responses virtually exclude the possibility of an IgE-mediated reaction, as the negative predictive value of SPTs exceeds 90% (3). Therefore, negative SPTs are an excellent means of excluding IgE-mediated food allergies, although they are not perfect, and positive SPTs are only suggestive of the presence of symptomatic allergy. However, a positive SPT is virtually diagnostic in patients who have experienced a systemic reaction to an isolated food (3).

Several key studies have looked at the performance characteristics of SPTs in predicting true food allergy at different wheal cutoffs compared to the outcome of DBPCFCs. Sampson (8), in a study of 87 patients (median age, 7.9 years) who all had atopic dermatitis and underwent DBPCFCs to rule out food hypersensitivities after SPTs, reported that a 3-mm wheal had a 96% diagnostic sensitivity in identifying children with cow's milk allergy, 98% with egg allergy, and 90% with peanut allergy, with corresponding diagnostic specificities of 51, 53, and 29%, respectively. Sporik et al. (9) showed corresponding diagnostic sensitivities for a 3-mm wheal of 74% for cow's milk, 84% for egg, and 96% for peanut, with respective diagnostic specificities of 79, 70, and 71% from 535 challenges in 467 children (median age, 3 years). For each food, the authors were also able to identify an SPT wheal diameter at and above which negative food challenges did not occur, thus in theory reducing the need for formal food challenges if the wheal size equaled or exceeded these values: 8 mm for cow's milk, 7 mm for egg, and 8 mm for peanut in a group of children with a median age of 3 years. For children 2 years of age or younger, the SPT wheal diameter cutoffs were lower: 6 mm for cow's milk, 5 mm for egg, and 4 mm for peanut. Finally, Eigenmann and Sampson (10) reevaluated SPTs in the diagnosis of food allergy in a group of children (median age, 4.6 years) with a history of atopic dermatitis. They used wheal sizes at the upper 95% confidence interval for food-tolerant patients as cutoffs; these were 5 mm for cow's milk, 4 mm for egg, and 6 mm for peanut. The corresponding diagnostic sensitivities were 89% for cow's milk, 98% for egg, and 63% for peanut, and the diagnostic specificities were 68, 61, and 71%, respectively.

When the test is appropriately performed, SPT results have been shown to be highly reproducible (8). The accuracy of SPTs does vary, however, depending on which food antigen is being studied, the quality of the food extract, and the technical skills of the tester. In addition, children <1 year old may have negative SPT responses but still have IgE-mediated disease, and infants <2 years old may have smaller wheals, which is presumably due to lower levels of food-specific IgE and skin reactivity.

SPTs have several advantages: they are quick, patients can see the reaction of a positive test result on the skin,

and they are relatively inexpensive compared with serologic methods for allergy investigation. They are also safe. No lethal reactions have been reported after SPTs. However, SPTs are often not helpful in determining if a patient who was allergic to a particular food has achieved tolerance to that food, as skin tests often remain positive for years following attainment of clinical tolerance (7).

Intradermal Skin Tests

In 1978, Bock et al. (11) performed DBPCFCs on 76 children aged 5 months to 15 years who exhibited a wheal of 3.0 mm or greater in response to an SPT with one or more of 14 foods, regardless of whether or not they reported a history of an adverse reaction to that food. Positive SPTs with 1:20 (wt/vol) food extracts identified all subjects who exhibited adverse reactions during their challenges. In addition, intradermal skin tests (IDSTs) were performed with 1:1,000 (wt/vol) extracts. For each of the 14 foods, between 19 and 39 additional patients (mean, 26) who were negative by SPT had a 3.0 mm or greater wheal in response to intradermal testing. Using peanut as an example, 26 patients were identified by SPT, 12 of whom failed DBPCFCs. An additional 28 patients, all of whom had negative DBPCFCs, had positive intradermal tests. Based on this study, IDSTs with food extracts have no advantage over SPTs and appear to produce more false-positive tests than seen with the prick technique.

Fresh Food Skin Prick Tests

Fresh food skin prick tests (FFSPTs) are not commonly performed since the indications for doing so are limited. Some commercially prepared extracts frequently lack the labile proteins that are responsible for IgE-mediated sensitivity to many fruits and vegetables (e.g., apples, oranges, bananas, pears, melons, potato, carrots, and celery), as is seen in patients with pollen-food allergy syndrome, because the proteins are degraded or lose allergenicity during extract preparation (12). Negative SPTs with commercially available extracts that contradict a convincing history of a food-induced allergic reaction should be repeated with the fresh food before concluding that food-specific IgE is absent. Rosen et al. (13) also suggested that patients should be tested with the food in the form that caused the reaction (e.g., raw or cooked). FFSPTs are usually done in one of two manners, depending on the type of food. In the prick-to-prick technique, the needle or lancet device is first embedded in the fresh food and is then immediately used to prick the patient's skin. In the second technique, foods with a harder consistency, such as peanut, are often ground first and diluted in buffered saline.

Several studies have compared FFSPTs, SPTs with commercial extracts, food-specific IgE levels, and/or food challenges. In a study by Ortolani et al. (12), 100 patients with pollen-food allergy syndrome (previously termed oral allergy syndrome) and 32 nonallergic control subjects were enrolled. Patients had FFSPTs, commercial extract SPTs, and specific IgE testing using the Phadebas radioallergosorbent test (RAST). The results showed that FFSPTs provided better diagnostic sensitivity to many foods, including carrot, celery, cherry, apple, and potato, but commercial extract SPTs provided greater diagnostic sensitivity for peanut, almond, banana, and pea. Rosen et al. (13) confirmed the superiority of fresh food extracts in a study of 22 patients, including 9 children. Fourteen of the 22 patients presented with a history of anaphylactic reactions, and the remaining 8 presented with a history of pollen-food allergy syndrome. For 18 of the 22 patients, the foods presumed to be the offending allergens were not limited solely to fruits or vegetables, but included fish, crustaceans, mollusks, milk, egg, peanut, and tree nuts. All of the patients demonstrated a negative response to SPTs with commercial extracts to suspected foods but positive responses to SPTs with fresh food extracts. In this study, however, no food challenges were performed to confirm that these foods were the ones that caused the previous symptoms. Rance et al. (14), using commercial extracts and fresh foods, compared SPT results for milk, egg, and peanut to the results obtained with labial and/or oral challenge. They found that the overall correlation between positive SPT ($\geq$3 mm) and positive challenges was 58.8% using commercial extracts and 91.7% using fresh foods. They also observed that challenges were positive for 40.5% of subjects with negative commercial SPTs, while only 7.4% of challenges were positive for subjects with negative FFSPTs.

Atopy Patch Tests

Atopy patch tests (APTs) have been proposed as a mode of diagnosis of non-IgE-mediated food allergy and for identification of allergens in delayed-onset clinical reactions. APTs are performed epicutaneously, usually on a patient's back. A small amount of a food is placed on filter paper, which is then applied to uninvolved skin and covered by an aluminum cup. The application sites are checked after 15 to 20 min for immediate reactions and then are usually kept occluded for 48 h. Results are usually read 20 min after removal of the cups and again 24 h later for the final evaluation. Final reactions are then scored; a typical scoring system used is 1+ for erythema and slight infiltration, 2+ for erythema and papules, and 3+ for erythema and vesicles. Irritant reactions, which have been described as sharply defined, brownish erythema, blistering, and a lack of clear infiltration, are not regarded as positive reactions (15).

Although the exact pathomechanism of the APT is not known, APT reactions are thought to represent T-cell-mediated allergen-specific immune responses (16). The patch test reaction to aeroallergens seems to be specific for sensitized patients with atopic dermatitis, as it does not occur in healthy volunteers or in patients suffering from asthma or rhinitis (17).

The outcomes of APTs in different studies are often incongruent due to differences in patient selection and, more importantly, differences in method. At this time, there are large disparities in the type and concentration of allergens used and in the duration of application and reading time (17). Nonspecific irritation is a common finding in standard patch testing and therefore requires considerable skill in differentiating it from a positive reaction. These facts make interpretation of studies somewhat difficult due to reliability issues, but a number of investigators have examined the use of APTs in addition to SPTs for the diagnosis of mixed or non-IgE-mediated food allergy, primarily in atopic dermatitis and eosinophilic esophagitis (18).

Roehr et al. (15) studied 173 challenges in 98 patients with atopic dermatitis and used APTs, SPTs, and food-specific IgE levels with cow's milk, egg, soy, and wheat to see if the combination of a positive APT result plus a positive food-specific-IgE level, a positive SPT, or both would make DBPCFCs unnecessary. Patients were observed for 48 h on an inpatient basis after challenges to document late-phase reactions (>2 h post challenge). Observed reactions included eczema exacerbations, which were counted as positive challenges if they occurred either alone or in combination with early reactions. Positive APT results alone correlated with high positive predictive values (PPVs) for cow's milk (95%), hen's egg (94%), and wheat (94%) compared to positive DBPCFCs, but with

only a 50% PPV for soy (only 4 children reacted to soy). The combination of a positive APT with positive specific IgE for cow's milk (≥0.35 kilounits [kU_A] of antibody per liter) and for egg (≥17.5 kU_A/liter) increased the PPVs to 100%, thus making DBPCFCs superfluous. The addition of SPTs to the other two tests did not further improve results. A study by Mehl et al. (19) utilized similar methods in evaluating 437 children, 90% with atopic dermatitis, who underwent 873 OFCs to milk, egg, soy, and wheat. Using results from APTs in combination with SPTs and food-specific IgE levels led to improved diagnostic sensitivity and specificity compared to the individual tests, but the addition of APT made OFCs unnecessary in 0.5 to 14% of patients, thus only adding minimal predictive value to SPT and food-specific IgE measurements. Spergel et al. (20) studied 941 patients with biopsy-proven eosinophilic esophagitis and performed SPTs, followed by APTs if the SPT to a particular food was negative. Causative foods were identified in 319 patients. A comparison of a diet eliminating foods positive on SPT or APT to an empirically determined six-food elimination diet showed equal success rates based on posttreatment biopsies showing resolution of esophageal eosinophilia. However, fewer foods were removed based on the SPT/APT-directed elimination diet.

Elimination Diets

The purpose of an elimination diet is to determine whether a patient's symptoms will resolve when foods are restricted from the diet. Once certain foods are suspected of being responsible for a food-induced allergic disorder, an elimination diet is started as an attempt to support the diagnosis. If a patient's symptoms persist despite a very strict avoidance diet, it is unlikely that the food accounts for the patient's complaints. There are three types of elimination diets: elimination of one or more suspect foods, elimination of all but a defined group of allowed foods that are rarely antigenic (oligo-antigenic diet), and an elemental diet consisting of a hydrolyzed or amino acid-based formula. The type of diet chosen depends on the age of the patient, the clinical presentation being evaluated, and sometimes the results of food-specific skin or serological IgE antibody tests.

Elimination of one or more foods may be diagnostic and therapeutic in patients who experience an acute reaction to a food and have a positive test for IgE antibody to that food. It may also be especially helpful in evaluating infants who are on a very limited diet. In the oligo-antigenic diet, a large number of foods suspected to cause a chronic problem are removed, and the patient is given a list of allowed foods. This type of diet can be useful for evaluation of chronic disorders, such as atopic dermatitis or chronic urticaria. In the most extreme diet, the elemental diet, an amino acid-based formula (Neocate, EleCare, PurAmino) provides the entirety of a patient's nutrition. The elemental diet provides the most definitive trial, but it can be difficult to undertake and maintain, especially in patients beyond infancy, where tube feeding may be required. This diet may be necessary when less restrictive diets have failed but the suspicion for food-related illness remains high, especially in disorders such as eosinophilic gastrointestinal disease, which is often associated with multiple food allergies. If a patient's symptoms do not improve on an elemental diet, then it is very unlikely that ingested substances are the problem. The length of trial is dependent on the type of symptoms, but 6 weeks is usually sufficient to see clinical improvement (4).

If symptoms resolve on an elimination diet, some form of food challenge is generally warranted, especially in chronic disorders such as atopic dermatitis. One must be careful when a food to which the patient is sensitized is removed from the diet for a prolonged period, as reintroduction may induce severe reactions (3, 4). With gastrointestinal allergies such as eosinophilic gastrointestinal disease, endoscopy and biopsies performed after 6 to 8 weeks on an elimination diet that show resolution of pathology confirms that the implicated food(s) were likely responsible for the disorder.

Oral Food Challenges

OFCs are performed by feeding suspected foods in gradually increasing amounts over hours or days under the supervision of a physician. OFCs can be done openly, where both the physician and the patient are aware of the food being challenged, single-blind, where only the physician is aware, or double-blind, placebo-controlled, where neither patient nor physician knows the content being challenged. Open food challenges are best performed when there is not a high likelihood that symptoms will develop and when there are few to no psychological factors that may bias results. The DBPCFC is considered the "gold standard" for the diagnosis of food allergy, and it is the least prone to bias and confounding factors (21, 22). OFCs can be used to assess any kind of adverse response to foods. When several foods are under consideration, tests for food-specific IgE are positive, and an elimination diet results in resolution of symptoms, an OFC for each food may allow expansion of the diet. For acute anaphylactic reactions in which no specific IgE for the suspected food is found, an OFC would be indicated to confirm the diagnosis or to safely reintroduce the food in the case of a false-negative skin test or food-specific IgE. If an elimination diet does not alleviate symptoms and suspicion is still high for a food-related cause, then the OFC may be needed to resolve the issue. For those who have been previously diagnosed with an IgE-mediated food allergy, the OFC can also be used to determine whether the patients have outgrown their clinical reactivity. Finally, for non-IgE-mediated reactions, OFCs are often the only means of diagnosis due to the lack of reliable testing for these types of reactions.

To optimize challenge conditions, the suspected food should be eliminated from the diet for 1 to 2 weeks (and up to 8 to 12 weeks in some gastrointestinal disorders); potentially interfering medications, including antihistamines and β-agonists, should be withdrawn; and chronic diseases, such as asthma and atopic dermatitis, should be adequately controlled. Fresh or dehydrated foods can be used, and challenge vehicles should not contain fat, which can interfere with protein absorption. The OFC should be administered in the fasting state and proceed in a graded fashion, starting with a dose that is less than the expected threshold dose, such as the approximate dose the patient reacted to previously. In suspected IgE-mediated reactions, if there is no reaction with the starting dose, then increasing doses are given every 15 to 60 min (the interval time may need to be increased for more delayed reactions). The total cumulative dose given in the OFC should be equivalent to a regular, age-appropriate serving size of the food. Some suggestions include a total of 8 to 10 g of dry food, 16 to 20 g of meat or fish, or 100 ml of wet food (22). Another suggested graded dosing schedule, using weight of food protein, consists of 3-mg, 10-mg, 30-mg, 100-mg, 300-mg, 1,000-mg, and 3,000-mg food protein doses (21). Once the challenge is completed, patients should generally be observed for up to 2 h. Once the patient has tolerated one of the above amounts in the challenge, then clinical reactivity has generally been ruled out, since a negative challenge has a high negative predictive value. However, for blinded challenges, negative challenges should be confirmed by an open feeding

of the suspected food to eliminate the rare possibility of a false-negative challenge.

Although any constellation of symptoms may occur during a positive food challenge, Ahrens et al. (23) analyzed the outcomes of 1,843 OFCs performed in children and found that certain foods were more likely to cause organ-specific symptoms than others during OFCs. Namely, gastrointestinal symptoms were more likely to occur during OFCs to egg and peanut compared to milk, soy, or wheat. Additionally, respiratory symptoms were more likely to occur with peanut compared to milk, egg, soy, or wheat OFCs.

In suspected non-IgE-mediated food allergies, such as food protein-induced enterocolitis syndrome, there are no specific laboratory tests, and the OFC may be the only way to identify causative foods. In OFCs for food protein-induced enterocolitis syndrome, patients need to be observed for at least 4 h postchallenge since reactions can occur up to 2 h postingestion, and intravenous access should be established prior to challenge since severe vomiting, diarrhea, and hypotension are common responses in failed challenges (22). For other, less acute non-IgE mediated gastrointestinal food allergies, patients may require several feedings over a 1- to 3-day period and these food introductions can usually be done in the home setting.

The decision to perform OFCs should not be taken lightly, as severe anaphylactic reactions can occur, and the challenges are time-consuming, cost-intensive, and may be stressful to the patients and their families. To aid in making the decision of when to challenge, the SPT wheal-size cutoffs described above that indicate the likelihood of true allergy based upon DBPCFCs should be considered. Other tools that can help guide whether to challenge a patient will be mentioned later in this chapter when food-specific IgE levels are discussed. Recent and severe anaphylaxis after an isolated ingestion of a food to which the patient is sensitized is a relative contraindication to performing a challenge, as the history is so convincing for a true food allergy that further investigation is not warranted. Because of the risk of anaphylaxis, the physician must be prepared to treat a severe reaction with emergency medications and equipment. Patients must be examined before the challenge begins as well as frequently during the OFC for objective signs of a reaction, and challenges need to be terminated promptly when a reaction becomes apparent.

As with any diagnostic test, false-positive and false-negative results may occur in OFCs. In the United States, the average false-negative rate for the DBPCFC was approximated at 1 to 3% (3). Caffarelli and Petroccione (24) reported that 5 of 193 patients (3%) challenged by DBPCFCs had passed a DBPCFC and then reacted the next day to an open feeding of the same food at home. Occasionally, an open challenge is positive in the face of a negative blinded challenge. Several possibilities explain this phenomenon. First, patients' threshold responses may vary even from day to day, or the open challenge could have contained more allergen than the blinded challenge. Second, the allergenicity of the food may have been different because of the way it was prepared. Third, the graded challenge may have actually induced a degree of desensitization that was not present when the full serving of the food was eaten (21).

IN VITRO TESTS

Quantification of Food-Specific IgE Antibodies

Another way to identify food-specific IgE that is more widely available to the general practitioner is the measurement of food-specific IgE in the serum. Various immunometric assays to measure results have evolved over time. The first widely used assay, initially described in 1967, was the RAST. In this type of test, the allergen in question is bound to a solid matrix and exposed to the patient's serum. If there is specific IgE for that allergen in the patient's serum, it binds to the protein matrix. After a buffer wash to remove unbound serum proteins, bound human IgE antibodies are detected with a radiolabeled anti-human IgE Fc. The RAST has since been replaced by fluorescence enzyme-labeled assays with improved analytical sensitivity and overall improved assay performance. The term "RAST," therefore, should no longer be used to refer to specific IgE assays. The most commonly used assay is currently the ImmunoCAP system (Thermo Fisher Scientific, Waltham, MA), which uses standardized allergens and is calibrated against the World Health Organization IgE standard. In this assay, results are reported on a scale from <0.35 or <0.1 kU_A/liter (undetectable) to the upper limit of >100 kU_A/liter. Results using ImmunoCAP have been shown in key studies to be predictive of symptomatic IgE-mediated food hypersensitivity. These studies provided support that certain concentrations of food-specific IgE were associated with a high likelihood of reactions, or true allergy. The 90 or 95% predictive values have been used to establish diagnostic decision points (25).

In a retrospective study of 196 children and adolescents (mean age, 5.2 years) with atopic dermatitis, Sampson and Ho (26) compared the levels of food-specific IgE with the results of DBPCFCs and found that concentrations of ≥ 6 kU_A/liter for egg, ≥ 32 kU_A/liter for cow's milk, ≥ 15 kU_A/liter for peanut, and ≥ 20 kU_A/liter for codfish were 95% predictive of an allergic reaction, thereby providing the 95% PPV. Therefore, a patient with a food-specific-IgE level greater than the 95% PPV could be considered reactive and an OFC would not be warranted. If, however, the level of food-specific IgE was less than the 95% PPV, a patient may be reactive but would need an OFC to confirm the diagnosis. There are caveats with this study that affect its use in the general population. First, all patients had atopic dermatitis, and these patients tend to have higher IgE levels. Second, this group of patients had a much higher prevalence of food allergy than is seen in most populations. Because of these factors, Sampson (25) performed a prospective study of 100 children (median age, 3.8 years) not selected for atopic dermatitis (only 61% had this disorder), with similar results, except the 95% PPV cutoff was lower for milk at 15 kU_A/liter.

Different results were obtained in studies of younger infants and children with different clinical histories. Garcia-Ara et al. (27) showed that an even lower concentration of food-specific IgE to milk had a high predictive capability, although their study included a much younger patient population of 170 infants (mean age, 4.8 months) without atopic dermatitis or gastrointestinal allergy. They determined the 95% PPV cutoff to be >5 kU_A/liter but recommended ≥ 2.5 kU_A/liter as the cutoff to not challenge because it still had a high probability of a positive challenge (90%) without a significant reduction in sensitivity. Osterballe and Bindslev-Jensen (28) determined the 95% PPV for egg to be 1.5 kU_A/liter in a population of 56 children with atopic dermatitis and a median age of 2.2 years. Boyano et al. (29), in a population of 81 children under 2 years of age (43% with atopic dermatitis), determined that an OFC was unnecessary to establish the diagnosis of egg allergy if the egg-white-specific IgE was ≥ 0.35 kU_A/liter and the patient had a history of immediate hypersensitivity to egg. Finally, Peters et al. (30) evaluated 5,276 infants 11 to 15 months of age from a population-based, longitudinal food allergy

study in Australia in order to determine SPT and specific IgE thresholds with 95% PPVs for challenge-proven allergy to egg, peanut, sesame, cow's milk, and shrimp in this age group. Eighty-three percent of infants with detectable SPTs underwent OFC. For SPTs, 95% PPVs were ≥8 mm for peanut, ≥4 mm for egg, and ≥8 mm for sesame. For specific IgE, 95% PPVs were ≥34 kU_A/liter for peanut and ≥1.7 kU_A/liter for egg.

Food-specific-IgE concentrations can also be helpful in monitoring a patient's ongoing sensitivity on an annual basis because they provide numerical values that can be monitored from an initial reference point. Moreover, food-specific-IgE cutoff values have been defined that can guide when patients should undergo OFCs to determine if they have outgrown their allergy. Perry et al. (31) retrospectively reviewed the levels of specific IgE for five major foods at the time of 604 open OFCs carried out in 391 patients. Challenges were performed when oral tolerance was suspected due to the lack of any reaction to the suspect food within the previous year and, for most patients, when the food-specific-IgE level was <0.35 kU_A/liter or approached one-fourth of the previously established 95% PPVs for milk, egg, and peanut or one-fourth of the 50 and 75% PPVs for soy and wheat, respectively. For analysis, patients were divided into two groups as follows, based on their reaction history: group 1, patients who clearly had a history of an allergic reaction or had previously failed a challenge to that food; and group 2, patients who were avoiding the suspect food solely on the basis of a positive test for food-specific IgE or who had an unclear history of reaction, such as worsening atopic dermatitis. The study identified food-specific IgE levels at which 50% of patients would pass an OFC to milk, egg, and peanut, a pass rate acceptable to both physicians and parents given the risk, expense, and time that each challenge entails. The proposed cutoff level for milk-specific IgE was 2 kU_A/liter, below which 53% of patients passed their challenge. For egg-specific IgE, the 50% cutoff was also 2 kU_A/liter, below which 60% of patients passed their challenge both with and without a clear history of reaction. For peanut, they recommended that patients with a clear history of reaction be challenged when the peanut-specific IgE level is <2 kU_A/liter, whereas a cutoff level of 5 kU_A/liter should be used for those patients with no clear history of ingestion. Firm recommendations could not be provided for soy and wheat, a problem seen with other studies as well (25, 26). However, in general, challenges should be considered for patients with a wheat-specific IgE <10 kU_A/liter or a soy-specific IgE <5 kU_A/liter, although higher levels may be appropriate for some patients, depending on their clinical history.

There are several important points regarding food-specific-IgE levels that need to be mentioned. The level of food-specific IgE, like the size of the SPT, does not correlate with the severity or type of reaction a patient will have, but especially high concentrations are associated with a very high likelihood of reaction (25). Also, food-specific IgE serological testing is preferable to SPTs in patients with significant dermatographism or severe skin disease and patients who cannot discontinue antihistamines, which can all lead to false-positive tests. Finally, SPTs may be dangerous in patients with intense sensitivity to certain foods (26).

Component Resolved Diagnostics

Component resolved diagnostics (CRD) has recently emerged as a tool that may provide improved accuracy in food allergy testing. CRD uses individual, purified allergenic proteins, rather than crude, whole allergen extracts, in assaying for IgE antibody-dependent sensitivity. This may, therefore, reduce false-positive tests that result from pollen cross-reactivity and may identify sensitivity to proteins that are more allergenic than others. Any diagnostic test with improved accuracy may prevent the need for unnecessary OFCs.

Several studies have suggested CRD may improve the specificity of food allergy diagnosis and allow for the differentiation between allergy and tolerance. Data are most convincing for peanut allergy, where sensitization to different peanut components best predicts the likelihood of true peanut allergy in sensitized patients. Nicolaou et al. (32) evaluated 933 children at age 8 years from a population-based birth cohort. They found that 110 (11.8%) children were sensitized to peanut, based on SPT and/or specific IgE measurement. Only 22.4% of peanut-sensitized patients were clinically allergic to peanut based on DBPCFC. CRD detected significant differences in component recognition between children with peanut allergy and those who were able to tolerate peanut. Allergic children had higher Ara h 1 to 3 values compared to peanut-tolerant children, and the storage protein Ara h 2 was identified as the most important predictor of peanut allergy. Conversely, the peanut component Ara 8, which is homologous with Bet v 1 in birch pollen, has been associated with peanut tolerance or mild oral allergy symptoms in peanut allergy. Asarnoj et al. (33) evaluated 144 children sensitized only to Ara h 8 and none of the major peanut components (Ara h 1 to 3). All but one child demonstrated tolerance to peanut, and the subject who reacted on DBPCFC was reevaluated and was found to have a rising peanut IgE level as well as sensitivity to Ara h 6, a stable peanut allergen.

A study by D'Urbano et al. (34) utilized CRD to predict food-challenge outcomes in 58 children with suspected cow's milk allergy and 46 with suspected egg allergy. The authors found that the cow's milk allergen casein (Bos d 8) and the egg allergen ovomucoid (Gal d 1) were the most predictive of true food allergy to milk and egg, respectively. Their 95% clinical decision points, or the food-specific IgE level above which 95% of patients would react, provided improved accuracy compared to specific IgE to the whole extracts of these foods. With respect to soy allergy, Holzhauser et al. (35) performed DBPCFCs in subjects with suspected soy allergy and concluded that sensitization to the soy storage proteins β-conglycinin (Gly m 5) and glycinin (Gly m 6) are associated with severe reactions to soy. The additional analysis of IgE to Gly m 2S albumin in one Japanese pediatric cohort aided in the diagnosis of soybean allergy (36).

Ando et al. (37) have suggested that the measurement of specific IgE antibodies to ovomucoid is useful in differentiating between children who react to heated egg white and those who are able to tolerate heated egg. This study evaluated 108 children with suspected egg allergy; all subjects underwent ImmunoCAP testing to egg white and ovalbumin and underwent DBPCFC to both regular and baked egg. They concluded that while egg-white IgE is most useful in diagnosing allergy to unbaked egg, ovomucoid is superior in diagnosing baked egg allergy, with an ovomucoid IgE of 10.8 kU_A/liter having 96% specificity in predicting clinical reactivity. Similarly, for milk allergy, Caubet et al. (38) evaluated 225 children with suspected milk allergy. They assessed IgE levels to cow's milk, casein, and β-lactoglobulin and performed OFCs to baked and regular milk. The study found that casein-specific IgE had the best accuracy in predicting baked milk reactivity, with a casein IgE of 20.2 kU_A/liter having 95% specificity in predicting a clinical reaction to baked milk.

While CRD represents an exciting advance that is likely to improve the diagnosis of food allergy over time, further

study is still needed to define its role in clinical practice. Like previous studies mentioned above using standard ImmunoCAP assays, several of the studies using CRD did not employ OFCs but based the diagnosis on clinical history and serology, which likely led to false-positive diagnoses (32, 35). Additionally, the number of studies evaluating the clinical utility of CRD in predicting food challenge outcomes in allergic subjects, while informative, has been sparse.

Quantification of Food-Specific IgG

Overall, levels of food-specific IgG, including IgG_4 antibodies, rise in response to long-term exposure in both symptomatic and asymptomatic patients and may comprise a normal, physiologic response to repeated food exposure. There has been no strong evidence to link the presence of IgG_4 antibodies to the mechanism of histamine release from basophils *in vivo*. IgG_4 levels are generally elevated in patients with food allergy affecting the gastrointestinal tract, but their specificities typically reflect the type of foods ingested and are not indicative of food-related pathogenesis (39).

IgG_4 antibodies may also reflect the induction of immunologic tolerance to specific antigens, such as food. Savilahti et al. (40) compared serial serum samples from 11 children with persistent IgE-mediated cow's milk allergy to 12 children with a history of cow's milk allergy who attained tolerance by age 3 years. They found that tolerance to cow's milk protein was associated with increasing IgG_4 binding to milk protein epitopes. It has also been shown that IgG_4 food-specific antibodies increase in patients who have successfully completed oral immunotherapy for milk and peanut allergy (41, 42). In summary, food-specific IgG antibodies play no role in the diagnosis of food hypersensitivity reactions.

Total IgE

IgE concentrations in serum are highly age dependent, rising gradually through childhood until they peak between ages 10 and 15 and then steadily decline throughout adulthood. Klink et al. (43) analyzed serum IgE levels in 2,657 subjects grouped into skin test-positive or skin test-negative rhinitic, asthmatic, or asymptomatic individuals. They found that although serum IgE concentrations tended to be higher in allergic children and adults than in nonallergic individuals, the range of IgE in all groups was extremely wide. There is usually a large overlap in the ranges of IgE between atopic and nonatopic populations, resulting in no single level of IgE that clearly distinguishes the different groups at a level of precision that is clinically meaningful. This large overlap greatly limits the diagnostic sensitivity of total serum IgE as a diagnostic screening test for allergy.

There are many atopic conditions that may be associated with elevated total IgE levels. In the realm of food allergy, the most common is atopic dermatitis (44). Elevated total serum IgE levels can lead to additional confusion in the diagnosis of food allergy as they further increase the probability of detecting falsely positive food IgE tests.

Another question has been whether the ratio of specific to total IgE may enhance the accuracy of food allergy diagnosis. Mehl et al. (45) compared the ratio of food-specific to total IgE to food-specific IgE alone in 501 children (median age, 13 months) undergoing 992 OFCs. The sensitivity and specificity of the clinical decision points of the ratio were similar to those of IgE levels to milk, egg, and wheat. Therefore, the predictive value of the ratio for these foods did not offer any additional advantage over the measurement of food-specific IgE alone in diagnosing food allergy.

Basophil Responses

Various laboratory tests have been developed to examine basophil responses to allergens, including foods. Basophil activation testing (BAT) measures the level of activation after incubation with allergen by evaluating the expression of cell surface proteins, such as CD63 or CD203c, via flow cytometry (46). BAT was shown to be useful in predicting outcomes of oral food challenges in patients with cow's milk allergy, with superior predictive values compared to SPT and food-specific IgE testing (47). Another study found that the use of BAT in children with peanut or egg allergy may help distinguish between patients who are simply sensitized to these specific foods and those with true clinical reactivity (48).

Basophil histamine release (BHR) after stimulation by antigen has been proposed as another *in vitro* correlate to *in vivo* allergic responses. BHR as a method of diagnosing food allergy was reported by Sato et al. (49), who determined that the threshold of histamine release, defined as the minimum concentration of egg white, cow's milk, or wheat antigen necessary to induce a 10% net histamine release, was useful in diagnosing food allergy to these respective foods, based on OFC outcomes or recent convincing history of reaction. Wanich et al. (50) studied both milk-allergic and milk-tolerant subjects and found that the basophils of those tolerant to milk were significantly less responsive to milk allergen stimulation compared to the basophils of milk-allergic subjects, suggesting extrinsic suppression of milk-specific basophil reactivity in those with tolerance. However, another study by Sampson et al. (51) that compared BHR, SPTs, and DBPCFCs found that the BHR assay was no more effective in predicting clinical sensitivity than SPTs.

The clinical use of BHR and BAT is complicated by several factors: (i) neither test is widely available; (ii) the blood needs to be processed within a relatively short period of time to ensure cellular viability; (iii) there are no standardized methods for performing these tests; and (iv) basophils from up to 80% of children with atopic dermatitis and food allergy documented by DBPCFC (51) can spontaneously release histamine, although the use of whole blood in these flow assays may overcome this issue. At present, basophil response assays remain primarily research tools.

Serum Tryptase

An increased level of serum tryptase, a neutral protease found almost exclusively in mast cells, has been found to be an excellent marker of mast cell activation in anaphylactic reactions. Basophils, the only other cell type in which tryptase has been found, contain 100 to 1,000 times less tryptase than mast cells (52). Tryptase level elevations are believed to begin at 1 h after mast cell stimulation (53), and the half-life of tryptase in the circulation is approximately 2 h (52).

An increase in serum tryptase in food-induced anaphylaxis, however, is rarely seen and therefore is not a reliable marker of food-related allergic reactions. The absence of a substantial increase in mast cell tryptase in food-induced reactions suggests that other mediators from mast cells may play a more central role, or that basophils, which contain significantly less tryptase, are the critical players in these reactions. Other cell types, including macrophages, monocytes, and endothelial cells that express FcεRI, the high affinity receptor for IgE, may also play a role in the allergic reaction to foods (54).

Specific Epitope Analysis

Recent technological advances have enabled investigators to map allergenic epitopes of many major food allergens, including milk, egg, and peanut, and determine specifically

where a patient's IgE antibodies bind to those proteins. As a result, it was discovered that conformational and sequential (or linear) epitopes can both be responsible for allergic reactions. Furthermore, individuals who possess IgE antibodies to sequential epitopes react to the allergenic food in any form, whether extensively cooked or partially hydrolyzed, while patients with IgE antibodies to conformational epitopes appear to tolerate small amounts of the food after extensive cooking or partial hydrolysis because the tertiary structure of the allergenic protein is altered and the conformational epitopes are destroyed (3).

Additionally, in several studies of egg- and milk-allergic patients (55, 56), it was shown that certain patients with IgE antibodies to sequential epitopes have a propensity to have persistent allergy, while patients with IgE antibodies primarily to conformational epitopes tend to more rapidly develop clinical tolerance. Therefore, screening for antibodies to specific epitopes may prove useful in identifying children who will not outgrow their allergy and thus may be candidates for immunotherapy when it becomes available. Further analysis of epitope binding in peanut-allergic patients demonstrated that there are differences in peanut-allergenic epitope-recognition patterns between patients with symptomatic peanut allergy and those who are sensitized but clinically tolerant (57, 58). Therefore, the addition of epitope-specific IgE determinations might prove to be a more valuable tool for diagnosing symptomatic peanut allergy than even CRD if this can be developed for clinical use. It has also been demonstrated that patients with peanut allergy with IgE antibodies to many epitopes, called broad epitope diversity, tend to have more severe allergic reactions than those who have IgE binding to relatively few epitopes (58).

CONCLUSIONS

The diagnosis of immunological reactions to foods must begin with a thorough history and physical exam, as this provides the basis for making decisions of what testing, if any, should be done to confirm the history. A number of valid diagnostic tools exist for diagnosing IgE-mediated food reactions, both *in vivo* methods, such as skin testing and food challenges, and *in vitro* methods, including measurement of serum food-specific IgE concentrations. Both methods of testing have their advantages and limitations, depending on the clinical situation, but for non-IgE-mediated food reactions, elimination diets and OFCs may be the only means of diagnosis. Tests that have not proven helpful in food allergy diagnosis include quantification of food-specific IgG and IgG_4, total serum IgE levels, and serum tryptase concentrations. Tests that warrant further study but show promise include allergenic component-based CRD and epitope-specific IgE measurements, both of which may provide improved diagnostic specificity. The APT may aid in the diagnosis of non-IgE-mediated disorders and delayed reactions to foods, but further research and standardization is required. Regardless of the test chosen, the DBPCFC still remains the gold standard for diagnosing food allergy. Finally, important features of the studies mentioned in this chapter for the described tests that should be appreciated by clinicians are (i) that the data generated may be particular to the study population and test material, and (ii) that the age and clinical disease of the patients are important variables. Clinicians must therefore be careful in applying the results in these published studies to their own individual clinical situations.

Diagnosis of Rare Eosinophilic and Mast Cell Disorders

CEM AKIN, CALMAN PRUSSIN, AND AMY D. KLION

85

HYPEREOSINOPHILIC SYNDROMES (HES)

Whereas mild to moderate eosinophilia has been reported in as many as 0.1% of North American outpatients (1) and may be due to seasonal allergies, asthma, or other common conditions, marked eosinophilia (>1,500/mm^3) is relatively infrequent and should always prompt a diagnostic evaluation. The differential diagnosis of marked eosinophilia is broad and includes secondary causes of eosinophilia (Table 1), such as hypersensitivity reactions, helminth infection, and neoplastic and inflammatory disorders, as well as several disorders for which eosinophilia is thought to be the primary etiology. In many cases, a thorough diagnostic evaluation will reveal a secondary cause of the eosinophilia, and appropriate treatment can be instituted. In other instances, a well-defined, single-organ-restricted, primary eosinophil disorder, such as eosinophilic esophagitis, eosinophilic fasciitis, or eosinophilia cystitis, is identified. Once secondary causes and alternative diagnoses have been excluded, however, a systemic primary eosinophil disorder should be considered.

Definition of HES

The term hypereosinophilic syndromes (HES) was first used in 1968 by Hardy and Anderson to describe three patients with marked peripheral eosinophilia, hepatosplenomegaly, and cardiac and/or pulmonary symptoms (2). Diagnostic criteria for HES were first proposed in 1975 by Chusid et al. (3), and they included idiopathic hypereosinophilia (>1,500 eosinophils/mm^3) of >6 months' duration, with signs and symptoms of eosinophil-mediated or unexplained end organ damage. However, as more-sophisticated diagnostic testing has become available and subgroups of patients with HES of known causes have been described, the "idiopathic" nature of HES has been called into question. Furthermore, the availability of effective treatment for HES often leads to the resolution of eosinophilia before the requisite 6 months has elapsed. Finally, the classification of eosinophilic syndromes of unknown cause with distinctive clinical patterns, such as episodic angioedema and eosinophilia (4), which are not excluded by this definition, and marked eosinophilia without current evidence of end organ manifestations (hypereosinophilia of unknown significance [5]), which is excluded by this definition, remains unresolved (see below).

In view of the above-described issues, a number of newer definitions and classification systems have been proposed (6–8). For the purposes of this review, HES will be defined as (i) eosinophilia (>1,500 eosinophils/mm^3 on at least two occasions), (ii) the absence of a secondary cause of eosinophilia other than the primary hematologic abnormalities described below, and (iii) end organ manifestations attributable to eosinophilia. Using this definition, HES is a group of heterogeneous disorders that typically occur between the ages of 20 and 50 years but may present in childhood or advanced age. The overall prevalences appear to be equal in men and women. The previously described male predominance (9:1) was likely due to an overrepresentation of platelet-derived growth factor receptor alpha (*PDGFRA*)-positive disease in early series. The clinical manifestations of HES are extremely varied, ranging from nonspecific complaints, such as fatigue, myalgias, and rhinitis, to severe end organ damage, including endomyocardial fibrosis, restrictive pulmonary disease, and neuropathy (9, 10). Furthermore, some patients may remain asymptomatic for decades despite markedly elevated eosinophil counts (5, 11). Although data from a number of published case series suggest that cardiac, neurologic, and dermatologic manifestations are most common (9, 10), any organ can be affected. Notably, increased susceptibility to infection is not a feature of HES. Thus, a history of recurrent infection should prompt an investigation for secondary causes of eosinophilia, including malignancy and immunodeficiency.

Diagnosis of HES

The first step in the diagnosis of HES is to exclude other disorders associated with marked peripheral eosinophilia. These include parasitic infections, drug hypersensitivity reactions, neoplasms, and immunodysregulatory disorders associated with secondary eosinophilia (Table 1). Once it is established that the patient has eosinophilia of >1,500/mm^3 of unknown cause, it is important to determine if the patient has one of the identifiable subtypes of HES, as this determination has prognostic and therapeutic implications (Table 2).

It is beyond the scope of this chapter to provide a comprehensive diagnostic approach to eosinophil-associated disorders. Nevertheless, several general principles apply. First, a thorough clinical history and physical examination are essential and should include a detailed travel history, medication and dietary history (including the use of dietary and herbal supplements), past medical history (including

doi:10.1128/9781555818722.ch85

TABLE 1 Secondary causes of marked eosinophilia[a]

Category and disease(s)
Allergic disorders
Asthma and/or atopic disease (rare)

Drug hypersensitivity reactions
Infectious diseases
Helminth infection
Ectoparasite infestations (scabies and myiasis)
Protozoal infection (rarely in isosporiasis and sarcocystis)
Fungal infection (especially coccidiomycosis)
HIV infection
Neoplasms
Leukemia, lymphoma, or adenocarcinoma
Hypoadrenalism
Diseases associated with immunodysregulation
Sarcoidosis, inflammatory bowel disease, or connective tissue disorders
Other
Cholesterol embolization, radiation exposure

[a]This list is not exhaustive.

risk factors for human immunodeficiency virus [HIV] infections), and family history. It should be noted that HES occurs in countries where helminth infections are common, and some helminth infections associated with marked eosinophilia, including strongyloidiasis, occur worldwide. Second, whenever possible, all medications and supplements should be discontinued for a minimum of 1 month (or longer, depending on the half-life of the particular agent). Finally, if routine laboratory results (including HIV testing) and diagnostic testing do not lead to an alternative diagnosis, computed tomography of the chest, abdomen, and pelvis, as well as a bone marrow examination, should be performed in all patients to exclude occult malignancy before a diagnosis of HES is confirmed.

Primary eosinophilic disorders affecting a single organ, such as eosinophilic gastrointestinal disorders (EGIDs), eosinophilic fasciitis, and chronic eosinophilic pneumonia, may be associated with peripheral eosinophilia of >1,500/mm^3. When this occurs, it can be difficult to determine whether the patient has HES with single-organ involvement or a distinct primary eosinophilic disorder. For the purposes of this review, EGIDs, irrespective of the peripheral eosinophil count, will be discussed in a separate section. It should be noted, however, that the initial evaluation of patients with a presumed single-organ eosinophilic disorder and peripheral eosinophilia of >1,500/mm^3 should include assessment for possible HES.

Classification of HES Subtypes

Although it has long been appreciated that HES are a heterogeneous group of disorders (3, 9, 10), it is only recently that advances in molecular and immunologic techniques have begun to delineate the precise pathogenesis of HES in some groups of patients. Of these defined groups, the most common appear to be a clonal myeloproliferative disorder associated with the constitutive activation of platelet-derived growth factor receptor alpha (PDGFRA) (12, 13) and a lymphocytic variant characterized by the presence of a clonal and/or aberrant population of lymphocytes (14, 15). An autosomal dominant familial form of HES that mapped to chromosome 5q31-33 has also been described, although the exact nature of the molecular abnormality remains to be elucidated (16, 17). Subtype identification is important since it has profound implications for the patient with respect to anticipated clinical manifestations, prognosis, and treatment.

Myeloproliferative HES

Epidemiology and Clinical Features

Approximately 30% of patients presenting with a clinical diagnosis of HES have features suggestive of myeloproliferative HES (MHES), including dysplastic eosinophils, elevated serum B_{12} levels, splenomegaly, anemia, thrombocytopenia, and bone marrow hypercellularity with reticulin fibrosis (18). The vast majority of these patients have a myeloproliferative neoplasm (MPN) associated with an interstitial deletion in chromosome 4, del(4)(q12q12), that results in the formation of a fusion tyrosine kinase, FIP1-like-1/platelet-derived growth receptor α (FIP1L1-PDGFRA) that is exquisitely sensitive to the tyrosine kinase inhibitor imatinib (12, 13, 18). Additional features of *PDGFRA*-associated MPN include a striking male predominance and almost universal involvement of the mast cell lineage, with elevated serum tryptase levels and increased numbers of spindle-shaped CD25-positive mast cells in the bone marrow (17). Although alternate fusion partners (19) and point mutations (20) in *PDGFRA* have been described for patients presenting with MHES, these abnormalities appear to be relatively infrequent, although this may be due in part to the fact that routine testing is not currently available. Other myeloproliferative disorders that

TABLE 2 Evaluation of patients presumed to have HES

Test(s) or measurement
Complete blood count with differential[a]
Bone marrow aspirate and biopsy (with staining for reticulin and tryptase)
Conventional cytogenetics
Assessment of end organ pathology
Echocardiogram
Pulmonary function tests
Skin or gastrointestinal biopsies, if indicated
Chest and abdomen computed tomography scan
Subtype differentiation for myeloproliferative disease
Examination of peripheral smear for myeloid precursors or dysplasia
Tryptase level in serum
Vitamin B_{12} level in serum
Testing for *FIP1L1-PDGFRA* fusion (by RT-PCR or FISH)
Testing for additional potential abnormalities (i.e., *PDGFRB*, *FGFR1*, *JAK2*)
Subtype differentiation for lymphoproliferative disease
Serum immunoglobulins, including IgE
Lymphocyte phenotyping[b]
TCR and B-cell receptor gene rearrangement analysis
TARC level in serum
Assessment of T-cell cytokine profile, if reliable assays are available

[a]A CBC with differential should be performed every 3 days for 1 month in the absence of steroid treatment (if possible) for patients presenting with angioedema to exclude episodic angioedema and eosinophilia.

[b]Antibodies specific for the following additional markers should be included if routine phenotyping is normal and the lymphocytic variant is suspected: CD2, CD5, CD6, CD7, CD8, CD25, CD27, CD45RO, TCR-α/β, TCR-γ/δ, HLA-DR, and CD95.

can present as MHES include chronic eosinophilic leukemia that is not otherwise specified and MPN associated with rearrangements or mutations involving other tyrosine kinases, the most common of which are *PDGFRB, JAK2* and *FGFR1*, and D816V *KIT*-associated systemic mastocytosis (19, 21). In rare cases, patients with lymphocytic leukemia can present with clinical and bone marrow features that are indistinguishable from MHES (22). Finally, it is important to recognize that, even in a research setting, causative abnormalities cannot be identified in all patients who present with a clinical picture consistent with MHES.

Diagnosis

A bone marrow examination is a crucial component of the diagnostic evaluation of presumed MHES and should include studies to exclude chronic eosinophilic leukemia not otherwise specified (see World Health Organization [WHO] diagnostic guidelines [7]) and D816V *KIT*-associated systemic mastocytosis (see the section on mastocytosis below). Routine cytogenetic analysis, fluorescent *in situ* hybridization (FISH) to look for rearrangements in *PDGFRB* and *FGFR1*, and V617F *JAK2* mutation testing are commercially available and should also be performed.

The *FIP1L1-PDGFRA* fusion gene can be detected in peripheral blood or bone marrow mononuclear cells by nested reverse transcription-PCR (RT-PCR) or FISH. The breakpoints in *FIP1L1* are varied but are typically located in a 40-kb region spanning introns 7 to 10 of *FIP1L1*. In contrast, the breakpoints in *PDGFRA* appear to be restricted to a region of exon 12 that contains the WW-like region of the juxtamembrane domain (23). Disruption of this WW-like domain has been shown to cause constitutive kinase activation in members of the PDGFR family of tyrosine kinases, including *PDGFRA* (23). This mutation is undetectable by standard cytogenetic analysis (12, 13). Although published data to date suggest that these methods have comparable sensitivities for the detection of the *FIP1L1-PDGFRA* fusion gene (24), FISH has the theoretical advantage of being able to detect cases with variant *FIP1L1* breakpoints, translocations, or alternative *PDGFRA* fusion partners that appear negative by nested RT-PCR. On the other hand, FISH is more technically challenging, and the high autofluorescence of eosinophil granules makes an exact quantification of the number of positive cells difficult. If neither of these tests is available, surrogate markers for *PDGFRA*-associated MPN can be used, as described below.

Nested RT-PCR for *FIP1L1-PDGFRA*

Following total RNA isolation from peripheral blood mononuclear cells by standard methods, first-strand cDNA is synthesized from 2 μg of total RNA by the use of random-hexamer primers. The fusion of *FIP1L1* to *PDGFRA* is detected by nested PCR. The first PCR amplifies 2 μl of cDNA in a 50-μl reaction mix, using primers FIP1L1-F1 (5′-ACCTGGTGCTGATCTTTCTGAT) and PDGFRA-R1 (5′-TGAGAGCTTGTTTTTCACTGGA) and the following cycle conditions: 3 min at 95°C followed by 35 cycles of 95°C for 30 s, 58°C for 30 s, and 72°C for 1 min and a final extension at 72°C for 4 min. The product is then diluted 1/100, and 1 μl is used in a second PCR with primers FIP1L1-F2 (5′-AAAGAGGATACGAATGGGACTTG) and PDGFRA-R2 (5′-GGGACCGGCTTAATCCATAG) and the same cycle conditions. Multiple bands are often present upon gel electrophoresis and represent splice variants (12, 18). The EOL-1 cell line (ACC386; available from the Deutsche Sammlung von Mikroorganismen und Zellkulturen [http://www.dsmz.de]) has been shown to possess the *FIP1L1-PDGFRA* mutation (13) and is useful as a positive control. RT-PCR for a housekeeping gene, such as the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene, should also be performed as a control for the amount and quality of the RNA template.

Fluorescent *In Situ* Hybridization

Slides for FISH are prepared by standard methods. BAC clones 120K16 (mapped centromeric of *FIP1L1*), 3H20 (mapped between *FIP1L1* and *PDGFRA*), and 24O10 (mapped telomeric of *PDGFRA*) can be obtained from the RPCI11 Roswell Park Cancer Institute library (http://bacpac.chori.org) for three-color labeling by nick translation. Following hybridization, interphase nuclei are examined for the presence or absence of the 3H20 signal, which is lost as a result of the interstitial deletion in cells with the *FIP1L1-PDGFRA* fusion gene (12).

One-color FISH with a probe for the cysteine-rich hydrophobic domain 2 (*CHIC2*) locus situated between *FIP1L1* and *PDGFRA* on chromosome 4q was initially described as a surrogate for detection of the fusion gene to identify patients with the *FIP1L1-PDGFRA* fusion gene (21). Although it is less cumbersome, this method is not useful for the detection of the *FIP1L1-PDGFRA* fusion genes, in which there is a translocation. A two-color modification of this approach was recently reported by the same authors (25) and appears to be comparable to the three-color strategy outlined above. FISH assays using the same strategy but different probes are commercially available.

Other (Bone Marrow Features and Level of Tryptase in Serum)

Clinical and laboratory features supportive of a diagnosis of *PDGFRA*-associated MPN (18) may serve as surrogates if formal testing for the mutation is not available. These include male gender, elevated tryptase levels in serum, splenomegaly, clinical evidence of fibrotic end organ involvement, bone marrow features of myeloproliferative disease (including hypercellularity and reticulin fibrosis), increased and spindle-shaped bone marrow mast cells, anemia, thrombocytopenia, and elevated vitamin B_{12} levels in serum. Although none of these features is by itself diagnostic of the *FIP1L1-PDGFRA* fusion gene, the presence of an elevated tryptase level in serum and four or more of the above-described clinical features has correlated with the presence of the fusion gene in all of the patients evaluated at our center to date and is predictive of a response to imatinib. It should be noted that rare patients with *FIP1L1-PDGFRA*-associated MPN have normal tryptase levels and no apparent involvement of the mast cell lineage. Several commercial laboratories measure serum tryptase levels. Enzyme-linked immunosorbent assay (ELISA) kits are also available from a number of sources.

Imatinib-responsive patients with HES in whom the *FIP1L1-PDGFRA* mutation cannot be demonstrated have been reported in several studies (10, 24). Clinical and hematologic responses in these patients are generally slower and require higher doses of imatinib than responses in patients with *PDGFRA*-associated MPN. A recent study suggests that the best predictor of imatinib response in these patients is the presence of four or more of the above-described myeloproliferative features (103).

Although the bone marrow features and elevated serum tryptase seen in *PDGFRA*-associated MPN sometimes fulfill the diagnostic criteria for systemic mastocytosis (see the Mastocytosis section below), it is extremely important to distinguish these patients from those with c-*kit*

mutation-driven disease, since D816V, the most common c-*kit* mutation associated with systemic mastocytosis, leads to resistance to imatinib (21). In this regard, clinical features, including the ratio of serum tryptase level to the eosinophil number, can be very useful (26).

Therapy

The dismal survival rates reported in the early HES literature (9, 27) likely reflect the high mortality from cardiac and neurologic complications in patients with *PDGFRA*-associated MPN prior to the availability of imatinib. Clinical, hematologic, and molecular responses are rapidly achieved with imatinib treatment in patients with *PDGFRA*-associated MPN and appear to be sustained (12, 28, 29). Consequently, whereas conventional first-line therapy for HES in most patients (including patients with MHES who are *PDGFRA* negative) should continue to be steroids, patients with *PDGFRA*-associated MPN are typically resistant to steroids and should receive targeted therapy with imatinib mesylate. It should be noted that imatinib therapy is not without risk, as life-threatening complications have occurred in patients with eosinophilic cardiac disease (22, 30). Troponin levels in serum have been proposed as a pretreatment marker for the development of this complication (30). Although uncommon in *PDGFRA*-positive MPN, primary and secondary resistance to imatinib has been reported (31, 32). Since the most common cause appears to be a mutation (T674I) that is homologous to the well-described T315I mutation in BCR-ABL, tyrosine kinase inhibitors that are active against this mutation should be used in a setting of imatinib resistance. Allogeneic bone marrow transplantation is a potentially curative alternative for patients with aggressive or treatment-refractory disease (33).

Lymphocytic Variant HES

Epidemiology and Clinical Features

Despite isolated reports of clonal populations of T cells in patients with HES as early as 1994 (14, 15), it was not until 1999 that a distinct subgroup of patients with lymphocyte-driven HES (LHES) was first described (34). Hypereosinophilia in these patients is believed to occur in response to the production of eosinophilopoietic cytokines, particularly interleukin 5 (IL-5), by clonal populations of activated phenotypically abnormal T lymphocytes. Although the levels of IL-5 in the serum are often normal, an increased production of IL-5 by stimulated peripheral blood mononuclear cells and/or phenotypically abnormal T-cell populations can be demonstrated in most patients with LHES, consistent with this hypothesis (34–36). Other evidence of Th2 activation in patients with this variant includes elevations of immunoglobulin E (IgE) and thymus- and activation-regulated chemokine (TARC) in serum (10, 37). Cytogenetic abnormalities are occasionally present in patients with the lymphocytic variant, although no consistent pattern has been delineated (36).

LHES appears to account for approximately 20% of HES cases, and LHES cases are equally distributed between men and women (10, 36). Although the clinical manifestations of this subgroup of patients can be extremely varied, tissue fibrosis, including endomyocardial fibrosis, is uncommon. In addition, patients with LHES share several clinical characteristics, the most striking of which is the predominance of dermatologic manifestations, including pruritus, urticaria, angioedema, and erythroderma (36). Gastrointestinal symptoms and obstructive pulmonary disease are also extremely common. Many patients have a history of atopic disease, and elevated IgE and IgG levels are common, but not restricted, to this subgroup of patients with HES.

Despite the relatively low mortality rate for this subgroup, the morbidity, due both to the underlying disease and to secondary effects of treatment, is significant. Furthermore, progression to T-cell lymphoma appears to be most common in this subgroup of patients and should be suspected in the setting of increasing numbers of aberrant T cells and/or the development of lymphadenopathy (35, 36). Two features that appear to be associated with an increased likelihood of progression to lymphoma are the $CD3^-$ $CD4^+$ surface phenotype and the presence of cytogenetic abnormalities.

Diagnosis

The diagnosis of LHES is based on the identification of a clonal population of phenotypically abnormal T cells in the peripheral blood by flow cytometry (see chapter 17 of this *Manual*). The sensitivity of this assay depends to a large degree on the number of antibodies used and the ability of the laboratory to detect subtle changes in the surface phenotype. Although T-cell clonality is not always present in cases with a demonstrable population of aberrant lymphocytes and is not essential for the diagnosis of the lymphocytic variant, identification of a clonal population of T cells by T-cell receptor (TCR) rearrangement analysis is strongly supportive of this diagnosis. Other diagnostic tests that may be helpful in establishing the diagnosis include the measurement of TARC levels in serum and the assessment of the lymphocyte production of eosinophilopoietic cytokines. Serum levels of IL-5 may be undetectable or elevated in patients with LHES and have no diagnostic or prognostic value.

Lymphocyte Phenotype

Although the most common aberrant phenotype of the lymphocytic variant of HES appears to be $CD3^-$ $CD4^+$, several other surface phenotypes have been described, including $CD3^+$ $CD4^-$ $CD8^-$ and $CD2^-$ $CD3^+$ (34). In many cases, the aberrant population may be identifiable only by markers that are not included in routine panels (such as CD5, CD6, CD7, CD27, and CD95) or by slight alterations in staining intensity. Therefore, if the lymphocytic variant is suspected and routine lymphocyte phenotyping is normal, surface staining for additional markers, including CD5, CD6, CD7, and CD27, should be considered. Activation markers, such as CD25 and HLA-DR, are commonly increased on the surfaces of aberrant T cells, providing additional markers.

Other (TCR Rearrangement Analysis, Measurement of TARC Levels, and Cytokine Assays)

T-cell clonality can be assessed in peripheral blood or bone marrow samples by PCR evaluation of TCR usage and has been reported to be present in approximately 75% of patients with the lymphocytic variant of HES, as defined by flow cytometry. When present, the demonstration of clonality may be helpful, although false-negative results may occur when the clonal population is very small or involves clonal deletion of TCR chain genes (35). In addition, restricted (or oligoclonal) patterns of TCR usage are common in all forms of HES, necessitating a very strict interpretation of banding results.

TARC is a CC chemokine thought to be involved in Th2-mediated immune responses. TARC levels in serum can be measured reliably by using several commercially available ELISA kits and are markedly elevated (>1,000 pg/ml) in patients with lymphocytic HES (10, 37). TARC levels in serum are also markedly elevated in patients with

cutaneous T-cell lymphoma (38) (a disorder that may overlap HES in clinical presentation) and rarely in patients with helminth infection (39) or atopic dermatitis (40). Thus, although TARC levels in serum may be a useful surrogate marker for T-cell clonality in HES, the presence of elevated levels should not replace a thorough diagnostic evaluation.

The ultimate proof of lymphocyte-driven HES is the documentation of an increased production of eosinophilopoietic cytokines by circulating lymphocytes. Enhanced levels of IL-3, IL-5, and/or granulocyte-macrophage colony-stimulating factor have been detected by ELISA in supernatants from *in vitro* cultures of peripheral blood mononuclear cells or purified T cells from patients with the lymphocytic variant of HES (34–36). Increased percentages of lymphocytes positive for eosinophilopoietic cytokines have also been demonstrated by intracellular flow cytometry in these patients. Although these assays are not routinely available in clinical laboratories at this time, they may be helpful, particularly in situations where an abnormal surface phenotype is not detected by more-standard methods.

Treatment

Imatinib does not appear to be useful for treating patients with LHES (41) and should not be used as first-line therapy for these patients. Historically, steroids have been used successfully in the majority of cases to control clinical symptoms, and significant decreases in clonal populations in response to steroid therapy have been described (10, 35). In patients with steroid-refractory disease or who are intolerant of the side effects of steroid treatment, a number of immunomodulatory agents with effects on Th2 cytokine production and T-cell proliferation, including alpha interferon, cyclosporine, and intravenous immunoglobulin, have been shown to have a therapeutic effect. Although stable responses have been achieved with relatively low doses of alpha interferon over prolonged periods of time, *in vitro* data demonstrating an inhibition of apoptosis of clonal $CD3^-$ $CD4^+$ T cells (42) suggest that interferon monotherapy should be avoided for this subgroup of patients. Newer agents, such as antibody to IL-5, that directly target eosinophilopoietic cytokines are currently in clinical trials and appear promising. In fact, subgroup analysis of a double-blind, placebo-controlled clinical trial revealed that mepolizumab, a humanized antibody to IL-5, was equally effective as a steroid-sparing agent in subjects with LHES and those with idiopathic HES (43).

Other

Several other HES of unknown etiology have distinctive clinical patterns that appear to set them apart. One of the most intriguing of these is episodic angioedema and eosinophilia (Gleich's syndrome) (44). Gleich's syndrome is characterized by episodic, but pronounced, eosinophilia and angioedema. In most cases, the episodes occur monthly and last for 7 to 11 days. Cyclical increases in eosinophilopoietic cytokines, most often IL-5, can be demonstrated preceding the rise in peripheral eosinophil counts. Although some patients with this syndrome ultimately progress to HES and/or develop clonal populations of lymphocytes (45), the unique clinical presentation is suggestive of a common and distinct etiology for this clinical subgroup of patients. The diagnosis should be suspected in patients whose primary complaint is swelling and/or weight gain and confirmed by the measurement of eosinophil counts every 3 days for several weeks off therapy. Often, the periodicity is missed because of intermittent steroid use and the measurement of eosinophil counts only when symptoms are present. Clonal $CD3^-$ $CD4^+$ T-cell populations have been described to occur in this subgroup of patients and should be assessed by flow cytometry and TCR rearrangement analysis.

The occurrence of marked eosinophilia in multiple members of the same family is rare, with only a few reports in the literature to date (46). Autosomal dominant transmission appears to be the most common form of transmission. In one such family, the gene responsible for the eosinophilia has been mapped to chromosome 5q31-33 (47). Despite marked eosinophilia (2,000 to 6,000/mm^3) from birth, a minority of family members with familial eosinophilia develop eosinophil-mediated end organ damage (48). This paucity of clinical manifestations is associated with a relative lack of eosinophil activation compared to that in patients with nonfamilial HES. Whether the sudden disease progression in a small number of these patients after a lifetime of asymptomatic eosinophilia represents a second mutation remains unknown at this time.

Another less well defined clinical subgroup of patients presents with marked eosinophilia and clinical features highly suggestive of eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg Strauss syndrome), including a long history of asthma, paranasal sinus abnormalities, and recurrent pulmonary infiltrates, without demonstrable vasculitis. Although some of these patients likely have occult EGPA, in some cases biopsies of affected tissues repeatedly fail to show evidence of vasculitis, and antineutrophil cytoplasmic antibodies are undetectable in serum. The pathologic basis of end organ damage in this subgroup of patients remains to be elucidated.

Controversies

A number of controversies remain surrounding the diagnosis of HES and its classification into subtypes. These include (i) the classification of patients with marked eosinophilia and no evidence of end organ damage, (ii) the distinction between HES and other organ-specific eosinophilic disorders of unknown etiology (e.g., eosinophilic gastroenteritis or chronic eosinophilic pneumonia) in patients with concomitant peripheral eosinophilia, and (iii) the diagnostic classification of patients with known etiologies, including *PDGFRA*-associated MPN and clonal lymphocytic disorders. As the number of chemotherapeutic agents with specific molecular and immunologic targets continues to grow, the resolution of these issues will become increasingly important for the appropriate management of patients presenting with a clinical syndrome consistent with HES.

EOSINOPHIL-ASSOCIATED GASTROINTESTINAL DISORDERS

Definition of EGIDs

Eosinophil-associated gastrointestinal disorders (EGIDs) are a family of related diseases characterized by eosinophilic inflammation of the gastrointestinal tract. The two major forms of EGID, eosinophilic esophagitis (EoE) and eosinophilic gastroenteritis (EGE), differ with regard to the site of inflammation (esophagus versus stomach/small bowel) (49, 50). EoE is the most common and best-characterized form of EGID. EoE was first described as a distinct clinical entity in the early 1990s (51) and in the past 15 years has emerged as an increasingly common clinical entity in both children and adults. Peripheral blood eosinophilia is a common feature of EGID, although it is rarely elevated above 1,500/mm^3. EGE, although less common than EoE, is more highly associated with peripheral eosinophilia and should be considered in

patients presenting with peripheral eosinophilia and GI symptoms.

One of the most notable features of EGID, particularly well established for EoE, is its responsiveness to highly restricted or amino acid-based elemental diets. Multiple clinical studies have demonstrated that >90% of patients with EoE have both clinical and histological remission after 1 month on an elemental diet (52). Case series suggest a similar dietary responsiveness in at least a subpopulation of patients with EGE (53). In sum, these findings strongly support the idea that EGID is a food allergen-driven eosinophilic inflammatory gut disease.

In EGID, food allergens directly activate antigen-specific Th2 cells and possibly mast cells or basophils, driving IL-5 and IL-13 expression. These two cytokines cause increased bone marrow eosinophil production and eosinophil tissue localization, respectively. The chronic eosinophilic inflammation in EoE ultimately results in tissue fibrosis. Although the exact mechanism of fibrosis is the subject of ongoing investigation, a number of profibrotic cytokines, such as IL-13 and transforming growth factor β, are expressed in active EGID sites of disease (54).

Although EoE was initially characterized in pediatric patients, the idea that it can occur at any age has been appreciated more recently. The clinical presentations of EoE vary with age; elementary school and younger patients often present with nonspecific symptoms, such as regurgitation, spitting up, and chest pain, whereas older patients present predominantly with dysphagia (55, 56). This difference is likely due to a greater duration of untreated disease in older patients, leading to remodeling, fibrosis, and stricture formation, which manifests as dysphagia. As in pediatric disease, adult EoE is highly responsive to diet therapy (52).

Diagnosis of EGID

EoE is the most common type of EGID and is the only form of EGID having consensus guidelines for diagnosis and management (57). The diagnosis of EoE requires both clinical and pathological findings. Clinically, the patient must have symptoms related to esophageal dysfunction, although in children these can be quite nonspecific. The pathological diagnosis requires ≥15 eosinophils per high-powered field (hpf) in the most affected biopsy area, commonly referred to as the "peak eosinophil count."

Gastroesophageal reflux can also cause esophageal eosinophilia; thus, to make the diagnosis of EoE, reflux must be ruled out. In practice, this is most commonly done by treatment with twice-daily proton pump inhibitors (PPIs) for 2 months prior to the esophageal biopsy procedure (57). Alternatively, the absence of gastroesophageal reflux can be confirmed by esophageal pH monitoring. Often, in cases where there is a low index of suspicion for EoE, biopsy specimens are obtained without proton pump inhibitor therapy. In these cases, the finding of >15 eosinophils/hpf is not diagnostic for EoE, as the majority of these patients have PPI-responsive esophageal eosinophilia due to gastroesophageal reflux and do not have EoE (58). In most cases, it is important to make a definitive diagnosis, and a second procedure must be undertaken to obtain biopsy specimens while the patient is on proton pump inhibitors. EoE is associated with many gross endoscopic features, such as esophageal rings, furrows, and strictures. However, multiple studies have shown that none of these are specific for the diagnosis of EoE (59). This further underscores the need for careful pathological diagnosis.

If it can be done safely, patients suspected of having EoE should be taken off diet or corticosteroid therapy for at least a month prior to the diagnostic esophagoduodenoscopy procedure. EoE is a patchy disease, and the affected tissue often looks normal; thus, multiple biopsy specimens are required to avoid a sampling error. To maximize the potential to make the diagnosis, a total of 6 biopsy specimens, including in both the distal and the midesophagus, are taken (57). Eosinophils are visualized using standard hematoxylin and eosin staining. Biopsy slides are then scanned to identify areas with the greatest number of eosinophils, and the numbers per hpf are counted.

Analysis of tissue eosinophils using immunohistochemistry for eosinophil granule proteins, such as eosinophil peroxidase or major basic protein, may provide additional information (60). However, at the present time, such analyses are limited to research applications and are not part of routine clinical care.

Unlike EoE, there are no consensus guidelines for the diagnosis of EGE. The diagnosis is based on typical symptoms coupled with increased gastric or intestinal eosinophils, in the absence of other potential causes of GI eosinophilia. There is no consensus on the requisite number of eosinophils needed for the diagnosis. Based on studies of healthy controls, peak eosinophil counts of 30 eosinophils/hpf in the stomach and 50 eosinophils/hpf in the duodenum have been proposed for the diagnosis of eosinophilic gastritis and duodenitis, respectively (61, 62). Additional features, such as epithelial eosinophils, intraglandular eosinophils, and eosinophils in the muscularis, also weight toward the diagnosis of EGE. Endoscopic biopsy specimens should be obtained from 5 to 6 sites per affected site, in a manner similar to those of the consensus procedures in cases of EoE. In EGE patients with peripheral eosinophilia, analysis of stool specimens for ova and parasites and serologic testing for *Toxocara* species (in children) and *Strongyloides* should be performed.

Treatment of EGID

There are no drugs currently approved for the treatment of EGID. As noted above, dietary therapy is highly effective in patients with EoE and in at least a subpopulation of patients with EGE. Systemic corticosteroids are highly effective in all forms of EGID, but their long-term use often results in side effects. Topical corticosteroids, such as fluticasone and budesonide, provide local anti-inflammatory activity with minimal systemic effects (63).

Use of Laboratory Tests in the Management of EGID

There are two major processes driving EoE symptoms. First, inflammation may directly cause symptoms, presumably by direct action on esophageal motility (64). Second, chronic eosinophilic inflammation drives esophageal fibrosis, ultimately resulting in rings, strictures, and remodeling (54). Although symptomatic improvement is an important treatment endpoint, the suppression of esophageal fibrosis is equally important. To that end, the management of EoE focuses on the treatment and monitoring of eosinophilic inflammation as a means to decrease esophageal fibrosis and dysfunction. Although there are no consensus targets, a posttreatment reduction to ≤6 eosinophils/hpf has been considered a successful response in clinical studies (65, 66).

EGID is highly associated with other allergic diseases, and IgE sensitization is associated with multiple food allergens. Some research groups have attempted to use food allergen-specific IgE tests to identify culprit foods driving EGID; however, others have not found such testing predictive (52). Given its uncertain value in managing EGID,

food allergen-specific IgE testing should not be used as a tool in the routine management of EGID dietary therapy.

MASTOCYTOSIS

Definition

Mastocytosis is a disorder characterized by the accumulation of aberrant mast cells in tissues, such as skin, bone marrow, gastrointestinal tract, liver, spleen, and lymph nodes (67). Most cases of mastocytosis are associated with gain-of-function mutations in c-*kit*, the receptor for the major mast cell growth factor, stem cell factor (68).

Classification and Diagnostic Criteria

The current WHO classification divides mastocytosis into seven categories (Table 3) (69, 70). The symptoms, prognosis, and treatment options vary according to the category of disease.

Cutaneous Mastocytosis

Cutaneous mastocytosis is the most common presentation in children (71). It is usually diagnosed within the first year of life. The most common skin lesion is urticaria pigmentosa (UP). The lesions are fixed (as opposed to a classic urticarial lesion, which is evanescent) and maculopapular and may be slightly raised and hyperpigmented. The diameters range from a few millimeters to a few centimeters. The lesions are generally nonpruritic at baseline but may be induced to urticate by stroking (Darier's sign), pressure, temperature changes, and exercise. Sterile blistering may be noted within the first 3 years of life. Less common forms of cutaneous mastocytosis include a mastocytoma(s) of the skin and diffuse cutaneous mastocytosis (72). The diagnosis of cutaneous mastocytosis is confirmed by a skin biopsy demonstrating increased numbers of mast cells in the upper dermis, usually around blood vessels.

Cutaneous mastocytosis has a good prognosis, with approximately 90% of patients experiencing resolution or improvement of disease by adolescence. By definition, cutaneous mastocytosis involves only the skin. It should not be confused with UP in adults, which is usually associated with systemic disease (bone marrow involvement). However, due to the low pretest probability, a bone marrow biopsy is generally not recommended for children who are diagnosed within the first 2 years of life and who do not have signs of hematologic involvement (unexplained abnormalities in a complete blood count with differential, hepatosplenomegaly, or lymphadenopathy) or a persistently elevated tryptase level greater than 20 ng/ml. In addition to having cutaneous symptoms, such as flushing and itching, patients with cutaneous mastocytosis may display gastrointestinal cramping, nausea, vomiting, and diarrhea. Anaphylactic episodes resulting in loss of consciousness may occur after hymenoptera stings or without provocation, but their prevalence is not as high as in the adult population (73). The incidence of IgE-mediated allergy is believed to be similar to that in the general population (74).

Systemic Mastocytosis

According to WHO criteria, systemic mastocytosis is diagnosed when pathologic mast cells are demonstrated in an extracutaneous tissue. The most common procedure for diagnosis is a bone marrow biopsy and aspiration. The disease is occasionally diagnosed in gastrointestinal biopsy specimens (75); however, we are not aware of a case of isolated GI disease without bone marrow involvement. In order to fulfill WHO criteria for systemic mastocytosis, the major criterion plus at least one minor criterion or three minor criteria must be fulfilled.

TABLE 3 Classification of mastocytosis from reference 69

Cutaneous mastocytosis
Indolent systemic mastocytosis
Systemic mastocytosis with an AHNMD
Aggressive systemic mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytomas
B findings
Infiltration by mast cells of >30% in a bone marrow biopsy specimen and 1 of the following:
Tryptase level of >200 ng/ml
Myelodysplastic or myeloproliferative changes in bone marrow without fully meeting the WHO criteria for MDS[a] or MPNs
Hepatomegaly or splenomegaly without end organ dysfunction
C findings
Cytopenias (neutropenia of <1,000/μl, hemoglobin of <10 g/dl, platelets of <100,000/μl) with extensive bone marrow mast cell infiltration or splenomegaly
Liver pathology indicating portal hypertension, ascites, elevated LFTs, hyperbilirubinemia
GI pathology indicating diarrhea with malabsorption, hypoalbuminemia, and weight loss
Bone pathology showing large osteolytes with pathologic fractures

[a]MDS, myelodysplastic syndromes.

Major Criterion

A major criterion is multifocal clusters of at least 15 mast cells per cluster. Mast cells in normal marrow or in reactive mast cell hyperplasia occur singly. Clustering of mast cells is a pathologic hallmark of systemic mastocytosis (76). Some patients with milder disease burden and relatively low serum tryptase levels may not display the major criterion. In those patients, there may be a smaller number of mast cells per cluster; however, close examination of an appropriately stained bone marrow biopsy specimen and aspirate may reveal evidence of mast cell pathology, such as spindle-shaped mast cells, CD25 expression, and perivascular or paratrabecular dominance of mast cells. The preferred stain to visualize mast cells is an immunohistochemical stain for tryptase. Mast cells are the only cells in bone marrow stainable for tryptase. Metachromatic stains are unreliable in bone marrow biopsy specimens and should not be relied upon for diagnosis.

Minor Criterion 1

Morphologic aberrancies in mast cells include spindle-shaped bi- or multilobed nuclei, cytoplasmic projections, and hypogranulation. A normal bone marrow mast cell should be round, with a single central nucleus and heavy granulation obscuring the nucleus. Detailed depictions of mast cell morphologic abnormalities are published and should be referred to by hematopathologists, since aberrant mast cells can sometimes be overlooked (77). Both aspirate

smears and a bone marrow biopsy specimen should be examined. In order to fulfill the criterion, at least 25% of the mast cells in the infiltrate should be abnormally shaped.

Minor Criterion 2

Minor criterion 2 is aberrant expression of CD25 and CD2. CD25 is not expressed by normal or hyperplastic mast cells. A mast cell expressing CD25 is highly specific and sensitive for the diagnosis of mastocytosis (78, 79). The only other disorder in which mast cells have been described to express CD25 is PDGFRA-associated myeloproliferative neoplasm (18). CD25 expression can be detected by flow cytometry or immunohistochemistry. Immunohistochemistry has the advantage that it can be performed on stored biopsy specimens. We currently recommend CD25 staining in all cases of suspected systemic mastocytosis, since patients with mild disease may not have a pathologically increased number or clustering of mast cells. Activated lymphocytes in the bone marrow can also express CD25, but the level of expression is much lower than on pathologic mast cells. Furthermore, mast cells can be recognized based on their distinct morphology. Flow cytometry of the bone marrow aspirate is also very helpful in demonstrating pathologic CD25 expression in freshly obtained bone marrow aspirate samples but is technically more challenging than immunohistochemistry, as it requires collection of at least 500,000 events (preferably more in cases suspected of having a low mast cell burden) and special gating to demonstrate the mast cell population. A detailed discussion of the recommended gating strategies and various pitfalls of this technique can be found in previous publications (80, 81). CD2 is a less sensitive marker and may be absent in advanced forms of mastocytosis, such as aggressive systemic mastocytosis or mast cell leukemia (82).

Minor Criterion 3

Minor criterion 3 is a codon 816 c-kit mutation in blood, bone marrow, or lesional tissue. c-kit is the transmembrane receptor for stem cell factor, the major growth and differentiation factor for mast cells (83). Its extracellular domain encodes five immunoglobulin-like domains that bind cell-bound or soluble stem cell factor (SCF) homodimers. Its intracellular domain has intrinsic tyrosine kinase activity. Under physiologic circumstances, dimerization of Kit triggers autophosphorylation of tyrosine residues, which can act as docking sites for downstream signal transduction and adapter proteins. More than 90% of patients with systemic mastocytosis (84) and approximately 40% of patients with cutaneous mastocytosis (85) carry a D816V activating point mutation affecting the tyrosine kinase domain of the receptor, resulting in ligand-independent autophosphorylation. D816V is a somatic mutation, and its detection is influenced by the degree of enrichment of mast cells in the sample, whether non-mast cell hematopoietic lineages are involved, and by the technique used to detect the mutation. For example, detection techniques based on sequence analysis of bulk tissue have low sensitivities (less than 20%) compared to those of PCR-based techniques using D816V mutation-specific primers but may be suitable for analysis of skin lesions, mastocytomas, or mast cell leukemias, where neoplastic mast cells are found enriched if the typical D816V mutation is absent. Enrichment of mast cells usually yields the best sensitivity, although this technique is available only on a research basis (68). Flow cytometric enrichment of mast cells from bone marrow tissue (based on high CD117 and high FceR1 and CD25 expression) or bulk sorting using magnetic beads or flow cytometry and anti-CD25 antibody followed by RT-PCR of c-kit mRNA yields the most-sensitive results. Recently, a more sensitive real-time quantitative PCR (qPCR)-based technique has been described. Sensitivity for the detection of the D816V mutation in peripheral blood is reported to approach 100% using this technique (86). Real-time qPCR was performed with a forward primer (5′-AGAGACTTGGCAGCCAGAAA-3′) and a reverse primer (5′-TTAACCACATAATTAGAATC ATTCTTGATCA-3′) with an intended mismatch to reduce cross-reaction with the wild-type c-kit allele. The fluorescent probe 5′-6-FAM-TCCTCCTTACTCATGGTCGGATCA CA-TAMRA-3′ (where FAM is 6-carboxyfluorescein and TAMRA is 6-carboxytetramethylrhodamine) was used for detection. Real-time qPCR was performed with 50 cycles of denaturation at 95°C for 15 s and annealing and elongation at 60°C for 1 min.

Mutations in c-kit residues other than D816V have been described but are less common. One study reported that approximately 40% of patients with cutaneous mastocytosis had an activating c-kit mutation outside codon 816 when lesional skin was analyzed (86). The prognostic significance of these mutations remains to be elucidated, however, since they can occur in both benign and aggressive forms of disease. In patients with advanced categories of disease, c-kit mutations can be present in other hematopoietic lineages in addition to mast cells (87). Patients with multilineage involvement have a poorer prognosis that those with limited mast cell involvement (87).

Minor Criterion 4

Minor criterion 4 is an elevated baseline serum tryptase level of >20 ng/ml. Tryptase is a protease that is abundantly produced and stored in mast cell granules. Mature tryptases (beta tryptase) are released from mast cell granules, and levels are generally elevated after mast cell activation episodes, such as anaphylaxis, if checked within 4 h of the event. Protryptases (alpha tryptase and pro-beta tryptase) do not possess enzymatic activity and are released constitutively from mast cells. Therefore, the level of serum tryptase at baseline (i.e., without an anaphylactic event) correlates with total body mast cell burden (88). Commercially available tryptase immunoassays measure total tryptase, which is a combination of both pro- and mature tryptases. A normal median serum tryptase level is approximately 5 ng/ml. Conditions other than mastocytosis that can be associated with elevated tryptase levels include chronic renal and liver disease, parasitic diseases, bone marrow suppression states, myeloproliferative and myelodysplastic disorders, mast cell activation syndromes, and idiopathic tryptase elevations. The serum tryptase levels in these disorders generally do not exceed 40 ng/ml. On the other hand, a normal tryptase level, while significantly decreasing the odds, does not completely exclude a diagnosis of systemic mastocytosis. Patients with normal or slightly elevated tryptase levels usually lack the major diagnostic criterion, and therefore it is important to look for minor criteria in these patients (89).

Well-differentiated systemic mastocytosis is a rare morphologic variant that is usually seen in patients with a history of pediatric onset UP that does not resolve spontaneously before they reach adulthood (90, 91). In this variant, the mast cells do not display major morphologic aberrancies, such as spindling, and lack surface CD25 expression and the c-kit D816V mutation. The major diagnostic criterion is present, and tryptase is usually elevated.

Monoclonal mast cell activation syndrome is a recently described diagnostic category. Patients present with recurrent mast cell activation symptoms but meet only 1 or 2

minor criteria of clonality (CD25 expression and/or c-kit D816V expression) (92).

Systemic mastocytosis is further subdivided into 4 categories based on clinical findings (69, 70).

Indolent Systemic Mastocytosis

This is the most common category in adults. Patients are usually diagnosed after their 2nd decade of life and have a life expectancy comparable to that of the general age-matched population. They are usually bothered by symptoms caused by mediator release from mast cells, variably resulting in flushing, itching, gastrointestinal cramping, nausea, vomiting, diarrhea, and/or presyncopal or syncopal episodes associated with hypotension and tachycardia. The episodes may last from a few minutes to a few hours and generally improve with antihistamine and epinephrine treatment. Some patients also experience bone and soft tissue pain similar to that from fibromyalgia, fatigue, memory and concentration problems, and osteoporosis. The pathologic basis of these symptoms is not well understood. The risk of progression of indolent systemic mastocytosis to a more advanced category is thought to be less than 5%; however, these patients should still be periodically monitored for disease progression by a complete blood count with differential and tryptase levels.

Systemic smoldering mastocytosis is a subgroup characterized by high tissue mast cell burden and high tryptase levels but no evidence of a separately identifiable hematologic disorder (B findings in Table 1). Whether these patients have a higher likelihood of progression remains to be determined.

Systemic Mastocytosis with an Associated Clonal Hematologic Non-Mast Cell Disease (SM-AHNMD)

Approximately 20% of patients with systemic mastocytosis have evidence of another associated hematologic disease at the time of diagnosis. These disorders are diagnosed upon examination of bone marrow, lymph nodes, or peripheral blood according to their respective WHO diagnostic criteria. Myeloid disorders, such as chronic myeloproliferative diseases and myelodysplastic syndromes, are most common. Concomitant detection of JAK2 V617F and D816V c-kit mutations has also been described (93). These disorders have an increased likelihood of progression to acute myeloid leukemia and therefore carry a poorer prognosis. Since tryptase can be produced in small quantities by myeloid blasts, serum tryptase levels cannot be used as a diagnostic criterion for patients in this category (94). Lymphoproliferative disorders, including non-Hodgkin lymphoma and myeloma, have also been reported in association with mastocytosis, albeit much less often than myeloid disorders.

Patients with PDGFRA-associated MPN often present with mildly elevated tryptase levels and increased numbers of spindle-shaped, CD25-positive mast cells in bone marrow biopsy specimens (18). Although this can present a diagnostic challenge in some cases, the mast cells are typically interstitially distributed in PDGFRA-associated MPN, do not form clusters, and do not display the D816V c-kit mutation. Clinical symptomatology and the tryptase/absolute eosinophil count ratio are also helpful in distinguishing patients with PDGFRA-associated MPN from those with mastocytosis.

Symptoms in patients with SM-AHNMD include a combination of mast cell mediator symptoms and the symptoms specific to the AHNMD, such as anemia, thrombocytopenia, and infections. Skin lesions of UP may be absent, and mastocytosis is usually diagnosed based on bone marrow findings during the workup of the associated hematologic disorder.

Aggressive Systemic Mastocytosis

Patients with aggressive systemic mastocytosis (ASM) display a high degree of mast cell burden, as evidenced by markedly elevated tryptase levels (generally greater than 100 ng/ml) and marked bone marrow infiltration (generally greater than 20%) associated with signs and symptoms of end organ dysfunction (C findings in Table 1). Organs involved include the hematopoietic system, liver, bones, and GI tract, with end organ dysfunction manifesting as cytopenias, portal hypertension/ascites, pathologic bone fractures, and malabsorption/weight loss, respectively.

Mast Cell Leukemia

Mast cell leukemia (MCL) is a rare diagnosis characterized by the presence of >10% mast cells in peripheral blood or >20% in aspirate smears in an aspicular area (95). Tryptase levels are significantly elevated (sometimes over 1,000 ng/ml), and the bone marrow is markedly hypercellular (often >90% cellularity, with the majority of the infiltrate consisting of pathologic mast cells). Mast cells display very immature morphology, including marked hypogranulation, bi-or multilobulated nuclei, and even mitotic figures. Aleukemic MCL is diagnosed when circulating mast cells are <10%. Mast cells may carry atypical codon 816 mutations, such as D816Y or D816H, which are not detected by D816V-specific PCR-based assays. Patients may present with signs of ASM along with coagulopathies and gastrointestinal bleeding. The prognosis of MCL is extremely poor due to the lack of an effective cytoreductive therapy.

Extracutaneous Mastocytoma and MCS

Extracutaneous mastocytoma and mast cell sarcomas (MCS) is an extremely rare diagnosis, which denotes benign and malignant mast cell tumors. Experience is limited to a few case reports. Mast cell sarcomas have been reported to develop in the setting of prior UP and MCL (102). MCS is characterized by its propensity to invade, which is not seen in benign mast cell tumors.

Pitfalls in Diagnosis

Both overdiagnosis and underdiagnosis of mastocytosis can be a problem in clinical practice. Overdiagnosis is usually encountered when WHO diagnostic criteria are not carefully documented for a patient with unexplained mast cell activation symptoms and a slightly elevated tryptase level. Some patients are diagnosed based on increased numbers of mast cells in non-bone marrow sites, such as the GI tract. Whereas some of these patients do have systemic mastocytosis, it should be emphasized that mast cell numbers vary widely in normal and pathologic GI tissue, and the WHO criteria, such as clustering and CD25 expression, should still be applied rather than depending on the absolute numbers of mast cells for diagnosis (75). Conversely, underdiagnosis is usually encountered in the setting of a low mast cell burden and lower tryptase levels, when appropriate histopathologic, immunohistochemical, and molecular diagnostic tests are not performed. Patients with recurrent episodes of hypotensive anaphylaxis and those with a history of systemic reactions to hymenoptera stings should be evaluated for mastocytosis. The incidence of mastocytosis in patients with idiopathic anaphylaxis may be as high as 30% (89), and as many as 10% of patients with systemic hymenoptera venom-induced reactions have elevated tryptase levels, most of whom have a clonal mast cell disease (96).

Interestingly, patients presenting with angioedema and urticaria as the main manifestations of anaphylaxis have a lower likelihood of mastocytosis than those with hypotensive events (97). Therefore, some authors advocate bone marrow examination in patients who present with hypotensive anaphylaxis without urticaria or angioedema, regardless of tryptase levels. It should be noted that patients presenting with recurrent mast cell activation symptoms and normal or slightly elevated tryptase levels will most likely lack the major criterion (multifocal clusters of mast cells), and therefore, special attention should be paid to appropriately investigate the minor criteria.

Therapy

Management of mastocytosis incorporates 3 major concepts: (i) avoidance of triggers of mast cell activation, (ii) symptomatic anti-mast cell mediator pharmacotherapy, and (iii) mast cell cytoreductive therapy in selected cases (98).

Mast cell activation can be triggered by various stimuli, including temperature changes; heat, cold, exercise, emotional, or physical stress; irritation or friction of the skin; fever; alcohol; spicy foods; *Hymenoptera* stings; and certain medications, such as opioids, analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), and perioperative medications, including muscle relaxants, general anesthetics, and antibiotics (70). The triggers differ in individual patients, and the individual patient history and known tolerances are helpful in guiding the patient to avoid these factors. For example, there would be no need to avoid NSAIDs in a patient who has been able to tolerate these medications without a problem. A detailed list of medications that can potentially cause or enhance mast cell activation can be found in the mastocytosis society patient support website www.tmsforacure.org.

Antimediator pharmacotherapy depends on the patient's symptoms. H1 and H2 antihistamines, leukotriene blockers, oral cromolyn sodium, and glucocorticoids are the most frequently used treatment options. Multiple doses of self-injectable epinephrine should be prescribed to patients to be used in case of an anaphylactic event.

Cytoreductive therapy is indicated only for patients with advanced disease categories, including ASM, SM-AHNMD, MCL, and MCS (99). Some authors suggest a trial of cytoreductive therapy in patients with indolent disease if the patient has a history of multiple anaphylactic episodes unresponsive to antimediator maintenance therapy. The most commonly used cytoreductive therapies are cladribine and alpha interferon, although neither is curative. Imatinib is a tyrosine kinase inhibitor with the capacity to inhibit wild-type Kit. Unfortunately, the most common mutation in systemic mastocytosis, D816V c-kit, confers resistance to imatinib. Consequently, most patients with mastocytosis are not candidates for imatinib (83). Bone marrow transplantation has been reported to yield mixed results in various case reports (100, 101).

Systemic Autoimmune Diseases

section M

VOLUME EDITOR: BARBARA DETRICK
SECTION EDITOR: WESTLEY H. REEVES

Introduction

WESTLEY H. REEVES

86

Systemic autoimmune diseases are often associated with the production of autoantibodies that recognize a diverse array of cytoplasmic and nuclear antigens. These autoantibodies are used as adjuncts in the diagnosis of autoimmune disease, for monitoring disease activity and severity, and for predicting the outcome of autoimmune disease. As the diagnosis of systemic autoimmune disease is not always straightforward, autoantibody testing has the potential to improve our ability to diagnose complex autoimmune disorders. However, autoantibody test results, particularly those based on enzyme-linked immunosorbent assays (ELISAs) and other solid-phase assays, must be interpreted with caution due to their high sensitivity and the possibility of false-positive results. It is important to interpret the results of autoantibody tests in light of both the clinical context and the methodology employed. In some cases, confirmatory testing, analogous to the use of Western blotting to verify positive ELISA test results for HIV infection, is warranted.

Conversely, it is important to understand that positive autoantibody tests can be harbingers of autoimmune disease in otherwise healthy individuals, especially in the case of disease-specific autoantibodies, which may appear months, years, or even decades before the onset of clinical symptoms. The detection of disease-specific autoantibodies or other immunological markers in asymptomatic individuals may permit early diagnosis and preventative treatment. Good examples are antimitochondrial antibodies in primary biliary cirrhosis, anti-Sm, RNP, Ro (SSA), and double-stranded DNA autoantibodies in systemic lupus erythematosus, and specific autoantibodies associated with rheumatoid arthritis, polymyositis, and scleroderma, all of which may appear prior to the onset of clinical manifestations. Thus, in the case of an unexpectedly positive autoantibody test, it is important to consider two possibilities: (i) that the test result is a false positive, or (ii) that the autoantibody is present, perhaps as the initial manifestation of an autoimmune disorder.

Autoantibody and immune testing for autoimmune diseases is an evolving field. Older autoantibody tests, such as double immunodiffusion in gels and agglutination assays, are highly specific but less sensitive than the more recently developed ELISAs, addressable bead assays, and autoantigen microarrays. The older tests also are frequently less amenable to automation, which has led to their rapid abandonment in favor of other tests. The past 20 years has seen a rapid shift from double immunodiffusion and agglutination assays to the ELISA format. Newer technologies are on the horizon, including fluorescence-based assays employing addressable beads and antigen arrays, which permit screening for multiple specificities in a single assay. Recent interest in the autoimmune biomarkers has led to the identification of molecular assays (e.g., the interferon signature) that may ultimately be employed clinically to subset patients and/or to choose appropriate therapies and/or the response to therapy. Assays for other markers, such as complement proteins/fragments, which have been used clinically for many years, are being refined and may be useful for novel clinical applications.

The chapters in this section reflect both the evolving technology and the need for reliable confirmatory tests, which frequently are older or more labor-intensive. Andrade and colleagues review the roles of a classical screening test, the fluorescent antinuclear antibody assay, versus solid-phase assays for antinuclear antibody screening in the serodiagnosis of systemic autoimmune disease. Although automated (ELISA) testing is widely available, it has not yet replaced the more labor-intensive fluorescence-based assay and is unlikely to do so in the near future. In the following chapter, Chan et al. discuss solid-phase assays, focusing on the use of recombinant autoantigens and peptides in ELISA, molecular line probe (LINE) assays, multiplex bead assays, and chemiluminescence assays. Following these methodology-focused reviews are a series of chapters outlining the approach to immunodiagnosis of major autoimmune syndromes, including the immunological evaluation of systemic lupus erythematosus in the clinical and research laboratory (Reeves et al.); autoimmune myopathies including polymyositis and dermatomyositis (Satoh et al.); scleroderma and its variants (Kuwana); rheumatoid arthritis (Chauffe and Bubb); antiphospholipid autoantibody syndrome (Murphy and Harris); and antineutrophil cytoplasmic antibody-associated vasculitis syndromes such as granulomatosis with polyangiitis (Wegener's granulomatosis), microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), and levamisole-induced vasculitis (Burlingame et al.). These chapters are followed by a discussion by Stone of the immunological assessment of IgG4-related syndrome, a recently described and frequently misdiagnosed inflammatory disorder involving plasma cells that secrete IgG4-class antibodies. At present, it is unclear whether this disorder is "autoimmune" or "inflammatory" in origin. The section

doi:10.1128/9781555818722.ch86

includes a discussion of where the field of immune testing and disease biomarkers for rheumatic disease is moving in the future (Sokolove).

The identification of disease-specific autoantibodies over the past 30 or more years and the increasing sophistication of autoantibody testing have greatly facilitated the diagnosis of systemic autoimmune disease. Automation of autoantibody testing is a more recent development, raising hope that in the future, screening for these biological markers may be useful not only for confirming a clinical diagnosis but also for defining risk and establishing a diagnosis during the preclinical phase of the illness, when it may be more amenable to therapy. Gene expression analysis (e.g., for gene expression "signatures") and assessment of genetic disease susceptibility loci represent future directions that are likely to move into the clinical arena within the next decade.

Antinuclear Antibody Tests

87

HISTORICAL BACKGROUND

Autoantibodies are historical hallmarks in the establishment of the concept of autoimmunity and in the definition of the clinical limits of several autoimmune diseases. On a day-to-day basis, autoantibodies are helpful elements not only in the diagnosis of autoimmune diseases, but also frequently in the establishment of prognosis and in the monitoring of disease activity.

The first assay that allowed the detection of an antinuclear antibody was the LE cell test, originally reported by Hargraves et al. in 1948 (1). This assay takes advantage of the opsonization property of antibodies and complement. By mixing crushed and intact peripheral blood cells with the serum sample to be tested, one allows IgG antibodies to deoxynucleoprotein (nucleosomes) present in the serum to bind the exposed chromatin from crushed cells and pave the way for phagocytosis of the opsonized nuclei by intact phagocytes. The detection of several phagocytes with the nucleus compressed to the periphery of the cell by a large amorphous mass represents a positive LE cell assay (Fig. 1). This assay was soon recognized to be very specific and relatively sensitive for the diagnosis of systemic lupus erythematosus (SLE), being incorporated in the first edition of the American College of Rheumatology criteria for classification of SLE (2). The LE cell test remained useful for several decades and was eventually replaced by more sensitive and straightforward assays.

One decade later, Holborow et al. and Friou et al. adapted the recently reported indirect immunofluorescence methodology to the detection of autoantibodies (3, 4). These investigators showed that serum from SLE patients frequently contained high levels of antibodies reacting with the nuclei of cells from a variety of substrates, including human leukocytes and rodent tissue. This assay, named the indirect immunofluorescence antinuclear antibody (IIF-ANA) test, became progressively popular and presented higher sensitivity than the LE test for the diagnosis of SLE. In addition, it was also positive in other systemic autoimmune diseases, including systemic sclerosis (SSc), mixed connective tissue disease, polymyositis, dermatomyositis, and Sjögren's syndrome. Finally, the IIF-ANA test had the additional advantage of allowing the recognition of a few distinct immunofluorescence nuclear patterns, namely homogeneous, speckled, and nucleolar. In the late 1970s and into the 1980s, monolayers of human tumor cell lines grown onto glass slides were tested as the substrate for the IIF-ANA test, and progressively the HEp-2 cell line became the universal substrate for the IIF-ANA assay (5). The HEp-2 cell line (CCL-23; American Type Culture Collection) was characterized originally as derived from larynx epidermal carcinoma; however, there is evidence of contamination with the HeLa cell line (6). Some of the advantages of this substrate for the IIF-ANA test are listed in Table 1. The higher sensitivity in relation to rodent tissue allows positive results in the majority of patients with nontreated active SLE and other systemic autoimmune diseases. The IIF-ANA assay on HEp-2 cells allows the detection of autoantibodies against antigens in cellular compartments other than the nucleus, such as the cytoplasm and the mitotic apparatus. Therefore, the name "antinuclear antibody" does not correspond to the comprehensiveness of the test, and some authors have proposed that it be renamed "anticellular antibody" test. Despite the appearance of alternative methods, the IIF-ANA assay on HEp-2 cells remains the gold standard for the screening of antinuclear or anticellular antibodies (7).

METHODOLOGICAL PLATFORMS

Indirect Immunofluorescence Assay on HEp-2 Cells

The IIF-ANA assay is considered the gold standard for screening for antinuclear or anticellular antibodies in systemic autoimmune diseases (7). This very sensitive test allows the detection of a large number of autoantibodies relevant to a variety of clinical conditions (8) (Table 2). It offers three important pieces of information: (i) the presence or absence of autoantibodies in the sample, (ii) the titer, and (iii) the immunofluorescence pattern. The titer represents a semiquantitative assessment of the autoantibody concentration in serum, which is clinically valuable information. Since autoantibodies occur in a certain fraction of the general population, it is relevant that most nonautoimmune individuals with a positive IIF-ANA test present low titers, while patients with systemic autoimmune diseases frequently present moderate-to-high IIF-ANA titers (9–12). The IIF-ANA pattern adds valuable information because it helps to discriminate positive tests in nonautoimmune individuals and in autoimmune patients (12). In addition, the IIF-ANA pattern often indicates the autoantibody specificities most likely to be present in a given sample, thus guiding

doi:10.1128/9781555818722.ch87

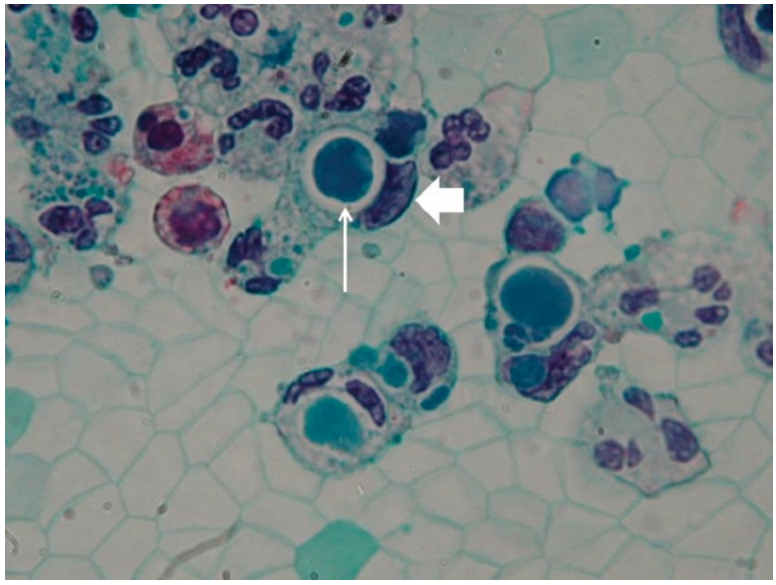

FIGURE 1 LE cell phenomenon. Viable neutrophils have their nucleus (thin arrow) displaced to the periphery of the cell due to the phagocytosis of a large piece of opsonized chromatin (wide arrow) from dead cells.

the next step in serologic analysis (8, 13–15). These aspects are discussed in "Interpretation of the IIF-ANA Test."

Automated Readers for the IIF-ANA Assay

The IIF-ANA assay is a labor-intensive, subjective, and reader-dependent procedure that requires highly skilled technicians. Several methodological factors affect intra- and interlaboratory result consistency of the IIF-ANA test. There is also considerable variability in the interpretation criteria of the several IIF-ANA patterns. In an attempt to overcome some of these limitations, efforts have been developed in applying digital technology to the acquisition and interpretation of IIF-ANA images. The automated ANA readers aim to minimize subjectivity and the requirement for expert microscopy analysts, as well as to assist on high-throughput operation. Conceptually, these devices can discriminate positive and negative reactivity, estimate the concentration of the autoantibodies (titer), and identify basic IIF-ANA patterns. The definition of the concentration of the autoantibodies is provided by the measurement of relative light units obtained with a given sample. Pattern recognition algorithms addressing basic IIF-ANA patterns are incorporated into the software for image analysis and help to determine the first-level approach in IIF-ANA pattern interpretation.

TABLE 1 Advantages of the ANA assay on HEp-2 cells

Monolayer arrangement of cells
Large nucleus, nucleoli, and cytoplasm
Possibility to appreciate fine details in the distribution of autoantigens
Figures at the various stages of the cell cycle
Absence of interstitial structures and extracellular matrix
Presentation of a vast array of autoantigens in optimal concentration
Easy handling and possibility of universal standardization of the substrate

Digitalized images are stored and available for analysis by the operator in order to supervise the preliminary classification provided by the automated device. Reliable positive/negative discrimination has been achieved with devices from different manufacturers, with an agreement rate in human reading of up to 96% (16–19). Several companies are involved in the development and upgrading of such systems, which represent a promising field, especially for high-throughput operation. However, it is controversial whether the available systems will be capable of determining all the subtle differences that exist in ANA patterns. At present, expert analyst supervision is required to a variable extent.

Enzyme-Based HEp-2 Cell ANA

An alternative method for the indirect immunofluorescence technique for ANA screening is the indirect enzyme-based HEp-2 cell ANA assay, in which the secondary antibody is conjugated to an enzyme instead of a fluorophore. Horseradish peroxidase and alkaline phosphatase are the main enzymes used in the available commercial kits. Reading requires a regular microscope with no need for a dark room. Slides can be kept as a permanent record since there is limited decay in comparison with the fluorescent dyes. The major limitations, however, are the low sensitivity and the low-resolution images compared to those obtained by the indirect immunofluorescence methodology. Therefore, the fine definition of IIF-ANA pattern nuances is not possible with the indirect enzyme-based ANA method.

Solid-Phase ANA

More recently, several companies have developed ingenious solid-phase assays intended for the screening of antinuclear or anticellular antibodies. The solid phase may be a standard polystyrene microtiter enzyme-linked immunosorbent assay plate, nitrocellulose strips, or beads made of a variety of materials. The autoantibody reactivity is usually detected by anti-human immunoglobulin antibodies conjugated to enzymes, fluorochromes, or chemiluminescent dyes. Regarding the antigenic substrate, these assays may be

TABLE 2 Ability of the ANA-HEp-2 test to detect clinically relevant autoantibodies[a]

Regularly detected	Sometimes not detected	Not detected
CENP-A, CENP-B , CENP-C, CENP-F	Actin	Acetylcholine receptor
p80-coilin and sp100/ PML	Aminoacyl-tRNA synthetase (Jo-1)	ANCA (MPO and PR3)
dsDNA	Centrosome/centriole	AQP-4
EEA-1 and GWB	Ku	ASCA
Fibrillarin and To/Th	La/SS-B	Cardiolipin
Golgi apparatus	Mi-2	Citrullinated peptides
Histones, nucleosome	PCNA	Desmoglein I and III
LEDGF/DFS 75	Ribosomal P proteins	Endomysial (IgG or IgA)
Mitochondria	Smooth muscle	LKM
Nuclear envelope (gp210, lamins, p63)	SS-A/Ro (Ro 60)	Lupus anticoagulant
NuMA	Tubulin	Rheumatoid factor
NOR-90 and PM/Scl	Vimentin SS-A/Ro(Ro-52)	Single-stranded DNA
RNA polymerase I, II, and III		SLA
Scl-70 (DNA topoisomerase 1)		
Sm and U1-RNP		Transglutaminase

[a]Abbreviations: EEA-1, early endosomal antigen 1; GWB, GW bodies; LEDGF, lens epithelium-derived growth factor; DFS, dense fine speckled pattern; NuMA, nuclear mitotic apparatus protein; ANCA, antineutrophil cytoplasm antibodies; AQP-4, aquaporin-4; MPO, myeloperoxidase; PR3, proteinase 3; ASCA, anti-*Saccharomyces cerevisiae* antibodies; LKM, liver kidney microsome; SLA, soluble liver antigen. Abbreviations not listed in this footnote are arbitrary designations.

divided into two general classes. One modality is based on cell extracts that may or may not be enriched with a particular set of autoantigens, therefore offering an unbiased and wide range of autoantigens. The other modality contains a predefined and limited array of recombinant or purified autoantigens for which the autoantibodies are clinically relevant. These arrays are usually built with the aim to address the screening for systemic autoimmune rheumatic diseases and usually include the following autoantigens: native DNA, Sm, U1-RNP, anti-Sjögren's syndrome antigen A (SS-A/Ro), SS-B/La, Jo-1, Scl-70, PM/Scl, Mi-2, CENP-B, and histones.

The antigen-unbiased method based on cell extracts has the advantage of allowing the recognition of a broad spectrum of autoantibodies, with the caveat of including some with uncertain clinical significance. In contrast, the methods based on arrays with a selected set of autoantigens tend to provide clinically specific results but may fail to recognize yet-undefined but clinically relevant autoantibodies. Usually, these assays attain lower sensitivity and higher specificity for the diagnosis of systemic autoimmune diseases than the ones based on whole-cell extract (7, 20, 21).

By proposing to replace the IIF-ANA test, the solid-phase ANA methods seek to provide the ability to detect most of the clinically relevant autoantigens present in the HEp-2 cell. These methods present some potential advantages, such as the lack of the subjectivity inherent to the microscopic analysis of IIF-ANA assay, the possibility of automation and high-throughput operation, and the possibility of quantitative analysis. In addition, these alternative methods do not require highly qualified personnel for the IIF-ANA slide interpretation. These features elicit great interest from industry and large laboratories. However, there are also important drawbacks inherent to this technology. The first one is that it is hard to reproduce the balanced dose of hundreds of autoantigens present in the HEp-2 cell. Also, detection of autoantibodies against poorly soluble autoantigens (e.g., lamins) is difficult in solid-phase assays. In addition, solid-phase immunoassays tend to detect low-avidity and low-concentration antibodies, causing considerable discrepancy with the IIF-ANA test, especially in the low-antibody-concentration range. Other elements that may affect the performance of solid-phase assays are the nature and purity of the antigenic substrate used to coat the solid phase, the binding capacity of the solid-phase scaffold, the nature of the blocking buffer, the stringency of the washing buffers, the quality of the conjugate, and the accuracy of the calibration curve. Not surprisingly, serious concerns have been raised about the appropriateness of this methodology at its present stage of development (22). Solid-phase-based assays may produce false-negative results, and this may be caused by the limited number of available autoantigens or by the absence of relevant autoepitopes in the available autoantigens. Several studies aiming to compare the diagnostic performances of the classical IIF-ANA and the solid phase-based methods were carried out. In general, it has been concluded that IIF-ANA has higher sensitivity and negative predictive value than the solid-phase-based tests (7, 21). A special task force designated by the American College of Rheumatology has produced a statement position document recommending that the IIF-ANA test should remain the gold standard for ANA testing and that the use of alternative methodology should be clearly stated in the laboratory report (7).

TECHNICAL RECOMMENDATIONS

There is a wide diversity of HEp-2 IIF-ANA commercial kits. Although the methodology sounds simple, careful slide processing is important to ensure reliable and consistent results, as small and important details can cause artifacts and misleading results. Here the procedure is detailed in successive steps with remarks for possible and common pitfalls.

Workspace

The procedure must be carried out in a temperature- and humidity-controlled, dust-free, and silent environment. The bench should be well illuminated, clean, and arranged with appropriate working equipment (pipettes, glassware, incubation tanks, reagents, etc.). The work maps with controlled identification of samples to be tested should be prepared in advance.

Standard Operating Procedure

It is recommended that each laboratory develop a standard operating procedure (SOP) document to be available at the bench with the detailed technical description of each step of the assay. This ensures that technicians follow the assay in a consistent fashion. The SOP document must be reviewed periodically by the technical supervisor or whenever there is any change in the technical procedure. This helps keep the SOP updated and consistent, avoiding potential deviations in the protocol.

Cell Substrate

Confluence of Cell Substrate

It is important that the distribution of cells be adequate for optimal visualization of all the cellular compartments, including the nucleus, nucleoli, cytoplasm, dividing cells, and mitotic apparatus. Cells should be neither overlapping nor scarce. In cases of excess of cells, appropriate visualization of cellular compartments is jeopardized. When the number of cells observed per field is low, the recognition of features that depend on specific stages of the cell cycle and mitotic figures may be affected. In addition, some features are best appreciated when there is some proximity among cells, such the characteristic "touch sign" observed in the nuclear envelope pattern.

Display of All Stages of the Cell Cycle

One of the advantages of using cell lines for the IIF-ANA test is the possibility of examining cells in all stages of the cell cycle, which allows the identification of cell cycle-related IIF-ANA patterns not seen in sections of animal tissue. The absence or paucity of cells undergoing division can hinder the proper interpretation of some IIF-ANA patterns, such as centromeric, nuclear dense fine speckled, and nuclear quasihomogeneous patterns and those associated with antibodies to Scl-70, fibrillarin, RNA polymerase I, NOR-90, NuMA, CENP-F, HsEg5, etc. To ensure that the substrate has an adequate number of dividing cells (3 to 5 mitotic figures per field at a magnification of ×200), each new batch of slides should be tested with appropriate control samples that highlight mitotic cells, such as those with antibodies to centromere, NuMA, or CENP-F.

Display of Relevant Autoantigens and IIF-ANA Patterns

Differences in the protocols used to grow, fix, and permeabilize cells can affect the availability of relevant epitopes and the natural location (vis-à-vis the IIF-ANA patterns) of some autoantigens (Fig. 2). Accordingly, several IIF-ANA patterns may show slight differences among different slide brands and even among different batches from the same supplier. For this reason, it is of paramount importance to use a panel of samples with known specificity to a variety of autoantigens in order to validate a new lot or a new slide brand. Adequate control samples can verify the availability of relevant epitopes in more fastidious autoantigens, such as SS-A/Ro, Jo-1, and P ribosomal proteins. In addition, a collection of known samples representing the several relevant IIF-ANA patterns helps to assess how these are represented in a new brand or batch of slides. Several reference serum samples systematized by the Autoantibody Standardization Committee affiliated to the International Union of Immunology Societies (IUIS) are distributed by the Centers for Disease Control and Prevention (CDC) (23). Such primary controls should be used to derive secondary controls that can then be used to assess each new slide batch from the same vendor or a new slide brand.

Assay Procedure

Controls

The use of control samples with known specificity and fluorescence intensity is essential in every run to ensure the quality of the reaction. The strong positive and negative controls usually provided in commercial kits may not be ideal because they characterize extremes that are not representative of most routine samples. It is recommended that a negative control and a low-intensity (1/80 to 1/160) positive control be assayed in each run. This will promote interassay consistency within the laboratory.

Samples

Blood samples should be collected in dry or separating gel-containing tubes. The serum may be stored under refrigeration (2°C to 8°C) for a maximum of 5 days. After this period, it is recommended that serum samples be kept at −20°C for some months or at −70°C for prolonged storage. Sodium azide (100 μg/ml) may be helpful in preventing bacterial and fungal contamination. Prolonged freezing may cause lyophilizing (resulting in titer increase) and successive freeze-thawing cycles may cause a decrease in antibody activity. It is important that the original serum tube and the working tubes be perfectly identified in order to preserve the traceability of samples. Samples showing fibrin clots and those with strong evidence of hemolysis or lipid content require caution because of possible interference with the reaction.

Sample Dilution

Most commercial kits provide salt sachet for reconstitution of phosphate-buffered saline (PBS) (0.15 M phosphate buffered saline, pH 7.2 to 7.4). It is highly recommended that the pH be checked after reconstitution and before each assay, because deviation from the pH 7.2 to 7.4 range can impair antibody reactivity drastically. Adding 0.5 mg/ml Tween 20 and 20 mg/ml bovine serum albumin to the dilution buffer may help with background reduction.

The recommended screening dilution is 1/80 to 1/160, and this range should account for variability in microscope and lighting conditions as well as peculiarities in IIF-ANA reactivity of normal individuals in different regions. Positive samples should be further tested using a geometric series of dilutions by the factor 2. Some authors recommend dilution up to the end titer, whereas others feel that there is no clinically significant gain in diluting samples above 1/1,280 (12, 14, 15).

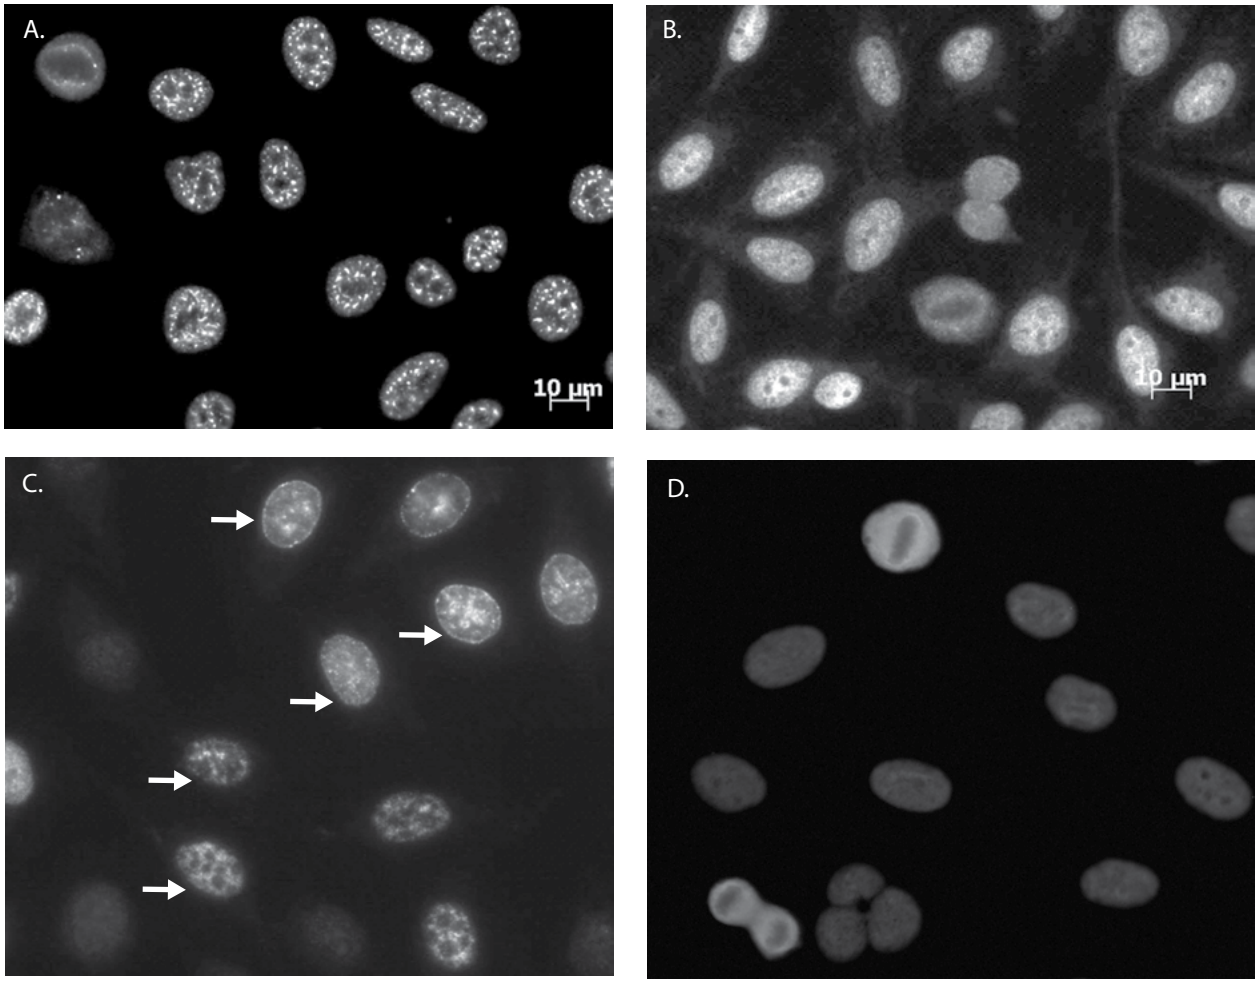

FIGURE 2 Influence of cell substrate on the ANA pattern. (A and B) Sample with anti-U1 RNP antibodies processed on slides from two different suppliers. The expected nuclear coarse speckled pattern is observed with the slide brand shown in panel A, whereas a nonspecific nuclear fine speckled pattern is observed the slide brand depicted in panel B. (C and D) Sample with anti-PCNA (proliferating cell nuclear antigen) antibody processed on slides from two different suppliers. The expected pleomorphic PCNA pattern is observed in the slide brand shown in panel C, whereas a nonspecific pattern is observed in the slide brand shown in panel D. Indirect immunofluorescence on HEp-2 cells; magnification, ×400.

Primary Antibody Incubation

Allow slides to reach room temperature over 30 min prior to opening their pouches and do not unpack them until immediately prior to pipetting the diluted samples. Slides must be kept in a humid chamber throughout the process since air drying may cause changes in the cell substrate and the appearance of spurious IIF-ANA patterns. Avoid touching the cell substrate with the pipette and ensure a perfect coverage of the cell carpet (usually, 30 µl is adequate). Be sure there is no overflow and contamination of neighboring wells. Incubation should proceed for 30 min in a humid chamber at room temperature or at 37°C, ensuring that no well dries out.

First Washing

With the slide at 45° to the table surface, a gentle stream of PBS is directed at the upper edge of the lower row of wells to remove the primary antibodies, avoiding contamination of neighboring wells. Rotate the slide and repeat the procedure for the other row of wells. Never aim the PBS stream directly on the cell carpet in order to prevent cell damage. Next, slides are immediately immersed in PBS for 5 to 10 minutes with shaking and one change of the PBS.

Incubation with Conjugate

Remove excess PBS from slides with a filter paper without touching the cell carpet, and immediately return the slides to the humid chamber. Never allow any well to dry out. If there are many slides being processed, it is recommended that a limited number at a time be transferred to the humid chamber and covered with conjugated secondary antibody. Conjugate incubation should occur for 30 min at room temperature in the dark, since light exposure promotes fluorochrome fading.

Affinity-purified anti-human γ heavy-chain plus κ and λ light-chain antibodies conjugated to fluorescein isothiocyanate are widely used. Kits usually provide ready-to-use conjugate. However, considering the wide variability in microscopes, lighting, and other operating conditions among laboratories, it is comprehensible that "one size may

not fit all." Therefore, it is recommended that the conjugate be titrated against preestablished laboratory controls prior to use for each new kit unit (Fig. 3).

Second Washing and Coverslip Mounting

Slides are briefly rinsed and washed in PBS for 10 min as before. If desired, adding 250 μg/ml Evans blue to the PBS will promote appropriate counterstaining. Remove PBS with filter paper without touching the cells, and pipette mounting medium onto each well, making sure that the cell carpet does not dry out. Kits provide mounting medium, which most often consists of alkaline-buffered glycerin. Specific antifading mounting medium is commercially available and may be useful when prolonged exposure is required. Gently position the coverslip onto the slide. Use clean high-quality glass coverslips. Avoid touching the surface of the coverslip to prevent fingerprints and fat deposition. It is important to inspect and remove air bubbles by placing a layer of filter paper over the assembled slide and gently "combing" the assembly by hand. Assembled slides should be read immediately at the microscope or may be kept at 2°C to 8°C in the dark for some days with little loss of fluorescence activity.

Semiautomated devices can assist on several of the above steps, saving on labor. These devices are particularly appropriate for laboratories with high-throughput operation. Some instruments can perform serum dilutions, and others can run the whole procedure up to the point of but not including the mounting of the coverslips. Naturally, the use of automated instruments is not a substitute for strict quality control procedures.

Microscope and Dark Room

Slides should be observed in an epifluorescence microscope equipped with filters appropriate for fluorescein detection. An objective with magnification of ×40 along with an eyepiece with magnification of ×10 (yielding a final magnification of ×400) allows optimal visualization of cell organelles and identification of most relevant IIF-ANA patterns. The microscope must be under routine preventive maintenance to ensure appropriate cleaning of filters, lenses, and eyepieces and monitoring of the lifetime of lamp bulbs. Lamps should be properly aligned to ensure perfect illumination of the entire microscopic field. A simple maneuver to assess lamp alignment is to place a piece of white paper on the stage with the lamp on and to look for the formation of a single well-defined circle. The formation of parallel or overlapping circles indicates the need to review the positioning of the lamp. The equipment must rest on a stable surface and should not be transported without proper monitoring to prevent misalignment of the optical system. Routine observation of the reactivity of control samples with known titer may help in detecting unexpected decay in the lamp

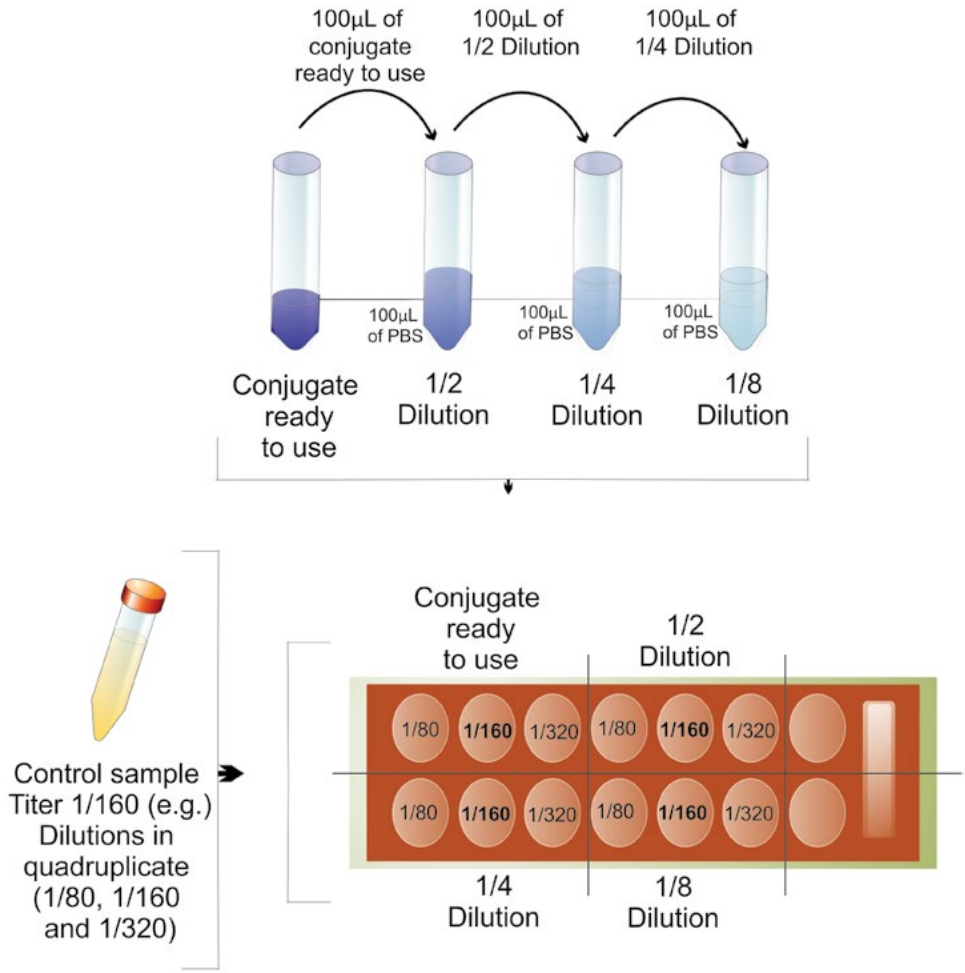

FIGURE 3 Checkerboard titration of the conjugate. A sample with known ANA titer is used to gauge the dilution of the conjugate that will reproduce the expected titer for that sample.

efficiency. The microscope should be in a dark room with a gentle spotlight at the bench to allow the analyst to make notes. Attachment of a digital camera allows recording images, and a network connection for laboratory computers simplifies working procedures.

READING THE IIF-ANA SLIDE

The IIF-ANA slide reading, especially the interpretation of morphological fluorescence patterns, is a highly complex activity that requires skilled analysts, the appropriate environment, and an organized strategy. The first step is the definition of what constitutes a positive reaction. Despite the inherent subjectivity, a common sense criterion is that a positive reaction should allow the determination of a well-defined IIF-ANA pattern. Low-intensity nonspecific staining usually does not allow a clear IIF-ANA pattern definition. Another helpful hint is that a positive reaction must appear as a minimally vivid green color, whereas low and nonspecific reactivity yields a dull greenish color. These criteria can also assist in determining the end titer for each sample.

It is important that each well be thoroughly examined. The periphery of the wells frequently stains stronger than central areas, and therefore, the definition of a positive reaction and end titer should not be estimated based on the peripheral areas. On the other hand, the examination of cells at the periphery of the well may be helpful in the definition of the IIF-ANA pattern in some cases. Focal areas of contamination with another sample, conjugate precipitation, drying of the well, and other unanticipated interferences may cause spurious staining in circumscribed areas of the well. This can be recognized by careful inspection of several areas of the well. It should be noted that some samples produce a diffuse low-intensity and poorly defined staining that cannot be defined as positive at the screening dilution but may become clearly positive at higher dilutions. If there is such a suspicion, the screening step should include two additional double dilutions.

A useful strategy for analyzing the IIF-ANA pattern is to follow a systematic sequence that includes the detailed inspection and registering of the staining of interphase and mitotic cells (Fig. 4). For interphase cells, specific attention must be paid to individual key cell elements: cytoplasm, nucleus, nuclear envelope, and nucleolus. The spatial distribution and the texture of the staining in each of these compartments must be carefully registered. For mitotic cells, one should focus on the metaphase and anaphase chromatin masses, the mitotic poles and centrosomes, mitotic spindles, intercellular bridge, and midbody.

The integrated analysis of the IIF-ANA pattern across the several cellular compartments along the sequential stages of the cell cycle increases the ability to identify the most probable autoantibodies in the sample. Several autoantigens occupy more than one cellular compartment and move across cellular compartments along the cell cycle. Such orchestrated and composite arrangements usually are not shared by many autoantigens and therefore narrow

Anti-Cellular Antibody Test (ANA)

Name: Gender: DOB:

Date:

Method: Indirect immunofluorescence on HEp-2 cells Biological specimen: serum

Reference range

Negative: no reactivity;

1/80: borderline;

1/160 – 1/320: weak reactivity;

1/640 – 1/1,280: moderate reactivity;

Above 1/1,280: strong reactivity;

Result

Nucleus: Fine speckled staining 1/320; Multiple discrete dots 1/2,560

Nucleolus: Not stained

Metaphase chromosome plate: Not stained

Mitotic apparatus: Not stained

Cytoplasm: reticular dotted mitochondria-like pattern 1/1,280

Interpretation

The sample contains multiple autoantibodies. Nuclear multiple discrete dots are suggestive of anti-sp100 antibodies. The cytoplasmic reticular dotted pattern is suggestive of anti-mitochondria antibodies. The nuclear fine speckled pattern has no specific association. Anti-sp100 and anti-mitochondria antibodies are strongly associated with primary biliary cholangitis.

FIGURE 4 Example of report of the IIF-ANA test.

TABLE 3 Specific composite IIF-ANA patterns

Composite IIF-ANA pattern	Features at interphase	Features at mitosis
Centromere	Discrete dots scattered in the nucleus	Discrete dots aligned at the chromatin mass
NuMA	Diffuse fine grainy staining of the nucleus	Sharp staining of the mitotic poles; delicate staining of the proximal parts of the mitotic spindles; nuclear staining in telophase cells; no staining of intercellular bridge and midbody
CENP-F	Variable-intensity fine speckled staining of the nucleus	Delicate centromere staining only in mitotic cells (prophase and metaphase); positive midbody staining
Scl-70	Nuclear diffuse fine grainy staining; nucleolar faint and inconsistent staining; cytoplasmic dot/ reticular network	The metaphase chromosome plate shows a diffuse fine grainy staining and a few (usually 1 to 5) bright discrete dots
RNA polymerase I and NOR-90	Nucleolar speckled staining	Few (usually 1 to 5) bright discrete dots

down the array of possible autoantibodies. In some cases, the composite IIF-ANA pattern is unique for one specific autoantigen. Examples of specific composite patterns are listed in Table 3.

In particular, the examination of the mitotic chromosome mass offers crucial clues for the nature of the autoantibodies in the sample because it is composed exclusively of chromatin and associated proteins. Therefore, a definite staining of the chromosome mass is compatible with autoantibodies to native DNA, nucleosomes (chromatin), histones, DNA topoisomerase I (Scl-70), LEDGF/p75, and other chromatin-associated autoantigens. The texture of the chromosome mass staining adds helpful information: a strong and hyaline staining of the chromosome mass is associated with antibodies to native DNA, nucleosomes, or histones (15); a fine grainy staining of the chromatin mass may be observed with antibodies to Scl-70 or nucleosomes (15, 24); a coarse speckled staining of the chromatin mass is most frequently due to anti-LEDGF/p75 antibodies (25). The observation of a few (usually 1 to 5) bright dots at the metaphase mass represents the staining of the nucleolar organizing regions (NOR) and indicates the possibility of antibodies to RNA polymerase I, DNA topoisomerase I (Scl-70), or NOR-90/human upstream binding factor (15).

The absence of staining of the mitotic chromosome mass, on the other hand, also provides valuable hints. For example, a nuclear speckled pattern with no staining of the metaphase mass argues against antibodies to chromatin-associated autoantigens and is frequently due to antibodies against RNA binding proteins, such as SS-A/Ro, SS-B/La, Sm, and U1-RNP. Additional information in such cases is obtained by observing the texture of the nuclear staining in interphase cells, since a coarse speckled pattern is usually associated with antibodies to Sm and U1-RNP, whereas a myriad discrete fine speckled pattern is most frequently caused by anti-SS-A/Ro 60-kDa autoantibodies (26). In contrast, a nonspecific fine speckled staining of the interphase nucleus with no staining of the metaphase plate may be due to several autoantibodies, including some of unknown specificity (Fig. 5).

It is important to bear in mind that one sample may contain more than one autoantibody specificity. In such cases, the resulting IIF-ANA pattern will be a mixture of the IIF-ANA patterns related to the individual autoantibodies in the sample. For example, the coexistence of antibodies to native DNA and U1-RNP renders a mix of the homogeneous and coarse speckled patterns in interphase nuclei and a homogeneous staining of the mitotic chromosome mass. The coexistence of more than one autoantibody specificity may preclude the definition of a standard IIF pattern. In such cases, it may be appropriate to define the IIF pattern as "mixed pattern" and indicate the possibility of more than one autoantibody specificity in the sample. However, if there is a difference in the concentration of the autoantibody specificities in the serum, it may be possible to identify individual IIF patterns along the several dilutions.

REPORT OF THE IIF-ANA TEST

The IIF-ANA test report should include information on the staining pattern and titer in each cell compartment, as follows: nucleus, nucleolus, metaphase plate, cytoplasm, and mitotic apparatus. More than one pattern may be reported

FIGURE 5 Panel of relevant IIF-ANA patterns. (A) Nuclear homogeneous pattern; (B) nuclear dense fine speckled pattern; (C) nuclear coarse speckled pattern; (D) nuclear SS-A/Ro pattern; (E) nuclear fine speckled pattern; (F) centromere pattern; (G) nuclear pleomorphic pattern; (H) ribosomal-P cytoplasmic pattern. Double arrows, cells in interphase; single arrow, cells in metaphase; arrowheads, cell nuclei with pleomorphic pattern and variable intensity. Indirect immunofluorescence using HEp-2 cells.

in the same cell compartment (Fig. 4). Due to the great diversity of possible ANA patterns, it is recommended that the report contain an item dedicated to the interpretation of the findings. In this field of the report, the pathologist should comment on the possible autoantibody specificities associated with the reported ANA patterns and the possible clinical significance.

The method used in the test must be stated because there may be differences in results obtained by indirect immunofluorescence with HEp-2 cells, indirect enzyme with HEp-2 cells, and the various solid-phase-based assays. As for a reference range in the IIF-ANA test, it is generally agreed that 1/80 represents a borderline reactivity and 1/160 or higher represents a positive reaction. However, this needs to be established according to the peculiarities of each laboratory.

INTERPRETATION OF THE IIF-ANA TEST RESULT

The ANA test cannot be interpreted in a straightforward fashion as, for example, an HIV test can. A positive ANA test does not necessarily mean systemic autoimmune disease, and a negative ANA test does not exclude the possibility of a systemic autoimmune disease. The appropriate diagnostic decision must be based on the integration of the clinical context with nuances in the ANA pattern/titer and tests for disease marker autoantibodies.

When To Order an ANA Test

Ideally, an ANA test should be requested in individuals with clinical symptoms and signs consistent with a systemic autoimmune disease. In this context, a positive result may be interpreted as an additional element in the construction of the clinical diagnosis. However, at the early onset, systemic autoimmune diseases frequently present with nonspecific complaints and symptoms, and these patients are frequently first seen by a variety of medical specialists other than those mostly acquainted with systemic autoimmune diseases. Early diagnosis and treatment of systemic autoimmune diseases are relevant for higher remission rates, prognosis, and prevention of irreversible damage. A delay in diagnosis may have serious clinical consequences and represent an economic burden. A high degree of suspicion is necessary for early diagnosis of such cases, and a positive ANA result may represent a valuable hint to foster further investigation, especially when associated with a disease marker autoantibody. In this context, a study analyzing 10,550 consecutive patients sent to a university rheumatology laboratory by diverse medical specialists over a 3-year period showed that 21% of the ANA-positive samples had at least one disease marker autoantibody identified and 7.9% had multiple autoantibody specificities that contributed to the final diagnosis (27). However, a large proportion of ANA-positive samples were not associated with any disease marker autoantibodies. Therefore, judicious ordering and interpretation of the IIF-ANA test are of utmost importance.

On the other hand, the ANA test is not meant for general screening (check-up) in asymptomatic individuals. In addition, there is no formal evidence to support the use of the ANA test in monitoring treatment and disease activity of patients with an already established diagnosis. It is known that some autoantibodies do exhibit modulation in concentration in serum according to disease activity, including autoantibodies to native DNA, nucleosomes, ribosomal P protein, Jo-1, and Scl-70. In contrast, some autoantibodies have a rather stable concentration in serum irrespective of disease activity, including autoantibodies to SS-A/Ro, SS-B/La, Sm, and U1-RNP. Accordingly, ANA titer and pattern may change in some patients, but such a finding should be interpreted judiciously.

The Meaning of a Negative ANA Test

A negative IIF-ANA test is a strong (but not absolute) element against the diagnosis of systemic autoimmune diseases, such as drug-induced lupus, SLE, mixed connective tissue disease (MCTD), and SSc. On the other hand, the IIF-ANA test has a low negative predictive value for diseases such as systemic or local vasculitis, rheumatoid arthritis, Sjögren's syndrome, and polymyositis. It should be emphasized that a negative IIF-ANA test does not mean that the sample has no autoantibody. In fact, the ability of autoantigens to be recognized in the IIF-ANA assay on HEp-2 cells varies considerably (Table 2). Even for autoantigens regularly present in the HEp-2 cell, autoantibodies in some selected patients may recognize epitopes that are available in specific assays (e.g., double immunodiffusion or enzyme-linked immunosorbent assay) but may not be available in IIF-ANA on HEp-2 cells. Hoffman et al. analyzed 494 consecutive samples referred by rheumatologists and found that 4.1% of the IIF-ANA-negative samples had at least one disease marker autoantibody detected by other methods (28). Therefore, a negative IIF-ANA result in a patient with consistent suspicion of systemic autoimmune disease may require further testing for appropriate disease marker autoantibodies in specific assays.

The Meaning of a Positive ANA Test

Maybe due to historical reasons, there is a general misconception that a positive ANA test is strongly linked to the diagnosis of SLE. However, a positive IIF-ANA result simply means that there is a detectable concentration of autoantibodies in the sample. The clinical relevance of this finding depends on the clinical scenario, the specificity of the autoantibodies in the sample, and other laboratory findings. IIF-ANA is a very sensitive test capable of detecting low-concentration and low-avidity autoantibodies, some of which are not ordinarily associated with systemic autoimmunity. In other words, a positive ANA result per se is not enough for diagnosis or a final clinical decision.

One very important element for the interpretation of a positive IIF-ANA test is the pretest probability. This corresponds to the chance of a given disease to be present before the diagnostic test result is known. This concept is illustrated in Fig. 6, showing that a very sensitive test can yield a high or low positive predictive value depending on the pretest probability. Considering that a positive IIF-ANA occurs in roughly 13% of the general population, one can easily appreciate that indiscriminate ordering of the IIF-ANA test can yield positive results most probably not associated to systemic autoimmune disease, especially at low titer. These "false-positive results" may lead to undesirable consequences, including emotional distress, unnecessary and expensive laboratory investigation, and inappropriate treatment of the patient.

How To Deal with a Positive ANA Test without Clinical Evidence of Systemic Autoimmunity

The occurrence of a positive ANA test without clinical evidence of systemic autoimmunity has been designated the "idiopathic positive ANA syndrome." There are some

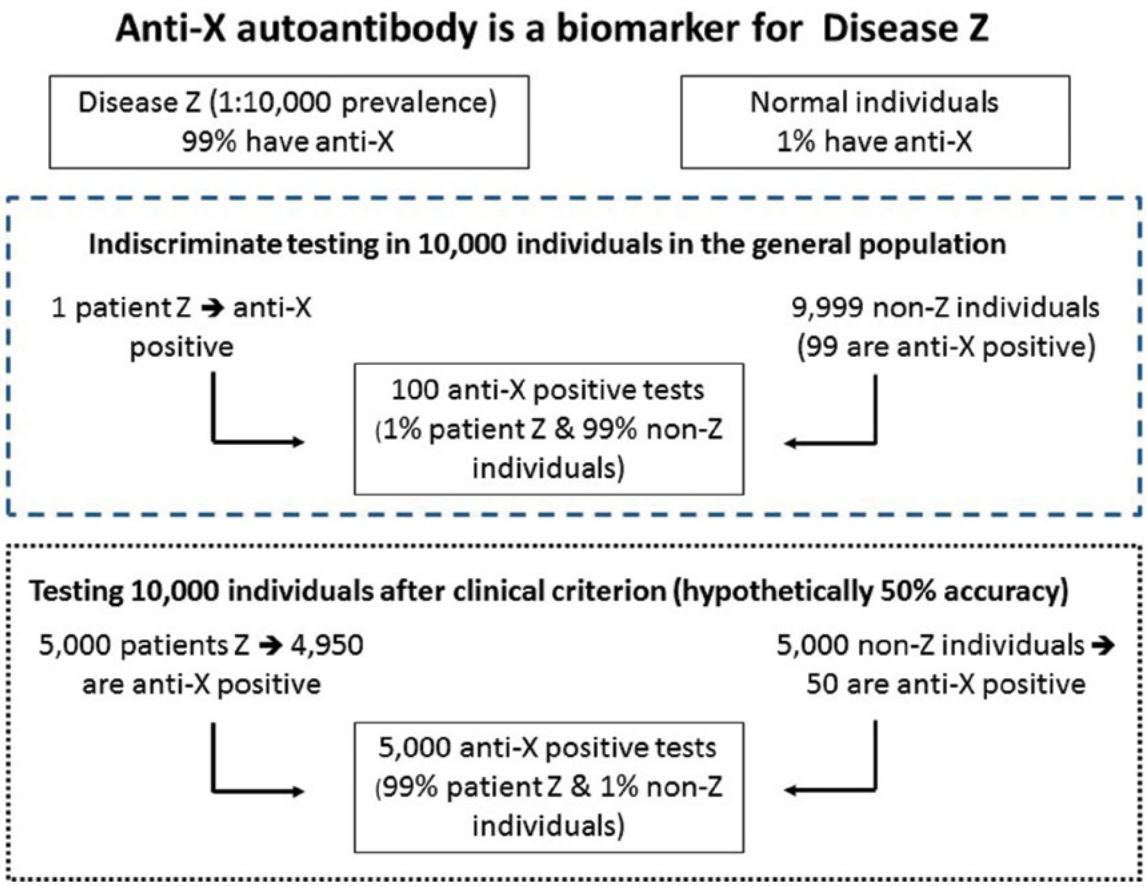

FIGURE 6 Pretest probability influences the diagnostic performance of tests. Anti-X antibody is a biomarker for the rare hypothetical disease Z and occurs in 1% of the general population. Indiscriminate testing for anti-X yields poor positive predictive value. Enrichment of the population sample to be tested according to clinical judgment restores the good performance of the anti-X antibody test.

possibilities to be considered for an individual with a positive ANA result and no apparent evidence of autoimmune disease:

- Impending autoimmune disease
- Nonautoimmune immunological derangement secondary to infection, cancer, or drug
- Minimal rank within the autoimmune disease spectrum or familial autoimmune trait
- Genuine "incidentaloma" (there is no immunological derangement at all)

In such scenarios, it may be helpful to analyze parameters that help to discriminate positive IIF-ANA results in patients with systemic autoimmune diseases and in nonautoimmune and healthy individuals. Two intrinsic dimensions of the IIF-ANA test are very useful in the interpretation of a positive result: the titer and the pattern. Although these correlations are not absolute, a high-titer IIF-ANA is more likely to be related to an underlying systemic autoimmune disease, and a low titer IIF-ANA is more likely to occur in nonspecific clinical scenarios. Exceptions do occur, as some autoimmune patients present low-titer ANA and some apparently healthy individuals present high-titer ANA. In this respect, it is important to bear in mind that some clinically relevant autoantibody specificities tend to yield high-titer ANA (e.g., anti-centromere, anti-U1-RNP) whereas some others may yield low- to medium-titer ANA (e.g., anti-native DNA) (29).

The second dimension of the IIF-ANA test, the IIF-ANA pattern, may be even more informative. The IIF-ANA pattern corresponds to the topographical distribution of the recognized autoantigens. This rationale may be used to distinguish autoantibodies to antigens belonging to the nucleus, nucleolus, and cytoplasm. A closer and more detailed observation allows the identification of several nuances in IIF-ANA patterns within each cellular compartment, and some of these subtle IIF-ANA patterns show strong association with a restricted set of autoantigens (Tables 3 and 4; Fig. 5). In fact, the topographical distribution of some autoantigens is peculiar enough to render the respective immunofluorescence pattern relatively specific for the autoantibodies reacting with that particular autoantigen (Table 4). The judicious interpretation of the IIF-ANA pattern may then direct further investigation of the appropriate autoantibody specificities, which will eventually help settle the diagnosis.

One particular IIF-ANA pattern, the nuclear dense fine speckled pattern (DFS), is of special importance because it is rather frequent, usually occurs at high titer, and is not associated with systemic autoimmune diseases. The DFS pattern (Fig. 5) is elicited by antibodies against the 75-kDa

TABLE 4 IIF-ANA patterns, targeted autoantigen, and disease associations[a]

ANA patterns	Autoantigen	Probable disease associations
Nuclear patterns		
Centromere	CENP-A/B/C	SSc (limited form), primary RP, PBC, SSj
Dense fine speckled	LEDGF	Usually denotes absence of systemic autoimmune disease. Interstitial cystitis, atopic dermatitis, asthma, prostate cancer.
Common fine speckled[b]	Unknown	Unknown clinical association
Type SS-A/Ro fine speckled	SS-A/Ro 60 kDa	Primary SSj, SLE, neonatal lupus, and subacute cutaneous lupus, SSc, polymyositis, PBC
Coarse speckled	Sm U1RNP	Anti-Sm: SLE Anti-U1 RNP: MCTD, SLE, SSc
Nuclear matrix-like[b]	hnRNP	Systemic autoimmune diseases and nonautoimmune diseases
Homogeneous	dsDNA, chromatin Histone	Anti-dsDNA and antinucleosome: SLE Antihistone: drug-induced LE, SLE, RA, oligoarticular JIA (especially with uveitis), Felty's syndrome, autoimmune hepatitis, PBC
Discrete nuclear dots[b]	p80 coilin sp100	Anti-p80 coilin: SSj, inflammatory conditions, HI Anti-sp100: PBC, autoimmune hepatitis
Nuclear envelope[b]	gp-210, p62 Lamin A/B/C, LBP	Anti-gp210 and anti-p62: PBC Nondefined autoantigens: PBC, autoimmune hepatitis, SLE, linear scleroderma, APS
Pleomorphic	PCNA	SLE
Nucleolar patterns		
Clumpy	Fibrillarin	SSc (diffuse and severe forms), hepatocellular carcinoma (rare)
Homogeneous	To/Th Nucleolin B23	Anti-To/Th: SSc (limited form with pulmonary hypertension) Antinucleolin: SLE, GVHD, hepatitis A, infectious mononucleosis Anti-B23 (nucleophosmin), SSc, APS, GVHD, cancer
Speckled	NOR-90; RNA pol I	SSc, cancer, SSj, RA, drug-induced LE, alcoholic liver disease SSc, rarely other systemic autoimmune diseases
Cytoplasmic patterns		
Fine speckled	tRNA synthetases	Jo-1 and other synthetases, specific for polymyositis, antisynthetase syndrome, rarely dermatomyositis
Dense fine speckled	PL7/PL12 Ribosomal P	Anti-PL7/PL12, polymyositis Anti-ribosomal P protein: SLE, type 1 autoimmune hepatitis
Golgi apparatus[b]	Golgin family	SLE, SSj, other systemic autoimmune diseases, idiopathic cerebellar ataxia, paraneoplastic cerebellar degeneration, viral infections.
Discrete dots[b]	EEA1 GWB	Anti-EEA1: subacute cutaneous LE, SLE, RA, primary RP Anti-GWB: SSj, motor/sensory neuropathy, ataxia, RA, PBC
Microfilaments[b]	Actin Myosin Keratin Vinculin Tropomyosin Vimentin	Antiactin: autoimmune hepatitis; cirrhosis Antimyosin: hepatitis C, hepatocellular cancer, MG, myocarditis Antikeratin: alcoholic hepatitis, inflammatory/infectious diseases Antivinculin: MG, Crohn's, ulcerative colitis Antitropomyosin: Crohn's disease, ulcerative colitis Antivimentin: nonspecific interstitial pneumonia.
Reticular/dots	Mitochondria	PBC; can be rarely found in isolated systemic sclerosis.
Mitotic apparatus patterns		
Centriole/centrosome[b]	Several	Several autoimmune and infectious diseases
Intercellular bridge[b]	Several	Various autoimmune conditions with low specificity
Mitotic spindles[b]	HsEg5 and others	Various autoimmune conditions with low specificity

[a]Abbreviations: SSc, systemic sclerosis; SLE, systemic lupus erythematosus; RP, Raynaud's phenomenon; PBC, primary biliary cholangitis; SSj, Sjögren's syndrome; MCTD, mixed connective tissue disease; RA, rheumatoid arthritis; HI, healthy individuals; APS, antiphospholipid syndrome; GVHD, graft-versus-host disease; MG, myasthenia gravis.

[b]When in low-to-moderate titer, may not have clinical relevance.

transcription coactivator LEDGF/p75 (30). Autoantibodies to LEDGF/p75 occur in 3 to 9% of the normal population (8, 30) and contribute to a sizable fraction of the cases of the idiopathic positive ANA syndrome, especially in those with high-titer ANA. Several studies have consistently shown that individuals with isolated anti-LEDGF/p75 antibodies do not present with systemic autoimmune diseases. In addition to apparently healthy individuals, the DFS pattern and anti-LEDGF/p75 antibodies have been reported in a variety of clinical scenarios, including interstitial cystitis, dermatitis atopica, asthma, and prostate cancer (30). Since the DFS pattern is clearly apparent only when anti-LEDGF/p75

antibodies are not overshadowed by the concomitant presence of significant levels of other autoantibodies, the identification of the DFS pattern has been considered an indication of absence of systemic autoimmune diseases (8, 25, 31).

In addition to the clinical context, the interpretation of the ANA result must take into account information from other tests, including the testing for autoantibody specificities associated with the particular IIF-ANA pattern observed. Useful tests include blood cell count, urinalysis, serum creatinine, liver function tests, acute-phase reactants, and the determination of the serum complement (CH50 and initial components of the classic pathway). The two following examples illustrate the integrated interpretation of information provided by the IIF-ANA test (titer and pattern), clinical context, and general laboratory tests. Patient A and patient B present with nonspecific musculoskeletal complaints and no other clinical finding. Patient A presents a 1:2,560 IIF-ANA with nuclear DFS pattern (with coarse staining of the metaphase plate). Patient B presents a 1:640 IIF-ANA test with a nuclear homogenous pattern (with strong hyaline staining of the metaphase plate). Patient A most probably presents no abnormality in blood cell count, urinalysis, acute-phase reactants, serum complement and creatinine, and liver tests and no reactivity in tests for disease marker autoantibodies, but it is highly probably that he/she presents positive reactivity to LEDGF/p75. For patient B, general laboratory exams may disclose unapparent abnormalities and specific tests for disease marker autoantibodies may reveal antibodies to native DNA, nucleosome, histone, Sm, or U1-RNP. Despite the higher-titer IIF-ANA, patient A most probably has no systemic autoimmune disease whereas patient B, despite moderate IIF-ANA titer, will probably develop evident SLE manifestations within the next few months or years. Patient A can be seen within 6 months for a "reassurance" visit and then discharged, but patient B must be closely followed with frequent laboratory investigation for impending SLE manifestations.

Limitations of the Test

Despite its recognized utility and its ranking as the gold standard for autoantibody screening, the IIF-ANA test presents some limitations and pitfalls. There is a high degree of inherent subjectivity in the definition of a positive test and in the interpretation of the ANA pattern. This can be minimized by delineating criteria for the establishment of a positive reaction and definition of each pattern. Continuous intra- and interlaboratory interaction among analysts is highly recommended. It is advisable that at least two analysts have the opportunity of examining each sample. The variability in the microscope and lighting conditions may contribute to nonreproducible results among laboratories. This can be partially overcome by the use of commercial precalibrated fluorescent beads. The heterogeneity in performance of the various slide brands may cause one sample to produce different results in different slides. This potential problem can be handled by validating each new slide lot or brand with an array of known samples representing diverse IIF-ANA patterns. In addition, some slide brands or some peculiar slide lots may yield spurious patterns not observed in other brands. This problem can be partially handled by retesting unusual patterns in more than one slide brand. Pattern recognition is a cognitive ability acquired by training and practice, which are obviously variable among analysts. This source of inconsistency must be overcome by continuous training and by exchanging experience within the group and with other groups.

Strategy for Ordering Autoantibody Tests in the Investigation of Autoimmune Diseases

The laboratory investigation strategy in autoimmune diseases varies according to the diagnostic hypotheses indicated by the clinical evaluation. There is a plethora of autoantibodies to be tested and an equally large array of methodological platforms, which may make the task difficult for those not familiar with the field. For systemic autoimmune diseases, the IIF-ANA test is useful as general screening for autoantibodies against antigens in several cellular compartments. Following the IIF-ANA test, additional tests are frequently necessary according to the clinical scenario and according to the IIF-ANA pattern. In case there is no firm evidence of a systemic autoimmune disease, a negative IIF-ANA test may be enough. In contrast, if there is compelling evidence of systemic autoimmunity, a negative IIF-ANA test must be complemented by the investigation of other autoantibodies. In fact, the ability of the IIF-ANA test in detecting the several autoantibodies varies substantially (Table 2). For example, it may be wise to test for anti-SS-A/Ro and anti-P ribosomal antibodies in patients with a suspicion of SLE and a negative IIF-ANA test. The same is true for anti-Jo-1 antibodies if the clinical scenario suggests polymyositis or antisynthetase syndrome. In addition, it is important to bear in mind that tissue-specific autoantigens are not available in HEp-2 cells. In such cases, specific tests for individual autoantibodies should be ordered. A corollary of that is that the ordering of autoantibody assays must obey a strategy dictated by the judicious analysis of the clinical scenario vis-à-vis the clinical associations of the several autoantibodies.

Quality Control

The careful execution of the standard operational protocol is of paramount importance, since it ensures appropriate elements for interpretation of the ANA reactivity and ANA patterns. In addition, a series of items are essential to ensure high-quality and consistent IIF-ANA results.

1. A set of controls should be used in each assay run, including (i) samples that clearly discriminate interphase and mitotic cells (e.g., centromeric, homogeneous, or dense fine speckled pattern) in dilution to present moderate fluorescence intensity, (ii) one sample with low fluorescence intensity (+/++++), and (iii) a negative sample. Samples with strong intensity of reaction yield beautiful images but do not add much information. The same set of controls should be used in each assay run in order to ensure day-to-day consistency.
2. A daily record should be registered with the results obtained with the set of controls used in each routine. Monitoring daily records of controls helps identify possible trends for deviation, allowing corrective actions to be implemented. These records should also register changes in PBS batch, lot of slides, and any unexpected event that may have occurred in the assay.
3. A panel of serum samples with reactivity to an array of autoantigens and representing several relevant ANA patterns should be used to validate any new lot or new brand of slides. Ideally, this validation panel should include samples reacting with SS-A/Ro, Jo-1, ribosomal P protein, LEDGF/p75 (DFS pattern), Scl-70, Sm/U1-RNP, mitochondria, sp-100, CENP-F, and PCNA. This panel can be constructed with secondary standards retrieved from the laboratory routine, exchange with expert laboratories, and samples obtained from the CDC.

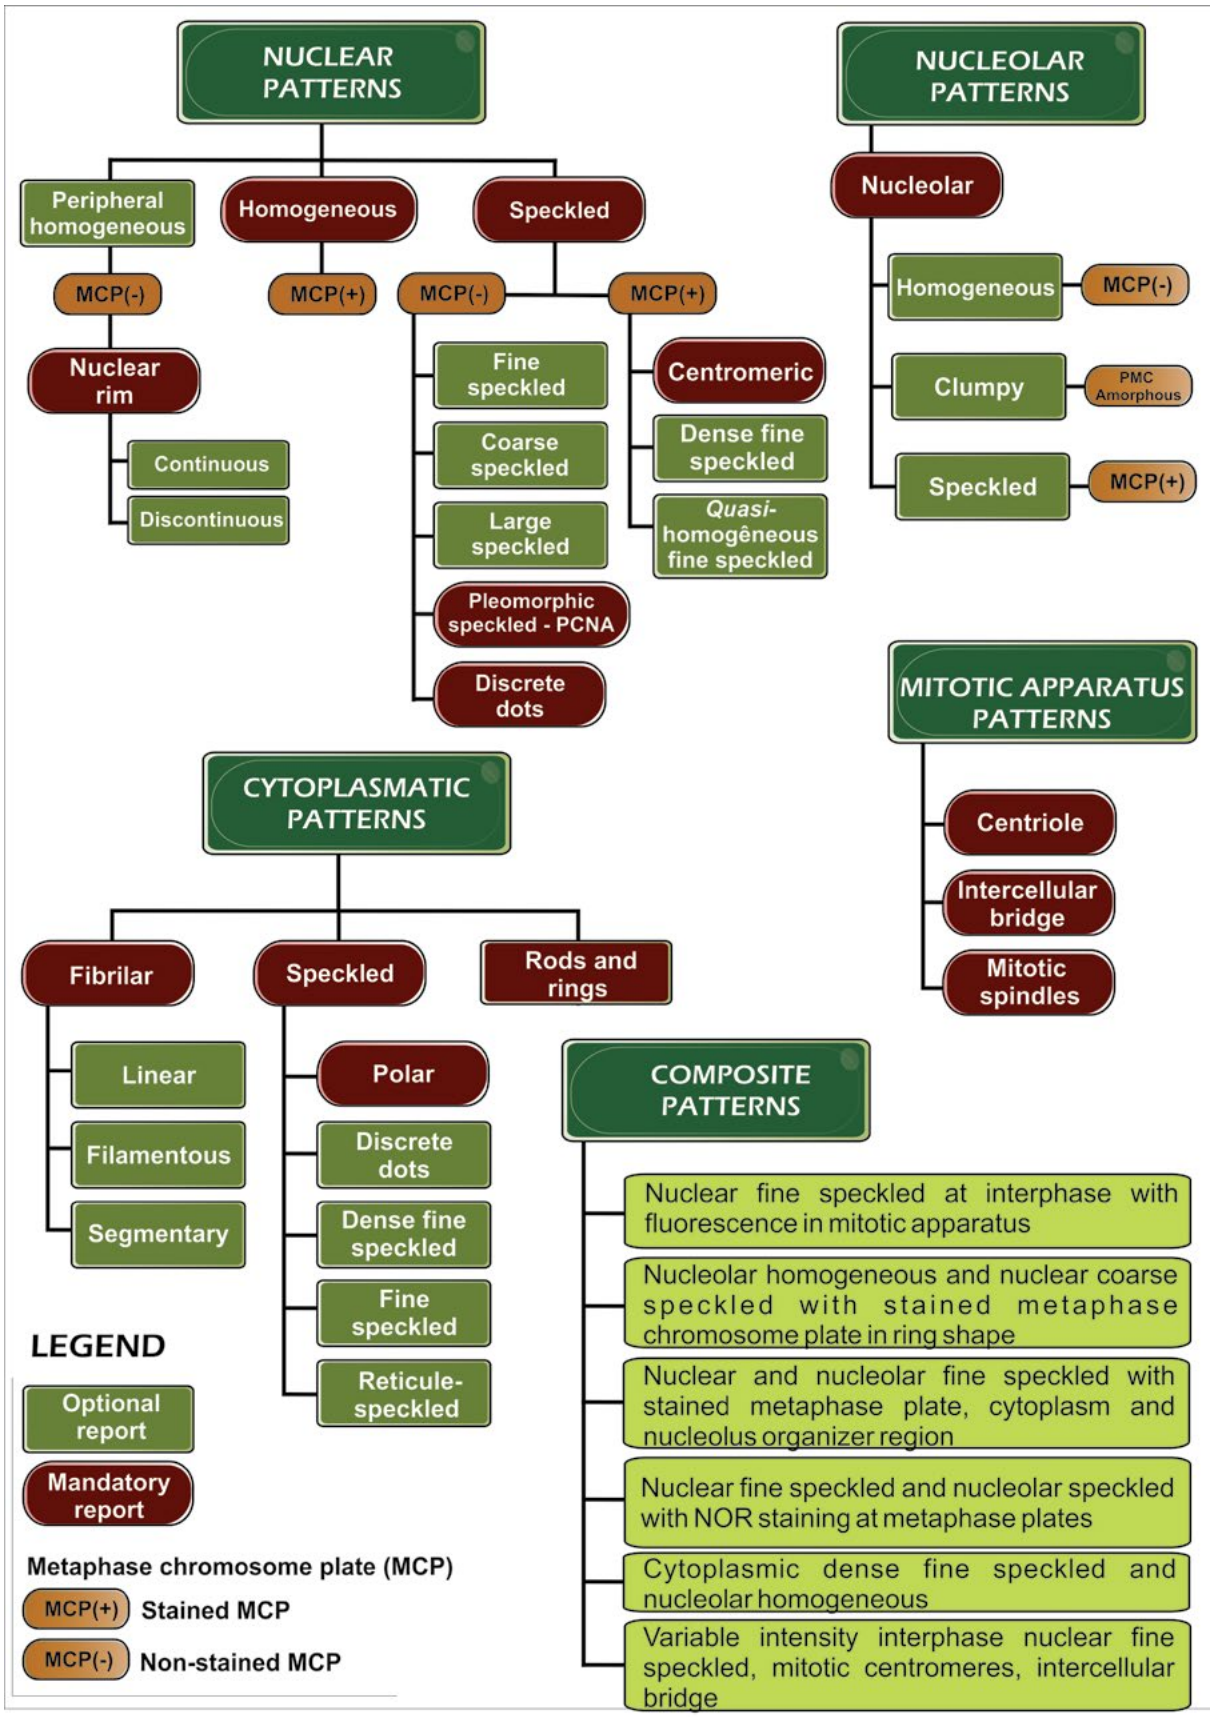

FIGURE 7 Decision-tree algorithm for classification of IIF-ANA patterns proposed by the IV Brazilian Consensus on ANA. MCP, metaphase chromatin plate.

4. Periodically, there should be checking of the PBS and mounting medium pH, microscope lamp lifetime, and the temperature of refrigerators used to store the kits and serum samples.
5. Regular preventive maintenance of microscopes to ensure the cleaning of filters, lenses, and eyepieces, centralization of lamps, and periodic calibration of automatic pipettes should be conducted.
6. Harmonization of the interpretation criteria among analysts. This can be achieved via a series of measures, including the following.
   a. Encouragement of discussion and sharing of routine IIF-ANA interpretation by analysts.
   b. The screening and titration steps should not be performed by the same analyst, ensuring that each positive ANA sample be seen by at least two analysts.
   c. Periodically, all analysts should blindly read and record a set of slides with various predefined patterns and titers; possible discrepancies may be identified and corrected.
   d. Continuous education and training of analysts.
7. Adherence to one of the available national and international external quality control programs is highly recommended. In addition, internal quality control can be implemented by assaying blinded samples with known reactivity.

There is a need to promote worldwide harmonization in the nomenclature of IIF-ANA patterns as well as in defining the characteristic features of each pattern, their immunologic associations, and their clinical relevance. A few consensus-building studies have been developed in different parts of the world (14, 15, 32) with the proposition of tree-decision algorithms for the classification of IIF-ANA patterns (Fig. 7). The International Consensus on ANA Patterns, recently launched during the 12th International Workshop on Autoantibodies and Autoimmunity held in Sao Paulo, Brazil, shall generate a continuous process of international harmonization and diffusing of useful information for those interested in performing and interpreting the IIF-ANA test (http://www.iwaa2014.org.br/home.html).

KEY MESSAGES

1. The designation "antinuclear antibody (ANA)" test should be updated to "anticellular antibody" test.
2. IIF-ANA on HEp-2 cells is the gold standard for autoantibody screening in systemic autoimmune diseases.
3. ANA testing in individuals with low pretest probability of systemic autoimmune disease often contributes to the idiopathic positive ANA syndrome. IIF-ANA is not recommended as general screening test (check-up).
4. A negative IIF-ANA speaks against, but does not formally exclude, the diagnosis of some systemic autoimmune diseases.
5. A positive ANA test by itself is not diagnostic of any autoimmune disease since patients with several other clinical conditions and even healthy people may present a positive ANA.
6. A high-titer ANA is most likely found in systemic autoimmune rheumatic diseases but may sometimes be found in apparently healthy individuals and in patients with nonautoimmune diseases.
7. Careful analysis of the IIF-ANA pattern provides valuable information regarding the possible autoantibody specificities in the sample.
8. The dense fine speckled (DFS) IIF-ANA pattern, even at high titer, is most likely found in healthy individuals and patients with nonautoimmune diseases.
9. The clinical significance of a positive IIF-ANA test must take into account the titer and pattern, the clinical scenario, and the results of other ancillary tests.

Detection of Autoantibodies by Enzyme-Linked Immunosorbent Assay and Bead Assays

EDWARD K. L. CHAN, RUFUS W. BURLINGAME, AND MARVIN J. FRITZLER

88

Autoantibodies directed against intracellular antigens are characteristic features of a number of human autoimmune diseases and certain malignancies (1–3). Studies of systemic autoimmune rheumatic diseases have provided strong evidence that autoantibodies are maintained by antigen-driven responses (4, 5) and that autoantibodies can be reporters from the immune system, revealing the identities of antigens involved in disease pathogenesis. Historically, autoantibody detection and analysis have relied on a number of different technologies, such as hemagglutination and particle aggregation, immunodiffusion, indirect immunofluorescence (IIF), complement fixation, counterimmunoelectrophoresis (CIE), Western and dot blotting, immunoprecipitation (IP), and enzyme-linked immunosorbent assay (ELISA), and on functional assays that demonstrate inhibition of the catalytic or other functional activity of the antigen of interest. These technologies have limitations because they tend to be labor-intensive and time-consuming, are limited in throughput, are semiquantitative, and are not adaptable to leading-edge research. Immunodiffusion has been used for over 50 years, and it is still used in some clinical laboratories because it is inexpensive and has high specificity, but it lacks sensitivity and can take up to 48 h before precipitin lines are interpretable. Western blotting is more costly and time-consuming, and not all autoantibodies are detected by this technique. For example, in the SS-A/Ro system, it has been observed that IP techniques are required to identify some sera that contain antibodies reacting only with the "native" SS-A/Ro particle (6). IP protocols that use extracts from [^{35}S]methionine-labeled cells are not suitable for the detection of all autoantibodies, such as antibodies to Ro52/TRIM21 protein (7). ELISA techniques have rapidly advanced, but highly specific, sensitive, and reliable assays that use highly purified or recombinant proteins are limited by intermanufacturer and interlaboratory variation of results (8). Immunodiffusion and CIE generally favor high-titer sera and often cannot discriminate multiple autoantibody responses that are characteristic of systemic autoimmune rheumatic disease sera.

Despite the advantages of IP, CIE, and ELISA, IIF remains the least expensive and, perhaps, the screening assay of choice for many autoantibodies (9–11). HEp-2 cells are currently the most commonly used cell substrate in diagnostic autoantibody tests for systemic autoimmune rheumatic diseases. However, the use of IIF on HEp-2 cells to detect autoantibodies can be limited by a lack of specificity and sensitivity when the antigen in question is of low abundance or when epitopes are hidden or lost through cell fixation (12). These factors have resulted in variability in the clinical performance of commercial HEp-2 cell substrates (13). In addition to variation in kits produced by various manufacturers, significant lot-to-lot variation from single manufacturers has been noted, and variations in different batches from the same manufacturer have also been observed. Another limitation of current IIF substrates is that there is significant variation in the sensitivities of different commercially available substrates to detect different antibodies. This limitation can be compounded by sera that contain multiple autoantibodies, for which it is necessary to use other techniques to definitively identify as many autoantibodies as possible in a single serum.

Human sera contain autoantibodies that are notably heterogeneous with respect to antigen and epitope specificity and the polyclonality of the B cell response that leads to their formation. For example, it is common to find sera that show a complex pattern of IIF staining that might include reactivity with the nuclear envelope, mitochondria, and other intracellular structures and organelles. Further analysis of these sera with a variety of techniques confirms that there is reactivity with a variety of antigens that might include chromatin, Ro60, pyruvate dehydrogenase (pyruvate dehydrogenase complex or M2 antigen), nuclear pore complex antigens (14), and processing bodies (GW bodies) (15). Complex sera like those referenced here point to the need of multiplexed autoantigen arrays to provide an accurate picture of the autoantibody profile of any patient.

With the use of expression cloning and autoantibodies as probes to screen λ phage cDNA libraries, the identities of many autoantigens have been determined and validated. A logical strategy is to take advantage of the availability of recombinant autoantigens generated from the cDNA in *Escherichia coli* or other appropriate expression systems as the substrates for immunoassays such as ELISA and multiplex assays. More recently, protein and peptide microarrays and mass spectroscopy have been used to detect novel autoantibody reactivity (16). This chapter will focus on the purification of recombinant autoantigens used in the authors' laboratories and advances in multiplex immunoassays that are being used for autoantibody detection.

doi:10.1128/9781555818722.ch88

ANTIGEN TECHNOLOGY

A rapid expansion of new technologies developed by basic and applied immunology is making a significant impact on a broad spectrum of biomedical investigations (16, 17). The identification of biomarkers of disease onset, progression, and response to therapy is now made possible with the application of a variety of reagents in a number of novel platforms (18–21). Polyclonal, monoclonal, and single-component antibodies have become valuable tools in basic research and diagnostic technologies and have been used very successfully as therapeutics in patients with cancer, a broad spectrum of systemic rheumatic diseases, a variety of autoimmune conditions, and cell and organ transplantation. Accompanying these developments has been the appearance of a broad spectrum of DNA, RNA, and protein microarrays. Protein arrays in particular are gaining acceptance as an approach to multiplexed detection of autoantibodies in biological fluids and the detection of changes in cell physiology after various physiological triggers and therapeutic interventions (22). To capitalize on these advances, there has been a need for the parallel development of new technology platforms to produce and utilize the arrays in clinical settings. These have included novel adaptations of fluorescence-activated cell sorting, which is now a standard technique in most clinical immunology centers (23). Some of these emerging technologies include addressable laser beads, microfluidics and laboratory-on-a-chip platforms, chemiluminescence (17, 24), and nanotechnology (25–29). In addition, devices that produce protein arrays by spotting analytes of interest on solid-phase substrates have become a necessary technology of research-intensive institutions. The use of antigen arrays for the analyses of autoantibodies has been reported, but the technology remains mostly limited to research laboratory settings (30, 31).

Purification of Natural and Recombinant Autoantigens

One requirement in the development of a successful immunoassay for the detection of autoantibodies is that the antigen must be recognized efficiently. Many recombinant autoantigens generated in bacterial, viral, or eukaryotic expression systems can be used successfully for functional as well as immunological assays. In the analysis of systemic rheumatic diseases, recombinant human SS-B/La antigen is an excellent example, since most human anti-SS-B/La sera recognize multiple epitopes, most of which are readily expressed in recombinant forms. However, some recombinant autoantigens are found not suitable at all. For example, Sm D1 antigen generated in *E. coli* is not suitable for ELISA, while the same antigen expressed from a baculovirus system is suitable (32). Recombinant antigens derived from the bacterial expression system are often not suitable for the detection of autoantibodies because they may lack posttranslational modifications required directly or indirectly for the functionality of the epitope(s). Another example is the Ro60 antigen. Only a small fraction of anti-Ro60 sera are reactive to the recombinant protein generated from *E. coli*, unlike with the native-affinity-purified bovine Ro60 protein. It is not clear why the native preparation is more immunoreactive than the one derived from *E. coli*, but probable explanations are that the native antigen has a conformation, a posttranslational modification, or a cofactor that the recombinant protein made in *E. coli* lacks. It should be noted that recombinant Ro60 with apparently superior antigenicity is now available from a commercial source (33). Ribonucleoprotein (RNP) autoantibody targets are another instance where cloned antigens do not have as much reactivity as the native proteins. In this case, the increased reactivity with the native antigen is related to autoantibodies in patients with mixed connective tissue disease that react only with the quaternary structure found in the RNA-multiprotein complex and not in the individual components (34).

Use of Natural Autoantigens

There are a number of reasons that autoantigens purified from natural sources are preferred over recombinant proteins. Historical uses and costs are some of the issues that lead to the use of bovine chromatin preparations for the detection of antichromatin antibodies. Classical biochemical purification is still used for the purification of large quantities of different chromatin fractions as well as subunits that are useful for detecting a clinically relevant subset of antibodies (35). Additionally, it has been demonstrated that some diagnostically important autoantibodies react with epitopes present on the native histone-DNA complex found in chromatin. These epitopes are absent in DNA-free histones and histone-free DNA (36). The antigen tissue transglutaminase, recognized by people with celiac disease, is easily isolated by biochemical techniques from red blood cells. To obtain native autoantigens that are in relatively low abundance in animal tissue, affinity column purification using well-defined human autoantibodies coupled to solid-phase matrices is routinely used. Because it is possible to obtain the large quantities of tissue that are needed at a relatively low cost, bovine spleen and thymus are often the starting materials for native antigens. Examples in this category include extractable nuclear antigens, such as Sm, RNP, Ro60, SS-B/La, Scl-70, and Jo-1.

Use of Peptide Antigens

Patients with autoimmune diseases make a spectrum of autoantibodies to specific antigens, and some of these antibodies will react with small peptides derived or deduced from the target protein (37). Usually, these peptides are not as reactive as the whole protein in immunoassays and thus are not clinically useful. However, in a few instances, antibodies against peptides have been shown to be at least as clinically useful as antibodies against the corresponding native protein. In particular, the 23 C-terminal amino acids of ribosomal P proteins is the immunodominant peptide in certain patients with systemic lupus erythematosus (SLE) (38), as is a dimethylated peptide from SmD3 antigen (39, 40). Citrullinated peptides derived from filaggrin and other sources are highly reactive with sera from patients with rheumatoid arthritis (41).

Production of Recombinant Proteins

The strategy for the design of recombinant constructs is beyond the scope of this chapter; however, we will discuss briefly some key aspects related to the production of recombinant autoantigens. The production of recombinant proteins to be used in the detection of autoantibodies should take into consideration the suitability of the construct design and the ease of purification of resulting proteins. Earlier attempts in the production of recombinant proteins were faced with lengthy biochemical purification protocols to remove unwanted cellular proteins. More importantly, most of these protocols have to be specifically designed for each individual recombinant protein, and these invariably have distinctive biochemical characteristics. Currently, it is preferable to design recombinant proteins with an affinity tag that can be utilized for subsequent purification using a

one-step, solid-phase affinity chromatography protocol that can be utilized for most recombinant proteins largely independently of their biochemical properties. The preferred affinity tag should be short, such as the 6 histidine tag that can be attached to the N terminus or C terminus of the recombinant protein using vectors such as pET28 (Novagen/EMD Biosciences, Inc., San Diego, CA) or pDEST17 (Invitrogen, Carlsbad, CA). The glutathione *S*-transferase (GST) fusion proteins, although used by many investigators for the expression of autoantigens, may not be suitable for general use since anti-GST antibodies have been reported in some patients with autoimmune hepatitis (42). In contrast, human autoantibodies binding the histidine tag, a short peptide of 6 histidine residues, have not been reported to date.

In most designed recombinant autoantigens, full-length constructs are preferred so as to ensure that all the epitopes are well represented. In cases where the autoantigen is a large protein, such as the Golgi complex protein giantin, which has a molecular mass of ~350 kDa, it is technically difficult to produce the complete protein in *E. coli* or even in eukaryotic expression systems. Thus, overlapping fragments of giantin that can be used alone or as a mixture for the detection autoantibodies were produced (43).

Purification of Recombinant Proteins

It is beyond the scope of this chapter to discuss purification of different types of recombinant proteins, and thus, the following discussion represents two key modifications or improvements in overcoming problems encountered during the production of 6 histidine-tagged recombinant proteins for use in the detection of autoantibodies. The first concern is the purity of the preparation to ensure that there are no false-positive results caused by contamination from *E. coli* proteins. A modification of the established purification protocol for 6 histidine-tagged proteins has been used to achieve a higher degree of purity by repeating the affinity purification step (44). Preliminary studies showed that twice-purified recombinant proteins had lower background reactivity with normal human sera than once-purified preparations. This 2-fold affinity purification protocol has been used in several studies (43, 45). In brief, 6 histidine-tagged recombinant proteins are purified from *E. coli* lysates under denaturing conditions as described in the Qiagen manual *The QIAexpressionist* (44) and are eluted from a nickel affinity column using buffer E (8 M urea, 100 mM NaH_2PO_4, 10 mM Tris-HCl, pH 4.5). Fractions are pooled, the pH is adjusted to 8.0 with 1 M NaOH, and the nickel column is regenerated by washing it in 2 volumes of buffer A (6 M guanidine hydrochloride, 100 mM NaH_2PO_4, 10 mM Tris-HCl, pH 8.0). The second purification simply utilizes the pooled fraction and the regenerated affinity column identically to the first purification.

Use of Rosetta Bacteria for the Production of Large Recombinant Proteins

The second improvement addresses the low yield of recombinant protein in *E. coli*, especially when the recombinant protein to be produced has a high molecular mass. Most recombinant autoantigens up to ~70 kDa have been successfully produced in standard *E. coli* strain BL21(DE3) or JM109(DE3). Examples include SS-B/La, Ro60, and Ro52 proteins. Problems are often encountered when proteins of ~100 kDa or higher are generated in these *E. coli* strains. Figure 1 illustrates the problem encountered when the Golgi autoantigen p115 (115 kDa) was expressed in JM109(DE3) and the major products were only about 60 kDa. Similarly,

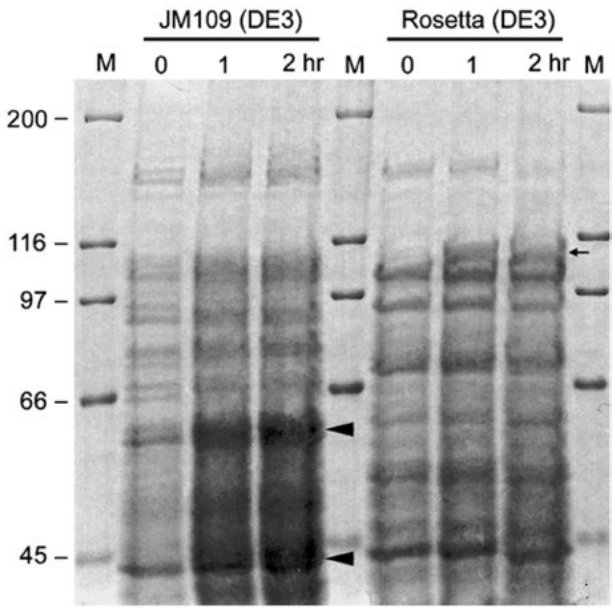

FIGURE 1 Enhanced expression of recombinant proteins is illustrated by the effect on the bacterial host. A construct, pET-p115, was transformed into either JM109(DE3) or Rosetta(DE3), and recombinant proteins were produced with the transformed bacteria using the same culture medium (2YT broth) and conditions. To the cultured bacteria was added 1 mM isopropyl-b-D-thiogalactopyranoside at time zero, and cells were harvested as pellets after 1 or 2 h, solubilized in gel sample buffer, and analyzed with SDS-PAGE using a 5% gel. Proteins were detected with Coomassie brilliant blue G-250 stain. Note that the recombinant JM109 culture generated major products of ~60 kDa (arrowhead) plus other lower-molecular-mass products, whereas the Rosetta culture yielded major products (arrow) corresponding to the native protein. Lane M, molecular mass markers (numbers at the left are masses in kilodaltons).

low-molecular-weight products were obtained with the BL21(DE3) bacteria. However, the expression was improved significantly using a new strain known as Rosetta(DE3), and a protein band corresponding to 115 kDa was generated (Fig. 1). Rosetta host strains from Novagen/EMD Biosciences, Inc. (La Jolla, CA), are BL21 *E. coli* derivatives engineered to increase the expression of eukaryotic proteins that contain codons rarely used in *E. coli*. These strains contain tRNA genes for AGG, AGA, AUA, CUA, CCC, and GGA on a chloramphenicol-resistant plasmid and thus provide for "universal" translation, which is otherwise limited by the codon usage of *E. coli*. Our experience is that the use of the Rosetta cells has made a significant positive impact on the production of recombinant human autoantigens in *E. coli*.

ADVANCES IN ASSAYS

Newer autoantibody assay systems include cell-based assays where selected tissue culture cells are transfected with the cDNAs of antigens of interest (46–48), "line" immunoassays (49, 50), solid-phase antigen arrays (51), addressable laser bead arrays, and paramagnetic bead arrays where relevant native or recombinant antigens are bound to a solid-phase matrix or to microbeads. The renewed interest in and use of cell-based immunoassays is due to the cellular overexpression of the autoantigen (i.e., particular cell surface or

transmembrane targets) in mammalian cells, where they are presented in a more native conformation (52). These advances are only the beginning of a rapid succession of newer technologies, such as microfluidics, lab-on-a-chip platforms, and nanotechnology (29). Comparison of the performance and costs of some of these technologies to those of conventional assays suggests that they are reliable, highly sensitive, and cost-effective. Clinical analyses suggest that gains in accuracy and repeatability obtained with these new technologies may be clouded by a need to reevaluate current paradigms of the diagnostic and prognostic specificities of autoantibodies (53). Each assay has limitations when determining the sensitivity, specificity and the positive predictive value for the detection of autoantibodies.

Bead-Based Immunoassays

Addressable Laser Beads

Addressable laser beads represent an application of array and flow technologies that has demonstrated flexibility in a variety of genomic, proteomic, ribonomic, and immunoassay applications (54). Although there are several applications of this technology, much experience has centered on the Luminex 100/200 platforms (Luminex Corp., Austin, TX), which incorporate laser-based flow technology that can analyze reactants in a microtiter plate format. A key component of this technology is the ability to differentiate more than 100 classes of microspheres based on various amounts of laser-reactive dyes embedded in each class, called 100 different colors for simplicity. This platform has been developed to measure antibodies in biological fluids (55, 56), screen supernatants for monoclonal antibodies of interest (57, 58), quantitate cytokines in cell extracts and biological fluids (59), detect bacterial pathogens, perform HLA typing, detect single nucleotide polymorphisms, track cell signaling responses, and monitor gene expression. The robust application of numerous technologies in this platform suggests that a future use may be to profile patients in a variety of diagnostic and therapeutic settings (54).

Addressable laser bead immunoassays (ALBIA) that utilize the Luminex LabMAP platform in research and clinical laboratory settings have been evaluated in a number of studies. In practice, an antigen of interest is chemically coupled to a specific colored microsphere. Other antigens are coupled to microspheres of different colors. After the coupling and stabilizing reactions, the antigen-coupled spheres are combined into a single microtiter well to provide a single assay that has the ability to detect multiple antibodies in a single specimen. The test samples (sera or other biological fluids) and a fluorochrome-coupled secondary antibody are added to the wells, and after an incubation time, they are analyzed. The principles of the assay are similar to those of flow cytometry, with one laser identifying the specific-antigen-coupled bead passing through the path and a second laser determining the presence and quantity of secondary antibody bound to the bead. The data are displayed in a number of formats but expressed as a quantitative analysis of multiple analytes and the relative amount of antibody bound to the antigen. We have found the development of our "in-house" assays to be easier, more efficient, and more economical than earlier technologies, such as Western blotting, IP, or ELISA. Research applications have included the development of assays to detect monoclonal antibodies and autoantibodies directed to a number of autoantigens, including early endosome antigen 1 (EEA1) (60, 61), GW182 (62, 63), the translocated promoter region (14), and valosin-containing protein (64).

In a clinical service laboratory setting, an autoantigen panel (Quanta Plex; INOVA Diagnostics, Inc.) based on that of ALBIA was evaluated and compared to the routine diagnostic protocol, which analyzed 870 sequential unselected sera received over a 6-month period (25). In this study, the sera were submitted primarily by clinicians who were considering a diagnosis of systemic rheumatic disease. The conventional serological algorithm used IIF on HEp-2 cell substrates (HEp-2000; Immuno Concepts, Inc.) to screen all sera. Antibodies to SS-A/Ro60 can be detected in this IIF assay because this substrate includes cells that are transfected with, and overexpress, the Ro60 autoantigen (47, 65). Sera that were found to be positive in this IIF assay were then evaluated by immunodiffusion for antibodies to Sm, U1-RNP, SS-A/Ro, SS-B/La, Scl-70 (topoisomerase I), and other saline-soluble autoantigens. Antibodies to double-stranded DNA (dsDNA) were detected by IIF on the *Crithidia luciliae* substrate (Immuno Concepts). This comparison showed that ALBIA results agreed with the conventional test result 92% of the time. An exception was a lack of high correlation of anti-dsDNA measured by the *Crithidia* assay and the ALBIA. Because of this, anti-dsDNA is no longer included in this profile. For some reason, the specificity of anti-dsDNA has been a problem with other ALBIA (i.e., TheraDiag FIDIS).

When the results of the ALBIA were compared to those of the conventional assay, it was noted that, on average, 25% of sera exhibited a positive result that was not detected by conventional autoantibody testing. The accuracy and validity of the ALBIA result might be confirmed by other techniques, such as IP and immunoblotting. This observed increase in the sensitivity of ALBIA was studied in various serological cohorts. The results of one such study are shown in Table 1; in that study were included 30 highly characterized sera that were previously shown to react with ribosomal P in at least one commercial ELISA (Euroimmun, MBL, Pharmacia Diagnostics) (66, 67). Comparison of the data show excellent agreement of ALBIA results with the ELISA results, including those that utilize the terminal C22 ribosomal P peptide (67).

Unselected sera from various disease cohorts were also studied to determine if the frequency of autoantibodies as detected by the ALBIA was consistent with the published frequency of autoantibodies (Table 2). This study showed that the frequencies of various autoantibodies in SLE, systemic sclerosis (SSc), Sjögren's syndrome (SjS), and rheumatoid arthritis were in keeping with those of published reports. Interesting exceptions included antibodies to Scl-70 (topoisomerase I), which were found in 8% of sera from SLE patients, and antibodies to Jo-1 (histidyl-tRNA synthetase), which were found in 15% of sera from SjS patients and 4% of sera from SSc patients. It was noted that the reactivity of sera from SLE patients with Scl-70 was in the borderline region of positivity. Similar observations were made with anti-Sm, which was found in 5% of sera from SSc patients, but all of these demonstrated a measurement of mean fluorescence units that was just above the cutoff. Follow-up testing of these sera found that none bound the SmD3 peptide, which is highly specific for SLE (39, 68). The observation that some sera from SLE patients bind Scl-70 is interesting in light of other reports that anti-Scl-70 antibodies were found in sera from SLE patients (69). Likewise, the finding of anti-Jo-1 antibodies in sera from SjS and SSc patients was surprising but may be related to more-recent observations that some sera with anti-Jo-1 antibodies contain antibodies to the Ro52/TRIM21 autoantigen (70). Early studies of ALBIA kits showed a high level (>90%) of agreement with antinuclear

TABLE 1 Comparison of results of ELISA and ALBIA detection of anti-ribosomal P autoantibodies in 30 sera[a]

[a]ID, identifier. Data are extracted from reference 66 and rounded to the nearest whole number, except in the Euroimmun column. Units are defined as per the manufacturer's protocol.

antibody and conventional ELISA techniques. For example, in a study of 37 sera from SjS patients that compared a conventional ELISA to an ALBIA kit (Athena Multi-Lyte antinuclear antibody test system), a 99% concordance between the two assays was found (55).

Taken together, there are advantages and challenges that come with the adoption of the ALBIA platform to detect autoantibodies (Table 3). The capacity of one assay to analyze and detect a complex array of autoantibodies in a single small serum sample (>10 μl) with speed and precision is a significant advantage. There are now several ALBIA kits on the market that detect 10 or more autoantibodies relevant to systemic rheumatic diseases. In some kits, the secondary antibody is added with no subsequent washing of the bead required.

Chemiluminescence Immunoassay

Chemiluminescence immunoassay (CIA) is a relatively newly developed immunoassay platform that employs a fully automated chemiluminescent analyzer and a growing spectrum of autoantibody assays (QUANTA Flash; Inova Diagnostics Inc., San Diego, CA) designed for the Bio-Flash instrument (Biokit s.a., Barcelona, Spain). The principles of the Bio-Flash CIA have recently been described (71). CIAs are developed using native or recombinant antigens covalently coupled to paramagnetic beads. Prior to use, the lyophilized beads are suspended in a buffer. A patient serum sample is prediluted with a sample buffer in a small disposable plastic cuvette. Small amounts of the diluted patient serum, the beads, and the assay buffer are all combined into a second cuvette, mixed, and then incubated for 9.5 min at 37°C. The magnetized beads are sedimented using a strong magnet in the internal washing station and automatically washed several times; next, isoluminol-conjugated anti-human IgG is added, and then the mixture is incubated for 9.5 min at 37°C. The magnetized beads are sedimented and washed repeatedly. The isoluminol conjugate is oxidized when sodium hydroxide solution and peroxide solutions ("triggers") are added to the cuvette, and the flash of light produced from this reaction is measured as relative

TABLE 2 Frequency of autoantibodies detected by the INOVA Quanta Plex assay in cohorts of patients with systemic rheumatic diseases and multiple sclerosis and in controls[a]

Cohort antigen	Frequency (%) of autoantibodies detected in indicated patients						
	SLE (n = 200)	SSc (n = 100)	SjS (n = 100)	RA (n = 200)	IBD (n = 50)	MS (n = 100)	Normal (n = 50)
Chromatin	60	20	20	8	2	4	0
dsDNA[b]	48	0	0	2	0	0	0
U1 RNP	24	10	0	4	0	8	0
Sm	18	4*	0	0	0	1	0
Scl-70	6	24	0	0	0	4	0
SS-A/Ro60	34	24	35	0	0	5	0
SS-B/La	8	5	20	2	0	10	0
Jo-1	0	3	15	0	0	4	0
Rib-P	16	2	0	0.5	0	5	0

[a]Abbreviations: IBD, inflammatory bowel disease; MS, multiple sclerosis; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SjS, primary Sjögren's syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis.
[b]Low positivity.

light units by the optical system. The relative light units are proportional to the amount of isoluminol conjugate that is bound to the human IgG, which is in turn proportional to the amount of autoantibodies bound to the antigen on the beads. The Bio-Flash CIA system also allows the user the option to reflex the individual assays of an autoantibody screening test, such as the QUANTA Flash using extractable nuclear antigen 7. In comparative studies with ELISA, the Bio-Flash CIA system performed very well (>93% agreement) (71, 72). Other advantages of the CIA system are the remarkable linearity of results throughout the dynamic range of the assay (72).

Advantages of Bead-Based Immunoassays

There are a number of advantages to bead-based immunoassays. First, test reports can be automatically generated through standard laboratory information systems and converted to standard encoded formats that can be directly uploaded into the patient's electronic medical record. Second, test results are generated very rapidly. In our laboratory, the turnaround time from receipt of the serum sample to generation of the laboratory report using the conventional technologies was 4 to 5 days. By comparison, the turnaround time using ALBIA and CIA is 1 to 2 days. This marked improvement is predicated on a laboratory algorithm that tests samples daily, as opposed to batch runs of ~90 sera. Last, although we have not performed detailed cost analyses, there is little additional cost because the sample throughput has been effectively doubled and this throughput was managed with the same staff complement as with the conventional protocols. In fact, the staff now has more time for quality assurance and research projects that were formerly delegated to other staff. The tradeoff for these apparent cost savings is more-expensive maintenance contracts, upgrades to software, and a budget allocation for replacement of lasers. However, it should be noted that one of us (M.J.F.) has been using Luminex technology for more than a decade, and laser replacement has not been required.

TABLE 3 Advantages, challenges, and opportunities relating to new array technologies

Advantage(s)[a]	Challenges and opportunities
Multiple autoantibodies are detected in a single assay	New clinical correlations and paradigms based on autoantibody and epitope profiling
Personnel costs	Costs of maintenance contracts and budgeting for laser replacement
Rapid test performance and automated test reporting	Medical centers not equipped or configured to accept digital reports can jeopardize rapid turnaround times
Small sample volumes	Adoption of new technologies that do not require conventional venipuncture
High correlation with other immunoassays, particularly ELISA	Low correlation with immunodiffusion
Ease of establishing new assays	Research and development required to provide broader spectrum of autoantigens (nucleolar, paraneoplastic, phospholipids)
Equipment and technology can be used for a variety of relevant assays: cytokine, SNP, HLA, gene activation, cell activation, drug discovery	Emergence of other microarray and nanotechnology platforms will complicate standardization

[a]SNP, single nucleotide polymorphism.

Challenges of Multiplexed Immunoassays

A major challenge and opportunity in the adoption of multiplexed autoantibody analyses is the breadth of autoantibody profiles provided in the laboratory reports (53). This increased amount of information presents a significant challenge to clinicians who are accustomed to dealing with one or two autoantibody results for any given patient. It is likely that with autoantibody profiling, a new wave of clinical studies and clinical correlations based on more-complete autoantibody profiles will emerge. The clinical picture may be enhanced by extending the breadth of this technology to epitope mapping and epitope spreading as an approach to monitoring disease progression or remission. Last, history has taught us that standardization of the new multiplexed platforms will be a significant challenge. The utilization of international reference sera for standardization of secondary antibodies to establish controls and cutoff values will be very important.

Immunodiagnosis and Laboratory Assessment of Systemic Lupus Erythematosus

WESTLEY REEVES, SHUHONG HAN, JOHN MASSINI, AND YI LI

89

This chapter deals with immunological tests that are useful in the diagnosis and monitoring of systemic lupus erythematosus (SLE). We review the detection and quantification of antibodies against self-antigens (autoantibodies), measurement of complement levels, and the interferon gene expression signature.

SLE is a multisystem autoimmune disorder characterized by a combination of clinical and immunological features. It is the prototype of human immune complex disease, and the production of autoantibodies that form immune complexes with self-antigens leads to complement fixation and inflammation. Clinical manifestations include characteristic skin rashes, serositis (pleuritis, pericarditis), arthritis, central nervous system involvement, hematological abnormalities, and immune complex-mediated glomerulonephritis. Immunological features include the production of antinuclear or antiphospholipid antibodies, and low levels of certain complement proteins. The detection and clinical use of assays for antinuclear antibodies and antiphospholipid autoantibodies are reviewed elsewhere in this volume and will not be discussed further here. Likewise, general methodology ELISA, multiplex bead assays, and arrays for autoantibody detection are discussed elsewhere.

Antinuclear antibodies (ANA) are associated with systemic autoimmune disease, but also can be seen at low titers in healthy individuals (1). Thus, there has been considerable interest in identifying ANA subsets with higher diagnostic specificity for particular diseases. Autoantibodies specific for SLE, systemic sclerosis (SSc), polymyositis or dermatomyositis (PM/DM), and other systemic autoimmune disorders have been identified and are of considerable importance as diagnostic markers. Some of the more useful autoantibody markers for various diseases are summarized in Tables 1 and 2.

Several autoantibodies are produced uniquely in SLE. Anti-double-stranded DNA (dsDNA) antibodies are found in ~70% of SLE patients' sera at some point during their disease, and are 95% specific. Their levels may vary reciprocally with complement levels, serving as a marker of disease activity. Anti-Sm antibodies are produced by 7 to 25% of lupus patients depending on ethnic origin and, like anti-dsDNA, are virtually pathognomonic of SLE (1, 2). Unlike anti-DNA antibodies, levels of anti-Sm antibodies generally do not correlate with disease activity. Anti-nRNP antibodies, which recognize proteins associated with the Sm antigen, are associated with lupus and mixed connective tissue disease (MCTD) but are not disease specific (1). The frequency of anti-nRNP in SLE is 20 to 40%. All but a few sera containing anti-Sm also contain anti-nRNP autoantibodies. However, anti-nRNP antibodies frequently occur without anti-Sm.

Anti-ribosomal antibodies, which recognize the P0, P1, and P2 antigens are found in 5 to 15% of SLE patients and are associated with neuropsychiatric lupus (3). Anti-proliferating cell nuclear antigen (PCNA) (2 to 5% of patients) and anti-RNA helicase-A autoantibodies (5% of patients) are specific for SLE as well (4, 5). Other lupus-associated (but not disease-specific) autoantibodies include anti-Ro (SS-A) and La (SS-B) autoantibodies, which are associated with Sjogren's syndrome and other autoimmune diseases (SLE, rheumatoid arthritis [RA], PM/DM, and primary biliary cirrhosis), especially when they are accompanied by sicca symptoms. Anti-Ro (SS-A) antibodies are found in 10 to 50% of SLE and in 60 to 80% of primary Sjogren's syndrome sera (1, 6).

A nucleolar pattern on fluorescent antinuclear antibody testing is common in scleroderma (SSc). Nucleolar antigens recognized by SSc-specific autoantibodies include fibrillarin, the To/Th ribonucleoprotein, and RNA polymerases I and III (10 to 20% of patients, Tables 1 and 2) (7). The nucleoplasmic and nucleolar enzyme topoisomerase I (Scl-70) also is an important marker found in ~15% of patients. These autoantibodies are discussed elsewhere in this volume.

Autoantibodies to a set of cytoplasmic antigens, many of which are tRNA synthetases, are diagnostic markers for PM/DM (Tables 1 and 2). The detection and clinical significance of these autoantibodies, which are rare in the absence of myositis, are discussed elsewhere.

DETECTION AND QUANTIFICATION OF AUTOANTIBODIES

Anti-Sm and Anti-RNP Antibodies

In the clinic, anti-Sm and RNP autoantibodies are reliably detected by commercially available ELISA or multiplex bead assays (see chapter 88 of this volume). In a research setting, they can be detected by the radioimmunoprecipitation or luciferase immunoprecipitation methods. Anti-Sm and anti-nRNP antibodies recognize different subsets of the protein components of the U1 small nuclear ribonucleoprotein

doi:10.1128/9781555818722.ch89

TABLE 1 Some non-DNA/chromatin autoantibodies useful in the diagnosis of systemic autoimmune disease

Disease(s)	Autoantibody	Protein component(s)	RNA component(s)
SLE	Sm	B′/B (29/28 kDa), D1/2/3 (16 kDa), E/F/G (12, 11, 10 kDa)	U1, U2, U4–U6, U5
	Ribosomal P	P0, P1, P2 (38, 19, 17 kDa)	Ribosomal RNA
	PCNA	36 kDa	None
MCTD and others	RNP	70K (70 kDa), A (33 kDa), C (23 kDa)	U1
Sicca syndrome	Ro (SS-A)	Ro60 (60 kDa), Ro52 (52 kDa)	HY1, hY3, hY4, hY5
	La (SS-B)	48 kDa	8-2, 7-2, 7SL, 5S, hY1, hY3, hY4, hY5, tRNAs
SLE, MCTD, PM, SSC	Ku	Ku80 (80 kDa); Ku70 (70 kDa)	None
SLE, SSC	RNA pol II	240 (IIO), 220 (IIA), 140 (IIB) kDa	None
PM/DM	Various tRNA synthetases	His (50 kDa), Thr (80 kDa), Ala (110 kDa), Ile (150 kDa), Gly (75 kDa), Leu (130 kDa), Asp (65 kDa)	Corresponding tRNAs
	SRP	72, 68, 54, 19, 14, 9 kDa	7SL
SSc	Topo I	100 kDa	None
	Fibrillarin	34 kDa	U3
	RNA pol I/III	RNAP I: 190 (IA), 126 (IB) kDa; RNAP III: 155 (IIIA), 138 (IIIB) kDa	None
	To/Th	40 kDa (not readily visualized)	7-2, 8-2

(snRNP), an RNA-protein complex consisting of the proteins U1-70K (70 kDa), A (33 kDa), B′/B (29 and 28 kDa, respectively), C (23 kDa), D1/2/3 (16 kDa), E (12 kDa), F (11 kDa), and G (10 kDa). The proteins are associated with a single U1 small nuclear RNA molecule (1, 8). Proteins B′/B, D, E, F, and G assemble into a stable "Sm core particle" reactive with anti-Sm, but not anti-nRNP, antibodies. The Sm core particle is a component of additional snRNPs, each with a unique uridine-rich (U) RNA species as well as unique proteins. These include the U2, U4/U6, and U5 snRNPs, as well as other less abundant U snRNPs. Anti-Sm, but not anti-nRNP, antibodies immunoprecipitate unique 200 to 205 kDa proteins of the U5 snRNP, which are associated with the Sm core particle (Fig. 1).

Clinical Significance

Anti-Sm antibodies are highly specific for the diagnosis of SLE, and their production can predate the onset of clinical SLE (1, 9). They are one of the American College of Rheumatology criteria for the classification of SLE (10). In contrast, anti-nRNP antibodies are not disease-specific and are of limited utility in diagnosing SLE or predicting its course. However, anti-Sm as well as anti-RNP antibodies are strongly associated with the interferon signature (see below), suggesting that they may have a common pathogenesis.

Anti-Ro (SS-A) and Anti-La (SS-B) Antibodies

Sera containing anti-Ro (SS-A) autoantibodies may recognize two proteins: a 60-kDa protein (Ro60) that binds to the stem of four small RNAs designated hY1, hY3, hY4, and hY5 and a 52-kDa protein (Ro52) reactive with many, but not all, anti-Ro (SS-A) sera (1). It is controversial whether or not Ro52 interacts with Ro60 or the Y RNAs. Anti-Ro60 autoantibodies are readily detected by protein immunoprecipitation (Fig. 1). Anti-Ro52 autoantibodies are not efficiently immunoprecipitated and are most reliably detected by ELISA or other solid-phase assays. Commercial assays are widely available for anti-Ro60 and anti-La but are less readily available for anti-Ro52.

La (SS-B) antigen is a 47-kDa protein associated transiently with the precursors of several small RNAs synthesized by RNA polymerase III (1). It can be detected readily by protein immunoprecipitation (Fig. 1), but the band often is distorted because it migrates near the immunoglobulin heavy chain ("heavy chain artifact"). Anti-La (SS-B) autoantibodies are virtually always associated with anti-Ro (SS-A), whereas anti-Ro antibodies frequently are detected in the absence of anti-La (6).

Clinical Significance

Anti-Ro and anti-La antibodies are highly associated with sicca symptoms (xerostomia, keratoconjunctivitis sicca). Anti-La (SS-B) autoantibodies are produced by 10 to 20% of SLE patients, and at a somewhat higher frequency in Sjogren's syndrome. Additionally, anti-Ro/La antibodies are strongly associated with subacute cutaneous lupus.

In neonates, cardiac conduction abnormalities, including complete heart block, are caused by maternal antibody against the Ro (especially Ro52) and La antigens (11). Screening for these autoantibodies is important in pregnant women with systemic autoimmune disease. Since they may be present in asymptomatic individuals, screening also is carried out in mothers of children with congenital cardiac conduction abnormalities.

TABLE 2 Prevalence of some non-DNA/chromatin autoantibodies by disease

Autoantibody to:	Prevalence in disease subset (%)			
	SLE (n = 288)	Sjogren's (n = 50)	PM/DM (n = 30)	Scleroderma (n = 42)
Sm	10	0	0	0
RNP	39	6	0	12
Ribosomal P	2	0	0	0
PCNA	0.3	0	0	0
Ro60 (SS-A)	33	58	13	12
Ro52[a]	28	36	49	15
La (SS-B)	11	28	7	0
Jo-1[b]	1	ND[c]	22	0
Alanyl tRNA synthetase[b]	0	ND	6	ND
Ku	2	0	0	2
RNA polymerase I/III	0	0	0	21
RNA polymerase II	5	2	0	7
Scl-70 (Topo I)	0.3	0	0	7

[a]Recombinant antigen ELISA (SLE, n = 265; Sjogren's, n = 50; PM/DM, n = 35; scleroderma, n = 40).
[b]Recombinant antigen ELISA (SLE, n = 74; PM/DM, n = 51; scleroderma, n = 36).
[c]ND, not done.

Anti-Ribosomal P

Anti-ribosomal P antibodies recognize three proteins of ~38, 19, and 17 kDa (P0, P1, and P2) that are components of the large (60S) ribosomal subunit (Fig. 1). They recognize mainly a conserved epitope on the C-terminal 22 amino acids of P0, P1, and P2. Antibodies to the ribosomal P0, P1, and P2 antigens are highly specific for the diagnosis of SLE and have been linked with neuropsychiatric lupus, especially psychosis (3, 12). Immunoprecipitation is probably the gold standard test for this specificity, but commercial ELISA and immunoblotting assays also are reliable.

Anti-Proliferating Cell Nuclear Antigen (PCNA) and Anti-RNA Helicase A Autoantibodies

PCNA is a 36-kDa protein recognized by autoantibodies found in about 2 to 5% of SLE sera (4). Although unusual, these antibodies are quite specific for SLE. Immunoprecipitation is probably the most reliable way to detect them (Fig. 1). Autoantibodies to RNA helicase A are produced mainly by non-black SLE patients (3 to 7.5% of patients) (5). They are highly specific for SLE and are more common early in disease. The antigen is a 140-kDa member of the DExD/H box family that can be detected by immunoprecipitation (Fig. 1). Commercial assays are not widely available for either anti-PCNA or anti-RNA helicase A.

Method: Radioimmunoprecipitation

The protein and nucleic acid constituents of many lupus autoantigens were identified and characterized by radioimmunoprecipitation, and this technique remains useful for the analysis of autoantibodies in a research laboratory setting. Radiolabeled antigens are allowed to form immune complexes with autoantibodies and are purified onto protein A-Sepharose beads. After dissociating the immune complexes from the beads, the radiolabeled proteins are separated by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis and detected by autoradiography (Fig. 1). A similar approach can be used to analyze the RNA components of small ribonucleoprotein particles (8). Required apparatus includes an electrophoresis power supply, vertical electrophoresis apparatus, tabletop centrifuge, CO_2 incubator, cell sonicator, and microcentrifuge.

Materials and Reagents

Phenylmethylsufonyl fluoride (PMSF, Sigma no. P7626), 50 mM in absolute ethanol stored at −20°C (= 100× stock)

Aprotinin (Sigma no. A6279), 24 TIU in H_2O (= 100× stock)

Protein A-Sepharose CL4B (PAS, Pharmacia no. 17-0780-01). Prepare the PAS as follows:

1. Add H_2O to 1.5 g of dry PAS in a 15-ml centrifuge tube and incubate with inversion for 20 to 30 min at room temperature to swell the beads.
2. Centrifuge for 1 min (1,500 rpm).
3. Wash three times with H_2O and centrifuge to pellet the beads.
4. To the packed beads, add an equal volume of H_2O. Add 2 M Tris-HCl (pH 8.0) to a final concentration of 20 mM (1:100). Add NaN_3 to a final concentration of 0.1%. The beads can be stored at 4°C in this buffer.

0.5 M NaCl NET/Nonidet P-40 (NP-40) buffer: 50 mM Tris-HCl (pH 7.5), 0.5 M NaCl, 2 mM EDTA, 0.3% NP-40

NET buffer: 50 mM Tris-HCl (pH 7.5), 0.15 M NaCl, 2 mM EDTA

3× sample buffer: mix 0.5 M Tris-HCl, pH 6.8 (6.0 ml), 1% bromophenol blue (0.6 ml), 2-mercaptoethanol (3.0 ml), 25% SDS (4.8 ml), glycerol (6.0 ml); store at −20°C until used.

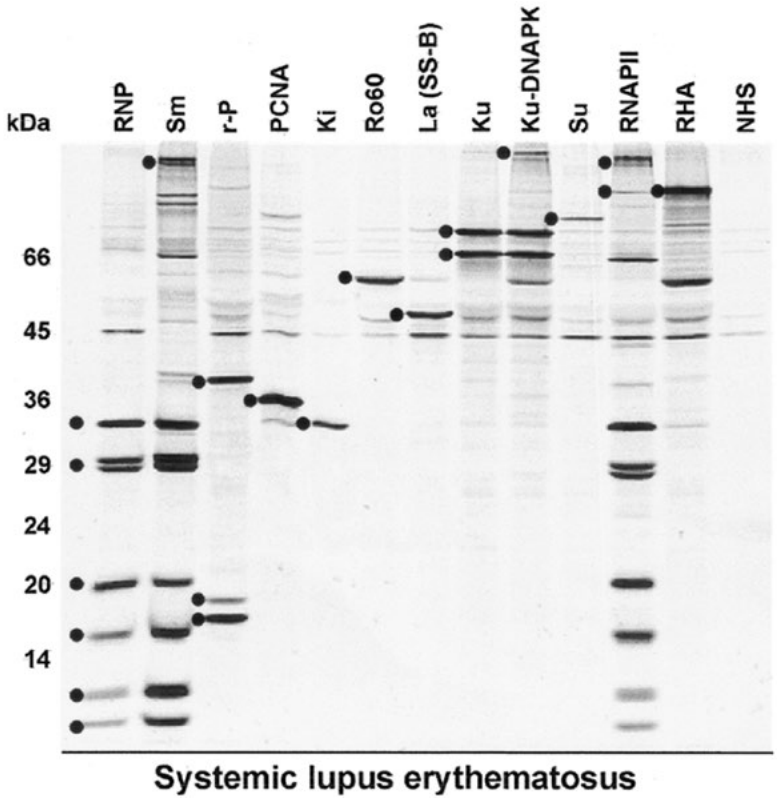

FIGURE 1 Protein immunoprecipitation for analyzing lupus autoantibodies. Sera were tested according to the protocol in the text, and immunoprecipitated proteins were resolved on a 12.5% gel. Sera containing the following autoantibodies were tested: anti-nRNP (RNP), anti-Sm, anti-ribosomal P (r-P), anti-proliferating cell nuclear antigen (PCNA), anti-Ki, anti-Ro60, anti-La (SS-B), anti-Ku, anti-Ku plus anti-DNA-PKcs, anti-Su, anti-RNA polymerase II (RNAPII), anti-RNA helicase A (RHA), and normal human serum (NHS). Positions of molecular weight standards are shown on the left (in kilodaltons). Protein components of the antigens are indicated (dots).

Sterile Dulbecco's phosphate-buffered saline (D-PBS)

D-PBS dialyzed fetal bovine serum: 50 ml fetal bovine serum is dialyzed for 3 days at 4°C against D-PBS (500 ml). Change the D-PBS twice daily.

[^{35}S]-Methionine/cysteine (DuPont/New England Nuclear NEG 072). Upon receipt, the isotope should be snap-frozen in small aliquots sufficient for one labeling reaction and stored at −80°C.

Methionine- and cysteine-free RPM1-1640 (Cellgro, Fisher no. 17-104-CI)

Penicillin (10,000 IU/ml)-streptomycin (10,000 μg/ml) (= 100× Pen-Strep, Gibco BRL no. 15140-031)

L-Glutamine, 200 mM (= 100×, Gibco BRL no. 25030-081)

[^{35}S]-Labeling medium is prepared as follows: 39 ml methionine- and cysteine-free medium, 4.5 ml D-PBS-dialyzed fetal bovine serum, 0.45 ml L-glutamine, 45 μl penicillin-streptomycin, 1.35 ml regular RPMI (for 10^8 cells).

Assay

Radiolabeled cell extract is prepared from log-phase K562 cells (ATCC no. CCL-243) grown at a density of 0.5 to 1.5 × 10^6/ml in RPMI 1640 plus L-glutamine (1:100), penicillin-streptomycin (1:100), and 10% fetal bovine serum in 750-ml tissue culture flasks at 37°C in a 5% CO_2 atmosphere. Rapidly growing cells are labeled more efficiently than slowly growing ones. *Note: K562 cells grow in small nonadherent or weakly adherent clusters when healthy.*

The night before use, collect the cells by centrifugation (1,000 rpm for 5 min), resuspend in 20 ml sterile D-PBS, and count. Cells should be adjusted to 10^8 cells per 45 ml of ^{35}S-labeling medium (recipe above) in a 250-ml flask. Add 2 mCi freshly thawed [^{35}S]methionine-cysteine and incubate the cells for 12 to 16 h at 37°C in a 5% CO_2 atmosphere. The following day, the cells are collected by centrifugation (1,000 rpm, 5 min). *Note: the level of RNA polymerase II antigen decreases after 16 h, so it is important not to label for too long.* After labeling, there should be ~1.8 × 10^8 cells. Collect by centrifugation. Make aliquots of 2 × 10^7 cells in 15-ml polypropylene centrifuge tubes. Centrifuge 5 min at 1,500 rpm and aspirate the supernatant. Freeze tubes with their cell pellets at −70°C. *Note: be sure to use polypropylene centrifuge tubes (e.g., Corning no. 430052) so they will not crack when frozen.*

Immunoprecipitation is carried out using serum that has been centrifuged (10,000 rpm for 5 min) to remove insoluble materials. Frozen serum samples (−20°C) should be recentrifuged before analysis. The procedure is as follows: in a 1.5-ml microfuge tube combine the following: 40 μl 50% PAS slurry in Tris-HCl (pH 8.0), 8 μl human serum, 500 μl 0.5 M NaCl NET/NP-40. The tube is rotated end-over-end at 4°C for 1 to 12 h or at room temperature for 1 to 3 h. *Avoid vortexing the beads at any stage of the procedure.* During incubation, prepare cell extract from radiolabeled K562 cells (see above, 2 × 10^6 radiolabeled cells per sample). Add 2 ml of 0.5 M NaCl NET/NP-40 + 1:100 (20 μl)

PMSF + 1:100 (20 μl) aprotinin to the pellet (final cell concentration, 10^7/ml). *Do not put PMSF directly on the cell pellet because the ethanol will denature the proteins.* Sonicate the cells for 1 min (duty cycle 30%, output 3). Place on ice for 1 min and then sonicate again for 1 min. *Avoid excessive heating of the cell suspension during sonication.* Transfer cell lysate to microfuge tubes and centrifuge at 10,000 rpm for 30 min. (4°C). Carefully collect the lysate and combine into one tube before dispensing. Extract from 2×10^7 cells is sufficient for 12 immunoprecipitations.

Pellet the serum-coated PAS beads by microfuging for 3 s. Aspirate the supernatant using a drawn-out Pasteur pipette attached to vacuum. Add 1 ml 0.5 M NaCl NET/NP-40 and microfuge for 3 s. Aspirate the supernatant. *Carefully remove any air bubbles on the surface of the samples first, since they may cause high background.* To each PAS pellet, add 150 to 160 μl of cell extract. Rotate end-over-end for 1 h at 4°C. Microfuge for 3 s and aspirate the supernatant. Wash beads three times with 1 ml 0.5 M NaCl NET/NP-40 and once more with NET. Carefully aspirate the supernatant. Add 50 μl 1× sample buffer to each pellet. Samples may be kept at −80°C for at least 1 month (half-life of ^{35}S is ~60 days). To analyze, boil the samples for 3 min, pellet the beads, and load 15 to 20 μl supernatant per lane of a 12.5% SDS-polyacrylamide gel. For large proteins (>100 kDa), resolution may be enhanced using a 10% or 8% gel. It usually takes 3 to 5 h for the tracking dye to reach the bottom of the gel at a constant voltage of 100 to 130 V. *Note: If performing immunoprecipitations with antibodies that do not bind protein A (e.g., human IgG3 or mouse IgG1), use protein G-Sepharose.*

Immunoprecipitated proteins are analyzed by SDS-polyacrylamide gel electrophoresis and fluorography. Reagents are as follows: 25% SDS (Fisher or BioRad) *[Note: filter this and all other stock solutions through a 0.45-μm bottle top filter]:*

Coomassie blue stain: Coomassie Brilliant Blue, R-250 (BioRad no. 161-0400) (5 g), methanol (1,200 ml), glacial acetic acid (400 ml); add distilled water to 4,000 ml

Destaining solution: 2 liters of glacial acetic acid, 7 liters of methanol, 11 liters of distilled water

2, 5 Diphenyloxazole (PPO) (Fisher no. D144-100), 20% (wt/vol) in dimethylsulfoxide (DMSO). *Note: PPO is carcinogenic.*

Glycerol

BioMax MR film (Eastman Kodak, catalog no. 870-1302)

5× Tris-glycine (for running buffer): 120 g Tris base plus 576 g glycine; add distilled water to 4 liters (no need to adjust pH, can be stored at room temperature).

Polyacrylamide minigels can be prepared "from scratch," or precast gels can be purchased from BioRad or other vendors. Run the gel as follows:

1. Make 1 liter of running buffer: 200 ml 5× Tris-glycine + distilled water to 1,000 ml; add 4 ml of 25% SDS and mix well.
2. Boil samples including molecular weight standards for 3 min in a water bath immediately before loading gel.
3. Carefully remove the comb and bottom spacer from the SDS-polyacrylamide gel.
4. Clamp gel to the gel apparatus and add running buffer to the top and bottom chambers to cover the top and bottom of the gel.
5. Remove air bubbles from the bottom of the gel using a syringe with a bent (90°) 18-gauge needle.
6. Gently wash out wells with running buffer using a Hamilton syringe.
7. Add 20 μl (or desired volume) of boiled sample per well.
8. Attach leads to the electrodes of the gel apparatus (proteins treated with SDS are negatively charged and will migrate toward the cathode).
9. Attach to power supply and run at 100 V until the blue tracking dye reaches the resolving gel. At this time, the voltage may be increased to 120 V.
10. Run the gel until the blue tracking dye reaches the bottom of the gel (do not run the dye off the gel).
11. Turn off the power, remove the electrodes, and unclamp the gel from the gel apparatus. Carefully pry the plates apart, leaving the gel adherent to one of the plates. Using a pizza cutter, cut off the stacking gel and diagonally cut off a small piece of the gel from the upper right hand corner to aid in orienting the gel.
12. Stain the gel for 20 min with Coomassie Blue solution. Destain and fix the gel with several changes of destaining solution.

After staining and fixation, the gel is fluorographed as follows:

1. Place the gel in a polyethylene or polypropylene (not polystyrene) container and remove as much of the destaining solution as possible. Immerse the gel in 100 to 200 ml of DMSO, cover the container, and rotate gently on a shaker for 30 min. Discard DMSO.
2. Transfer to 100 to 200 ml fresh DMSO, cover, and rotate for 30 min. After use, this DMSO solution is removed and can be saved for use as the first DMSO wash for another gel.
3. Add 100 to 200 ml of 20% PPO in DMSO (wt/vol), cover, and rotate gently for 60 min. Save the DMSO-PPO mixture. It can be reused for several gels, although the effectiveness gradually diminishes. *Note: PPO is a carcinogen and DMSO can penetrate standard laboratory gloves. Wear heavy rubber gloves (e.g., Playtex) and handle DMSO-PPO solution carefully.*
4. Wash the gel with several changes of water to rehydrate (at least 30 min). The PPO will precipitate in the gel. Add glycerol to the final wash to a concentration of ~3%. Remove the gel, which will have turned white and opaque, place on 3MM paper (Whatman), and dry using a vacuum gel dryer. Wash out the tray with ethanol to remove traces of PPO (which is insoluble in water). We use a BioRad gel dryer (model no. 583) at 60°C with the timer set to 3 h. After 1.5 h, the gel is removed. Vent the gel dryer and remove the gel and attached 3MM paper.
5. Tape dried gels to a used piece of X-ray film. If it is sticky, dust the gel lightly with talc to prevent sticking. Place this in a cassette and (in the darkroom) place in direct contact with BioMax MR film. *The film is coated on one side and the coated side must contact the gel.* Expose the gel to film for 3+ days at −70°C before developing.

QA/QC and Test Validation

Include a sample of normal human serum as a negative control and, if possible, a positive-control serum (reference serum). Expression of individual antigens may vary depending on the cell line used. Multiple weak bands using normal human serum may indicate problems with washing. Molecular weight standards (Sigma, catalog no. SDS-7 [low molecular

weight] or SDS-6H [high molecular weight]) also are run on the gel and stained with Coomassie blue. Migration of molecular weight standards and immunoglobulin heavy and light chains (~50 and 25 kDa, respectively) can be used to assess the quality of separation.

Radioimmunoprecipitation is a highly sensitive and specific technique for detecting a variety of autoantibodies. However, clinical application of this approach is limited because it is labor intensive, technically demanding, and requires the use of radioisotopes. Nevertheless, the immunoprecipitation technique is extremely useful for validating other assays, such as ELISAs.

Method: LIPS Assay for Anti-RNP

The luciferase immunoprecipitation system (LIPS) assay is a sensitive, nonradioactive variation on the immunoprecipitation method (13). A fusion protein comprised of a *Renilla* luciferase reporter and the test antigen is produced in mammalian cell culture, ensuring the addition of mammalian posttranslational modifications. Test serum is mixed with fusion protein and passed over immobilized protein A/G-agarose beads. After washing, the only luciferase-tagged antigens retained are those bound by specific antibodies, which can be quantified using chemiluminescence upon the introduction of coelenterazine. Due to the liquid-phase nature of the LIPS assay and the highly linear light output of the luciferase reporter, some antibodies can be detected over a dynamic range of 7 orders of magnitude. The protocol below for anti-U1A (RNP) autoantibodies can be adapted to detect other specificities.

Generation of *Renilla* Luciferase U1A (Ruc-U1A) Fusion Construct

A pET-28a(+) plasmid containing the human U1A cDNA sequence was ligated into *Bam*HI-Hind III-cut mammalian *Renilla* luciferase expression vector pREN2 and transformed into One Shot Top10 *E. Coli* (Invitrogen, catalog no. C4040-10). The pREN2-U1A plasmid was purified from bacterial lysates using a Qiagen Max kit and the integrity of the DNA construct was verified by sequencing.

Preparation of Antigen

Materials are as follows:

Buffer A: 20 mM Tris (pH 7.5), 150 mM NaCl, 5 mM $MgCl_2$, 1% Triton X-100

Sterile PBS

DMEM + 10% fetal bovine serum

Renilla luciferase assay system (Promega, catalog no. E2810)

96-well Multi Screen HTS filter plate (EMD Millipore, catalog no. MAFB N0B)

Protein A/G agarose beads (Santa Cruz Biotech, catalog no. SC-2003)

LUMIstar Omega plate reader (BMG Labtech)

Berthold Lumat LB9507

Lipofectamine 2000 (Invitrogen, catalog no. 11668)

Multi Screen HTS vacuum manifold (EMD Millipore).

Ruc-U1A fusion protein extracts are prepared as follows: one day before transfection, plate 2 to 6×10^6 293T cells in 15 ml of DMEM/10% FBS without antibiotics in a 100 mm dish. Allow the cells to become 90 to 95% confluent before transfecting.

Prepare Ruc-U1A plasmid DNA and Lipofectamine 2000 complex as follows: dilute 24 μg of DNA in 1.5 ml of serum-free DMEM. Mix Lipofectamine gently and dilute 60 μl into 1.5 ml of serum-free DMEM. Incubate for 5 min at room temperature and combine with the diluted DNA. Mix gently and incubate for 20 min at room temperature. Complexes are stable for 6 h. Add the complex drop by drop to the cells and gently rock the dish back and forth. Incubate cells at 37°C in a CO_2 incubator for 48 h. Remove the supernatant, add 1 ml of 1× *Renilla* luciferase assay lysis buffer, and incubate for 15 min on a rotary shaker at room temperature. Collect cell lysate into a 15 ml tube and sonicate for 15 s three times. Transfer the cell lysate into a 1.5-ml microfuge tube and centrifuge at maximum speed for 15 min at 4°C. Collect the cleared cell lysate and measure *Renilla* Luminometer Units (RUC) with a Berthold Lumat LB9507: 0.1 μl cell lysate should give ~5×10^7 RUC. Aliquot the Ruc-U1A extract and store at −80°C.

Determine the Appropriate Amount of Extract for Assay

Select a reference serum with high-titer anti-U1A antibodies and a normal control serum. In each well of a 96-well microtiter plate, add 50 μl of diluted Ruc-U1A fusion extract (0.1 μl Ruc-U1A fusion extract + 49.9 μl PBS) and 50 μl of serially diluted serum (2-fold dilutions from 1:500 to 1:64,000 in PBS/0.5% bovine serum albumin [BSA]). Incubate duplicate samples at 4°C overnight on a rotary shaker. Prepare a 96-well filter plate and add 10 μl of protein A/G beads (50% vol/vol in PBS). Transfer extract-serum mixture to the filter plate. Incubate for 2 h at 4°C on a rotary shaker, then attach filter plate to the MultiScreen HTS vacuum manifold. Protein A/G beads are washed under suction eight times with buffer A. Dry bottom of the plate and add 20 μl PBS. *Renilla* luciferase substrate is added and luciferase activity is measured in the LUMIstar Omega plate reader. The amount of cell extract can be varied to optimize signal-to-noise ratio at low serum concentrations. Once the assay is optimized, unknowns, reference sera, and normal control sera can be tested as above.

Anti-DNA Antibodies

Genomic DNA is packaged in histone and non-histone chromatin proteins. The histones form nucleosomes, consisting of two molecules each of H2A/H2B, H3, and H4, around which the DNA is coiled (145 base pairs per nucleosome). Between the nucleosomes is "linker" DNA, which is packaged in histone H1. Many lupus patients produce autoantibodies against nucleosomes, which recognize DNA-histones, H2A-H2B dimer, individual histones, single-stranded (ss) DNA, and double-stranded (ds) DNA. Anti-dsDNA antibodies are highly specific for the diagnosis of SLE (1, 14), whereas anti-ssDNA and anti-chromatin autoantibodies are not. The latter may be seen in drug-induced lupus and other systemic autoimmune diseases in addition to SLE. Anti-dsDNA antibodies have been implicated in the pathogenesis of lupus nephritis, and in some patients, their levels correlate with disease activity. Thus, assays for anti-dsDNA antibodies are more important clinically than anti-ssDNA assays. Anti-dsDNA antibodies are not reliably detected by immunoprecipitation. The most commonly used anti-dsDNA assays are ELISA, *Crithidia luciliae* kinetoplast staining assay, and radioimmunoassay (Farr assay). In anti-dsDNA antibody ELISAs and the Farr assay, it is important to treat the DNA with S1 nuclease to ensure the removal of contaminating ssDNA. This is unnecessary in the *Crithidia* assay, since the dsDNA substrate (the kinetoplast) is a closed circular DNA molecule packaged in histones. *Crithidia luciliae* organisms are fixed onto

microscope slides and incubated sequentially with serially diluted (1:10 to 1:160) patient serum followed by fluorescein isothiocyanate-conjugated goat anti-human immunoglobulin antibodies. A titer is determined as is done for the fluorescent ANA assay.

About 70% of SLE patients develop anti-dsDNA antibodies at some time in their disease. Although the clinical utility is somewhat controversial, anti-dsDNA antibody levels and complement component C3 and C4 levels vary reciprocally in some patients, with high anti-dsDNA and low C3 and C4 during flare-ups of disease activity (15). The affinity of anti-dsDNA antibodies may be important, and it has been suggested that the Farr assay (which measures only high-affinity antibodies) may be the assay most predictive of disease activity (15). Anti-dsDNA antibody levels may increase 10 or more weeks before a flare, and some would institute corticosteroid therapy at that time, although this remains controversial (16). The ELISA detects low-, intermediate-, and high-affinity anti-dsDNA antibodies, whereas the *Crithidia* assay detects moderate- and high-affinity anti-DNA antibodies. The Farr and *Crithidia* assays are relatively labor intensive and the Farr assay uses a radioisotope (^3H) to label the target DNA, although kits are available commercially. Most commercial laboratories employ either the ELISA or the *Crithidia* assay. We have developed an ELISA suitable for use in a research setting that correlates well with the *Crithidia* assay.

Method: Anti-dsDNA ELISA

The presence of anti-dsDNA antibodies using the following ELISA protocol generally correlates well with positivity by the *Crithidia* assay. We use this assay in a research setting. The following materials and reagents are used:

Reacti-Bind DNA coating solution (Pierce, catalog no. 17250)

S1 nuclease 100 U/μl (Promega, store at −20°C)

Calf thymus DNA (Sigma-Aldrich, catalog no. D-4522)

Alkaline phosphatase-conjugated goat anti-human IgG (Southern Biotechnology, catalog no. 2040-04)

TBS/Tween-20: 150 mM NaCl, 20 mM Tris (pH 7.5), 0.1% Tween-20 NET- NP-40: 150 mM NaCl, 2 mM EDTA, 50 mM Tris-HCl (pH 7.5), 0.3% Nonidet P-40

Diethanolamine buffer, pH 9.6: dissolve 97 ml diethanolamine, 0.1 g $MgCl_2 \cdot 6H_20$, and 0.2 g NaN_3 into ~900 ml dH_2O, and adjust pH to 9.6 with HCl. Adjust volume to 1 liter and filter. For ELISA substrate, dissolve one 5-mg phosphatase substrate (Sigma-Aldrich, catalog no. S-0942) in 5 ml diethanolamine buffer

96-Well flat-bottom Reacti-Bind plates (Pierce) or NUNC Immobilizer amino F96 plates.

Preparation of dsDNA

Carefully dissolve the DNA in sterile PBS. Mix by gentle pipetting (final concentration 0.5 mg/mL). Dialyze against 0.03 M sodium acetate, 0.1 M NaCl, 1 mM ZnCl, pH 4.4 at 4°C. Change buffer twice daily for 3 days then transfer the DNA into a 50-ml conical tube. Centrifuge at 3,000 rpm for 10 min to remove aggregates. Transfer supernatant into a clean tube and measure the optical density (A_{260}) of a small aliquot (1:200 in water). Add S1 nuclease to a final concentration of 0.1 U/μg of DNA and incubate for 3 h at 37°C in a water bath. After digestion, dialyze the DNA solution against PBS (3 days, change buffer twice daily). Centrifuge as before and determine A_{260} for calculating the final DNA concentration.

Assay

1. Coating of plates: adjust DNA to 6 μg/ml in distilled water, then dilute 1:2 with Reacti-Bind DNA coating solution in a glass tube (DNA/Reacti-Bind will stick to anything plastic). Final DNA concentration is 3 μg/ml. Mix gently on a shaker for 10 min. Dispense 100 μl/well of a 96-well microtiter plate. Incubate overnight at 4°C in the dark.
2. Wash the wells three times with TBS-Tween-20 and block for 3 h (150 μl/well NET/ NP-40, 0.5% BSA, 0.05% NaN_3).
3. Add diluted serum (100 μl/well, 2 h at room temperature protected from light). We use 1:500 patient serum in blocking buffer. To generate a standard curve, use high-titer anti-dsDNA serum at serial 5-fold dilutions (1:100 to 1:1,562,500 in blocking buffer). Wash three times with TBS-Tween-20.
4. Add second antibody (alkaline phosphatase-conjugated goat anti-human IgG, 1:1,000 in blocking buffer, 100 μl/well, 1 h at room temperature). Wash as before.
5. Add alkaline phosphatase substrate (100 μl/well) and measure OD_{405} nm 30 to 60 min afterward using an automated ELISA reader (e.g., VERSAmax, Molecular Devices). A standard curve is generated using serially diluted anti-dsDNA reference serum, and anti-DNA antibody levels (units) are calculated using a four-parameter logistic equation as part of the Softmax Pro 3.0 ELISA plate reader software. We use a group of 10 normal control serum samples to determine the cutoff for positive (mean + 2 SD).

EVALUATION OF COMPLEMENT IN SLE

The complement system links innate immunity to adaptive immunity. Complement can lyse cells via the pore-forming membrane attack complex (MAC), enhance phagocytosis through opsonization, and facilitate clearance of immune complexes and apoptotic cells by complement receptors on red blood cells and in the spleen (17, 18). Certain complement split products, such as C3a and C5a, act as chemoattractants for neutrophils and other phagocytes. There are three main pathways of complement activation: the classical, alternative, and lectin pathways. Most relevant to SLE is the classical pathway, in which C1q binds the Fc portion of membrane-bound IgM or IgG, leading to binding of C1r and C1s. Activated C1 cleaves C4 into C4a and C4b and cleaves C2 into C2a and C2b, forming C4b2a, the C3 convertase of the classical pathway. Cleavage of C5 initiates formation of the MAC (C5b-C9) and promotes inflammation (C5a). The role of late complement components and the MAC to lupus pathogenesis is unclear.

Importance of the Early Classical Complement Pathway in SLE

The early classical complement pathway plays a key role in immune complex clearance, and hereditary defects in C1, C2, C3, and C4 are associated with a substantially increased risk of SLE (18). Patients with homozygous C1q deficiency have approximately a 90% likelihood of developing lupus; those with C1r, C1s, or C4 deficiency have a ~75% risk; and those with homozygous C2 deficiency have a 10 to 30% risk. Interestingly, the female predominance in SLE is not seen in lupus-like disease associated with complement deficiency (18). Hereditary complement deficiencies are complex and have been reviewed recently (19). C4 deficiency is the most common hereditary complement deficiency in SLE. C4 is

encoded by two different but highly homologous genes: C4A and C4B, each of which exhibits copy number variation. Their products are indistinguishable using standard C4 assays. Complete C4A deficiency requires the absence of all copies of C4A/B and is very rare. Partial C4 deficiency (most commonly, C4A) is seen in ~10% of white SLE patients versus ~2% of controls (18).

Elevated levels of immune complexes in SLE also result in consumption of the early classical complement components with deposition of C4b and C3b in tissues, release of C3a/C5a, and MAC formation (18). Measurement of the early classical complement components can provide a measure of immune complex generation and disease activity. The total hemolytic complement (CH_{50}), a functional measure of the entire classical pathway, should be determined at least once in most SLE patients, as a defect in any of the individual components will be reflected in a low CH_{50}.

Assays of Complement Function

(More detailed descriptions of the complement assays [CH50 and assays for individual complement components] can be found in chapter 13 of this volume). The CH_{50} is used to assess integrity of the classical complement cascade (C1 to C9). Sheep erythrocytes are coated with rabbit anti-sheep erythrocyte antibodies (EA). Patient serum is added, leading to binding and activation of the C1 complex. This activates C3, leading ultimately to assembly of the membrane attack complex and erythrocyte lysis. The reciprocal of the serum dilution necessary to lyse 50% of the EA in the assay is defined as the CH_{50} (expressed as CH_{50} U per ml of serum). Reagents for performing this test are available commercially. The classical and lectin pathways are calcium ion dependent, whereas the alternative pathway is not. If the lysis of unsensitized rabbit erythrocytes is measured in the presence of ethylene glycol tetraacetic acid (EGTA) to chelate the calcium (with addition of Mg^{2+}), activation of the alternative and lectin pathways can be measured (AH_{50}). The CH_{50} and AH_{50} can be used to screen for hereditary complement deficiency (19). An absent or very low CH_{50} with a normal AH_{50} implies deficiency of C1q, C1r, C1s, C2, or C4. Subsequent testing should include assays for individual complement components.

Levels of Individual Complement Components

If a single component remains persistently low, a hereditary complement deficiency is likely (the exception being deficiency of a regulatory protein, such as C1-Inh). Immunoassays for measuring serum levels of complement components C1 to C9 are available. They measure component levels, but not function. Nephelometry, radial immunodiffusion, radioimmunoassay, and ELISA are the most common methodologies. Nephelometry is most commonly used to measure C3 and C4 levels, as these components are present in high concentrations in serum. Radial immunodiffusion and ELISA are used for components that are present at lower concentrations. Specificity of the antibodies used to measure complement components is critical for obtaining reliable results. Since certain complement components are acute-phase reactants produced in response to inflammation, it can be useful to measure complement split products as a measure of complement activation.

Testing for Activation Products

Complement deficiencies can be recognized by the presence of depressed individual component levels without increased complement breakdown/activation products. C3a, C3d, C4a, and C5a are measured using enzyme immunoassays or nephelometry. The main drawback is the short half-lives of most activation products. These assays are best performed on EDTA-anticoagulated plasma, which avoids generation of complement activation products *in vitro*. C3a has a half-life of 30 min, which limits its usefulness in clinical settings. C3dg has a half-life of 4 h but the assay is not widely available. C3dg is generated constitutively at a low level, so comparison with C3 (C3dg/C3) makes the measurement more informative. Complement activation products are present in low concentrations, making ELISA the most practical method for detecting them.

Lab Collection Techniques

Complement components are labile and spontaneously degrade, an important consideration when obtaining functional assays, such as the CH_{50}. The sample must be placed immediately on ice and brought to the lab immediately. Samples must be centrifuged within 30 min and frozen within 1 h. Sample collection is less critical in the case of immunoassays, which detect the protein (e.g., C3, C4) but are independent of function.

Monitoring Complement Activation in SLE

Although the CH_{50} is probably the best clinical test for monitoring complement activation in SLE, immunoassays for C3 and C4 are more practical in view of the difficulty of assuring proper handling of CH_{50} samples. There is not a consensus on the utility of monitoring complement levels in SLE, and hypocomplementemia is not one of the classification criteria for SLE. Nevertheless, many feel that low CH_{50}, C3, and/or C4 levels are a worthwhile measure of complement activation that may correlate with or precede increased activity of lupus nephritis or other manifestations. Active SLE also may be associated with high levels of the breakdown products C3d and C3dg.

Acquired Complement Component Deficiency in SLE

Acquired complement deficiency in SLE may be due to autoantibody production. Hypocomplementemic urticarial vasculitis (HUVS), a disorder caused by autoantibodies against C1q, is the best example (20). Autoantibodies against collagen-like region of C1q may be seen in up to 30% of SLE patients, though most patients do not develop HUVS. Clinically, HUVS is characterized by a leukocytoclastic cutaneous vasculitis (chronic urticaria lasting >24 h that resolves leaving hyperpigmented plaques) and activation of the classical complement pathway. Additional manifestations include glomerulonephritis, arthralgias, uveitis, and a severe form of chronic obstructive lung disease. HUVS can be suspected on clinical grounds, and diagnosis is based on skin biopsy and depressed C1q, C3, and C4 levels and CH_{50} with elevated activation products such as C3d. The detection of serum anti-C1q autoantibodies confirms the diagnosis.

MEASURING THE TYPE I INTERFERON GENE EXPRESSION SIGNATURE IN SLE

Type I interferons (IFN-I) include IFNα and IFNβ, which are produced by leukocytes, fibroblasts, and plasmacytoid dendritic cells. Their binding to the Type I interferon receptor leads to increased expression of 100 or so interferon-stimulated genes (ISGs). About 20 of these are involved in antiviral responses, and increased expression of these genes

in peripheral blood mononuclear cells is seen in SLE patients (21, 22). This "interferon signature," present in about two-thirds of adults and nearly all children with SLE, is associated with renal involvement and anti-dsDNA, Sm/nRNP, SSA/Ro, and SSB/La autoantibodies. There is considerable interest in using the interferon signature to monitor disease and/or disease susceptibility, although the clinical utility of doing so remains to be validated. Several assays are used, including the calculation of an "interferon score" by quantitative PCR (qPCR) (23), a bioassay using the induction of ISG expression in a standard cell line by patient serum (24), and flow cytometry-based assays for the expression of the proteins encoded by ISGs in blood leukocytes (25).

Method: Interferon Score by qPCR

An "interferon score" can be determined by quantifying the expression of three ISGs in peripheral blood leukocytes by qPCR (23). A number of the ISGs have been used for this purpose, but we generally use myxoma-resistant gene-1 (Mx1), interferon-inducible protein 44 (IFI44), and Ly6E (26). Human blood is collected in PAXgene tubes and RNA is isolated using the PAXgene RNA kit (Qiagen). The RNA (1 to 2 μg/sample) is treated with DNase I to remove contaminating genomic DNA and is then reverse transcribed (Superscript II First Strand Synthesis System, Invitrogen). Gene expression is quantified by real-time PCR (SYBR Green Core Reagent Kit, Applied Biosystems) using published forward and reverse primer sequences (26), and the expression is normalized to that of a housekeeping gene (β-actin) using the $2^{-\Delta\Delta Ct}$ method. Amplification conditions are: 95°C × 10 min, followed by 45 cycles of denaturation (94°C × 15 s), annealing (60°C × 25 s), and elongation (72°C × 25 s). After a final extension (72°C × 10 min), a melting curve analysis is performed to verify specificity of the products. Interferon scores are calculated as the number of standard deviations above or below the mean expression in a group or 10 healthy controls. The ISG score is calculated as follows: (Mx1 + Ly6E + IFI44) ÷ 3.

Method: Assessment of the Interferon by Flow Cytometry

Human peripheral blood monocytes constitutively express FcγRI (CD64), but expression is induced by IFN-I (and not other cytokines) (25). The level of CD64 expression on circulating $CD14^+$ monocytes can be measured rapidly by flow cytometry as a measure of total IFN-I production. IFN-I levels obtained by this assay correlate well with levels determined by the labor-intensive qPCR assay.

Reagents and Assay

PerCP-conjugated anti-CD14 (clone Mϕ P9) and phycoerythrin (PE)-conjugated anti-CD64 (clone X54-5/7.1.1), both from BD Bioscience, are used. Heparinized whole blood (100 μl) is incubated with labeled anti-CD64 + anti-CD14 antibodies for 20 min in the dark. Erythrocytes are lysed and the cells are washed with PBS/1% BSA/0.01% NaN_3 and fixed in 2% paraformaldehyde in PBS. Cells are analyzed by flow cytometry; gating on monocytes is based on their forward/side scatter and CD14 expression. At least 10^5 events are analyzed. Surface expression of CD64 is expressed as geometrical mean fluorescence intensity on monocytes. A PE-labeled irrelevant isotype control should be used. Since human $CD14^+$ monocytes constitutively express CD64, staining of peripheral blood from healthy controls should be carried out in parallel to define a normal range for CD64 mean fluorescence intensity. We have found that the monocyte CD64 expression level in heparinized blood is stable for at least 24 h at room temperature after blood collection.

Immunodiagnosis of Autoimmune Myopathies

MINORU SATOH, ANGELA CERIBELLI, MICHITO HIRAKATA, AND EDWARD K. L. CHAN

90

Certain autoantibodies can be clinically useful biomarkers associated with a particular disease and/or clinical features. Some of them, called disease marker antibodies, are highly specific for a particular diagnosis and have predictive value for the development of the disease, and they are included in classification criteria for systemic autoimmune rheumatic diseases (1, 2). The majority of disease-associated autoantibodies in systemic lupus erythematosus and scleroderma (systemic sclerosis) have been known for decades. However, autoantibody research in polymyositis/dermatomyositis (PM/DM) has been highly active in recent years as several new, clinically important autoantibody specificities with strong clinical impact have been identified, such as antibodies to transcription intermediary factor 1γ/α (TIF1γ/α; p155/140), which are frequently found in cancer-associated DM (3–5); and to melanoma differentiation-associated gene 5 (MDA5), associated with clinically amyopathic DM (CADM) with rapidly progressive interstitial lung disease (ILD) (6–9). Autoantibodies that are found in PM/DM are often classified into myositis-specific autoantibodies (MSAs) and myositis-associated autoantibodies (10, 11). MSAs are found almost exclusively in PM/DM among systemic rheumatic diseases, although some are also found in patients classified into idiopathic ILD, such as anti-PL-12 and anti-KS antibodies (12, 13).

Autoantibodies in PM/DM have been tested by a combination of immunoprecipitation (IP) analysis of proteins and RNA components of the target antigens along with enzyme-linked immunosorbent assay (ELISA) using purified or recombinant antigens, Western blot, and IP-Western blot as necessary (1, 14). In this chapter, we focus on experimental procedures of IP and ELISA using recombinant proteins, revising the previously published chapter of this manual (15). This chapter does not discuss details of molecular targets or the clinical significance of each autoantibody specificity, as many recent review articles on MSAs are available (11, 16–18).

IP ANALYSIS OF PROTEIN COMPONENTS

Radioimmunoprecipitation analysis of protein components of autoantigens using [^{35}S]methionine-labeled cell extract is a very powerful technique that allows screening for almost all known PM/DM autoantibodies in a single assay. Many of them can be interpreted almost conclusively, while a few may require additional techniques for confirmation (1). Advantages of IP include (i) screening of almost all known MSAs by a single assay, (ii) antigens being closer to the native condition compared with those in other immunoassays such as Western blot or ELISA, (iii) detection of multiproteins or multiprotein-nucleic acid complexes, and (iv) confirmation of the specific reactivity to the target antigen of the corresponding molecular weight (versus optical density [OD] in ELISA, which may not reflect the reactivity with the actual target in some cases).

Technology and Instrumentation

Antibodies in sera are affinity-purified onto beads coated with protein A or protein G. Beads with purified antibodies are mixed with radiolabeled cell extract. Antigens recognized by autoantibodies are affinity-purified onto the beads. Radiolabeled proteins are separated by SDS-PAGE and detected by autoradiography. A similar approach can be used to analyze the nucleic acid components of RNA-protein complex autoantigens. Required apparatus includes an electrophoresis power supply, vertical electrophoresis apparatus, tabletop centrifuge, CO_2 incubator, cell sonicator (Branson, Thomas Scientific, Swedesboro, NJ), and microcentrifuge.

Materials and Reagents

The following materials and reagents are needed.

1.5 g protein A-Sepharose CL4B (PAS) (17-0780-01; GE Healthcare, Little Chalfont, United Kingdom)

Prepare PAS stock solution as follows.

1. Add deionized H_2O (dH_2O) to 1.5 g of dry PAS in the vial, transfer to 15-ml centrifuge tubes, and let it swell by leaving at room temperature for 20 to 30 min.
2. Centrifuge for 30 s in a tabletop centrifuge (300 × *g*).
3. Aspirate water, add water to the top of the tube, and mix by inverting tubes. Wash the beads three times by centrifuging and aspirating supernatant.
4. Based on the volume of the beads, add dH_2O to make 50% (vol/vol) solution. Usually 14 to 15 ml of 50% (vol/vol) solution can be made from 1.5 g of PAS.
5. Add 1/100 amount of 2 M Tris-HCl (pH 7.5) to a final concentration of 20 mM and 10% NaN_3 to a final concentration of 0.1%. The beads can be stored at 4°C in this buffer.

doi:10.1128/9781555818722.ch90

Protein A, protein G, and protein A/G-Sepharose or -agarose beads are sold by many companies with variable binding capacity and nonspecific background. Although we have been using PAS for almost all IP experiments (including mouse IgG1 monoclonal antibodies), some mouse IgG1 and human IgG3 may not bind PAS efficiently; thus protein G or A/G may be more suitable for these.

0.5 M NaCl NET/IGEPAL buffer: 50 mM Tris-HCl (pH 7.5), 0.5 M NaCl, 2 mM EDTA, and 0.3% IGEPAL CA-630 (Sigma I3021; Sigma-Aldrich, St. Louis, MO). Nonionic, nondenaturing detergent Nonidet P-40 was replaced by IGEPAL CA-630, which is chemically indistinguishable from Nonidet P-40.

NET/IGEPAL buffer: 50 mM Tris-HCl (pH 7.5), 0.15 M NaCl, 2 mM EDTA, and 0.3% IGEPAL CA-630

Phenylmethylsulfonyl fluoride (PMSF) (Sigma P7626): 50 mM in absolute ethanol stored at −80°C

Aprotinin (Sigma A6279): Aprotinin from bovine lung aseptically filled solution in 0.9% NaCl and 0.9% benzyl alcohol. Activity: 3 to 7 trypsin inhibitor units (TIU)/mg protein; 5 to 10 TIU/ml solution.

3× sample buffer: mix 0.5 M Tris-HCl (pH 6.8) (6.0 ml), 1% bromophenol blue (0.6 ml), 2-mercaptoethanol (3.0 ml), 25% SDS (4.8 ml), and glycerol (6.0 ml). When it is used for IP samples, make 1× by mixing 1 volume of 3× sample buffer with 2 volumes of dH_2O.

Sterile phosphate-buffered saline (PBS)

[^{35}S]Methionine EXPRESS Protein Labeling Mix, [35S]-, 14 mCi (518 MBq), 50 mM Tricine (pH 7.4), and 10 mM 2-mercaptoethanol (NEG-072; PerkinElmer, Waltham, MA). Available in 2-, 7-, or 14-mCi vial.

Methionine- and cysteine-free culture medium RPMI 1640 (17-104-CI; Cellgro, ThermoFisher, Waltham, MA)

Penicillin (10,000 IU/ml)-streptomycin (= 100× Pen-Strep; Gibco BRL, ThermoFisher)

L-Glutamine, 200 mM (= 100× Gibco BRL catalog no. 25030-081)

HEPES (100×)

PBS-dialyzed fetal bovine serum (FBS) (SH3007902; HyClone, ThermoFisher)

^{35}S-labeling culture medium: 39 ml methionine- and cysteine-free RPMI, 4.5 ml PBS-dialyzed FBS, 0.45 ml L-glutamine, 0.45 ml HEPES, and 45 μl Pen-Strep

Assays: Cell Culture

Radiolabeled cell extract is prepared using K562 cells (human erythroleukemia cell line; ATCC CCL-243). The cells are thawed for 2 to 3 days before use and grown in RPMI 1640 with 10% FBS, 1:100 L-glutamine, 1:100 Pen-Strep, and 1:100 HEPES in a 5% CO_2 atmosphere at 37°C. Cells should be visually inspected carefully using an inverted microscope at high magnification for viability and contamination before labeling.

Note: K562 cells grow in clusters that can sometimes be quite large (20 to 30 to hundreds of cells per cluster) when they are proliferating rapidly. When clusters are smaller or rarely seen, with most of the cells as a single cell, proliferation may be slow and not optimal for efficient radiolabeling. When K562 cells start adhering, which indicates differentiation, expression of topoisomerase I (Scl-70) is very weak to deficient. When Plasmocin is used as an antibiotic in culture, cells proliferate normally without making any clusters. No clear differences in expression of known autoantigens are noted when K562 cells cultured with Plasmocin are used for radiolabeling and IP.

Radiolabeling

Collect cells by centrifuge (300 × *g* for 5 min in a tabletop centrifuge). Typically, 10^8 cells are cultured in 45 ml of complete methionine- and cysteine-free ^{35}S-labeling culture medium in a 250-ml flask. Add 3 mCi of [^{35}S]methionine (4.2 mCi as total radioactivity) and incubate cells for 12 to 14 h at 37°C in a 5% CO_2 atmosphere. After 12 to 14 h radiolabeling, add clean PBS to the culture and divide into 10 15-ml tubes, centrifuge (300 × *g*, 5 min), aspirate supernatant, and freeze at −80°C. Polypropylene tubes should be used to avoid cracking. Aliquots contain ~2×10^7 cells and can be used immediately or frozen at −80°C until use. After radiolabeling, there should be ~1.8×10^8 cells and the medium turns yellow. It is normal not to observe big clusters, and some apoptotic cells are seen after radiolabeling. However, contamination of bacteria and fungi should be carefully monitored after radiolabeling using high magnification.

Note: Levels of RNA polymerase II phosphorylated form were low after labeling for >16 h. It is better not to label for >14 h, though this also may depend on the condition of cells.

Preparation of PAS Beads with Purified Antibodies

Serum or plasma stored frozen or at 4°C can be used. Usually sera stored at 4°C with NaN_3 maintain their autoantibody reactivity for 10 to 15 years, though reduction of autoantibody reactivity in some sera was noticed. When sera are frozen, avoid repeat freezing and thawing. Clearing of sera by centrifuge is unnecessary. A heat-inactivated serum sample cannot be used because it causes very high background that makes interpretation of IP results impossible. This problem was not solved by microcentrifuging or filtering of sera.

Prepare labeled 1.6-ml microcentrifuge tubes and add 25 μl of 50% (vol/vol) PAS, followed by adding 8 μl of serum (or plasma). When serum is added, place the pipette tip in the PAS and pipette several times, as this will allow most IgG to bind to PAS immediately. Then add 500 μl of 0.5 M NaCl NET/IGEPAL. Microcentrifuge tubes are placed on a rack, which is then wrapped using plastic film and rotated for 1 h at 4°C up to 24 h.

Avoid vortexing the PAS beads at any stage of the procedure.

Preparation of Radiolabeled Cell Extract

When the beads are ready for washing, cell extract is prepared. Beads are washed and buffer aspirated while centrifuging the cell extract. For a standard reaction, radiolabeled cell extract from ~2×10^6 cells/sample is used. Add 2 ml of 0.5 M NaCl NET/IGEPAL to the frozen cell pellet (~2×10^7 cells; final cell concentration, 10^7/ml), then add 1:100 (20 μl) PMSF and aprotinin and leave on ice. Do not try to thaw at 37°C, as once the cells are thawed, they are disrupted and protein degradation commences. Also, avoid excessive heating of the cell suspension during sonication. With the above standard condition, heating is not a concern, but when the condition is changed, it will need to be carefully monitored for possible overheating. Do not put PMSF directly onto the frozen cell pellet because the 100% ethanol will denature the proteins. Sonicate the cells for 45 s (Branson Sonifier, duty cycle 25%, output 2.5), then place the tube on ice for 1 min, then sonicate again for 45 s. Transfer the cell lysate to microcentrifuge tubes and centrifuge at 9,000 × *g* for 30 min at 4°C. Carefully collect the

supernatant; avoid disturbing the small pellet that is usually seen at the bottom toward the outside. Combine all of the lysate in a 50-ml tube on ice. Use a 50-ml tube to avoid contamination of a pipette, as it is virtually impossible not to touch the inside wall with the pipette if a 15-ml tube is used.

Incubation with Cell Extract

Pellet the antibody-coated PAS beads by microcentrifuging for 8 s; aspirate the supernatant using a Pasteur pipette attached to a vacuum. For each aspiration step, carefully remove the bubbles on the surface of the liquid first since they may cause high background. Add 1 ml of 0.5 M NaCl NET/IGEPAL and microcentrifuge for 8 s and aspirate the supernatant. To each tube with PAS beads, add 160 μl of cell extract per sample. It is unnecessary to mix tubes as the beads and cell extract will be mixed completely during incubation. Make sure that caps are closed completely and tightly to prevent leaking of radioactive sample during incubation. Put tubes on a plastic rack, wrap with a plastic film, and rotate end over end to incubate for 1 h at 4°C.

Washing Beads

Microcentrifuge for 8 s, aspirate supernatant, add 1 ml of 0.5 M NaCl NET/IGEPAL, wash the inside of the cap by inverting once, and microcentrifuge for 8 s. Repeat washing three times and then once with NET/IGEPAL buffer. At each step, aspirate as completely as possible to reduce the background. Tubes can be aspirated in a horizontal position (versus vertical) for more complete aspiration. In the presence of proteins or detergent, PAS beads stay together and will not be easily aspirated (versus buffer without proteins or detergent such as PBS).

Add 50 μl of 1× SDS-PAGE sample buffer and freeze at −80°C or −20°C until running gels or proceed to boiling. Boiling could be before freezing or just before running gels. Boil samples for 3 min and absorb water around the cap using a paper towel immediately after boiling as it could get into the tubes when the air inside cools down and the pressure inside becomes negative. Microcentrifuge for 8 s and load 20 to 25 μl in each lane.

SDS-PAGE Gels

Since the smallest proteins that can be fractionated on 8% gels are ~25 kDa, while proteins of >100 kDa are not separated well on 12.5% gels, both 8 and 12.5% gels are run in routine screening of sera with unknown specificities. When running medium-size gels, it takes 3 to 5 h at a constant voltage of 100 to 130 V for the tracking dye front to reach to the bottom of the gels. For 8% gels, it is fine to let the dye front run out of the gels. For 12.5% gels, the thick blue dye band moves slower than the front of the samples; thus they need to be stopped when the thick blue dye band is 3 to 4 mm from the bottom. When a very thin blue line or a clear line at the sample front is seen, stop gels when it reaches the bottom of the gels.

SDS-PAGE Fluorography Reagents

Proteins immunoprecipitated are analyzed by SDS-PAGE, fluorography, and autoradiography after IP. Reagents are as follows.

25% SDS (Fisher, Sigma, or Bio-Rad, Hercules, CA). Filter this solution and all other stock solutions through a 0.45-μm bottle-top filter.

Coomassie blue stain (4 liters): Coomassie brilliant blue R-250 (catalog no. 161-0400; Bio-Rad) (5 g), methanol (1,200 ml), glacial acetic acid (400 ml), and dH_2O (2,400 ml)

Destaining solution (20 liters): 2 liters of glacial acetic acid, 7 liters of methanol, and 11 liters of dH_2O

2,5-Diphenyloxazole (PPO) (catalog no D144-100; Fisher), 20% (wt/vol) in dimethyl sulfoxide (DMSO). *Note:* PPO is carcinogenic.

Glycerol

BioMax MR film (catalog no. 870-1302; Eastman Kodak, Rochester, NY)

30% acrylamide–0.8% bisacrylamide stock: 30% (wt/vol) acrylamide (catalog no. BP 170-500; Fisher) plus 0.8% bisacrylamide (catalog no. 160-0201; Fisher) (wt/vol) in water (ratio, 37.5:1). Filter through a 0.45-μm bottle-top filter. Protein migration and mobility are affected by the ratio of acrylamide/bisacrylamide used. For detection of Ro52 protein, it is necessary to use acrylamide/bis = 166:1. Protein mobility on 12.5% acrylamide/bis = 166:1 gel is similar to 8% acrylamide/bis = 37.5:1 gel. However, 52-kDa Ro can be distinguished only on the former gel.

5× Tris-glycine (SDS-PAGE running buffer): 120 g of Tris base plus 576 g of glycine; add dH_2O to 4 liters (do not adjust pH; store at room temperature)

The procedure for preparing gels is as follows. *Note:* Precast minigels may be substituted for homemade ones. They can be purchased from Bio-Rad and other vendors. Identifying autoantibody specificities characterized by multiprotein complexes such as small nuclear ribonucleoproteins should not be difficult; however, a single protein autoantigen of close molecular weight (such as the ones of ~140 kDa [MDA5 and MJ; Table 1]) (19) will be difficult to differentiate with minigels.

If casting your own gels, keep in mind that acrylamide is a neurotoxin and suspected carcinogen. Gel plates, spacers, and rubber gaskets are washed thoroughly with detergent (e.g., PCC-54; Pierce, Rockford, IL), rinsed carefully, and wiped dry with ethanol. Gel plates should be assembled and clamped together with clips carefully to avoid leaking.

Preparation of SDS-PAGE Gels

We run both 12.5 and 8% SDS-PAGE for routine screening. Mix everything except 10% ammonium persulfate and TEMED (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine; Bio-Rad) in 50-ml plastic tubes. Stacking gels are common regardless of the percentage of acrylamide in resolving gels. Add ammonium persulfate and TEMED to resolving gel solutions only to start polymerization. Mix thoroughly, but avoid excess bubbles by inverting the tubes several times. Pour the gel solution between glass plates. Usually bubbles go up to the surface, but when they stick to the glass in the middle, they can be removed by gently tapping the side of the plates. This needs to be done prior to overlaying ethanol. After checking bubbles, gently overlay 70% ethanol on the gel solution. Add from one site and avoid disturbing the gel solution. A spreading of ethanol on the surface with a clear border should be seen. Adding a 3- to 5-mm layer of ethanol is enough. Make sure the plates stand vertically at an ~90° angle to the bench and leave them without disturbing until the gels polymerize. Speed of polymerization depends on temperature but usually takes 30 to 40 min. The line between the overlaid ethanol and gel solution becomes unclear, and when it appears clearly again, it is a sign of polymerization.

After polymerization of resolving gels, pour out ethanol and rinse with dH_2O ~10 times to wash out ethanol, then completely remove water using small pieces of Whatman

TABLE 1 Identification of myositis autoantibodies by IP analysis

Autoantibodies	Target molecule	Function	Protein	RNA
Aminoacyl-tRNA synthetase				
Jo-1	Histidyl-tRNA synthetase	Incorporate histidine into proteins	50 kDa	$tRNA^{His}$
PL-7	Threonyl-tRNA synthetase	Incorporate threonine into proteins	80 kDa	$tRNA^{Thr}$
PL-12	Alanyl-tRNA synthetase	Alanine and aspartate biosynthesis and alanine incorporation into proteins	110 kDa	$tRNA^{Ala}$
EJ	Glycyl-tRNA synthetase	Glycine, serine, and threonine metabolism and aminoacyl-tRNA biosynthesis	75 kDa	$tRNA^{Gly}$
OJ	Isoleucyl-tRNA synthetase	Incorporate isoleucine into proteins	150 kDa (multienzyme complex, 170, 130, and 75 kDa)	$tRNA^{Iso}$
KS	Asparaginyl-tRNA synthetase	Glutamate, alanine, and aspartate metabolism	65 kDa	$tRNA^{Asp}$
ZO	Phenylalanyl-tRNA synthetase	Incorporate phenylalanine into proteins	60/70 kDa	$tRNA^{Phe}$
YRS (HA)	Tyrosyl-tRNA synthetase	Incorporate tyrosine into proteins	59 kDa	$tRNA^{Tyr}$
Anti-SRP	Signal recognition particle	Protein maturation in the ribosome	72, 68, 54, 19, 14, and 9 kDa	7SL RNA
Anti-Mi-2	Helicase protein	Transcriptional regulation	240, 150, 72, 65, 63, 50, and 34 kDa	
Anti-MDA5/ CADM140	MDA5	RNA-specific helicase that mediates the antiviral response	140 kDa	
Anti-TIF1γ/α (p155/140)	TIF1γ/α	Transcription and RNA metabolism	155 and 140 kDa	
Anti-MJ	NXP-2 (MORC3)	Transcriptional regulation and activation of the tumor suppressor p53	140 kDa	
Anti-SAE	SAE	Posttranslational modifications	90 and 40 kDa	
Anti-PMS1	PMS1 (postmeiotic segregation increased 1)	DNA mismatch repair enzyme	120 kDa	

filter paper. In particular, water tends to stay at each corner; thus, it should be removed completely until the sharp 90° angle can be seen. When plates are ready for stacking gels, add ammonium persulfate and TEMED to the stacking gel solution. Mix gently by inverting the tubes and pour the solution between glass plates. Insert combs, avoiding bubbles under the comb. If bubbles are seen under the comb, remove it and insert again. Resolving gels can be polymerized in 30 min. We usually leave gels at 4°C overnight because we feel the protein bands are sharper in 8% gels by this step. The polymerization step should be at room temperature.

SDS-PAGE Procedure

The gels are run as follows.

1. Make 1 liter of running buffer: 1 liter is used for a pair of gels; 200 ml of 5× Tris-glycine plus distilled water to make 1,000 ml; add 4 ml of 25% SDS and mix well by inverting a measuring cylinder.

2. Boil samples, including molecular weight marker if necessary. Prestained molecular weight marker is relatively expensive but convenient, as the quality and progress of running gels can be monitored.

3. Carefully remove the combs and silicone rubber spacer from the gel, and then remove clips.

4. Clamp the gel to the gel apparatus and add running buffer to the top and bottom chambers of the apparatus.

5. Flush out bubbles from the bottom of the gel immersed in the bottom chamber, using a 5- to 10-ml syringe with a bent (90°) 18-gauge needle.

6. Gently flush out each well with running buffer using a Hamilton microsyringe. Pieces of gels in the wells should be carefully removed.

7. Load a 20- to 25-μl sample to each well, using either a Hamilton syringe or pipette.

8. Attach leads to the electrodes of the gel apparatus (proteins treated with SDS are negatively charged and will migrate toward the cathode).

9. Attach the power supply and run at 100 V until the blue tracking dye reaches the resolving gel; the voltage can later be increased to 120 to 130 V.

10. Run the gel until the blue tracking dye reaches the bottom of the gel or to the appropriate level as discussed earlier.

11. Turn off the power, remove the electrodes, and unclamp the gel from the gel apparatus. Carefully pry the plates apart, leaving the gel adherent to one of the plates. Using a pizza cutter, cut off the stacking gel (leave 1 to 2 mm of stacking gel) and avoid cutting resolving gel. Also, diagonally cut off a small piece of the gel from the upper right-hand corner to aid in orienting the gel.

12. Stain the gel for 30 to 60 min with Coomassie blue solution in a box, making sure gels are not stacked together and freely moving on a shaker. Use low-speed orbital shaking. Prolonged staining makes gels fragile and should be avoided.

13. Gels can be destained in the solution overnight. Proteins can still be transferred to other gels at this stage if they stick together. Separating each gel in a small plastic box is ideal.

Fluorography

After staining and destaining, the gels are fluorographed as follows.

1. Place the first DMSO (100 to 150 ml, enough to cover all gels and allow them to move freely) in a Tupperware or similar (polyethylene or polypropylene, but not polystyrene) box and add gels after removing as much excess destaining solution as possible. Incubate in the first DMSO for 30 min on an oribital shaker at low speed.

2. Discard/save the first DMSO (can be reused for up to ~8 gels; keep in a glass bottle with a tight cap) and add 100 to 150 ml of the second DMSO and shake for another 30 min.

3. Discard/save the second DMSO and add 100 to 150 ml of 20% (wt/vol) PPO in DMSO and shake for 1 h. The second DMSO can be reused for up to ~8 gels and then can be used as a first DMSO.

4. Save the PPO-DMSO in brown glass bottles for reuse. It can be used a few times, though the effectiveness gradually diminishes.

5. Wash the gels with many changes of water (tap water is fine) to remove DMSO and make PPO precipitate in the gels. Clear gels will turn white and opaque upon washing with water. Repeat, changing water and putting on a shaker. Minimum washing will be 30 min, but it is important to change water frequently rather than keeping on a shaker with the same water. Removing DMSO is critical to make thinner, nonsticky gels after drying.

6. Add glycerol to a concentration of ~3%. Insert a piece of filter paper under the gel in a box, pick up, and set on a gel dryer (Bio-Rad model 583) at 60°C with the timer set to 3 h. Gels can be dried completely after 2 to 2.5 h; however, minor air leaking in the system or other reasons could delay this process. Thus, check the appearance of the water droplets inside of the vacuum tubing (large water droplets indicate gels are still wet) carefully prior to stopping the vacuum of the gel dryer. *Note:* Higher temperature should be avoided because PPO can be destroyed at >60°C.

7. Remove gels from gel dryer. Tape filter paper with the dried gel on a solid flat support, such as a used piece of X-ray film; avoid taping over the dried gels. If it is sticky, dust the gel lightly with talc powder to prevent sticking. Place the gels in a film cassette and place in direct contact with BioMax MR film in the darkroom. The film is coated on one side, and the coated side must contact the gel directly. Expose films for 3 to 5 days at −70°C before developing. Exposure time can be adjusted based on the decay of ^{35}S (half-life, 89 days) and the signals of the molecules of interest for the experiment. Wash the box used for PPO using 100% ethanol (PPO is insoluble to water) a few times to remove PPO.

Interpretation

As a basic rule in interpretation of IP, observation of any protein bands that are present in a particular lane but not in other lanes means that they are specifically recognized by autoantibodies to these proteins. Interpretation of specificity of autoantibodies by IP is based primarily on the migration of immunoprecipitated proteins, ideally by comparing with the size and the pattern of proteins immunoprecipitated by reference sera. Representative IP analysis of autoantigenic proteins is shown in Fig. 1. Molecular weight and other characteristics of each MSA are summarized (Tables 1 and 2). Identifying a multiprotein or multiprotein-nucleic acid complex characterized by a set of proteins, such as anti-OJ, anti-SRP (signal recognition particle), anti-Mi-2, anti-TIF1γ/α (p155/140), and anti-SAE (small ubiquitin-like modifier-1 [SUMO-1] activating enzyme), is usually not so difficult. Nevertheless, occasionally patterns that look similar to OJ or TIF1γ/α are seen. For identification of SAE, there are many other proteins recognized by sera close to 90 kDa and 40 kDa where components of SAE migrate; thus, the mobility of the candidate proteins needs to be carefully assessed. Conclusively identifying SRP72/68 and SRP54 is not always easy, as there are many proteins that are recognized by patients' sera in this range of molecular weight. Detecting a set of the smaller subunits of 19, 14, and 9 kDa appears more unique, though a high-percentage (e.g., 12.5%) gel is necessary to separate these components. Jo-1 is seen as a thin band of ~50 kDa that is shifted due to interference of IgG heavy chain (not shown; this effect is unclear in Fig. 1 due to a small amount of anti-Jo-1 serum used). The presence of Jo-1 can be suspected in most cases based on IP; however, confirmation by other tests such as ELISA or Western blot is necessary for anti-Jo-1. IP of an ~50-kDa thin band and confirmation of tRNA (it cannot be confirmed specifically as $tRNA^{His}$) is practically considered anti-Jo-1. Although interpretation of a single protein autoantigen needs to be done carefully, strong anti-PL-7 or -EJ can be easily interpreted by IP in most cases, though weak bands need additional confirmation. PL-12 also shows a strong band; however, there are several autoantigenic ~120-kDa proteins that migrate close to PL-12. Mobility of TIF1β is identical to that of PL-12; however, a good-quality gel can show a characteristic appearance of the band: a sharp line in the middle and diffuse band around it. MJ/NXP-2 (nuclear matrix protein 2) is a sharp thin band, and interpretation needs to be done carefully as MDA5 migrates very close and there are many other proteins of ~140 kDa recognized by some sera. IP-Western blot or ELISA will be necessary to confirm (19). Identification of MDA5 in IP is not easy, as the expression of MDA5 in culture cells varies and there are MJ and other proteins of ~140 kDa to be differentiated (7).

Quality Assurance, Quality Control, and Test Validation

Having positive controls is ideal, but running all references each time is not practical. As far as the cells in good condition are radiolabeled, expression of all autoantibodies discussed in this chapter appears consistent except MDA5 (7, 19). As there are proteins that are nonspecifically immunoprecipitated by virtually all sera, including negative controls is necessary.

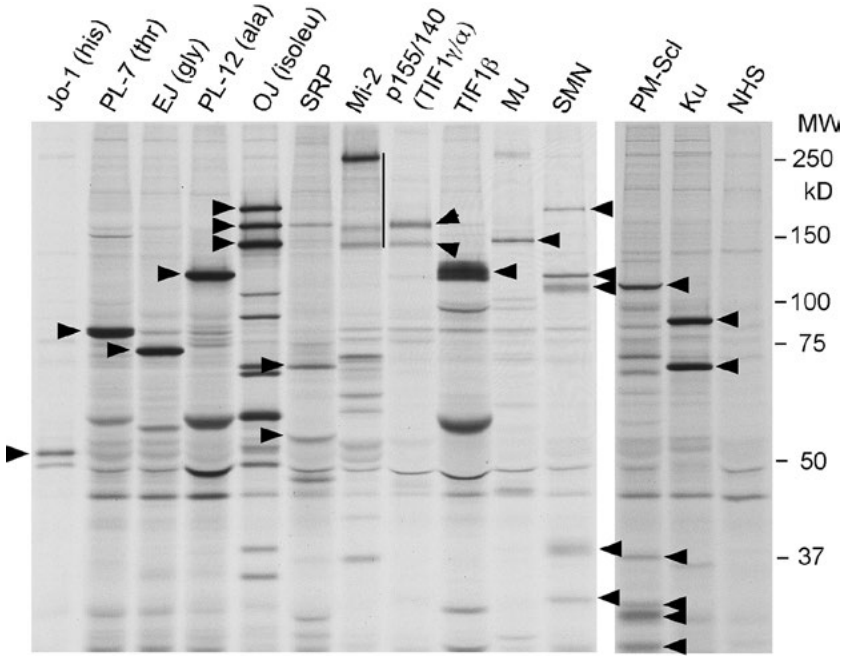

FIGURE 1 IP analysis of protein components of autoantigens recognized by autoantibodies in PM/DM. [^{35}S]Methionine-labeled K562 cell extract was immunoprecipitated by sera from patients with PM/DM. The main components of each autoantigen are indicated by arrowheads or a line drawn on the right (Mi-2). Jo-1, histidyl-tRNA synthetase; PL-7, threonyl-tRNA synthetase; EJ, glycyl-tRNA synthetase; PL-12, alanyl-tRNA synthetase; OJ, isoleucyl-tRNA synthetase multienzyme complex; SMN, survival of motor neuron; NHS, normal human serum; MW, molecular weight.

IP ANALYSIS OF SMALL RNAs

Small RNAs, components of autoantigens recognized by sera from patients, can be identified based on IP analysis of RNAs, similar to the IP procedure described above for proteins using radiolabeled K562 cells. The main differences are that (i) instead of [^{35}S]methionine-labeled cells, either unlabeled cells with silver staining of RNAs or [^{32}P]orthophosphate-labeled cells with autoradiography are used; and (ii) RNAs are extracted at the end of IP for analysis by urea-PAGE gels.

Due to concerns about strong β radiation produced by [^{32}P]orthophosphate-labeled cells, most laboratories working on autoantibody analysis switched from ^{32}P-radioimmunoprecipitation to silver staining analysis of RNAs. Thus, the method for the nonradioactive procedure is described in the following section.

In general, try to use autoclaved reagents and high-quality deionized water to avoid RNA degradation and reduce background in silver staining. Avoid any possible contamination of metal throughout the step because it will cause background in silver staining.

Steps for preparing PAS beads, stock, and incubation with sera are the same as the method for protein analysis by IP. Beads after incubation with sera can be refrigerated for several days in NET/IGEPAL buffer. Aspirate buffer before adding cell extract.

Cell Lysate

Unlabeled K562 cells (either frozen pellet or fresh cells; 5×10^6 cells/sample) are used. The number of cells necessary depends on specificities, but this number of cells is enough to detect RNA components for all MSAs that recognize RNA-protein complexes.

1. Add 2 ml of 0.5 M NaCl NET/IGEPAL plus PMSF (1:100) and aprotinin (1:100) to 50×10^6 cell pellets (20 μl each to 2 ml of the buffer). Final concentration: PMSF, 0.5 mM; aprotinin, 0.24 TIU/ml (Sigma). Do not put PMSF directly on cell pellets since ethanol will denature proteins. When frozen cell pellets are used, *do not* try to thaw cell pellets. Once the cells are thawed, cells will be disrupted and proteases and nucleases will be active. Also, it is unnecessary to mix and resuspend cells as they will be resuspended soon after sonication is started.

2. Sonicate cells for 45 s at duty cycle 25%, output control 2.5 (Branson Sonifier). Put on ice for 1 min. Sonicate again for 45 s. Keep samples on ice when it is possible. Transfer cell lysate to microfuge tubes. Microfuge for 30 min at 9,000 × *g* in a cold room (not at room temperature).

3. Wash PAS beads incubated with sera while clearing the cell lysate.

4. Carefully collect supernatant, avoiding the pellet. If there is more than one tube, pool all supernatant together in a tube before adding to samples. Add cell extract on beads (usually 200 μl/sample, but this can be adjusted depending on the experiment).

5. Put tubes on a plastic rack, wrap with a plastic film, and rotate at 4°C for 1 h.

Preparation of a Total RNA Sample as a Standard

1. Take 20 μl (extract from ~5×10^5 cells) and add 400 μl of NET/IGEPAL, 16 μl of 25% SDS, and 40 μl of 3 M Na acetate (pH 5.2). Add 400 μl of phenol/chloroform/isoamyl alcohol (25:24:1, pH 5.2) (Fisher). *Note:* Phenol/chloroform/isoamyl alcohol is available at pH 5.2 and pH 8.0. The pH 8.0 solution is supposed to allow extraction of both DNA and

TABLE 2 Prevalence and clinical association of myositis autoantibodies

Autoantibodies	Prevalence (%)	Clinical association/significance
Aminoacyl-tRNA		
Jo-1	15–30	Anti-synthetase syndrome (myositis, ILD, polyarthritis, Raynaud's phenomenon, mechanic's hands)
PL-7	<5	Myositis, ILD, DM-specific skin manifestations (heliotrope rash, Gottron's sign)
PL-12	<5	ILD, CADM, DM-specific skin manifestations (heliotrope rash, Gottron's sign)
EJ	<5	Myositis, ILD, DM-specific skin manifestations (heliotrope rash, Gottron's sign)
OJ	<5%	Anti-synthetase syndrome
KS	<5 (rare)	ILD
ZO	<1 (rare)	Myositis
YRS (HA)	<1 (rare)	Myositis
Anti-SRP	5	Myositis (necrotizing)
Anti-Mi-2	10	DM with typical skin lesions and mild myositis
Anti-MDA5/CADM140	15–20	CADM, rapidly progressive ILD, severe skin manifestations
Anti-TIFγ/α (p155/140)	10–15	Malignancy-associated DM
Anti-MJ/NXP-2	1–5	Adult and juvenile DM with severe skin disease
Anti-SAE	1	DM

RNA, whereas the pH 5.2 stock is designed mainly for RNA extraction.

2. Vortex vigorously for 1 min.

3. Spin for 1 min at room temperature at 9,000 × *g*.

4. Handle tubes very carefully and transfer supernatant to a clean new tube, avoiding the protein layer at the interphase between supernatant and phenol phase. Use a P200 pipette and harvest ~150 μl × 2 = ~300 μl.

5. Add 900 μl of 100% ethanol (200 proof) and *mix well by inverting tubes* (IMPORTANT).

6. Leave at −80°C overnight (>1 h is probably enough).

Washing Beads

1. After incubation of beads with cell extract, spin for 8 s and aspirate cell extract.

2. Add 1 ml of 0.5 M NaCl NET/IGEPAL. Wash the inside of the cap by inverting tubes.

3. Wash four times with 0.5 M NaCl NET/IGEPAL. Spin for 8 s.

4. Add 1 ml of NET/IGEPAL (50 mM Tris-HCl [pH 7.5], 150 mM NaCl, 2 mM EDTA, and 0.3% IGEPAL CA-630). Spin for 8 s and aspirate supernatant completely.

Extraction of RNAs

1. Mix 400 μl of NET/IGEPAL, 16 μl of 25% SDS, and 40 μl of 3M Na acetate (pH 5.2) and add 456 μl of the mixture to the beads.

2. Add 400 μl of phenol/chloroform/isoamyl alcohol (25:24:1). Vortex vigorously for 1 min.

3. Purify RNA as described above in "Preparation of a Total RNA Sample as a Standard."

Preparation of RNA Samples for Urea-PAGE

RNA samples in microcentrifuge tubes are spun at 9,000 × *g* for 15 min in a cold room. The supernatant can be discarded by gently pouring, and then carefully aspirate liquid using a thin Pasteur pipette (heat the thin part of the Pasteur pipette over a gas burner and pull to make a thin glass pipette).

The RNA pellet is usually not visible, but the RNA pellet will stay on the surface of the tubes if aspiration is along the opposite side of the tube, where the pellet is supposed to be. Leave tubes under a biological safety hood to dry.

Preparation of Urea-PAGE Gel

1. Wash a 100-ml glass beaker and stirrer using detergent and rinse very well with Milli-Q water.
2. Weigh 21 g of urea, add 20 ml of 30% acrylamide/bis and 5 ml of 10× Tris-borate-EDTA (TBE), and stir until urea is completely dissolved.
3. Wash a measuring cylinder, and rinse with Milli-Q water and transfer the above solution.
4. Adjust the volume to 50 ml using Milli-Q water. Make fresh 10% ammonium persulfate using Milli-Q water.

5. Add 300 μl of ammonium persulfate and 30 μl of TEMED and mix completely.
6. Pour between a pair of glass plates and a spacer, assembled using clips, and insert comb.

Urea-PAGE

1. Start running gel at a constant voltage of 480 to 500 V (current and watts at maximum position; adjust output by voltage). Check the temperature of the gel using a paper thermometer and try to keep the temperature between 55 and 60°C. This range of temperature can be reached with voltage between 480 and 500 V, but the necessary voltage could be different in different systems.
2. Add 50 μl of urea-PAGE sample buffer to each sample tube and vortex to dissolve RNA. Turn the power off. Load 20 μl of sample using thin plastic pipette tips with a P20 pipette, quickly before the gel cools down.
3. Before prerun and before loading samples, quickly flush each well using a Hamilton microsyringe. Urea emerges from the gel and may collect at the bottom of the wells, disturbing the sample.
4. Two dye bands are seen while running gels, a blue dye band of bromphenol blue and a purple dye band of xylene cyanol. Run until the xylene cyanol dye reaches the bottom of the gel (it may go out). It usually takes ~1.5 to 2 h to run with medium-size gels.

Silver Staining of Nucleic Acids (Silver Stain Plus; Bio-Rad)

Follow the manufacturer's instructions.

12% Urea-PAGE Gel for RNA Analysis

30% (acrylamide/bis = 37.5:1) acrylamide/bis	20 ml
10× TBE	5 ml
Urea	21 g

Bring the volume to 50 ml with Milli-Q water.

10% ammonium persulfate	300 μl
TEMED	30 μl

RNA Sample Buffer

10 M urea

0.025% bromophenol blue

0.025% xylene cyanol in 1× TBE

Make 1% dye solution and add 1/40 amount of bromophenol blue and xylene cyanol to 10 M urea to a final concentration of 0.025%.

10× TBE

900 mM Tris	108 g
900 mM boric acid	55 g
20 mM Na_2EDTA	40 ml of 0.5 M stock

Adjust final volume to 1 liter.

Interpretation

Detecting tRNAs in IP samples is not difficult; however, the only interpretable information is that the antibodies in the serum recognize autoantigen that has tRNA as a component; it is not possible to identify the specificity of tRNAs by IP. Nevertheless, it is reasonable and practical to conclude a specificity of anti-tRNA synthetase antibodies based on IP of protein of the right molecular weight corresponding to each tRNA synthetase combined with IP of the tRNA. Detection of 7SL RNA for anti-SRP is not difficult, though having a positive control is ideal. Detection of U small nuclear RNAs is easy with a positive control as well. Representative silver staining gel to analyze RNA components of autoantigens is shown in Fig. 2.

Quality Assurance, Quality Control, and Test Validation

Most small RNAs associated with MSA antigens can be detected easily with good-quality IP and staining. A positive control of anti-Jo-1 and negative controls are useful as a standard for quality control.

ELISA USING RECOMBINANT MYOSITIS AUTOANTIGENS

The following protocol is based on ELISA using recombinant Jo-1 antigen, but the same protocol can be used for any other myositis autoantibody ELISA using recombinant autoantigens.

When ELISA is performed for the detection of autoantibody, there will be differences in the reactivity between samples. However, it should be noted that it does not mean the observed OD reflects the actual recognition of the target autoantigen. Quality/purity of recombinant proteins and ELISA varies, and validation for each ELISA compared with results from a previously established standard method such as IP is necessary.

1. Coat a 96-well microtiter plate (Nunc Immobilizer Amino; Nunc/Thermo Fisher Scientific, Roskilde, Denmark) with purified recombinant Jo-1 antigen by adding 0.5 μg/ml in PBS, 50 μl/well, at room temperature for 2 h or at 4°C overnight. The concentration of antigens may need to be optimized by titration analysis and adjusted for each assay. Any other type of high-binding microtiter plate may be used. The Immobilizer Amino plate covalently cross-links proteins to the plastic surface at amino acid positions of lysine and cysteine. This cross-linking process will not work in the presence of amines such as Tris or glycine. Other types of plate may not be affected by amine.

2. Tap the side of the plate gently and make sure that the whole bottom area of the wells is covered with coating solution. With 50 μl/well it will not spread, but 100 μl/well or more will spread without tapping. Using 50 μl/well will save on the cost of reagent.

3. After the coating/cross-linking step, remove antigen solution completely by tapping on dry paper towels.

4. Block with 0.5% bovine serum albumin (BSA) NET/IGEPAL (150 mM NaCl, 2 mM EDTA, 50 mM Tris-HCl [pH 7.5], and 0.3% IGEPAL CA-630)–0.05% NaN_3, 150 μl/well, for 1 to 3 h at room temperature (or 4°C overnight).

5. Dump blocking buffer and tap on paper towels.

6. Add 100 μl/well of serum diluted in blocking buffer (0.5% BSA NET/IGEPAL–0.05% NaN_3, usually at 1:250 to 1:500, i.e., 2 μl of serum in 500 or 1,000 μl of blocking buffer). Incubate for 1 to 3 h at room temperature.

7. Wash plate three times with Tris-buffered saline (TBS)/Tween 20. There are many alternative types of washing buffer in common use.

8. Add 100 μl/well of alkaline phosphatase-conjugated goat F(ab)′2 anti-human IgG (γ-chain specific) second antibody at 1:1,000 in 0.5% BSA NET/IGEPAL–0.05% NaN_3. Incubate for 1 to 2 h at room temperature.

9. Wash three times with TBS/Tween 20.

10. Prepare the developing solution ~10 min before needed by adding 1 tablet (5 mg) of Sigma 104 substrate/5 ml

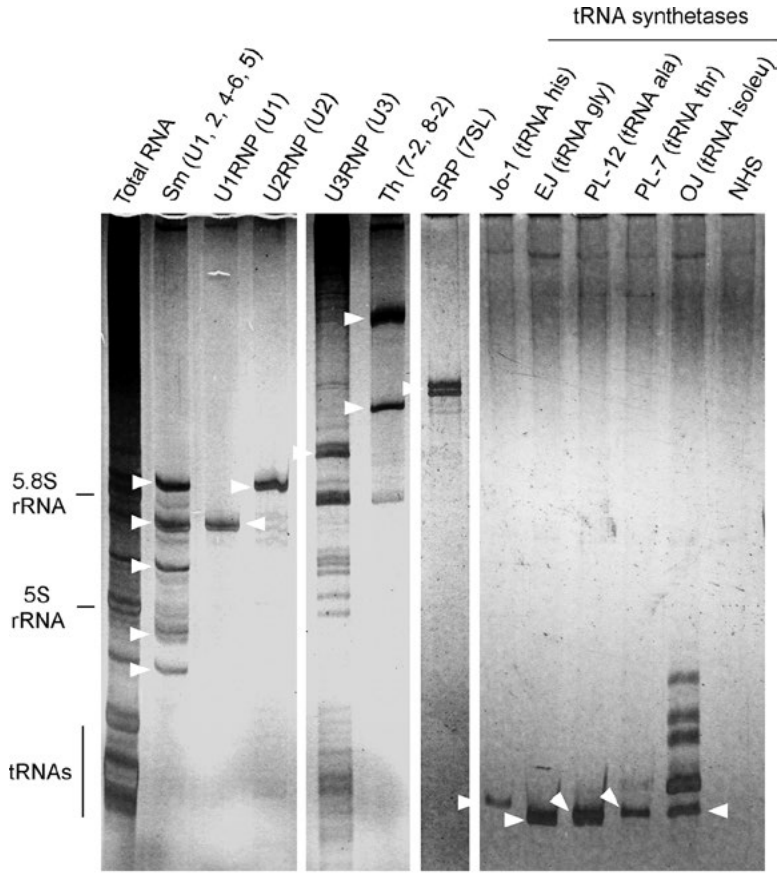

FIGURE 2 IP analysis of RNA components of autoantigens recognized by autoantibodies. K562 cell extract was immunoprecipitated by autoimmune sera. RNA components were extracted, fractionated on urea-PAGE, and silver stained. RNA components of autoantigen are indicated by arrowheads. Sm (U1, 2, 4-6, 5), U1, 2, 4-6, 5 small nuclear RNAs; U1RNP (U1), U1 small nuclear RNA; U2RNP (U2), U2 small nuclear RNA; U3RNP (U3), U3 small nucleolar RNA; Th (7-2, 8-2), 7-2 and 8-2 RNAs; SRP (7SL), 7SL RNAs; NHS, normal human serum. Y1-5 RNAs are also seen in the anti-OJ lane due to coexisting anti-Ro60 antibodies.

diethanolamine buffer. You need 10 ml/plate (100 μl/well × 96 wells = 9.6 ml). Put on rotator or shaker in a 50-ml tube to dissolve. Sigma 104 tablets are sensitive to temperature and humidity. Take the necessary amount quickly and do not leave the vial at room temperature for an extended period of time.

11. Develop plates by adding 100 μl/well of developing solution.

12. Read OD_{405} on a microtiter plate reader. Read OD more than once, including the one when the highest OD is ~1.5 to 2. If samples with low OD are important, overdevelop and read it again. Try to read at least twice for each plate.

VERY IMPORTANT: Do not push pipette all the way when developing solution is added because this will leave bubbles in the wells, which will directly and significantly affect the absorbance of wells. Depending on the operator's pipetting technique, there may still be bubbles. Check all wells for bubbles after pipetting and break them using a 25-gauge needle.

Blocking Buffer: NET/IGEPAL, 0.5% BSA, 0.05% NaN_3

0.15 M NaCl
2 mM EDTA
50 mM Tris-HCl (pH 7.5)
0.3% IGEPAL
0.5% BSA
0.05% NaN_3

Washing Buffer (TBS/Tween 20)

20 mM Tris-HCl (pH 7.5)
150 mM NaCl
0.1% Tween 20

Diethanolamine Buffer

Diethanolamine	97 ml
$MgCl_2 \cdot 6H_2O$	0.1 g
NaN_3	0.2 g
dH_2O	

Adjust pH to 9.6 with concentrated HCl, adjust volume to 1 liter with dH_2O, and filter using a 0.45-μm bottle-top filter.

Interpretation

It is ideal to set a cutoff in each laboratory based on a ROC (receiver operating characteristic) curve established by a large number of positive and negative controls.

Quality Assurance, Quality Control, and Test Validation

Quality and reliability of ELISA depend heavily on the quality of recombinant protein used. Positive controls selected based on conventional methods and negative controls are essential as standards for quality control. Weak but true positive versus false positive is often not easy to differentiate with ELISA.

FUTURE DIRECTIONS OF MSA TESTING

Currently anti-Jo-1 ELISA is the only widely available testing for most clinicians. Line immunoassay is available in certain countries but has not been used extensively. Although IP is a very powerful and reliable technique, it has been performed at only a limited number of laboratories and is not likely to become a routine assay in clinical practice. ELISAs and bead-based assays for several MSAs are currently under development and will become available in the future. Recently identified autoantibodies such as anti-TIF1 and anti-MDA5 have strong clinical significance, and development of commercial immunoassays is in progress. They will be widely available in the near future, and tests for these autoantibodies may become a part of standard tests in clinical practice for inflammatory myopathy.

Immunodiagnosis of Scleroderma

MASATAKA KUWANA

91

Systemic sclerosis (SSc) or scleroderma is a connective tissue disease characterized by excessive fibrosis, microangiopathy, and the presence of circulating autoantibodies to various cellular components (1). Clinical presentation is highly heterogeneous in patients with SSc: some have only Raynaud's phenomenon and sclerodactyly without any symptomatic organ involvement for >10 years, but others have progressive functional impairment in lungs, heart, kidneys, or gastrointestinal tract, leading to death. Distinct specificities of antinuclear antibodies (ANAs) are selectively detected in SSc patients and are associated with unique disease manifestations (2). The detection of individual SSc-related ANAs is useful in the diagnosis, disease subgrouping, and prediction of future organ involvement and prognosis. Therefore, SSc-related ANAs are important biomarkers in routine rheumatology practice.

A new group of autoantibodies reactive with cell-surface receptors or extracellular matrix proteins also have been identified in SSc patients. These include anti-platelet-derived growth-factor receptor, anti-angiotensin II type 1 receptor, anti-endothelin-1 type A receptor, and anti-fibrillin-1 antibodies, and appear to directly activate pathways that may contribute to tissue and vascular remodeling. However, reproducibility of the published reports is very poor, probably because of difficulty in reproducing antigenicity of the autoantigens with highly complicated conformation in the assays. This results in lack of reliable commercial assay kits for detection of these autoantibodies to functional molecules.

To date, at least 10 specificities were identified and characterized as ANAs specific to SSc. Two classic autoantibodies discovered in the late 1970's are anti-Scl-70 or anti-topoisomerase I (topo I) antibody, and anti-centromere antibody (ACA). Another group of antibodies, including anti-U1 ribonucleoprotein (RNP), anti-Ku, and anti-PM-Scl antibodies, were first identified using double immunodiffusion (DID). The remaining ANA specificities were discovered using immunoprecipitation (IP) assay. However, these conventional techniques are of limited use in routine clinical practice because they are labor-intensive and time-consuming, and are limited in throughput. DID, or the Ouchterlony, method has been used for more than 50 years and is still used in clinical laboratories because it is inexpensive and specific, but it lacks sensitivity and requires a large amount of reference serum and considerable experience in judging the assay results. The IP assay is a valuable detection method that is able to detect all SSc-related ANAs except ACA, but this assay requires complicated procedures using cellular extracts freshly prepared from radioisotope-labeled cultured human cells. Therefore, many efforts have been made to develop convenient and accurate assays for detection of individual SSc-related ANAs.

SSc-Related ANAs

ANAs are a hallmark of SSc, and are detected in >95% of the patients (2). The majority of autoantigens specifically recognized by SSc sera have been already identified. At this point, at least 10 ANA specificities associated with SSc have been reported and well characterized, and approximately 80% of SSc patients have one of those SSc-related ANAs in their circulation. These SSc-related ANAs target various nuclear components involved in essential cellular processes, such as cell division and transcription (Table 1). These autoantibodies are rarely seen in patients with other connective-tissue diseases without SSc features and thus are important diagnostic markers. In addition, detection of SSc-related ANAs is clinically useful in classifying SSc patients into subtypes that are almost exclusively associated with characteristic clinical phenotypes (Table 2). SSc-related ANAs are usually present at the onset of SSc symptoms and do not switch from one antibody to another during the course of the disease. These autoantibodies remain throughout the course of the disease regardless of whether patients receive treatment or not. Patients rarely have two or more SSc-related ANAs together, indicating mutual exclusiveness. Thus, SSc patients can be divided into a number of disease subsets stratified by SSc-related ANAs (Fig. 1).

Anticentromere Antibody (ACA)

The frequency of ACA in SSc patients has been reported to be 20% to 30% in many ethnic groups. ACA produces discrete speckled staining on indirect immunofluorescence (IIF). The recognition of kinetochore proteins located at the centromeric regions of individual metaphase chromosomes is highly specific to ACA. However, IIF using chromosomal spreads as the substrate is necessary to confirm the presence of ACA, especially when other high-titer ANA specificities coexist. ACA is sometimes detected in patients with primary Sjögren's syndrome or primary biliary cirrhosis as well as in individuals without an apparent connective

doi:10.1128/9781555818722.ch91

TABLE 1 Structure and function of molecules targeted by SSc-related ANAs

ANA specificity	Structure	Cellular localization	Main cellular function
Anticentromere	CENP-A, B, and C	Chromatin	Separation of chromosome
Anti-Scl-70	DNA topoisomerase I	Chromatin	Relaxation of supercoiled DNA
Anti-RNA polymerase III	Multi-subunit components of RNA polymerase III, including RPC155	Nucleoplasm	Transcription of small nuclear RNAs
Anti-U3 RNP/ fibrillarin	U3RNA and related components including fibrillarin	Nucleoli	Processing of pre-ribosomal RNAs
Anti-Th/To	RNase P/RNase MRP	Nucleoli	Processing of transfer RNAs and other small RNAs
Anti-U11/U12 RNP	U11/U12 RNA and related components	Nucleoplasm	Regulation of mRNA splicing
Anti-PM-Scl	Exosome complex containing PM-Scl-100 and PM-Scl-75	Nucleoli	Processing and degradation of RNAs
Anti-Ku	Ku80 and Ku70	Nucleoplasm	DNA repair
Anti-RuvBL1/2	Double hexamer consisting of RuvBL1 and RuvBL2	Nucleoplasm	DNA repair and chromatin remodeling
Anti-U1 RNP	U1RNA and related components including 70K, A, and C proteins	Nucleoplasm	mRNA splicing

tissue disease, who are almost always elderly. Non-SSc patients with ACA often lack Raynaud's phenomenon. The natural history of ACA-positive SSc patients includes long-standing Raynaud's phenomenon followed by appearance of puffy fingers. The presence of ACA in patients with Raynaud's phenomenon and/or nailfold capillary abnormalities is predictive of future development of SSc (3). Patients with ACA are often classified as having limited cutaneous SSc (lcSSc), in which skin sclerosis is restricted to distal to the elbows and knees in the presence or absence of facial skin sclerosis. Severe interstitial lung disease (ILD) or renal crisis almost never occurs in ACA-positive patients, but 10% to 20% of them develop pulmonary arterial hypertension (PAH) later in the course of the disease. Overall survival in SSc patients with ACA is better than those without, but PAH is the major cause of death in this subset.

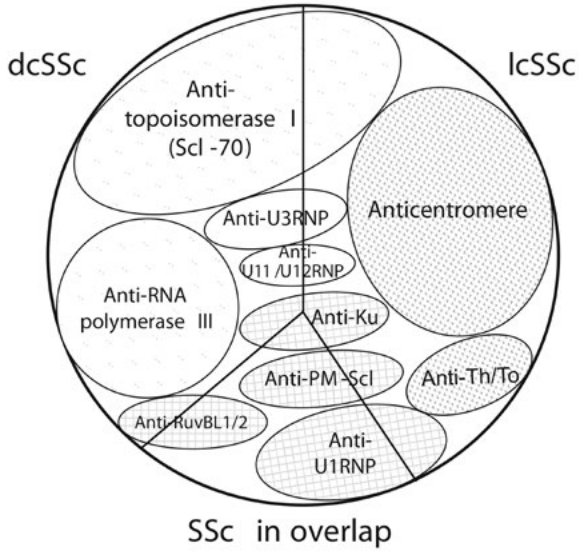

FIGURE 1 Diagram showing SSc subsets stratified by autoantibodies. Areas of individual circles represent approximate proportions in the entire SSc patients. dcSSc: diffuse cutaneous systemic sclerosis, lcSSc: limited cutaneous systemic sclerosis.

Anti-Topo I Antibody

Anti-topo I or anti-Scl-70 antibody is detected in 20 to 30% of SSc patients in many ethnic groups. The majority of anti-topo I-positive patients have diffuse cutaneous SSc (dcSSc), in which skin sclerosis extends to proximal to elbow or knee, but progression of skin thickening is slower than those with anti-RNA polymerase (RNAP) III antibody. Anti-topo I antibody is associated with a high risk for severe ILD and peripheral vascular complications, such as digital ulcers and gangrene, particularly early in the disease course. Anti-topo I antibody is considered to be a marker for poor prognosis, and patients typically die of ILD at an average of 10 years after onset of SSc.

Anti-RNAP III Antibody

Anti-RNAP III antibody often coexists with other classes of RNAP, such as RNAP I and II (4). Sera positive for anti-RNAP III antibody produce a speckled staining pattern with or without nucleolar staining on IIF. Frequency of anti-RNAP III antibody in SSc patients varies among ethnic groups: a higher frequency in North American Caucasian and British patients (20% to 25%) in comparison with French or Japanese patients (5%). Nearly all patients with this antibody have dcSSc with rapidly progressive skin thickening. Patients with anti-RNAP III antibody

TABLE 2 Methods for detection and clinical associations with SSc-related ANAs[a]

ANA specificity	Staining pattern on IF (ANA test)	Assay for detection	Disease subset	Clinical phenotype
Anticentromere (ACA)	Discrete speckled	IIF, IA	lcSSc	PAH Severe peripheral vascular disease
Anti-Scl-70	Speckled (with or without nucleolar staining)	IA, DID, IP	dcSSc	Severe ILD Severe peripheral vascular disease
Anti-RNA polymerase III	Speckled (with or without nucleolar staining)	IA, IP	dcSSc	Rapid progressive skin thickening Renal crisis
Anti-U3 RNP/ fibrillarin	Nucleolar	IP	dcSSc/lcSSc	ILD, PAH, renal crisis, small bowel disease
Anti-Th/To	Nucleolar	IP	lcSSc	ILD, PAH
Anti-U11/U12 RNP	Speckled	IP	dcSSc/lcSSc	Severe ILD
Anti-PM-Scl	Nucleolar	DID, IP	lcSSc (myositis overlap)	Mild myositis DM rash
Anti-Ku	Speckled	DID, IP	lcSSc (myositis overlap)	Mild myositis
Anti-RuvBL1/2	Speckled	IP	dcSSc (myositis overlap)	Mild myositis
Anti-U1 RNP	Speckled	IA, DID, IP	lcSSc ("MCTD")	Inflammatory arthritis, myositis, PAH

[a]DM, dermatomyositis; MCTD, mixed connective tissue disease.

have the highest risk for developing renal crisis, but they do not develop severe ILD. In many patients, skin thickening regresses over time even without treatment. Survival in patients with anti-RNAP III antibody is better than those with anti-topo I antibody since renal crisis is more easily treated with angiotensin-converting enzyme inhibitors than ILD. Several recent cohorts indicate that patients with anti-RNAP III antibody have better long-term survival rates compared with those with ACA or anti-Th/To antibody.

Anti-U3 RNP Antibody

Anti-U3 RNP antibody reacts with fibrillarin complexed with U3 RNA. This antibody produces bright nucleolar staining on IIF. Anti-U3 RNP antibody is found in 4% to 10% of patients with SSc, and is most frequent in African Americans (5). One third of the patients have lcSSc, but the remaining patients have typical features of dcSSc. Severe internal-organ involvement, including ILD, PAH, renal crisis, and small-bowel involvement with pseudo-obstruction and malabsorption is fairly common. Prognosis in this subset is comparable to that in patients with anti-topo I antibody. An unusual combination of PAH and renal crisis is occasionally found in patients with dcSSc and anti-U3 RNP antibody.

Anti-Th/To Antibody

Anti-Th/To antibody is one of SSc-related anti-nucleolar antibodies, and occurs in patients with lcSSc, although its frequency overall in SSc patients is only 2% to 5%. Like ACA-positive patients, anti-Th/To-positive patients are predominantly Caucasians, but tend to have a shorter duration of Raynaud's phenomenon before onset of other symptoms, such as puffy fingers. Digital ulcers and gangrene are infrequent, but patients with anti-Th/To antibody can have significant ILD or PAH, which occurs early in the disease course. This increased frequency and severity of pulmonary complications result in a decreased survival compared with lcSSc patients without this antibody (6).

Anti-U11/U12 RNP Antibody

Anti-U11/U12 RNP antibody is a rare antibody specificity found in 1% to 3% of patients with SSc (7). This antibody produces speckled nuclear staining on IIF, and sometimes is associated with low-titer anti-U1 RNP antibodies. Patients with this antibody are classified as having either dcSSc or lcSSc. A characteristic feature of patients with anti-U11/U12 RNP antibody is a high frequency of severe ILD, which is associated with a 2.25-fold greater risk of death

in comparison with anti-U11/U12 RNP-negative patients with ILD.

Anti-PM-Scl Antibody

Anti-PM-Scl antibody produces a homogenous nucleolar pattern, and is rarely found in non-Caucasian patients. The anti-PM-Scl-positive patients often present with the subacute onset of myositis, but also have typical Raynaud's phenomenon and scleroderma skin changes, usually lcSSc. A significant proportion of the patients have rashes consistent with dermatomyositis. This antibody is found in approximately 25% of SSc patients with myositis overlap, but in 2% of SSc patients overall. Serious internal-organ involvement is rare, leading to a favorable prognosis. Myositis is usually mild and shows a good response to moderate-dose corticosteroids.

Anti-Ku Antibody

Anti-Ku antibody is primarily detected in patients with SSc in overlap. The majority of patients have typical Raynaud's phenomenon and scleroderma skin changes, usually lcSSc. Concomitant myositis is common, but some have additional features of lupus. Anti-Ku antibody is rarely detected in patients with systemic lupus erythematosus without SSc features, but additional lupus-associated autoantibodies are always positive in such patients (8). Disease onset in these patients is usually younger than 50. Internal-organ involvement is infrequent and usually mild if present, but arthritis is common. Myositis is usually mild and shows a good response to moderate-dose corticosteroids, leading to favorable prognosis.

Anti-RuvBL1/2 Antibody

This newly identified antibody recognizes a double hexamer consisting of RuvBL1 and RuvBL2, which is located in nucleoplasm (9). Anti-RuvBL1/2 antibody is a rare antibody specificity detected in 1% to 2% of patients with SSc. This antibody produces speckled nuclear staining with a high antibody titer on IIF. Patients with this antibody have a unique combination of clinical features, including myositis overlap and diffuse cutaneous involvement. Internal-organ involvement is mild in general, but some patients develop severe myocardial dysfunction.

Anti-U1 RNP Antibody

Anti-U1 RNP antibody, which produces a pure speckled pattern with a high antibody titer, is primarily detected in patients with SSc in overlap. This antibody is preferentially detected in African Americans and Orientals. Anti-U1 RNP antibody was first described as a serologic marker for mixed connective-tissue disease. Disease onset in these patients is younger than others. The patients usually present with inflammatory symptoms, such as myositis and arthritis. Raynaud's phenomenon and puffy fingers occur early in the disease, but later these patients develop typical manifestations of SSc. Most of them have lcSSc, although approximately 20% develop dcSSc. Serious complications are relatively uncommon, but pulmonary complications, including PAH and ILD, are sometimes life-threatening. Prognosis is favorable, but PAH is the most common cause of death.

Screening of SSc-Related ANAs

A conventional method for ANA detection is IIF on cultured HEp-2 cell slides. This technique is recommended as the first ANA-screening test because it is highly sensitive and provides additional information on the antibody titer and staining pattern. Speckled staining is often detected in patients with dcSSc and suggests the presence of anti-topo I antibody in case of a high antibody titer ($\geq$1:320) or anti-RNAP III antibody in case of a low titer ($<$1:160). Anti-U1 RNP and anti-RuvBL1/2 antibodies, which are associated with SSc overlap, also produce the high-titer speckled pattern, while titers of anti-U11/U12 RNP antibody vary among the positive sera. A nucleolar pattern is fairly specific to SSc. The three major SSc-related anti-nucleolar antibodies are anti-U3 RNP, anti-Th/To, and anti-PM-Scl antibodies. Anti-RNAP III antibody also produces a nucleolar pattern when anti-RNAP I antibody coexists, but a concomitant speckled pattern is always present. A discrete speckled pattern is often detected in patients with lcSSc and suggests the presence of ACA, which recognizes a pair of dots located at the centromeric lesion of individual metaphase chromosomes. Serum dilution is an important issue for IIF used for the ANA screening. For immunofluorescence detection of ANAs on HEp-2 cells, a 1:10 or 1:20 dilution would produce a high false-positive rate from normal samples. Therefore, many clinical laboratories use a 1:40 dilution. Since the frequency of ANAs varies with age, it can be argued that a 1:160 dilution might be preferable for patients $>$65 years of age. However, this results in missing some clinically important low-titer ANAs, including anti-RNAP III antibody. It has been recommended that samples should be tested at both 1:40 and 1:160 dilutions (10).

Commercial solid-phase ANA assays have been available since the early 1990s, and might be viable alternatives to ANA detection on HEp-2 cells. This method has considerable potential, but it is of note that many SSc-related ANAs, including anti-RNAP III antibody and anti-nucleolar antibodies, are not identified with these assays, and thus are reported as "a negative ANA." This is because the sensitivity ultimately depends on the choice of autoantigens used. Therefore, it is currently recommended to use the conventional IIF for screening SSc-related ANAs.

Methods for Detection of Individual SSc-Related ANAs

Identification of individual SSc-related ANAs requires additional techniques, such as DID, IP assay, and specific immunoassays including enzyme immunoassay (EIA). The solid-phase immunoassays have several advantages over other traditional techniques in terms of simplicity, reproducibility, quickness, and ability to handle many samples at the same time. Typically, in immunoassays, the wells of plastic microwell strips are sensitized by passive absorption with the purified autoantigen. The test procedure involves three incubation steps with properly diluted test sera, enzyme-conjugated anti-human immunoglobulin antibodies, and an enzyme substrate. After the reaction is stopped, the color intensity of the solution is measured photometrically. The majority of commercially available immunoassays utilize recombinant autoantigens, which are expressed in the bacterial or eukaryotic system, while some assays still use native proteins purified from cellular extracts. However, solid-phase assay requires the availability of highly purified autoantigens that contain the major epitopes recognized by virtually all sera positive for given SSc-related ANAs. This is a critical limitation for developing immunoassays. For example, it is easy to prepare topo I as an antigenic source for immunoassays because the autoimmune target is a single molecule. However, the majority of autoantigens recognized by SSc-related ANAs are multiprotein complexes consisting of many constituents, and, in some cases, small RNAs. In this case, it is necessary to determine the antigenic subunit that is commonly recognized by autoantibodies. For example, RNAP III

exists as multiprotein complexes consisting of >12 subunits, requiring identification of the antigenic subunit recognized by all anti-RNAP III-positive sera. A series of experiments using individual subunits successfully identified the largest subunit RPC155 as the antigenic subunit, resulting in development of a sensitive immunoassay (11). Immunoassays for detection of ACA, anti-topo I, anti-RNAP III, and anti-U1 RNP antibodies are currently available in many countries (Table 3). Due to lack of comprehensive studies that compare sensitivity and specificity of individual commercial kits, it is not known which kit is the best.

EIA or enzyme-linked immunosorbent assay (ELISA), which uses enzyme-conjugated secondary anti-human immunoglobulin antibodies, has been the mainstream technique, but commercial kits utilizing chemiluminescent immunoassay (CIA) and fluorescence enzyme immunoassay (FEIA) have become available in recent years. CIA potentially shows a superior discrimination (signal-to-noise ratio) between the positive and negative samples (12). FEIA is a new assay system designed as a sandwich immunoassay. In this system, the enzyme conjugated to secondary antibodies transforms an added substrate into a fluorescent product.

		Zeus Scientific	AtheNA Multi-Lyte ANA III

A recent study evaluating the sensitivity of a commercial autoantibody-screening method (EliA CTD screen, Thermo Fisher Scientific) revealed that the sensitivity is insufficient for the assay to be used as a screening test for anti-U3 RNP and anti-RNAP III antibodies, but appears to be satisfactory for ACA, anti-topo I, anti-PM-Scl, and anti-U1 RNP antibodies (13).

Assay Procedures of Immunoassays

Most commercial EIA kits contain the following components: antigen-sensitized microplates (usually 96-well plates), positive and negative control sera, serum calibrators, conjugated anti-human immunoglobulin antibodies, sample diluent, enzyme substrate, reaction-stop solution, and washing-buffer concentrate. Here is a general procedure, but instructions are somewhat different among kits. It is highly recommended to follow the instructions provided by the manufacturer.

1. Remove the individual components from storage and allow them to warm to room temperature (20–25°C).
2. It is better to use the entire kit all at once. When the number of samples is insufficient, some commercial kits allow use of a portion of the package. In this case, allow the required number of control/calibrator determinations, including blank, negative control, positive control, and calibrators. Return unused reagents to 4°C immediately after use.
3. Dilute serum samples as well as positive and negative control sera, and serum calibrators as indicated.
4. Incubate the plate at room temperature for the designated time period.
5. Wash the microwell strips either by manual or automated wash procedure. If necessary, the microwell plate may be inverted over a paper towel and tapped firmly to remove any residual wash solution from the microwells.
6. Add the conjugate solution to each well at the same rate and in the same order as the specimens were added.
7. Incubate the plate at room temperature for the designated time period.
8. Wash the microwells by following the procedure previously described in step 5.
9. Add substrate to each well, including reagent blank well, at the same rate and in the same order as the specimens were added.
10. Incubate the plate at room temperature for the designated time period.
11. Stop the reaction by adding stop solution to each well, including the reagent blank well, at the same rate and in the same order. Tap the plate several times to ensure that the samples are thoroughly mixed.
12. Set the microwell reader to read at the designated wavelength and measure the optical density of each well against the reagent blank. The plate should be read within 30 minutes after the addition of stop solution.
13. Calculate the autoantibody level as an index or unit according to the instruction. A cutoff value for positive samples is usually provided by the manufacturer.

Precautions

The human-serum controls are potentially hazardous materials despite the absence of known infectious agents such as HIV-1 and hepatitis B and C viruses. Adherence to the specified time and temperature of incubations is essential for accurate results. Ideally, serum samples that have been freshly collected should be used. Storage at 4°C is sufficient for samples analyzed up to a week after collection, while for longer periods storage at −20°C is preferable. Frequent thawing and freezing of the sample may lead to a decrease of the antibody activity. Addition of sodium azide (10 to 100 μg/ml) is recommended for storage for more than a month.

Quality Assurance, Quality Control, and Test Validation

It is best to assess the intra-assay and inter-assay variability of the test procedure. Specifically, a strong positive, a low positive, and a negative sample should be tested many times (usually at least 6) on each of three days. The coefficient of variance should be calculated for each sample, and it should be ≤10%. A positive and negative control, and reagent blank must also be included in each assay. At least one positive-control serum is included in the kit, but positive reference sera are also available from the Centers for Disease Control and Prevention (AF-CDC ANA Reference Lab, Immunology Branch, 17-3040, A25, Centers for Disease Control and Prevention, Atlanta, GA 30333) and commercially. It is convenient to develop a set of in-house positive and negative standards. Once appropriate sera are found, try to obtain a large amount (>10 ml) of each in order to maintain a stock that can be used over a period of several years. The antibody levels of each reference serum should be recorded to assess reproducibility. There are several national, international, and commercial quality-assurance schemes, including The College of American Pathologists (available at http://www.cap.org/) and The United Kingdom National External Quality Assessment Schemes for Autoimmune Serology (available at http://www.ukneqas.org.uk/). These schemes are widely used and cover the common autoantibodies. Samples are issued several times a year and a consensus report is produced so that individual laboratories can compare their performance with that of other participants.

Interpretation of Results

Results of immunoassays are not always reliable, although for the majority of commercial kits sensitivity and specificity are both >95%, in comparison with results measured by the gold-standard assay. One of the main reasons for false-negative results is insufficiency or lack of antigenicity of the antigens used for the assay. This is particularly the case in measurement of anti-topo I and anti-RNAP III antibodies. In some patients' sera, these antibodies recognize conformational epitopes present on native molecules alone. On the other hand, contaminants in the antigen preparation may cause the false-positive results. It has been previously reported that sera with anti-DNA antibodies occasionally provide a false-positive result on some anti-topo I antibody-assay kits because of contamination of native DNA in the purified topo I antigen preparation. This is not a problem anymore since nearly all commercially available immunoassays now utilize recombinant topo I as antigen. Specimens that give equivocal results should be repeated or evaluated using an alternate technique, such as DID and IP assay.

Multiplex Technologies for Detection of SSc-Related ANAs

During the last 20 years, several multiplex technologies have been developed and used in laboratory medicine (14). Line-blot immunoassay (LIA) is considered as the first-generation multianalyte immunoassay, and is commercially available for detection of a series of SSc-related ANAs

(EUROLINE, Euroimmune) (15). This system adopts the principle of immunoblots, in which membrane strips are coated with thin parallel lines of a panel of purified antigens. It can be performed manually, but automated systems have become available. LIA is principally a non-quantitative assay, but the intensity of the bands is shown to correlate with the antibody titer. The software has been developed to enable quantitative evaluation of test strips, to facilitate management of data, and to provide detailed documentation of results. One study reported that sensitivity and specificity of LIA were similar to those of immunoassays (EIA and FLIA) in terms of detection of ACA and anti-topo I antibody (16).

ANA-screening technology has become available as the next-generation multianalyte immunoassays based on multibead arrays, which can be measured by the newest flow cytometers, e.g., Luminex system (Luminex) and FACSarray (BD Biosciences) (17). Such systems allow for the screening of samples while at the same time providing semi-quantitative results on individual specificities for positive samples. However, the multiplex platforms are limited by their dependence on the autoantigens of choice. Currently, ACA and anti-topo I and anti-U1 RNP antibodies can be measured using commercially available platforms (18). Due to the infancy of multiplex systems, it is difficult to predict their impact on the preeminence of the conventional immunoassay.

Detection of Minor SSc-Related ANAs

At this moment, only a few research laboratories can identify a whole panel of SSc-related ANAs, because this can be done only by use of a cumbersome IP assay. Commercially available immunoassay kits are able to detect ACA, anti-topo I, anti-RNAP III, and anti-U1 RNP antibodies, but up to 20% of sera positive for known SSc-related ANAs will be missed. A recently developed LIA system is able to detect anti-U3 RNP, anti-Th/To, anti-PM-Scl, and anti-Ku antibodies (19), but side-by-side comparisons with the gold-standard IP assay have never been done. Our preliminary evaluations revealed that there may be some problems in sensitivity for detecting anti-U3 RNP and anti-Th/To, and in specificity for detecting anti-RNAP III, anti-PM-Scl, and anti-Ku antibodies. In this situation, old-fashioned DID is still useful for detection of anti-PM-Scl and anti-Ku antibodies. All SSc-related ANAs except ACA can be detectable by IP assays combined with electrophoretic detection of RNA and protein components, but availability of these techniques is restricted to special laboratories because of a complicated procedure involving a radioisotope. The RNA-IP assay was originally developed using ^{32}P-labeled cultures cells, but utilization of sensitive silver staining has enabled us to avoid use of radioisotope (20). This assay is capable of detecting anti-U3 RNP, anti-Th/To, and anti-U11/U12 RNP antibodies with high sensitivity and specificity, although identification of anti-RuvBL1/2 antibody still requires a protein-IP assay using ^{35}S methionine-labeled cultured cells. Recently, an immunoassay was developed to measure anti-Th/To antibody using Rpp25, one of the components of the Th/To complex, as an antigen (21). Anti-Th/To antibody detected by this immunoassay showed excellent agreement with anti-Th/To antibody detected by RNA-IP assay. An outline flowchart for identification of SSc-related ANAs including minor ones is shown in Fig. 2.

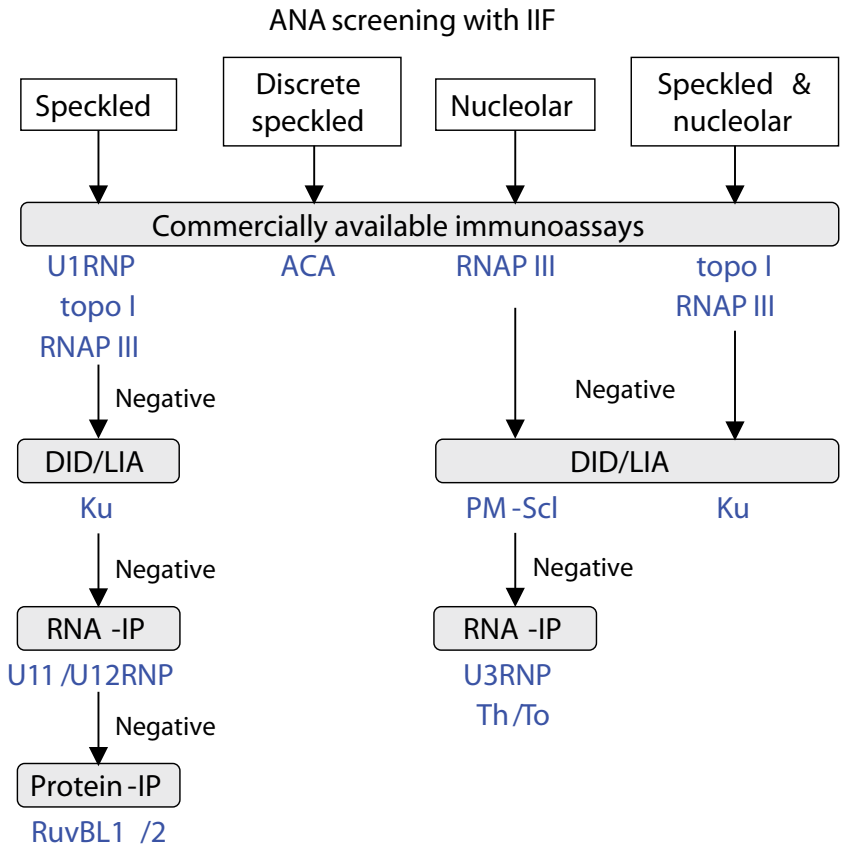

FIGURE 2 An outline flowchart for identification of SSc-related ANAs including minor ones.

TABLE 4 The American College of Rheumatology/European League Against Rheumatism criteria for the classification of SSc

Item	Sub-item(s)	Weight/ score
Skin thickening of the fingers of both hands extending proximal to the metacarpo-phalangeal joints	—	9
Skin thickening of the fingers (only count the higher score)	Puffy fingers Sclerodactyly of the fingers	2 4
Fingertip lesions (only count the higher score)	Digital tip ulcers Fingertip pitting scars	2 3
Telangiectasia	—	2
Abnormal nailfold capillaries	—	2
PAH and/or ILD (maximum score is 2)	PAH/ILD	2
Raynaud's phenomenon	—	3
SSc-related autoantibodies (maximum score is 3)	ACA Anti-topo I Anti-RNA polymerase III	3

[a]These criteria are applicable to any patient considered for inclusion in an SSc study. The criteria are not applicable to patients with skin thickening sparing the fingers or to patients who have a scleroderma-like disorder that better explains their manifestations. The total score is determined by adding the maximum weight (score) in each category. Patients with a total score of ≥9 are classified as having definite SSc.

CLINICAL SIGNIFICANCE OF MEASURING SSc-RELATED ANAs

Over the past decade, many studies have confirmed a strong association between ANA specificities and unique clinical phenotypes in SSc (1). However, it remains uncertain whether these autoantibodies play a direct pathogenic role or merely represent markers of particular disease manifestations. Measurement of SSc-related ANAs is essential in the clinical management of SSc patients. Because of the highly specific nature of SSc-related ANAs, their detection is useful in the diagnosis of SSc. In this regard, the presence of ACA, anti-topo I, or anti-RNAP III antibody is included in one of the criteria domains of a new classification system for SSc, which has been proposed by the American College of Rheumatology and the European League against Rheumatism (Table 4) (22). However, it is of note that a diagnosis should not be made solely on the basis of autoantibody-test results. Clinical features and prognosis in SSc patients are remarkably heterogeneous and grouping patients based on autoantibody profiles is a useful approach for clinicians. For example, the presence of anti-topo I antibody predicts future development of severe ILD; in contrast, patients with ACA should be monitored closely for development of PAH. It is generally believed that serial measurement of the antibody titers of SSc-related ANAs is not useful for assessment of disease severity and activity.

Antibody and Biomarker Testing in Rheumatoid Arthritis

ANN DUSKIN CHAUFFE AND MICHAEL RAYMOND BUBB

92

Rheumatoid arthritis (RA) is a chronic systemic disease characterized by autoimmune-mediated joint destruction. RA affects 1% of the global population with a predilection for females. The pathogenesis of RA has not been fully elucidated; however, it is thought to be due to an environmental trigger stimulating an immune response in a genetically susceptible host. The resultant inflammatory cascade mediates synovial proliferation and ultimately joint destruction. Disease expression is not limited to the joints. Extra-articular manifestations occur in the lungs, eyes, skin, and the cardiovascular system culminating in significant morbidity and premature mortality (1). Moreover, numerous studies show substantial irreversible joint damage occurs within the first 2 years of disease onset. Thus, early diagnosis and aggressive treatment is paramount in preventing morbidity and mortality (2).

Risk factors associated with RA include female sex, Caucasian race, and tobacco use (3). Familial studies have also identified specific human leukocyte antigen (HLA) genotypes associated with disease development. HLA-DR4 has been recognized for more than 20 years as a risk factor. More recent data suggests a stronger association with particular DR4 alleles known as the "shared epitope," which confers the risk for more aggressive disease.

In 1958, the American Rheumatism Association developed a classification criterion for RA. This was revised by the American College of Rheumatism (ACR) in 1987. Importantly, the 1987 criterion was designed to identify a uniform population of patients with RA for research purposes. The criterion is effective at distinguishing between established RA and other arthritides, as most of the patients studied had long-standing disease. The utility of the diagnostic criterion was limited in clinical practice because it was not helpful in identifying early disease. Two of the seven criteria, nodules and radiographic changes, are infrequently evident early in the disease but rather accumulate with time. Additionally, the more recent discovery of an antibody that is highly associated with RA, anti-cyclic citrullinated peptide antibody (ACPA), was not part of the original criterion, as it had not been identified. In 2010 the ACR and the European League Against Rheumatism (EULAR) sought to rectify these issues and developed a new criterion with the express purpose of aiding in identifying early RA. The 2010 criteria includes a point system with the presence of synovitis in a pattern suggestive of RA, rheumatoid factor (RF) and ACPA serologic positivity, elevation of inflammatory markers (CRP and ESR), and duration of symptoms greater than 6 weeks. A score of at least 6 of 10 possible points from all four domains indicates RA (4). To date of this publication, studies have generally shown superiority of the 2010 criteria in identifying early RA while failing to identify the so-called "seronegative" patients, those lacking RF and ACPA. Thus, RF and ACPA seropositivity have been identified as independent predictors of disease development. Moreover, the presence of these antibodies also portends a more aggressive disease phenotype (5). A newer laboratory test, the multi-biomarker disease activity (MBDA) score, measures 12 proteins and has also been found to correlate with RA disease activity (6). The remainder of this chapter will further explore the array of diagnostic testing and serologic markers in RA.

RHEUMATOID FACTOR

Rheumatoid factor (RF) is an antibody that was first described by Waaler in 1939 when he noted that sera from RA patients caused agglutination of sheep erythrocytes coated with rabbit antibodies (7). RF was later found to be an antibody directed against the Fc portion of human IgG. RF-IgG immune complexes deposit in tissues and activate the classical complement pathway, perhaps contributing to the extra-articular manifestations of RA. Although RF may be IgG, IgM, IgA, or IgE, the IgM isotype is the most commonly measured in commercial assays. RF has a sensitivity of 68 to 81% and a specificity of 60 to 85% in RA (8). As previously mentioned, RF has prognostic value in RA. In general, RF-seropositive patients have a more aggressive joint disease course, as well as increased extra-articular manifestations, such as nodules and vasculitis (8). There are some reports that RF isotypes other than IgM are associated with particular disease manifestations, but these findings have not been widely applied in clinical testing. In the context of drug trials, a decrease in IgM-RF titers has been shown to correlate with clinical response, and serial measurements may be helpful in guiding response to treatment with disease-modifying anti-rheumatic drugs. Finally, loss of RF positivity confers improved prognosis (9).

However, RF has been identified in a host of other autoimmune conditions, such as Sjögren's syndrome, systemic lupus erythematosus (SLE), vasculitis, and idiopathic pulmonary

doi:10.1128/9781555818722.ch92

fibrosis. RF is also seen in 3 to 5% of young healthy individuals, as well as 10 to 30% of elders in good health (10). Tobacco smokers have also been found to have chronically elevated RF titers. Longitudinal data indicates that smoking a little as six to nine cigarettes per day for more than 20 years increases the risk of developing seropositive RA. In one study, female smokers had an odds ratio of 1.7 (95% confidence interval [CI], 1.2–2.3), while male smokers had an odds ratio of 1.9 (95% CI, 1.0–3.5). The risk of developing RA was proportionate to smoking intensity while the increased risk of RA was conserved for 10 to 19 years after cessation (11).

Clinical Interpretation of Rheumatoid Factor

Rheumatoid factor (RF) is a serological marker for RA. Although RF seropositivity is frequently misinterpreted as indicative of the diagnosis of RA, it is not, and the specificity of RF is limited to ~60%. The diagnosis of RA must include a consideration of clinical context that factors in pretest probability based on Bayes' theorem (12). Patients with other autoimmune diseases (Sjögren's, vasculitis) are often seropositive for RF. Interestingly, RF-positive Sjögren's patients have a worse prognosis, and significant changes in RF titer should alert the clinician to the development of lymphoma. It is important for the clinician to keep in mind that RF is often seen in other malignancies, such as Waldenström's macroglobulinemia, non-Hodgkin's lymphoma, other B-cell malignancies, and chronic lymphocytic leukemia, as the patients acquire monoclonal gammopathies with RF activity. RF seropositivity is also common in infections such as tuberculosis, leprosy, osteomyelitis, syphilis, bacterial endocarditis, infectious mononucleosis, and, most notably, hepatitis C virus (HCV) (13). The prevalence of RF in the HCV population is estimated to be 50%, but few patients have arthritis. RF is the major constituent of mixed cryoglobulins, which are often found in HCV patients. The cryoglobulins, or RF immunoglobulin-complement complexes, precipitate out of the serum in cool temperatures, leading to small vessel vasculitis. The typical manifestations include arthralgias, purpuric or ulcerative skin lesions, and membranoproliferative glomerulonephritis (14). Finally, RF frequently is positive in a substantial portion of the healthy population, particularly the elderly (10).

In RA, most patients are seropositive for RF within 6 months of onset of symptoms; however, studies have also identified seropositivity years prior to disease onset. RF functional avidity changes over time and persistently high levels of RF have been shown to be associated with more severe radiographic joint destruction. Although not often followed clinically, RF titers may correlate with RA disease activity. Changes in the RF concentration can reliably be measured by nephelometry and enzyme-linked immunosorbent assay (ELISA), but not agglutination (15).

ANTIBODIES AGAINST CITRULLINATED PROTEINS

Several apparently distinct autoantibodies have been described in RA over the last few decades. Gradually, several of these autoantibodies have been identified as recognizing related determinants containing peptides that have post-translational modification of the amino acid arginine to citrulline by enzymatic citrullination. These antibodies include anti-perinuclear factor (APF), anti-keratin antibody (AKA), anti-filaggrin (AFA), anti-Sa, and the synthetically produced anti-cyclic citrullinated peptide. Collectively, these antibodies are referred to as ACPAs, or anti-citrullinated protein antibodies (16).

Citrullination

Citrulline is produced when the enzyme peptidyl-arginine deiminase (PAD) modifies arginine with a corresponding change in charge from positive to neutral. There are four related isoforms of PAD in humans which can citrullinate arginine, and some proteins have a higher affinity for citrullination by the various isoforms of PAD. Moreover, the amino acids neighboring arginine residue influence its susceptibility to citrullination (17).

Citrullination is a normal physiological process that typically occurs in dying cells. The immune system does not typically encounter citrullinated proteins as these apoptic cells are quickly ingested by clearing cells such as macrophages. Several hypotheses are generally reported to explain the evolution of citrullinated antibodies in RA. In the first hypothesis, the immune trigger is due to inefficient or inadequate clearance of PAD enzymes and citrullinated proteins in highly inflammatory states. In support of this hypothesis, studies have identified citrullinated proteins at inflammatory sites (18).

An alternative hypothesis attributes citrullinated antibody production to aberrantly expressed PAD. The increased PAD generates additional citrullinated antigens in the synovium, thereby supplying the opportunity for immune recognition and stimulation. Studies have demonstrated genetic polymorphisms in one of the PAD genes (19). Moreover, this same PAD haplotype, PADI4, has been associated with RA susceptibility (17, 19).

A final theory suggests that citrullinated proteins are not pathologic. Rather, RA patients develop an abnormal humoral response to these proteins. Interestingly, citrullinated proteins have been identified in the synovium of RA patients, as well as in patients with osteoarthritis and reactive arthritis. There is strong evidence of a genetic predisposition to the development of citrullinated antibodies (20). This will be further discussed below in the Genetics section.

Specific Antibodies Against Citrullinated Proteins

APF was identified in 1964 when human buccal mucosal cells were evaluated under indirect immunofluorescence. In 1979, AKA was identified similarly as an IgG directed against rat esophageal epithelium. It was not until 1995 that APF and AKA were found to have a shared specificity for a cytokeratin-filament aggregating protein, filaggrin, and were designated AFA (21). Since then, the shared specificity was found to be more related to citrullination than the target protein. A diverse number of synthetic cyclical citrullinated peptides bind AFA, including 20 different epitopes on profilaggrin and the α- and β-chains of fibrin. AFA was found to be highly specific, 92 to 99%, for RA and present at disease onset. AFA testing has not been widely available as the original immunofluorescence assay was laborious and difficult to standardize. However, a more recently developed ELISA to the major epitopes of filaggrin has addressed this by providing automation and standardization (20).

In 1998, a synthetic antigen was developed for detection of citrullinated proteins known as ACPA. The synthetic antigen conformation was chosen to optimize antibody sensitivity and specificity and is not the natural antibody determinants. The cyclic conformation enables more efficient recognition of the citrullinated epitope by the antibody. The first-generation ELISA assay, anti-CCP1, used a filaggrin-derived cyclic peptide as the antigenic substrate. It had outstanding specificity for RA, 95%, but lacked in sensitivity, 53% (20). In 2002, a second-generation assay (anti-CCP2) was developed after screening 12 million peptides from dedicated synthetic peptide libraries against RA

sera. The best citrullinated peptides were incorporated into a new format and the assay captured the antigenic determinants for APF, AKA, AFA, and anti-CCP1. Anti-CCP2 has been found to have a greater sensitivity, 68%, than anti-CCP1 in diagnosis of RA. Moreover, there was no loss of specificity; 98% (20). A third-generation assay, anti-CCP3, was designed by combinatorial peptide engineering and contains multiple citrullinated epitopes displayed in a conformational structure to increase epitope exposure and thus immunoreactivity, particularly for early RA. The sensitivity of anti-CCP3 is slightly superior to anti-CCP2. Finally, another assay, anti-CCP3.1, has been developed to include the IgA isotype of anti-CCP to the standard IgG assay. The addition of IgA increased the sensitivity by 4.3% over anti-CCP2 (22).

Another autoantibody, anti-Sa, was named for the French-Canadian patient in which it was first identified. Anti-Sa was later found to react with citrullinated vimentin. Vimentin is a cytoskeletal protein widely expressed by macrophages and mesenchymal cells. It is modified in macrophages undergoing apoptosis and antibodies are thought to be generated when there is delayed clearance. Vimentin has been identified in the human placenta, spleen and, notably, in the pannus of rheumatoid patients (23). Likewise, anti-Sa is often found in patients with severe articular disease. In one study, anti-Sa was found to be three times more prevalent in patients with a highly destructive RA phenotype. Anti-Sa is least sensitive in early RA as titers increase as the disease progresses. Research has also demonstrated that the presence of anti-Sa predicts higher joint counts and requires more aggressive treatment (24).

As the technology for citrulline antibody testing evolves, new assays are being developed. One such test is the mutated (or modified) citrullinated vimentin, anti-MCV. An ELISA assay has been developed for anti-MCV but a systematic review found anti-MCV to have similar sensitivity to ACPA in the diagnosis of RA (25); however, anti-MCV has been identified in ACPA-seronegative RA patients. Thus, it may be useful in identifying RA in seronegative patients. Of particular interest in monitoring disease activity, one study found that anti-MCV titers decreased in conjunction with DAS-28 in patients receiving infliximab (26).

Fibrin binding globulin (FBG) is a glycoprotein found in blood plasma that is also a target of citrullination. During inflammation, the concentration of FBG increases from ~3 mg/ml to more than 7 mg/ml (27). It is hypothesized that the deimination of FBG that has been found in inflamed RA joints may be mediated by PAD (18, 19). Anti-FBG has not been widely studied outside of animal models, so its significance is not well characterized (27).

ACPA Clinical Significance

Testing for ACPA is now widely practiced, as about 35 to 40% of RF-negative RA patients are seropositive for ACPA (28). Likewise, there is a voluminous literature demonstrating the clinical significance of ACPA in RA (2, 28). Multiple studies have found ACPA to be more specific for RA than RF. Overall, the sensitivity and specificity of ACPA is ~60% and 95%, respectively. Moreover, ACPA seropositivity has been identified in healthy blood donors years before clinical disease activity was identified, demonstrating its positive predictive value in RA (29). Seropositivity for ACPA has also been associated with a heightened risk of destructive joint disease (28). The utility of ACPA for monitoring response to RA treatment is controversial. Levels for ACPA may decrease early in disease if prompt treatment is instituted. Although the literature is not completely clear, the preponderance of data suggests that patients with established RA do not experience sustained decreases in ACPA titers (26).

OTHER ANTIBODIES ASSOCIATED WITH RA

Anti-glucose-6-phosphate isomerase (anti-GPI) has been recognized in 64% of RA patients. Anti-GPI appears to be produced in the synovium, as titers have been found to be higher in the synovial fluid than the sera. Interestingly, anti-GPI has been identified in T-cell receptor-transgenic mice. Moreover, passive transfer of anti-GPI to healthy mice resulted in arthritis (30).

Anti-calpastatin antibodies have also been reported in RA. Calpains are ubiquitous calcium-dependent proteases. There are a diverse number of substrates for these enzymes, including cytoskeletal, nuclear, and extracellular proteins. Some researchers theorize that calpains play a role in cartilage destruction, as they have been identified in inflamed synovium (31). Calpastatin is the natural inhibitor of calpains. Thus, an antibody to calpastatin increases the protease. Immunoblot testing for anti-calpastatin has identified the antibody in 45% of RA patients, but also identified it in patients with SLE, myositis, and systemic sclerosis, as well as healthy controls (32).

Another antibody associated with RA is anti-RA33, an antibody to heterogeneous nuclear ribonucleoprotein A2. Anti-RA33 is found in approximately 35% of RA patients and is thus less specific than ACPA or RF in diagnosing RA. In one study it was also identified in 20% of SLE and 40% to 60% of mixed connective tissue disease patients. Interestingly, anti-RA33 has been identified in RF- and ACPA-seronegative RA patients. Moreover, anti-RA33 has been identified in early RA. Longitudinal studies have found patients with anti-RA33 to have a good prognosis, having less radiographic destruction than patients who are seropositive for ACPA or RF (33).

Binding immunoglobulin proteins (BiP) are molecular chaperones located in the lumen of the endoplasmic reticulum (ER), which play a critical role in maintaining cellular homeostasis. One such BiP is the 78-kDa glucose-regulated ER chaperone which has been identified as an autoantigen in RA (anti-BiP). This particular BiP is overexpressed in the synovium of rheumatoid joints, and anti-BiP has been identified in early and pre-disease sera. In addition, some have theorized that BiPs also have immunomodulatory properties and may represent a future therapeutic target (34).

ANTIBODIES LESS SPECIFIC FOR RA

A variety of other antibodies are seen in the sera of RA patients. However, these other antibodies are not very specific for RA. These include anti-collagen type II, antifibronectin, and anti-neutrophil cytoplasmic antibodies, which will be briefly discussed for the sake of completeness.

Antibodies against collagen type II (anti-CII) have been found in 30% of RA patients. Unfortunately, anti-CII has been found in nearly 50% of relapsing polychondritis, 20% of SLE, 15% of systemic sclerosis, and in 50% of those with leprosy. Thus, it is not specific for RA (35). Antifibronectin is a glycoprotein that interacts with collagens and adhesion molecules. Antifibronectin antibody has only been identified in 14% of RA patients, while being identified in 34% of SLE patients, thus it is not a good marker in RA (36). Anti-cytoplasmic antibodies are most notably associated with vasculitis. However, they were first identified in the sera of an RA patient and can be found in up to 30% of RA

TABLE 1 Summary of well-characterized autoantigens in rheumatoid arthritis

Class	Autoantigen
Citrullinated proteins	ACPA, Sa, vimentin, filaggrin, fibrin binding globulin
Articular cartilage	Collagen II
Serum protein	RF
Nuclear components	RA33
Enzymes	Calpastatin, glucose-6-phosphate isomerase
Stress protein	BiP
Glycoprotein	Fibronectin

patients, as well as in other autoimmune conditions and in a variety of infections (37). Table 1 summarizes the autoantigens associated with RA.

TESTING METHODS

There are several assays used to identify antibodies (Table 2). The original method of RF identification employed visible particle agglutination of human or rabbit IgG bound with a variety of substrates, including erythrocytes, latex, and charcoal. Another method, laser nephelometry, utilizes light scatter by latex particles coated with IgG. Finally, ELISA utilizes either the human or rabbit Fc region of IgG to bind the various RF subtypes (38). The latter two approaches are better suited for automation and consequently represent the bulk of commercially available testing. The antigen source for most RF assays is usually gamma globulin pools from humans, rabbits, or cattle. The various species' IgG fractions differ in RF binding capacity leading to result variability. The most commonly used IgG source is rabbit because it is more specific, although less sensitive, for RA when compared to other species (39).

Agglutination

The classical agglutination assay, the Waaler-Rose test, utilized sheep erythrocytes coated with rabbit IgG. If RF was present, the erythrocytes agglutinated (40). Testing was originally performed in test tubes with agglutination prompted by temperature-controlled incubation and centrifugation. A more rapid method involves quantification of agglutination on a glass slide, negating the need for incubation and centrifugation. IgM antibodies are more efficient in agglutination reactions, so it is most sensitive for the IgM RF isotype. The RF content is reported at the last doubling dilution at which agglutination can be visualized. The reciprocal of this dilution is known as the antibody titer. A major limitation of this method is the significant inconsistency in reported results due to condition variability and the subjective nature of determining when agglutination ceases (41).

Nephelometry

Laser nephelometry utilizes an antigen, heat-aggregated or chemically cross-linked IgG aggregates, which form antigen-antibody complexes. A beam of light is then passed through tubes containing fixed amounts of antibody and variable concentrations of antigen. The light scatter is a result of the formation of the concentration of immune complexes. Latex methods utilize IgG-coated latex particles, but again measure light scatter. Nephelometry is commonly used because it is automated and provides reliable results (15).

ELISA

ELISAs measure the amount of immunoglobulin that binds to target IgG absorbed to a solid phase, usually a polystyrene microtiter plate. Microwells are coated with the antigen, human IgG, and patient serum is added allowing the patient's RF to form antigen-antibody complexes. Unbound serum proteins are removed by washing the microwells. Enzyme-conjugated anti-human IgM (or IgG for IgG RF) is added to the wells. The enzyme conjugate binds to the antigen-antibody complex, and excess conjugate is washed away. Addition of a specific substrate begins a hydrolytic reaction with the bound enzyme conjugate, causing color

TABLE 2 Comparison of antibody assays

Assay	Equipment expense	Automation	Interlaboratory precision	Interferences	Sensitivity
Sheep cell agglutination	Low	No	Low	C1q, anti-rabbit IgG, anti-sheep erythrocytes	Low
Latex-fixation agglutination	Low	No	Low	C1q, fibrin	Medium
Nephelometry	High	Yes	High	Fibrin, cryoglobulins, other immune complexes if assay is polymer enhanced	High
ELISA	Moderate to high	Variable	Moderate	Nonspecific plastic binders heterophilic antibodies	High
Multiplex immunoassay	High	Yes	Moderate	RF, heterophilic antibodies	Medium

development. The intensity of the color change is proportional to the amount of IgM (or IgG) RF antibody. A spectrophotometer analyzes the result, which is expressed in international units per milliliter (IU/ml). There may be nonspecific binding of serum IgG to the plastic wells, a phenomenon known as "background binding." This is overcome by subtracting the optical density from wells that are blocked but not coated with antigen. In general, ELISA testing is considered reasonably precise (42).

Calibration

To promote consistency in IgM-RF identification, the World Health Organization (WHO) or the Centers for Disease Control and Prevention provide sera for nephelometer and ELISA calibration. The WHO standard does not contain IgG or IgA, so cannot be used for IgG or IgA RF. Each assay should be run with control sera; ideally, the control should detect one negative and two positive sera, one at a low positive cutoff and the other at a high positive cutoff (43). The WHO standard was developed in 1970 and its activity was projected to decrease by 50% over 8 years. However, it is not clear just how long the calibration sera is good for with ranges reported from 1 to 250 years (44).

Shortly after the first ELISA for ACPA was developed, multiple companies developed their own assays. Likewise, there is variance in the antigens utilized, making it difficult to compare the results. Euro-Diagnostica has proposed a freeze-dried standardized reference serum to the International Committee. The selected serum was tested in 12 commercially available ELISA-ACPA kits. Sera from 20 RA patients with variable antibody concentrations were analyzed, and the relative concentrations were calculated using both the kit's own curve and the six dilutions of the reference serum as a calibration curve. Additionally, sera from 50 healthy controls were used as cutoff values for the reference serum. Utilizing the reference serum led to significant reduction in variability of the results. The mean coefficient of variation (CV) was reduced from 76.4% to 27.9% ($P = 0.018$) and from 85.9% to 33.5% ($P = 0.028$) for the medium/high and negative samples, respectively. Low positive sera CV was also reduced, but to a smaller degree, from 82.5% to 55.5% ($P = 0.043$). Thus, this reference serum may be used in the future to establish a calibration curve and reduce the dispersion of antibody values, while allowing comparison of results from different manufacturer assays (45).

Multiplex Testing

Multiplex immunoassays test multiple antibodies simultaneously from the same specimen sample. Multiplex testing typically utilizes combinations of non-human-derived analyte-specific antibodies. Bead-based immunoassays can test up to 96 targets at once. A similar assay, cytometric bead assay (CBA), is based on membrane-based ELISA technology. Both of these techniques enable testing of multiple antibodies from one small-volume sample. Though these methods are efficient, there are technical concerns regarding the use of antibody-based technology in RF-positive RA. RF has specificity for antigenic epitopes on Fc portions of IgG. In states such as RA, where there are high titers of RF, there is the potential for RF interference. Excess RF can bind to the antibodies used to detect them, resulting in analyte-independent signaling. Heterophilic antibodies also have the potential to bind with analyte antibodies. Techniques to minimize the confounding effects of RF and heterophilic antibodies include blocking of IgG and IgG removal with PEG 6000 (Fluka). However, evaluation of bead-based multiplex assays with interference removing techniques has revealed high numbers of false positives. Not surprisingly, the low specificity was found to correlate with interfering antibody titers, with titers greater than 100 IU/ml escaping the interference removal mechanism. Surprisingly, the cytometric bead assay was not affected by the presence of RF, but the sensitivity of the assay was found to be quite low, missing true positives (46).

Multi-Biomarker Disease Activity Analyses

A multiplex assay has been developed to simultaneously measure multiple biomarkers of RA disease activity, with the result summarized in a single score from 1 to 100. This assay, known as Vectra DA (Crescendo Bioscience, California), measures 12 serum proteins to calculate an MBDA score. The 12 chosen biomarkers were screened from 396 candidate markers identified in 1900 RA sera samples. Biomarkers utilized were validated against disease activity scores (DAS28) (6). The selected biomarkers include: adhesion molecule, vascular cell adhesion molecule 1 (VCAM-1); growth factors, epidermal growth factor (EGF) and vascular endothelial growth factor A (VEGF-A); cytokine-related proteins, interleukin 6 (IL-6) and tumor necrosis factor receptor type I (TNF-RI); matrix metalloproteinases (MMP), MMP-1 and MMP-3; skeletal-related protein, human cartilage glycoprotein 39 (YKL-40); hormones, leptin and resistin; acute-phase proteins, serum amyloid A (SAA) and C-reactive protein (CRP). As would be expected from the additional information, the MBDA performs as well as or better than the CRP alone when assessing the level of RA activity over time and predicting radiographic progression (47). However, longitudinal follow-up is needed to assess the long-term effect of lowering MBDA scores on disease progression. Future studies are likely to prove that individual components of the MBDA (or assays not in the original MBDA) have utility in answering specific clinical questions regarding disease activity, prognosis, and response to individual therapy, raising the possibility that it is premature to focus on an aggregate compilation of these assay values at this time.

As previously discussed, multiplex assays are at risk for RF interference. The 12 biomarkers included in the Vectra DA have been evaluated for RF, human anti-mouse antibody, and antibody cross-reactivity interference. Analysis did not demonstrate significant interference in any of these domains. Additionally, testing was performed to assess for the possibility of pharmacologic interference. Testing did not identify any drug confounders in the MBDA score. Finally, freeze-thaw stability was evaluated. Assays chosen had less than 15% difference when compared to fresh samples (48).

FACTORS THAT INTERFERE WITH RF MEASUREMENTS

RF measurement can be obscured by several factors. In agglutination and nephelometric assays, high levels of C1q bind and cross-link with IgG, giving false-positive results. C1q is an acute-phase reactant and is often elevated in inflammatory disorders. Heating the serum to 56°C for 15 to 30 minutes circumvents this issue as C1q is heat labile. Complement inhibition can be avoided by adding polyvinyl sulfonate to the reaction mixture (49). Incompletely clotted serum, fibrin, and fibrinogen can interfere with or induce agglutination or aggregation in both nephelometric and agglutination assays, leading to false-positive or false-negative results. Nephelometric techniques that use polyethylene glycol or similar polymers to accelerate immune complex formation may give false-positive results from polymer-enhanced aggregation of fibrin, lipoproteins, cryoglobulins, or other immune complexes (50).

This can be avoided by subtracting background light scatter in specimens that are allowed to react in the absence of aggregated IgG target antigen or by simply avoiding the use of an accelerating polymer. Additionally, mixed cryoglobulins are composed mainly of RF, which can precipitate from the remainder of the serum at cool temperatures, resulting in a low titer or false negative (51). A plasma protein, histidine-rich glycoprotein, inhibits formation of RF complexes and enhances the solubility of RF-immune complexes, likely through competitive binding to IgG, leading to false negatives (52).

Heterophilic anti-immunoglobulin antibodies are naturally occurring polyreactive antibodies against poorly defined antigens. They generally demonstrate low affinity and weak binding. About 15% of the heterophilic antibodies recognize the Fc portion of IgG and are considered true positives. The remaining 85% recognize the Fab region of IgG and are not RF, rendering a false-positive result. Interference by heterophilic antibodies may be eliminated by using rabbit F(ab) or F(ab′)2 fragments, as there is little cross-reactivity (53).

GENETICS OF RA

Twin and family data suggest a heritability estimate of 60% for RA. Thus, more than genetic factors contribute to the variability in disease expression. The major histocompatibility complex (MHC) of chromosome 6 was explored as a potential candidate for RA because it was known to contribute to the strength and pattern of immune response (54). The genes for a particular human leukocyte antigen, HLA-DR, were first reported in 1976 by Stastny when he recognized an association with RA. Since then, a 5-amino-acid sequence motif in the allelic hypervariable region of the HLA-DR B chain has become known as the "shared epitope" (SE), as it is a major contributor to RA risk. The HLA-DRB1*0401 allele has been found to be the most strongly associated polymorphism in white patients with RA. Other alleles have seen been identified, including DRB1*1001, DQB1*0302, DQB1*0302, and DQB1*0501, which are associated with ACPA seropositivity. Likewise, these patients have more aggressive, erosive disease. Not surprisingly, studies combining RF and ACPA seropositivity and portions of the SE suggest that the presence of both is strongly predictive of the future development of RA (55). Interestingly, the contribution of HLA alleles to the genetic variance is 40% for ACPA-seropositive disease, but only 2% for ACPA-negative patients (56).

Genomic-wide association studies (GWAS) in RA have identified seven RA risk loci. These single nucleotide polymorphisms (SNPs) are in close proximity to genes associated with immune function (57). The susceptibility loci identified include: interlukin 2A and B (IL2RA and IL2RB, respectively); signal transducer activator of transcription 4 (STAT4); interferon-related factor 5 (IRF5); peptidylarginine-deiminase 4 (PADI4); protein tyrosine phosphatase, non-receptor type 22 (PTPN22); tumor necrosis factor receptor-associated factor 1(TRAF1); CD40; CC chemokine ligand 21 and CC chemokine receptor 6 (CCL21 and CCR6); CD2 and Fc gamma receptor (FCGR2A) (57).

ENVIRONMENTAL TRIGGERS

One feature of RA occurrence that seems to point to an environmental trigger is disease clustering. Population-based incidence studies have demonstrated trends in new cases. There have been a large number of infectious agents suspected to be linked to RA. Infection agents have included Epstein-Barr virus, parvovirus B-19, and mycoplasma. However, epidemiological studies have generally not found evidence to support this link. Additionally, seasonal variation has not been recognized (58).

Thus far, the only unequivocally identified risk factor for RA is a history of tobacco use (3). In particular, ACPA seropositivity has been linked with cigarette smoking. A major gene-environment interaction between smoking and the SE has been identified in ACPA-seropositive RA, but not for ACPA-negative RA. Moreover, the risk for RA increases 21-fold when patients have a history of smoking and double copies of the SE genes. As an interesting corollary, citrullinated antigens have been identified in the bronchoalveolar lavage of smokers (59).

COMBINED TESTING ACPA AND RF

The presence of certain autoantibodies, such as RF and ACPA, are distinguishing features in RA. They are incredibly valuable in making a prompt diagnosis of RA. The group of citrullinated antibodies, exemplified by ACPA, is highly specific for RA at 95%. Moreover, the sensitivity is 50% to 80%, similar to that of RF in RA (20). Although RF is less specific (75%), it is also very useful in making the diagnosis of RA. Both are particularly important in early synovitis, as RF and ACPA independently contribute to the diagnosis of RA. Thus, there is value in testing for both antibodies early in disease to maximize predictive value (38). The importance of early treatment has been well established, as delayed diagnosis often leads to delays in treatment. These antibodies are not only useful for diagnosis, but also in providing insight into prognosis. The use of these two antibodies together has an additive predictive value for the development of erosions (28). Likewise, patients who are seronegative for both RF and ACPA may have a different syndrome, as they typically have a milder disease course with less erosions and fewer extra-articular manifestations (60).

FINAL THOUGHTS

What laboratory tests should be performed in a patient presenting with synovitis? As outlined above, typically both RF and ACPA are evaluated. Inflammatory markers, such as CRP and ESR, and CBC, for evaluation of anemia that often is found in inflammatory states, are also useful to gauging the disease activity. A newer multi-biomarker disease activity (MBDA) test is also available as a tool to measure disease activity in RA, but its clinical role has yet to be established. Radiographs are often procured but typically are normal early in disease. Despite this, it is helpful to have a baseline study for future comparisons of disease activity. Although this chapter focused on serologic and laboratory evaluation of RA, the importance of history and physical cannot be overstated in making the correct diagnosis.

Antiphospholipid Antibody Syndrome: Clinical Manifestations and Laboratory Diagnosis

MARTINA MURPHY AND NEIL HARRIS

93

BACKGROUND AND DIAGNOSTIC CRITERIA

Antiphospholipid antibody syndrome (APS) is an acquired thrombotic disorder caused by a heterogenous group of antibodies directed against plasma proteins that bind phospholipids. These are termed "antiphospholipid antibodies" (aPLs), and while they are required for the diagnosis for APS, they can also be detected in otherwise healthy individuals. The clinical manifestations of APS can be divided into thrombotic and obstetrical. Thrombotic complications include both venous and arterial thrombosis. Obstetrical complications include recurrent first trimester miscarriage and second trimester fetal demise, as well as other pregnancy complications like preeclampsia and placental insufficiency (1). APS is classified as "primary" when not associated with an underlying disease and accounts for over 50% of cases (2). Secondary APS is the distinction given to APS associated with an underlying autoimmune connective tissue disorder such as SLE.

The diagnosis of APS requires not only a clinical event but also the persistent presence of one or more of a unique set of antibodies that bind specific phospholipid binding proteins. Because aPLs can be detected in healthy individuals and in the setting of other disease states (e.g., infection, HIV, malignancy), it important that their persistence be documented in individuals suspected of having APS. While the presence of these antibodies is central to the diagnosis, the exact mechanisms by which they cause hypercoagulability are not well understood.

Most authorities diagnose APS based on the classification criteria (Sapporo criteria) as outlined in the International Symposium on Antiphospholipid Antibodies in 1998, which were subsequently updated in 2006 (3) (Table 1). The clinical criteria include objectively confirmed venous, arterial, or small vessel thrombosis or pregnancy complications that may be attributed to placental insufficiency, including pregnancy loss or premature birth. The laboratory criteria require that a moderate or strongly positive laboratory test for aPLs be found on 2 or more occasions at least 12 weeks apart. Low-level positivity for aPLs is thought to be nonspecific and nondiagnostic of the syndrome. The aPLs recognized in the international criteria include lupus anticoagulant (LA) detected according to guidelines published by the International Society on Thrombosis and Haemostasis, anticardiolipin (aCL) antibody (IgG or IgM) exceeding 40 IgG or IgM phospholipid units, or anti-β_2GPI antibody (IgG or IgM) at levels exceeding the 99th percentile. Patients who have aPLs not currently recognized in the diagnostic criteria (e.g., antiphosphotidylserine antibodies, antiprothrombin antibodies, IgA aCL, or anti-β_2GPI antibodies) or who have clinical manifestations other than thrombosis or pregnancy morbidity are not formally recognized as having APS at present, but diagnostic criteria continue to evolve. Testing for these alternative, noncriterial aPLs is not currently recommended in routine clinical practice.

The 2006 update included the advisement that patients be classified into those with positivity for only a single aPL and those that were positive for two or more laboratory criteria (present in any combination). The rationale for this change was the consensus that patients with single positivity carry a lower risk of thrombosis or pregnancy complications than those with multiple (especially triple) positivity (2).

CLINICAL MANIFESTATIONS

Virtually any organ system can be affected in APS, and recurrent thrombosis despite appropriate anticoagulation can be seen. The most common features seen in APS are venous thrombosis, thrombocytopenia, livedo reticularis, stroke, superficial thrombophlebitis, pulmonary embolism, fetal loss, transient ischemic attack, and hemolytic anemia (2, 4). In addition to the cerebrovascular system, the pulmonary, cardiovascular, renal, ocular, cutaneous, endocrine, gastrointestinal, and hematologic systems can be affected. APS in the background of SLE does not have a distinctly different array of clinical or laboratory manifestations. A small fraction of cases (<1%) may exhibit catastrophic APS (CAPS) resulting from widespread thrombosis in multiple organ systems, leading to organ failure and a mortality rate of nearly 50% (5). The distinction between APS and CAPS is important, as treatments are different and include consideration of immunosuppression as well as the addition of therapeutic plasmapheresis in patients with CAPS.

Fetal morbidity associated with APS typically occurs after 10 weeks of gestation (4, 6). Criteria for APS-associated fetal morbidity include three or more losses prior to the 10th week of gestation, one or more losses after the 10th week, or one or more premature deliveries at or before the 34th week because of preeclampsia, eclampsia, or placental insufficiency with the exclusion of other causes.

doi:10.1128/9781555818722.ch93

TABLE 1 Criteria for the diagnosis of antiphospholipid syndrome[a]

Clinical criteria
Vascular thrombosis (one or more episodes of arterial, venous, or small vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall.
Pregnancy morbidities attributable to placental insufficiency, including (i) three or more otherwise unexplained recurrent spontaneous miscarriages, before 10 weeks of gestation, (ii) one or more fetal losses after the 10th week of gestation, (iii) stillbirth, and (iv) episode of preeclampsia, preterm labor, abruption placentae, intrauterine growth restriction, or oligohydramnios that is otherwise unexplained.
Laboratory criteria
Medium or high levels of anticardiolipin or anti-β2-glycoprotein I IgG and/or IgM antibodies present on two or more occasions at least 12 weeks apart as measured by standard ELISAs
Lupus anticoagulant in plasma on two or more occasions at least 12 weeks apart, detected according to the guidelines of the Subcommittee on Lupus Anticoagulant/Phospholipid-Dependent Antibodies of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis

[a]Definite antiphospholipid syndrome is considered to be present if at least one of the clinical criteria AND one of the laboratory criteria are met. Table modified from references 3 and 18.

LABORATORY ASPECTS OF TESTING FOR ANTIPHOSPHOLIPID SYNDROME

The laboratory definition of the antiphospholipid syndrome requires the presence of either a so-called "lupus anticoagulant" or a significant and persistent titer of antiphospholipid antibodies. A lupus anticoagulant is detected by an *in vitro* clot-based laboratory assay, while antiphospholipid antibodies are detected by immunoassay.

Lupus Anticoagulant Testing

A "lupus anticoagulant" is a laboratory-defined phenomenon by which *in vitro* clot-based assays (typically those dependent upon the intrinsic and common pathways) are prolonged by the presence of antiphospholipid antibodies. The LA phenomenon does not have an *in vivo* correlate. These antibodies are not "anticoagulants" *in vivo*; instead, they trigger inflammation and are capable of inducing a thrombophilic state. Lupus anticoagulant assays are performed on citrated platelet-poor plasma (7, 8). The assays are frequently formatted to have a screening step and a confirmatory step, and frequently there is an additional mixing study step (7–9). The classic lupus anticoagulant causes a prolongation of the activated partial thromboplastin time (APTT), which does not correct in a 1:1 mix with normal pooled plasma (NPP). In practice, APTT reagents vary in their sensitivity to LA; the more-sensitive assays are those that should be used for LA screening. Another commonly used assay is the dilute Russell Viper Venom time (dRVVT) assay, in which the common pathway is activated by a snake venom (from *Daboia russellii*) that converts Factor X to Xa (7, 8). The advantage of the dRVVT assay is that it is not affected by hemophilia, antibodies to factors VIII and IX, or an elevated FVIII. It is frequently recommended that both types of assays (APTT and dRVVT) be used in the diagnosis.

The dRVVT assay requires an initial baseline reaction (referred to as "screening") followed by a confirmatory step in which the reaction is supplemented by exogenous phospholipid (7, 8). A true LA shows shortening of the clotting time on phospholipid supplementation, while factor deficiencies are impervious to this step. Mixing studies with NPP are often incorporated into the reaction sequence. For example, a factor X or II deficiency may prolong the dRVVT screen; this prolongation does not respond to the addition of phospholipid in the confirmatory step, but the addition of NPP results in a significant shortening of the clotting time. As a cautionary note, weak lupus anticoagulants can show correction when normal plasma is added because the plasma dilutes the inhibitory antibody (9). For this reason, the mixing study should be used with caution and only if the confirmatory step shows no response to phospholipid. Because two reactions are carried out in the dRVVT assay, this type of approach is referred to as a "paired LA test."

Many dRVVT reagents contain a cationic heparin neutralizer that binds and inactivates unfractionated heparin in the therapeutic range. Polybrene (hexadimethrine bromide) is one of these. The aim is to prevent interference by heparin, which would otherwise prolong both the dRVVTs.

In order to assess if the clotting time of the confirmatory step is shortened relative to the screening step, it is common practice to establish a ratio of screening-to-confirm times (7–10). These ratios are typically accepted as positive for a lupus anticoagulant effect if they are greater than 1.2. The cutoff ratio may vary among different labs from 1.15 to 1.3. For example, a dRVVT screening time of 59 seconds and a confirm time of 45 seconds yield a ratio of 1.31, which would be deemed positive by most laboratories.

Recently, this approach has been modified by several national and international organizations such as the Clinical and Laboratory Standards Institute (CLSI) (7), the International Society on Haemostasis and Thrombosis, and the British Committee for Standards in Haematology. The important modification is that both the screening and confirm times themselves be converted to normalized ratios by dividing the clotting time of the patient specimen by the clotting time of normal plasma. The clotting time of the normal plasma can be determined by using either the NPP or the mean of the population reference interval (RI). The example below illustrates how this is performed for a dRVVT assay.

1. dRVVT patient screen time:	65 seconds
2. dRVVT (NPP or mean of RI) screen:	44 seconds
3. Normalized screen ratio:	1.48
4. dRVVT patient confirm time:	46 seconds
5. dRVVT (NPP or mean of RI) confirm:	41 seconds
6. Normalized confirm ratio:	1.12

Divide the value in no. 3 by the value in no. 6: 1.48/1.12
Final ratio = 1.32
This is greater than 1.2 and is therefore positive.

A third type of assay is available from a single vendor (STACLOT-LA Hexagonal Phospholipid Neutralization;

Diagnostica Stago) (7). This assay integrates the baseline and mixing assays. The reaction involves mixing the patient plasma specimen with NPP (to control for warfarin) as well as a heparin neutralizer (see above, to control for therapeutic heparin in the specimen). An APTT is initiated by recalcification and by a surface activator. A second independent reaction is performed as described above but with the addition of a specialized phospholipid preparation termed a "hexagonal (II) phase phospholipid." This is an alternative nonlamellar physical form of phospholipid. In this phase, the lipid (most commonly phosphatidylethanolamine) forms long tubes, with the polar head groups on the inside and the hydrophobic, hydrocarbon tails on the outside. Positivity is assessed by observing a significant difference between the two reactions (one with the hexagonal phase phospholipid and one without) of greater than 8 to 10 seconds.

ANTIPHOSPHOLIPID ANTIBODY TESTING

Antiphospholipid antibodies are those that interact with phospholipid-binding proteins. International guidelines recommend detection of either IgG or IgM antibodies to cardiolipin (aCL) or to beta2 glycoprotein I (aβ2GP1) (3). Antiphospholipid antibodies are identified by a solid-phase noncompetitive immunoassay that does not require activation of the coagulation pathway. These assays are commonly performed in enzyme-linked immunosorbent assay (ELISA) wells and are processed either manually or on a semiautomated platform. The wells are coated with the antigen. The specimen from the patient is added, and if the appropriate antibodies are present, they will bind to the target antigen. The remaining proteins are removed by a wash step, and the reaction is developed by adding labeled antibodies directed to human IgG or IgM.

In order to improve specificity of the assay, the guidelines focus on specificity, duration, and antibody level.

Specificity

The anticardiolipin assay should be β2GP1 dependent (11). This is achieved by supplementing the reaction with either human or bovine β2GP1, which acts a binding cofactor. The rationale behind this is that infections may induce transient aCL antibodies and these are typically not dependent on β2GP1.

Duration

The laboratory definition of antiphospholipid syndrome requires that a significant titer of aCL or aβ2GP1 persist for at least 12 weeks (3).

Antibody Level

International guidelines recommend that antibody levels should be at >99th percentile of the population reference range. One challenge is that levels are dependent upon the type of calibrator that is used. The original calibrators (Harris standards) utilized sera with defined concentrations of antibodies. One GPL unit and 1 MPL unit were defined as 1 μg/ml of affinity-purified IgG and 1 μg/ml of affinity-purified IgM, respectively. Use is now being made of the "Sapporo standards," which are monoclonal antibodies termed EY2C9 and HCAL for IgM and IgG, respectively. In the case of the latter, using the Inova QUANTA Lite anticardiolipin ELISA, 15 GPL would correspond to 0.0282 μg/ml of HCAL antibody, while 12.5 MPL would correspond to 0.0195 μg/ml of EY2C9 antibody. An important principle therefore is that anti-cardiolipin IgG values obtained with different manufacturers' assay methods may not be used interchangeably (12).

International standards are not available for aβ2GP1 testing, and these may be expressed as U/ml or SGU or SMU units.

Another challenge is that the guidelines set 2 different criteria for a significant level for anticardiolipin antibodies: (i) either >99th percentile or (ii) levels exceeding 40 units (3, 11). These may represent very different levels (13). In laboratory medicine, a population reference range either is the mean ± 1.96 standard deviations (if the distribution is Gaussian) or includes everything up to the 97.5% centile and down to the 2.5% centile (if the distribution of results is non-Gaussian). For example, in the case of one commonly used antiphospholipid antibody assay (Inova QUANTA Lite), 97.6% of "normals" are less than 15 GPL for aCL IgG. Only 1.4% of the normal population had aCL IgG levels above 20 GPL units, which would correspond to the 98.6th percentile. If one is therefore setting the cutoff at 40 GPL units, this is clearly a much higher level and more stringent criterion than the 99th percentile.

WHOM TO TEST

The diagnosis of APS should be considered in patients with venous/arterial thrombosis and/or a history of recurrent pregnancy loss in the absence of other clear risk factors. This is especially true in younger patients (<50 years of age), patients with thrombosis at unusual sites, patients with late pregnancy loss, and patients with autoimmune disorders experiencing thrombosis or pregnancy loss. Strong consideration should be given to testing in young patients with cerebral thrombosis including cerebrovascular accident without risk factors. The utility of testing is unclear in other neurologic symptoms such as chorea, migraines, etc.

CONSIDERATIONS WHEN TESTING

Accurate laboratory testing carries significant implications for patients who have suffered from one of the APS-defining clinical events. As such, it is important to take into consideration patient characteristics such as underlying medical comorbidities and medications when interpreting results of aPL studies. As previously discussed, aPLs are often identified in the elderly, patients with cirrhosis and other liver disease, patients with HIV, patients with autoimmune disease, and patients with cancer (14–17). In the absence of clinical sequelae of APS, the clinical significance of positive aPLs remains uncertain.

Several medications are associated with the development of aPLs, such as quinine, procainamide, phenothiazines, and anti-tumor necrosis factor drugs, but there has been no clear association with the use of these medications and the clinical syndrome of APS (18).

Importantly, it should be noted that several medications interfere with testing for aPLs, specifically testing for LA. Medications that prolong or have the potential to prolong the patient's baseline PTT may lead to false-positive aPL studies. This is particularly true of anticoagulant medications such as heparin, enoxaparin, or the targeted oral anticoagulants rivaroxaban, apixaban, dabigatran, and edoxaban.

Antineutrophil Cytoplasmic Antibodies (ANCA) and Strategies for Diagnosing ANCA-Associated Vasculitides

R. W. BURLINGAME, C. E. BUCHNER, J. G. HANLY, AND N. M. WALSH

94

DISEASE DIAGNOSIS

Inflammation of and damage to blood vessel walls are the shared defining features of all vasculitides. The symptoms vary depending on the size of the vessels affected, the organs they serve, the underlying cause of the vasculitis, and the activity of the disease. The vasculitic diseases are rare. Since there are only 20 to 50 new cases of antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitides per 1,000,000 people per year (1, 2), a systematic and thorough diagnostic algorithm is needed to correctly identify patients with the disease (3, 4). Missed or delayed diagnosis can result in permanent organ injury or even death (5, 6).

The most appropriate diagnostic criteria for the vasculitides are still the subject of debate (7). Classification criteria (8, 9, 10, 11, 12) are used in patients already diagnosed to ensure homogeneity of groups of patients with vasculitis enrolled in clinical studies. The new nomenclature for vasculitis (13) includes microscopic polyangiitis (MPA), which was not included in the earlier classifications by the American College of Rheumatology.

The patient's clinical history and physical examination are key factors in making a diagnosis of vasculitis since the symptoms are varied and the disease often takes a relapsing and remitting course. Exclusion of diseases other than vasculitis as the cause of the clinical presentation is necessary. Besides the normal careful patient workup, certain questions need to be answered by the patient if vasculitis is suspected. Has the patient traveled to any countries where they might have contracted an infectious disease associated with vasculitis? Is this patient taking any prescription drugs, such as propylthiouracil, or recreational drugs, such as cocaine, that sometimes cause vasculitis?

When feasible, a positive biopsy specimen provides the most robust evidence of vasculitis. The anatomical site of biopsy is guided by the presentation in a given patient. Common sites include skin, kidney, lung, nasal passage, temporal artery, and muscle. Biopsy of the kidney can be particularly important both for the initial diagnosis and to help direct treatment based on the histopathological evidence of disease activity, severity, and damage. For example, the histopathological diagnosis of crescentic necrotizing glomerulonephritis is a serious manifestation of several types of vasculitis and requires prompt treatment with corticosteroids and immunosuppressive therapy to avoid irreparable renal damage (5, 6).

The laboratory workup should be comprehensive in order to capture information about all potential organs involved and may have to be repeated if the disease is still in evolution and new manifestations of the illness appear (14). A complete blood count may indicate anemia, eosinophilia, or neutropenia. Urinalysis identifies proteinurea, hematuria, and red cell casts that are indicative of active renal disease as well as urinary tract infection. Laboratory markers of inflammation such as C-reactive protein and erythrocyte sedimentation rate are neither sensitive nor specific for vasculitis but if elevated may help monitor the activity of the disease. Both complement and cryoglobulins should be evaluated since low levels of complement proteins in the circulation correlate with active disease in immune complex mediated vasculitis such as cryoglobulinemia.

A workup for thrombophilia including measurement of anti-thrombin 3, protein C, and protein S, as well as evaluating autoantibodies to cardiolipin and beta-2 glycoprotein 1 and lupus anticoagulant, can help elucidate causes of thrombosis other than vasculitis. A careful search for infection, including hepatitis B and C as well as HIV infection, and underlying malignancy, including lymphoma, should be considered part of the differential diagnosis in all cases of systemic vasculitis.

TESTS FOR ANCA

A key diagnostic aid in certain types of vasculitis is the indirect immunofluorescent assay (IFA) to detect ANCA on ethanol-fixed neutrophils (15, 16, 17). Neutrophil-specific autoantibodies were first recognized by IFA in the mid-1960s, but their association with specific types of vasculitis and glomerulonephritis was not made until the mid-1980s (18). If the IFA on ethanol-fixed neutrophils is positive, follow-up testing with more-specific assays that detect autoantibodies against two proteins found in azurophilic granules, proteinase 3 (PR3) and myeloperoxidase (MPO), is necessary. These are the most diagnostically important ANCAs. Native PR3 antigen from human neutrophils appears to function better in solid-phase assays than recombinant PR3, possibly because the tertiary structure is preserved in the native antigen (3). The autoimmune diseases associated with them are discussed in detail later in this chapter. A previous edition of this *Manual* contained detailed instructions for making slides to test for ANCA by IFA (19) and

doi:10.1128/9781555818722.ch94

enzyme-linked immunosorbent assays (ELISAs) to detect specific autoantibodies (19, 20), so those procedures are not reproduced here. Slides with fixed neutrophils for ANCA testing are available from several commercial sources, as are specific solid-phase tests for detecting anti-PR3 and anti-MPO.

On ethanol-fixed neutrophils, antibodies to PR3 yield a characteristic granular cytoplasmic pattern (C-ANCA) with interlobular accentuation, consistent with its cellular location in azurophilic granules (Fig. 1A). Anti-MPO antibodies usually give a perinuclear pattern (P-ANCA) rather than a cytoplasmic pattern because MPO is cationic and migrates from cytoplasmic granules to the nucleus, where it binds anionic chromatin when the membranes around these organelles are dissolved during fixation (Fig. 2A). These and other antineutrophil nuclear autoantibodies (ANNA) are perhaps paradoxically still considered ANCA. The term ANNA, which is an alternative and more appropriate acronym for these antibodies, never became widely accepted. Autoantibodies to several other proteins from azurophilic granules also show P-ANCA by IFA because of the same phenomenon. Immunofluorescent patterns that are not C-ANCA or P-ANCA and are not directed to MPO or PR3 are considered atypical (A-ANCA). Some A-ANCA may be neutrophil-specific autoantibodies, and some react with the neutrophil nuclear membrane (21), while others may be caused by autoantibodies such as anti-DNA that are reactive to antigens found in many cell types. Patients without vasculitis may have autoantibodies that yield C-ANCA, P-ANCA, or A-ANCA patterns by IFA but are negative for anti-MPO and anti-PR3 by solid-phase assays, so it is absolutely necessary to perform follow-up testing for these specific autoantibodies (15, 16, 17, 21). Rarely, a PR3-ANCA yields a P-ANCA IFA pattern and an MPO-ANCA yields a C-ANCA pattern on ethanol-fixed neutrophils for unknown reasons.

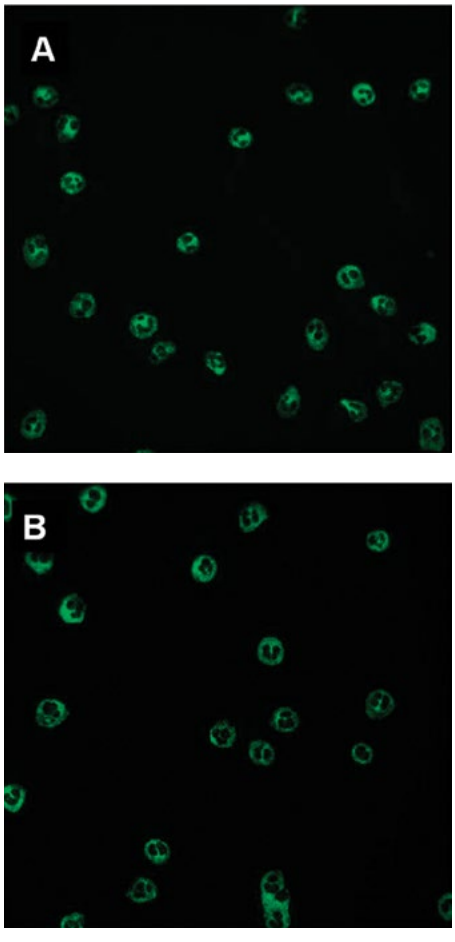

FIGURE 1 Indirect immunofluorescence of a PR3-ANCA-positive sample expressing cytoplasmic staining with interlobular accentuation on both ethanol-fixed (A) and formalin-fixed (B) neutrophils.

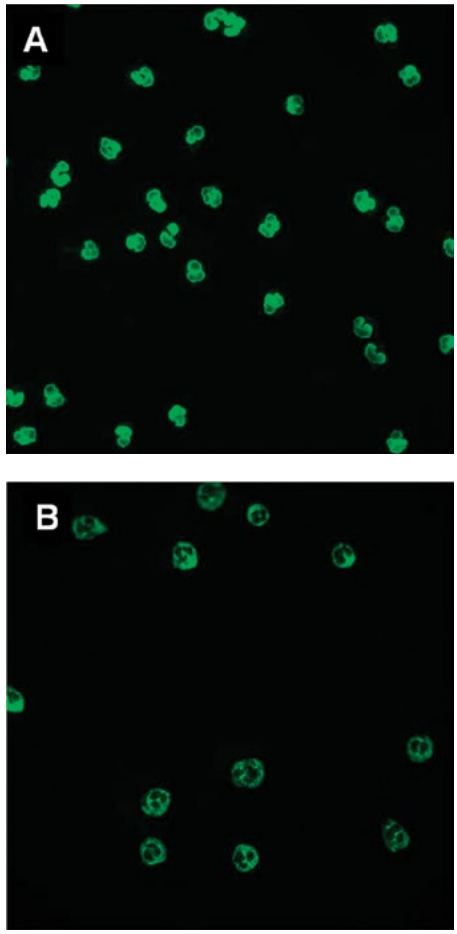

FIGURE 2 Indirect immunofluorescence of an MPO-ANCA-positive sample expressing perinuclear staining on ethanol-fixed neutrophils (A) and cytoplasmic staining with interlobular accentuation on formalin-fixed neutrophils (B).

It is useful to perform IFA on formalin-fixed neutrophils on samples that are positive on the initial IFA on ethanol-fixed neutrophils. PR3-ANCA remains positive with the C-ANCA pattern, while MPO-ANCA now shows a C-ANCA pattern since the antigens have been cross-linked in place by formalin fixation (Fig. 1B and 2B). The reactive epitopes of some A-ANCA antigens are destroyed by formalin fixation, so some of those samples become negative on formalin-fixed neutrophils.

If the ANCA IFA is positive but the specific anti-MPO and anti-PR3 follow-up tests are negative in patients in which vasculitis is suspected, it can be valuable to perform further tests to characterize the autoantibodies causing the positive ANCA IFA. A test for antinuclear antibodies, such as IFA on HEp-2 cells, can help differentiate neutrophil-specific antibodies from general ANA, with the caveat

that HEp-2 IFA is often performed at a 1:80 dilution while ANCA IFA is often performed at a 1:20 dilution, and thus the sensitivities of the two assays may be different. If the ANA assay is negative, which implies that the antibodies are neutrophil specific, follow-up testing for autoantibodies to other proteins found in azurophilic granules, such as elastase, lactoferrin, lysozyme, cathepsin G, and bacterial-permeability-increasing protein may be informative. Autoantibodies to these antigens have been found primarily in vasculitis induced by a wide class of therapeutic drugs (22, 23) or by levamisole-laced cocaine (24, 25) and in chronic liver disease (26) and other nonvasculitic diseases (27).

It is often necessary to test for a panel of other autoantibodies, since symptoms of vasculitis can be secondary to other autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and antiphospholipid syndrome. This panel should include tests for autoantibodies reactive with SS-A/Ro, SS-B/La, Sm, RNP, double-stranded DNA, chromatin, citrullinated proteins, rheumatoid factor, beta-2 glycoprotein 1, cardiolipin, and lupus anticoagulant.

In summary, the most accepted way to test for ANCA is to start with the IFA screen and to follow up positive results by specific ELISAs to MPO and PR3 autoantibodies. There are many commercially available kits to measure anti-MPO and anti-PR3 autoantibodies that have various sensitivities based on the cutoff chosen to differentiate positive and negative results rather than any inherent poor performance of the ELISA (28). However, different laboratories can get similar results if they standardize their testing with each other (15). One study suggests that a more cost-effective yet equally good strategy is to screen with the 2 ELISAs and follow up the positives with IFA on neutrophils (29). Native proteins are preferred over recombinant proteins (3) as the solid-phase antigens in ELISA. The capture PR3 ELISA has good performance (28), but it may not be better than the standard PR3 ELISA (29). Commercial kits to measure antibodies to the nonstandard proteins in the azurophilic granules mentioned above are available (Aesku Diagnostics, Wendelsheim, Germany). In-house ELISAs can be developed by following standard ELISA techniques (19, 20, 25, 27) with antigens from Athens Research and Technology, Athens, GA, USA, or other sources for individual antigens.

NOMENCLATURE OF VASCULITIS

The names of various forms of vasculitides have recently been revised to replace eponyms with key features of the disease (13). When a type of vasculitis is known to be caused by infectious agents, the name reflects that. Examples include rickettsial vasculitis, syphilitic aortitis, and aspergillus arteritis. Infectious organisms such as hepatitis C virus can induce cryoglobulinemia, which in turn indirectly causes vasculitis. The primary therapeutic strategy is with agents to remove infection and not with immunosuppressive agents. It is important that the diagnostic algorithm for vasculitis include tests to identify infections when the presentation suggests this as the most likely primary cause of the inflammation.

Large Vessel Vasculitis

Some types of vasculitis are not associated with ANCA. Large vessel vasculitis predominantly affects the aorta and large aortic root vessels. Smaller vessels within organs, particularly in the eyes, may also be affected. The etiologies of these diseases are not known. The two most common forms of large vessel vasculitis are Takayasu's arteritis and giant cell arteritis (GCA). It is not clear if these are separate diseases or represent a continuum of the same illness with different clinical phenotypes in different age groups. Takayasu's arteritis is found mainly in people younger than 50 (9), and GCA is seen in older individuals (10). A biopsy specimen of the temporal artery in patients with GCA is characterized histopathologically by a granulomatous inflammatory infiltrate of the inner muscular layer, where multinucleate giant cells are associated with fragmentation and destruction of the internal elastic lamina. Noninvasive tests such as magnetic resonance imaging, ultrasound, and positron emission tomography (30, 31) have been shown to be useful for diagnosing large vessel vasculitis.

Medium Vessel Vasculitis

Medium vessel vasculitis is found primarily in visceral arteries, though any size vessel may be affected. Histopathologically, there is acute inflammation and fibrinoid necrosis of vessel walls, which can culminate in aneurysm formation. Polyarteritis nodosa is the major medium vessel vasculitis. Symptoms include weight loss, fever, myalgia, rash, and neuropathy, and it is often associated with hepatitis B infection.

Kawasaki disease affects medium and small vessels but may also affect the coronary arteries. It is associated with the mucocutaneous lymph node syndrome and is predominantly found in children. Symptoms include fever, bilateral conjunctivitis, and erythema of the lips, palms of the hands, and soles of the feet. Mesenteric and renal angiograms and magnetic resonance imaging may be useful to detect gastrointestinal tract vasculitis and renal artery vasculitis (but not glomerulonephritis).

Small Vessel Vasculitis (SVV) and Non-ANCA SVV

As the name states, SVV primarily involves small vessels such as arterioles, capillaries, and venules. As all tissues contain small blood vessels, an appropriately directed biopsy based on clinical indication of affected sites is particularly useful to diagnose SVV. There are numerous types of non-ANCA-associated SVV that are described in detail in reference 13 and are briefly mentioned below. In one type of SVV, complement-fixing immune complexes are deposited within the vessel walls. These may be cryoglobulins induced by hepatitis C infection or immune complexes associated with systemic diseases like SLE or RA. Anti-glomerular basement membrane (GBM) disease, formerly Goodpasture's syndrome, is named after the specificity of the autoantibody typically found in patients with this disease. It must be diagnosed promptly and treated aggressively because of the severe pulmonary and renal symptoms that can progress rapidly. The autoantibodies in this disease bind to both GBM and pulmonary alveolar capillary basement membranes, linking the renal and pulmonary lesions to the specificity of the autoantibodies. Some patients with GBM disease are also ANCA positive. IgA vasculitis (IgAV), formerly Henoch-Schönlein purpura, is characterized by IgA immune complexes in the skin and gastrointestinal tract. Hypocomplementemic urticarial vasculitis is characterized by anti-C1q autoantibodies. Some non-ANCA SVVs are not systemic but are localized to a single organ such as the kidney or lung.

ANCA-ASSOCIATED VASCULITIS

ANCA-associated vasculitis (AAV) is characterized by ANCA that yield positive C-ANCA or P-ANCA patterns on IFA of ethanol-fixed neutrophils and react with MPO or PR3 antigens or, in the case of drug-induced vasculitis, with other proteins in the granules. The suggested nomenclature

includes the specific reactivity of the antibody: PR3-ANCA, MPO-ANCA, or ANCA negative. AAV is a necrotizing vasculitis of the small vessels with few or no immune deposits (Fig. 3). It typically affects the lungs and kidneys in addition to a skin rash, typically palpable or retiform purpura (Fig. 4). When AAV is suspected, it is strongly advised to perform IFA on ethanol-fixed neutrophils rather than just the specific solid-phase assays for anti-MPO and anti-PR3 because some patients with AAV are negative for MPO-ANCA and PR3-ANCA. This pattern of ANCA can be found in most patients with drug-induced vasculitis who have autoantibodies to other proteins in the azurophilic granule (22–25), in a minority of patients with granulomatosis with polyangiitis (GPA), formerly Wegener's granulomatosis, and in MPA patients (27). A positive ANCA IFA with negative results on the specific anti-PR3 and anti-MPO assays can also be found in nonvasculitic conditions such as inflammatory bowel disease (26, 27). In addition, some patients are ANCA negative but have all of the other features of AAV and follow the same disease course. These patients may have a seronegative vasculitic disease equivalent to seronegative SLE, RA, or antiphospholipid syndrome.

There is debate about the pathogenicity of MPO- and PR3-ANCA, in part because they may occur in the absence of vasculitis, implying that other factors besides the autoantibodies themselves are important. It is possible that the fine specificity of the autoantibodies may be different in ANCA-positive patients with and without AAV (3). Importantly, MPO and PR3 antigens are found on the surface of activated, but not resting, neutrophils, and MPO and PR3 autoantibodies can induce a reactive oxygen burst in these neutrophils. In a large cohort of 502 patients with vasculitis, it was found that three different classification systems, the Chapel Hill Consensus Nomenclature, the European Medicines Agency system, and MPO- or PR3-ANCA positivity, yielded different percentages of patients diagnosed with GPA and MPA (17). The best correlation with relapse was the presence of anti-PR3 autoantibodies, consistent with a pathogenic role for that autoantibody.

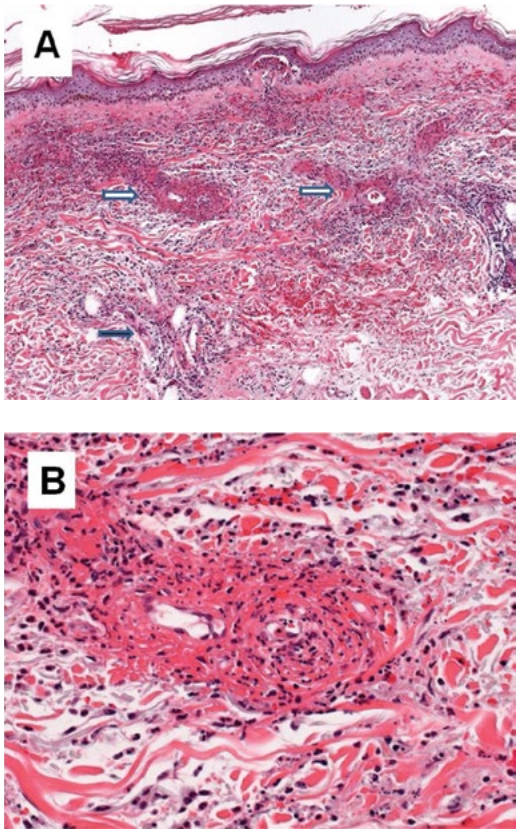

FIGURE 3 Photomicrograph of a skin biopsy displaying features of a leukocytoclastic vasculitis, such as that caused by ANCA. (A) At medium power, capillaries in the upper dermis, denoted by the white arrows, appear to have prominent thickened walls. These can be contrasted with normal dermal vessels denoted by the black arrow. Red blood cell extravasation is an additional feature. (B) At high power, the abnormal capillary wall displays fibrinoid change in association with a neutrophil-rich intramural inflammatory infiltrate.

FIGURE 4 Clinical photograph of a patient with palpable purpura on the legs. This is a cutaneous manifestation of a leukocytoclastic vasculitis, such as that caused by ANCA.

Granulomatosis with Polyangiitis

Patients with GPA have pauci-immune necrotizing granulomatous inflammation of the small to medium vessels, usually in the upper and lower respiratory tract (12, 13). Larger arteries are not frequently involved. Histopathology often shows extravascular inflammation with geographic zones of necrosis. Necrotizing crescentic glomerulonephritis without immune deposits is a serious manifestation. It should be noted that patients with GPA show the typical histopathology only 85% of the time (14), since not all specimens show granulomas and they are not present in all stages of the disease. So, patients with the correct clinical presentation and nonspecific inflammation on biopsy who are C-ANCA and PR3-ANCA positive are appropriately and frequently diagnosed with GPA (3, 12, 13). In some cases of GPA, the symptoms are very localized, such as in renal-limited necrotizing crescentic glomerulonephritis or pulmonary limited disease. These patients may still progress to systemic disease, so they must be closely monitored.

Similarly, with the correct clinical presentation and histopathologic features of vasculitis, albeit nongranulomatous, a patient can be diagnosed with GPA with negative ANCA since only approximately 85% of GPA patients are autoantibody positive (3, 13, 15, 17). In a GPA cohort derived from patients from 14 centers, 85% were ANCA positive by IFA. Approximately 65% were C-ANCA and/or PR3-ANCA positive, and 20% were P-ANCA and/or MPO-ANCA positive (15). Levels of ANCA fluctuate during the course of AAV,

so the ANCA-negative GPA patients may have been in a stage of decreased autoantibody production, or they may be true cases of seronegative GPA. There is evidence to support (32) and refute (33) the association between ANCA levels and clinical disease activity, but the majority of studies do not support the association. It was found that lung involvement and PR3-ANCA positivity were the best prognostic markers for the likelihood of disease flare in another GPA cohort (17).

Microscopic Polyangiitis

MPA is a pauci-immune necrotizing vasculitis that primarily affects small vessels, although medium vessels may also be involved. Necrotizing crescentic glomerulonephritis is a common feature and must be treated aggressively. One difference between GPA and MPA is that histopathology in MPA does not usually show granulomatous lesions or extravascular inflammation. In addition, the primary autoantibody in MPA is anti-MPO, which yields a P-ANCA pattern on IFA. P-ANCA and anti-MPO are found in nearly 60% of MPA patients, while C-ANCA and anti-PR3 are seen in about 25% (15).

EGPA, Formerly Churg-Strauss Syndrome

Eosinophilic granulomatosis with polyangiitis (EGPA) is a rare disease characterized by necrotizing vasculitis of the small and medium vessels of the respiratory tract. Eosinophilia in the blood, eosinophil-rich granulomatous inflammation on histopathology, and asthma are differentiating features (11). In some instances, EGPA is confined to the respiratory tract, while in other cases it may progress in 3 phases, with asthma followed by eosinophilic pneumonia or gastroenteritis and then necrotizing vasculitis. About 40% of EGPA patients show positive ANCA by IFA. Of these, about 70% are MPO-ANCA, 10% PR3-ANCA, and 20% atypical ANCA (34). A positive ANCA is strongly correlated with renal involvement.

Drug-Induced Vasculitis

Drug-induced vasculitis (DIV) presents with arthralgia, myalgia, skin rash, and autoantibodies to more than one protein found in azurophilic granules. These include human neutrophil elastase, cathepsin G, catalase K, bacterial-permeability-increasing protein, lactoferrin, and occasionally MPO (22–25). Usually, these are P-ANCA positive by IFA and negative for PR3-ANCA on follow-up specific-autoantibody testing. If the drug is continued for a substantial period after the onset of symptoms, severe manifestations that are the same as those seen in other AAV can occur.

Interestingly, many of the offending drugs can cause neutropenia. These include the thyroid drugs carbimazole, methimazole, and propylthiouracil, the antipsychotic clozapine, and the antihelminthic levamisole (22, 23). Several of these as well as other offending drugs have thiol groups. Propylthiouracil is the drug most frequently reported in the literature to be associated with DIV. Recently, levamisole-induced AAV has been reported in people using cocaine laced with levamisole (24, 25). When the patient stops taking the offending drug, the symptoms of drug-induced vasculitis usually resolve in a few weeks. If the disease is severe or the symptoms do not resolve, immunosuppressive therapy may be considered. However, treatment can be discontinued when the symptoms abate.

TREATMENT OF AAV

It is crucial to diagnose AAV as quickly as possible since many forms of the disease, including GBM, GPA, MPA, and EGPA, may rapidly progress to serious manifestations such as pulmonary hemorrhage or renal failure. Some DIV can quickly become life threatening (5, 35). Early and aggressive therapy with glucocorticoids and cyclophosphamide is necessary to bring acute manifestations under control (14, 17) with the goal of inducing remission as quickly as possible. This approach, which has been the standard therapy for over 40 years, has revolutionized the clinical outcome of AAV from a high probability of death to a low probability. Absolute and relative contraindications for aggressive treatment, such as concurrent infection, liver disease, pregnancy, or the desire to become pregnant, need to be addressed. After induction therapy, important clinical decisions are the types and dosages of drugs to maintain remission. In view of the significant comorbidity associated with the continued use of induction therapies over time, it is important to select treatment regimes with the least toxicity in striving to keep patients in remission.

A large, clinically well-characterized cohort of ANCA-positive vasculitis patients that were classified using the Chapel Hill system, using the European Medicines Agency system, or just on the basis of ANCA specificity were studied for prognostic markers of disease. The presence of PR3-ANCA was the best predictor of relapse regardless of the original diagnosis (17), with a nearly 2-fold increase in the likelihood of relapse. However, neither the presence of PR3-ANCA nor the level of autoantibody reliably predicts the time of onset of flare or relapse. Patients with GPA, MPA, or limited disease who were PR3-ANCA positive were more likely to have necrotizing granulomatous vasculitis, particularly in the lung, while those with MPO-ANCA were more likely to have limited disease, often confined to the kidney.

The Birmingham vasculitis activity score version 3 has been validated in a large cohort and can help define the current level of disease activity (6). It correlates well with the physician's global assessment of this parameter, but it does not predict relapse or remission.

Due to drug toxicity during long-term treatment with glucocorticoids and immunosuppressive drugs, there is a need to find alternative therapies. Biologic drugs have been explored with variable results (36). Tumor necrosis factor alpha inhibitors may be effective for the treatment of Takayasu's arteritis but not GCA, and their role in the treatment of other forms of vasculitis remains controversial. A large study showed that the addition of etanercept (Enbrel, another tumor necrosis factor alpha inhibitor) to standard treatment was not more effective than standard treatment alone in patients with GPA (37).

Early experience with rituximab (Rituxin), a drug that depletes circulating CD20-positive B cells, in the treatment of several forms of vasculitis has been quite promising, particularly in AAV. A single treatment of rituximab was as successful as continuous treatment with cyclophosphamide at inducing remission in patients with AAV (33). In addition, a single course of treatment with rituximab was statistically superior to cyclophosphamide at preventing relapse for 6 to 12 months, with comparable toxicity in the two groups (38). By 18 months, most patients had regained their circulating B cells, and while the rate of relapse in the rituximab group was still lower than in the cyclophosphamide-treated group, it did not reach statistical significance. An additional difference between these therapies was that rituximab was more effective in reducing the levels of PR3-ANCA. Fifty percent of patients became negative for PR3-ANCA following rituximab treatment, compared to 17% of patients treated with cyclophosphamide (33).

These new treatments are promising, but challenges remain. Individuals with the same disease may react differently to a particular drug, and a medication that is effective for one form of vasculitis may not be effective for another. Determining the right drug and correct dose for an individual with vasculitis is still a significant challenge.

NEUTROPHIL EXTRACELLULAR TRAPS

About 1 decade ago, a new antibacterial mechanism of neutrophils was discovered, neutrophil extracellular traps (NETs) (39). During a type of cell death termed NETosis, the neutrophil releases decondensed chromatin decorated with proteins from its azurophilic granules, effectively concentrating these proteins in the extracellular space. The NET can trap bacteria, stop them from spreading, and kill them with the associated proteins. Moreover, there are indications that in patients with AAV, this mechanism is involved in the autoantibody response and in thrombosis, as outlined below.

MPO, PR3, and other bactericidal proteins from azurophilic granules are found in NETs (40, 41, 42). The binding of these proteins to chromatin is a natural function of these proteins, required to concentrate these enzymes around the bacteria caught in the NETs. Thus, what was thought to be artifactual migration of MPO and other granule proteins to the nucleus during ethanol fixation of neutrophils, yielding the P-ANCA pattern on IFA, may actually be a normal expression of their chromatin binding capacity once the granule and nuclear membranes are destroyed by the fixation procedure.

When mice were injected with NETs, the NETs were taken up by dendritic cells and induced ANCA and vasculitis (40). Uptake by dendritic cells and autoimmunity were prevented when the NETs were first treated with DNase, suggesting that the structural integrity of the NETs was necessary for full expression of its antigenicity. The same study evaluated biopsies of skin lesions from MPO-ANCA-positive patients with MPA. The vascular inflammatory infiltrates were rich in neutrophils with MPO on their surface, and extracellular MPO was also detected, presumably attached to NETs. Myeloid dendritic cells were found in proximity to MPO-positive neutrophils, and some of the dendritic cells showed cytoplasmic MPO, consistent with uptake of NETs by these cells (40). Another group used immunofluorescence to study needle biopsy specimens of kidneys from 15 patients with SVV and acute renal failure (42). Extracellular chromatin decorated with MPO and PR3 was found in close proximity to neutrophil infiltrates in the glomeruli. These findings suggest a mechanism whereby MPO and PR3 could be presented to the immune system in a strongly antigenic form in a microenvironment with highly activated immune cells.

NETs can also induce thrombosis, which is likely a mechanism to encase bacteria trapped in NETs. An *in vitro* model system showed that platelets adhered to NETs and then became activated, and when blood flowed over this substrate, additional platelets adhered and aggregated in a self-perpetuating manner. Treatment with either DNase or heparin caused dismantling of NETs and prevented platelet aggregation (43). Tissue factor (TF), a critical component in the activation of the coagulation cascade, has recently been found in NETs from neutrophils isolated from patients with AAV (44). The neutrophils from patients with active disease based on the Birmingham vasculitis activity score (17 ± 7) before receiving immunosuppressive treatment spontaneously released NETs containing TF *in vitro*. After successful treatment, the release of NETs and the expression of TF decreased significantly to the levels of control subjects. TF and elastase that colocalized with extracellular DNA were found with specific staining of nasal biopsy specimens from the patients with active disease. The highest levels of TF colocalized with elastase and DNA, implying that TF was derived from neutrophils and trapped in NETs. In the same study of patients with active AAV, TF was identified in glomerular lesions from patients with kidney involvement (44). In a case report of a patient with MPA, histopathological evidence of NETs was found in glomerular crescents and thrombi. Extensive histone citrullination, which is a hallmark of histones in NETs, was found in the thrombus of this patient but not in control thrombi from patients without MPA (45).

Neutrophils are the main leukocytes found in histopathologic lesions in patients with AAV. Well-known properties of neutrophils such as the production of reactive oxygen species and recruitment of other mediators of the immune response can account for much of the inflammation observed in AAV. In addition, several aspects of AAV pathogenesis now can be linked to NETs, including the specificity of the autoantibodies, excess thrombosis, and possibly the initiation of the disease by bacterial infection. It has been proposed that MPO and PR3 autoantibodies are pathogenic because these antigens are on the surface of activated neutrophils, which can then become further activated by the autoantibodies. Adding the properties of NETs to this cycle of positive reinforcement of neutrophil activation by autoantibodies may explain more of the pathology found in these diseases.

IgG4-Related Disease: Diagnostic Testing by Serology, Flow Cytometry, and Immunohistopathology

JOHN H. STONE

95

IgG4-related disease (IgG4-RD) is a multiorgan immune-mediated condition that mimics many malignant, infectious, and inflammatory disorders (1–3). The diagnosis links numerous conditions once regarded as isolated, single-organ diseases that existed outside of any known underlying systemic condition (Table 1). The histopathological findings in IgG4-RD are consistent across the wide range of organ systems that can be involved. IgG4-RD is often confused with a malignancy upon presentation because it has a tendency to form mass lesions. In addition, IgG4-RD can mimic a host of immune-mediated conditions, e.g., primary sclerosing cholangitis, idiopathic interstitial lung disease, Sjögren's syndrome, granulomatosis with polyangiitis, and idiopathic membranous nephropathy.

CLINICAL FEATURES

IgG4-RD can affect essentially any organ in the body. The presentation of the disease is typically subacute, with symptoms and signs of organ dysfunction present months or even years before the diagnosis. Weight loss and fatigue are common but fevers and highly inflammatory presentations are not. Lymphadenopathy, when present, is seldom dramatic but can present in either a generalized form or as disease localized adjacent to an affected organ (4). The lymph nodes involved are generally 1 to 3 cm in diameter and non-tender.

The organ manifestations, organized according to anatomic location, are summarized briefly below:

Head and Neck

The brain parenchyma is seldom if ever involved, but IgG4-RD is among the most common causes of "idiopathic" hypertrophic pachymeningitis and can also cause hypophysitis. Dacryoadenitis leading to lacrimal gland enlargement is the most common feature of ophthalmic disease in IgG4-RD. Proptosis can result from combinations of orbital lesions, such as pseudotumors that do not affect the lacrimal gland and inflammation and thickening of the extraocular muscles. The triad of dacryoadenitis and enlargement of both the parotid and submandibular glands, once known as "Mikulicz's disease," is a classic presentation of IgG4-RD. Isolated submandibular gland enlargement is also a common finding in IgG4-RD.

The prevalence of atopy among IgG4-RD patients is similar to that of the general population, but a subset of nonatopic patients has peripheral blood eosinophilia and elevated IgE levels (5). Allergic rhinitis, nasal polyps, chronic sinusitis, nasal obstruction, and rhinorrhea are common in IgG4-RD. Mild to moderate peripheral eosinophilia and serum IgE concentration elevations that sometimes exceed ten times the upper limit of normal are common.

Mass lesions in the sinuses, destructive lesions in the middle ear and facial bones, midline destructive disease, and diffuse inflammation in the pharynx and hypopharynx, frequently associated with mass lesions, can all occur in IgG4-RD. Tracheal inflammation and vocal cord involvement have also been described. Riedel's thyroiditis is linked convincingly to IgG4-RD.

Chest

The lung is associated with a remarkable diversity of clinical and radiologic findings in IgG4-RD. IgG4-RD tends to track along bronchi and blood vessels, leading to thickening of the bronchovascular bundle on imaging studies. Pulmonary nodules, ground-glass opacities, pleural thickening, and interstitial lung disease can also occur. Fibrosing mediastinitis can lead to the compression of vital mediastinal structures from proliferation of invasive fibrous tissue.

IgG4-related aortitis is often diagnosed either on the basis of an incidental radiological finding or an unexpected finding at surgery. IgG4-related aortitis can lead to aneurysms or dissections in the thoracic aorta. Coronary artery lesions in IgG4-RD, sometimes associated with aneurysm formation, are observed in IgG4-RD.

Abdomen

The pancreas was the first organ recognized to be associated with elevated serum IgG4 concentrations (6, 7). AIP associated with IgG4-RD, sometimes termed type 1 (IgG4-related) AIP, demonstrates the classic histopathological findings of lymphoplasmacytic sclerosing pancreatitis. The most common clinical presentation of type 1 AIP is obstructive jaundice, induced by concomitant IgG4-related sclerosing cholangitis. IgG4-related sclerosing cholangitis must be differentiated from both primary sclerosing cholangitis and cholangiocarcinoma.

Retroperitoneum

Tubulointerstitial nephritis (TIN) is the most characteristic form of IgG4-related kidney disease (8). Computed tomographic scanning in IgG4-related TIN can reveal substantial

doi:10.1128/9781555818722.ch95

TABLE 1 Names of previously recognized conditions that comprise parts of the IgG4-related disease spectrum[a]

Mikulicz's disease (affecting the salivary and lacrimal glands)
Küttner's tumor (affecting the submandibular glands)
Riedel's thyroiditis
Eosinophilic angiocentric fibrosis (affecting the orbits and upper respiratory tract)
Lymphomatoid granulomatosis, grade 1 (commonly affecting the lungs)
Multifocal fibrosclerosis (commonly affecting the orbits, thyroid gland, retroperitoneum, mediastinum, and other tissues/organs)
Lymphoplasmacytic sclerosing pancreatitis/autoimmune pancreatitis
Inflammatory pseudotumor (orbits, lungs, kidneys, and other organs)
Mediastinal fibrosis
Retroperitoneal fibrosis
Sclerosing mesenteritis
Periaortitis/periarteritis
Inflammatory aortic aneurysm
Idiopathic hypocomplementemic tubulointerstitial nephritis with extensive tubulointerstitial deposits

[a]Modified with permission from the Massachusetts Medical Society (reference 29)

renal enlargement and hypodense lesions within the renal parenchyma. IgG4-related TIN is often distinguished from other organ manifestations of IgG4-RD by profound hypocomplementemia. The hypocomplementemia in IgG4-RD could result from the formation of immune complexes that contain IgG1 or IgG3, subclasses that bind complement more effectively and are often elevated to a lesser degree. Membranous glomerulonephropathy also occurs in IgG4-RD, but the pathophysiology of this entity appears to differ from that of IgG4-related TIN.

"Idiopathic" retroperitoneal fibrosis (RPF) is now considered to belong to a larger disease spectrum now known as chronic periaortitis. The three major components of chronic periaortitis are IgG4-related RPF, IgG4-related abdominal aortitis, and IgG4-related perianeurysmal fibrosis. IgG4-RD is responsible for most but not all (approximately two-thirds) of cases of "idiopathic" RPF. Sclerosing mesenteritis often appears to originate at the mesenteric root. The ensuing process often merges imperceptibly with RPF.

PATHOLOGY

IgG4-RD is characterized by the similarity of histologic appearance, regardless of the organ affected (9). The hallmark morphologic findings are a dense lymphoplasmacytic infiltrate rich in $IgG4^+$ plasma cells, an irregularly whorled fibrotic process referred to as "storiform" fibrosis, and obliterative phlebitis. A moderate tissue eosinophilia is also often observed. A disproportionate number of plasma cells within tissue lesions stain for IgG4.

PATHOPHYSIOLOGY

Many patients with IgG4-RD have striking elevations of serum IgG4 concentrations. In addition, except for advanced cases characterized primarily by fibrotic lesions, IgG4-positive plasma cells are nearly always present in abundance at sites of disease. Substantial elevations of plasmablasts have also been reported in IgG4-RD, and these cells appear to mirror disease activity (10, 11). Consequently, the IgG4 antibody and humoral immunity have been emphasized most prominently in discussions of pathophysiology thus far. However, the theory that IgG4 itself is a crucial player in disease etiology, which held sway for many years after the first recognition of the elevated serum IgG4 concentrations in "sclerosing pancreatitis," is now being revised.

The IgG4 Molecule

The IgG4 molecule has unique chemical properties that render it unlikely to play a central inflammatory role. The subclasses of IgG differ from each other in important ways, defined by the sequences of their heavy chain constant domains. IgG4 normally accounts for only about 4% of the total immunoglobulins among healthy individuals and is the least abundant of all of the IgG subclasses. IgG4 demonstrates weak binding to C1q and to Fc-gamma receptors because of a critical few amino acid differences in its CH2 domain (12, 13). Consequently, IgG4's ability to activate the classical complement pathway and participate in antibody-dependent cell-mediated cytotoxicity is attenuated substantially, compared, for example, to the capabilities of IgG1 (13).

IgG4 also has the unique ability to form "half-antibodies" through the process of Fab arm exchange. Amino acid variation at the hinge region of IgG4 permits the reduction of the disulfide bonds that join the two halves of an IgG4 molecule. Recombination of the dissociated arms leads to the random formation of "asymmetric antibodies" composed of half-antibody fragments directed against different antigens (12, 13). Fab-arm exchange results in the formation of IgG molecules with two different binding specificities (13). The consequence is a reduced ability to cross-link antigens and form immune complexes.

An alternative view of IgG4 is that its presence can be ascribed to a downregulatory role. The specific function of IgG4 in IgG4-RD may be to serve as a noninflammatory "antigen sink," "mopping up" antigen through its monovalent binding in a process that tends to dampen inflammation (2). Indeed, it has been demonstrated that the IgG4 response develops after chronic antigen exposure as a part of a tolerogenic response (12, 13).

The B-Cell Lineage

B cells and the cells of their lineage play important roles in IgG4-RD. Serum IgG4 concentrations decline swiftly following B-cell depletion, suggesting that the cells making most of the serum IgG4 are short-lived plasmablasts and plasma cells (14, 15). Plasmablasts are found in high concentrations in IgG4-RD, regardless of the serum IgG4 concentration (10, 11, 16). The roles of the B-cell lineage in IgG4-RD include not only infiltration into tissue sites of disease and the production of IgG4, but also antigen presentation to T cells. The circulating plasmablasts in IgG4-RD demonstrate intense somatic hypermutation, a hallmark of interaction with T cells within the germinal centers of lymph nodes (30). The fact that B-cell depletion does not lead to the complete normalization of serum IgG4 concentrations implies the presence of long-lived plasma cells that continue to make this immunoglobulin.

What Drives the Immunoglobulin Class Switch?

A T-follicular helper-cell response probably mediates the development of germinal centers within lymph nodes and other organs affected by IgG4-RD. T-follicular helper cells

may produce the cytokines (e.g., IL-4) that drive the IgG4 class-switch, culminating in the creation of IgG4-secreting plasmablasts and long-lived plasma cells.

T-Cell Pathways

T cells play a central role in IgG4-RD pathogenesis in a variety of ways, in addition to the class switch. $CD4^+$ T cells are typically dispersed throughout localized IgG4-RD lesions and are the most abundant cell found within affected tissues. Conflicting reports have implicated Th1 cells and Th2 cells in the pathophysiology of IgG4-RD (17, 18). Recent studies suggest that Th2 cells accumulate in the blood only in subjects with concomitant atopy (19).

A Novel "CD4 Killer" Cell

The recent identification of a clonally expanded population of $CD4^+$ cytotoxic T lymphocytes in both the peripheral blood and fibrotic lesions of IgG4-RD patients suggests that these cells are central to the disease. These cytotoxic T cells make products such as granzyme B and perforin that are associated more commonly with $CD8^+$ T cells. The T cells also elaborate interleukin-1, which may be an important mediator of the fibrosis.

TREATMENT

No randomized clinical trials evaluating the comparative effectiveness of different treatment regimens have been performed. Glucocorticoids are currently the first-line treatment for IgG4-RD. Most data on the use of glucocorticoids are derived from the treatment of IgG4-related pancreatitis (type 1 autoimmune pancreatitis) and have been extrapolated to the treatment of extrapancreatic IgG4-RD. Treatment of IgG4-related pancreatitis with glucocorticoids typically results in a symptomatic response within 2 weeks and remission within 2 to 3 months in most cases (20). However, the majority of patients relapse if the glucocorticoids are tapered or discontinued (20). Conventional immunosuppressive medications such as azathioprine and mycophenolate mofetil do not appear to have substantial efficacy in IgG4-RD in the absence of glucocorticoids (21). Treatment with rituximab to induce B-cell depletion has yielded promising results (14, 15, 22).

IMMUNODIAGNOSIS: TISSUE, SERUM, FLOW CYTOMETRY

Immunohistology of Tissue

"Positive" IgG4 immunostaining lends additional support to the diagnosis of IgG4-RD but is not diagnostic in and of itself. Neither the number of $IgG4^+$ plasma cells per high-power field (hpf) nor the $IgG4^+/IgG^+$ plasma cell ratio is specific for the diagnosis of IgG4-RD, and no number of $IgG4^+$ plasma cells within a biopsy sample is sufficient on its own to support the diagnosis of IgG4-RD. Rather, the finding of the characteristic histopathology in the right clinical context allows the pathologist and clinician to reach the diagnosis in collaboration.

The preponderance of plasma cells within tissue lesions stain for IgG4. An increase in the number of $IgG4^+$ plasma cells/hpf and an elevated $IgG4^+/IgG^+$ plasma cell ratio can therefore support the diagnosis of IgG4-RD, but careful clinicopathologic correlation and sound clinical judgment must be exercised in rendering the diagnosis of IgG4-RD. One may expect fewer $IgG4^+$ plasma cells in biopsies from patients with fibrotic lesions such as RPF because of the overwhelmingly fibrotic nature of the pathology at the time of biopsy in most patients. The $IgG4^+/IgG^+$ plasma cell ratio can also be a useful metric to aid in diagnosis. Most cases of documented IgG4-RD have an $IgG4^+/IgG^+$ plasma cell ratio >40% (9).

Performance and Evaluation of IgG4 Immunostaining of Tissue

Slides must be evaluated for immunohistochemistry for CD138 and IgG as well as for IgG4. IgG4 immunostaining is performed as follows: mouse monoclonal antihuman IgG4 antibody of IgG1/k isotype is diluted 1:200 for use in staining. Immunohistochemical studies are performed using appropriate controls to validate staining. Endogenous peroxidase activity is blocked by H_2O_2 before antibody incubation. Antigen retrieval is achieved by treating the tissue sections for 4 minutes with commercially available protease solutions prior to primary antibody incubations. The tissues sections are washed and incubated with the primary anti-IgG4 antibody for 24 minutes, followed by incubation with the antibody reagent. Three high-power fields with the most dense concentrations of IgG4-positive plasma cells are counted. One high-power field corresponds to a field area of 0.2375 mm^2 (10× eyepiece and 40× lens). Immunoreactive plasma cells are counted within the same three fields on the slide stained for IgG. The ratio of IgG4- to IgG-positive plasma cells is calculated.

SERUM IgG4 CONCENTRATIONS

A serum IgG4 level is often the first diagnostic test ordered when IgG4-RD is suspected. Although serum IgG4 measurements continue to play an important role in the diagnosis and management of IgG4-RD, several major considerations are important in interpreting serum IgG4 concentrations.

First, large elevations of serum IgG4 concentrations, e.g., measurements 6 to 8 times the upper limit of normal, strongly suggest the diagnosis. Serum IgG4 concentrations in patients with multiorgan disease sometimes have dramatic elevations, occasionally exceeding 4 mg/dl (16). The elevations of IgG4 are usually disproportionate to those of the other IgG subclasses, but the concentrations of IgG1, -2, and -3 are also increased in some patients (16).

Second, despite the frequently striking serum IgG4 concentrations observed in patients with this disease, elevated levels are far from universal among IgG4-RD patients. In fact, a large proportion of patients with biopsy-proven, clinically validated IgG4-RD have normal serum IgG4 concentrations, even before beginning treatment (16). Reliance upon serum IgG4 concentration elevations for diagnosis, therefore, can lead to a high rate of underdiagnosis.

Third, mild IgG4 elevations are common across a variety of conditions that can mimic IgG4-RD. Vasculitides such as granulomatosis with polyangiitis (formerly Wegener's) and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome), bronchiectasis, biliary diseases such as primary sclerosing cholangitis, pancreatic cancer, and multiple others can have confoundingly high serum IgG4 concentrations, though they rarely if ever reach the highest values achieved by some patients with IgG4-RD (23).

Similar caveats apply to the use of serum IgG4 concentrations as a correlate of disease activity. Among patients with IgG4-RD whose serum IgG4 concentrations are elevated at the start of treatment, the serum IgG4 declines substantially in essentially all patients yet only normalizes entirely in about half. Declines in serum IgG4 concentration occur

quickly following the institution of treatment but continue for many weeks following clinical improvement.

In a large retrospective study of type 1 autoimmune pancreatitis from 17 centers in Japan (24), serum IgG4 levels declined in all patients following treatment with glucocorticoids but remained above the upper limit of normal in 63% of the patients despite good clinical responses. Thirty percent of the patients who relapsed had normal serum IgG4 levels at the time of relapse. Thus, serum IgG4 concentrations should not be relied upon exclusively as an indicator of disease activity.

Serum IgG4 Assays

Measurement of serum IgG4 has been performed using several different methodologies, including immunodiffusion and immunoelectrophoresis, immunonephelometry, enzyme-linked immunosorbent assay (ELISA) and liquid chromatography-tandem mass spectrometry (LC-MS/MS).

Early studies relied on the use of immunodiffusion and immunoelectrophoresis techniques. However, overall these methods lacked the necessary sensitivity and specificity required to detect IgG4 immunodeficiencies, had to be performed manually, and were time-consuming (25).

Most currently available serum IgG4 assays are nephelometry-based. As stated above, the original purpose for developing most IgG subclass assays was to detect immunodeficiencies. Thus, many of the original IgG4 assays were optimized for the detection of low serum IgG4 concentrations. The principles involved in nephelometry measure the amount of light scattered at a given wavelength by a particulate suspension. The amount of light scatter is dependent upon the size and amount of aggregates formed by the binding of antibodies present in the reagent to antigens (i.e., IgG4 in this case) present in the sample. However, this methodology is prone to antigen excess prozone effects in which the multi-fold elevations above the upper limit of normal that are frequently observed in IgG4-RD can result in falsely low values. The prozone effect can be circumvented by diluting the test sample to allow the antibody concentration to remain in excess of that of the antigen concentration. One study of serum IgG4 measurements in a patient population from one center found the prozone effect to be responsible for spurious IgG4 undermeasurement in 26% of samples. The same study also demonstrated that the use of nephelometric reagents from different vendors can lead to widely different results even when analyzed on the same instrument (26).

Commercially available 96-well ELISA formats are a suitable alternative to nephelometry and typically involve the binding of IgG4 in the patient sample to wells coated with antibody to IgG4 (27). The wells are washed, and the amount of bound IgG4 is detected by the formation of a colored product that is quantified versus a standard calibration curve of known concentrations of IgG4. Use of the ELISA format would address the issue of the prozone effect. In the case of high testing volumes, instrumentation allowing for automation of the assays could be added.

The newest methodology involves the use of LC-MS/MS as an alternative to the constraints of nephelometric analysis. The method involves the tryptic digestion of IgG subclass proteins followed by the analysis of subclass-specific peptides by LC-MS/MS. This assay is traceable to the results obtained by nephelometry and offers the simultaneous quantification of not only IgG4 but all of the subclasses and total IgG in a single analysis. Use of this method also overcomes interferences such as those due to the prozone effect as well as M-spikes from monoclonal gammopathies (28).

FLOW CYTOMETRY

Plasmablasts are found in high concentrations in IgG4-RD, regardless of the serum IgG4 concentration (10, 11, 16). Both total plasmablasts and IgG4+ plasmablasts are good biomarkers for disease activity in IgG4-RD, and their measurement might also be useful in diagnosis. Flow cytometry gating for these cells is not widely available at this time, even though transcriptional profiling of whole blood has proved useful in other disorders.

Flow Cytometry Assay for Plasmablasts

Fluorescence labeling for flow cytometry is performed by incubating cells in a staining buffer containing optimized concentrations of fluorochrome-conjugated antibodies. Monoclonal antibodies useful in flow cytometry for plasmablasts include those directed against CD19, CD27, CD38, CD24, and IgG4.

Future Perspectives for Rheumatoid Arthritis and Other Autoimmune Diseases

JEREMY SOKOLOVE

96

Immunologic biomarkers are intrinsic to the field of rheumatology both for making a clinical diagnosis and in potentially detecting early signs of disease in at-risk individuals when symptoms are absent. In this brief chapter, we discuss developing and future directions in the use of biomarkers in rheumatology with an emphasis on rheumatoid arthritis. We discuss the role of the "mechanistic" biomarker, a subtype of the biomarker that measures a process directly linked to disease pathogenesis, thus increasing both diagnostic reliability and potentially identifying phenotype-targeted therapies. As such mechanistic biomarkers have begun a revolution in the approach to cancer, we attempt to provide parallels as to how such markers can be applied to diagnosis and targeted treatment in the rheumatic diseases.

DEFINITION OF A "BIOMARKER"

A biomarker is defined as a characteristic that can be objectively measured as an indicator of normal or pathologic biological processes or as an indicator of response to therapy (1). Although most commonly used to describe a biochemical variable, such as a circulating protein or other biomolecule, this definition can apply to many types of biological data. To this point, many biomarker studies focus on anatomical and structural variables visualized by conventional X-ray, ultrasound, computed tomography (CT) scanning (e.g., positron emission tomography), or magnetic resonance imaging (MRI), including functional MRI scans that can provide information about the biological activity in certain regions of the brain (2). Other variables that might be considered biomarkers include immune cells (number and/or type), genetic traits, and histolopathologic characteristics of diseased tissue, as well as proteins or RNA expressed at the tissue level. This review focuses primarily on the use of laboratory biomarkers, including autoantibodies, markers of inflammation, and genetic and cellular variables that might be of use for diagnosis and/or treatment of the rheumatic diseases.

MECHANISTIC BIOMARKERS

We would offer that the best biomarkers are those that are interlinked with the mechanism of a disease and refer to these as "mechanistic biomarkers." Notably, biomarkers need not be directly involved in disease pathogenesis to be useful. For example, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) can be used as rough surrogates for the assessment of disease activity in rheumatoid arthritis (RA) and other inflammatory immune diseases. Nevertheless, such markers of inflammation are very nonspecific to any one inflammatory condition and can be seen in a variety of rheumatic as well as nonrheumatic inflammatory disorders, including infection and malignancy. Such markers often represent byproducts of disease pathophysiology rather than representing intrinsic players in disease pathogenesis. The usefulness of descriptive biomarkers is therefore limited, and alone they provide limited diagnostic and/or prognostic information (3). Furthermore, the utility of a mechanistic biomarker could be its ability to more specifically identify a disease process and, in addition, to differentiate otherwise subtle subtypes of the same disease and thus stratify them in terms of both expected outcome and optimal treatment. Such mechanistic biomarkers could serve as guideposts in the quest for more personalized treatment options as well as inform the development of future mechanism-based therapies.

Biomarkers linked to underlying disease pathophysiology have already proven invaluable in the treatment of multiple types of cancer with increasingly targeted therapies. Examples of such include the expected, but highly valuable observation that expression of the estrogen receptor indicates responsiveness to antiestrogen therapy in breast cancer (4, 5). Similarly, the presence of the pathogenic BCR-ABL translocation in chronic myelogenous leukemia was in part used to identify the therapeutic utility of tyrosine kinase inhibitors, including imatinib (6). Additional subphenotyping of cancers includes the observation that overexpression of the human epidermal growth factor receptor 2 (HER2) predicts responsiveness to specific anti-HER2 monoclonal antibodies (i.e., trastuzumab) and to specific tyrosine kinase inhibitors (i.e., lapatinib) in breast cancer (7). Other biomarkers that allow targeted therapy include several novel kinase mutations in patients with non-small-cell lung cancer. Mutations in kinases such as epidermal growth factor receptor (8) and anaplastic lymphoma kinase (9) have yielded targeted therapy effective for a small but clinically significant subpopulation of lung cancer patients.

Potential Mechanistic Biomarker in Rheumatology

Unlike the many cancers in which a specific mutation leads to a malignant clone (10) that can be identified, the

doi:10.1128/9781555818722.ch96

pathophysiology involved in both the generation of autoimmunity and the effector phase of disease such as RA and systemic lupus erythematosus (SLE) seems far more complex. Despite the lack of complete mechanistic understanding, many components of disease pathophysiology are being elucidated. For example, as discussed in the previous chapter, anti-citrullinated protein antibodies (ACPAs) have been utilized as both a specific diagnostic marker and a predictor in disease severity. They have similarly been suggested to differentiate a unique subphenotype of RA. In addition to clinical features typically characteristic of ACPA-associated RA, studies on RA suggest that ACPA could serve as a biomarker of responsiveness to methotrexate and to B-cell depletion therapy (11, 12).

If truly rooted in disease mechanism, these are biomarkers that can not only stratify disease but also provide a basis for selecting mechanism-based therapies. Allergy skin testing is perhaps the best current example in which mechanistic antibody biomarkers are utilized for antigen-specific therapy. For such testing, purified allergens are injected subcutaneously with the aim of identifying those antigens to which an individual is reactive, information that can guide the development of antigen-specific tolerizing immunotherapy. Though it would seem ideal to apply such an approach to autoimmune disease, efforts to this end have thus far been limited by the breadth and complexity of systemic autoimmunity. We attempt to evaluate the current status of mechanistic biomarkers in rheumatic disease, including their limitations and future potential.

Mechanistic Biomarkers in Rheumatic Diseases—Are We There Yet?

Studies of the pathogenesis of rheumatic diseases have just begun to identify potential mechanistic biomarkers. This is perhaps best exemplified by a group of rare and often genetically defined, autoinflammatory diseases including familial Mediterranean fever, Muckle Wells disease, the related cryopyrin-associated periodic fever syndrome, and systemic onset juvenile idiopathic arthritis, all of which have been tightly associated with activation of the inflammasome and production of interleukin-1 (IL-1) (13). As such, therapies targeting IL-1 have proven highly efficacious for each of these conditions. Unfortunately, neither levels of IL-1 in the blood nor levels of IL-1 derived from peripheral blood mononuclear cells have reliably predicted response to anti-IL-1 therapy (14), and thus biomarkers downstream of IL-1, such as IL-1-induced transcriptional profiles (15), are now being investigated.

Autoantibodies have long been a characteristic measurement in autoimmunity and especially the rheumatic diseases. Such autoantibodies are used both diagnostically and potentially for prediction of disease manifestation and/or severity. Recent evidence now links certain autoantibodies to underlying pathophysiology, suggesting that autoantibodies observed in diseases including RA and SLE could represent mechanistic biomarkers. For instance, in SLE, autoantibodies that target RNA-binding proteins (i.e., Ro, La, RNP) or DNA are associated with high interferon alpha (IFN-α) activity (16). By activating Toll-like receptor 9 (TLR9) (17, 18) and TLR7 (19, 20), respectively, immune complexes containing RNA or DNA can induce human plasmacytoid dendritic cells to produce type I IFN (21), a key player in SLE pathogenesis (22). Similarly, although measuring type I IFN directly is challenging because there are many different IFN isoforms, some groups are now measuring levels of transcripts induced by type I IFN as a surrogate of type I IFN burden. At the clinical level, increased levels of IFN-associated gene transcripts have been associated with SLE disease activity (23), and such transcriptional profiles have been proposed as surrogate measures of disease activity in early-phase clinical trials (24). Thus, levels of type I interferon or IFN-associated gene transcripts could prove to be mechanistic biomarkers for SLE and potentially identify subphenotypes of SLE patients most amenable to anti-IFN therapy.

In RA, anti-citrullinated protein autoantibodies can target a wide variety of citrullinated antigens, including citrullinated fibrinogen and citrullinated vimentin. Recent studies have suggested a potential mechanism by which these antibodies might mediate disease pathophysiology. For example, immune complexes comprising autoantibody-bound citrullinated fibrinogen can stimulate the production of tumor necrosis factor alpha by costimulating TLR4 and the Fc receptor (25), and anti-citrullinated vimentin antibodies have been associated with the development of erosive bone loss in RA (26). Thus, future studies will need to focus on mechanistic implications for these previously identified biomarkers.

Use of autoantibodies as predictive tools for the identification of disease before clinical onset has been limited in both rheumatic and nonrheumatic autoimmune diseases. However, early studies utilizing autoantibodies for prediction of disease onset are being conducted. Recent studies have suggested that the presence of ACPA identifies a population of early arthritis patients more likely to benefit from early initiation of methotrexate therapy (27), and RA prevention studies are ongoing and are for the most part being guided by currently available autoantibody biomarkers. Other studies have suggested that specific ACPA and cytokines present during the asymptomatic phase (28–30) may not only improve the identification of those at risk of developing clinical RA but also pinpoint the time closest to the onset of clinical RA—a time at which the disease may be most amenable to immunomodulatory intervention. In SLE, the core diagnostic autoantibodies, including ANA and anti-double-stranded DNA autoantibodies, have also been suggested to provide markers of responsiveness to belimumab, a monoclonal antibody that neutralizes the B-cell survival factor BLyS. Subgroup analysis of phase II trials showed that only those SLE subjects with an ANA titer of 80 or greater and/or a positive anti-double-stranded DNA test responded better to therapy than placebo (31). Though perhaps only serving to more clearly define those with active SLE, it provides a roadmap to the future use of immunologic correlates that might be most central to disease physiology.

THE FUTURE OF BIOMARKERS FOR RHEUMATIC DISEASES

As we develop a deeper understanding of rheumatic disease pathogenesis, we anticipate that we will uncover an increasing number of putative mechanistic biomarkers. It is anticipated that the use of immunologic biomarkers will both establish a primary diagnosis (RA, SLE, etc.) and potentially define a molecular taxonomy of disease guided by molecular subtypes, which cannot be ascertained by clinical phenotype alone. Given the heterogeneity in disease course, disease-related damage, and response to therapy, defining the molecular features of rheumatic diseases and identifying these subphenotypes could provide improved options for targeted therapeutic interventions.

Rheumatology has long been at the forefront of immunologic biomarker discovery; some of the currently known biomarkers may prove to be mechanistic (Table 1). But as our understanding of the molecular mechanisms underpinning

TABLE 1 Current and future biomarkers for rheumatoid arthritis: diagnosis and prediction[a]

[a]CCP, cyclic citrullinated peptide; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; MMPs, matrix metalloproteinases.

the rheumatic diseases advances, so too will the identification of mechanistic biomarkers, some of which will have the capacity to guide more efficacious and targeted treatment of rheumatic disease.

Organ-Localized Autoimmune Diseases *section N*

VOLUME EDITOR: JOHN L. SCHMITZ
SECTION EDITORS: C. LYNNE BUREK AND PATRIZIO CATUREGLI

Introduction

C. LYNNE BUREK

97

Autoimmunity is common, while autoimmune disease is not. It is not clear how or why a benign autoimmune response becomes "malignant," thereby leading to pathogenic changes of a target organ. Few autoimmune diseases fulfill the strict criteria by which the autoimmune response is directly related to pathogenesis. However, many findings, either cellular or humoral, can provide strong circumstantial evidence that autoimmunity is strongly associated with a particular disease. Often, the humoral responses detected in the laboratory are best considered to be markers rather than causes of disease. The autoantibodies are useful for diagnosis or prognosis, for excluding other conditions, for classifying disease, or for monitoring therapy. Whenever we test for autoimmune disease by evaluating autoantibodies, we must consider that individuals without evidence of disease may also exhibit these autoantibodies. Therefore, all results must be evaluated in context with the entire clinical picture; autoantibodies are rarely the sole criterion for disease. However, since autoantibodies are a significant marker of disease, often developing years before symptoms are present, the autoantibodies may indicate future disease.

Autoimmune diseases can be divided into two types. The first type, the systemic diseases, consists of conditions in which the whole body may be involved. They include such disorders as systemic lupus erythematosus and rheumatoid arthritis. The second category consists of the organ-specific autoimmunities. These conditions generally involve one particular organ of the body. In early editions of this *Manual*, the section covering organ-specific autoimmunity was small and was combined within the overall section on autoimmune diseases. In the 5th edition, organ-specific autoimmune diseases warranted their own section. In the 6th edition, the section was expanded approximately 25%. In the 7th edition, topics were expanded to include molecular methods of diagnosis. In this edition, many of the methodologies described use recombinant antigens in the assays. There are now many companies that offer FDA-approved test kits for the various autoantibody evaluations using these proprietary molecules. For other newly recognized autoimmune conditions, such as hypophysitis, laboratories still use the basic assay of indirect immunofluorescence since the antigen(s) has not been identified.

In certain chapters, such as the chapter on endocrinopathies, some things have changed only a little. As in the previous edition, the chapter on endocrinopathies contains collected descriptions of the various procedures currently used to detect circulating autoantibodies in patients with immune-mediated endocrine disease, e.g., thyroiditis, Graves' disease, insulin-dependent diabetes mellitus, Addison's disease, and pernicious anemia. Since the number of target-organ-specific diseases that display diagnostically important autoantibodies is ever expanding, we have included autoimmune hypophysitis. The test strategies change once individual antigens are identified. More and more of the assays are now based on enzyme-linked immunosorbent assay using purified antigens or recombinant antigens. However, there is still a role for the "older" assays, such as indirect immunofluorescence, that can be used for screening tests and for identification of antibodies for which the precise antigen is not yet known. Certain new assays use immunoblots of tissue extracts or digested purified antigens. These assays have promise for screening several antigens or epitopes simultaneously.

More and more commercial sources are producing reagents for assays in the form of FDA-approved kits for antigens that have been identified. However, manufacturers often use different processes to obtain components (e.g., native antigens versus recombinant peptides). There is no standardization among the assays. The result is that different antibody specificities may be recognized, which is one reason not all kits give identical results. Each commercial test kit used in the laboratory must be evaluated for quality assurance, including reproducibility, precision, and distinction of negative versus positive samples. The role of the clinical laboratory is changing from one in which new assays are developed to one of evaluating the new technologies. Yet, our goal of helping the patient remains the same.

Endocrinopathies: Chronic Thyroiditis, Addison Disease, Pernicious Anemia, Graves' Disease, Diabetes, and Hypophysitis

C. L. BUREK, N. R. ROSE, GIUSEPPE BARBESINO, JIAN WANG, ANDREA K. STECK, GEORGE S. EISENBARTH,† LIPING YU, LUDOVICA DE VINCENTIIS, ADRIANA RICCIUTI, ALESSANDRA DE REMIGIS, AND PATRIZIO CATUREGLI

98

AUTOANTIBODIES IN CHRONIC THYROIDITIS, ADDISON DISEASE, AND PERNICIOUS ANEMIA

(This section was written by C. L. Burek and N. R. Rose.)

Chronic lymphocytic thyroiditis (CLT), also known as Hashimoto thyroiditis, is an autoimmune disease characterized by lymphocytic infiltration of the thyroid gland, with the concomitant production of autoantibodies to thyroid antigens, primarily thyroglobulin and/or thyroperoxidase (TPO), formerly known as microsomal antigen (1). Although few epidemiological data are available, the prevalence of CLT is estimated to be 1 in 1,000 people, with an incidence of 0.2 to 2% and a female-to-male ratio of about 18:1 (1). Clinical signs and symptoms manifest slowly and may involve many systems of the body (1). Accumulations of hydrophilic mucoproteins with edema, a condition called myxedema, affects skin and connective tissue and can affect the appearance of the individual. Lethargy may ensue, with a loss of mental acuity. Systems commonly affected are the gastrointestinal tract, the hemopoietic system, the endocrine system, and the urogenital system (1). Enlargement of the thyroid gland due to lymphocyte invasion, called goiter, is a frequent manifestation, although there is an atrophic variation. Demonstration of autoantibodies to the thyroid antigens aids in the diagnosis of CLT, distinguishing it from other causes of hypothyroidism.

Antibodies to Thyroglobulin

Thyroglobulin is a 660-kDa homodimeric glycoprotein produced by the thyroid gland, which functions as a matrix for thyroid hormone synthesis and for storage of iodine (2).

Thyroglobulin antibodies have been demonstrated by several procedures, such as precipitation in agar, indirect immunofluorescence (IF), passive hemagglutination of cells coated with thyroglobulin, radioimmunoassay, and enzyme-linked immunosorbent assay (ELISA) (3). Precipitation in agar is simple to perform but of low sensitivity, detecting only antibodies present in relatively large amounts. Passive hemagglutination tests with the use of tanned erythrocytes (tanned-cell hemagglutination [TCH]) or chromic-chloride-treated erythrocytes (chromic-chloride hemagglutination [CCH]) are very sensitive and thus detect antibodies to thyroglobulin in patients with a variety of conditions other than thyroiditis, a possible disadvantage from the diagnostic point of view. ELISA procedures for thyroglobulin antibodies are also highly sensitive and demonstrate both agglutinating and nonagglutinating antibodies.

Recent evidence shows that the antigenic specificities of autoantibodies to thyroglobulin in patients with thyroiditis are different from those in people with antibody but no disease. The naturally occurring antibodies from healthy individuals are directed primarily to sites on the molecule that are shared among species (i.e., conserved sites), whereas those found primarily in patients are directed to human-specific regions (4). In the future, a test for thyroglobulin autoantibodies specific for those individuals with disease may be of more value in diagnosis.

Antibodies to TPO

The microsomal antigen of the thyroid epithelial cell has been identified as thyroid peroxidase (TPO) (5). TPO is a glycoprotein of 933 amino acids. It is an enzyme that catalyzes the oxidation of iodide and is essential for the incorporation of iodide onto tyrosine residues in thyroglobulin, a process known as organification, and for the coupling of iodotyrosyls to generate thyroid hormones (6). Formerly, the most commonly used tests for determining TPO antibodies were indirect IF and a commercially available tanned-cell hemagglutination assay or ELISA. Preparations of isolated thyroid microsomes are often contaminated with thyroglobulin. Therefore, the commercially prepared tanned-cell kit uses a special diluent containing thyroglobulin to block any antibody that may inadvertently react. Special attention must be paid to any serum that contains high titers of thyroglobulin autoantibodies. There may be insufficient thyroglobulin to remove all traces of the antithyroglobulin antibody, and the serum will give a false-positive result. Serum titers obtained by the indirect IF procedure may reach 1,200 or higher. Titers of TPO antibody obtained by TCH may reach well over 25,000 (7).

Newer technology for the detection of TPO antibodies uses recombinant TPO antigens in ELISAs, thereby removing the necessity of blocking any contaminating thyroglobulin. More details will be discussed below.

Newer Methodology for Thyroglobulin and TPO Autoantibodies

The earlier methods for detecting both thyroglobulin and TPO autoantibodies have virtually been superseded by

†Deceased.

doi:10.1128/9781555818722.ch98

commercially available FDA-approved test kits. Therefore, the detailed procedures for chromic-chloride hemagglutination, the ELISA for thyroglobulin autoantibodies, and the indirect immunofluorescence assay for TPO antibodies are not included in this edition of the *Manual*. Please refer to the seventh edition of the *Manual* for details of these procedures.

Several companies provide FDA-approved ELISA procedures for the semiquantitative detection of thyroid autoantibodies. Chemiluminescence-based tests are also available, allowing those laboratories with random-access instruments the benefit of automated testing platforms. The instructions provided by the vendor must be followed exactly.

There are many advantages in using these kits. The test procedures are identical for thyroglobulin and TPO autoantibodies, and the same serum sample can be used in both tests. Quality control reagents are provided. Interpretation guidelines are included. However, additional quality assurance procedures must be performed. For example, before the tests can be implemented in the laboratory, additional validation must be performed for precision and reproducibility. Additionally, 20 known-positive and 20 known-negative samples should be tested for determining performance parameters in a particular laboratory. Each laboratory should establish its own normal range according to established procedures. Furthermore, an additional external control should be included in every run to ensure that the kit is working properly. This control should be a known-positive serum that has been previously tested in the laboratory, aliquoted, and stored frozen at −20°C until used.

Interpretation

Interpretation of the results of the assays should follow the guidelines presented in the information provided by the individual vendors. Often, the results will be expressed in units. The units will generally be categorized in ranges for negative, weakly positive, moderately positive, and strongly positive reactions. The negative range suggests that only low levels or no antibodies to thyroid antigens are present. A positive result indicates that antibodies to thyroid antigens are present and suggests the possibility of CLT. The assays for thyroid autoantibodies are an aid in the diagnosis of CLT and are not diagnostic by themselves.

TPO antibodies are found in 90 to 95% of patients with CLT, while thyroglobulin antibodies are found in 60 to 80% (1).

In addition to being found in chronic-thyroiditis patients, these antibodies may be found in patients with other thyroid disorders, such as primary myxedema, hyperthyroidism, colloid goiter, nodular goiter, and thyroid tumors (3). Thyroid antibodies have also been observed in the sera of patients with pernicious anemia, adrenal insufficiency, type 1 diabetes mellitus, hypophysitis, and other autoimmune conditions. The presence of these antibodies is indicative of an ongoing pathology within the thyroid gland and subsequent end-stage CLT (1). Screening for thyroid autoantibodies in pregnant women represents an effective way to identify individuals who may develop postpartum thyroiditis (8). Approximately 7% of women develop postpartum thyroiditis within 6 months of delivery (1). This condition is detected by the presence of thyroid autoantibodies (1). The antibodies can be transient or a predictor of future hypothyroidism, so continuing to monitor for disease is indicated. Finally, antithyroid antibodies are seen in a certain proportion of healthy subjects (3). The prevalence of such antibodies in subjects without overt thyroid disease is higher in women than in men. The incidence also increases with age, so that 18% of women over 40 years old have antibodies to thyroglobulin. However, a word of caution: the continued presence of these antibodies does not necessarily mean that no disease activity is occurring within the thyroid. The autoantibodies may be a significant marker of later disease (9).

Antibodies to Adrenal Antigens

Primary Addison disease is a rare disorder, with prevalence estimates of 1 in 8,000 in Western countries (10). Autoimmunity accounts for 68 to 94% of the cases from the different studies, but the real prevalence is unknown (10). Clinical manifestations are often vague, so a diagnosis may take years. Typically, for chronic disease, signs and symptoms may include weakness, fatigue, weight loss, dizziness, and darkening of the skin (10). Acute disease may result in or manifest as nausea, vomiting, lethargy, coma, and shock (10).

Patients with idiopathic Addison disease have circulating antibodies to adrenal antigens. Such antibodies have been detected by a variety of procedures (3), but the method most commonly used is indirect IF. Antibodies detected by IF mark the cytoplasm of cells of the adrenal cortex and are directed to an antigen associated with the microsomes of these cells. The antibodies belong predominantly to the IgG class and, in general, have rather low titers (not higher than 100). Recent studies suggest that different steroidogenic enzymes of the cytochrome P-450 family may be the target antigens of autoimmune Addison disease. Sera from patients with autoimmune Addison disease contain autoantibodies to 21-hydroxylase (21-OH) or 17-c-hydroxylase (11–13). A sensitive radioimmunoassay using the 21-OH antigen has been developed, but its usage is limited (12). Patients with autoimmune polyendocrine syndrome type I (Addison disease plus hypoparathyroidism and chronic mucocutaneous candidiasis) have circulating autoantibodies to the P-450 cholesterol side chain cleavage enzyme. It is still uncertain whether these autoantigens are expressed on the surfaces of adrenal cells or are otherwise accessible to adrenal antibodies *in vivo*.

Indirect IF Test for Antibodies to Adrenal Antigens

Materials

1. Frozen sections (4-μm thick) of primate adrenal tissue (used as the substrate). These sections are available commercially from some venders that deal with autoimmune test kits. Positive- and negative-control sera can also be purchased commercially.
2. Phosphate-buffered saline (PBS), pH 7.2, and rabbit or goat antiserum to human immunoglobulins conjugated to fluorescein isothiocyanate (FITC conjugate). Most conjugates are commercial preparations, and information on the characteristics of a conjugate (i.e., an immunologic analysis of the conjugate to show its specificity, the antibody, protein, and fluorescein concentrations, and the fluorescein-to-protein ratio) are provided by the company. When a commercial conjugate is obtained, the lot number should be recorded, and the optimal dilution should be checked by testing several dilutions in a chessboard titration. One lot should then be used as long as possible.
3. Buffered glycerol. Mix 9 volumes of glycerol with 1 volume of phosphate buffer (pH 7.2).
4. Coverslips.

Procedure

1. Prepare 1:5 dilutions in PBS of all sera to be tested (unknown and positive and negative controls). Sera may be screened at 1:5 dilutions or titrated in serial 2-fold dilutions until the endpoint is reached.

2. Incubate diluted sera with cryostat-cut sections of tissue in a humid chamber at room temperature for 30 min.
3. Wash the slides in PBS for 30 min at room temperature. Effective washing can be performed by gently stirring the solution with a magnetic stirrer and changing the wash solution three times.
4. Incubate sections with the appropriate dilution of FITC conjugate in a humid chamber at room temperature for 30 min.
5. Wash the slides again for 30 min as described in step 3.
6. Mount the coverslip with buffered glycerol, and read the results with a microscope equipped for fluorescence microscopy.

Interpretation of Test Results

Antibodies to adrenocortical cells are detected in the sera of 38 to 60% of patients with idiopathic Addison disease (3, 12). The antibodies are present in 7 to 18% of patients with tuberculous Addison disease and in 1% of healthy subjects. The presence of antibodies to adrenocortical cells is an indication that the disease is idiopathic and not of tubercular or other nature. Different patterns of staining have been observed; most sera stain the whole cortex, with a brighter fluorescence in the glomerulosa zone (Fig. 1 and 2), but a few sera stain only the fasciculata and reticularis zones, not the glomerulosa zone. The latter pattern has been reported with sera that also stain the interstitial cells of the testis and the theca interna cells of the ovary.

Antibodies to Antigens of Ovary, Testis, and Placenta

Antibodies staining the cytoplasm of cells of the theca interna, interstitial, and corpus luteum cells of the ovary, interstitial cells of the testis, and trophoblast of the placenta have been detected in the sera of patients with Addison disease and of patients with premature ovarian failure (3, 12). The antigens involved have not been very well characterized, and the test itself is at present more of research than of diagnostic interest.

Antibodies to Gastric Parietal Cells

Autoimmune gastritis is a chronic condition that may be asymptomatic for many years before progression to end-stage disease resulting in depletion of vitamin B_{12} and the development of pernicious anemia. Pernicious anemia affects about 2% of the population over 60 years of age (14). Prevalence is estimated to be 151/100,000, with a 66% female preponderance (15). Clinical manifestations of end-stage disease result from complications of anemia, which include pallor and fatigue (14). However, the presence of parietal cell antibodies is indicative of an ongoing gastric pathology which may ultimately lead to end-stage disease (14).

Circulating autoantibodies to intracytoplasmic antigens of gastric parietal cells (parietal cell antibodies), to the B_{12} binding site of intrinsic factor, and to the intrinsic factor Blt complex occur with high frequency in patients with autoimmune gastritis leading to end-stage disease of pernicious anemia (16, 17). Antibodies to intrinsic factor may be detected by several radioassay procedures. However, these methods are not yet regularly performed in most hospitals. Parietal cell antibodies are detected primarily by indirect IF. Parietal cell antibodies, when detected by indirect IF, bind to the cytoplasm of parietal cells of the gastric fundal mucosae of humans and various animals, like monkeys, rats, and guinea pigs (Fig. 3). As noted above, the pattern of staining resembles that seen with mitochondrial antibodies; therefore, a control test on kidney should be performed. The autoantigens to which gastric parietal cell antibodies are directed have been identified as the alpha- and beta-subunits of the gastric H/K ATPase, the enzyme responsible for acid secretion in the stomach (17).

Indirect IF Test for Antibodies to Gastric Parietal Cells

Materials and Procedure

The materials used are the same as those described previously for IF tests to adrenal antibodies but starting at a 1:10 dilution of serum. Unfixed sections of rat stomach (gastric

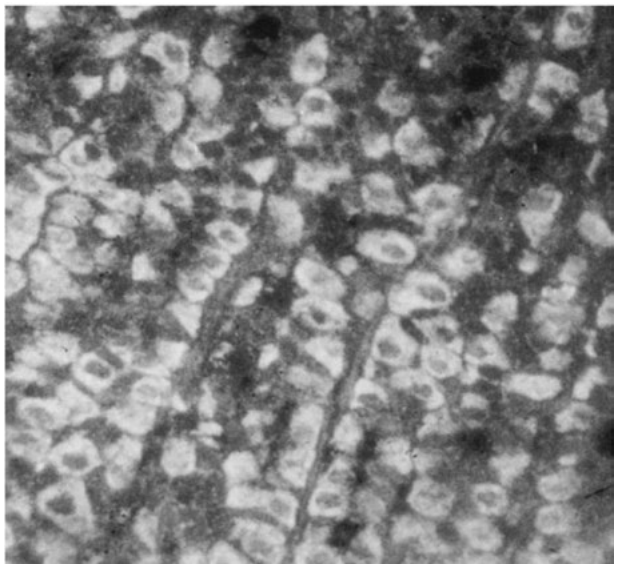

FIGURE 3 Indirect IF for antibodies to parietal cells using an unfixed, air-dried section of rodent stomach mucosa. The cytoplasm of only the parietal cells is stained. Magnification, ×100.

mucosa) are used as the substrate. Unfixed rat kidney sections are used as controls for staining because of mitochondrial antibodies.

Interpretation of Test Results

Parietal cell antibodies are found in about 90% of patients with pernicious anemia (16). These antibodies are also present in patients with a number of other conditions, such as chronic thyroiditis (33%), Sjogren's sicca syndrome (15%), atrophic gastritis (60%), and gastric ulcer (22%). Antibodies to parietal cells have been reported in about 20 to 30% of patients with *Helicobacter pylori*-associated gastritis, although the titers are usually lower than in patients with autoimmune gastritis (16). Whether *H. pylori* is an environmental agent triggering the autoimmune condition is still not known. Parietal cell antibodies are also found in the healthy population, with an incidence that varies according to age, i.e., from 2% in subjects younger than 20 years to 16% in subjects older than 60 years. They are more common in women than in men. It is also not known whether these antibodies are a biomarker of latent disease, as the interval between autoimmune gastritis with parietal cell antibodies and pernicious anemia may be as long as 20 to 30 years (16). As yet, no longitudinal studies have addressed this issue.

GRAVES' DISEASE, HYPERTHYROIDISM, AND ANTIBODIES TO THE THYROTROPIN RECEPTOR

(This section was written by Giuseppe Barbesino.)

Graves' disease (GD) is a relatively frequent and uniquely human autoimmune disease in which ongoing activation of the thyroid gland and hyperthyroidism is a consequence of circulating immunoglobulin capable of binding and activating the thyroid-stimulating hormone receptor (TSHR) on the surfaces of thyroid follicular cells. The TSHR is a cell-membrane receptor belonging to the superfamily of G protein-coupled receptors. The TSHR is closely related to the luteinizing and follicle-stimulating receptors in the same superfamily. The native TSHR is a 764-amino-acid protein. Posttranslational changes involve the cleavage of a 50-amino-acid peptide, yielding two subunits, termed A and B, linked by disulfide bonds and anchored to the thyroid cell membrane. The B subunit contains the seven membrane-spanning domains typical of all G protein-coupled receptors and a small intracellular domain. The A subunit is almost entirely extracellular (ectodomain) and contains nine leucine-rich repeats. Binding of TSH to this leucine-rich region results in structural changes along the whole receptor, ultimately resulting in the activation of the intracellular cyclic AMP (cAMP) cascade and initiation of the many TSH-dependent thyroid cell functions. The TSHR tightly controls all differentiated functions of the thyroid gland. These include transmembrane transport of iodine, the synthesis of thyroid hormone and its inclusion in the primary structure of thyroglobulin, and thyroid cell proliferation. The TSHR appears to have mild constitutive activity, in that some cAMP production occurs *in vitro* in the complete absence of the ligand.

The role of TSHR-blocking antibody (TRAb) in GD hyperthyroidism was first demonstrated with the discovery that hyperthyroidism could be caused in animals by the transfer of sera from GD patients (18). The serum factor, originally termed long-activating thyroid stimulator (LATS), was later identified as an immunoglobulin capable of stimulating the TSHR. It then became evident that while most patients with TRAb have hyperthyroidism, a subset of patients with TRAb but without TSHR-stimulating activity is capable of blocking the receptor and causing hypothyroidism (thyroid-blocking antibody [TBAb]) (19). Because of the heterogeneity of these antibodies and because of the different methods employed to determine them, the nomenclature has been the cause of some confusion. For the sake of simplicity, in this section I will abbreviate TSHR antibodies in general as TRAb, independently of their functional activity. Antibodies with TSHR-stimulating antibody will then be termed TSAb, while antibodies with blocking activity will be abbreviated TBAb, which partly follows recent recommendations (20).

In the decades since the discovery of LATS, both the TSHR and the TRAb have been studied extensively and have yielded a great deal of information on both molecules. Not only have these studies contributed tremendously to our understanding of thyroid dysfunction, but they have also resulted in the development of very sensitive and specific tests for the TRAb and expanded the clinical uses of such tests.

Nature and Properties of the TRAb

Human TRAbs are oligoclonal antibodies. Earlier studies suggested restriction to the IgG1 subclass (21), but it was subsequently suggested that TRAbs devoid of stimulating activity could also be found in the IgG2 and IgG3 subclasses (22). The ability of TSAbs to cause unremitting hyperthyroidism is due to their much longer half-life than that of TSH and to the absence of feedback regulation of thyroid hormone on plasma cells. Several monoclonal murine and human TRAbs are now available. These have been employed to gain understanding of the physiology of the TSHR and provided excellent tools in clinically useful assays for the detection of TRAbs, as described below. A large body of evidence suggests that TSAbs bind conformational epitopes on the A subunit of TSHR in a region also containing the TSH binding site (23). Early studies suggested that TSAb bound epitopes on the TSHR ectodomain but not necessarily epitopes coinciding with the TSH binding site (24).

Studies of the crystal structure of the complex TRAb-TSHR ectodomain later showed that TSH, TSAb, and TBAb bind the same region (23, 25). As a consequence, both TSAb and TBAb result in displacement of radiolabeled TSH from its receptor and are capable of competing with each other. It is interesting that the crystal structure of the bound TSHR ectodomain revealed no major conformational differences when either a TBAb or a TSAb was bound. However, the main orientations of bound Fab fragments were dramatically different when the two types of antibodies were examined (25). The mechanism for the difference in activity between TBAb and TSAb remains therefore somewhat obscure.

Assays for TRAb

Most autoantibodies in human autoimmune conditions really represent "markers" for the disease and therefore are associated with the disease with variable precision but are typically not necessary or sufficient for the clinical condition to be present. As a consequence, clinicians have to settle with limited diagnostic and predictive properties of such autoantibodies, even when excellent assays are available. Since TSAbs are the direct cause of true GD hyperthyroidism, they are expected to be present in all GD patients. On the basis of this rationale, great effort has been spent in designing and improving a TRAb assay for use in clinical practice. Indeed, over the past few decades, the performance of clinical assays for TRAb and TSAb has steadily improved, so that commercially available assays now provide outstanding tools in the management of GD. Based on the properties of TRAb, in general two types of assays are available: assays exploiting the completion of TRAb for the TSH receptor (binding assays) and assays exploiting the ability of TSAb to activate the TSH receptor (stimulating assays).

Binding Assays

Before the cloning of the human TSHR, binding assays relied on the use of human, porcine, or rodent thyroid membranes and analyzed the displacement of radiolabeled human or bovine TSH from the preparation (26, 27). These tests required fresh thyroid tissue from experimental animals or from cadaveric or surgical human thyroids and therefore were difficult to apply extensively in clinical practice. However, these studies provided fundamental information on the species specificities of TSAbs and on their binding properties. When binding data were compared with data from the bioassays available at the time, these early studies also provided evidence that the binding property of TRAb could in some cases be dissociated from the stimulating activity (26). With the cloning of the human TSHR, cell lines stably expressing the TSHR became available and provided a larger amount of the protein both for testing and for the immunization of animals (28). Monoclonal mouse TSHR antibodies thus obtained were then employed to immobilize the human or porcine TSHR to enzyme-linked immunosorbent assay plates or plastic tubes for use in solid-phase assays, with either radioactive, fluorescent, or chemiluminescent ligands, thus simplifying the assays, increasing the reproducibility of results, and making these assays available to a larger number of routine labs (29, 30). In the latest modification, TSH was replaced by a human biotinylated or enzyme-linked monoclonal TRAb (termed m22). m22 is a potent human TSAb demonstrated by crystallography to bind the TSH binding site on the TSHR (23, 31). Assays employing m22 as a ligand demonstrated greater analytical sensitivity in the low range (32) than assays employing biotinylated TSH. This translated to higher clinical sensitivity, approaching 100%, without loss in specificity (33).

TSAb Assays

The functional heterogeneity of TRAb has long been recognized. Hence, TRAb identified with binding assays may or may not also have TSAb properties. Historically, assays for TSAb were actually developed before TRAb assays. Soon after the discovery of LATS, McKenzie employed several variation bioassays in which the disappearance of radioiodine from mice's blood was measured after the infusion of GD sera (34), clearly a method not suitable for routine testing. Subsequently, *in vitro* systems employing primary thyroid cell monolayers, cryopreserved porcine thyroid cells, or a line of rat thyroid cancer cells, FRTL-5, were developed. The basic designs of these first-generation assays were similar: the patient's immunoglobulin fraction was obtained from the patient's serum and incubated with the cultured, thyroid-derived cells or tissues. The supernatant was then collected, and the cAMP production was measured by radioimmunoassay (35–38). The introduction of hypotonic medium allowed the use of serum directly, eliminating the fractionating step and allowing the use of smaller serum samples (39, 40). The cloning of the TSHR fostered the second generation of *in vitro* thyroid-stimulating immunoglobulin (TSI) assays. Chinese hamster ovary (CHO) cells were transfected with human recombinant TSHR. The transfected CHO cells were then used in the TSI tests in a manner very similar to that used for the assays described above (28, 41, 42). These assays certainly represented a major step forward but still required a laboratory to have nuclear medicine and cell culture capabilities. With the third-generation TSI assays, the need for measuring cAMP and therefore for a radioimmunoassay was eliminated. Cells were transfected with both the human TSHR and the luciferase gene, controlled by a cAMP response element. With this design, stimulation of the TSHR by the patients' sera results, as usual, in cAMP production and, in turn, transcription of the luciferase gene, which is then measured in a chemiluminescence assay (43). As an additional modification, a chimeric TSHR-luteinizing hormone receptor (LHR) has lately been introduced. In this chimeric receptor, the LHR binding site has been replaced with the homologous section of the TSHR. The rationale is that only TRAb with affinity to the TSHR binding domain will interact, while the remainder of the LHR guarantees posttranslational processing and a conformational structure similar to that of the native TSHR. This would eliminate interference from the patient's TRAb, which is devoid of stimulating activities but binds other regions of the TSHR and is capable of interfering with the detection of TSAb in the patient's oligoclonal mixture. While this assay displays excellent clinical performance in the published study (44), the theoretical basis for its advantage is not universally accepted (20).

TBAb Assays

Thyroid follicular cell destruction by the immune system is the cause of hypothyroidism in the vast majority of patients with hypothyroidism. However, in a minute fraction of patients, TBAb causes hypothyroidism. As mentioned before, TBAbs generally provide positive results and can be measured through a variation of the TSAb assay. Simply, the ability of TSH to stimulate the TSHR in any of the cellular systems used for TSAb is measured before and after the addition of the patient's serum (20). Although the assay is straightforward when the patient's serum contains only TBAb, there are analytical problems when the serum contains a mixture of TSAb and TBAb, a phenomenon that has been well documented in some cases (45). In such a situation, a mild TSAb level can act as a partial antagonist

and therefore yield positive inhibition results, even when its overall effect is as a stimulant (20).

Clinical Uses of TRAb

The major clinical use of a TRAb assay is in the differential diagnosis of hyperthyroidism. GD, the most common cause of hyperthyroidism in iodine-replete regions, can be clinically differentiated from other forms of hyperthyroidism by demonstrating a diffuse uptake of radioiodine. Indeed, in the presence of a suppressed TSH, such a finding unequivocally indicates the TSH-independent activation of all thyroid tissue by the same factor (hence the appellation toxic diffuse goiter). However, the thyroid uptake and scan test (radioactive iodine uptake) is expensive and time-consuming, unreliable when the patient has been exposed to large amounts of cold iodine, and contraindicated in pregnant patients. The recognition of TSAb as the causative factor has prompted extensive investigations into the clinical uses of TRAb assays as a diagnostic tool in the differential diagnosis of hyperthyroidism. First-generation assays, while contributing tremendous understanding of the pathophysiology and natural history of GD, were too insensitive, labor-intensive, and costly to warrant widespread clinical use: they were essentially clinical research tools. However, the last decade has brought tremendous technical advances with second- and third-generation assays, as detailed in the preceding sections. The clinical performance of these tests in accurately diagnosing GD in overtly hyperthyroid patients has now reached a sensitivity and specificity above 95% (46). The use of non-isotope-based methods has reduced costs significantly (47), while scanning for radioactive-iodine uptake remains an expensive test. As a consequence, it seems reasonable to adopt TRAb as the primary tool in the differential diagnosis of hyperthyroidism. This will allow us to accurately diagnose a large majority of patients with GD from the minority of patients with thyrotoxicosis from other causes. TRAb is particularly useful in differentiating GD from painless thyroiditis. In painless subacute thyroiditis, patients have hyperthyroidism and a diffuse nontender goiter, so the distinction from GD is difficult to make on clinical grounds alone (48). The distinction is also important, as patients with painless subacute thyroiditis will not benefit from radioiodine or antithyroid drugs (ATD), treatments used for GD. In the setting of hyperthyroidism, binding-based assays are equivalent to TSAb assays in terms of specificity and sensitivity. Patients with positive results will not need any additional tests, while a thyroid scan may still be useful in patients with negative TSAb (49). A few patients with painless thyroiditis also have a positive TSAb test. While it is important to be aware of potential false positives, this situation is quite rare. It should be noted that the clinical performance of TSAB has been studied only in patients with overt hyperthyroidism, so some caution should be exerted in extending these results to patients with subclinical hyperthyroidism.

TRAb tests can also be used in predicting which patients with GD have entered a remission and can therefore stop ATD. Patients with GD, as with many other autoimmune diseases, undergo remissions and flare-ups. Patients in remission do not need to continue ATD, while patients unable to achieve a remission while on these medications may prefer definitive treatment with surgery or radioactive iodine. Since ATD keep patients euthyroid independently of their GD activity, thyroid function tests are typically not helpful. TSAb can be employed in this situation, with some limitations. A negative test suggests that the patient is likely to remain euthyroid in the short term if ATD treatment is discontinued. However, such a result has limited efficiency in predicting which patient will remain euthyroid (i.e., free of relapses) in the long term. The cutoff for predicting remission was found to be somewhat higher than the cutoff used to diagnose Graves' disease (50, 51). This may indicate that the ongoing autoimmune process may reduce the thyroid capacity to respond to TSAb to some extent in some patients. It is also possible that during the natural history of the disease, some patients may develop a mixture of blocking and stimulating antibodies and would still test positive in a binding assay, but these circumstances may not be able to cause hyperthyroidism (52).

TRAb tests are also useful to screen GD women who are pregnant for the risk of fetal and neonatal hyperthyroidism. The mechanism for this condition is indeed the transplacental transfer of TSAb to the fetus. This event is clinically most relevant when the mother has undergone definitive treatment of her GD with radioactive iodine or surgery. In that situation, there is no maternal hyperthyroidism warning the clinician of the persistence of TSAb, and the absence of ATD treatment leaves the fetus unprotected. Several studies have shown that this dangerous syndrome occurs only in some mothers with high-titer TSAb (53). It is therefore recommended that mothers with a history of Graves' disease be screened by the TSAb assay at the 24th to 28th weeks of gestation (54) and that, in those with high titers (3 times the cutoff for a positive test), the fetus be monitored for fetal hyperthyroidism.

Conclusions

The past decades have greatly advanced our understanding of autoimmunity to the TSHR. These advancements have helped to unravel the molecular phenomena leading to the hyperthyroidism of GD but have also provided the basis for the development of reliable tests for diagnosing and monitoring GD. Both modern-day clinicians and clinical laboratorians should be familiar with these tests in order to exploit them to the full extent of their possibilities.

AUTOANTIBODIES IN DIABETES

(This section was written by Jian Wang, Andrea K. Steck, George S. Eisenbarth, and Liping Yu.)

Diabetes mellitus is made up of a heterogeneous group of metabolic disorders characterized by hyperglycemia. Approximately 10% of patients with diabetes mellitus have the immune-mediated form of the disease, now termed type 1A diabetes (American Diabetes Association [55]). Prior terms for this form of diabetes include juvenile-onset diabetes and insulin-dependent diabetes. Given that as many patients develop type 1A diabetes during their adult years as they do during childhood and that the disease results from a cellularly mediated autoimmune destruction of the β-cells of the pancreas, the term type 1A has been adopted to reflect disease etiology. A type 1B (idiopathic) form of diabetes represents severe loss of insulin secretion on a nonautoimmune basis, but at present, a clear example of this form of the disorder is lacking. Type 2 diabetes is characterized by insulin resistance and moderate loss of insulin secretory capacity, and the majority of patients with diabetes have this form of the disease. Finally, separate diabetes mellitus categories consist of gestational diabetes and "other specific types of diabetes," which include genetic defects, such as MODY (maturity onset of diabetes in the young) and diabetes due to an accompanying pathology (e.g., pancreatic abnormalities, endocrinopathies, drug-induced diabetes).

The great majority (>90%) of non-Hispanic Caucasian children and approximately 50% of Hispanic and African American children who develop diabetes have the type 1A form of the disease, while between 5 and 15% of adults presenting with diabetes (depending upon the population) have type 1A diabetes. Type 1A diabetes is highly associated with specific HLA class II (DR and DQ) alleles, with both high-risk and protective genotypes having been reported. In particular, DQ8 (DQA1*0301 DQB1*0302) and DQ2 (DQA1*0501 DQB1*0201) are present in 90% of Caucasian patients with the disease and 40% of the general population, and DQ6 (DQA1*0102 DQB1*0602) is present in 20% of the population and 1% of children with type 1A diabetes. The nomenclature and detailed associations of specific HLA alleles and additional genetic polymorphisms associated with type 1A diabetes can be found at www.barbaradaviscenter.org and in chapter 7 of *Type 1 Diabetes: Cellular, Molecular & Clinical Immunology* (56). There are no tests that can absolutely exclude a diagnosis of type 1A diabetes, and it is possible for individuals to have evidence of both type 1A diabetes (e.g., anti-islet autoantibodies) and type 2 diabetes (e.g., severe insulin resistance). In general, however, the presence of anti-islet autoantibodies measured with highly specific assays (≥99% specificity) in a patient with diabetes are pathognomonic of the disorder, and multiple autoantibodies are present in the majority of prediabetic individuals (57–59). The presence of anti-islet autoantibodies can be used to predict the disease, with varied positive predictive values depending on the number of autoantibodies expressed (Fig. 4) (60, 61). Though there is general agreement that T lymphocytes rather than autoantibodies are the primary pathogenic mechanism, at present there is a lack of assays for anti-islet T cells with sufficient specificity and sensitivity to contribute to laboratory diagnosis or disease prediction.

Autoantibodies

Anti-islet autoantibodies are usually present years before the clinical onset of type 1A diabetes. A decade ago, anti-islet autoantibody tests were limited to measuring cytoplasmic islet cell autoantibodies (ICA) and insulin autoantibodies (IAA). Currently, recombinant autoantibody assays with biochemically defined autoantigens, including insulin (62), glutamic acid decarboxylase (GAD) (63), insulinoma antigen-2 (IA-2 or ICA512) (64), a homologous antigen, I-A2β (phogrin), zinc transporter-8 (ZnT8) (65), and carboxypeptidase H, are available (Table 1).

Cytoplasmic ICA were first discovered in the early 1970s in patients with polyendocrine autoimmunity (66), and antibodies in the sera from these patients reacted with frozen sections of human pancreas. These polyendocrine patients with type 1A diabetes have ICA that frequently persist for decades, while in the majority of patients with type 1A diabetes, the ICA slowly disappear. The ICA were soon identified in patients with the more common form of type 1A diabetes and were found to be present long before the clinical onset of diabetes (67, 68). The Diabetes Prevention Trial—Type 1 (DPT-1) demonstrated that in relatives, all anti-islet autoantibodies tested for in the trial, including ICA, GAD autoantibodies (GAA), and IA-2 autoantibodies (IA-2A), were relatively stable, with 75 to 85% of all positivity (90 to 95% with high levels) confirmed during follow-up. ICA have been shown to be present in 70 to 80% of patients newly diagnosed with type 1A diabetes and are predictive for the development of diabetes in both relatives of patients with diabetes and the general population. ICA are a heterogeneous mixture of IgG isotype autoantibodies against a variety of islet cell molecules. To date, four autoantigens that contribute to ICA positivity, including GAD, IA-2/ICA512, ZnT8, and glycolipids, have been defined (63, 65, 69–72). However, there are likely other autoantibodies still to be identified (Fig. 5). Approximately 5% of ICA-positive individuals without biochemical autoantibodies in the DPT-1 trial progressed to diabetes, suggesting that there are other autoantigens playing roles in type 1A diabetes autoimmunity. We believe that the four current major autoantibody assays in general can replace the ICA test for initial screening even though there probably remains an additional unidentified ICA autoantigen(s) ("antigen X") (Fig. 5).

The first ICA antigen component to be determined was a 64-kDa protein that was later identified (62) as the enzyme GAD. GAD is present in all human islet cells (e.g., α, β, and δ) and other endocrinological organ tissues, like

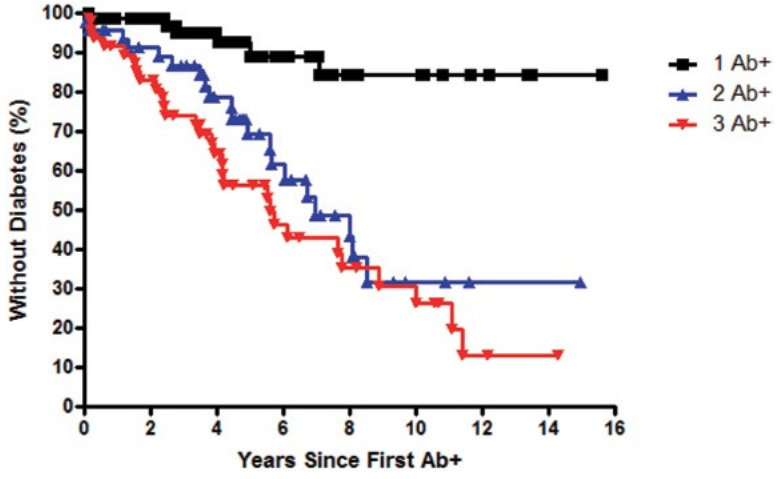

FIGURE 4 Progression to diabetes in children positive for anti-islet cell autoantibodies in DAISY (Diabetes Autoimmunity Study in the Young) relative to the number of anti-islet cell autoantibodies expressed (autoantibodies to GAD65 [glutamic acid decarboxylase], ICA512 [IA-2, insulinoma-associated antigen], and insulin). Adapted with permission from *Diabetes Care* (60).

TABLE 1 Biochemically characterized autoantigens

Autoantigen	% Sensitivity	Comment
Insulin	49–92	Higher levels in young children than in adults
GAD (glutamic acid decarboxylase)	84	High sensitivity for adult-onset type 1A
ICA512/IA-2	74	Tyrosine phosphatase-like molecule
ZnT8	70	Zinc transporter 8
IA-2β/phogrin	61	Tyrosine phosphatase-like molecule
Carboxypeptidase H	10	Infrequent
GLIMA38	14–38	Not yet sequenced
GM2-1	?	Ganglioside for chromatography assay
ICA69	?	Used in Western blot assay with poor specificity
ICA12	<20	Diabetes relatedness requires further study

testes, ovary, and neurons, though only pancreatic beta cells are destroyed in type 1A diabetes. The anti-GAA of patients with stiff-man syndrome (SMS) had been previously identified and are unusual in that they react with fixed sections of the brain and react with denatured GAD molecules on Western blots and with GAD protein fragments (73). In contrast, most diabetic sera target only GAD protein epitopes, depending on protein conformation, and do not bind GAD protein fragments or react with denatured GAD protein. There are two isomers of GAD, GAD65 and GAD67, which are 76% homologous in amino acid sequence. Autoantibodies to GAD65 are predominant over those to GAD67, and the autoantibodies binding to GAD67 in patients with diabetes seem to represent antibodies to epitopes shared with GAD65 (74).

The second-identified ICA antigen component was IA-2 (or ICA512), a protein tyrosine phosphatase (71, 72), and its homologous antigen IA-2β (phogrin). The two isomers are most homologous in their antigenic intracellular regions, to which essentially all of the autoantibodies are directed. Almost all autoantibodies to I-A2β also react with IA-2, while approximately 10% of patients with diabetes have autoantibodies reacting only with IA-2 and not with IA-2β. In addition, two differentially spliced ICA512 (IA-2) mRNAs are expressed in islets, with one form lacking exon 13, which includes the transmembrane region of the molecule (75). In our laboratory, an IA-2ic clone is used, but another clone (ICA512bdc) is still being used for some ongoing diabetes clinical trials. Approximately 10% of patients developing type 1 diabetes have autoantibodies reacting with only one of the two forms of alternatively spliced IA-2 molecules.

The most recently discovered ICA antigen component was ZnT8, a zinc transporter protein related to insulin secretion in humans coded by a gene, *SLC30A8* (65), and interestingly, certain alleles of this gene may increase the risk for developing type 2 diabetes (76). Most of the full-length molecule is hydrophobic, as it is within the membranes of secretory granules, and a highly specific and sensitive assay was achieved using the C terminus of the molecule (65). Of note, there are two major polymorphic variants of ZnT8, one with a tryptophan and the other with an arginine at position 325 of the molecule (77) (also, a glutamine variant is more common in African Americans). The majority of patients have autoantibodies recognizing both variants, but a subset have autoantibodies recognizing only one variant. Those recognizing the specific arginine variant are patients genetically homozygous for the arginine variant and vice versa for the tryptophan variant. This is a unique demonstration that islet autoimmunity in terms of epitopes recognized is truly autoimmune, with patients recognizing their own sequence.

To date, insulin is the only known beta-cell-specific autoantigen of humans (all other islet autoantigens are also produced by human non-beta islet cells). IAA were found by Palmer and coworkers (78) in patients with newly diagnosed type 1A diabetes and were soon demonstrated to be present for many years before the clinical onset of disease. IAA are so far the only autoantibodies dramatically age dependent in their prevalence and levels (79, 80). The levels of IAA inversely correlate with the age of disease onset (60, 80), and less than half of individuals developing type 1A diabetes after age 15 have detectable IAA levels. IAA is usually the first autoantibody to appear in young children developing type 1 diabetes (81, 82). For most patients, treatment with exogenous insulin also induces insulin antibodies (IA). The current IAA assay is not able to distinguish between natural insulin autoantibodies and induced insulin antibodies. In the rare insulin autoimmune syndrome (83), also termed Hirata syndrome, patients express high levels of IA, often with episodes of severe hypoglycemia.

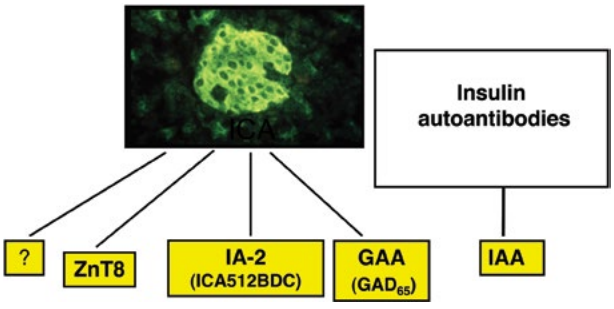

FIGURE 5 Current biochemical anti-islet autoantibody assays.

General Assay Methodology

The first useful islet autoantibody assay was the ICA test utilizing indirect immunofluorescence with frozen sections of human pancreas as the substrate. A standard for ICA utilizing a serial dilution of a calibrated serum with assigned Juvenile Diabetes Foundation (JDF) units was established. To date, the ICA test remains cumbersome, and Immunology of Diabetes Society (IDS) workshops demonstrated that there existed large variation between laboratories in terms of sera called ICA positive.

The current major format for determination of islet autoantibodies uses fluid-phase radioimmunobinding assays, applied to all four major islet autoantibody tests, including GAA, IA-2A, ZnT8A, and IAA. There is available a semi-automated format in which labeled antigen is incubated with patient sera, and then both are placed in 96-well filtration plates. The immune complex is precipitated with protein A- and/or protein G-coupled Sepharose, free radioactivity is separated by filtration washing, and then scintillation fluid is added directly to the 96-well filtration plates, and counting is performed on multichannel beta counters able to handle the plates (Fig. 6).

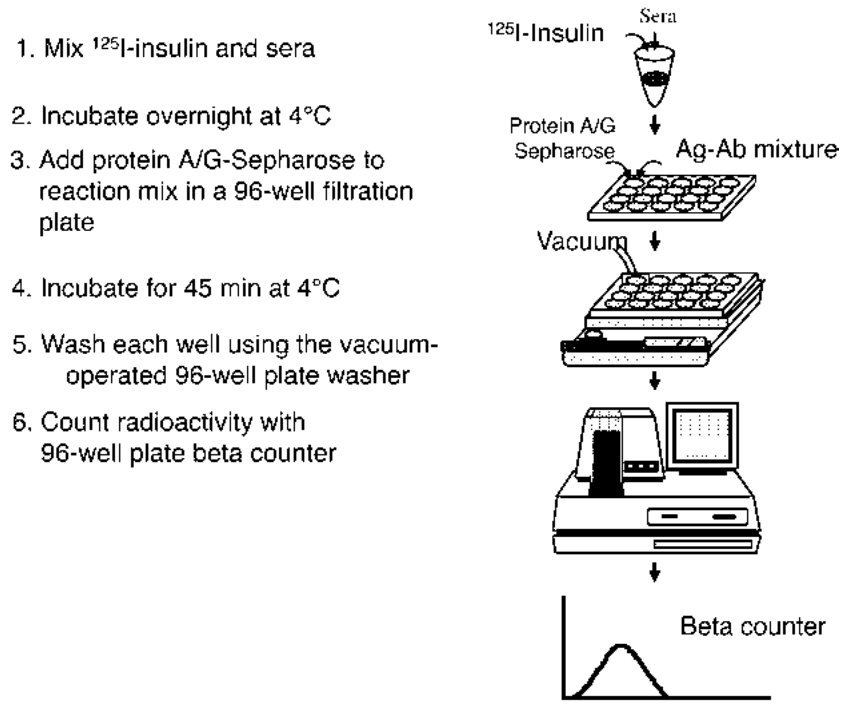

FIGURE 6 General outline of high-throughput fluid-phase 96-well plate assays for anti-insulin autoantibodies. In the illustrated example, ^{125}I-insulin is utilized, but the assay formats are identical for the GAD65, IA-2, and ZnT8 assays. Ag, antigen; Ab, antibody.

Given a lack of linear correlation between the laboratories, an islet autoantibody harmonization program (84) has been launched with the effort of an international collaborative group convened by the NIDDK. A standardized assay protocol and a set of common calibrator sera currently for GAA and IA-2A were developed to improve harmonization of measurement of these autoantibodies (84). The harmonization program eventually aims to have all islet autoantibody assays standardized, including those for IAA and ZnT8A. Utilization of the standard harmonized assays allows us to analyze and to compare the data between laboratories and between trials done by different laboratories, with expression of the assay results as NIDDK units.

ELISAs employing plate-bound antigen are the most common assay formats for basic immunologic research. In multiple diabetes autoantibody workshops, for either human or mouse models, standard ELISA formats lack both sensitivity and specificity compared to the fluid-phase radioassay formats, especially for the IAA assay. In the international workshop, a modified ELISA for GAA attained a level of specificity and sensitivity equivalent to that of the radioassays (85). In the 2012 Islet Autoantibody Standardization Program (IASP) workshop, a ZnT8A ELISA with an identical modified ELISA format was shown to have a level of sensitivity equivalent to that of the radioassay with less specificity.

It is recommended that all laboratories attempting to measure anti-islet autoantibodies take part in IASP workshops organized by the IDS and the NIDDK. As demonstrated with multiple workshops, although the majority of laboratories have excellent assays for GAA, IA-2A, and ZnT8, many laboratories have IAA assays with unacceptable sensitivities and specificities when evaluating in blind trials the IASP panel of 100 control sera and 50 sera from patients with type 1A diabetes of recent onset.

Determination of ICA by Indirect Immunofluorescence

Sample Requirements

Samples for indirect immunofluorescence were stored at −20°C or below until analyzed. Approximately 200 μl of serum per sample is needed for this assay. Hemolyzed or lipemic blood samples may have artificially low ICA titers and thus should not be used for analysis with this method. In order to obtain high-quality serum and prevent or decrease the possibility of hemolysis, the yellow-top gel serum separator tubes are recommended.

Materials, Reagents, and Equipment

- Cryostat
- Frozen 5-μm sections of human blood group O pancreas tissue
- Fluorescein-antibody conjugate [goat anti-human IgG $F(ab)_2$ fragment-FITC, rabbit fluorescein-conjugated antihuman IgG (Behringwerke AG, Marburg, Germany), or sheep anti-human IgG FITC conjugate (Sigma, St. Louis, MO, USA)]
- Fluorescence microscope with an epi-illumination 20× objective (Leica, Wetzlar, Germany)
- Reciprocal shaker

Principle

We highly recommend human pancreas with blood type O of cadaveric donors taken while the heart is still beating, because the pancreas is very prone to autolysis. Five-millimeter cubes of the pancreas are quickly frozen in isopentane at −70°C, sealed in a freezer container, and stored at −80°C. Five-micrometer-thick frozen sections are cut while the temperature of the cryostat is held between

−25 and −30°C, placed onto the glass microscope slides (usually four sections per slide), air-dried for 30 min with a fan, and then directly used or stored at −80°C. The freezer-stored slides must be brought up to room temperature with air-drying in front of a fan for 30 min before use. The slides to be used should be well labeled, and the sections on the same slide need to be isolated from each other with a hydrophobic marker. A serum sample is then applied to each section, and tissue-bound specific autoantibodies from the patient's serum will be revealed by an animal (goat, sheep, or rabbit) anti-human IgG-fluorescein conjugate under a fluorescence microscope with epi-illumination.

Procedure

1. In the initial experiment, 50 μl of undiluted serum is applied to each tissue section and incubated for 30 min at room temperature in a moisture chamber.
2. Each slide is rinsed gently with 0.5 M PBS (pH 7.4), with care taken not to damage or remove each tissue section.
3. The slides are completely submerged in 0.5 M PBS (pH 7.4) and gently washed on a reciprocal shaker for 5 min, and this wash step is repeated twice, each time in fresh PBS for 5 min.
4. Both sides of the slides are quickly dried with a low-lint Kim wipe, with care taken not to touch the tissue sections on each slide, and then placed back into the incubation chamber to prevent complete dehydration before the next step.
5. Each section is then covered with 50 μl of diluted (often a 1/20 dilution determined empirically) fluorescein-antibody conjugate in PBS (containing 1% bovine serum albumin [BSA]) and incubated for 30 min at room temperature in a moist chamber.
6. The slides are washed as in steps 2 and 3.
7. The slides are quickly dried as in step 4, and a slide cover is put on with a glycerol solution (90% glycerol-10% [wt/vol] PBS [the coverslip is applied and sealed with nail polish]).
8. Islet cell-specific fluorescence is observed under a fluorescence microscope fitted with 20× epi-illumination.
9. All samples with detectable ICA are titrated by retesting the serum in serial dilution. The endpoint titer is compared with the 80-JDF unit international standard used by the IDS workshops.

Standardization, Quality Control, and Quality Assurance

1. To determine the appropriate dilution of fluorescein-antibody conjugate, known-negative, weakly positive, and strongly positive sera need to be tested with various dilutions of conjugate, and the optimal dilution is the highest dilution that gives the strongest specific islet cell reaction with the least nonspecific staining.
2. A standardization procedure should be applied for each new lot of pancreas by serially diluting the 80-JDF unit standard in both negative sera and PBS. A five-point curve of standard diluted in negative serum versus standard diluted in PBS should be linear, and JDF units are calculated from this curve by interpolation of patient serum endpoint titers in PBS.
3. Strongly positive, weakly positive, and negative-control samples should be included in each assay. It is recommended that a known-positive serum sample be stored in aliquots and tested every 3 months to monitor assay drift. The ICA assay, including quality control samples, should be analyzed with the reader blind to the sample identity.

Biochemically Defined Autoantibody Radioassay

Sample Requirements

We recommend obtaining the serum from red-top or tiger-top (separator) blood-collecting tubes and ideally to be hemolysis and lipemia free. Only 5 μl of serum is required to measure GAA, IA-2A, or ZnT8A, and 12 μl of serum is required for micro-IAA (mIAA).

Materials, Reagents, and Equipment

- Human GAD65 cDNA clone
- Human IA-2 cDNA clone (the most utilized clone is IA-2ic [intracytoplasmic IA-2])
- TNT Sp6 coupled *in vitro* translation kit (Promega)
- RNasin RNase inhibitor (Promega)
- [^{35}S]methionine (PerkinElmer)
- ^{125}I-insulin (PerkinElmer)
- Protein A-Sepharose Fast Flow (GE Healthcare)
- Protein G-Sepharose Fast Flow (GE Healthcare)
- NAP-5 column (GE Healthcare)
- 96-Well PCR plate (Fisher)
- 96-Well filtration plates (Fisher)
- Bottle-Top 50-ml filter units (Fisher)
- TopSeal (PerkinElmer)
- Microscint-20 (PerkinElmer)
- TopCount β-counter (PerkinElmer)
- Plate autowasher (BioTek) or vacuum-operated 96-well plate washer (Millipore)
- 96-Well plate shaker (Wallac-Delfi)

GAA and IA-2A Assays

General Principle

The cDNA constructs used in the GAA and IA-2A assays are the full length of human GAD65 and an intracellular domain of IA-2 (IA2ic). The GADA and IA-2A assays are identical and use the NIDDK-harmonized standard protocol. Labeled GAD65 and IA-2 are produced by *in vitro* transcription/translation with [^{35}S]methionine. The patient serum is incubated with labeled antigen overnight, and antibody-bound labeled antigens are separated from unbound labeled antigens with protein-A Sepharose precipitation in a 96-well plate. Radioactivity is counted on a 96-well plate β-counter. Results are calculated with a standard curve from a set of NIDDK calibrator sera and expressed as standard NIDDK units. Many laboratories are currently still using their own index, which adjusts the counts per minute (cpm) of the test serum for the cpm of positive- and negative-control sera in each assay. A cutoff for positivity above the 99th percentile of normal controls is often utilized.

Procedure

Part I: *In Vitro* Transcription/Translation To Produce Labeled GAD65 and IA-2

Important notes. All reagents, tubes, and tips must be RNase free. All reagents should be kept on ice while on the bench. An incubation temperature of 30°C is critical for production efficiency. The reticulocyte lysate must be stored

at −80°C and thawed rapidly just before use. Each tube can be thawed only twice, after which there will be a significant decrease in its efficiency.

Procedure.

1. Follow the kit protocol for the one-step *in vitro* transcription/translation reaction. The total reaction volume can be adjusted, decreased, or increased, as needed.
2. Purify the labeled product with a NAP-5 column.
3. Analyze the activity of the labeled antigen by counting the activity in 5 μl of a 100-fold-diluted aliquot. The labeling efficiency significantly varies with different cDNAs and plasmids.

Part II: Radioassay (2 Days)

Day 1.

1. Prepare the buffers. The assay buffer consists of 20 mM Tris-HCl, 150 mM NaCl, and 0.15% Tween 20 (pH 7.4), and for the antigen buffer, add 0.1% BSA in assay buffer.
2. Prepare the antigen buffer solution. With the optimized conditions, 20,000 cpm in 50 μl of antigen buffer is usually applied per well. For a 96-well plate with 25% extra volume to ensure enough volume for aliquoting into each well, the total cpm is calculated as follows: $96 \times 20{,}000 \text{ cpm} \times 125\% = 2.4 \times 10^6$ cpm for either ^{35}S-GAD65 or ^{35}S-IA-2. The total volume is calculated as follows: $96 \times 50\ \mu l \times 125\% = 6$ ml.
3. Prepare the serial dilution of a calibrated standard serum with known NIDDK units. Calibrated standard sera with known NIDDK units in serial dilution are available from the NIDDK. We recommend a standard curve covering a wide range of antibody levels with a calibrated standard set of sera in each assay or every 4 plates if more than 4 plates are used in each assay.
4. In the incubation of serum with antigen buffer, duplicates are recommended for each sample. Add 2.5 μl of serum and 60 μl of antigen buffer solution containing either ^{35}S-GAD65 or ^{35}S-IA-2 into a 96-well PCR plate and incubate overnight at 4°C. The standard positive-control and negative-control serum samples for GAA or IA-2A must be included in each assay.
5. In preparing the 96-well filtration plates, coat the plate with BSA by adding 200 μl of antigen buffer to each well, put the plate on aluminum foil, and incubate it overnight at room temperature.
6. In preparing protein A-Sepharose, use only plastic tubes because protein A sticks to glass. Pull 20 ml of protein A-Sepharose into a 50-ml tube, spin the solution down at 1,000 × *g* for 3 min, remove the fluid phase, and resuspend it into assay buffer. Repeat this twice, and make a final 50% (vol/vol) solution of protein A-Sepharose/antigen buffer.

Day 2.

1. Remove the antigen buffer from the 96-well filtration plate and add 25 μl of well-mixed 50% protein A-Sepharose to each well.
2. Transfer 50 μl from each well of the overnight incubation to the 96-well filtration plate, and shake the plate on a plate shaker at low speed for 45 min at 4°C.
3. Place the plate on a plate washer, and wash the plate three times with 200 μl of assay buffer per well each time. Then remove the plate, add 100 μl of assay buffer per well, and shake the plate for at least 5 min at 4°C.
4. Wash the plate two more times with 200 μl of assay buffer per well each time, change the plate orientation, and wash the plate another two times.
5. Blot the plate with a paper towel, and place the plate under a lamp for about 15 min. After the plate is dry, add 25 μl of scintillation liquid (MicroScint-20) to each well, seal the plate with a piece of Top-Seal, and count the radioactivity of the plate on a TopCount β-counter.
6. Obtain the cpm for each well, and obtain mean cpm for each sample if duplicates are performed.
7. Calculate the index with the following formula: (cpm of the test serum – cpm of the negative serum)/(cpm of the positive serum – cpm of the negative serum).
8. Calculate NIDDK units. Using the cpm from the serial dilution (5 points) of a calibrated standard serum with known NIDDK units, plot a chart with log 2 NIDDK units versus cpm in an Excel sheet as in Fig. 7. With the curve formula, log 2 NIDDK units can be calculated for each test sample by replacing (*x*) in the formula with the cpm of the test sample and then converting log 2 units into NIDDK units by anti-log 2 (power of 2).

Standardization, Quality Control, and Quality Assurance

1. The laboratory should keep enough of the volume of the calibrated standard sera and the positive- and negative-control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
2. All the assays are run in duplicate, with a standard curve for NIDDK unit calculation, and include high/low-positivity and negative-control samples for quality control purposes and for lab index calculation. In our assay, GAA positivity is any value greater than 20 NIDDK units and IA-2A positivity is greater than 5 NIDDK units.
3. The results of analysis of positive controls from each assay should be plotted in a preestablished Shewhart plot, with the mean ± 3 standard deviations (SD) to monitor the assay drift and evaluate assay performance. Our positive-control range for both GAA and IA-2A should be within 3 SD. The negative-control value must be less than the 99th-percentile value for

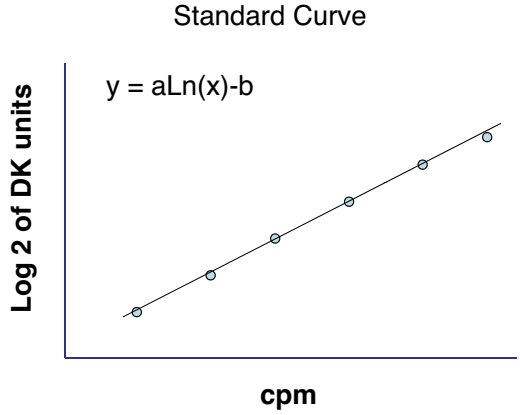

FIGURE 7 Standard curve for calculation of NIDDK units. The *x* axis is the number of cpm from the assay after removal of the background cpm, and the *y* axis is log 2 NIDDK units.

normal controls for the assay results to be valid (e.g., <20 [GAA] or <5 [IA-2A]).
4. Every positive sample in the first assay is confirmed by repeating that sample in a different assay. If the second confirmatory assay result is negative, a third run is performed. We utilize the results of two assays, which agree (−,− or +,+), for the determination of a positive or negative result.

mIAA Assay

General Principle

The mIAA assay is a competitive radioassay. The patient serum is incubated with ^{125}I-insulin with and without cold human insulin overnight, and antibody-bound labeled antigens are separated from unbound labeled antigens with protein A/G-Sepharose precipitation in a 96-well plate. Radioactivity is counted directly on a 96-well-plate β-counter for the βemission of ^{125}I. The levels are expressed as an index that adjusts the Δcpm of the test serum for the Δcpm of positive- and negative-control sera in a particular assay. An NIDDK unit is not available for IAA at present.

Procedure (2 Days)

Day 1.
1. Prepare the buffers. Assay buffer consists of 20 mM Tris-HCl, 150 mM NaCl, 0.15% Tween 20, 0.1% sodium azide, and 0.1% BSA (pH 7.4), and antigen buffer is the same as assay buffer except that it contains 1% BSA.
2. Prepare the ^{125}I-insulin-buffer solution with and without cold human insulin. Use 1 ml of 5% BSA in PBS to dissolve the powder of 10 μCi of ^{125}I-insulin as a stock solution. We utilize 20,000 cpm in 30 μl of antigen buffer per well. For a 96-well plate with 10% extra to ensure enough volume for aliquoting into each well, the total cpm equals 96 times 20,000 cpm times 110%, which equals 2.1 times 10^6 cpm or 160 μl of ^{125}I-insulin stock solution; the total volume is equal to 96 times 30 μl times 110% or 3.2 ml, which needs to be divided in half (half with and half without cold human insulin [100 U/ml]) as follows: 1,520 μl of buffer 1 plus 80 μl of ^{125}I-insulin (for a total of 1.6 ml) and 1,392 μl of buffer 1 plus 128 μl of cold insulin and 80 μl of ^{125}I-insulin (for a total of 1.6 ml).
3. Incubate the serum with antigen buffer. Four wells per serum sample will be used for both competition and noncompetition in duplicate. Add 6 μl of serum and 30 μl of antigen buffer into a 96-well PCR plate, mix well, leave the plate at room temperature for 2 h, and then incubate overnight at 4°C. The index positive control, low-positivity control, and negative-control serum samples must be included in each assay.
4. To prepare 96-well filtration plates, coat the plate with BSA by adding 200 μl of assay buffer to each well, put the plate on an aluminum foil sheet, and incubate it overnight at room temperature.
5. To prepare protein A/G-Sepharose, use only plastic tubes because protein A/G sticks to glass. Put 20 ml of protein A-Sepharose and 5 ml of protein G-Sepharose individually into two 50-ml tubes, spin the solution down at 1,000 × *g* for 3 min, remove the fluid phase, and resuspend it into assay buffer. Repeat this twice, and make a final 62.5% (vol/vol) solution for protein A-Sepharose with assay buffer and 40% (vol/vol) solution for protein G-Sepharose. Mix 4 parts of protein A-Sepharose solution with 1 part of protein G-Sepharose solution to form a final working solution with 50% (vol/vol) protein A-Sepharose and 8% protein G-Sepharose.

Day 2.
1. Remove the assay buffer from the 96-well filtration plate and add 50 μl of well-mixed protein A/G-Sepharose to each well.
2. Transfer 30 μl from each well of the overnight incubation to a corresponding well on the 96-well filtration plate, and shake the plate on a plate shaker at low speed for 45 min at 4°C.
3. Place the plate on a plate washer and wash the plate three times with 200 μl of assay buffer per well each time. Then remove the plate, add 100 μl of assay buffer per well, and shake the plate for at least 5 min at 4°C.
4. Wash the plate two more times with 200 μl of assay buffer per well each time, change the plate orientation, and wash the plate another two times.
5. Blot the plate on a paper towel and place the plate under a lamp for around 15 min. After it is dry, add 50 μl of scintillation liquid (MicroScint-20) to each well, seal the plate with a piece of TopSeal, and count the radioactivity of the plate on a TopCount β-counter.
6. Calculate the index with the following formula: (Δcpm of the test sample − Δcpm of the negative control)/(Δ cpm of the positive control − Δcpm of the negative control).

Standardization, Quality Control, and Quality Assurance

1. The laboratory should keep enough volume of the positive- and negative-control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
2. All the assays are run in duplicate and must include positive/negative-control samples. An ultralow positive control just above the 99th percentile is highly recommended to be included in each mIAA assay, particularly to monitor the sensitivity of the assay. Our ultralow standard positive-control range is an index from 0.011 to 0.030. In our assay, a positive mIAA value is any value greater than the index value, 0.010, the 99th percentile of normal controls.
3. The results of the analysis of negative and positive controls from each assay should be plotted in a preestablished Shewhart plot with means ± 3 SD to monitor the assay drift and evaluate assay performance. Our positive-control range should be within 3 SD. The negative control must be <0.01 for results of the assay run to be utilized.
4. Every positive sample in the first run is confirmed to be positive by repeating that sample in a different assay. If the second confirmatory assay comes out negative, a third assay is necessary. The results of two assays that agree (e.g., +,+ or −,−) will be the final determination of a positive or negative result.

ZnT8A Assay

General Principle

The ZnT8A assay is similar to the GAA or IA-2A assay. The cDNA construct ZnT8RW is a dimmer of two identical intracellular domains of ZnT8, with one having arginine and the other tryptophan at amino acid position

325, representing two major polymorphisms in the white population that are important for antibody binding. Labeled ZnT8 protein is produced by *in vitro* transcription/translation with [^{35}S]methionine. The patient serum is incubated with labeled antigen overnight, and antibody-bound labeled antigens are separated from unbound labeled antigens with protein-A Sepharose precipitation in a 96-well plate. Radioactivity is counted on a 96-well plate β-counter. Results are calculated against our internal standard positive and negative controls and expressed as indexes. A cutoff for positivity above the 99th percentile of normal controls is often utilized.

Procedure

Part I: *In Vitro* Transcription/Translation To Produce Labeled ZnT8

Important notes. All reagents, tubes, and tips must be RNase free. All reagents should be kept on ice while on the bench. An incubation temperature of 30°C is critical for production efficiency. The reticulocyte lysate must be stored at −80°C and thawed rapidly just before use. Each tube can be thawed only twice, after which there will be a significant decrease in its efficiency.

Procedure.
1. Follow the kit protocol for the one-step *in vitro* transcription/translation reaction. The total reaction volume can be adjusted, decreased, or increased, as needed.
2. Purify the labeled product with a NAP-5 column.
3. Analyze the activity of the labeled antigen by counting the radioactivity in 5 μl of a 100-fold-diluted aliquot. The labeling efficiencies significantly vary with different cDNAs and plasmids.

Part II: Radioassay (2 Days)

Day 1.
1. Prepare the buffers. Assay buffer consists of 20 mM Tris-HCl, 150 mM NaCl, and 0.15% Tween 20 (pH 7.4). For antigen buffer, add 0.1% BSA to the assay buffer.
2. Prepare the antigen buffer solution. Under optimized conditions, 20,000 cpm in 50 μl of antigen buffer is usually applied per well. For a 96-well plate with 25% extra volume to ensure enough volume for aliquoting into each well, the total cpm is 96 times 20,000 cpm times 125%, which equals 2.4 times 10^6 cpm for [^{35}S]ZnT8; the total volume is 96 times 50 μl times 125%, or 6 ml.
3. Incubate the serum with antigen buffer. Duplicates are recommended for each sample. Add 2.5 μl of serum and 60 μl of antigen buffer solution containing ^{35}S-ZnT8 into a 96-well PCR plate and incubate it overnight at 4°C. The standard positive-control and negative-control serum samples for ZnT8A must be included in each assay.
4. Prepare 96-well filtration plates. Coat the plate with BSA by adding 200 μl of antigen buffer to each well, put the plate on aluminum foil, and incubate it overnight at room temperature.
5. Prepare the protein A-Sepharose. Use only plastic tubes because protein A sticks to glass. Pull 20 ml of protein A-Sepharose into a 50-ml tube, spin the solution down at 1,000 × *g* for 3 min, remove the fluid phase, and resuspend it into assay buffer. Repeat this twice, and make a final 50% (vol/vol) solution of protein A-Sepharose-antigen buffer.

Day 2.
1. Remove the antigen buffer from the 96-well filtration plate and add 25 μl of well-mixed 50% protein A-Sepharose to each well.
2. Transfer 50 μl from each well of the overnight incubation to the 96-well filtration plate, and shake the plate on a plate shaker at low speed for 45 min at 4°C.
3. Place the plate on a plate washer and wash the plate three times with 200 μl of assay buffer per well each time. Then remove the plate, add 100 μl of assay buffer per well, and shake the plate for at least 5 min at 4°C.
4. Wash the plate two more times with 200 μl of assay buffer per well each time, change the plate orientation, and wash the plate another two times.
5. Blot the plate on a paper towel and place the plate under a lamp for around 15 min. After the plate is dry, add 25 μl of scintillation liquid (MicroScint-20) to each well, seal the plate with a piece of TopSeal, and count the radioactivity on the plate on a TopCount β-counter.
6. Obtain the number of cpm for each well, and obtain mean numbers of cpm for each sample if duplicates are performed.
7. Calculate the index with the following formula: (cpm of the test serum − cpm of the negative serum)/(cpm of positive serum − cpm of the negative serum).

Standardization, Quality Control, and Quality Assurance

1. The laboratory should keep large enough volumes of the positive- and negative-control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
2. All the assays are run in duplicate and must include positive- and negative-control samples for quality control purposes and for lab index calculation. In our assay, ZnT8A positivity is any value greater than an index of 0.020.
3. The results of analysis of negative and positive controls from each assay should be plotted in a preestablished Shewhart plot with means ± 3 SD to monitor the assay drift and evaluate the assay's performance. Our positive-control range should be within 3 SD. The negative control must be <0.020 for results of the assay run to be utilized.
4. The result for every positive sample in the first run is confirmed by repeating that sample in a different assay. If the second confirmatory assay comes out negative, a third assay is necessary. A result of two assays which agree (e.g., +,+ or −,−) will be the final determination of a positive or negative result.

New Technology

ECL Assay

We have recently developed a plate capture electrochemiluminescence (ECL) IAA assay and a GADA assay (86, 87), which are nonradioactive assays that may help to disseminate islet autoantibody testing possibly to the point of care. As shown in Fig. 8 for the ECL assay format, autoantibodies cross-link two antigen molecules,

one biotinylated and the other labeled with ruthenium, allowing plate capture with streptavidin. This assay detects high-affinity IAA and was more sensitive than the micro-IAA (mIAA) radioassays in the last (2013) Islet Autoantibody Standardization Program (IASP) workshop yet is equally specific, while the ECL GADA assay had sensitivity similar to that of the standard GADA radioassay. Interestingly, the ECL IAA assay antedated the detection of IAA in young DAISY (Diabetes Autoimmunity Study in the Young) children by a mean of 2.3 years (range, 0.3 to 7.2 years) in a comparison with the standard micro-IAA (mIAA) radioassay (88). Very remarkably, both the ECL IAA and ECL GADA assays were able to discriminate high-affinity, high-risk-diabetes-specific autoantibodies from those "low-risk" low-affinity signals; i.e., they are more disease specific since they are able to distinguish disease-associated antibodies from non- or less-disease-associated antibodies among single IAA- or GADA-positive subjects by radioassay (86, 87).

Materials, Reagents, and Equipment

- Human proinsulin
- Human GAD65
- Biotinylation kit (Thermo Scientific)
- Sulfo-Tag (Meso Scale Discovery [MSD])
- 96-well PCR plate (Fisher)
- Streptavidin-coated MSD plate (MSD)
- Zeba sizing spin column (ThermoScience)
- Blocker A buffer (MSD)
- Reader buffer (MSD)
- Chemicals: acetic acid, Tris base, HCl, 10× PBS buffer, BSA
- 96-Well plate shaker (Wallac-Delfi)
- Sector 2400 or Sector 6000 (MSD)
- Benchtop centrifuge with a bucket rotary (Beckman)

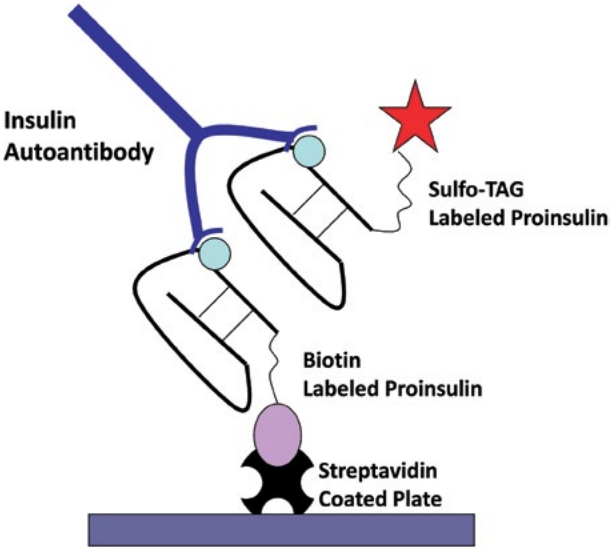

FIGURE 8 Format of the electrochemiluminescence (ECL) assay. In the illustrated example, biotin and Sulfo-Tag proinsulin were utilized, but the assay format is identical for GAD65. Adapted with permission from *Diabetes* (86).

ECL IAA Assay

General Principle

Given the need for improved IAA assays and the hypothesis that the binding of insulin to solid phases obscures a key determinant for recognition by human autoantibodies as seen also by Rojas et al. for specific murine monoclonals (89), we set out to immobilize "insulin" to a solid phase in a manner that preserved critical determinants recognized by human insulin autoantibodies. We had previously failed to develop a plate capture assay for human insulin autoantibodies, though we have developed such an assay (nonradioactive) for the insulin autoantibodies of the NOD mouse (90). The two fundamental components for our recent success were utilization of proinsulin rather than insulin and use of streptavidin rather than avidin for plate capture of biotinylated proinsulin (Fig. 8). The ruthenium assay system of MSD is a third important component. In our prior studies, all human insulin autoantibodies reacted with proinsulin in fluid-phase radioassays (91).

Procedure

Part I: Label Human Proinsulin with Biotin and Sulfo-Tags

Important notes. Biotin and Sulfo-Tag powder should be dissolved just before the labeling procedure every time. The proinsulin must be stored at −80°C and thawed on ice before use. The protein in either the Tris or glycine buffer system should be exchanged with 2-fold PBS buffer (pH 7.9) by sizing with a spin column.

Procedure.

1. Calculate the molar ratio of proinsulin with biotin or Sulfo-Tag. We recommend using a 1:5 molar ratio for proinsulin labeling.
2. Mix proinsulin with either biotin or Sulfo-Tag, cover the reaction tubes with aluminum foil to avoid light, and incubate them at room temperature for 1 h.
3. During the 1-h incubation, prepare a Zeba sizing spin column by washing the column three times with full-strength PBS buffer and centrifuging at 1,000 × *g* for 2 min each time in a centrifuge.
4. Stop the labeling reaction and purify labeled proinsulin by passing the reaction mixture through the prepared Zeba sizing spin columns at 1,000 × *g* for 2 min in a centrifuge.
5. Measure the protein concentration.
6. Aliquot the labeled proinsulin and store the samples in a −80°C freezer.

Part II: Plate Capture Assay (2 Days)

Day 1.

1. Prepare the buffers. The buffer is 0.5 M acetic acid with 1 M Tris-HCl (pH 9.0), and antigen buffer is full-strength PBS with 5% BSA. PBST is full-strength PBS with 0.05% Tween 20.
2. Treat the serum samples with acid. Mix 15 μl of serum with 18 μl of 0.5 M acetic acid and incubate it at room temperature for 45 min.
3. Prepare antigen buffer containing both biotin and Sulfo-Tag-labeled proinsulin with the same concentration of 100 ng/ml, and add to a new PCR plate 35 μl of solution per well.
4. Just before the completion of the 45-min incubation (step 2), add 8.3 μl of 1 M Tris (pH 9.0) buffer per well

into the antigen plate of step 3 (try to add it onto the side wall of each well; avoid complete mixing at this time); immediately afterwards, transfer 25 μl of the acid-treated serum of step 2 into the well, and then mix entirely. Cover the plate with sealing foil to avoid light.
5. Shake at room temperature on the low setting for 2 h.
6. Put in a 4°C refrigerator to incubate overnight (18 to 24 h).

Prepare the streptavidin plate.

1. Let MSD streptavidin plate(s) come to room temperature.
2. Add 150 μl of 3% blocker A (in PBS) per well.
3. Cover the plate with foil.
4. Incubate it in a 4°C refrigerator overnight.

Day 2.
1. Remove the streptavidin plate from the refrigerator. Dump out the buffer and bang the plate on a paper towel to dry it.
2. Wash it three times with 150 μl of PBST.
3. Transfer 30 μl of the serum-antigen mixture into the MSD streptavidin plate.
4. Cover it with foil to avoid light and shake it at room temperature for 1 h on the low speed setting.
5. Dump out the incubated contents and wash the plate three times with 150 μl of PBST.
6. Add 150 μl/well of 2-fold Read buffer (avoid any bubbles).
7. Count the reactivity on an MSD machine.

Standardization, Quality Control, and Quality Assurance

1. The mouse anti-human proinsulin monoclonal antibody is used as an internal-standard positive control. The monoclonal antibody should be diluted with normal human serum and treated identically as for human serum in the assay.
2. The laboratory should keep a high enough volume of the positive- and negative-control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
3. All the assays are run in duplicate and must include positive- and negative-control samples for quality control purposes and for lab index calculation. In our assay, IAA positivity is any value greater than an index of 0.006.
4. The results of the analysis of negative and positive controls from each assay should be plotted in a preestablished Shewhart plot with means ± 3 SD to monitor the assay drift and evaluate assay performance. Our positive-control range should be within 3 SD. The negative control must be <0.006 for results of the assay run to be utilized,
5. The result for every positive sample in the first run is confirmed by repeating that sample in a different assay. If the second confirmatory assay comes out negative, a third assay is necessary. The results of two assays which agree (e.g., +,+ or −,−) will be the final determination of a positive or negative result.

ECL GADA Assay

General Principle

The format of the ECL GADA assay is adapted from the ECL IAA assay except for acid treatment of serum. In a way similar to that of the ECL IAA assay, the molecule of a full-length human GAD65 protein is set out to be immobilized to a solid phase in a manner that preserves all critical determinants recognized by human GAD65 autoantibodies.

Procedure

Part I: Label Human GAD65 with Biotin and Sulfo-Tag

Important notes. Biotin and Sulfo-Tag powder should be dissolved just before the labeling procedure every time. The GAD65 must be stored at −80°C and thawed on ice before use. The protein in either the Tris or glycine buffer system should be replaced with 2-fold PBS buffer with a pH of 7.9 with the sizing spin column.

Procedure.
1. Calculate the molar ratio of GAD65 with biotin or Sulfo-Tag. We recommend using a 1:20 molar ratio for GAD65 labeling.
2. Mix GAD65 with biotin or Sulfo-Tag, cover the reaction tubes with aluminum foil to avoid light, and incubate them at room temperature for 1 h.
3. During the 1-h incubation, prepare the Zeba sizing spin column by washing the column three times with full-strength PBS buffer and centrifuge at 1,000 × *g* for 2 min each time in a centrifuge.
4. Stop the labeling reaction and purify labeled GAD65 by passing the reaction mixture through the prepared Zeba sizing spin columns and centrifuging it at 1,000 × *g* for 2 min.
5. Measure the protein concentration.
6. Aliquot the labeled GAD65 and store the specimens in a −80°C freezer.

Part II: Plate Capture Assay (2 Days)

Day 1.
Prepare the serum samples.

1. Each serum is diluted five times with PBS.
2. Prepare antigen buffer containing both biotin and Sulfo-Tag-labeled GAD65 with a concentration of 125 ng/ml of Sulfo-Tag-labeled GAD65 and 500 ng/ml of biotin-labeled GAD65.
3. Mix 5 μl of diluted serum with 35 μl of labeled antigen solution per well in a PCR plate.
4. Cover the plate with sealing foil to avoid light.
5. Shake the plate at room temperature on the low setting for 1 to 2 h.
6. Put it in a 4°C refrigerator to incubate overnight (18 to 24 h).

Prepare the streptavidin plate.

1. Let an MSD streptavidin plate(s) come to room temperature.
2. Add 150 μl of 3% blocker A (in PBS) per well.
3. Cover the plate with foil.
4. Incubate it in a 4°C refrigerator overnight.

Day 2.
1. Remove the streptavidin plate from the refrigerator. Dump out the buffer and bang the plate on a paper towel to dry it.
2. Wash the plate three times with 150 μl of PBST.
3. Transfer 30 μl of the serum-antigen mixture into the MSD streptavidin plate.

4. Cover the plate with foil to avoid light and shake it at room temperature for 1 h on the low speed setting.
5. Dump out the incubates and wash the plate three times with 150 μl of PBST.
6. Add 150 μl/well of 2-fold Read buffer (avoid any bubbles).
7. Count the reactivity on an MSD machine.

Standardization, Quality Control, and Quality Assurance

1. The mouse anti-human GAD65 monoclonal antibody is used as an internal-standard positive control. The monoclonal antibody should be diluted with a normal human serum specimen and treated identically to human serum in the assay.
2. The laboratory should keep a large enough volume of the positive- and negative-control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
3. All the assays are run in duplicate and must include positive- and negative-control samples for quality control purposes and for lab index calculation. In our assay, GAA positivity is any value greater than an index of 0.023.
4. The results of an analysis of negative and positive controls from each assay should be plotted in a preestablished Shewhart plot with means ± 3 SD to monitor the assay drift and evaluate the assay's performance. Our positive-control range should be within 3 SD. The negative control must be >0.023 for the results of the assay run to be utilized.
5. Every positive sample in the first run is confirmed by repeating that sample in a different assay. If the second confirmatory assay comes out negative, a third assay is necessary. The results of two assays which agree (e.g., +,+ or −,−) will be the final determination of a positive or negative result.

Other Technology

ELISA

For most autoimmune disorders and for basic immunologic research, ELISAs employing plate-bound antigen are popular. Many laboratories and biotech companies have adopted this method for anti-islet autoantibody assays, and different ELISA kits are available. Multiple workshops utilizing sera from patients with type 1 diabetes and multiple mouse strains have demonstrated that standard ELISA formats lack both sensitivity and specificity compared to fluid-phase radioassay formats (92). For insulin autoantibodies, the ELISA formats were able to detect high-capacity antibodies following insulin immunization (e.g., therapy with subcutaneous injections of human insulin) but not the insulin autoantibodies of prediabetic individuals. To date, in international workshops, a modified ELISA for GAA attained a level of specificity and sensitivity equivalent to those of the radioassays. This assay depends on using a free-antibody arm to capture biotinylated GAD (developed by Kronus and published in May of 2003 [85]). In brief, the ELISA plate was coated with GAD65 protein, and 25 μl of test sera was added to the plate before incubation with shaking for 1 h at room temperature. The wells were then washed three times with washing buffer, and 100 μl of biotinylated GAD65 was added. After another hour of incubation, the plate wells were washed three times and the plate was incubated for 20 min with 100 μl of streptavidin-peroxidase conjugate. A wash step was then followed by addition of 100 μl of tetramethylbenzidine and, after 20 min, 100 μl of 0.5-mol/liter H_2SO_4. Absorbance at 405 and 450 nm was then measured. This "ELISA" is actually a form of a fluid-phase reaction of labeled antigen with bound autoantibody, with specificity enhanced by the requirement for each arm of the immunoglobulin to react with antigen. Most recently, a ZnT8A ELISA kit by Kronus using a protocol format identical to that of the GAA ELISA kit has also achieved a sensitivity equivalent to that of the ZnT8A radioassay with less specificity than in the 2012 IASP international workshop.

Epitope Assays

Comparisons of the epitope repertoires of autoantibodies to insulin, GAD65, and IA-2 provide a tool to further analyze type 1 diabetes-related autoantibodies (75, 82, 93). Most type 1 diabetes sera target only GAD65 protein epitopes, dependent on protein conformation, and do not bind GAD65 protein fragments or react with denatured GAD65 protein with immunoblotting. In contrast, sera from patients with stiff-man syndrome (SMS) have antibodies that bind GAD65 protein fragments consisting of N-terminal, middle, and C-terminal regions (73). The majority of type 1 diabetes sera target more than two epitopes on IA-2 molecules, and epitope spreading may be an indicator of the risk of progression to type 1A diabetes (94). For the methodology of these epitope assays, laboratories usually use the same radioimmunoassay format as described above with cloned protein fragments containing the epitope to be utilized or with chimeric proteins (e.g., GAD65/GAD67), which contain epitopes of GAD65 and sequences of non-antibody-reactive GAD67 to retain protein conformation. For IAA epitope testing, proinsulin, insulin analogs, and insulin molecules from different species are used as competitive inhibitors in the regular IAA radioassay.

Autoantibody Subclass and Isotype Determination

Some reports have shown heterogeneity of immunoglobulin subclass antibodies to GAD65 in newly diagnosed type 1A diabetic patients and ICA-positive first-degree relatives who progressed or did not progress to diabetes (95). New-onset diabetic patients and progressors were found to have a predominance of IgG1, GAA, and ICA, while nonprogressors had predominantly IgG2 and/or IgG4 (94). A study on IAA also indicated that heterogeneity of IgG subclass is related to the risk of developing type 1A diabetes (96).

For the methodology of isotype analysis, a modified standard radioimmunoassay format is used. On day 1, reagent and serum mixtures are prepared for overnight incubation at 4°C in two separate tubes. In one tube, 2.5 μl of serum is incubated with 25 μl of radiolabeled antigen, and in the other tube, 5 μl of biotin-labeled anti-IgG subclass monoclonal antibody with 10 μl of streptavidin-Sepharose (per well) is added (BD Pharmingen), with shaking. On day 2, after the Sepharose incubation tube is washed three times, the contents of the two incubation tubes are mixed together in a 96-well filtration plate and incubated for 1 h at 4°C with shaking. The rest of the steps for washing and counting are the same as described above.

Interpretation

Analysis of Data

In general, it is important to utilize assays for anti-islet autoimmunity that have high specificity, usually defined as specificity of ≥99%. Even with specificities set at this level, if one measures three different anti-islet autoantibodies, 3% of the "normal" population will express one or more of the autoantibodies. Obviously, expression of multiple anti-islet

autoantibodies is a relatively rare event, though even for low-risk populations (for instance, 1/300 general-population children in the United States develop type 1 diabetes), there will be some individuals expressing anti-islet autoantibodies who may never progress to overt diabetes. As with all autoantibody tests, it is also important to recognize that a repeat assay of the same sample (particularly for levels just above the cutoff points of "positivity") may fail to confirm the presence of the autoantibody as often as one-third of the time (97). Repeat analysis of an independent sample is important to assess risk, as subjects with "transient" islet autoantibodies are at relatively low risk. After the onset of type 1A diabetes, a significant subset of patients lose (over decades) their GAD65, IA-2, and ZnT8 anti-islet autoantibodies.

A major caveat regarding insulin antibodies is that most individuals treated with subcutaneous insulin (even human insulin) will develop insulin antibodies. Thus, after approximately 10 days of insulin therapy, the presence of insulin antibodies (cannot be distinguished from autoantibodies with current assays) should not be used to diagnose type 1A diabetes.

Clinical Application

Anti-islet autoantibodies find their primary application in the differential diagnosis of the forms of diabetes and in predicting the risk of progression to overt diabetes.

It is clear that adults presenting with diabetes who express anti-islet autoantibodies (in particular, GAD65 autoantibodies) more rapidly progress to utilization of insulin than typical patients with type 2 diabetes (98). For many endocrinologists, having the diagnosis of autoimmune diabetes leads to the immediate initiation of insulin therapy rather than a trial of oral hypoglycemic agents. In children, anti-islet autoantibodies have become increasingly helpful in distinguishing the different forms of diabetes, as there have been increasing incidences of both type1A diabetes and type 2 diabetes (99) as well as an overall increase in obesity rates. Making the correct diagnosis is important not only for starting the correct treatment but also for monitoring of diabetes complications. A diagnosis of type 1A diabetes alerts one to the risk of accompanying autoimmune disorders (e.g., thyroid autoimmunity in 25% of patients, celiac disease in 5 to 10% of patients, and Addison's disease in approximately 1/200). Prediction of type 1A diabetes at present is based upon genetic, immunologic, and metabolic information. Though genetic markers can identify varying risk, it is only once autoimmunity has begun (marked by the presence of multiple autoantibodies to pancreatic beta-cell antigens, such as insulin, GAD65, IA-2, or ZnT8) that a high positive predictive value (>90%) can be achieved, and multiple autoantibodies are present in the great majority of prediabetics (57–59). Research studies such as DAISY have shown that children identified to be at risk for type 1A diabetes through islet autoantibody testing and educated about diabetes rarely present with ketoacidosis and have markedly lower glucose levels at diagnosis (100, 101).

HYPOPHYSITIS

(This section was written by Ludovica De Vincentiis, Adriana Ricciuti, Alessandra De Remigis, and Patrizio Caturegli.)

Detection of Pituitary Antibodies in Autoimmune Hypophysitis

The detection of serum antibodies recognizing the pituitary gland has been technically challenging, mainly because the targeted pituitary autoantigens still remain unknown (102) and because these antibodies seem to be present at titers that are low and decrease over time. After a brief review of autoimmune hypophysitis, the condition in which pituitary antibodies are predicted to be the highest, we will review the techniques used over the years to measure pituitary antibodies, focusing on indirect immunofluorescence (IF) because it remains the most widely used detection system.

Autoimmune Hypophysitis

The term pituitary autoimmunity comprises a spectrum of clinico-pathological conditions related to an autoimmune inflammation of the pituitary gland, ranging from biopsy-proven lymphocytic (autoimmune) hypophysitis to clinically suspected hypophysitis and to the sole finding of pituitary antibodies in patients with pituitary hormone deficiencies or other autoimmune diseases or even in healthy subjects. Autoimmune hypophysitis, first reported in 1962 by Goudie and Pinkerton (103), can affect either the anterior and/or posterior pituitary lobe, be present in isolation or in association with other autoimmune diseases (such as Hashimoto thyroiditis), and be primary, meaning without identifiable causes, or secondary to a traceable event, like the injection of a monoclonal antibody blocking cytotoxic T-lymphocyte antigen 4 (104). The disease is more common in women than in men; in women, it has a unique temporal association with pregnancy or the early postpartum condition (105), although some pathological variants, like the one related to IgG4-producing plasma cells, predominate in men (106). Autoimmune hypophysitis is rare but nevertheless clinically significant since it enters into the differential diagnosis of all the other non-hormone-secreting sellar masses, with which it shares similar clinical and radiological findings (107), especially the vastly more common condition of nonfunctioning pituitary adenoma. Currently, a diagnosis of certainty can be established only after pathological examination of a pituitary biopsy specimen, which is obtained through a relatively invasive procedure, such as transsphenoidal surgery. Theoretically, the demonstration of pituitary antibodies should be useful in distinguishing a mass that has an autoimmune pathogenesis from masses that arise through neoplastic, developmental, vascular, or infectious mechanisms. Practically, however, pituitary antibodies have not yet entered the clinical arena and are still detected predominantly in a research setting.

Techniques Used To Detect Pituitary Antibodies

Pituitary antibodies have been measured mainly by non-antigen-specific techniques, considering that the targeted pituitary autoantigens remain to be validated, but also by antigen-specific assays as novel candidate autoantigens are discovered. The first description in humans of antibodies recognizing pituitary antigens was made in 1965 using a complement consumption test based on protein homogenates prepared from human adenohypophysis (108). The authors tested 128 women with Sheehan syndrome before, at, and after delivery and reported that pituitary antibodies, absent at the end of pregnancy and delivery, developed in 23 (18%) puerperae between 5 and 7 months postpartum and later correlated with signs and symptoms of hypopituitarism. Following this initial report, which was not carried out further, the story of human pituitary antibodies really began in 1975, when they were measured by IF, and then unfolded to include newer techniques (Table 2). We will briefly review the less common techniques and then focus on IF, which remains the most widely published approach.

TABLE 2 Summary of techniques used to detect pituitary antibodies in human serum[a]

Technique	Initial paper		Total no. of papers
	Yr of publication	First author (reference)	
Non-antigen-specific techniques:			
Complement consumption	1965	Engelberth (108)	1
Indirect immunofluorescence	1975	Bottazzo (119)	118
Western blotting	1993	Crock (109)	20
ELISA	1998	Kobayashi (111)	6
Antigen-specific techniques:			
In vitro transcription/translation for:			
Growth hormone, PGSF1a, and PGSF2	2002	Tanaka (114)	1
Alpha-enolase	2003	Tatsumi (115)	1
Prohormone convertases 1, 2, and 7B2	2003	Tatsumi (115)	1
Tudor domain-containing protein 6	2007	Bensing (116)	1
Testis antigen 10	2011	Smith (117)	1
Corticotroph-specific transcription factor TPIT	2012	Smith (118)	1
Western blotting for:			
Corticotroph, thyrotroph, growth hormone	1993	Crock (109)	1
Growth hormone	2001	Takao (112)	1
Alpha-enolase	2002	O'Dwyer (113)	1
ELISA for:			
Growth hormone	1992	Wilkin (••)	1
Surface plasmon resonance for:			
Growth hormone	2013	German (••)	1

[a]The year and first author of the initial publication, as well as the overall number of publications, are indicated.

Western Blotting

In Western blotting, whole protein antigens are extracted from normal pituitary glands within a short period postmortem, size fractionated on a gel by electrophoresis, blotted onto a solid support, and then reacted with the patient's antibodies. Pituitary Western blotting was first reported in 1993 to study 19 children with idiopathic growth hormone deficiency, comparing their reactivities to those of 27 healthy controls (109). The authors found that 2 (10%) patients specifically recognized a 43- or 45-kDa pituitary membrane protein that was not recognized by healthy controls. Over the ensuing 2 decades, approximately 20 additional papers have studied pituitary antibodies by Western blotting. Results have been inconclusive, and it is overall safe to say that Western blotting, although useful in a discovery-driven mode, has not yet translated into clinically useful diagnostic tests for pituitary autoimmunity.

ELISA

In enzyme-linked immunosorbent assay (ELISA), wells of a microtiter plate are coated with proteins and incubated with the patient's antibodies. The binding is then detected by the addition of a commercial antibody that recognizes human immunoglobulins and that has been conjugated with a substance that allows color change detection. Whole pituitary protein extracts have been used to coat ELISA plates in an effort to express pituitary antibody results more quantitatively, rather than as binary values (present/absent) or titers. The first studies utilizing this approach were published in 1998 for patients with polyendocrine autoimmunity (110) or non-insulin-dependent diabetes mellitus (111). A few additional studies based on ELISA detection have been published since then. Overall, this ELISA has poor sensitivity and specificity, likely due to the use of crude pituitary protein extract as the antigen, and has no clinical value.

In Vitro Transcription/Translation Followed by Immunoprecipitation

In this assay, the cDNA encoding the protein of interest is incubated *in vitro* with the molecules necessary to synthesize mRNA and translate a protein in which the amino acid methionine is radiolabeled. The patient serum is then incubated with the radiolabeled protein, and the potential binding of antibodies to this protein is revealed by immunoprecipitation and counting of the radioactivity. It is a very useful approach to validate new candidate antigens as they are discovered through library screening or proteomics. It has been applied to numerous pituitary-gland-specific or -related targets: growth hormone (112), alpha-enolase (113), pituitary gland-specific factor 1a and 2 (114), prohormone convertases 1 and 2 and their regulatory protein 7B2 (115), tudor domain-containing protein 6 (116), testis antigen 10 (117), and the corticotroph transcription factor TPIT (118). As with Western blotting and ELISA, the *in vitro* transcription/translation technique, however, has not yet proven useful in the clinical arena since antibodies to the candidate antigens indicated above cannot reliably identify patients with autoimmune hypophysitis before surgery or distinguish them from patients with other, non-immune-related pituitary masses.

Indirect Immunofluorescence

The first successful detection of pituitary antibodies by IF was reported in 1975 by Bottazzo and colleagues in patients

with polyendocrine autoimmune diseases (119). Those authors found that 19 of 287 patients (7%) had serum antibodies recognizing cytosolic antigens in the human anterior pituitary gland. Using four of the strongest sera, they were then able to show that these antibodies recognized antigens contained in granules of prolactin-secreting cells but not prolactin itself (119). From 1975 to 2013, a total of 118 papers, 42 cohort studies, and 76 case reports have reported the measurement of pituitary antibodies by IF using the pituitary gland as the experimental substrate. These papers analyzed patients from a wide spectrum of conditions, ranging from biopsy-proven hypophysitis to cryptorchidism, often comparing results to a smaller group of healthy controls. Authors used different pituitary gland species (human, baboon, rat, *Macaca mulatta*, bovine, guinea pig, sheep, swine), different section fixatives, and different blocking solutions, in part explaining the large variability in the results. The IF protocol used in our laboratory (120) is presented below.

Pituitary Collection and Sectioning

Human pituitary glands are collected at autopsy within 24 h of death, embedded in optimal cutting temperature compound, and frozen on dry ice. Four- to 5-μm sections are then cut at the cryostat, attached to Superfrost Plus microscope slides, and allowed to air dry.

Fixation

Sections are fixed for 20 min at room temperature in alumina-filtered ice-cold acetone, with the goal of avoiding additional tissue breakdown during the staining procedure and thus maintaining a better tissue morphology. Fixation, instead, does not seem to negatively affect antigenicity (121).

Blocking of Unwanted Antibody Binding

The primary antibody (that is, the patient immunoglobulins) or the secondary fluorochrome-conjugated antibody can theoretically attach to tissue targets independently of their specific (Fab-mediated) binding sites. This "unwanted" attachment is thought to occur through two main mechanisms: the binding of the antibody tail (crystallizable fragment, Fc) to tissue Fc receptors (122) and the "adhesion" of the antibody to tissue macromolecules via ionic and hydrophobic interactions (123). Although the subject of blocking continues to remain the subject of considerable debate and some authors even question its utility (123), we block our sections for 1 h at room temperature in 0.25% casein.

Addition of Patient Serum

Sera are diluted 10 times in phosphate-buffered saline and then incubated for 1 h at room temperature on the sections.

Addition of the Fluorochrome-Conjugated Secondary Antibody

After three 2-min washes in phosphate-buffered saline supplemented with 0.2% Tween 20, sections are incubated for 1 h at room temperature in the dark with a fluorescein isothiocyanate (FITC)-conjugated $F(ab')_2$ anti-human IgG, diluted 1:400 in phosphate-buffered saline.

Nuclear Counterstaining and Quenching of Autofluorescence

Before the slide is coverslipped, sections are incubated for 10 min at room temperature in a solution of DAPI (4′,6-diamidino-2-phenylindole at 4 μl in 200 ml of phosphate-buffered saline), washed as described above, and then incubated under the same conditions in Sudan black B (0.3% in 70% ethanol), a dye known to quench autofluorescence (124).

Reporting of the Results

In addition to differing in substrate species, fixation, and blocking methods, publications have varied widely in the way IF results are reported. With IF being largely a subjective technique, it is important to develop an interpretation scheme that ensures consistency across samples and readers. After selecting intact and not peripherally located pituitary areas with a 10× objective, we scored sections for positivity using a 20× objective and considered positive those sections where stained cells were found in at least 2 of 10 fields. Positive sections were then classified according to area of involvement, cellular location, staining features, and staining intensity. The area of involvement can be classified as focal (Fig. 9A) or clustered (Fig. 9B) to indicate the staining of a few isolated cells within an acinus, or multiple aggregated cells. These two staining patterns have been identified since the very beginning of pituitary IF experiments and are called the type 1 (single-cell) or type 2 (multiple-cell) pattern by Pouplard and colleagues (125, 126). Cellular

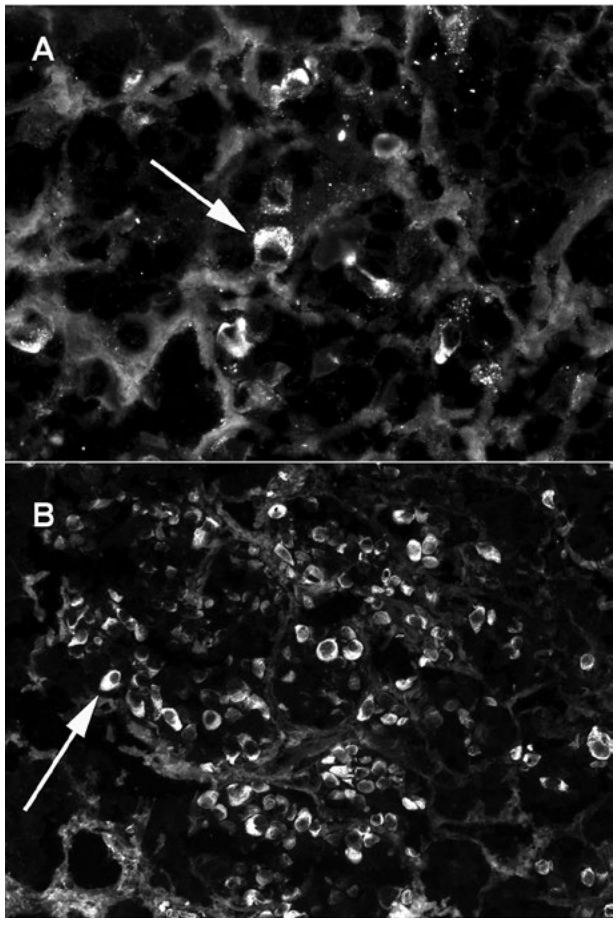

FIGURE 9 Detection of serum pituitary antibodies by indirect immunofluorescence using acetone-fixed cryostat sections cut from a human anterior pituitary gland. (A) A few isolated cells are recognized by the patient antibodies (type 1 pattern). The arrow shows the granularity, suggesting that antibodies recognize small vesicles scattered in the cytosol. (B) Multiple clustered cells are highlighted by the patient serum (type 2 pattern), which diffusely stains the entire cytosol (arrow).

location theoretically includes cytosolic, nuclear, plasma membrane, or nuclear membrane staining, although practically, pituitary antibodies stain predominantly the cytosol. The staining can be diffuse (homogeneous) when it involves uniformly the entire cytosol, granular when numerous small vesicles are seen in the cytosol, reticular when fine filaments are scattered throughout the cytosol, perinuclear when a ring of staining encircles the nucleus, and mixed for a combination of the above (Fig. 9). The staining intensity can be classified as weak (+), moderate (++), or strong (+++).

Double IF Staining

If needed, it is possible to identify the type of anterior pituitary cell recognized by the patient antibodies by adding a commercial antihormone antibody along with the patient serum during the primary incubation. This commercial antibody, directed, for instance, against growth hormone or prolactin, is raised in a nonhuman species, and its binding can be detected with a secondary antibody directed against the immunoglobulins of that species and conjugated with a fluorochrome that is different from the fluorochrome used on the anti-human antibody secondary reagent. Through these double-IF studies, investigators have shown that patient antibodies most often recognize antigens that are different from the hormone itself (119).

Clinical Significance and Utility of Pituitary Antibodies

During the past 5 decades, numerous studies have measured pituitary antibodies in a variety of diseases, with the goal of developing a biomarker that can aid in the diagnosis and prognosis of patients with pituitary autoimmunity. Results, thus far, have been somewhat disappointing. If we limit the analysis to IF, which remains the technique most commonly published (Table 2), and analyze the 42 papers that have used the pituitary gland as the experimental substrate, we note that pituitary antibodies are indeed more common in patients with biopsy-proven hypophysitis (57% prevalence) (Table 3) than in patients with other conditions. However, these antibodies are also found in patients with conditions not typically associated with pituitary autoimmunity, such as traumatic brain injury, as well as in patients with other autoimmune diseases. It thus seems that pituitary antibodies, although significantly more common in disease than in health, do not currently associate with a particular disease in a form strong enough to make it clinically useful. It is to be predicted that the diagnostic validity of pituitary antibody tests will improve once pathogenic pituitary autoantigens are discovered and confirmed in the clinical arena.

Additional information can be gathered by refining the interpretation of the pituitary antibody results, which are typically reported as present or absent without further specifications. It has been apparent since the early studies that patients produce antibodies recognizing different types of anterior pituitary endocrine cells (119), as well as different antigenic components within a given cell (127), so that type 1 (single-cell) and type 2 (multiple-cell) stainings have been described (125, 126). After almost 3 decades, these two staining patterns have been shown to possess clinical relevance. In fact, patients with type 1 antibodies go on to develop various degrees of hypopituitarism, whereas those with type 2 antibodies do not acquire pituitary function defects (128).

In summary, the field of pituitary antibodies remains a work in progress. Advances will be made in the near future when standardizations in IF techniques and result interpretation are integrated and in the more distant future when the pathogenic pituitary autoantigens are finally identified and related to the various clinical facets and stages of pituitary autoimmunity.

TABLE 3 Summary of 42 cohort studies using IF and pituitary gland substrate to detect the presence of serum pituitary antibodies

Diagnosis	No. of papers	No. of patients	No. of IF-positive patients	% IF-positive patients
None (healthy controls)	31	2,115	40	2
Other pituitary diseases	11	881	108	12
Miscellaneous diseases	18	911	116	13
Isolated pituitary hormone deficiencies	10	350	67	19
Other autoimmune diseases (nonpituitary)	20	2,737	541	20
Traumatic brain injury	3	115	39	34
Hypophysitis (clinically suspected)	3	66	25	38
Hypophysitis (biopsy proven)	1	14	8	57

Myasthenia Gravis

ARNOLD I. LEVINSON AND ROBERT P. LISAK

99

Myasthenia gravis (MG) is a disease of striated muscles which clinically manifests as weakness. It is caused by impaired neuromuscular transmission due to a reduction in the number of receptors for the neurotransmitter acetylcholine (ACh) at the postsynaptic myoneural junction. This reduction is caused predominantly by the action of anti-acetylcholine receptor (anti-AChR) antibodies in most instances. The disease occurs with a reported prevalence of 0.5 to 5/100,000 and an incidence of 0.4/100,000/year. MG can occur at any age; however, it typically presents in the second and third decades of life, with a later peak occurring after age 50 (late-onset disease). A female preponderance (3:1 to 4:1) has been reported in the first 40 years of life; thereafter, the incidences are comparable between the sexes.

CLASSIFICATION

MG patients have typically been divided into those with generalized disease and those presenting with disease limited to the ocular muscles (1). Within these two groups, patients can be further subdivided on the basis of age of onset. Neonatal MG affects 10 to 20% of offspring born to myasthenic mothers. Disease manifestations are those of generalized MG (see below) but are transient, dissipating with the metabolism of maternal anti-AChR antibodies that had been transmitted across the placenta during the third trimester of pregnancy. Several congenital myasthenic syndromes have been described. In general, these manifest during the neonatal period, persist into adulthood, and do not have an autoimmune basis (2). Patients with juvenile MG present between 1 year of age and puberty. Apart from the age of onset, juvenile myasthenics, in general, behave like adult patients with MG.

Adults may present with ocular involvement or signs of more generalized disease. The ocular involvement is characterized by impaired ocular muscle motility and lid weakness, manifesting as diplopia and ptosis, respectively. Most MG patients experience ocular involvement, with roughly 50% of patients presenting with ocular signs at the time of diagnosis. If generalized disease does not develop in such patients by 2 years, the likelihood of its development is about 10 to 20%. If generalized disease does not develop by 5 years, the chances of developing generalized disease are probably no greater than 2 to 5% (3).

In the generalized-disease group, patients can be classified into those having mild, moderate, and severe disease on the basis of clinical activity. Any skeletal muscle group may be affected, but typically the palatal, pharyngeal, and upper esophageal muscles are involved. This results in dysarthria, dysphagia, and difficulty in handling secretions. Involvement of respiratory muscles, including intercostal muscles and the diaphragm, is seen in many individuals. Concomitant involvement of bulbar muscles may lead to "myasthenic crisis" requiring intubation. Involvement of muscles of the extremities and trunk occurs in 20 to 30% of patients at initial presentation and causes difficulties with activities of daily living. Sensory complaints accompanied by sensory findings are not a feature of MG. Autonomic nervous system-related complaints or problems with cognition or level of consciousness, in the absence of CO_2 narcosis or hypoxia, are also not part of the presentation of MG. While many patients report fatigue, fatigue in the absence of weakness is rarely, if ever, seen in MG and often reflects the confusion between fatigability of strength with sustained or repetitive effort (repetitive stimulation) and diffuse fatigue without any weakness, which more often represents systemic disease or depression. The hallmark of all muscle involvement in MG is its variability over time, with weakness usually exacerbated by repetitive use.

IMMUNOPATHOGENESIS OF AUTOIMMUNE MG

The Principal Autoantigen: Neuromuscular nAChR

The nicotinic AChR (nAChR) is a member of a larger family of ligand-gated ion channels. The muscle-type receptor, which is involved in myasthenia, can be subclassified further into mature junctional receptors and immature, extrajunctional or denervated receptors. The nAChR at a mature myoneural junction is composed of four subunits, labeled α, β, δ, and ε. In fetal muscle and adult denervated muscle or nonjunctional membrane, a γ subunit replaces the ε subunit found in mature innervated muscle endplates. This form of the receptor differs from the mature junctional form by its lower density (500 receptors/μm^2) and its distribution over most of the surface of the sarcolemma.

Two α subunits and one of each of the other subunits are assembled to form an asymmetric hourglass channel

doi:10.1128/9781555818722.ch99

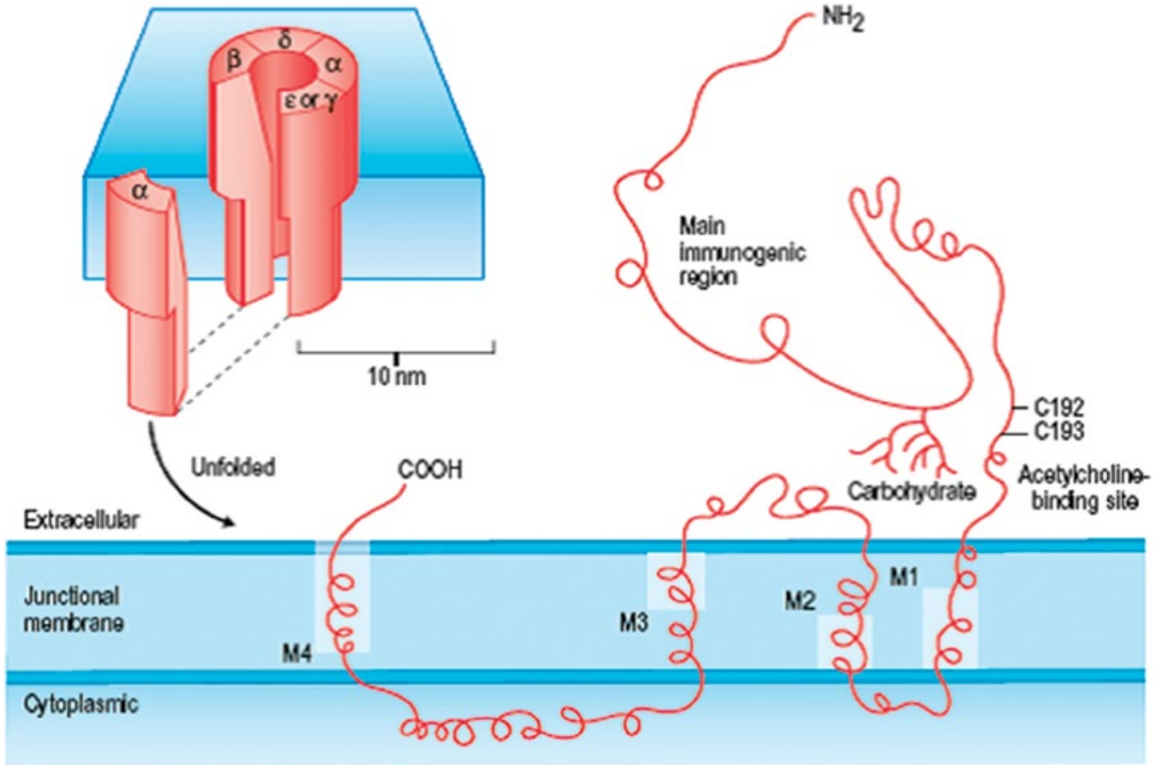

FIGURE 1 The AChR. The subunits of the AChR—α, β, δ, and γ or ε—are arranged like barrel staves around the central ion pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3, and M4). In the unfolded view of the α subunit, the amino-terminal end of the α subunit is extracellular, where it is accessible to ACh, which binds at the site shown (amino acids 192 and 193). In MG, autoantibodies may bind to various epitopes of all subunits, but a high proportion of antibodies bind to the main immunogenic region of the α subunit.

spanning the membrane (Fig. 1). Each subunit has a large amino terminus located extracellularly, four transmembrane regions, and a short cytoplasmic tail formed by a loop between the third and fourth transmembrane domains. The receptor appears as a dimer owing to disulfide bonding between the δ subunits of two receptors. The two α subunits are not contiguous in each receptor but are separated by another subunit. One ACh-binding site is found on each of the α subunits around the pair of cysteines at amino acids 192 and 193. The binding of ACh to the α subunits is believed to engender a conformational change, possibly resulting in rearrangement of charged groups. The binding of ACh to both α subunits increases the probability of transition of the channel to an open conformation. Binding of curare or α-bungarotoxin, a snake venom-derived neurotoxin, to the α subunits blocks this channel.

The receptors are concentrated at the top of the folds in the muscle endplate, adjacent to the nerve terminus, at a density of 10,000/μm^2 (Fig. 2) This localization reflects the action of agrin (4), an extracellular matrix protein secreted by neurons, which is critical in the development and maintenance of the neuromuscular junction. The AChRs are organized into clusters by rapsyn, a 43-kDa cytoplasmic protein (4). The clustered AChRs are linked to the cytoskeleton by connections between rapsyn and a dystrophin-glycoprotein complex.

PRINCIPAL EFFECTOR MOLECULES: ANTI-AChR ANTIBODIES

Properties of Anti-AChR Antibodies

Anti-AChR antibodies are detected in 80 to 90% of generalized MG patients and are responsible for the decreased number of nAChRs and impaired neuromuscular transmission (reviewed in reference 5). This statement is based on the following lines of evidence: (i) IgG, along with C3 and the terminal attack complex (C5-C9), is deposited at AChR-containing areas of the postsynaptic membrane; (ii) anti-AChR/AChR complexes can be extracted from the muscles of patients with MG; (iii) transfer of myasthenic serum from mother to fetus, or from human to mouse, results in symptoms or signs of myasthenia in the recipient; and (iv) plasmapharesis, which decreases anti-AChR antibody levels, is associated with clinical improvement.

Anti-AChR antibodies are predominantly IgG1 and IgG3, but IgG2 and IgG4 isotypes have also been found. IgA and IgM anti-AChR antibodies are present in some patients but never in the absence of IgG anti-AChR antibodies. The IgA and IgM anti-AChR antibodies tend to appear in patients whose disease is of longer duration and greater severity, and in association with high IgG titers. Pathogenic anti-AChR antibodies are considered to be directed at conformationally dependent structures.

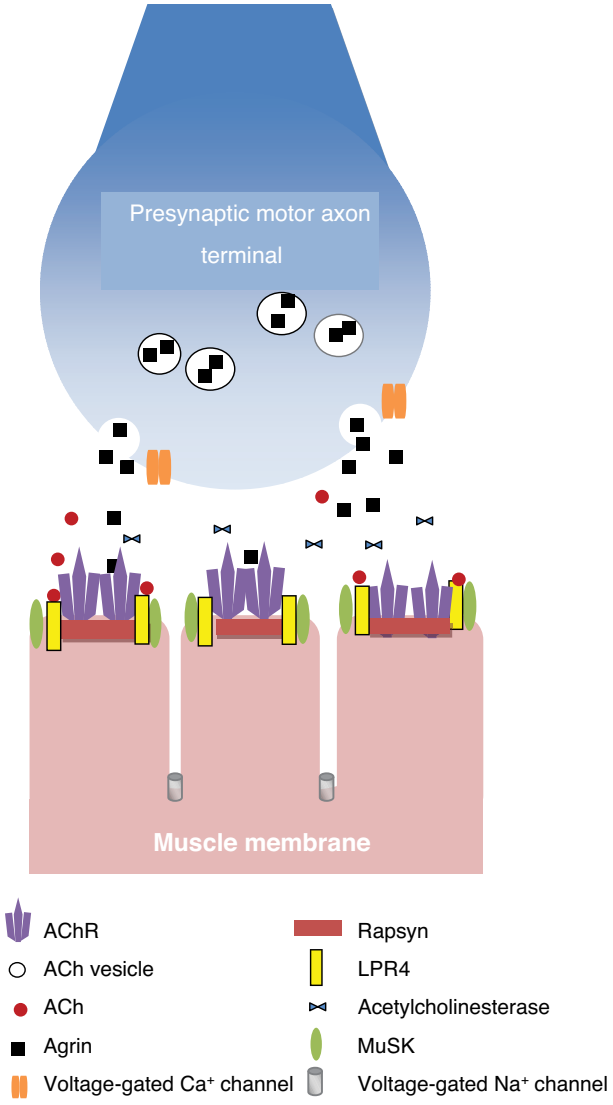

FIGURE 2 Schematic representation of the myoneural junction. Vesicles of ACh release their contents at active zones across from AChRs in response to impulses conducted down nerve axons. ACh diffuses across the synaptic cleft and binds to AChRs when not interdicted by AChE, with opening of the ion channel and the generation of endplate potentials. Action potential is propagated to muscle when sufficient amplitude of summated endplate potentials is attained. MuSK is a neuromuscular protein that anchors AChRs to the muscle membrane. LRP4 is a receptor for agrin, which activates clustering of MuSK and AChRs.

Approximately 60% of these antibodies are directed against the α subunit, particularly to a small region on the extracellular portion referred to as the main immunogenic region (6). Approximately 60% of the anti-AChR antibodies are directed against this region, which encompasses a set of overlapping epitopes clustered around amino acids 67 to 76 of the α subunit (7). However, not all disease-producing antibodies in humans or experimental rodents appear to be directed to this region. Many patients also have antibodies recognizing the γ-containing embryonic form of AChR. This observation has led to speculation about a nonmuscle source of sensitization.

Effector Mechanisms of Anti-AChR antibodies

Complement-Mediated Damage

As noted above, the critical problem in MG is the anti-AChR antibody-mediated reduction in the number of nAChRs at the myoneural junction. There are several possible mechanisms by which anti-AChR antibodies could lead to impaired neuromuscular transmission (8). Ultramicroscopy shows marked destructive changes in some endplates, particularly at the peaks of the postsynaptic folds, where AChR is usually present in greatest concentration. The architecture of the muscle endplate is simplified, with loss of junctional folds and widening of the synaptic cleft that contains membrane debris. C3, C9, and the membrane attack complex are deposited at the muscle endplate, suggesting a role for complement in membrane destruction (9). Indeed, the anti-AChR antibodies in many patients can fix complement *in vitro* when bound to skeletal muscle and can damage cultured rat myotubes, with a resultant decrease in AChR content. Although antibody-directed complement-mediated destruction is important in the pathophysiology of MG, it is not the entire story. The rapid clinical improvement in MG following certain therapeutic interventions and the lack of destructive changes in many neuromuscular junctions of symptomatic areas despite prominent immunoglobulin deposition suggest that a more readily reversible process is in play.

Acceleration of AChR Degradation

It is clear that anti-AChR antibodies can accelerate the rate of degradation of extrajunctional and junctional receptors (10). This reaction is complement independent and is due to the endocytosis of AChRs via shallow depressions, presumably clathrin-coated pits. The reaction can be mediated by $F(ab)_2$ fragments, but not Fab fragments, of anti-AChR antibodies. This indicates that cross-linking of adjacent AChRs is required.

Receptor Blockade

The inhibition of binding of α-bungarotoxin to AChRs by MG serum has been studied to detect so-called blocking anti-AChR antibodies. Such blocking antibodies are found in a variable number of MG sera. Blockade has been generally attributed to steric hindrance of the ligand-binding site, rather than direct binding to the ACh-binding site (11). The importance of these different antibodies in the pathophysiology of MG remains unclear. However, in one study, the functional ability of an individual serum to accelerate degradation and cause blockade of AChRs paralleled most closely the clinical status of the patient. The *in vivo* significance of such antibodies has also been demonstrated by passive transfer of certain rat monoclonal anti-AChR antibodies into chicks. Complete paralysis was observed within 1 h of the transfer, presumably before there was time for complement-mediated damage. It has been reasoned that in MG patients, such blocking antibodies could further diminish synaptic function already decreased owing to complement-mediated damage and/or accelerated receptor degradation. This could result in acute clinical deterioration or the rapid clinical improvement seen after plasmapharesis before the repair of damaged membrane and regeneration of new AChRs.

A number of other autoantibodies in the sera of MG patients have been described. Most of these autoantibodies are directed against other components of the neuromuscular junction. The mechanisms by which they may cause disease is still not completely understood. These autoantibodies as

well as some of the possible immunopathogenic mechanisms are discussed in the section below on diagnostic testing.

THE UNRESOLVED ROLE OF THE THYMUS

Interest in a primary role for the thymus in the pathogenesis of MG has been fueled by pathological, clinical, and immunological lines of evidence, although the nature of its involvement remains to be elucidated (reviewed in reference 12). The thymus is pathologically abnormal in 80 to 90% of MG patients. The majority of patients (65 to 75%) have thymic follicular hyperplasia with germinal center formation. The architecture of the hyperplastic thymi is generally preserved, with well-demarcated cortical and medullary regions. However, the medulla is crowded by numerous germinal centers that display the architectural features and cellular constituents of germinal centers in the secondary follicles of peripheral lymph nodes from normal individuals. Although these germinal centers in patients are generally thought to occupy an intraparenchymal position, some observers feel that they may actually lie extraparenchymally in the perivascular space.

Thymomas are seen in approximately 10% of MG patients who tend to be older than those with hyperplastic thymi (12). The thymomas are characterized by a loss of cortico-medullary demarcation and consist largely of neoplastic epithelial cells admixed with thymocytes. The affected epithelial cells belong to the cortical epithelial compartment, and the thymocytes have the immunophenotypic properties of normal immature cortical thymocytes.

Further evidence for a pathogenic role of the thymus comes from the results of empiric trials of thymectomy. Despite the absence of a controlled study, for years there has been general agreement that removal of the thymus, particularly in young patients with follicular hyperplasia, leads to clinical improvement. Very recently a controlled international multicenter study was completed which compared clinical outcome in MG patients treated with corticosteroid versus those treated with corticosteroid plus thymectomy. All patients were anti-AChR antibody positive and lacked thymoma. Those receiving thymectomy demonstrated a more favorable clinical outcome (personal communication). The underlying mechanism of the beneficial effect of thymectomy remains unknown.

INTRATHYMIC FACTORS POSSIBLY CONTRIBUTING TO LOCAL ANTI-ACHR ANTIBODY RESPONSE

The MG thymus, particularly hyperplastic thymus, is characterized by several unique features that strongly suggest that it plays a primary role in the immunopathogenesis of MG (reviewed in reference 12). It contains important constituents necessary for and indicative of an immune response directed against nAChRs. There is considerable evidence that resident cells in the thymus, including myoid cells and epithelial cells, express various subunits of AChR, including the α subunit. Additional factors found uniquely in hyperplastic MG thymus include increased expression of chemokines that attract immigrant $CD4^+$ T and B cells; the presence of nAChR-reactive B and $CD4^+$ T cells and anti-AChR antibody-secreting plasma cells; cytokines that can facilitate B cell activation, differentiation, and survival; and possibly decreased $CD4^+$ $CD25^+$ regulatory T cell function (12).

As yet it is not known whether or how such perturbations of the thymus lead to a breach in self-tolerance and the induction of anti-AChR antibodies. However, an understanding of this enduring mystery likely holds the key to unlocking the immunopathogenesis of this disease. The reader is referred elsewhere for a discussion of this topic (12).

DIAGNOSIS

In the appropriate clinical setting, the diagnosis of MG depends on combinations of clinical neurophysiological and/or pharmacological testing and immunological testing.

Clinical Neurophysiological Testing

The demonstration of a decrement in the amplitude of the muscle response to repetitive stimulation of a motor nerve at low rates of frequency (2 to 5 Hz) is highly diagnostic of MG. It is found in approximately 75% of patients with generalized MG and 50% of patients with purely ocular MG. Demonstration of a decline of 10% or more is highly diagnostic of a postsynaptic disorder, of which the most common is autoimmune MG. There are important technical considerations in performing this test, which are covered in basic clinical neurophysiology texts. Certainly, repetitive stimulation should be carried out for any patient who is seronegative and for some who are seropositive if the clinical picture is at all atypical. If serologic and classic repetitive nerve stimulation studies are negative, then single-fiber electromyography can prove useful. This technique, which requires considerable experience, allows measurement of neuromuscular transmission in individual muscle endplates (13).

Pharmacological Testing

The rationale behind the use of pharmacological agents as diagnostic probes in MG relates to our understanding of the physiology of neuromuscular transmission. Inhibition of acetylcholinesterase (AChE), the enzyme that is responsible for the breakdown of the transmitter ACh, results in increased amounts of ACh to bind to and activate AChR. In patients with MG, inhibition of AChE results in improvement in strength, which can then be demonstrated on the neurological examination or, if available, electrophysiological testing (reversal of decremental pattern following repetitive muscle stimulation). Edrophonium, an ultrashort-acting inhibitor of AChE, is given intravenously and improvement is sought in the clinical exam. However, this drug is currently very difficult to obtain for diagnostic testing. Pyridostimine or neostigmine, longer-acting AChE inhibitors used orally for treatment of MG, can also be used for diagnostic testing when given via the intramuscular route, along with atropine to reduce muscarinic side effects (13).

Immunological Testing

Anti-AChR Antibodies

As previously noted, 80 to 90% of patients with generalized MG have binding antibodies to nAChR, as do 50 to 70% of those with ocular MG. The presence or absence of AChR antibodies at onset does not predict the future clinical course. While some report that patients with ocular MG tend to have lower titers of AChR antibodies, there are enough exceptions to make the use of the binding antibody titer as a predictor of whether a patient will go on to have generalized MG not useful in individual patients. In addition, the titer or level of antibody does not correlate with severity of disease across patients. However, in an individual patient, an increase or decrease in anti-AChR antibody levels often accompanies deterioration or improvement, respectively, in clinical activity, particularly over the short-term response to plasmapheresis (reviewed in reference 14). Some laboratories also provide assays of the modulating antibodies and blocking

antibodies discussed previously, which may occasionally provide additional diagnostic information. Modulating and blocking antibodies are seen in 65 to 70% of patients with generalized MG. Only 0.4% of patients whose serum is negative for both binding and blocking anti-AChR antibodies have modulating antibodies. Testing for modulating antibodies, which some feel is important in prognosis (15, 16), involves incubating test serum with a human muscle sarcoma cell line, which serves as a target for anti-AChR antibodies. Radiolabeled bungarotoxin is then added to bind the remaining AChR. The bound fraction is separated from the free radiolabeled bungarotoxin and then quantified. The specificity of binding is assessed by preaddition of carbamylcholine agonist in parallel cultures. However, this test really measures both modulating and blocking antibodies. Measurement of only blocking antibodies, which is not widely employed, involves incubating test serum and calibrators with detergent-solubilized fetal and adult AChR along with ^{125}I-radiolabeled bungarotoxin. Blocking antibodies, if present, compete with the bungarotoxin for AChR. The AChR-blocking antibodies are precipitated. Radioactivity is inversely proportionate to the amount of blocking antibody. Commercial assays that detect complement-fixing AChR antibodies are not widely available for diagnostic testing. As noted previously, binding anti-AChR antibodies are predominately of the IgG1 and IgG3 isotypes.

The "gold standard" for detecting binding AChR antibodies is still the radioimmunoassay. The assay is widely available in the United States, Canada, Europe, the Middle East, Australia, New Zealand, and many parts of Asia. In this assay, serum is reacted with a nAChR preparation (generally human sourced) labeled with ^{125}I-α-bungarotoxin, a snake venom polypeptide that binds irreversibly to the receptor. Bound antibodies are immunoprecipitated by an anti-immunoglobulin reagent or staphylococcal protein A, and the quantity of antibodies detected is expressed in terms of the amount of α-bungarotoxin bound. Since sensitivity varies among laboratories, laboratories should provide the cutoff for normal, equivocal, and positive values. Many laboratories consider values of >0.5 nM/liter to indicate positivity, whereas some define positivity as >0.02 nM/liter. Specificity is also very high, although when a very sensitive assay for anti-AChR antibodies is used, it has been reported that as many as 11% of patients with neuromyelitis optica spectrum disorder have AChR antibodies, with 2% of these having concomitant MG (17). It has been recognized for more than 50 years that patients with MG have an increase in concomitant autoimmune diseases as well as other autoantibodies (18). Rarely, patients with Lambert-Eaton myasthenic syndrome (LEMS), an autoimmune disease of the neuromuscular junction caused by antibodies to the presynaptic P/Q voltage-gated calcium channel, have antibodies to AChR. Antibodies to AChR and/or cross-striational antibodies (antibodies that bind to molecules that are intracellular components of skeletal muscle) can be seen in up to 13% of patients with LEMS as well as in some other immune-mediated diseases (19, 20). It has been suggested that some patients have both MG and LEMS, but on the basis of clinical and clinical neurophysiological testing, there are no well-documented cases of patients with both clinical entities.

One laboratory has reported antibodies to AChR for some MG patients who do not have detectable AChR antibodies using the standard assays for detecting binding, blocking, and/or modulating antibodies. These presumably low-affinity antibodies can be detected by increasing the clustering of AChR on muscle cells in culture (21). This assay is not available on a commercial basis at this time.

Anti-MuSK Antibodies

Approximately 50% of patients with generalized MG and no detectable AChR antibodies have antibodies to muscle-specific kinase (MuSK) (22–24). MuSK is a neuromuscular junction protein that is important in anchoring AChR in the muscle membrane. Inhibition of MuSK negatively affects the availability of AChR. The currently available assay is a radioimmunoassay using recombinant human MuSK. The test is sometimes reported as negative (<1:10), borderline (1:10), or positive (≥1:20) without any further quantitation within the positive range. Other laboratories report the results as nanomolar concentration per liter, with values above 0.05 nM/liter being positive (25). In the appropriate clinical setting, a positive result confirms the diagnosis of MG. It is rare for a patient to have both anti-AChR and anti-MuSK antibodies. From the point of view of diagnosis, if a patient has anti-AChR antibodies, testing for anti-MuSK antibodies does not have diagnostic utility. Originally, anti-MuSK antibodies were described for patients with marked facial and bulbar weakness, including tongue weakness (24, 26), and respiratory involvement with relative sparing of upper- and lower-extremity muscles (24, 27). Ophthalmoparesis was also seen but was not a first symptom in at least one series of patients (28). Subsequently, it has become clear that patients with MuSK antibodies can also have a more traditional clinical phenotype similar to that seen with AChR patients. Most MuSK antibodies are of the non-complement-fixing IgG4 isotype. The pathogenic effects of MuSK antibodies are still not fully clear (23) but might result from inhibition of the effects of MuSK on normal AChR expression (29, 30).

Anti-LRP4 Antibodies

There are now three independent reports of serum from MG patients having antibodies binding to lipoprotein-related protein 4 (LRP4) (31–33). LRP4 is an important component of the neuromuscular junction, which serves as a receptor for agrin and which is required for agrin-induced activation of MuSK and AChR clustering. The prevalence of reactivity to LRP4 varied from 2 to 50% of patients who are negative for anti-AChR and MuSK antibodies (double seronegative), with the differences possibly being related to geography or ethnicity. Anti-LRP4 antibodies were found in the sera of 3% of patients with anti-MuSK antibodies in one study but otherwise were limited to double seronegative patients. Anti-LRP4 antibodies were not present in the sera of a large number of patients with other neurological diseases with the exception of neuromyelitis optica spectrum disorder, where 12.5% of patients had anti-LRP4 antibodies. If larger studies demonstrate that anti-LRP4 antibodies are found in MG patients without anti-AChR or MuSK antibodies and are rare in other neurological disorders, the test could become important in the diagnosis of MG. The antibodies are detected using enzyme-linked immunosorbent assay (ELISA) technique with recombinant human LRP4 by the three laboratories which have reported the findings (31–33). All three groups failed to find a positive test, as defined in their assays, for other diseases, but more experience is needed in order to be certain of the diagnostic utility of finding LRP4 antibodies in the serum. The assay is not commercially available at this time. LRP4 antibodies were able to inhibit LRP4-agrin interaction and/or alter AChR clustering in muscle cells *in vitro* (33).

Anti-Agrin Antibodies

Anti-agrin antibodies have recently been reported by two groups, often for MG patients with anti-AChR or anti-MuSK antibodies, but occasionally for MG patients who

are "triple seronegative" (AChR$^-$ MuSK$^-$ LRP4$^-$) (34, 35). These antibodies can be detected by cell-based assays (34) and by ELISA employing recombinant human agrin (35). In one study, no patients with other neurological disorders had agrin antibodies. Studies of larger numbers of patients and studies from other groups will be necessary to determine the prevalence of anti-agrin antibodies in triple seronegative MG patients as well as the degree of specificity for MG.

Other Autoantibodies

In addition to antibodies to neuromuscular junction molecules, MG patients may have antibodies to other autoantigens, some organ specific (thyroid, gastric parietal cells, red cells) as well as non-organ specific (antinuclear antibodies [ANA], double-stranded DNA, rheumatoid factor) even in the absence of evidence or presence of another autoimmune or immunologically mediated diseases (thyroiditis, pernicious anemia, hemolytic anemia, systemic lupus erythematosus, and rheumatoid arthritis). Some MG patients also have serum antibodies directed against one or more molecules that are specific for or relatively specific for skeletal muscle (36). In fact, antibodies that react with several intracellular muscle proteins were initially identified in patients with MG. Two of the many molecules that have been identified as antigens for these antibodies, titin and ryanodine receptors, may be important in indicating the presence of a thymoma (37) or as a factor in disease severity (38). Titin is a giant filamentous protein of striated muscle. Titin filaments are involved in muscle assembly and contribute to the muscle's ability to recoil following stimulation. Ryanodine receptors are Ca^{2+} release channels which are critically involved in muscle contraction. They are located in the sarcoplasmic reticulum of striated muscles. An antibody ELISA is commercially available for titin, and increased levels (>0.6), like that of anti-striational (skeletal muscle) antibodies (see below), are associated with thymoma or "elderly onset." Ryanodine receptors are not used for diagnosis and are rarely used for management of patients with MG, although an immunoblot test is available through a Swedish company. Striational-antibody (skeletal muscle antibody) assays are available from several commercial laboratories. Demonstration of increased titers of cross-striational (skeletal muscle) antibodies were first demonstrated using immunofluorescent techniques with frozen muscle and raises the likelihood that a patient with MG has a thymoma. Some laboratories continue to employ the indirect immunofluorescent assay using monkey skeletal muscle as the substrate. An ELISA employing proteins extracted from rat skeletal muscle is used, and the results are expressed as antibody titer in comparison to those of 4 normal sera run in each assay (20). Striational antibodies are also seen in MG patients with elderly onset (39, 40) and have also been reported for patients with thymoma who were said to not have MG as well as in other disorders (20, 41, 42).

Autoantibodies to Glycolipids in Peripheral Neuropathy

HUGH J. WILLISON

100

Peripheral neuropathies constitute a diverse group of diseases caused by a wide range of genetic, toxic, metabolic, and inflammatory insults to the peripheral nervous system. A considerable proportion of neuropathies are believed to have an autoimmune basis, either as a feature of systemic autoimmune diseases, vasculitides, or paraneoplastic or postinfectious syndromes, in association with lymphoproliferative diseases, or as isolated peripheral nerve syndromes. In clinical practice, the cause of sporadic neuropathies is often obscure, resulting in the frequent use of multiple screening tests to aid in diagnosis. Over the last 20 years, there has been a widespread increase in the use of antiganglioside antibody assays as diagnostic tools, based on the recognition from research studies that gangliosides are important autoantigens in many patients with autoimmune peripheral nerve disorders (1).

Early progress in this field stemmed from the discovery that IgM paraproteins with anti-myelin-associated glycoprotein (anti-MAG) activity present in patients with IgM paraproteinemic neuropathy also reacted with carbohydrate epitopes on a sulfated glucuronic acid-containing glycosphingolipid termed sulfated glucuronyl paragloboside (SGPG) (2). Further studies soon showed that cases of IgM paraproteinemic neuropathy that were anti-MAG/SGPG antibody negative often had antibodies reactive to various other glycolipid and ganglioside antigens.

Anti-GM1 ganglioside IgM antibodies were then found in a large proportion of patients with a syndrome termed multifocal motor neuropathy (MMN), thereby catalyzing a vast body of clinical research into the association between anti-GM1 antibodies and other motor nerve syndromes (3). At the same time, interest centered on identifying antiganglioside antibodies in Guillain-Barré syndrome (GBS) and its variant forms, including Miller Fisher syndrome (MFS) (4, 5), and these areas of research remain highly topical.

Both preceding and in parallel with this evolving field of neuropathy research and clinical practice, antiganglioside and antiglycolipid antibodies have also been reported for a vast range of other diseases and syndromes, including normal health (6, 7). Antiglycolipid antibodies are viewed as forming an important part of the natural autoantibody repertoire directed towards microbial carbohydrate structures, which has the potential to be expanded in both specific and nonspecific ways (8). This may explain their ubiquitous presence in both healthy and diseased patient populations and may account for some of the potentially misleading studies that have claimed disease-specific associations, which are further confounded by technical difficulties in antiganglioside antibody measurement. This chapter addresses only their relationship to autoimmune neuropathy, for which diagnostic testing is widespread.

Table 1 displays the main clinical syndromes for which a well-defined antiglycolipid antibody specificity has been identified. In patients with IgM paraproteinemic demyelinating neuropathy, paraproteins with anti-MAG activity also react with carbohydrate epitopes on sulfated glucuronic acid-containing glycosphingolipids, i.e., SGPG and its higher-lactosaminyl homologue, SGLPG (2). Another paraproteinemic neuropathy syndrome is chronic large-fiber sensory neuropathy with prominent ataxia (9). The IgM paraprotein reacts with gangliosides bearing NeuNAc(alpha2-8) NeuNAc-linked disialosyl groups, including but not limited to GD3, GD1b, GT1a, GT1b, and GQ1b. The patients may also have cold agglutinin disease by virtue of the presence of sialylated glycoprotein epitopes on human red blood cells with which the IgM paraproteins can cross-react. Ophthalmoplegia is also variably present in this syndrome.

In MMN with demyelinating conduction block, IgM antibodies to the GM1 ganglioside are present in about half of cases (10). A small number of patients have antibodies to GM2. Recently, it was demonstrated that the addition of galactocerebroside to the anti-GM1 antibody assay might improve detection rates; however, this has yet to be applied widely in clinical diagnostic practice (11). Patients with MMN and anti-GM1 antibodies are mostly male and have a clinical picture comprising a chronic asymmetric motor syndrome, usually with distal onset in an upper limb. The average age of onset is in the 4th decade, and the illness runs an indolent course, with patients usually remaining ambulant and physically independent 10 to 20 years after onset. The electrophysiological examination classically shows focal motor conduction block, and intravenous human immunoglobulin is the standard therapy.

In GBS, a wide variety of antiganglioside and antiglycolipid antibodies have been reported for up to 50% of cases in many series (12, 13). Anti-GM1, -GD1a, -GM1b, and -GalNAc-GD1a antibodies mark a form of GBS with prominent motor axonal involvement, now called acute motor axonal neuropathy (AMAN). In MFS, an acute, self-limiting variant of GBS comprising ataxia, areflexia,

doi:10.1128/9781555818722.ch100

TABLE 1 Clinical syndromes associated with specific antiglycolipid autoantibodies

Clinical syndrome	Antibody specificity	Antibody isotype
Chronic sensorimotor demyelinating neuropathy	MAG, SGPG, SGLPG	IgM (monoclonal)
Chronic ataxic neuropathy	NeuNAc(alpha2-8)NeuNAc epitopes on GD1b, GD3, GQ1b, GT1b, GT1a, and GD2	IgM (monoclonal)
MMN	Gal(beta1-3)GalNAc epitopes on GM1, GA1, and GD1b	IgM
Chronic motor neuropathy	GM2, GalNAc-GM1b, GalNAc-GD1a	IgM
AMAN	GM1a, GM1b, GD1a, GalNAc-GD1a	IgG
Demyelinating GBS	GalC, LM1, SGPG, GM1, GM2	IgG
MFS	GQ1b, GT1a, GD3, GD1b	IgG

and ophthalmoplegia, anti-GQ1b and anti-GT1a IgG antibodies are present in over 90% of cases; the antibodies also react with GD1b and/or GD3 in about half of cases (1, 5). Recently, antibodies that bind a combination of two glycolipids that interact with each other to form a heteromeric glycolipid complex were reported (14, 15). Universally recognized methods for detecting these have not yet been incorporated into clinical laboratory practice, although considerable progress towards this is being made (16).

As research into clinical-serological associations between neuropathy phenotypes and antiglycolipid antibodies evolves, it is likely that more requests for clinical testing will enter the diagnostic laboratory. The most commonly sought antibodies at present are those to GM1 and GQ1b gangliosides.

METHODS

Sample Requirements

Antiganglioside antibodies are best measured in serum, although they can also be estimated by using plasma. Cerebrospinal fluid may contain small amounts of antiganglioside antibody (filtered from the systemic circulation), but there is no evidence to indicate any local intrathecal synthesis of antibody, and therefore measurement in cerebrospinal fluid has no advantage over that in serum. Serum antiganglioside antibodies are stable for short periods (days) at standard ambient temperature and can be stored at 4°C for 1 to 2 weeks without adverse effects. Interlaboratory shipping of serum can be conducted at ambient temperature. Repeated freeze-thawing prior to testing should be avoided, as titers will fall. In chronic peripheral neuropathy syndromes, antiganglioside antibodies are usually IgM antibodies, occurring either as paraproteins (often monoclonal gammopathies of undetermined significance) or as polyclonal antibodies. Measurement can be performed at any stage of the clinical illness. For acute-onset, self-limiting neuropathies, such as GBS, the antiganglioside antibodies are usually IgG but may be IgM and IgA. They are at their highest titer at clinical onset and then disappear over the ensuing weeks or months and should therefore be sought immediately after clinical presentation, ideally before any therapeutic intervention. Plasma exchange or intravenous immunoglobulin therapy may substantially reduce or mask titers.

Materials and Reagents

Gangliosides are sialic acid-containing glycosphingolipids composed of a long-chain aliphatic amine, ceramide, attached to one to five hexoses, at least one of which must be sialylated. It is the presence of a sialic acid molecule(s) attached to a galactose residue(s) in the hexose core which defines a glycosphingolipid as a ganglioside. In the human nervous system, the sialic acid is *N*-acetylneuraminic acid (NeuNAc). Common structures are shown in Fig. 1. Ganglioside nomenclature is assigned according to the system of Svennerholm (17), in which the prefix G refers to "ganglio," M, D, T, and Q refer to the number of sialic acid molecules (mono, di, tri, and quad), and arabic numerals and lowercase letters refer to the order of migration of the gangliosides on thin-layer chromatograms (TLC).

Although total chemical or enzymatic synthesis of gangliosides is possible in specialized laboratories, most diagnostic laboratories purchase purified gangliosides from commercial sources or purify them from bovine brains. Chloroform-methanol extraction with DEAE-Sephadex chromatography is one of several commonly used procedures (18). Characterization is aided by chemical and enzymatic derivatization, TLC, and more sophisticated techniques, such as fast atom bombardment mass spectrometry and high-performance liquid chromatography. The major gangliosides in the brain are GM1, GD1a, GD1b, and GT1b, but there are also many minor gangliosides in both the brain and peripheral nerves and in other tissues.

Gangliosides can be purchased from a wide variety of commercial sources. Rare gangliosides should be sought by personal requests to relevant investigators. Many preparations are only partially pure; for example, commercial preparations of GT1a and GT1b may be contaminated by significant amounts of GQ1b and *vice versa*. Care should be taken to control for this in nondiscriminatory immunoassays, such as enzyme-linked immunosorbent assays (ELISAs) or dot blots. Various commercial kits are now available, using either an ELISA-based format or a dot blot or strip assay. Assays are also conducted by commercial companies upon receipt of clinical samples.

Antiganglioside autoantibodies are generally referred to by their specificity, either in terms of individual gangliosides (e.g., anti-GM1 IgG antibodies) or, less often, in terms of the reactive carbohydrate epitope [e.g., anti-Gal(beta1-3) GalNAc or antidisialosyl antibodies]. When generalizing, it is often more appropriate to use the term antiglycolipid antibodies (as opposed to antiganglioside antibodies), since many neuropathy-associated autoantibodies react with glycolipids which are not strictly gangliosides, such as SGPG, LM1, sulfatide, asialo-GM1 (also termed GA1), and galactocerebroside, as these molecules do not contain sialic acid.

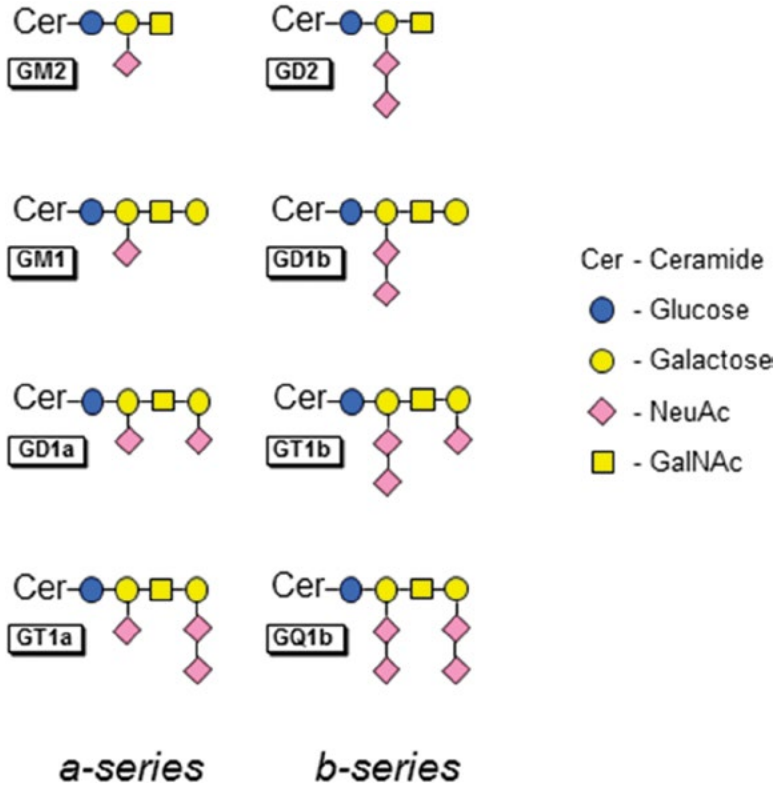

FIGURE 1 Examples of clinically relevant ganglioside structures.

The Current Procedure

The methodology for antibody detection presents difficulties, largely because the physical properties of gangliosides do not lend themselves well to development of uniform assays. Although antiganglioside antibodies can be detected by a variety of different methods, the principal and most commonly used screening method is ELISA (19, 20). A typical ELISA procedure is as follows.

1. Using a standard 96-well ELISA plate selected for high glycolipid binding properties (e.g., Immulon 2 [Dynatech]), coat each well of rows A, C, E, and G with 200 ng of GM1 or GQ1b in 100 μl of 100% ethanol and each well of rows B, D, F, and H with 100 μl of 100% ethanol alone by evaporation to dryness at room temperature and then store the plate for at least overnight at 4°C. Coated plates are stable at 4°C for up to 2 weeks.
2. Block all 96 wells with 200 μl phosphate-buffered saline (PBS)–bovine serum albumin (BSA) (pH 7.4; 1% BSA) for 2 h at 4°C. Discard PBS-BSA by flicking or automated washing.
3. Prepare serum samples by mixing gently and then centrifuge out any fibrin or particulate debris. Dilute the test serum to 1/100 in PBS-0.1% BSA, add samples in duplicate to ganglioside-coated and uncoated wells, and serially dilute the samples from 1/100 to 1/500, 1/2,500, and 1/12,500.
4. Leave the test serum to incubate overnight at 4°C.
5. Wash the plate six times in PBS wash buffer cooled to 4°C by dunking and flicking or using an automated washer.
6. Add 100 μl of peroxidase-conjugated anti-human IgM or IgG, diluted 1/3,000 (dilution optimized by checkerboard analysis) in PBS-0.1% BSA. Incubate for 2 h at 4°C.
7. Wash the plate six times in PBS wash buffer.
8. Develop the plate by adding a substrate solution comprising one 15-mg *o*-phenylenediamine tablet in 60 ml citrate buffer with 20 μl of 30% hydrogen peroxide for 20 min.
9. Stop the peroxidase reaction with 50 μl 3 M H_2SO_4.
10. Read optical densities (ODs) in an automated plate reader at 490 nm.
11. Calculate titers by endpoint dilution analysis as follows.
    (i) Subtract blank well ODs from coated well ODs to obtain working ODs.
    (ii) Obtain the mean of working ODs for duplicate wells.
    (iii) On semilog paper, plot linear OD values (*x* axis) against log test serum dilutions (*y* axis).
    (iv) Draw a best-fit dilution curve and assign the titer to the point at which the dilution curve crosses an OD of 0.1.

There have been some attempts to recommend a standard methodology, although most laboratories have established in-house protocols. In multicenter comparative studies, there has been a fair amount of agreement on clearly positive or negative cases but variable results with borderline samples (21). Important factors in setting up the ELISA include (i) the choice of ELISA plates, including glycolipid binding properties, batch variations, and storage conditions—checks on individual batches of plates are made by using a positive serum sample and calculating the lowest coefficient of variance over the whole plate while

still giving an optimal signal; (ii) the temperature at which the assay is performed, including all incubation and washing steps, with 4°C being the most commonly recommended temperature; (iii) the duration of serum incubation, which should be at least 4 h; and (iv) the presence or absence of Tween 20 as a detergent (gangliosides are soluble in detergent and will therefore be removed from the polystyrene plate). Assay results are usually reported as titers calculated by endpoint analysis.

In addition to ELISA, the TLC overlay technique is widely used (22). TLC overlay involves separating glycolipids on aluminum-backed silica plates in a solvent system and then performing an immuno-overlay with serum and labeled antibodies. Although not readily amenable to quantitative titration, TLC overlay has the advantage of allowing unambiguous identification of a particular glycolipid and is thus considered the gold standard method. This is especially useful when specific glycolipids are not available in pure form. Dot blots are also widely used, but as with TLC, it is harder to obtain readily quantifiable data (16). A technically straightforward and rapid agglutination assay was recently reported (23). Antibodies that react with ganglioside complexes were recently described (24), and the important role of accessory lipids also needs consideration; however, at present, these issues remain outside the remit of a routine diagnostic laboratory.

COST ASSESSMENT

There is no antiganglioside antibody investigation that is absolutely essential for diagnosis of a particular subtype of peripheral neuropathy, since independent investigation, principally electrodiagnostic tests in the context of an appropriate clinical picture and exclusion of other causes, is usually adequate. However, an antiganglioside antibody investigation may be useful (i) to confirm a diagnosis, such as MMN, AMAN, or MFS; (ii) to subclassify an existing diagnosis, such as classifying cases of IgM paraproteinemic neuropathy into those with anti-NeuAc(α2-8)NeuAc activity or anti-SGPG activity; or (iii) to exclude or differentiate between several possible diagnoses, such as between botulism, brain stem demyelinating disease, and MFS (anti-GQ1b antibody testing) or between MMN and amyotrophic lateral sclerosis (anti-GM1 antibody testing).

INTERPRETATION

A normal range of IgG and IgM titers for each glycolipid antigen must be established within a laboratory, since antiglycolipid antibodies form part of the normal autoantibody repertoire and antibodies to some gangliosides may be found at low titers in both normal and disease control sera. The distribution of antiganglioside antibodies in the population does not follow a normal distribution but is skewed, with some control subjects having high antibody levels against some gangliosides (titers of >1/1,000) and most having undetectable levels (titers of <1/100). As a result, defining a clinically meaningful normal range, even using logarithmically transformed data, is problematic. In my laboratory, we set the upper limit of the normal range to 2 standard deviations above the titers obtained using a panel of at least 50 healthy control subjects of all ages and both sexes; for most antiganglioside antibodies, this equates to an antibody titer being positive if it is >1/500 by endpoint dilution analysis (19).

With respect to the sensitivity and specificity of antiganglioside antibodies in particular clinical settings, no clear data are available from large multicenter studies. Some syndromes (e.g., "anti-MAG neuropathy") are defined to an extent by the presence of a particular antiglycolipid antibody. Anti-GQ1b IgG antibodies are a highly sensitive (>90%) and specific (>90%) marker of MFS and related syndromes accompanied by ophthalmoplegia (25). Anti-GM1 IgM antibodies are found in ~50% of cases of MMN (10, 26, 27), although this may rise with the advent of the GM1/galactocerebroside complex assay mentioned above (11). Anti-GM1/GD1a IgG antibodies are very specifically associated with acute motor-dominant forms of GBS, including AMAN, occurring in ~50% of cases (13). Anti-MAG antibodies are found in ~50% of cases of IgM paraproteinemic neuropathy, and a proportion of the remainder react with other glycolipid antigens. Anti-GD1b IgM antibodies are highly specific for a rare form of chronic ataxic neuropathy termed CANOMAD, although the sensitivity is unknown, and anti-GD1b IgG antibodies mark a rare GBS variant termed acute ataxic neuropathy (28).

Detection of Antimitochondrial Autoantibodies in Primary Biliary Cholangitis and Liver Kidney Microsomal Antibodies in Autoimmune Hepatitis

PATRICK S. C. LEUNG, MICHAEL P. MANNS,
ROSS L. COPPEL, AND M. ERIC GERSHWIN

101

The immunodetection of autoantibodies in autoimmune liver disease has been technically difficult because of the following: (i) serum autoantibodies from these patients usually react to a broad spectrum of antigens; (ii) some of these autoantibodies may have low titers; (iii) the biochemical nature of these autoantigens is unknown; and (iv) many autoantigens have low concentrations, and their biochemical purification often requires sophisticated procedures. The development and application of immunohistochemical, biochemical, and molecular biological techniques have provided new approaches to the study of autoimmune diseases and, in particular, the immunological detection of autoantigens. This is exemplified by two autoimmune diseases of the liver, namely, primary biliary cholangitis (PBC, formerly known as primary biliary cirrhosis) and autoimmune hepatitis (AIH). This chapter focuses on the detection of antimitochondrial autoantibodies (AMA) in PBC and the detection of liver kidney microsomal (LKM) antibodies in AIH.

PRIMARY BILIARY CHOLANGITIS

PBC is an autoimmune disease of the liver characterized by autoimmune-mediated destruction of intrahepatic bile ducts with progressive inflammatory scarring and eventual liver function failure (1). Immunologically, PBC is characterized by the presence of AMA in the circulation (2) and the infiltration of T cells into the liver (3). AMA can be detected in over 95% of patients with the disease (4, 5). These mitochondrial autoantigens are the E2 subunits of the 2-oxo-acid dehydrogenase complex (6–8) (Table 1). Extensive molecular and immunological studies of PBC, including cloning of mitochondrial autoantigens (9), antigen-specific isotype studies (7, 10), mapping of B and T cell epitopes (3, 11–17), and analysis of human and murine monoclonal antibodies (14, 16, 18–20), have provided valuable information and reagents for an understanding of the immunopathogenesis of PBC as well as for the development of accurate and specific diagnostic reagents with recombinant autoantigens (21–23). Immunohistochemical studies have shown the presence of either PDC-E2 or a cross-reactive molecule at the luminal region of bile duct epithelial cells of PBC patients but not controls (18, 19, 24–26). These data suggest that antibody targeting of bile duct epithelial cells of PBC livers may be pathogenic. Recently, IgG and IgA AMA were detected in the saliva and urine of patients with PBC, suggesting that a locally driven mucosal response is involved in PBC (27, 28).

Detection of AMA

AMA can be detected by the following methods: (i) indirect immunofluorescence (IF) (29), (ii) immunoblotting (13), (iii) enzyme-linked immunosorbent assay (ELISA) (21, 23), and (iv) bead assay (30).

Immunohistochemical Staining for AMA in PBC Sera by IF

Among the various methods of detection of AMA, IF is by far the most commonly used clinical test for AMA, using HEp-2 cells or tissue sections from mice or rats. A detailed protocol is as follows.

1. Prepare smears of HEp-2 cells on a clean glass slide and air dry.
2. Fix cells in cold acetone for 10 min at 4°C and air dry.
3. Place glass slide in phosphate-buffered saline (PBS) for 5 min.
4. Apply diluted patient serum to slide and incubate for 60 min at room temperature.
5. Wash with PBS 3 times for 3 min each.
6. Apply diluted fluorescein isothiocyanate (FITC)-conjugated goat anti-human IgG with Evan's Blue and incubate for 60 min at room temperature.
7. Wash with PBS 3 times for 3 min each.
8. Mount with 90% glycerol in PBS.
9. Examine by fluorescence microscopy.

HEp-2 slides can also be obtained commercially (e.g., Immunoconcepts, Sacramento, CA). Results of a typical IF test of AMA-positive PBC serum on HEp-2 cells are shown in Fig. 1. Alternatively, rat and mouse kidney sections can also be used for immunohistochemical staining for AMA. However, IF lacks the specificity of identifying specific antigens. In addition, background signals caused by nonspecific binding are common. Therefore, accurate detection of AMA by IF requires serial dilutions of sera (usually 1:40, 1:80, 1:160, 1:320, and 1:640) and also an optimal dilution of FITC-labeled anti-human Ig. The precise optimal dilution of the secondary FITC-conjugated antibody may also vary from batch to batch. In addition, thorough washing steps and changes of washing solutions are necessary to reduce the background.

doi:10.1128/9781555818722.ch101

TABLE 1 Summary of 2-oxo-acid dehydrogenase mitochondrial antigens in PBC

Antigen	Molecular mass (kDa)[a]	Frequency (%) in PBC patients[b]
Pyruvate dehydrogenase complex E2 subunit (PDC-E2)	70	>95
Branched chain 2-oxo-acid dehydrogenase complex E2 subunit (BCOADC-E2)	52	53–55
2-Oxo-glutarate dehydrogenase complex, E2 subunit (OGDC-E2)	48	39–88
Pyruvate dehydrogenase complex, E1 alpha subunit (PDC-E1α)	41	41–66
E3BP (protein X)	55	>95

[a]Determined by immunoblotting of beef heart mitochondrial preparations.
[b]Determined from different studies.

Immunoblotting for Detection of Specific AMA against Mitochondrial Antigens

A total mitochondrial homogenate from mammalian tissues is best suited for testing of AMA by immunoblotting. Briefly, mitochondrial preparations from bovine heart, rat liver, human placenta, or other tissues are resolved in an SDS-polyacrylamide gel, transferred to nitrocellulose filters, and probed with sera from patients with PBC. AMA reactivity against mitochondrial antigens is detected by use of enzyme-conjugated or ^{125}I-labeled anti-human Ig.

Preparation of Mitochondria from Mammalian Liver

A convenient method to prepare mitochondria is as follows.

1. Homogenize rat/mouse liver (15 g) in 30 ml of ice-cold buffer I (0.5 M sorbitol, 0.1 mM EDTA, 50 mM Tris, pH 7.4) and centrifuge the homogenate at 250 × *g* for 10 min.
2. Filter supernatant through 4 layers of cheesecloth.
3. Spin supernatant at 250 × *g* for 10 min at 4°C.
4. Take supernatant, and spin it again at 8,000 × *g* for 10 min at 4°C.
5. Resuspend pellet in 15 ml buffer I. Spin it again as in step 4.
6. Repeat step 5.
7. Resuspend pellet in 4 ml of buffer I with 0.05% bovine serum albumin (BSA), and store sample in 1-ml aliquots at −20°C. The final concentration should be approximately 40 to 60 mg/ml.

Test of AMA Reactivity against Mammalian Mitochondria by Immunoblotting

1. Electrophoretically resolve 20 μg of mitochondrial preparation in a 10% SDS-polyacrylamide gel with a preparative comb (Hoefer Scientific, San Francisco, CA). Run molecular weight protein standards in parallel.
2. Stop the gel when the bromphenol blue dye reaches the bottom of the gel, and transfer the resolved protein to a nitrocellulose filter.
3. After transfer, stain the blot with Ponceau S (Sigma, St. Louis, MO) to check for the efficiency of transfer. If the transfer is satisfactory, cut 3-mm strips from the blot by use of a sharp razor blade.
4. Incubate each strip with 1 ml of diluted PBC serum (1:1,000) for 1 h at room temperature. Run positive-control sera and negative-control sera in parallel.
5. After incubation, wash each strip with PBS containing 0.05% Tween 3 times for 10 min each.
6. Incubate each strip with a predetermined optimal dilution of secondary antibody (e.g., enzyme-conjugated secondary antibodies or ^{125}I-labeled anti-human Ig). Wash as in step 5.
7. Detect signals with a substrate for enzyme-conjugated secondary antibodies or expose the strips to X-ray film for ^{125}I-labeled anti-human Ig-treated strips. If horseradish peroxidase-conjugated secondary antibodies are used, the blots can be blocked with milk for 10 min after washing and the signals can be detected by chemiluminescence on X-ray film. Chemiluminescence kits can be obtained from common vendors, such as Pierce.

Figure 2 depicts typical patterns of AMA reactivity against various subunits of the 2-oxo-acid dehydrogenase complex. AMA reactivities are directed against the 70-kDa PDC-E2, 55-kDa E3BP (protein X), 52-kDa BCOADC-E2, 48-kDa OGDC-E2, and 41-kDa PDC-E1α proteins. Note that sera from PBC patients do not necessarily react to all five mitochondrial autoantigens and that the pattern of reactivity may vary from patient to patient (13, 14, 31).

Test for AMA Reactivity in PBC Sera by ELISA with Recombinant Autoantigens

Several studies have demonstrated the successful application of recombinant proteins as test antigens for detection of PBC by ELISA (13, 23, 31, 32). ELISAs using recombinant proteins are versatile, specific, and sensitive. In addition, ELISA is also efficient and allows the testing of multiple sera at several serial dilutions simultaneously. cDNAs encoding PDC-E2, BCOADC-E2, OGDC-E2, and PDC E1α have been cloned and expressed in *Escherichia coli* with IPTG

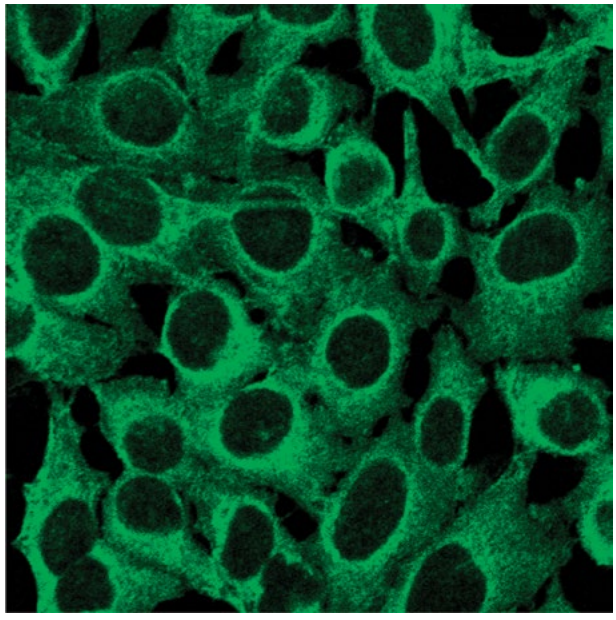

FIGURE 1 Detection of AMA by IF on HEp-2 cells. Note the characteristic mitochondrial staining pattern by PBC sera.

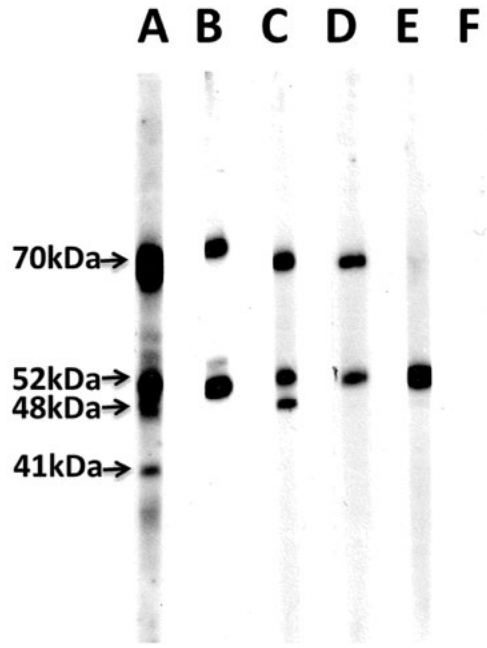

FIGURE 2 Reactivities of PBC sera with bovine heart mitochondria. Bovine heart mitochondria were resolved by SDS-PAGE, transferred to a nitrocellulose filter, and tested for reactivity with PBC sera (lanes A to F). Note the different patterns of AMA reactivities from various patients with PBC to the 70-kDa pyruvate dehydrogenase E2 subunit, the 52-kDa branched-chain 2-oxo-acid dehydrogenase E2 subunit, the 48-kDa 2-oxo-acid dehydrogenase E2 subunit, and the 41-kDa pyruvate dehydrogenase E1alpha subunit.

(isopropyl-β-D-thiogalactopyranoside)-inducible plasmid vectors. Recombinant proteins can easily be purified from IPTG-induced bacterial cultures as described previously (9, 21, 23, 32). Recently, the use of "designer molecules" (22) expressing AMA-reactive epitopes has greatly facilitated the testing of multiple sera for AMA. The availability and application of recombinant proteins clearly provide the cleanest and most specific reagents for AMA assays.

A standard procedure is as follows.

1. Dilute recombinant antigen to 2 to 5 μg/ml in carbonate buffer, pH 9.6.
2. Coat a 96-well ELISA plate with 100 μl/well of recombinant antigen from step 1. Store the plate at 4°C overnight.
3. Wash the plate with 100 μl of PBS containing 0.05% Tween (washing buffer) three times. Shake off the washing buffer between each wash.
4. Block the plate with 100 ml of 1% BSA in PBS; incubate at room temperature for 1 h.
5. Add test sera (serial dilutions) in PBS containing 1% BSA and 0.05% Tween; incubate at room temperature for 1 h.
6. Wash as in step 3, and then add 100 μl of a predetermined dilution of secondary antibody, such as horseradish peroxidase-conjugated anti-human Ig. Incubate at room temperature for 1 h.
7. Wash as in step 3. The presence of bound AMA can be determined by adding 100 μl of substrate for horseradish peroxidase [e.g., 2,2′-azinobis(3-ethylbenzthiazolinesulfonic acid) (ABTS); Sigma]. Incubate for 10 min at room temperature, and stop the reaction by adding 100 μl of 5% SDS. The intensity of color developed can be measured in an ELISA plate reader at 405 nm. Alternatively, 3,3′,5,5′-tetramethylbenzidine (TMB; BD Biosciences) can be used as a substrate for color development.

In ELISA, it is necessary to include a positive serum control, a negative serum control, and a well containing no primary antibody to correct any data or values caused by nonspecific binding of antibodies and background. A test serum is considered positive when the optical density reading is at least 2 times higher than the normal serum reading and the data are reproducible.

Test for AMA by Bead Assay

More recently, the technology of coupling protein antigens to beads was developed to improve the sensitivity associated with spatial presentation, which is essential for conformational epitopes, allowing the detection of multiple antigens at once. This approach of a multiplex bead assay has been applied and validated successfully for the detection of AMA, with specificity directed against three antigens (PDC-E2, BCOADC-E2, and OGDC-E2). The three antigens were chosen to standardize the technique and define applicability, preserving the method's advantages but also reducing potential sources of bias. Notably, an excellent correlation with previous analysis was seen for 100% of patients defined as AMA positive by Western blotting. Strikingly, several sera displayed consistent reactivity at dilutions of up to 1:100,000, 100 times the average dilution for Western blotting, undoubtedly proving the advantages potentially connected to the different spatial presentation allowed by the bead structure. Furthermore, this assay incorporates the advantages of a fully automated procedure that minimizes operator variability and allows a high level of standardization.

Briefly, recombinant antigens (PDC-E2, BCOADC-E2, and OGDC-E2) are initially dialyzed into PBS and conjugated to different nonmagnetic COOH-activated beads according to the manufacturer's recommendations (Bio-Rad). The validity of the assay and baseline fluorescence values are initially determined using specific monoclonal antibodies to the mitochondrial antigens; positive and negative controls are included and tested in quadruplicate. Once the assay is validated, serum samples from either patients or controls are diluted to final concentrations of $1{:}10^{-3}$, $1{:}10^{-4}$, $1{:}10^{-5}$, and $1{:}10^{-6}$ in Blotto blocker (Pierce, Rockford, IL) and added to a premixed bead solution with Luminex beads (1,250 beads/10 ml) in each well of filter microplates (Millipore). After washing, biotinylated IgG, IgA, and IgM detection antibodies are used, followed by a streptavidin R-phycoerythrin (streptavidin-PE) conjugate. The bead suspension is analyzed using a Bio-Plex 200 reader (Bio-Rad) with the default settings. The median fluorescence intensity of the reporter signal is then measured. A detail protocol is as follows.

1. Prewet the filter plate by pipetting 100 μl of assay buffer into each well of the plate. Seal and mix on a plate shaker for 10 min at room temperature.
2. Remove assay buffer by vacuum. Blot excess assay buffer from the bottom of the plate with paper towels.
3. Vortex and add 10 μl of premixed beads to each well.
4. Wash the wells twice by aspiration with the wash buffer (200 μl).
5. Add 30 μl of assay buffer or diluted serum samples to the designated wells.
6. Seal the plate with a plate sealer, and cover it with the lid and aluminum foil. Incubate with mild agitation on a plate shaker for 1 h at room temperature.

7. Gently remove fluid by vacuum.
8. Wash plate 2 times with 200 μl/well of wash buffer, removing wash buffer by vacuum filtration between each wash. Blot excess wash buffer.
9. Add 50 μl of detection antibody (5 μg/ml) to each well. (Allow the detection antibody to warm to room temperature prior to addition.) The detection antibody stock is made up of 1 μl of biotinylated anti-human IgG plus 1,999 μl of detection antibody diluent (1:2,000 dilution).
10. Seal, cover with lid, and incubate with agitation on a plate at room temperature for 30 min. Do not vacuum after incubation.
11. Add 50 μl of streptavidin-PE to each well containing 50 μl of detection Ab. Make up streptavidin-PE by using 100× streptavidin-PE (10 μl) plus assay buffer (990 μl).
12. Seal, cover with lid and aluminum foil, and incubate with agitation on a plate shaker for 30 min at room temperature.
13. Gently remove all contents by vacuum.
14. Wash plate 2 times with 200 μl/well wash buffer, removing wash buffer by vacuum filtration between each wash. Wipe any excess buffer from the bottom of the plate with paper towels.
15. Add 125 μl of assay buffer to each well. Resuspend the beads on a plate shaker (1,100 rpm) for 1 to 3 min.
16. Read the plate with a Bio-Plex 200 reader.

Interpretation of Data

Although AMA are highly reliable for diagnosis of PBC, some limitations and precautions are noted below. First, the high titers of AMA and the sensitivity of the test demand extreme caution to avoid cross-contamination of sera and false-positive results. Second, about 5 to 10% of PBC patients are AMA negative. Other clinical diagnostic features are also critical for differential diagnosis (Table 2). Third, neither the titer nor the specificity of autoantigens is related to the severity of the disease and therefore cannot be used to monitor the clinical course. Most importantly, positive and negative antibody controls should be included in the assays. Despite these limitations, cloned autoantigens and their recombinant proteins are extremely valuable diagnostic tools for the clinician.

AUTOIMMUNE HEPATITIS

Chronic hepatitis is a heterogeneous syndrome characterized by clinical, biochemical, and morphological criteria (33). Hepatitis B and C viruses may cause chronic hepatitis. In contrast, AIH, drug-induced hepatitis, and cryptogenic hepatitis are other subgroups of chronic hepatitis that presumably differ etiologically. AIH is a syndrome of unknown etiology. The loss of tolerance against the patient's own liver is regarded as the main pathogenic mechanism. While hitherto poorly defined defects of the immune system are responsible for chronic viral hepatitis, a hyperreaction of the patient's immune system towards autologous liver tissue is responsible for AIH. AIH was redefined (33, 34). Autoantibodies are the hallmarks of the diagnosis of AIH (Table 3). It is debated whether different patterns of autoantibodies characterize clinically or etiologically distinct subgroups of AIH (35–37). For example, antinuclear antibodies (ANA) are very heterogeneous, and their association with autoimmune liver diseases has not been identified, whereas smooth muscle antibodies in autoimmune liver diseases are particularly directed against F-actin. Recently, significant progress has been achieved in the characterization of microsomal antigens associated with liver diseases (Table 4). Three members of the cytochrome P450 supergene family and two members of the UDP-glucuronosyltransferases have been identified as hepatocellular autoantigens. These antigens are

TABLE 2 Clinical characteristics of primary biliary cholangitis

Characteristic
Clinical symptoms
Skin itching or jaundice appears in some cases
Portal hypertension and ascites or esophageal varices may appear
Osteoporosis according to the insufficiency of vitamin D or calcium may occur
Laboratory data
Presence of AMA
Elevation of serum bile duct-associated enzymes (ALP, g-GTP)
Elevation of serum bile acid
Elevation of total cholesterol
Elevation of serum IgM
Histological parameter
Chronic nonsuppurative destructive cholangitis (CNSDC) in middle-size interlobular or septal bile ducts, vanishing bile ducts, and granuloma
Complications
Skin xanthoma (especially if hypercholesterolemia continues)
Autoimmune diseases, including scleroderma, Sjogren's syndrome, rheumatoid arthritis, and chronic thyroiditis, may coexist.
Diagnosis
The patient is determined to have PBC when one of the following features is recognized.
1. CNSDC is recognized in liver specimen and laboratory data are compatible with PBC. In some cases, the patient is negative for AMA but positive for ANA.
2. AMA or anti-PDC antibody test is positive and liver histology is compatible with PBC, even though CNSDC is not recognized.
3. AMA or anti-PDC antibody test is positive and clinical feature or present history is compatible with PBC, even though liver histology is not checked.

of particular interest because they characterize subgroups of AIH and some forms of drug-induced hepatitis and also occur in a small proportion of patients with chronic viral hepatitis C or D (38).

LKM antibodies have been defined by their typical immunofluorescence staining of liver and kidney tissue. LKM-1 antibodies homogeneously stain the whole liver lobule and the proximal renal tubule (39). They react mainly with human cytochrome P45O 2D6 (40–42). LKM-2 antibodies react with cytochrome P450 IIC9 (43), and LM antibodies react with liver-specific cytochrome P45O IA2 (44). LKM-3 antibodies react with a major autoepitope on family 1 UDP-glucuronosyltransferases, and some sera react in addition with a minor epitope on family 2 UDP-glucuronosyltransferases (45). LKM-1 antibodies are serological markers of AIH type 2 (Table 4), a syndrome that frequently starts in childhood. In AIH, the main epitope is an 8-amino-acid linear epitope that shares sequence homology with the immediate early protein of herpes simplex virus type 1 (IE175). LKM-1 antibodies occur in 0 to 7% of patients with hepatitis C; these microsomal antibodies react with either a larger sequence of P450 IIC9, other epitopes on this protein, or conformational epitopes that are not recognized on immunoblots. Furthermore, hepatitis C sera may react with other microsomal proteins. LKM-2 antibodies did occur in a drug-induced form of hepatitis caused by a diuretic drug called tienilic acid which has only been used in the United States and France. This drug has been withdrawn from the market, and thus these antibodies have been described only in France. LKM-3 antibodies are associated with 5 to 13% of patients with chronic hepatitis D and also occur in some patients with AIH type 2 (Table 4). In rare cases, they may be the only marker of AIH (46). LM antibodies occur in a proportion of patients with AIH type 2 and drug-induced hepatitis caused by dihydralazine. Interestingly, as with LKM-1 antibodies, LKM-3 autoantibodies in autoimmune liver diseases have high titers and a linear and small autoepitope compared to that of low-titer antibodies to conformational epitopes in viral hepatitis. It is unknown whether LKM antibodies are involved in pathogenesis. It is likely that the antibodies themselves do not mediate tissue destruction but rather that tissue damage is mediated by liver-infiltrating T lymphocytes possibly directed against the corresponding cytochrome P450 molecules.

TABLE 3 Diagnostic criteria for AIH[a]

Parameter[b]	Score
Hypergammaglobulinemia	+3
Presence of autoantibodies	
ANA, SMA, LKM-1	+3
SLA, ASGPR, LP	+2
AMA	−2
Female gender	+2
AST or ALT of <3.0	+2
Complete response to immunosuppression	+2
Anti-HAV IgM, HBsAg, anti-HBc IgM	−3
Presence of HCV RNA (PCR)	−2
Other virus infections	−3
Ethanol intake (<35 g/day for males, <25 g/day for females)	+2
Immunogenetics (HLA-B8-DR3 or -DR4)	+1

[a]If the total score is >15 before and >17 after therapy, then AIH is certain; if the total score is 10 to 15 before and 12 to 17 after therapy, then AIH is probable.
[b]SMA, smooth muscle antibodies; SLA, antibodies against soluble liver antigen; ASGPR, antibodies against asialoglycoprotein receptor; LP, anti-liver-pancreas antibodies.

TABLE 4 Heterogeneity of microsomal antigens

Antibody	Molecular mass (kDa)	Target antigen	Disease
LKM-1	50	Cytochrome P450 IID6	AIH type II (hepatitis C)
LKM-2	50	Cytochrome P450 IIC9	Ticrynafen-induced hepatitis
LKM-3	55	Family 1 UGT[a]	Hepatitis D-associated AIH

Detection of LKM Antibodies

LKM autoantibodies can be detected by the following methods: (i) IF (39), (ii) competitive ELISA (47), (iii) immunoblotting with human liver microsomes (48, 49), and (iv) immunoblotting with recombinant antigens (41, 50).

Detection of LKM Autoantibodies in AIH by IF

IF on rat liver and kidney sections (39, 50) is commonly used to detect LKM autoantibodies in patients with AIH. Patient sera are serially diluted 1:40, 1:80, and 1:160. Additionally, the optimal dilution of the FITC-conjugated secondary antibody must be determined for each batch of antibody to avoid strong background fluorescence, which makes the evaluation of LKM-positive sera difficult. The method is described in detail below.

Test for LKM Antibodies by Indirect Immunofluorescence

1. Prepare frozen sections from rat liver and kidney on glass slides and air dry.
2. Apply patient sera to slides at an appropriate dilution and incubate at room temperature for 1 h.
3. Wash 3 times with PBS.
4. Apply FITC-conjugated goat anti-human IgG and incubate for 30 min at room temperature.
5. Wash 3 times with PBS.
6. Mount with 90% glycerol in PBS.
7. Evaluate slides under a fluorescence microscope.

There are some similarities between AMA and LKM antibodies, and these sometimes create problems for inexperienced investigators performing routine immunofluorescence assays. While LKM antibodies do not stain distal renal tubules, LM antibodies do not stain the kidney at all, since they react with a liver-specific antigen. In IF, LKM antibodies stain the whole liver lobule very strongly (Fig. 3A),

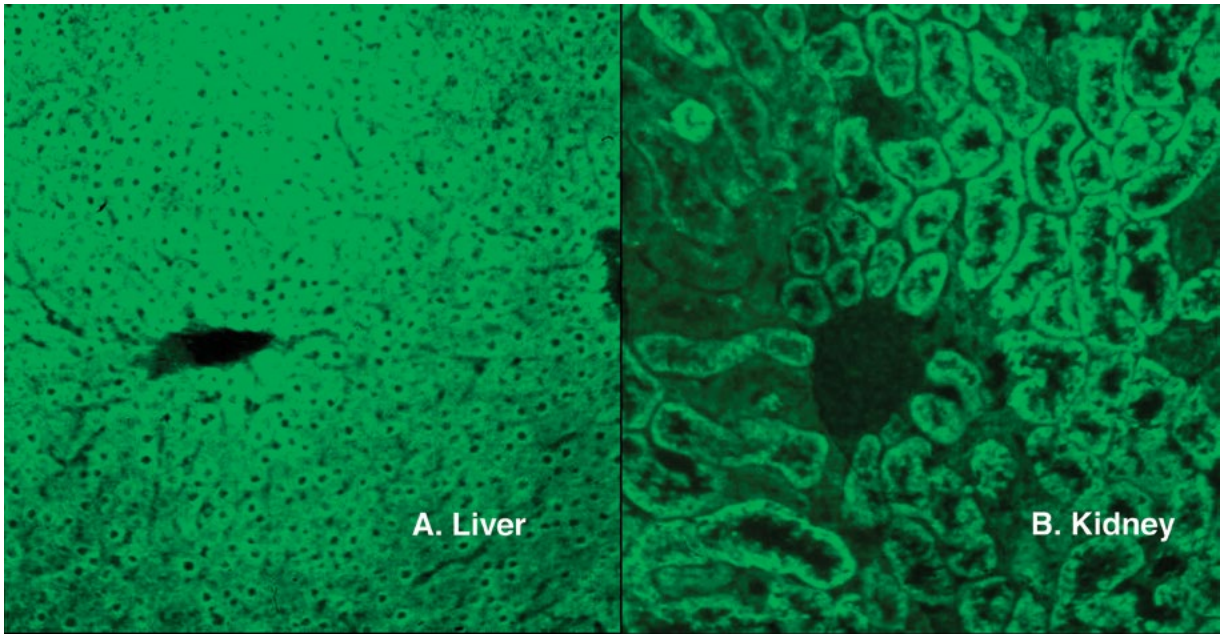

FIGURE 3 Detection of LKM antibodies and AMA by IF on cryostat rat liver and kidney sections. (A) Staining of liver lobule by LKM-1 antibodies. (B) Staining of proximal renal tubules by LKM-1 antibodies.

while in kidney tissue, they stain only the proximal renal tubules (Fig. 3B). In contrast, AMA stain proximal and distal renal tubules. If the medulla of the kidney is not part of the tissue, LKM antibodies may be misdiagnosed as AMA. Since PBC does not occur in childhood, a positive AMA result for children is almost always due to LKM antibody. If in IF only the liver stains and no reaction is seen in the kidney, one must suspect LM antibodies, which are directed against the liver-specific cytochrome P450 IA2.

Detection of LKM Autoantibodies by Competitive ELISA

An additional method to detect and further differentiate LKM autoantibodies in patient serum is by using a competitive ELISA. An Ig fraction, e.g., an LKM-1- or LKM-3-positive serum, is used to coat the plates. At the same time, an aliquot of this Ig fraction is biotinylated.

Preparation of Microsomes from Rat Liver for ELISA

Microsomes from rat liver tissue isolated by differential centrifugation are used as antigens for the competitive ELISA to test for LKM autoantibodies. The procedure is as follows (all steps should be done at 4°C).

1. Remove liver and wash in 0.9% NaCl.
2. Homogenize liver in ice-cold 250 mM sucrose.
3. Centrifuge sample for 10 min at 1,800 × *g*.
4. Centrifuge supernatant for 15 min at 12,000 × *g*.
5. Spin supernatant for 60 min at 200,000 × *g*.
6. Resuspend pellet in a small volume of PBS and determine the protein concentration.

Biotinylation and Preparation of IgG Fraction from Patient Sera for ELISA

An IgG fraction is prepared from LKM-1- or LKM-3-positive patient sera by precipitation with ammonium sulfate. An aliquot of this fraction is biotinylated according to the instructions given by the manufacturer.

Test for LKM Antibodies by Competitive ELISA

1. Dilute the IgG fraction of an LKM-positive patient serum to a concentration of 20 μg/ml in PBS.
2. Coat an ELISA plate with 50 μl/well of the IgG fraction.
3. Wash the plate once with PBS containing 0.1% Tween.
4. Block the plate with 200 μl/well 1% BSA in PBS and incubate it for 24 to 48 h at 4°C.
5. Wash once with PBS-Tween.
6. Dilute liver microsomes to a concentration of 100 μg/ml and place them in an ultrasound water bath for 3 min.
7. Add liver microsomes to the plate (50 ml/well) and incubate the plate at room temperature for 60 min.
8. Wash 2 times with PBS-Tween.
9. Dilute patient serum (1:10) in PBS containing 10 mM EDTA, add 50 μl to each well, and incubate the plate for 60 min at room temperature.
10. Wash as in step 8.
11. Dilute biotin-labeled Ig fraction (1 mg/ml) 1:100 in PBS-BSA, add 50 μl to each well, and incubate the plate for 60 min at room temperature.
12. Wash 3 times with PBS-Tween.
13. Dilute avidin-peroxidase appropriately in PBS-BSA, add 50 μl to each well, and incubate the plate for 60 min; wash as in step 8.
14. Add ABTS (50 μl/well), wait for the color reaction, and then add stop buffer (100 mM citric acid, pH 2) and measure the color intensity at 450 nm in an ELISA reader.

Interpretation

For each test, a positive control with known reactivity and a negative control (normal serum) should be included. Each serum sample should be tested in duplicate. Inhibition is calculated as the percentage of the serum sample value versus the negative-control value, which is defined as 0% inhibition. Serum is considered positive if the optical

density is reduced >40%. Serum samples with 20% to 40% inhibition are considered borderline.

Immunoblotting with Human Liver Microsomes To Test for LKM Antibodies

1. Prepare liver microsomes as described for ELISA. Instead of rat liver, use a small piece of human liver tissue.
2. Resolve 1 mg microsomes in sample buffer by 10% SDS-PAGE. In parallel, run a molecular weight standard.
3. Stop the gel when the bromphenol blue reaches the bottom of the gel, and transfer the proteins to a nitrocellulose filter.
4. Cut the nitrocellulose filter into 3-mm strips, block for 60 min in Tris-buffered saline (TBS)–Tween containing 2% milk powder, and then add patient sera, positive-control sera, and negative-control sera diluted 1:100. Incubate the strips in 1-ml aliquots of diluted sera for 60 min at room temperature.
5. Wash each strip 3 times with TBS-Tween for 5 min.
6. Add 1 ml of an appropriately diluted alkaline phosphatase-conjugated goat anti-human IgG and incubate for 60 min at room temperature.
7. Wash 3 times and then detect the signal by using a substrate for the enzyme-conjugated secondary antibody, such as NBT/BCIP (Nitro Blue Tetrazolium–5-bromo-4-chloro-3-indolylphosphate), or by chemiluminescence.

Interpretation

Characteristic LKM-1 autoantibodies react with a 50-kDa microsomal protein of human liver microsomes. Some sera from patients with AIH type 2 react with a protein of 64 kDa. LKM-1 antibodies in patients with chronic hepatitis C are more heterogeneous (51). They may react with other microsomal proteins, of 59 and 70 kDa. Approximately 50% of hepatitis C sera do not react with human microsomes in immunoblots, since these antibodies react with conformational epitopes.

Immunoblotting with Recombinant Liver Antigens

P450 IIC9 (50) and P450 IA2 (44) cDNAs are expressed in *E. coli*. UGT 1.1 cDNA (45) is expressed in baculovirus. The procedure for immunoblotting with these antigens is as follows.

1. Resolve 50 mg recombinant P450 IID6 or IA2 or 200 mg UGT 1.1 by 10% SDS-PAGE. In parallel, run a molecular weight standard.
2. Stop the gel when the bromphenol blue reaches the bottom of the gel, and transfer the proteins to a nitrocellulose filter.
3. Follow steps 3 to 7 in the protocol described in "Immunoblotting with Human Liver Microsomes To Test for LKM Antibodies."

Interpretation

Since almost all cytochrome P450 enzymes have molecular masses of approximately 50 kDa, a precise differentiation of different cytochrome P450 antibodies may be possible only if recombinant antigens are used. The identification of cytochrome P450 IA2 as a hepatocellular antigen resulted from the observation that a serum reacted with a 50-kDa protein but not with the recombinant cytochrome P450 IID6. In immunoblots with human liver microsomes, a distinction between P450 IID6 and P450 IA2 is not possible.

GENERAL REAGENTS

PBS, pH 7.4: Dissolve 32 g NaCl, 0.8 g KCl, 4.6 g Na_2PO_4 (anhydrous), and 0.8 g KH_2PO_4 (anhydrous) in 4 liters of distilled water. Adjust the pH to 7.2 to 7.4.

TBS-Tween: Dissolve 1.2 g Tris and 8.7 g NaCl in 1 liter of distilled water. Adjust the pH to 8.0 and add 500 μl Tween 20.

3% milk in PBS: Dissolve 3 g of nonfat dry milk in 100 ml of PBS, and adjust the pH to 7.2 to 7.4 by adding a few drops of 2 N NaOH.

Carbonate coating buffer: Dissolve 0.8 g of Na_2CO_3, 1.46 g of $NaHCO_3$, and 0.1 g of NaN_3 in distilled water; adjust to pH 9.6 and a final volume of 500 ml.

5× citrate buffer, pH 5.2: Dissolve 50.0 g of citric acid monohydrate and 7.4 g Na_2HPO_4 in 150 ml of distilled water, and adjust the pH to 5.2. Adjust the final volume to 200 ml.

ABTS substrate: Prepare 1 mM ABTS solution by adding 55 mg of ABTS to 100 ml of citrate buffer. Add hydrogen peroxide to 0.05% immediately before use.

NBT/BCIP substrate: Mix together 33 μl NBT and 16.5 μl BCIP in 5 ml alkaline phosphatase buffer.

Alkaline phosphatase buffer: Dissolve 12.1 g Tris and 1.0 g $MgCl_2$ in 1 liter of distilled water. Adjust the pH to 9.5.

102

SEROLOGIC DIAGNOSIS AND ASSESSMENT OF ACUTE MYOCARDIAL INJURY

Acute myocardial injury (AMI) most often results from a lack of sufficient blood supply to the myocardium. When patients present with symptoms of chest pain, rapid diagnosis of potential AMI and characterization of the extent of cardiac injury are essential for delivering appropriate treatment, e.g., intervention with thrombolytic therapy or angioplasty. Such interventions are aimed at minimizing the risk of (further) cardiac injury and death. Distinguishing patients with unstable angina from those with AMI is necessary to triage whether patients may be managed in the outpatient setting versus inpatient admission and immediate intervention. Serologic measurements of soluble biomarkers released during myocyte necrosis are used in conjunction with electrocardiograms and with more sophisticated imaging techniques like echocardiography and perfusion scintigraphy. Serum biomarkers have the greater advantage of detecting recent myocardial injury, which is not easily distinguishable by cardiac imaging techniques in patients with clinical evidence of preexisting heart disease (Table 1).

Serological monitoring of myocardial injury relies on the correlation of serum levels of biomarkers with the degree of cardiac myocyte injury and necrosis. Myocardial injury in acute coronary syndrome results from insufficient oxygen during episodes of ischemia. Whether the cellular damage is reversible or irreversible depends on the duration of ischemia. Myocyte necrosis is an example of irreversible injury that results in the rapid and complete release of cytoplasmic proteins of myocyte origin, which then become detectable in the serum. In contrast, proportionally lower levels of myocytic cytoplasmic proteins and macromolecules are released from cardiac myocytes during mild ischemic conditions, and these levels often correlate with reversible myocardial tissue injury.

The earliest conventional serum biomarkers used to assess AMI were enzymes involved in cellular metabolism, including aspartate aminotransferase, lactate dehydrogenase, and creatine kinase MB (CK-MB); however, the sensitivity and specificity of these biomarkers limited their clinical utility in detecting AMI. For example, CK-MB was generally considered a specific biomarker for irreversible myocardial injury; yet vigorous exercise, chronic renal failure, skeletal myopathies, and hypothyroidism can all increase plasma levels of CK-MB. Furthermore, studies of endomyocardial biopsies performed on patients with unstable angina revealed evidence of micronecrosis in the absence of elevated serum levels of CK-MB (1).

Cardiac troponins (cTns) represent a class of serum biomarkers that have become the gold standard for diagnosis of AMI due to their greater specificity and sensitivity for myocardial necrosis. The Tns comprise a group of regulatory proteins uniquely located on the thin filament of striated muscle. The Tn complex is composed of three subunits: (i) TnT, which attaches the Tn complex to tropomyosin; (ii) TnI, which regulates actin-myosin interactions; and (iii) TnC, which binds calcium (2). Immunoassays for cTnT and cTnI were first introduced in the early 1990s and have since then been improved and widely implemented. Tn levels are now included in the Joint European Society of Cardiology/American College of Cardiology Committee's consensus definition of AMI (3). Cardiac-specific isoforms exist for TnI (cTnI) and TnT (cTnT) and can be detected in plasma or serum by specific monoclonal antibodies without detectable cross-reactivity with skeletal muscle Tns. Unlike CK-MB, cTns are not found in the sera of normal patients (i.e., in the absence of cardiac tissue injury), thus providing troponin measurements with a superior signal-to-noise ratio and enhancing their usefulness for risk stratification and for the evaluation of patient response to therapy.

Additional biomarkers have been or are being studied to aid in the diagnosis of AMI, likely to be used in conjunction with cTns and CK-MB. These include myoglobin, copeptin, and heart-type fatty acid-binding protein (4–7). Each of these additional biomarkers has limitations, and their use clinically is not currently recommended for the diagnosis of AMI. It has been suggested that some of these biomarkers might have important prognostic applications or be used in specific clinical settings (8, 9).

SEROLOGIC DIAGNOSIS AND ASSESSMENT OF CHRONIC MYOCARDIAL INJURY

Chronic myocardial injury (CMI) is characterized by a much slower process than the acute myocyte necrosis typically seen in AMI. Slow and progressive myocyte dropout in CMI is usually associated with apoptotic processes involved in the pathogenesis of dilated cardiomyopathy (DCM). DCM results from maladaptive compensatory tissue remodeling responses secondary to reduced cardiac

doi:10.1128/9781555818722.ch102

TABLE 1 Serum biomarkers used for diagnosis of AMI

Plasma/serum biomarker	Specificity/sensitivity (%)					
	2–4 h		6–10 h		18–24 h	
	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity
Enzymes						
Lactate dehydrogenase					95	90
CK-MB activity	40.7	98.8	97.5	96.2	97.9	96.9
CK-MB mass	39.3	98.8	100	90.4	95.7	99.6
CK-MB isoforms	46.4	88.9	96.2	90.2	80.9	89.9
Structural and regulatory proteins						
Cardiac troponins						
cTnT	35.7	98.3	86.5	96.4	78.7	95.7
cTnI	57.5	94.3	92.3	94.6	95.7	93.4
Myosin light chains	75	64.2	78.6	61.1	81.5	52.5

output, which evolve in a complex manner and in the context of different genetic and environmental backgrounds over time. These remodeling responses are mediated by a variety of endogenous stress-induced proteins that act on cardiac myocytes to induce hypertrophy, cytoprotection, and repair, and on nonmyocyte cells to increase vascularization and effect extracellular matrix (ECM) remodeling and fibrosis (10–13).

Left ventricular (LV) hypertrophy and dilatation with reduced ejection fraction is a compensatory response to chronic volume overload that results from myocyte loss and reduced contractile function. Tissue remodeling responses are initiated and directed in part by innate immune cells residing within cardiac tissues, such as cardiac mast cells and dendritic cells. These responses are focused on reorganizing the cardiovascular architecture by degrading ECM components through matrix metalloproteinases (MMPs), promoting replacement fibrosis, developing new ECM and vascular beds, and recruiting and directing adaptive immune cells to remove damaged and necrotic tissues. During this process of remodeling and repair, certain cryptic cardiac antigens, e.g., myosin, mitochrondrial proteins, heat shock proteins, etc., become exposed to immature dendritic cells, which, under the influence of other "danger signals" present, undergo maturation and become capable of initiating subsequent cardiac-specific autoimmune responses. Such responses may or may not contribute significantly to further cardiac tissue injury.

Increases in hemodynamic burden and volume overload can also contribute to cardiomyocyte damage and DCM. Several reports from different laboratories indicate that cardiac hypertrophy is associated with signaling through the Gαq subtype of G proteins (GTP-binding proteins) expressed by cardiac myocytes (14, 15). Molecules such as endothelin-1 and angiotensin II, which are upregulated in response to increased pulmonary pressure and chronic volume overload, signal through Gαq-mediated pathways. This signaling causes reactivation of embryonic genes, such as atrial natriuretic factor, skeletal α-actin, and β-myosin heavy chain, which ultimately results in cardiac myocyte hypertrophy. Excessive hemodynamic stress can alternatively lead to myocyte apoptosis, instead of hypertrophy, resulting in rapid decompensation and DCM.

Chronic overstimulation of the renin-angiotensin-aldosterone system in patients with congestive heart failure (CHF) leads to increases in blood pressure and edema (16). A-type natriuretic peptides are produced by and released from the atria in response to dilatation. C-type natriuretic peptides are produced by cardiovascular endothelial tissues in response to shear stress. B-type natriuretic peptides (BNPs) are released from the ventricles in response to prolonged increases in end-diastolic volume and pressure and thus have emerged as excellent biomarkers for left ventricular dysfunction in DCM. BNP is derived from its high-molecular-weight precursor, pro-BNP (amino acids [aa] 1 to 108), whose expression is genetically regulated and which is not stored preformed in vesicles. The mature form, BNP-32, consists of the 32 C-terminal amino acid residues (aa 77 to 108) of the parent pro-BNP. Elevated plasma levels of the mature BNP or the amino-terminal pro-BNP (Nt-pro-BNP) may be used as indicators of cardiac dysfunction. Increasing concentrations of serum BNP or NT-pro-BNP have been shown to significantly correlate with decreasing ejection fraction ($P < 0.001$) and with increasing New York Heart Association classification of heart failure (17).

Biomarkers that are associated with CMI fall into three overlapping categories: (i) markers of tissue remodeling, (ii) markers of inflammation, and (iii) markers of vascular endothelial activation (Table 2). Myocardial tissue remodeling is triggered by LV dysfunction and is associated with cardiomyocyte hypertrophy and death. Such events in turn lead to remodeling of the ECM with replacement fibrosis. Chronic low, but significant, levels of myocyte dropout induce structural remodeling of LV ECM to compensate for loss of LV function. Increased plasma and tissue expression of MMPs and cardiac mast cell tryptase correlate with evidence of LV remodeling and dysfunction in CHF (18, 19).

Plasma levels of interleukin-6 (IL-6) and related cytokines of the IL-6 family, e.g., cardiotrophin-1, have been shown to increase proportionally with the severity of CHF in both human clinical studies and in experimental animal models (20, 21). Although the exact tissue sources of IL-6-related cytokines have not been identified, vascular endothelium and smooth and cardiac muscle tissues have been implicated. Intracellular signaling on cardiac myocytes is mediated via different multimeric IL-6 family cytokine receptors, which share a common gp130 transmembrane subunit. Homeostatic regulation of IL-6 expression during CHF is complex and appears to be influenced by a larger network of other cytokines and neurohormones, including tumor necrosis factor (TNF), angiotensin II, epinephrine, and norepinephrine. Indeed, angiotensin-converting enzyme inhibitors or β blockers have been shown to have a lowering effect on IL-6 expression during CHF (22). IL-6

Placental growth factor
Nitric oxide

appears to mediate the detrimental effects of CHF by influencing hypertrophy and apoptosis of cardiac myocytes (23).

Other inflammatory cytokines implicated in the pathogenesis of chronic myocardial injury include TNF and IL-1. TNF promotes LV remodeling by altering the ECM. TNF mediates such structural modifications through its ability to activate proenzyme forms of MMPs in myocardial tissues. TNF also promotes activation of the vascular endothelium. The expression of TNF is triggered by myocardial tissue damage and by inflammation, especially in viral myocarditis. IL-1 expression is also interrelated to the cascade of proinflammatory mediators released during CHF. IL-1 causes a negative inotropic effect in LV function by inducing nitric oxide expression and by promoting the production and release of IL-18.

Inflammation associated with tissue remodeling and the progression toward CHF in DCM results in increases in serum levels of soluble adhesion molecules, e.g., soluble intercellular adhesion molecule 1 (sICAM-1), E-selectin, P-selectin, and vascular cellular adhesion molecule 1, expressed by activated cardiovascular endothelial cells. Research reports have shown that serum levels of sICAM-1, measured by capture enzyme-linked immunosorbent assay, accurately correlated ($P < 0.001$) with intramyocardial expression of ICAM-1 in patients with DCM and correlated with the New York Heart Association classification of DCM (24). Thus, multiple serum biomarkers of tissue remodeling, inflammation, and endothelial activation have been shown to correlate with the development and progression of DCM (Table 3); however, other more invasive procedures involving immunohistochemical characterization of endomyocardial biopsies are required for confirmatory/definitive diagnosis and staging of inflammatory cardiomyopathies.

MOLECULAR DIAGNOSTICS FOR CARDIOMYOPATHIES

The field of molecular diagnostics is rapidly expanding the role of the clinical laboratory in almost all areas of medicine, and is consequently helping to usher in a new era of personalized medicine. Elucidating the genetic mutations and signatures associated with specific cardiomyopathies has fundamentally changed the clinical approach to patients with familial myocardial disorders. Genetic testing enables discrimination between various etiologies of myocardial dysfunction, as well as provides valuable information for family members who might be at increased risk for the development of certain types of cardiac disease. In addition, molecular techniques might provide relevant information about disease progression in a number of cardiomyopathies, including hypertrophic cardiomyopathy (HCM) and DCM.

For cardiomyopathies with well-recognized familial clustering, like HCM, genetic testing has identified key genes and mutations responsible for the disease phenotype. HCM is characterized by myocardial thickening, which interferes with cardiac output by limiting ventricular filling and outflow. More than 900 unique mutations in 13 genes have been identified and reported in patients with HCM (25, 26). Most of these mutations occur within genes encoding for sarcomere (thick and thin filaments) or sarcomere-associated (Z-disc and intercalated disc) proteins, which are important for myocyte contraction. Molecular diagnosis of HCM remains challenging since each family usually has a unique mutation (27); however, improved DNA sequencing techniques continue to evolve and are overcoming this problem. Once identified, pathogenic mutations can be subsequently assessed in relatives more easily and at a lower cost. Although there has not been strong correlation between the different genetic causes of DCM and the degree of cardiac hypertrophy, helpful prognostic information is gleaned from defining the mutation. Specifically, patients with a known sarcomere mutation have significantly worse outcomes than patients with an unknown cause of HCM (28). Finally, and importantly, molecular genetics can distinguish HCM from other genetic causes of cardiac hypertrophy, such as metabolic cardiomyopathy secondary to mutations in *PRKAG2*, *LAMP2*, or *GLA* (29).

In contrast to HCM, DCM is a far more genetically heterogeneous disease. Despite this fact, molecular genetics is emerging as a unique way to uncover important clinical clues in familial cases of DCM. The hallmark feature of DCM is ventricular dilation or enlargement, which impairs both systolic and diastolic function. About half of the cases of DCM are secondary to cardiac ischemia, often with multifactorial contributions from conditions like hypertension, valve dysfunction, and various toxic, metabolic, and immunologic abnormalities. The remainder of DCM cases are unrelated to cardiac ischemia, and of these, up to 50% are familial (30). Such cases of familial HCM result from a single mutation in any of a number of genes that encode various cytoskeletal, nucleoskeletal, mitochondrial, or calcium-handling proteins. In fact, >50 genes have been linked to familial DCM (31). For this reason, genetic testing currently relies on multigene panels that test large numbers of genes simultaneously. The availability of next-generation and whole-exome sequencing in clinical laboratories is rapidly expanding the feasibility of identifying unique index mutations in diseases like DCM (32).

Genetic testing for familial DCM, however, remains challenging given the number of candidate genes and the variable penetrance within family members. Familial DCM is passed down as a single gene mutation, most often with

autosomal dominant inheritance and less often with X-linked recessive inheritance. The latter has been described with several genes, including *DMD*, encoding dystrophin; *TAZ*, encoding tafazzin; and *EMD*, encoding emerin. Maternal inheritance of mitochondrial mutations has also been reported in familial DCM. Not surprisingly, several genes implicated in familial DCM overlap with genes identified in HCM, including genes that encode sarcomere and sarcomere-associated proteins. One such protein is titin, encoded by *TTN*, which plays a role in regulating sarcomere length by serving as a stretch sensor and communicating between the sarcomere and the cardiomyocyte (33). Titin mutations have been estimated to account for a quarter of the cases of DCM (34). While many patients with DCM have been found to have truncating *TTN* mutations, many others have *TTN* coding variants of unknown significance. The role of such variants, especially in patients with cardiac comorbidities like hypertension and valve defects, remains to be fully understood. Nevertheless, studies evaluating the pathogenicity of rare DCM variants through the use of computational prediction alogorithms are under way (35).

PATHOGENESIS AND DIAGNOSIS OF INFLAMMATORY CARDIOMYOPATHIES

Inflammatory cardiomyopathy is defined as myocarditis with cardiac dysfunction resulting from infectious, autoimmune, or idiopathic myocarditis. It represents a subset of DCM unrelated to ischemia, and can be associated with any number of infectious (viral, bacterial, fungal, or parasitic) and/or

TABLE 3 Infectious and noninfectious etiologies of inflammatory cardiomyopathy

Category	Disease or organism	Etiology
Infectious		
Viral myocarditis	Enterovirus	Coxsackie B3, B4 virus
	Herpesvirus	Cytomegalovirus, varicella-zoster virus
	Orthomyxovirus	Influenza virus
	Paramyxovirus	Parainfluenza virus
	Parvovirus	
	Retrovirus	HIV
	Adenovirus	
	Flavivirus	Hepatitis C virus
	Reovirus	
Bacterial myocarditis	*Streptococcus*	Group A strep
	Staphylococcus	*S. aureus*
	Serratia	*S. marcescens*
	Chlamydia	
	Salmonella	
	Aerococcus	*A. urinae*
	Ehrlichia	
	Vibrio	*V. cholerae*
Parasitic/protozoal/spirochetal myocarditis	Chagas' disease	*Trypanosoma cruzi*, *Toxoplasma gondii*
	Lyme disease	*Borrelia burgdorferi*
Rickettsial myocarditis	Q fever	
	Rocky Mountain spotted fever	
	Scrub typhus	
Fungal myocarditis	*Cryptococcus*	*C. neoformans*
	Candidiasis	*Candida albicans*
	Histoplasmosis	
	Aspergillus	
Noninfectious		
Autoimmune myocarditis	Rheumatic fever	
	Systemic lupus erythematosus	
	Sjögren's syndrome	
	Dressler's syndrome	Post-myocardial infarction
	Postpartum cardiomyopathy	
	Kawasaki disease	
	Sarcoidosis	
Drug-induced myocarditis	Cardiotoxic myocarditis	Cocaine 999, catecholamines, doxorubicin
	Hypersensitivity myocarditis	Antibiotics, diuretics, others

TABLE 4 Autoantibodies detected in inflammatory cardiomyopathies

Antigen specificity	Type of mimicry
Cardiac α-actin	Enterovirus
Heat shock protein 60	Enterovirus
β-Adrenergic receptor	*T. cruzi*
M2-cholinergic receptor	*T. cruzi*
Laminin	
Actin	
Myosin	Bacterial, enterovirus
Adenine nucleotide translocator	
Vimentin	
Sarcolemma	Enterovirus
Desmin	
Mitochrondrial antigen	Bacterial, enterovirus
Carnitine	
Laminin	
Myolemma	
Sarcolemma	
DNase B	Bacterial
Hyaluronidase	
Streptozyme	

noninfectious (drugs, genetic background, nutritional status, age, or pregnancy) conditions. These are outlined in Table 3. A list of autoantibodies that may be detected in inflammatory cardiomyopathies is provided in Table 4.

Myocyte damage in infectious myocarditis occurs through both the direct and indirect effects of pathogenic agents (36). Certain cardiotropic viruses, like coxsackie B virus, directly damage myocytes and cause necrosis. Adenoviruses induce apoptosis as a way of escaping immune recognition. Infectious agents can also cause heart disease indirectly by inducing immunologic responses (inflammatory cytokines as well as cell-mediated responses) that injure myocytes. Furthermore, the same immune responses engendered during the infectious phase of myocarditis may persist after viral clearance and develop into autoimmune postinfectious myocarditis. Autoimmune myocarditis can occur from a breakdown of tolerance to self antigens due to epitope mimicry, as in chronic rheumatic fever, or from a breakdown in immunologic ignorance due to exposure of normally cryptic self antigens, which can occur during necrosis.

Diagnosis of myocarditis, inflammatory myocarditis, or lymphocytic myocarditis has traditionally been determined by immunohistochemical analysis of endomyocardial biopsies (EMBs) using the Dallas criteria in conjunction with evidence of a 4-fold increase in virus-specific antibody titers between acute and convalescent sera (37). The Dallas criteria, established in 1986, define active, borderline, and absent myocarditis (38). Active myocarditis is the presence of lymphocytic infiltrates with adjacent myocyte necrosis, while borderline myocarditis is the presence of lymphocytic infiltrates without myocyte necrosis. The absence of infiltrating lymphocytes characterizes absent myocarditis. Collection of EMBs presents several challenges, including the fact that the procedure is relatively invasive. In addition, accurate diagnosis relies on histological evidence of a focal lesion that is often expressed only during the acute phase of infection, when obtaining a biopsy may be clinically contraindicated. Even when biopsies are obtained, they are often limited and lesions may be missed.

Currently, immunohistochemical staining and molecular immunological techniques, e.g., PCR and *in situ* hybridization, are being applied to EMB to enhance the sensitivity and specificity of this procedure for the diagnosis of myocarditis. Enzyme-conjugated monoclonal antibodies are used to distinguish different subsets of infiltrating lymphocytes, macrophages, and neutrophils. Molecular assays, e.g., PCR and *in situ* hybridization, are used to detect specific viral sequences within EMBs. These techniques, which help distinguish between productive and nonproductive infections, are useful in discriminating between active, chronic, and postinfectious cases of myocarditis.

Although the immunohistological characterization of leukocytic infiltrates in EMBs is improving, histological confirmation of myocyte damage has been a greater challenge and a source of interobserver variability in the clinical diagnosis of myocarditis using the Dallas criteria. This difficulty in assessing myocyte damage in EMBs may be one explanation for the low frequency (10%) of Dallas criteria-positive EMBs reported in the results of the 1996 Myocarditis Treatment Trial, which enrolled >2,200 patients with reduced ventricular function and no evidence of coronary artery disease (39). A number of new immunohistochemical and molecular assays are currently available. These include annexin binding assays, terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling (TUNEL)-based assays, and immunohistochemical assays for the detection of apoptosis-related caspases, all of which may be used clinically to identify and discriminate between apoptotic and necrotic cells. Assays for detection and characterization of inflammatory heart disease are listed in Table 5.

Biomarkers are also showing clinical utility in the assessment of certain types of inflammatory cardiomyopathies. Specifically, a role for biomarkers in peripartum cardiomyopathy (PPCM) is rapidly emerging, especially as the pathophysiologic mechanism of this disease is elucidated. PPCM is defined as the new onset of heart failure in a previously healthy woman during pregnancy or shortly postpartum. A unified hypothesis for the pathogenesis of PPCM was recently proposed whereby any number of factors during pregnancy, whether genetic susceptibility, altered immune response, or infection with cardiotropic viruses, ultimately leads to an imbalance in cytokines and cellular immune mediators that results in inflammatory cardiomyopathy and heart failure (40). Focusing on a common pathway leading to myocarditis in pregnancy, despite the various triggers, may allow for the detection of biomarkers suggestive of PPCM earlier and correlation with recovery outcomes.

Studies of PPCM have illuminated racial and ethnic disparities in disease prevalence. A population-based study of PPCM in the United States revealed a birth prevalence of 1 case for every 4,266 live births among white non-Hispanics, which is 4-fold lower than the birth prevalence of 1 case for every 1,087 live births among black non-Hispanics (41). Although the exact mechanism of disease remains uncertain, current observations support an immune-mediated process. Immune alteration in pregnancy ensures that the maternal immune system tolerates foreign paternal fetal antigens while still providing effective antimicrobial responses. However, studies of patients with PPCM have shown striking imbalances of cytokines and subsets of immune cells as compared to patients without PPCM (42, 43). These include the observation that patients with PPCM have an increase in activated regulatory T cells and a decrease in natural killer cells. A large prospective study, Investigations in Pregnancy

TABLE 5 Clinical immunological assays for detection and characterization of inflammatory heart disease[a]

Specimen	Result	Method	Criteria
EMB	Lymphocytic infiltrates	H&E histology	Cellular morphology
	B-cell infiltrates	IHC/IFA	Detection of CD20 surface antigen
	$CD4^+$ T-cell infiltrates	IHC/IFA	Detection of CD3/CD4 surface antigen
	$CD8^+$ T-cell infiltrates	IHC/IFA	Detection of CD3/CD8 surface antigen
	NK-cell infiltrates	IHC/IFA	Detection of CD56 surface antigen
	Macrophage infiltrates	IHC/IFA	Detection of CD14/CD68 surface antigen
	Infection with specific virus	ISH/PCR	Detection of virus-specific DNA or RNA
	Necrosis	H&E histology	Cellular morphology
	Apoptosis	Cardiac TUNEL assay	Fragmented DNA
Serum	Heart-reactive antibodies	IFA/EIA	Detection of IgG anti-cardiac myosin antibodies
	Cardiac myocyte damage	EIA	Dectection of TnT, TnI, or CK-MB
	Cardiac myocyte damage	Anti-myosin scintigraphy	Nuclear imaging with ^{111}indium–anti-myosin
	Diagnosis of viral myocarditis	ELISA	4-fold rise in specific IgG titer
	Diagnosis of rheumatic myocarditis	Anti-streptolysin O test	

[a]H&E, hematoxylin and eosin; IHC, immunohistochemistry; IFA, immunofluorescence assay; ISH, *in situ* hybridization; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay.

Associated Cardiomyopathy (IPAC), is currently under way by the Peripartum Cardiomyopathy Network to assess any correlation between immune system activation and patient outcomes in PPCM.

Several biomarkers believed to play a role in PPCM have been proposed to aid in diagnosis. These include prolactin metabolites, sFLT1, high-sensitivity C-reactive protein (hsCRP), and certain cardiac autoantibodies (44). Investigators have found that prolactin metabolites, called vasoinhibins, generated during pregnancy by oxidative stress can be cardiotoxic and actually drive the PPCM phenotype (45). This has led to studies evaluating the use of the prolactin antagonist bromocriptine for the treatment of PPCM (46). Another candidate biomarker for PPCM is sFLT1, an enzyme in the tyrosine kinase family with known antiangiogenic effects. Plasma sFLT1 appears to be cardiotoxic and is significantly elevated not only in patients with PPCM but also in patients with preeclampsia (47, 48). hsCRP is a nonspecific proinflammatory cytokine; still, its measurement may have utility in PPCM diagnosis and prognosis. Multiple studies, including those being conducted in Haiti, China, and South Africa, have shown that women with PPCM have significantly elevated levels of hsCRP compared to non-PPCM mothers (49–51). Conclusions drawn from the Haitian study implicate a role for hsCRP levels in predicting the chance of disease recovery, since recovered PPCM patients had significantly higher mean serum hsCRP levels compared to nonrecovered PPCM patients. Finally, cardiac autoantibodies are believed to contribute to the pathogenesis of PPCM and may potentially serve as biomarkers, as in other subtypes of inflammatory cardiomyopathy. Evidence comes from reports of cardiac β1-adrenoreceptor antibodies and cardiac myosin heavy chain antibodies in patients with PPCM. Detection of such antibodies early in the disease course may not only aid in diagnostic recognition but also limit their pathogenic contribution later in the disease course (52, 53). Widespread adoption of cardiac biomarker testing for disease diagnosis, prognosis, and monitoring of all types of cardiomyopathy is expected as evidence regarding the clinical utility of biomarker assays becomes increasingly available.

Celiac Disease and Inflammatory Bowel Disease

MELISSA R. SNYDER

103

Celiac disease (CeD) and inflammatory bowel disease (IBD) are chronic inflammatory diseases affecting the gastrointestinal tract. They share certain characteristics, including autoimmune features, the presence of both gastrointestinal and systemic clinical symptoms, and pathogenic contributions by genetic and environmental factors. However, there are several stark differences that must be appreciated. The immunogenic mechanisms of the two diseases are unique, with differing contributions by the innate and adaptive immune responses. Histologically, CeD is distinct from IBD, which is useful diagnostically as well as for gaining insight into disease mechanisms. Lastly, the role of diagnostic laboratory testing, both serologic and genetic, differs greatly between CeD and IBD. The purpose of this chapter is to provide a summary of what is currently known about the pathogenesis, epidemiology, clinical presentation, and diagnostic testing for CeD and IBD.

CELIAC DISEASE

Introduction

CeD results from an inflammatory reaction within the small intestine that is initiated, in genetically predisposed individuals, by ingestion of gluten (1, 2). The incidence of CeD appears to be on the rise in a number of populations throughout the world. Patients may present with gastrointestinal and/or systemic symptoms consistent with malabsorption. The diagnosis of CeD is based on histological evidence of small intestinal villous atrophy and positive antibody serology.

Pathology

For an individual to develop CeD, two criteria must be met: an appropriate genetic background and the necessary environmental exposure. The genetic component of CeD has long been recognized, based on observations that first-degree relatives of patients with CeD have a higher risk of developing the disease compared to the general population (3). At least 50% of the genetic predisposition is associated with HLA-DQ2 and HLA-DQ8. These alleles are closely linked to the second criterion—the environmental exposure—which is dietary gluten.

Gluten is a protein found in wheat, barley, and rye. Gliadin, which is the alcohol-soluble component of gluten, contains large numbers of proline residues, making it particularly resistant to proteolytic degradation (4). As a result, large peptides, some >30 amino acids in length, are produced within the small intestine. Gliadin also contains many glutamine residues, making these peptides attractive substrates for tissue transglutaminase (tTG) (5). tTG converts glutamine residues present in peptides and proteins, specifically in Q-X-P sequences, to glutamic acid, leading to an overall increase in the number of negative charges. HLA-DQ2 and HLA-DQ8 preferentially bind to peptides with negatively charged side chains, particularly deamidated gliadin (DG) peptides (6). The HLA/gliadin complex, present on the surface of antigen-presenting cells, interacts with $CD4^+$ T cells, leading to activation and expansion of DG-specific T cells. These $CD4^+$ T cells then stimulate B cells, resulting in activation of the humoral immune response and production of the anti-DG and anti-tTG antibodies that are characteristic of CeD. In addition, cytotoxic intraepithelial lymphocytes (IELs) are activated and kill enterocytes, which leads to damage of the small intestinal villi, resulting in blunting and atrophy. The only treatment currently available for CeD is strict adherence to a gluten-free diet (GFD). Removal of the inciting antigen downregulates the immune response, resulting in reconstitution of villous structure and decreased production of celiac-specific antibodies.

Epidemiology

In the United States, CeD is estimated to affect 1% of the population, which is similar to the findings of epidemiological studies in northern Europe (7, 8). In some southern European and sub-Saharan African countries, estimates of CeD prevalence are as high as 5 to 6%. In most Asian countries, including China and Japan, CeD is rarely diagnosed and only case reports exist in the literature. Differences in prevalence across geographic areas may reflect genetic diversity, variations in wheat consumption, or a combination. It appears that the prevalence of CeD is increasing in the United States and Europe (8, 9). This can, at least partially, be attributed to improved diagnostic testing and greater awareness of the disease. However, several studies using retrospective sample sets analyzed with current serologic tests have shown that the actual incidence of CeD is increasing (8). The exact reason behind this is unclear, although possibilities include changes in wheat genetics and/or processing,

doi:10.1128/9781555818722.ch103

altered exposure to cereal grains (particularly in childhood), and/or differences in childhood infections.

Clinical Manifestations

The direct consequences of the villous atrophy characteristic of CeD is chronic malabsorption (10). Malabsorption can result in weight loss in adults or "failure to thrive" in children. Ultimately, malabsorption can lead to steatorrhea, abdominal pain, and/or bloating. However, it is estimated that <50% of patients with CeD present to their physician with overt gastrointestinal symptoms (1). Many patients are identified based on more general manifestations of malabsorption, such as iron deficiency anemia, hypoproteinemia, or hypocalcemia/osteoporosis. Patients with CeD may also display liver function abnormalities, such as increased alanine aminotransferase levels. These elevations, however, are usually an incidental finding, with clinically significant liver disease being relatively rare.

CeD is also associated with a number of other immune-mediated diseases. Many of these coexisting conditions have an autoimmune etiology, including type 1 diabetes, autoimmune thyroid disease, and Addison's disease (11). The incidence of CeD in type 1 diabetics ranges from 2 to 8%. Some recommendations suggest that all type 1 diabetics should be routinely screened for CeD, although this remains controversial. Dermatitis herpetiformis (DH) is a relatively uncommon condition that occurs in the context of CeD (12). DH manifests as intensely pruritic lesions, most frequently on the elbows, knees, and forearms. DH is triggered by gliadin peptides and responds to a GFD. In the vast majority of patients with DH, villous atrophy is evident on small intestinal biopsy, although mostly in the absence of gastrointestinal symptoms. Another immune system abnormality, selective IgA deficiency, is also found more frequently in patients with CeD compared to the general population (13). Selective IgA deficiency is defined as low or undetectable concentrations of IgA in the presence of normal IgG and IgM production. Most individuals with selective IgA have no clinical evidence of immunodeficiency. However, because the serological evaluation includes IgA isotypes, selective IgA deficiency must be considered during testing for suspected CeD.

Diagnosis

Biopsy

Atrophy of the small intestinal villi can be visualized histologically. Most recommendations suggest that four to six biopsy samples be obtained during endoscopy in order to avoid false-negative results associated with patchy inflammation. The modified Marsh criteria are frequently used for evaluation of small intestinal biopsies (14). According to these criteria, type 0 is characterized by normal villous architecture; type 1 by increased numbers of IELs; type 2 by increased IELs and crypt hyperplasia; and type 3 by increased IELs, crypt hyperplasia, and villous atrophy (ranging from partial to total). Although often considered the gold standard for diagnosis of CeD, villous atrophy of the small intestine can be observed in a variety of other conditions, including tropical sprue, bacterial overgrowth, and infectious enteritis.

EMAs and Anti-tTG Antibodies

Endomysial antibodies (EMAs) are specific for the tissue that surrounds smooth muscle fibers, known as the endomysium (Fig. 1). EMAs were ultimately shown to be specific for the antigen tTG. EMA testing in the clinical lab is performed by immunofluorescence assays (IFAs), while testing for anti-tTG antibodies is generally performed by some type of solid-phase immunoassay. Testing for IgA and IgG isotypes is frequently available for both EMA and anti-tTG antibodies.

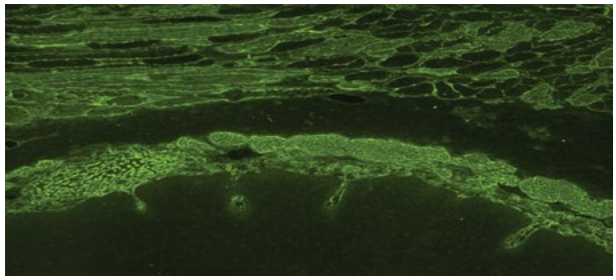

FIGURE 1 EMA by indirect immunofluorescence. The presence of an EMA is identified based on the appearance of latticework staining of the endomysium surrounding the smooth muscle fiber. This photo is a 10× magnification of an indirect immunofluorescence method using monkey esophagus. (Photo courtesy of the Immunodermatology Laboratory, Mayo Clinic, Rochester, MN.)

The specificity of EMA-IgA for CeD approaches 100%, with sensitivities in the range of 90 to 95% (15, 16) (Table 1). Anti-tTG-IgA tends to have very similar diagnostic performance, with sensitivities and specificities as high as 90 to 95% having been reported for CeD. In addition, the anti-tTG-IgA tests overcome some of the limitations of the EMA IFA, including improved quantitation and reduced subjectivity. However, it is important to realize that some variations in anti-tTG-IgA assays exist, related in large part to the source of the antigen (17).

In comparisons of anti-tTG-IgA and anti-tTG-IgG, most data indicate that anti-tTG-IgA has significantly better sensitivity and specificity compared with anti-tTG-IgG (15, 16, 18). However, most studies of this type have been performed in CeD cohorts composed primarily of patients with normal total IgA. For patients with IgA deficiency, testing for anti-tTG-IgG is clearly necessary to avoid false-negative results that would occur in the absence of the IgA isotype.

Anti-Gliadin and Anti-DG Antibodies

Anti-gliadin (GL) antibodies were the first serological marker identified in patients with CeD. However, as EMA and anti-tTG tests were developed, it became clear that these markers offered improved diagnostic sensitivity and specificity compared with anti-GL antibodies (15, 16, 19) (Table 1). Because gliadin is an excellent substrate for tTG, it was hypothesized that antibodies to DG might serve as a better serological marker. Anti-DG-IgA does, in fact, have very similar diagnostic sensitivity and specificity compared to anti-tTG-IgA, especially in adults (20). In children, anti-DG-IgA may offer some improvements in sensitivity (16). In terms of the IgG isotypes, anti-DG-IgG may have better diagnostic utility compared with anti-tTG-IgG, in large part due to improved sensitivity (19). However, these data again come mostly from unselected CeD groups; whether the increased sensitivity of anti-DG-IgG holds true for patients with selective IgA deficiency is still largely unanswered.

HLA Typing

CeD is one of the few chronic inflammatory diseases in which genetic testing, specifically for HLA-DQ2 and HLA-DQ8, plays a role in diagnostic testing. Identification of celiac-associated HLA genotypes requires characterization of both the α and β chains (21). HLA-DQ2.5

TABLE 1 Summary of serologic tests available for evaluation of suspected CeD and IBD

Disease	Antibody	Antigen specificity	Methodology	Isotype	Sensitivity (reference[s])	Specificity (reference[s])	Testing recommendations
CeD	EMA	tTG	Indirect immunofluorescence	IgA	90% (15)	99% (15)	Use as screening test limited by manual methodology; Testing should only be performed in patients on a gluten-containing diet
				IgG	NA[a]	NA	Should be restricted to patients with IgA deficiency
	Anti-tTG	tTG	Solid-phase immunoassay	IgA	78% (18, 19)	98% (18, 19)	Optimal screening test for patients with normal total IgA
				IgG	28% (18, 19)	97% (18, 19)	Should be restricted to patients with IgA deficiency
	Anti-DG	Deamidated gliadin	Solid-phase immunoassay	IgA	74% (18, 19)	95% (18, 19)	May be most useful for diagnosis of CeD in children
				IgG	65% (18, 19)	98% (18, 19)	Should be restricted to patients with IgA deficiency
	Anti-GL	Unmodified gliadin	Solid-phase immunoassay	IgA	63% (18, 19)	90% (18, 19)	No longer recommended for routine testing and should be replaced with anti-tTG and anti-DG
				IgG	42% (18, 19)	90% (18, 19)	
IBD: UC and CD	Atypical pANCA	Unknown	Indirect immunofluorescence	IgG	55% for UC (combined with negative ASCA result) (44)	81% for UC (combined with negative ASCA result) (44)	Not recommended for screening or differentiating IBD from non-IBD, but may be useful, in combination, for subset of patients for whom the diagnosis of UC vs CD is unclear
	ASCA	Cell wall mannan of *S. cerevisiae*	Solid-phase immunoassay	IgA	38% for CD (combined with negative pANCA result) (44)	94% for CD (combined with negative pANCA result) (44)	
				IgG			

[a]NA, not available.

is composed of DQA1*05:xx and DQB1*02:01. A single copy of this genotype is sufficient for predisposing an individual to development of CeD, although homozygosity increases the risk further. HLA-DQ2.2, composed of DQA1*02:01 and DQB1*02:02, also confers some risk for CeD, although generally only in homozygous individuals. Lastly, heterozygosity for DQA1*03:xx and DQB1*03:02, which forms the HLA-DQ8 molecule, also is a substantial risk factor for CeD.

In most populations, 90 to 95% of patients with CeD carry an HLA-DQ2 genotype, with the remaining 5 to 10% being positive for HLA-DQ8 (21). However, in North America and Europe, ~30 to 40% of the total population can be expected to be positive for either allele. Therefore, the presence of HLA-DQ2/DQ8 is necessary, but not sufficient, for the development of CeD.

Testing Recommendations

The multitude of options available for CeD testing can be overwhelming and can cause significant confusion regarding which tests are most appropriate for a given patient. Numerous guidelines and diagnostic algorithms have been published (22–24), based on which it is possible to make several general recommendations:

1. Testing for anti-tTG-IgA is the optimal screening test in patients who have normal concentrations of total IgA.
2. Testing for anti-tTG-IgG and anti-DG-IgG should be restricted to patients with documented selective IgA deficiency.
3. In children, especially those <2 years of age, anti-DG-IgA and anti-DG-IgG testing could be combined with anti-tTG-IgA to improve diagnostic sensitivity.
4. All serologic testing should be performed in patients on a gluten-containing diet.
5. Histological evaluation for villous atrophy is a useful confirmatory test in patients with positive serology or in patients with a high pretest probability of CeD based on clinical evaluation.
6. HLA-DQ2 and HLA-DQ8 typing should only be used to exclude CeD as a diagnosis in certain situations, such as in patients with equivocal biopsy results or in patients on a GFD at the time of serology testing.

Monitoring of Patients with Diagnosed CeD

Following a diagnosis of CeD, monitoring for responses to the GFD is an important part of patient management. Consultation with and guidance from a dietitian is a critical component, not only for exclusion of dietary gluten but also to ensure maintenance of adequate nutrition. Implementation of a successful GFD is accompanied, for most patients, by improvements in clinical symptoms, healing of the small intestinal villi, and decreasing concentrations of gluten-specific antibodies. Serological assessment provides a relatively noninvasive approach to monitoring of the gluten-initiated inflammatory response. The choice of which serological marker depends on which specific antibody the patient was positive for at diagnosis. For most patients, this is likely anti-tTG-IgA or EMA (25–27). Anti-tTG-IgA offers some advantages over EMA for the purposes of monitoring, including numerical quantitation (compared to positive/negative or titer), improved precision, and less subjective interpretation. Although decreasing concentrations of these antibodies are associated with downregulation of the gluten-initiated immune reaction, even conversion to negative serology is not always indicative of complete mucosal healing. Only histological analysis of a small intestinal biopsy can determine if a patient, despite improved clinical symptoms and negative serology, has any remaining degree of villous atrophy.

INFLAMMATORY BOWEL DISEASE

Introduction

IBD encompasses two distinct disorders: ulcerative colitis (UC) and Crohn's disease (CD) (28, 29). UC and CD can be distinguished from one another based on clinical presentation, patterns of inflammation, and, on a limited basis, serologic testing. The pathogenesis of UC and CD involves interactions between the innate immune response and the intestinal microbiome. Epidemiologic studies indicate that IBD is a disease of the developed world. The diagnosis of IBD, and classification as UC or CD, remains challenging due to varied clinical manifestations and lack of sensitive serological biomarkers.

Pathology

IBD results from a complex association between genetic and environmental factors. The genetic component is well recognized, including observations that close to 10% of patients with IBD have an affected first-degree relative (30). Many of the genes identified as risk factors for IBD have a role in the innate immune system. This has led to the hypothesis that disruption of the balance between luminal bacteria and the host immune response may be the initiating event in IBD, ultimately leading to the chronic inflammation characteristic of the disease (31). This is supported indirectly by evidence showing the efficacy of antibiotics and probiotics in the treatment of IBD. In addition, mouse models have demonstrated that experimental colitis can develop only in animals with gastrointestinal biota.

One gene clearly shown to be associated with IBD, specifically CD, is *NOD2/CARD15*. In some populations, homozygosity for certain *NOD2/CARD15* polymorphisms has an odds ratio of >15 for development of CD (30). The *NOD2/CARD15* gene encodes a pattern recognition protein that binds to muramyl dipeptide, a component of bacterial peptidoglycans. It has been suggested that mutations in *NOD2/CARD15* could lead to impaired negative regulation of normal gut biota. Other IBD-related genes also appear to be relevant to the innate immune response (31). *ATG16L1* and *IRGM* are important autophagic factors that play a role in the degradation of microbes and damaged cells. Disruption of autophagy could lead to reduced pathogen clearance, setting the stage for an enhanced inflammatory reaction. *IL23R*, the gene that encodes the interleukin-23 receptor, also plays an important role in several inflammatory pathways, including potentiation of Th17 cellular activation. Polymorphisms in *IL23R* could lead to increased activation of Th17 cells, a mechanism that has been proposed in a number of chronic inflammatory diseases.

Environmental factors are equally important in the pathogenesis of IBD, as highlighted by the observation that concordance in monozygotic twins is only ~20% in UC and ~50% in CD (30). As genetic studies implicate the interaction between the innate immune system and the intestinal microbiota in the development of IBD, one might expect that alterations in the intestinal biota caused by environmental factors could initiate an abnormal immune response in a genetically susceptible individual (32). However, because of the complexity, it has been difficult to demonstrate conclusively that any differences exist between the microbiota of

patients with IBD and control groups. Another piece of evidence suggesting a role of the environment is the observation that IBD is a disease primarily of industrialized populations (33). The reason for this is likely multifactorial. Developed societies tend to have improved sanitation, suggesting that decreased exposure to microbes might prevent development of a normal immune repertoire, predisposing individuals to abnormal immune responses (hygiene hypothesis). However, industrialized societies have additional environmental exposures, along with differences in diet, that could contribute to the risk of IBD. Other environmental factors suggested to have a role in IBD include smoking, breastfeeding as infants, and antibiotic use in children. However, published reports on these various factors are conflicting, which may reflect differences in patient populations or simply the overall complexity of IBD (32).

Epidemiology

Epidemiologic studies of IBD are challenging, primarily because a gold standard diagnostic test for IBD remains elusive. However, most studies have concluded that the highest reported rates are found in North America and Europe, where upper estimates for the incidence of UC are 19.2/100,000 and 24.3/100,000, respectively, compared to 6.3/100,000 in Asia and the Middle East (34). Similar geographic trends are observed for CD. In addition, the incidence of IBD appears to be on the rise, particularly as countries become industrialized. In a recent systematic review, 107 studies were identified in which there were at least three IBD incidence rate estimates over a period of at least 10 years (34). In 75% of the CD studies and 60% of the UC studies, a statistically significant increase in disease incidence was observed. This review also included studies that, collectively, determined that for both UC and CD, the peak age of incidence appears to occur during the third and fourth decades of life. Because IBD strikes at younger ages, and with the increasing incidence of disease, there are concerns that IBD could pose a serious burden to health care resources, particularly in developing countries.

Clinical Characteristics

Patients with UC and CD may present with intestinal and/or extraintestinal symptoms. The gastrointestinal symptoms differ significantly between UC and CD, largely due to differences in affected anatomical sites and patterns of inflammation (35). Most patients with UC have involvement of the rectum, with variations in the degree of proximal colonic involvement. The inflammation in UC is usually restricted to the mucosa, although it tends to be continuous across all affected areas. The most common gastrointestinal symptom in UC is the presence of blood and/or mucus in the stool; patients may also complain of significant cramping in the lower abdomen. CD, in contrast, may affect any part of the gastrointestinal tract. The inflammation often is transmural and is mostly "patchy," with affected areas interspersed with normal tissue. Because of the segmental nature of the inflammation and the more varied localization, the clinical symptoms of CD tend to be subtler in comparison to those of UC. Patients may present with abdominal pain, nausea, epigastric pain, or dysphagia. In addition, because of the transmural inflammation, patients with CD are at risk for the development of fistulas.

Some of the extraintestinal symptoms of IBD, such as weight loss, delayed growth in children, and osteopenia, are a direct result of the gastrointestinal involvement (35). In contrast, for other manifestations, such as fever, the link is less clear. Arthralgias are a common symptom associated with IBD, sometimes even appearing prior to any gastrointestinal symptoms. Patients may also develop oral ulcers or cutaneous symptoms, such as erythema nodosum. Other extraintestinal manifestations of IBD include episcleritis and primary sclerosing cholangitis, primarily in the context of UC. For most patients, the resolution of the extraintestinal symptoms, particularly the arthralgias and oral/skin lesions, parallels successful treatment of the underlying IBD.

Diagnosis

The diagnosis of IBD is based on endoscopic, histologic, imaging, and/or laboratory studies, in conjunction with a comprehensive clinical evaluation (36–39). The clinical evaluation should include assessment of patient history, such as recent travel, medication use, and risk factors. The specific imaging and endoscopy studies are dictated by the clinical presentation of the patient. Endoscopy can be used to characterize the inflammation (patchy or continuous) and to identify its location within the gastrointestinal tract. Biopsies should be obtained from at least five sites, with a minimum of two biopsies per site. In UC, histopathology can be expected to show diffuse mucosal inflammation with distortion of the crypt architecture, which can be distinguished from the transmural inflammation, sometimes with noncaseating granulomas, characteristic of CD. Imaging studies may not be needed to establish a diagnosis of IBD, although there may be some utility in evaluating the extent or severity of the inflammation. Some useful imaging modalities include radiography, ultrasound, computed tomography, and magnetic resonance imaging. Each modality has advantages and disadvantages. However, most guidelines suggest the use of imaging techniques that minimize radiation exposure, as studies may need to be repeated periodically during a patient's disease course.

Laboratory testing for diagnosis of IBD has a more indirect role. Fecal testing is important to rule out the presence of infectious organisms, as well as to assess for occult blood (36–39). In addition, quantitation of fecal calprotectin is increasingly becoming available (40). Calprotectin is an enzyme present in neutrophils. An elevation of calprotectin in stool samples is indicative of localized inflammation within the gastrointestinal tract. Although not specific for IBD, it can be used to rule out noninflammatory conditions, such as irritable bowel syndrome. Also, some publications have shown that routine testing of fecal calprotectin in patients with confirmed IBD may be useful for monitoring for treatment response and disease flares. Other lab testing for IBD, specifically autoantibody serology, is more controversial. The best-characterized antibodies in IBD, and those most frequently used in clinical practice, are anti-neutrophil cytoplasmic antibodies (ANCAs) and anti-glycan antibodies (41, 42) (Table 1). ANCAs associated with IBD produce an atypical perinuclear staining pattern (pANCA) by immunofluorescence using ethanol-fixed neutrophils. This atypical pANCA pattern generally appears as broad, peripheral fluorescence around the nucleus, which contrasts with the perinuclear cytoplasmic fluorescence observed in a pANCA pattern associated with anti-myeloperoxidase antibodies in systemic vasculitis. The specific antigen recognized by pANCAs in IBD is not known. Many candidate antigens have been studied, including elastase, cathepsin, lactoferrin, bactericidal/permeability-increasing protein, enolase, catalase, and high-mobility group 1 and 2 nonhistone chromosomal proteins (43). Unfortunately, significant variability exists across studies in terms of the individual antigen specificities and association with UC or CD, likely due in part to methodological differences and variability in patient cohorts. At this point, it is unclear exactly which antigen specificity

is responsible for the pANCA reactivity associated with IBD, and routine testing is limited to assessment for the pANCA pattern by immunofluorescence. The anti-glycan antibodies are a group of antibodies that are specific for microbial cell wall carbohydrates. Anti-*Saccharomyces cerevisiae* antibodies (ASCAs) bind to terminal mannan groups in the cell wall of the yeast *S. cerevisiae*. In routine clinical labs, testing for IgA and IgG isotypes for ASCAs is generally available. ASCAs tend to be associated with CD, while pANCAs are found more frequently in UC. The specificity of ASCAs and pANCAs for IBD in general is on the order of 80 to 90%. However, the sensitivity is relatively poor, only in the range of 15 to 30% (41, 42). For this reason, neither ASCAs nor pANCAs are considered appropriate for screening or to establish a diagnosis of IBD. However, combined use of ASCAs and pANCAs can be helpful in distinguishing UC from CD, primarily in individuals for whom the specific diagnosis is unclear from endoscopy or histology (43). Other antibodies have been described, including additional anti-glycan, anti-OmpC, anti-I2, and anti-CBir1 antibodies. However, most of these are not widely available, and most testing guidelines discourage their use for diagnostic purposes.

QUALITY ASSURANCE FOR CLINICAL TESTING

Maintaining high-quality testing for CeD and IBD autoantibodies follows principles applicable to any serological analysis. Given the number of assays on the market, most clinical labs elect to use Food and Drug Administration (FDA)-cleared kits for CeD and IBD testing, rather than development of in-house methods. Despite the fact that this classification of kits has undergone review by the FDA, there is little standardization. Different kits have different performance characteristics, often related to differences in the specific capture antigen. The specific kits chosen by a laboratory for either CeD or IBD diagnosis should be dictated by how clinicians intend to use the assay, the specific patient population, and the expertise of the lab.

Even with FDA-cleared reagents, the laboratory must still conduct validation studies prior to implementation. According to regulatory requirements, lab validation of FDA-cleared tests requires assessment of precision, accuracy, reference range, and reportable range. Additional parameters may be necessary, such as documentation of carryover (if using automated pipetting instruments), analyte stability (particularly if specimen transport to a centralized lab within a health system or to a reference lab is necessary), and specimen type (if testing both serum and plasma is desired).

Once the CeD or IBD serology tests are implemented, a robust, ongoing quality assurance program is critical. For both enzyme immunoassay and IFA methods, routine quality control should minimally include a positive and negative sample. For IFAs, if the patient results are reported with a titer, the titer of the positive control should also be monitored. For enzyme immunoassays, the negative control is often a "<" value, limiting its use as a quantitative control. The positive control should be designed to fall within the reportable range of the assay, allowing for the quantitative value to be monitored over time. This is particularly important for analytes, such as anti-tTG-IgA, which are used to monitor patients over the course of their disease. Additionally, labs may find it beneficial to include controls around clinically relevant cutoffs, such as between "indeterminate" and "positive." This should help labs identify any drift in the assay over time, which could result in different interpretations. Although most autoantibody kits include positive and negative controls, labs may want to consider maintaining patient serum pools for use as "in-house controls." These controls, prepared by pooling previously tested patient samples, have the advantage of having the identical matrix as patient samples and being independent of the kit, thereby serving as a bridge when reagent lot changes occur.

Another approach that laboratories might include as part of a quality assurance program is frequency monitoring of patient results. This involves assessing the frequency of positive and negative patient results generated by a laboratory for a given test over time. This approach makes two assumptions—that both the patient population being tested and the prevalence of the disease remain stable. For most autoimmune diseases, including CeD and IBD, these assumptions generally hold true. Even regarding prevalence of disease, although studies have generally concluded that the incidences of these diseases are increasing, the changes are small and are occurring over relatively long time periods. Monitoring of positive and negative frequencies allows laboratories to determine whether a given assay is performing consistently over time, particularly as changes in reagent lots occur.

Autoantibodies Directed against Erythrocytes in Autoimmune Hemolytic Anemia

R. SUE SHIREY AND KAREN E. KING

104

AUTOIMMUNE HEMOLYTIC ANEMIA

Immune-mediated hemolytic anemia can be broadly divided into two categories: alloimmune and autoimmune (1–4). Autoimmune hemolytic anemia may be further classified according to the immunoglobulin type of the autoantibody and its optimum temperature of reactivity (1–4). Warm autoimmune hemolytic anemia is due to IgG autoantibodies that bind to erythrocytes optimally at 37°C, while cold autoimmune hemolytic anemia is caused by IgM autoantibodies that preferentially react with red cells at low temperatures. A mixed-type autoimmune hemolytic anemia may occur when both warm IgG and cold IgM autoantibodies are implicated in clinical hemolysis. The rarest form of autoimmune hemolytic anemia, paroxysmal cold hemoglobinuria (PCH), is associated with IgG autoantibodies that are biphasic, sensitizing erythrocytes at lower temperatures and activating complement as the temperature increases to 37°C.

The characteristics of these different forms of autoimmune hemolytic anemia are outlined in Table 1. Warm autoimmune hemolytic anemia is the most common of the four types, and may be seen secondary to malignancies, such as chronic lymphocytic leukemia or lymphoma, or it may be idiopathic in nature (1, 2, 5, 6). Some drugs (e.g., α-methyldopa and fludarabine) can induce the production of warm autoantibodies (7). In ~90% of cases, warm autoimmune hemolytic anemia presents with a positive direct antiglobulin test (DAT) due to sensitization of the patient's red cells with IgG and complement or IgG alone (2, 8). An eluate prepared from the patient's red cells typically demonstrates antiglobulin reactivity with all test cells since the IgG autoantibodies usually have a broad specificity (3, 9). However, in ~4% of cases, the eluate may demonstrate an Rh antibody specificity, such as auto-anti-e (9). Detection of IgG warm autoantibodies in the serum or plasma is variable; ~60% have a positive antibody screen at the anti-human globulin (AHG) test phase, depending on the sensitivity of the assay (2, 8).

Cold autoimmune hemolytic anemia, or cold agglutinin disease, may occur acutely secondary to a *Mycoplasma pneumoniae* infection or as a chronic disease in elderly individuals sometimes associated with lymphoma or other malignancies (10, 11). In contrast to warm autoimmune hemolytic anemia, samples from patents with cold autoimmune hemolytic anemia generally demonstrate a high-titer (e.g., ≥1,000 at 4°C) IgM autoagglutinin in the serum (2, 8). Cold autoantibodies implicated in clinical hemolysis have a wide thermal range, reacting optimally at 4°C, but are capable of agglutinating red cells from room temperature (RT) (22 to 25°C) up to 30°C or, in some instances, 37°C (2, 8). The IgM antibodies can directly agglutinate red cells, so anticoagulated blood samples may appear to be clotted due to autoagglutination at ambient RT. IgM autoagglutinins are efficient in activating complement *in vivo*, and thus DATs are positive due to C3 sensitization of the red cells (2, 3, 8).

As is evident from the name, mixed-type (also known as combined-type) autoimmune hemolytic anemia has features of both warm and cold autoimmune hemolytic anemia (2, 8, 12). Usually the patient's red cells are sensitized with both IgG autoantibodies and complement. The serum contains an atypical IgM cold autoantibody that may not have a high titer, but has a high thermal amplitude capable of causing agglutination at temperatures of ≥ 30°C (2, 3, 8). IgG warm autoantibodies may also be detected in the serum reacting at an AHG test phase.

PCH is a very rare, acute illness that is most often seen in pediatric patients following a flu-like illness (13). Because of the biphasic nature of the IgG autoantibodies implicated in PCH, these antibodies are generally not detected in the serum using routine antibody screening methods. The patient's red cells are sensitized with complement alone; IgG is rarely detected on the red cells because the autoantibody dissociates *in vivo* at 37°C. A Donath-Landsteiner (D-L) test, which is designed to detect this unusual biphasic antibody, is diagnostic for PCH (2, 3, 8).

LABORATORY INVESTIGATION

Erythrocyte autoantibodies may cause accelerated intravascular and/or extravascular hemolysis or the autoantibodies may be entirely clinically benign (2). Therefore, the diagnosis of autoimmune hemolytic anemia relies on the clinical presentation and evidence of hemolysis, as well as serologic findings consistent with the presence of autoantibodies (2). The laboratory investigation of suspected autoimmune hemolytic anemia begins with a fundamental DAT using a polyspecific reagent for the detection of *in vivo* IgG and/or complement (C3) sensitization of the patient's red cells (2, 3, 8, 14). DATs should be performed using EDTA-anticoagulated blood, which inhibits complement binding

doi:10.1128/9781555818722.ch104

TABLE 1 Typical serologic characteristics in autoimmune hemolytic anemia (AIHA)

AIHA characteristic	Warm	Cold	Mixed-type	PCH
Immunoglobulin type	IgG	IgM	IgM and IgG	IgG
Optimum temperature	37°C	4°C	4°C and 37°C	Biphasic: 4°C to 37°C
Red blood cell sensitization	IgG alone (30%); IgG and C3 (60%); C3 alone (10%)	C3	IgG and C3	C3
Specificity	Usually broad specificity	Auto-anti-I	Unclear	Auto-anti-P
Serum autoantibody	60% of cases reactive at AHG phase	Cold autoagglutinin; reactive at ≥30°C	IgM cold autoagglutinin; reactive at ≥30°C; possibly IgG autoantibody	Detected only by D-L test

to red cells *in vitro*, ensuring the detection of only *in vivo*-bound complement (14).

Direct Antiglobulin Test

Specimen

Red cells from an EDTA-anticoagulated blood sample

Reagents

Polyspecific AHG reagent
0.9% saline
IgG-coated control red cells (available commercially)

Procedure

1. Prepare a 3 to 4% saline suspension of the patient's red cells from an EDTA-anticoagulated blood sample.
2. Dispense 1 drop of the saline-suspended red cells into a 12- by 75-mm test tube.
3. Wash the test tube three to four times with saline.
4. Completely decant the final wash.
5. Immediately add 2 drops of polyspecific AHG reagent and mix.
6. Centrifuge and immediately read for agglutination.
7. A negative test should be validated by adding 1 drop of IgG-coated control red cells to the tube and recentrifuging.
8. The test is valid if the tube shows agglutination.
9. The test is invalid if the tube shows no agglutination with the IgG-coated control red cells, which may be due to improper washing or failure to add the AHG reagent. The DAT should be repeated starting with step 1.

If the DAT is positive, then a DAT battery or profile is necessary using monospecific AHG reagents, anti-IgG and anti-C3, to specifically identify the sensitizing proteins. The DAT with polyspecific AHG reagent is repeated with the battery as a positive control. A negative (saline) control is included with the DAT battery to rule out the possibility of autoagglutination that may cause false-positive results.

DAT Battery

Specimen

Red cells from an EDTA-anticoagulated blood sample

Reagents

Polyspecific AHG reagent
Monospecific anti-IgG reagent
Monospecific anti-C3 reagent
0.9% saline
IgG-coated control red cells (available commercially)
C3-coated control red cells (available commercially)

Procedure

1. Label four test tubes: PS (polyspecific), IgG, C3, and Control (saline control).
2. Add 1 drop of 3 to 4% saline-suspended red cells into each tube.
3. Wash the tubes three to four times with saline.
4. Immediately add 2 drops of the appropriate AHG reagents to the test tubes and add 2 drops of saline to the control tube.
5. Mix and centrifuge the tubes.
6. Immediately read the tubes for agglutination.
7. The validity of a negative test should be confirmed by adding the appropriate IgG-coated or C3-coated reagent control cells and recentrifuging.
8. The test is valid if agglutination is observed with the control cells. If there is no agglutination with the control cells, then the test is invalid and must be repeated beginning at step 1.

The saline control must be negative to validate the DAT battery results. A positive saline control is usually due to autoagglutination mediated by IgM autoantibodies. In this situation, the patient's saline-suspended red cells should be washed three to six times with warm (37°C) saline to dissociate the IgM antibody. The warm-washed red cells can then be resuspended in saline to a 3 to 4% concentration and the DAT battery can be repeated.

The DAT profile or reaction pattern of IgG alone, IgG and C3, or C3 alone is helpful in determining what additional tests may be indicated for the differential diagnosis of autoimmune hemolytic anemia (Table 2).

Eluate Studies

If the DAT is positive due to IgG sensitization of the red cells (with or without C3), then eluate studies can be performed

TABLE 2 Interpretation of serologic findings in suspected cases of autoimmune hemolytic anemia (AIHA)

Typical serologic reaction pattern	Laboratory test results					Presumptive diagnosis
	DAT profile		Eluate studies	Serum antibody screen		
	Anti-IgG	Anti-C3		Result	Optimum reaction phase	
1	+	+/0	Panagglutinin	+/0	AHG	Warm AIHA
2	0	+	Not applicable	+	RT	Cold AIHA
3	+	+	Panagglutinin	+	RT and AHG	Mixed-type AIHA
4	0	+	Not applicable	0	D-L test positive	PCH

to identify the specificity of the antibodies. Many techniques have been described for eluting or disrupting IgG antibody from red cells (15). Perhaps the most commonly used procedure is the acid elution method, which is available commercially as a kit. A cold acid elution procedure that is also effective in eluting IgG antibodies is described below (15).

Cold Acid Elution Procedure

Specimen

1 ml of red cells from an EDTA-anticoagulated blood sample washed four to six times with large volumes of saline

Reagents

Glycine-HCl (0.1 M, pH 3.0), prepared by dissolving 3.75 g of glycine and 2.922 g of sodium chloride in 500 ml of deionized or distilled water. Adjust the pH to 3.0.

Phosphate buffer (0.8 M, pH 8.2)

0.9% saline kept cold at 4°C

Procedure

1. Place the glycine-HCl and the saline in an ice water bath.
2. Place 1 ml of red cells in a 13- by 100-mm test tube and chill in an ice water bath for 5 min.
3. Add 1 ml of chilled saline and 2 ml of cold glycine-HCl to the red cells.
4. Mix and incubate the tube in an ice water bath for 1 min.
5. Quickly centrifuge the tube at 900 to 1,000 × *g* for 2 to 3 min.
6. Transfer the supernatant eluate into a clean test tube, and test in parallel with the supernatant saline from the final wash ("last wash" control).

The eluate and "last wash" control can be tested in parallel with reagent antibody detection cells or panel cells using standard antibody identification methods. The last wash control should be negative, indicating that all unbound antibodies were removed by the washing process.

Serum or Plasma Studies

Antibody screening of the patient's serum or plasma for antibodies is particularly useful for the detection of cold autoagglutinins that may be implicated in cold or mixed-type autoimmune hemolytic anemia (Table 2). The following procedure is a saline antibody screening procedure by test tube methodology and includes an ambient RT test phase (8, 16).

Antibody Screen

Specimen

0.5 ml of serum or plasma

Reagents

Group O reagent red cells for antibody detection (I and II) (i.e., antibody screening cells) (available commercially)

Monospecific anti-IgG reagent

IgG-coated control red cells (available commercially)

0.9% saline

Procedure

1. Label three 12- by 75-mm tubes: I, II, and Auto.
2. Add 2 drops of serum or plasma into each tube.
3. Add 1 drop of screening cell I to the tube labeled "I" and 1 drop of screening cell II to the tube labeled "II." Add 1 drop of a 3 to 4% saline suspension of the patient's autologous red cells to the tube labeled "Auto."
4. Mix and incubate at RT for 5 min.
5. Centrifuge the tubes and read for agglutination.
6. Place the three tubes in a 37°C incubator for 30 min.
7. Centrifuge and read for agglutination.
8. Wash the tubes three to four times with 0.9% saline.
9. Immediately add 2 drops of anti-IgG reagent to each tube.
10. Centrifuge and immediately read for agglutination.
11. To validate a negative test, add 1 drop of IgG-coated control red cells and recentrifuge.
12. The test is valid if the tube shows agglutination with the IgG-coated control red cells. If the tube shows no reactivity with the control cells, then the test is invalid and must be repeated starting with step 1.

Cold autoagglutinins implicated in autoimmune hemolytic anemia are invariably reactive at the RT phase with the screening cells and the autologous control. However, reactivity at the RT phase does not necessarily indicate that the autoagglutinin is causing *in vivo* hemolysis (2, 8). Although the RT reactivity may persist or "carry over" to the 37°C and AHG test phases in the antibody screening procedure, the actual thermal range of the cold autoantibody would require tests that are performed only in specialized immunohematology reference laboratories. Cold autoagglutinins with a thermal amplitude of ≥30°C have been associated with autoimmune hemolytic anemia (2, 3, 8). Titration of the cold autoagglutinin may provide some additional supportive information, but the titer does not necessarily correlate with clinical significance (8).

IgG autoantibodies in warm or mixed-type autoimmune hemolytic anemia may be detected in the plasma or serum at the AHG test phase.

Antibody identification studies using a commercial panel can be performed using the same method as described above (16).

D-L Test

A D-L test may be indicated when the serologic findings are consistent with PCH, as shown in Table 2. In the D-L test, the patient's serum is incubated with test cells at cold temperatures to allow the antibody to bind to red cells and activate complement when the test is then warmed to 37°C, resulting in hemolysis (8).

Specimen

~1 ml of serum separated from a clotted blood sample that has been maintained at 37°C to prevent loss of antibody from autoadsorption

Reagents

Fresh normal serum as a source of complement. (Complement is added to the test, since patients with PCH may have low levels of complement.)

Group O, P-positive reagent red cells washed and resuspended in 0.9% saline to a 25% concentration. (The autoantibody in PCH is usually directed against the high-frequency P antigen; only very rare individuals are P negative. Reagent antibody screening cells are P positive and can be used as indicator red cells.)

Procedure

1. Label five 12- by 75-mm tubes: Test 1, Control 1, Test 2, Control 2, and Complement Control.
2. Dispense 5 drops of the patient's serum into each of the four tubes labeled Test 1, Control 1, Test 2, and Control 2.
3. Add 5 drops of fresh normal serum to the tubes labeled Test 2, Control 2, and Complement Control.
4. Add 1 drop of 25% group O reagent red cells to each of the five tubes. Gently mix and cork the tubes.
5. Place the patient's control tubes (Control 1 and Control 2) in a 37°C water bath for 90 min.
6. Place the patient's test tubes (Test 1 and Test 2) and the Complement Control tube in a melting ice bath for 30 min.
7. After 30 min, gently mix the tubes in the melting ice and transfer them to the 37°C water bath and incubate for 60 min.
8. Gently mix and centrifuge all tubes.
9. Observe the tubes for hemolysis, comparing the Test tubes with the corresponding Control tubes.

Hemolysis observed in the patient's Test 1 and/or Test 2 tubes when compared to the corresponding Control tubes indicates a positive D-L test. If no hemolysis is observed, the D-L test is negative.

The Complement Control tube is a negative control and should show no hemolysis. Hemolysis observed in the Complement Control tube may be related to the source of fresh complement or technical problems. In this situation, repeat the D-L test using a different source of fresh normal serum.

If hemolysis occurs in both the Test and Control tubes, then there may be a monophasic cold agglutinin present in the serum.

DIFFERENTIAL DIAGNOSIS OF AUTOIMMUNE HEMOLYTIC ANEMIA

Table 2 outlines the serologic findings for the DAT battery, eluate studies, and serum antibody screening tests that are typically seen for each type of autoimmune hemolytic anemia. It is essential that the serologic findings are interpreted in the context of the clinical presentation and medical history of the patient. The interpretation can be complicated by a history of recent blood transfusions, medications that can induce warm autoantibodies or drug-dependent antibodies, and the presence of multiple antibodies that may make it difficult to distinguish allo- from autoantibody activity (2, 7, 17, 18).

Not all cases of autoimmune hemolytic anemia can be categorized into the four types described here. A spectrum of unusual cases has been reported, ranging from DAT-negative autoimmune hemolytic anemia to warm autoimmune hemolytic anemia due to IgM autoantibodies (19–22). However, in the majority of cases of autoimmune hemolytic anemia, a presumptive diagnosis can be made based on the testing outlined in this chapter and clinical correlation.

Immune Thrombocytopenia

THOMAS S. KICKLER

105

GENERAL OVERVIEW

Immune thrombocytopenia (ITP) is an autoimmune disorder characterized by a platelet count of <100,000/μl in the absence of any underlying cause. The incidence of newly diagnosed ITP in adults ranges from 1.6 to 3.9 per 100,000 person-years. The female-to-male ratio ranges from 1.2 to 1.9. The general consensus is that the diagnosis is one of exclusion based on patient clinical history, physical examination, review of medication history, and performance of a complete blood count with review of the peripheral blood smear. One can classify the illness based on duration: (i) newly diagnosed with a duration of up to 3 months, (ii) persistent ITP of 3 months to 1 year, or (iii) chronic ITP of >1 year (1).

ITP can be further defined as either primary or secondary. About 20% of ITP cases are secondary to other illnesses, including autoimmune rheumatologic diseases; lymphoproliferative disorders; and infections including hepatitis C virus, *Helicobacter pylori*, and HIV infection (2).

PATHOPHYSIOLOGY

Antibodies are responsible for the enhanced platelet clearance by the reticuloendothelial system in ITP. The autoantigenic targets are found on the platelet glycoproteins IIb/IIIa, Ib/IX, and Ia/IIa. In some cases no antibodies may be detected. The spleen, being the major site of platelet destruction, is also a major site of autoantibody production (3).

There is a growing body of research that suggests that T-cell abnormalities in ITP are linked to the pathogenesis of the disorder. At the level of T-cell-related cytokine abnormalities, data suggest that interleukin-18 may play an important role in the pathogenesis of ITP. Investigators have shown that levels of interleukin-18 are increased during active disease, whereas in remission these levels fall to those of normal subjects. In addition, T-cell-related abnormalities include Fas-related T-cell apoptosis and deficiencies in T regulatory cell expression (4).

For decades, enhanced platelet destruction was considered the primary pathophysiology in ITP. There are now substantial data showing that autoreactive cytotoxic thymic lymphocytes induce megakaryocyte damage and impaired thrombopoiesis. As a result of these observations, administration of thrombopoietin to stimulate megakaryocytopoiesis is now an important therapeutic modality (4).

DIAGNOSTIC APPROACH TO PATIENTS WITH SUSPECTED ITP

In the majority of ITP cases, reaching the correct diagnosis is possible by taking a complete history, doing a physical examination, and performing a complete blood count with differential and review of the peripheral blood smear. Response to therapy with corticosteroids, high-dose intravenous gamma globulin, or anti-Rh(D) immunoglobulin provides supportive evidence of the immune basis of the thrombocytopenia. It is important to note that additional studies may be necessary to exclude secondary immune thrombocytopenia. Table 1 outlines consensus recommendations for the diagnosis of ITP in both children and adults (5, 6).

Platelet Autoantibody Detection

A variety of methods to measure platelet autoantibodies are available (7). Since the primary antigenic target is platelet glycoproteins, any assay that employs measurement of antibodies to these proteins increases the specificity. It has been noted that the surface of the platelet contains many species of immunoglobulin, so flow cytometric assays or other labeled anti-human globulin tests for platelet-associated immunoglobulin are of low diagnostic utility.

The monoclonal antibody-specific immobilization of platelet antigen assay (MAIPA) is both sensitive and specific (Fig. 1). This test is a laboratory-developed test that is validated by the testing laboratory. The test may be used to measure plasma antibodies or the antibodies that are contained on the surface of the platelet and that are directed toward platelet glycoproteins. When the MAIPA is employed, ~80% of samples will have detectable antibody when a panel of monoclonal antibodies is employed to capture the platelets. The relative sensitivity for plasma antibodies may be as low as 30%.

Test Procedure: MAIPA

Reagents

Coating buffer: 1.6 g of Na_2CO_3, 2.9 g of $NaHCO_3$, and 0.2 g of NaN_3. Add distilled water and adjust pH to 9.6.

TBS (Tris-buffered saline) wash buffer: 3.03 g of Tris, 22 g of NaCl, 12.5 ml of Nonidet P-40, 1.25 ml of Tween 20, and 1.25 ml of 1 M $CaCl_2$. Add distilled water to 2.5 liters.

doi:10.1128/9781555818722.ch105

TABLE 1 International ITP Working Group consensus recommendations for the diagnosis of ITP in children and adults (8)

Basic initial evaluation	Ancillary studies	Tests of unknown utility
Patient history	Antiphospholipid antibodies	Thrombopoietin level
Family history	Thyroid stimulating hormone or antithyroid antibodies	Reticulated platelets
Medication and over-the-counter drug history	Antinuclear antibodies	Platelet-associated immunoglobulin
Complete blood count	Pregnancy test in women of childbearing age	Bleeding time
Quantitative immunoglobulins	Platelet glycoprotein-specific antibodies	Platelet survival and sequestration studies
HIV		
Hepatitis C virus		
Helicobacter pylori		
Bone marrow not necessary in most patients		

Solubilization buffer: 1.21 g of Tris dissolved in 950 ml of saline, pH 7.4. Add 5 ml of Nonidet P-40 and add saline to 1 liter.

Goat anti-mouse IgG (from Jackson ImmunoResearch Laboratories, West Grove, PA). Dilute to 3 μg/ml in coating buffer.

Peroxidase-labeled goat anti-human IgG (Jackson ImmunoResearch). Dilute to 1 in 5,000 to 1 in 25,000 in TBS, as determined by positive and negative control titration.

Substrate. Dissolve four 3.5-mg tablets of 1,2-phenylenediamine dihydrochloride in 12 ml of water in a foil-covered container. Add 10 μl of 30% H_2O_2 before use.

Stop solution. Add 28 ml of 95 to 97% H_2SO_4 to 972 ml of water.

Warning: Use only freshly prepared reagents.

Method

Preparation of Anti-Mouse Antibody-Coated Microtiter Plate

1. Prepare goat anti-mouse IgG as described above and aliquot 100 μl per well into flat-well microplates for duplicate testing and incubate overnight at 4°C. The plates may be stored for up to 14 days.

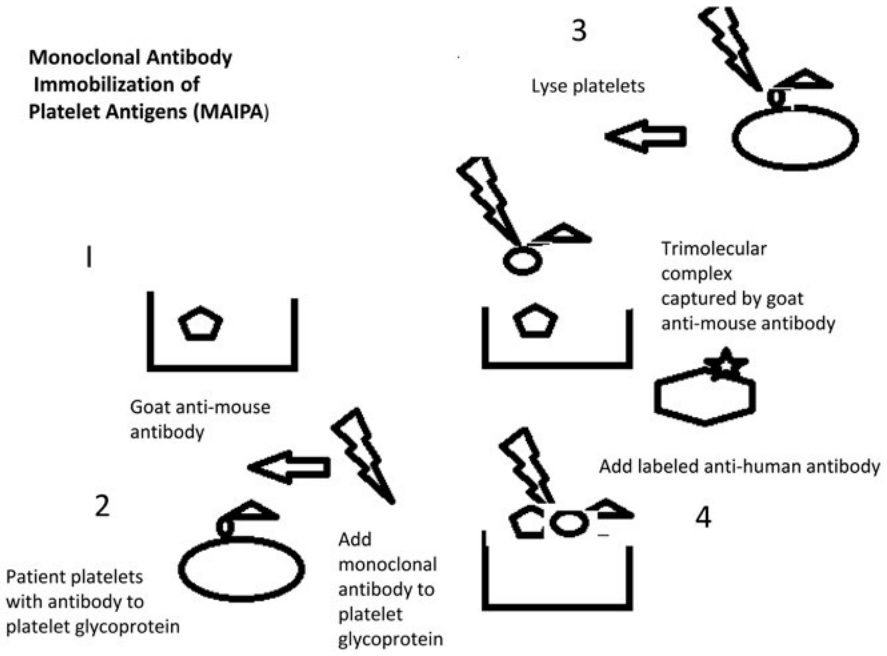

FIGURE 1 The general outline of the MAIPA. Murine monoclonal antibody, such as antibody to glycoprotein IIb/IIIa, is added to the autoantibody-sensitized platelets and the mixture is lysed. The trimolecular complex is captured by goat anti-mouse antibody, enzyme-labeled anti-human antibody is added, and the results are read by adding the appropriate substrate.

2. Before using, wash the plates with TBS wash buffer. Leave the last wash in the well for 30 min to block nonspecific binding of proteins.

Platelet Preparation
1. Take platelets from normal donors for plasma antibody testing. In case of testing patient platelets, collect platelets from blood. Either EDTA or citrate anticoagulant is satisfactory.
2. Prepare platelet-rich plasma using standard centrifugation methodology.
3. Resuspend platelets and adjust final concentration to 200,000/μl.

First Incubation for Plasma Antibody Detection
1. For each sample to be tested, aliquot 100 μl of platelet suspension into a U-well microplate and spin at 1,500 × *g* in a benchtop microplate centrifuge for 3 min. Include two negative controls and a weakly positive control.
2. Decant the supernatant and then suspend the plate pellet in 50 μl of test plasma and incubate at 37°C for 30 min.
3. Wash platelets by adding 200 μl of phosphate-buffered saline-EDTA to each test and centrifuge at 1,500 × *g* for 3 min.
4. Resuspend the platelet pellet using a microplate shaker and wash once more.

Incubation with Monoclonal Antibody

Resuspend platelet pellets in 40 μl of diluted mouse monoclonal antibody (antibodies to IIb/IIIa, Ib/IX, or Ia/IIa; Dako, Carpinteria, CA) and incubate for 30 min, followed by three washes with wash buffer.

Lysis
1. Lyse plates by resuspending each pellet in 130 μl of solubilization buffer.
2. Block the coated microplate with TBS wash buffer.
3. Centrifuge at maximum speed in a benchtop centrifuge. For each test, aliquot 130 μl of TBS wash buffer into each well.
4. Remove 100 μl from each supernatant and dilute in 130 μl of wash buffer.

Attachment to Solid Phase
1. Transfer 100 μl of diluted platelet lysate in duplicate to a precoated and blocked well, and add 100 μl of wash buffer to four reagent blank wells.
2. Incubate at 4°C for 90 min or overnight.
3. Wash microplate wells four times with wash buffer.

Anti-IgG Incubation
1. Add 100 μl of labeled anti-human IgG to each well and incubate at 4°C for 90 min.
2. Wash six times with buffer and blot between washes to dry.

Color Development
1. Add 100 μl of substrate solution to each well and leave at room temperature.
2. Stop the reaction with 100 μl of H_2SO_4.
3. Read the absorbance at 490 nm.

Interpretation

While the diagnosis of ITP is considered one of exclusion without the need for immunologic confirmation, clinicians still find the testing important. We recommend testing in those patients who fail to respond to standard therapy. If the testing is negative, clinicians should be advised to pursue investigation for other, less common causes of thrombocytopenia, especially congenital thrombocytopenia or thrombocytopenia associated with myelodysplasia. Standardization of the testing is demanding and requires expertise in this type of testing. For this reason, this assay is typically only done in platelet reference laboratories.

Calculate the mean optical density for all negative and positive controls and samples. The positive cutoff is the mean of the negative controls plus three standard deviations. The positive control should produce an optical density of least 3 times the negative control.

Monitoring Autoimmune Reactivity within the Retina

JOHN J. HOOKS, CHI-CHAO CHAN, H. NIDA SEN,
ROBERT NUSSENBLATT, AND BARBARA DETRICK

106

IMMUNE REACTIVITY IN THE EYE

The identification of immune reactivity against self components is a key element in the characterization of autoimmunity and autoimmune diseases. This autoimmune reactivity is most frequently monitored by the detection of specific autoantibodies or the presence of T-cell reactivity to self peptides. Numerous studies have now demonstrated that distinct profiles of autoantibodies are seen in clinically distinct autoimmune syndromes, such as systemic lupus erythematosus, myositis, and insulin-dependent diabetes mellitus. Moreover, the autoantigens are targets of an adaptive immune response.

Despite remarkable features of immune privilege in the eye, inflammatory processes do occur in the eye, and these are frequently referred to as uveitis (1, 2). Uveitis is the fifth-leading cause of vision loss in the world and accounts for 10 to 15% of all cases of total blindness in the United States (3). Most ocular inflammatory processes are associated with a cellular component. Ophthalmologists have a clear advantage in monitoring disease since the severity of the intraocular inflammation can be graded by direct visualization using slit-lamp biomicroscopy and fundoscopy.

Retinal degeneration is a primary cause of visual impairment and vision loss in the world. In the United States alone, there are presently more than 6 million people diagnosed with retinal diseases. This number includes patients with diabetic retinopathy and age-related macular degeneration, as well as patients with the broad diagnosis of retinal degeneration. Immune-mediated vision loss is a rapidly expanding area of research and therapy. It is becoming increasingly clear that retinal degenerative processes can also have an immune component that may be associated with the presence of antiretinal antibodies (4). In fact, several recent studies have focused on the role of antibody-mediated pathology in the retina. The identification of specific antiretinal antibodies may have application in the diagnosis and management of retinal degeneration. This chapter highlights retinal diseases associated with the identification of antiretinal immune reactivity or T-cell immune reactivity. Laboratory assays designed to detect and characterize antiretinal antibody reactivity are reviewed.

CLASSIC EXAMPLES OF AUTOIMMUNE DISEASE IN THE RETINA

Retinal autoimmunity exists as a naturally occurring disease in humans and as an experimentally designed animal model system. In humans, sympathetic ophthalmia and birdshot chorioretinopathy are classic examples of T-cell-mediated autoimmune diseases (5, 6). Sympathetic ophthalmia is an ocular inflammatory (autoimmune) disease that occurs after a perforating injury to one eye. The injured eye undergoes a massive granulomatous infiltration. At any time from the first week to several years following the trauma (peak is second week to 3 months), a spontaneous granulomatous infiltration occurs in the noninjured, "sympathizing" eye. Several studies have shown that the infiltrate consists predominantly of T cells. Birdshot chorioretinopathy is a posterior uveitis that has a strong association with HLA-A29 and the endoplasmic reticulum aminopeptidase (ERAP) 2 gene (7). More recently, this autoimmune disease was shown to be associated with production of Th17 cells (8). Peripheral blood mononuclear cells from patients respond to retinal lysates by producing interleukin-17 (IL-17). This is associated with a significant induction of Th17 cells and not Th1 cells.

Animal model systems have been developed to mimic human retinal diseases. Within the retina, a number of uveitogenic antigens have been identified and characterized. Two of these, retinal S antigen (arrestin) and interphotoreceptor retinal binding protein (IRBP), have been used to develop rodent models of T-cell-mediated autoimmune ocular disease, termed experimental autoimmune uveoretinitis (9). These retinal proteins are now also utilized to monitor human T-cell reactivity to retinal tissue. We have also developed a model of infection-associated retinal autoimmunity, referred to as experimental coronavirus retinopathy (10–12). This degeneration is triggered by the murine coronavirus mouse hepatitis virus and is characterized by genetic predisposition and autoimmune reactivity. Interestingly, the genetic predisposition is correlated with an augmented innate immunity and may be a classic example of innate immunity driving autoimmune responses (13).

doi:10.1128/9781555818722.ch106

RETINOPATHIES ASSOCIATED WITH ANTIRETINAL ANTIBODIES

Human retinopathies associated with the production of antiretinal antibodies can be categorized into three groups: (i) autoimmune retinopathy (AIR), consisting of two subgroups, paraneoplastic disorders and nonparaneoplastic retinopathy; (ii) infection-associated retinopathies; and (iii) retinal degenerative disorders (Table 1).

Autoimmune Retinopathy

AIR is an inflammation-mediated retinopathy characterized by vision loss, scotomas, visual field deficits, photoreceptor dysfunction, and the presence of circulating antiretinal antibodies. AIR is divided into two groups: paraneoplastic and nonparaneoplastic retinopathy. Progressive blindness as a remote effect of cancer was first reported in 1976 (14). The two most frequently observed forms of ocular paraneoplastic disorders are referred to as cancer-associated retinopathy (CAR) and melanoma-associated retinopathy (MAR). Clinical and experimental observations in CAR and MAR probably provide the best evidence for a pathological role of autoreactive antibodies in human retinopathies. First, affected patients suffer from a retinopathy that is characterized by retinal tissue damage and the presence of antiretinal antibodies. Second, some patients respond to plasma exchange and immunosuppressive therapy. Third, in experimental models, retinal cell damage can be induced by the autoreactive antibodies and there is evidence of passive transfer of disease to animals (15, 16).

CAR is most commonly associated with small-cell carcinoma of the lung, but it has also been reported in patients with breast, endometrial, and other cancers (17, 18). In these patients, antibodies develop with reactivity to the retina, and this response is associated with rod and cone dysfunction. Visual loss occurs over months and may even precede the identification of the malignancy. Using immunofluorescent-antibody (IFA) assays on normal retinal tissue sections, it has been demonstrated that sera from CAR patients reacts with the photoreceptor outer segments and ganglion cells. Further analysis of retinal antigens has revealed that a variety of antigens may be involved in this process. The primary antigens identified are a 23-kDa antigen (recoverin); a retinal enolase (46 kDa); and a group of reactivities with retinal antigens identified as 40-, 43-, and 60-kDa molecules. Although >15 retinal antigens have been described in the CAR syndrome, the most common antigen linked to CAR is the 23-kDa recoverin, a calcium-binding protein found in both rods and cones.

MAR is a second paraneoplastic syndrome that occurs in patients with melanoma (1, 19, 20). Progressive visual loss develops over months and is frequently associated with metastatic cutaneous melanoma. Again, IFA technology has been used to identify antibody in MAR patient sera that reacts to bipolar cells in the outer nuclear layer and their dendrites in the outer plexiform layer of the retina. The primary target antigen in MAR has been identified as transient receptor potential melastatin 1 (TRPM1) (21, 22).

TABLE 1 Antibody responses directed against retinal antigens in sera from patients with retinal diseases[a]

Retinal disease	Immunologic reactivity	Antigen
Autoimmune retinopathy (AIR)		
Paraneoplastic		
CAR	Photoreceptor inner and outer segment and ONL	Recoverin (23 kDa), enolase, TULP1, and others
MAR	Outer plexiform layer and INL	Bipolar cells
Nonparaneoplastic	Neuroretina, RPE, and ganglion cell layer	Variety of retina antigens
Infection-associated retinopathy		
Toxoplasmosis	Photoreceptor layer	Not known
Onchocerciasis	Neural retina and RPE	Cross-reactivity between *O. volvulus* Ag (OV39) and RPE Ag (hr44)
Retinal degenerative diseases		
RP	Neural retina	Carbonic anhydrase II (30 kDa) and enolase (45 kDa)
RAR	Photoreceptor	Recoverin
AMD	Photoreceptors	Neurofilaments
Sympathetic ophthalmia	Neural retina	Multiple antigens (T-cell reactivity)
VKH syndrome	Photoreceptors	Unknown
Neurologic disease (stiff man syndrome)	Neural retina	GAD

[a]Ag, antigen; RP, retinitis pigmentosa; RAR, recoverin-associated retinopathy; AMD, age-related macular degeneration; VKH, Vogt-Koyanagi-Harada syndrome; GAD, glutamic acid decarboxylase.

Nonparaneoplastic AIR is a rare disease constituting <1% of all cases of uveitis. The real prevalence of this condition is difficult to determine because of the overlap of clinical features with other retinal degenerative disorders and the lack of standardized laboratory diagnostic criteria. Studies are presently under way to develop standardized laboratory diagnostic criteria. Numerous retinal proteins have been identified as targets for antiretinal antibodies in AIR. These include α-enolase, lens epithelium-derived growth factor, carbonic anhydrase, arrestin, tubby-like protein 1 (TULP1), neurofilament protein, heat shock protein 70, and photoreceptor cell-specific nuclear receptor (23–26).

Infection-Associated AIR

The second group of retinopathies associated with antiretinal antibodies is retinal disorders that are triggered by an infectious agent (11). In humans, onchocerciasis and toxoplasmosis fall into this category. Infection with the nematode parasite *Onchocerca volvulus* can result in severe eye disease, often referred to as river blindness. Humans are infected with the helminth larvae by the bite of a black fly of the *Simulium* genus. It is estimated that ~18 million people in tropical Africa, the Arabian Peninsula, and Latin America are infected with this organism, and of these, ~1 million to 2 million are blind or have severe visual impairment.

Posterior ocular onchocerciasis is characterized by atrophy of the retinal pigment epithelium (RPE), and as lesions advance, subretinal fibrosis occurs. A number of studies indicate that affected patients have antiretinal antibodies in their sera and vitreous (27). Reactivity was observed in the inner retina and photoreceptor layers by IFA analysis. Characterization of the autoantigens revealed that a recombinant antigen in *O. volvulus* showed immunologic cross-reactivity with a component of the RPE. By Western blot analysis, an antibody to a 22,000-molecular-weight antigen (OV39) of *O. volvulus* recognized a 44,000-molecular-weight component (hr44) of the RPE cell. Although OV39 and hr44 are not homologous, they did show limited amino acid sequence identity. Immunizations of Lewis rats with either OV39 or hr44 induce ocular pathology. These studies indicate that molecular mimicry between *O. volvulus* and human RPE protein may contribute to the retinopathy found in patients with onchocerciasis (28, 29).

Toxoplasmosis, which occurs in >500 million humans worldwide, is caused by the obligate intracellular parasite *Toxoplasma gondii*. *T. gondii* is also the most frequently identified infectious agent in posterior uveitis, and *Toxoplasma* retinochoroiditis is an important cause of blindness in young adults. Since the 1980s, several reports have documented a high prevalence of antiretinal antibodies in sera from *T. gondii*-infected patients (30). These antibodies are directed against the photoreceptor layer. Moreover, leukocytes from these patients have been shown to proliferate in response to retinal S antigen (31).

Autoimmunity Associated with Retinal Degenerative Diseases

The third group of retinopathies associated with antiretinal antibodies is classified as the retinal degenerative disorders. These include retinitis pigmentosa with cystoid macula edema, recoverin-associated retinopathy, age-related macular degeneration, idiopathic retinopathies, and retinopathies associated with autoimmune neurologic diseases (32). Table 1 identifies serum antibody responses directed against retinal antigens in patients with retinal diseases. These are described in more detail in reference 16.

LABORATORY MONITORING OF ANTIRETINAL ANTIBODIES

Historically, the detection of autoantibodies has served as an invaluable laboratory tool for the diagnosis, monitoring, and management of patients with autoimmune diseases. Studies to monitor antiretinal antibodies have been performed using one of three assay systems, immunohistochemical assays (such as indirect IFAs and immunoperoxidase assays), enzyme immunoassay (EIA), and Western blot. There is a lack of consensus for the standard screening assay, and thus, there is a need to develop standardized laboratory diagnostic criteria. One such approach has been to use a two-tier testing system consisting of a screening assay, such as an indirect IFA on rodent and/or primate retinal tissue, followed by a second confirmatory test, i.e., an EIA or Western blot. The second-tier test can incorporate known retinal autoantigens, such as recoverin and α-enolase (23). As new retinal autoantigens are identified, they can be incorporated into this test system.

Immunohistochemical Assay System

Standard immunohistochemical assays or immunofluorescent assays are used to identify antibody reactivity within the retina. In addition to human retina, rodent (mouse or rat) or monkey eyes are frequently used as the substrate.

Preparation of Tissue Sections

After enucleation, eyes are immediately placed in OCT and frozen and stored at −70°C. Using a cryostat, whole rodent eye sections can be prepared and placed on SuperFrost slides. When using monkey or human eye tissue as the substrate, the frozen eye must be cut into smaller blocks of tissue before cryosections of the eye are cut. Slides containing the retina are stored at −70°C until used.

Procedure

1. Briefly, the standard procedure consists of fixing and permeabilizing the ocular tissue sections with acetone-methanol (1:1) and rinsing them with phosphate-buffered saline (PBS), pH 7.4. Endogenous peroxidase activity is quenched by incubating the sections in 0.6% H_2O_2 prior to incubating the tissue in a blocking solution. A standard blocking solution is 10% normal goat or rabbit serum in PBS. Bovine serum albumin, glycine, and/or cold-water fish gelatin can be added to the standard blocking solution if necessary to reduce nonspecific binding by the primary antibody.
2. Serial 2-fold dilutions of sera (1:40 to 1:640) from patients with retinal degeneration and healthy controls are incubated with the tissue sections either for 90 min at room temperature or overnight at 4°C.
3. Slides are then washed in PBS with 1% normal goat or rabbit serum, and a dilution of the secondary antibody (horseradish peroxidase-conjugated anti-human IgG) is applied to the tissue for 1 h. For IFA assay, the secondary antibody is labeled with fluorescein isothiocyanate.
4. Detection of bound immunoglobulin molecules is accomplished using a peroxidase substrate such as 3,3′-diaminobenzidine. Instead of horseradish peroxidase, the secondary antibody may be conjugated to alkaline phosphatase. However, the peroxidase substrates produce more-pronounced precipitates and give sharper localization than alkaline phosphatase substrates.
5. Slides are counterstained and dehydrated, and coverslips are mounted prior to examining the tissue sections under a microscope. For IFA assay, the slides are read under a fluorescent microscope.

Interpretation

Studies in our laboratory demonstrate that immunofluorescence or immunocytochemical tests using rodent or primate tissue and serum from individuals without a history of retinal disease are usually negative or reactive only at low serum dilution (<1:80). In contrast, high titers of antibody (>160) are detected in patients with selected retinal degenerative diseases. Sera from 18 healthy individuals demonstrated immunoreactivity to normal mouse ocular tissue in 33% of samples at a 1:40 dilution, in 13% of samples at a 1:80 dilution, and in 3% of samples at a 1:160 dilution, and no reactivity was noted at a dilution of 1:320 or 1:640. In contrast, in selected patients with retinal degenerative disorders, we can detect reactivity in serum samples at dilutions of 1:160 to 1:1,280. We have evaluated 12 patients with primary AIR in this system and have demonstrated a sensitivity of 90% and a specificity of 97% at a serum dilution of 1:160. Based on these data, we have selected 1:160 as the dilution that can discriminate between healthy individuals and patients with retinal degenerative disorders. It is interesting that this is similar to the dilution scheme used to discriminate antinuclear antibody reactivity in patients with systemic lupus erythematosus from positive antinuclear antibody results for healthy individuals (33).

In patients with antiretinal antibodies, the cellular location can be important to report and may provide clues to help distinguish the disease entity. At least five patterns of immunostaining are commonly observed in tissue: photoreceptor inner and outer segments, inner nuclear layer (INL), outer nuclear layer (ONL), ganglion cells, and RPE cells. In CAR patients, reactivity with the outer segment layer of photoreceptors is frequently seen and is associated with antirecoverin antibodies. In MAR patients, staining is frequently observed in bipolar cells of the INL. An example of patterns of immune reactivity in the retina is shown in Fig. 1. This serum was obtained from a patient with AIR and illustrates immune staining at multiple sites in the retina, including ganglion cell layer, INL, ONL, and RPE cell.

LABORATORY MONITORING OF T-CELL REACTIVITY

Procedure

1. Approximately 10 ml of heparinized or EDTA venous blood is needed for T-cell assays. Peripheral blood leukocytes (PBLs) are recovered following Ficoll-Hypaque separation techniques. PBLs are resuspended in RPMI medium supplemented with 5% (vol/vol) fetal bovine serum.
2. Determine the number of viable PBLs by trypan blue exclusion. Adjust the cell concentration to 2×10^6/ml.
3. Deliver 100 μl of the cell suspension into triplicate wells of a 96-well plate.
4. Add 100 μl of stimulant or control as follows: medium (negative control), phytohemagglutinin or concanavalin A (positive control), and retinal antigen (S antigen or IRBP).
5. Incubate the cells at 37°C for 72 h.
6. Assay the response of the stimulated lymphocytes by monitoring cell proliferation or production and release of cytokines. The cell proliferation assay can measure [^{3}H]thymidine incorporation into cellular DNA. Alternatively, one can use the standard EIA methodology to measure the release of gamma interferon or IL-2 in the supernatant fluid.

Interpretation

The appropriate incorporation of controls into these assay systems is essential for interpretation. PBLs from a healthy individual (known nonresponder) should be used each time the test is performed. In addition, in each test a medium control (negative/baseline) and a T-cell stimulant (phytohemagglutinin, concanavalin A, etc.) must be included. When determining cell proliferation by [^{3}H]thymidine assay, the samples are evaluated by stimulation index (SI). The SI is obtained by dividing the counts per minute for retinal antigen-treated cells by those for medium-treated

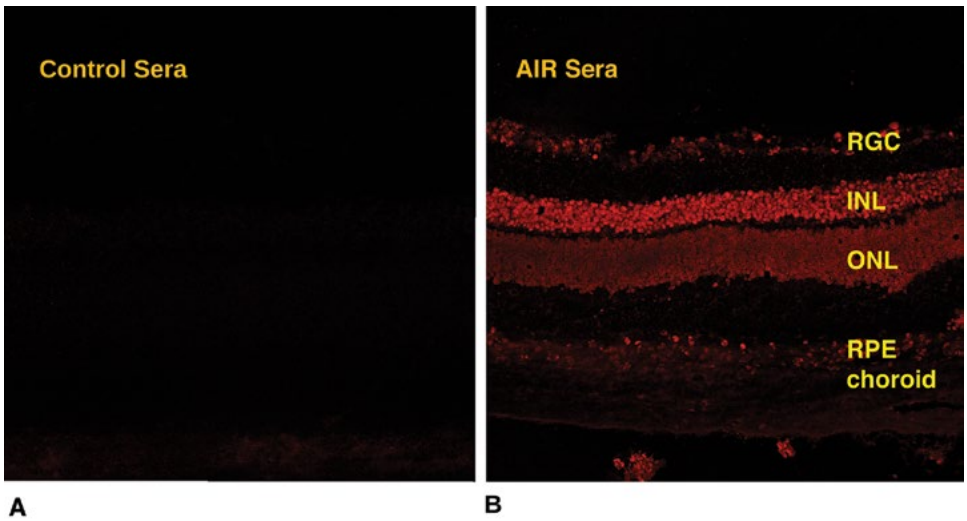

FIGURE 1 Immunofluorescence staining for antiretinal antibodies. Frozen sections of normal mouse retina were incubated with "normal" nonreactive human sera (A) or with sera from a patient with AIR (B). Both sera were tested at a 1:160 dilution. Note reactivity with several marked areas of the retina: retinal ganglia cell layer (RGC), INL, ONL, and RPE.

cells. An SI of > 2.0 is considered positive. An alternative, nonisotope method is the quantification of cell proliferation with Alamar Blue (BioSource, Rockville, MD) (34).

LABORATORY MONITORING OF OCULAR CYTOKINES (IL-6 AND IL-10)

Vitreous biopsies are frequently performed to distinguish between ocular inflammation associated with uveitis and ocular malignancy due to primary vitreoretinal lymphoma (PVRL; previously known as primary intraocular lymphoma) and/or primary central nervous system lymphoma (PCNSL). Cells within the vitreous are collected by cytospin and evaluated by a cytopathologist to identify lymphoma cells. The majority of PVRLs and PCNSLs are diffuse large B-cell lymphomas (24, 27, 35, 36). These tumor cells produce high levels of IL-10, a growth and differentiation factor for B cells. In contrast, the inflammatory cells in uveitis produce high levels of IL-6, a proinflammatory cytokine. We and other investigators have found elevation of vitreal IL-10 with a ratio of IL-10 to IL-6 of >1 in PVRL (37–40). Using this ratio analysis, the sensitivity and specificity of the assay are 85% (41). Evaluation of IL-10 and IL-6 concentrations in vitreous samples is performed using standard EIA methodology.

SUMMARY AND FUTURE DIRECTIONS

Analysis of immune-mediated vision loss is in its infancy. In patients with established retinal disease, the presence of autoantibodies can help define the nature of the disease and provide markers to classify the disease and to monitor therapy. Today, laboratory monitoring of antiretinal antibodies is frequently used to diagnose patients with AIR. Laboratory monitoring of T-cell reactivity to retinal antigens is used to assess uveitic patients undergoing immunomodulatory therapies. Finally, laboratory monitoring of ocular cytokines is frequently used to aid in the differential diagnosis of ocular inflammation and ocular malignancy.

Measurement of antiretinal immune reactivity is difficult to perform in the clinical laboratory. Analysis of immunocytochemical or immunofluorescent staining of retina tissue sections requires special training for interpretation. Nevertheless, with the characterization of specific retinal antigens, the future should include the development of standard EIA methodologies and Western blot assays to monitor patients with this important form of vision loss.

CANCER

section O

VOLUME EDITOR: ROBERT G. HAMILTON
SECTION EDITORS: DANIEL CHAN AND LORI J. SOKOLL

Introduction

ROBERT G. HAMILTON

107

The National Cancer Institute has defined cancer as a group of diseases in which abnormal cells divide without control and are able to invade other tissues. Cancers can be broadly categorized into five groups depending on their origin: carcinoma (skin), sarcoma (bone, cartilage, fact muscle, and blood vessels), leukemia (blood-forming tissue and bone marrow), lymphoma/myeloma (cells of the immune system), and central nervous system (brain and spinal cord).

The four chapters in the Cancer section of the 8th edition of this *Manual* discuss immunological methods that are used to detect and quantify proven and investigational markers of tumor presence and growth. Since many tumor markers are not elevated under all cancerous conditions and others are elevated under noncancer conditions, this is a challenging area of diagnostic immunology.

The first chapter in this section, by Godbey et al., discusses the design and performance of a number of well-established tumor marker assays that are used in the screening, diagnosis, and management of cancers. The authors provide a detailed description of the assay designs used, validation strategies, and assay interferences. Illustrative tumor markers and algorithms are overviewed, including those for ovarian cancer (CA125, HE4, ROMA, and OVA1), prostate cancer (prostate-specific antigen), and mesothelioma. In chapter 109, Jaffe and Raffeld discuss the classification of the immunologic and molecular tumor markers involved in the diagnosis of lymphomas and nonlymphoid neoplasms that originate from cells involved in antigen presentation and processing. Their chapter describes the current classification system based on the starting lymphoid or mononuclear phagocytic lineage. They then discuss the design and interpretation of molecular assays for clonality or cytogenetic characterization and immunological tests (flow cytometry or immunohistochemistry of paraffin or frozen sections) that are utilized in the diagnosis of lymphomas.

Chapter 110, by Whiteside, provides a comprehensive overview of cellular, humoral, and cytokine assays that use immunologic reagents and are used in the monitoring of immunologic therapies. These involve the quantification of soluble cellular products (immunoglobulin and cytokine levels), phenotypic markers using flow cytometry, and functional (cytotoxicity and chemotaxis) assays. In the final chapter of this section, Danila et al. extend the discussion in the prior chapter to demonstrate how immunological methods are used to identify and quantify circulating tumor cells.

Diagnostic oncology and immunology laboratories employ the methods discussed in these four chapters throughout the world to assist oncologists in making more-accurate diagnoses, assess neoplasm recurrence, and aid in the management of patients with cancer.

Immunoassay-Based Tumor Marker Measurement: Assays, Applications, and Algorithms

ELIZABETH A. GODBEY, LORI J. SOKOLL, AND ALEX J. RAI

108

Tumor markers are molecules derived from patient body fluids or tissues that are measured and can provide information useful for the management of cancer patients. Applications include detection of cancer, monitoring of disease progression, and evaluation of the effectiveness of therapeutic regimens, among others. Henry Bence-Jones discovered the first tumor marker in 1846—a protein seen in acidified urine of patients with multiple myeloma (1). Since that time, many more tumor markers have been described for a variety of other cancers. The Food and Drug Administration (FDA) has approved several of these markers (Table 1), and many more are being investigated and evaluated for clinical use. The goal of this chapter is to review how tumor marker assays are evaluated, describe the applications of tumor markers, provide details on the detection of tumor markers using immunoassays, and then list examples of clinically useful tumor markers that are used in the clinical laboratory today. Although the last few years have witnessed a plethora of developments in molecular testing of tumor markers, these will not be discussed here, as we will restrict our discussion to immunoassay-based detection methods.

EVALUATION OF TUMOR MARKER ASSAYS

Tumor marker assays, as with other laboratory assays, are evaluated based on their performance characteristics, including sensitivity, specificity, positive predictive value, and negative predictive value. These are important concepts that are applied across the laboratory sciences. A few important definitions follow.

Sensitivity: the fraction of all patients *with disease* that a test is able to correctly identify

Specificity: the fraction of all patients *without disease* that a test is able to correctly identify

Positive predictive value: the probability that a patient with a positive test result is *truly disease positive*

Negative predictive value: the probability that a patient with a negative test result is *truly disease negative*

Every lab must carefully select cutoff values for all tests offered. A cutoff value set too low will have many false-positive results but will miss very few truly positive patients. This type of error results in a high sensitivity but low specificity. The positive predictive value of such a test would be lowered, whereas the negative predictive value would be high. On the other hand, if the cutoff value is set too high, true-positive patients will be missed. Such a test would have a low sensitivity and high specificity. The positive predictive value would be higher than expected while the negative predictive value would be lower than expected.

As these two examples indicate, sensitivity and specificity are inversely related, as are positive predictive value and negative predictive value. The sensitivity and specificity for a test are a reflection of the cutoff value. Thus, the cutoff value for a given assay must be selected with the desired sensitivity and specificity in mind. The disease that a particular assay detects determines the balance between sensitivity and specificity: what are the effects of missing a disease-positive person versus incorrectly diagnosing a truly negative patient? Receiver operating characteristic curves graphically depict "[sensitivity]" versus "[1-specificity]." These curves present performance characteristics at multiple thresholds and are used in the selection of ideal cutoff values.

UTILIZATION OF TUMOR MARKERS

As mentioned earlier, tumor markers have a wide range of potential applications. These include cancer screening and detection, evaluation of the effectiveness of cancer therapies, detection of disease recurrence, therapy selection, and other potential uses. These applications are further discussed in this section.

Screening

One of the most desired goals for application of tumor markers is their utilization in screening for cancer. Unfortunately, the vast majority of tumor markers do not have the requisite sensitivity or specificity to be widely used for screening. Some tumor markers (with low sensitivity) are not elevated in all disease cases (this is very common because cancer, by its nature, is a heterogeneous disease), and thus will not detect all patients with a particular cancer. This false-negative result could be quite damaging to a patient, as it will generate false comfort and may allow a case to progress without treatment. Other markers (with low specificity) are elevated in many conditions and do not strictly indicate the presence of cancer, but can also indicate benign conditions. These positive test results may generate false cancer diagnoses, unnecessary follow-up testing, and emotional trauma to patients who are truly cancer negative.

doi:10.1128/9781555818722.ch108

TABLE 1 FDA-approved tumor markers

Cancer type	Tumor marker(s)[a]	Applications	Gene ontology classification
Breast	CA 15-3, CA 27.29	Detection of recurrence; monitoring of therapy and disease progression in metastatic disease	Membrane protein fragment
	HER2/neu	Prognosis; detection of recurrence	Membrane protein, extracellular domain
Prostate	PSA (total, free, and complexed)	Screening; diagnosis; detection of recurrence; as component of *phi*	Secreted protease
Ovarian	CA125	Monitoring of therapy; prognosis; detection of recurrence	Membrane protein fragment
	HE4	Detection of recurrence	Glycosylated protein
	OVA1	Preoperative mass evaluation	Multiple protein components in algorithm: β_2-microglobulin, transferrin, transthyretin, and apolipoprotein A1
	ROMA	Preoperative mass evaluation	Multiple components in algorithm: HE4, CA125, and menopausal status
Colorectal	CEA	Disease stratification—identification of aggressive disease; prognosis; detection of recurrence; monitoring of therapy and response to treatment	Membrane protein fragment
Pancreatic	CA 19-9	Monitoring of therapy and disease progression; detection of recurrence	Membrane protein fragment
Liver	AFP	Screening (in high-risk population, with ultrasound); detection of residual disease; monitoring of therapy; detection of recurrence	Secreted protein
Bladder	NMP-22 (urine)	Detection of residual disease	Nuclear matrix protein
Mesothelioma	SMRP	Monitoring of disease progression	Membrane protein fragment

[a]Abbreviations: CEA, carcinoembryonic antigen; AFP, α-fetoprotein; NMP, nuclear matrix protein.

At this time, prostate-specific antigen (PSA) is the most common tumor marker used for screening (in conjunction with digital rectal exam, or DRE). However, an elevated PSA can result not only from prostate cancer but also from a host of other benign conditions, such as prostatitis or benign prostatic hyperplasia. Although PSA is widely used for screening, this example illustrates that its specificity is lowered at the expense of a higher sensitivity so that the majority of disease-positive patients are identified. However, the disadvantage of this approach is that many men with an elevated PSA are subject to unnecessary workup and potentially unnecessary treatment, resulting in morbidity.

Diagnosis

Another highly desirable goal for tumor marker application is the ability to diagnose cancer. Again, the sensitivity and specificity of most tumor markers cannot accommodate this goal. The gold standard in the diagnosis of cancer is pathologic analysis, most of which is done using histology and immunohistochemistry of biopsy tissues. In the past, one approach to improve the sensitivity and specificity of serum biochemical tumor markers has been to utilize multiple markers instead of single analytes, or to incorporate multiple tumor markers into a more comprehensive algorithm involving other testing modalities. One exception to the general rule, where a tumor marker is diagnostic, is that of the presence of a monoclonal spike (M-spike) in the analysis of serum protein electrophoresis from patients with plasma cell dyscrasias. This test is virtually diagnostic, as the presence of the M-spike indicates an abundance of a particular immunoglobulin clone that is detectable in the γ region of fractionated serum. This situation can occur only in the setting of a plasma cell dyscrasia.

Monitoring of Treatment

Blood, urine, and fluid samples are easily procured from the human body and thus are an ideal way to measure tumor markers and monitor a patient's response to treatment in real time. The measurement of tumor markers should rise and fall with increasing and decreasing disease severity, respectively. Clinicians must remember the importance of establishing a patient's baseline and monitoring tumor marker levels by consistently using the same assay, preferably in the same laboratory. The use of different laboratories and/or different assays could result in falsely rising or falling tumor marker levels; such a result may not be due to a true rise or fall in the marker, but instead may be due to the use of different assays utilizing differing antibodies, instruments, methodologies, and/or reagents. Any one or more of these can result in variation of the detected protein species and can dramatically alter quantitation of the tumor marker of interest. As with other tumor marker applications, lack of sensitivity and/or specificity of a marker may cause misleading results. An example in which different assays measuring the same tumor marker can produce widely discrepant results is that of the CA 19-9 assay. College of American Pathologists proficiency testing summary results (2014; http://www.cap.org/web/home/lab/proficiency-testing) reveal a discrepancy (at certain levels) when the exact same sample is measured on the Architect (Abbott Diagnostics, Lake Forest, IL), ADVIA Centaur (Siemens Healthcare, Erlangen, Germany), AIA (Tosoh Bioscience, South San Francisco, CA), and Access (Beckman Coulter, Brea, CA) assay.

Detection of Disease Recurrence

Patients being evaluated for this purpose have already been diagnosed via pathology and have undergone treatment, so determining the origin of disease is not the major question. Analytical sensitivity, however, is exceedingly important, because rising levels of the tumor marker are interpreted as cancer recurrence. An example of a tumor marker assay that is useful for detecting disease recurrence is PSA, particularly the newer-generation, ultrasensitive PSA assay. Such a test can accurately measure very low levels of the analyte of interest, providing an early indication that the patient's disease has recurred or is no longer responding to treatment.

Therapy Selection

Specific tumor markers may be used to define appropriate therapy for disease. The most common example of this category is the detection of HER2/neu and estrogen receptor in breast cancers to predict disease response to targeted therapy or to cytotoxic agents. HER2 positivity suggests response to HER2-directed therapy, such as trastuzumab. Estrogen receptor positivity suggests response to tamoxifen. Although these tests utilize immunohistochemistry and are not immunoassays *per se*, they are commonly used to direct the treatment of breast cancer patients. Other examples of "predictive biomarkers," i.e., those used to predict response to therapy, include the *EGFR* L858R mutation, which indicates sensitivity to cetuximab in lung cancer patients; and the *BRAF* V600E mutation, which indicates sensitivity to the melanoma drug vemurafenib. These are also molecular assays and not protein-based analyses—DNA sequencing is straightforward and much easier than detection of the encoded protein for these particular applications.

IMMUNOASSAY DESIGN METHODS

Most tumor marker quantification assays are immunoassays based on variations of enzyme-linked immunosorbent assay (ELISA) methods. Antibodies can be used to isolate target molecules in many different clinical sample types, including whole blood, plasma, serum, urine, and other fluids. For an introduction to immunoassays and their utilization, see reference 1.

TYPES OF IMMUNOASSAYS

Immunoassays fall into two large categories, the first of which are limited-reagent assays. In this type of assay, a defined amount of antibody is present on a solid phase. Both labeled antigens and sample antigens compete for binding sites on the antibody. Thus, these are also known as competitive binding assays. Greater concentrations of sample analyte result in decreased binding of the labeled antigen and thus decreased signal. This is illustrated in Fig. 1.

The second category of immunoassays is termed excess-reagent assays. In contrast to the first category, this group of assays involves an excess of antibody that will bind the sample antigen. The "sandwich assay" (also known as a two-site immunometric assay) is one of the most common immunoassay designs, and it falls into the excess-reagent category. A capture antibody, bound to a solid phase, is

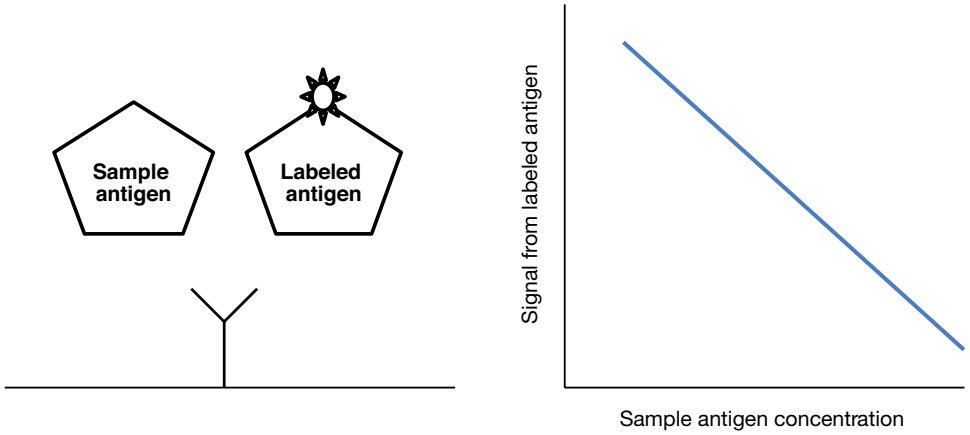

FIGURE 1 (Left) Schematic diagram of a competitive binding (labeled-antigen) immunoassay. In this assay, a limited amount of immobilized antibody binds both labeled and unlabeled forms of the tumor marker antigen of interest. (Right) The higher the concentration of unlabeled tumor marker antigen in the subject's serum, the lower the signal generated by bound labeled antigen.

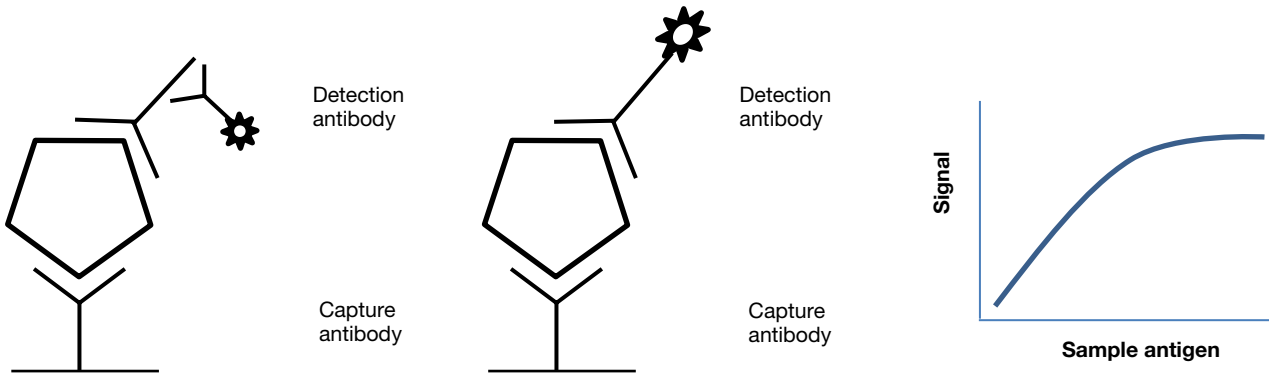

FIGURE 2 Schematic diagram of a noncompetitive binding two-site sandwich immunometric (labeled-antibody) assay. In this assay, molar excess immobilized antibody specific for the tumor marker binds unlabeled forms of the tumor marker antigen in the patient's serum. Bound antigen is then detected with a second antitumor marker antibody that binds to a different antigenic epitope. Either the second antibody can be detected by a third labeled antibody (left) or the second antibody can be directly labeled (middle). The higher the concentration of unlabeled tumor marker antigen in the subject's serum, the higher the signal generated by bound detection antibody (right).

present in excess. The sample antigen is added and allowed to bind to the capture antibody. A second antibody, termed a detection antibody, is added to the mixture. The capture antibody and the detection antibody each target a different epitope of the sample analyte and thus "sandwich" the analyte between them. In contrast to the first category of assays, these assays do not involve a competition among antigens and are thus known as noncompetitive assays. The detection antibody either is directly labeled or is bound by a third labeled antibody. The sample antigen present is measured indirectly by measuring the amount of labeled, bound antibody present. See Fig. 2 for an illustration of this concept.

Two different designs are available to complete a sandwich assay. The first involves a one-step incubation during which both the sample analyte and detection antibody are added simultaneously to the solid-phase capture antibody. While this design minimizes the number of steps and hence the time required to complete the test, the hook effect may interfere with accurate result reporting. See Fig. 3 for a schematic and explanation of the hook effect. The second possible design of a sandwich assay involves a two-step procedure. First, the sample analyte is added to the capture antibody. Then, in a second step, the detection antibody is added. Although this second method is more time-consuming, it may reduce interferences that are present in the single-step method, thus increasing specificity.

CLINICAL TEST DESIGN: IDENTIFICATION OF APPROPRIATE ANTIBODIES

The characteristics of an ideal antibody for use in immunoassays are perhaps intuitive. Antibodies should have low cross-reactivity and should be able to identify analytes at low concentrations. In other words, they should have high specificity and sensitivity. In cases in which an assay requires multiple antibodies (capture and detection), the antibodies should bind different epitopes, be complementary, and also not interfere to target the analyte of interest.

IMMUNOASSAY INTERFERENCES

Immunoassays are a popular laboratory methodology because of their sensitivity and specificity and can be used to quantify targets obtained from minimally invasive procedures such as urine collection or phlebotomy. Unfortunately, as with any laboratory method, interferences may falsely increase or decrease reported analyte values. Several

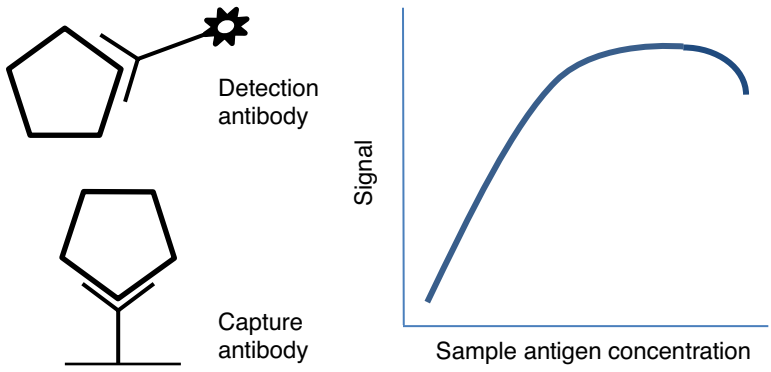

FIGURE 3 In immunometric assays, a hook effect can occur when the capture and detection antibodies bind to different molecules, without the formation of a "sandwich," as shown on the left panel. This results in an erroneous decrease in the measured signal at high concentrations of analyte; the effect on the dose-response curve is shown on the right panel.

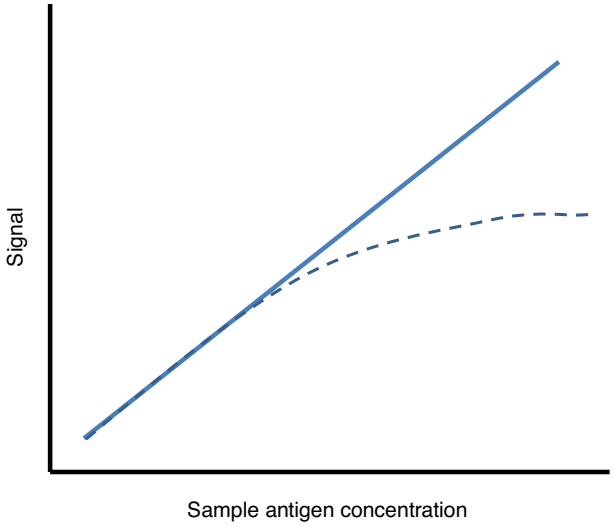

FIGURE 4 Schematic diagram showing result deviation from linearity that may be caused by interference.

interferences can be identified and corrected if proper quality assurance and quality control procedures are upheld. Examples are shown in Table 2. Interferences resulting in altered test values pose a significant problem to patient care. It is important to avoid interferences, identify them when they occur, and correct them (if possible). For example, blocking reagents can be used to avoid negative effects of heterophilic antibodies (see http://scantibodies.com). Endogenous autoantibodies may also interfere with accurate laboratory results. For example, patients with thyroid carcinoma are followed prospectively using serum thyroglobulin measurements. Following thyroidectomy, an increase in thyroglobulin is interpreted as disease recurrence. Endogenous autoantibodies directed against thyroglobulin may be a source of interference and result in a false-negative report (2). This source of interference has obvious negative implications for patient care and outcomes.

If an interference is suspected, serial dilutions should be performed and the samples retested. Samples with interferents often will not dilute linearly. If a linear response does not result, it can be presumed that an interference is affecting results of the test (see Fig. 4). The sample should be further examined, and an appropriate means should be taken to identify the interference. Use of heterophilic blocking preparations and assaying on an alternate method can help solidify the presence of an interference. When applicable, such as for β-human chorionic gonadotropin, testing for the analyte in urine can also be helpful.

EXAMPLES OF TUMOR MARKERS

This section discusses tumor markers and algorithms that incorporate tumor markers utilized in ovarian cancer, prostate cancer, and mesothelioma.

Ovarian Cancer: CA125, HE4, ROMA, and OVA1

CA125 (cancer antigen 125) is used by clinicians to monitor patients with ovarian cancer. The molecule is an antigen present on a large (>200-kDa) glycoprotein that resides on the plasma membrane. The protein antigen for CA125 is encoded by the *MUC16* gene, which is located on chromosome 19. Several different assays are currently available to measure CA125 levels. These make use of different antibodies, all of which target different epitopes of this molecule.

CA125 is FDA approved in its use to monitor the response to therapy in ovarian cancer patients. It is also useful to assess the progression of disease. As tumor burden decreases, so do levels of CA125 in the blood of cancer patients. In contrast, CA125 levels increase in patients with increasing tumor burden.

Although CA125 is often considered a nonspecific indicator of ovarian cancer, it is usually not elevated in nonserous ovarian cancers (other ovarian cancer subtypes include mucinous, endometrioid, and clear cell ovarian cancers). In contrast, the marker is increased in most (>80%) nonmucinous epithelial ovarian cancers. As previously discussed in relation to other markers, several common benign conditions can result in a falsely elevated CA125 level, including pregnancy, menstruation, and endometriosis. Therefore, as with any laboratory test result, CA125 levels must be evaluated in the context of the entire clinical presentation.

HE4 is a glycosylated protein encoded by the *WRDC2* gene localized to chromosome 20q12-13.1. It has been found to be moderately elevated in many types of cancer, but most significantly elevated in ovarian cancer. In a study leading to its FDA approval, HE4 and CA125 were found to have comparable sensitivity (80%) and specificity (95%) when differentiating between patients with and without ovarian cancer (3). The FDA approved HE4 testing in 2009 as a method to evaluate ovarian cancer recurrence. It is not applicable for use in diagnosing ovarian cancer.

Following the discovery of HE4 as a marker for ovarian cancer, investigators began to combine CA125, HE4, and other markers in an effort to improve the performance characteristics over the single markers. As a result of such studies, an algorithm abbreviated as ROMA (Risk of Ovarian Malignancy Algorithm) was developed. ROMA creates a score based on a patient's levels of HE4 and CA125, as well as their menopausal status. In premenopausal patients, a ROMA score of >1.31 favors malignancy. In postmenopausal patients, a ROMA score of >2.77 favors malignancy. Of note, rheumatoid factor serum levels of >250 IU/ml will alter ROMA scores. The ROMA algorithm was approved by the FDA in 2011 for use during preoperative evaluation of pelvic masses along with clinical and/or radiologic studies. In the studies leading to its FDA approval, ROMA was found to have a sensitivity of 88.7% and a specificity of 74.7% (3). For additional information on ROMA, see reference 4.

A separate panel of tumor markers, called OVA1, has also been developed. Four markers (β_2-microglobulin, transferrin, transthyretin, and apolipoprotein A1) were selected via proteomic studies. The OvaCalc software generates a score based on the serum levels of these four markers, as well as the CA125 serum level. In premenopausal patients, a score of ≥5.0 highly favors malignancy. In postmenopausal patients, a score of ≥4.4 highly favors malignancy. OVA1 earned FDA approval in 2009 as an aid in preoperative mass evaluation. The FDA specifies that OVA1 is not to be used for screening or for surgical evaluation. The sensitivity and specificity of OVA1, as reported in clinical trials, were 92.5% and 42.8%, respectively (3). For additional information on OVA1, see references 5 through 7.

Prostate Cancer: PSA and *phi*

PSA, also known as human kallikrein 3 (hK3), is a serine protease of ~28 kDa. As a secreted protein, PSA undergoes maturation during its progression through the secretory

TABLE 2 Assay interferences that cause falsely elevated or decreased tumor marker results

Interference type	Examples and characteristics	Effect on tumor marker results
Sample interferences	Lipemia, hemolysis, or icterous	Usually decrease
Cross-reactivity	More common with polyclonal antibodies	Usually decrease
Antireagent antibodies	Heterophilic antibodies	Either increase or decrease
Rheumatoid factor	Presence of autoantibodies	Usually decrease
Protein complexes	Prolactin, steroids, and troponin	Usually decrease
Hook effect	Presence of excess antigen	Decrease

pathway in prostate epithelial cells. It is initially expressed in a "prepro" form in these cells. This prepro protein contains a 17-amino-acid signal sequence that is later removed to form proPSA, with a 7-amino-acid leader sequence. This proPSA molecule is inactive but is targeted for cleavage by hK2, expressed in the prostate lumen ducts. The hK2 protease cleaves PSA and converts it into its mature, active form of 237 amino acids.

PSA plays an important role in monitoring prostate cancer disease course and response to treatment. Because PSA is produced in the prostate, it is an extremely useful marker for detecting recurrence of disease following definitive therapy. PSA also plays a role in the early detection of prostate cancer. However, although it is prostate gland specific, it is not prostate cancer specific and can be elevated in benign conditions such as benign prostatic hyperplasia and prostatitis. A number of approaches have been proposed to overcome this limitation of PSA and improve its specificity, including measurement of the circulating molecular forms of PSA. The majority of immunoreactive serum PSA is bound to the protease inhibitor α_1-antichymotrypsin, while the remaining 10 to 30% is unbound and is known as free PSA. Men with a higher percentage of free PSA as a function of total PSA have a lower probability of cancer, while men with a lower percentage of free PSA have a higher probability of cancer. The utility of free PSA has subsequently been improved with the knowledge that free PSA consists of cancer-specific (proPSA) and benign (BPSA) isoforms. An automated immunoassay for [−2]proPSA has been developed and approved by the FDA and incorporated into an algorithm with total and free PSA called *phi* (Prostate Health Index) to aid in distinguishing prostate cancer from benign conditions in men with a total PSA between 4 and 10 ng/ml and a negative DRE. In a multicenter trial of 892 men undergoing biopsy with a PSA of 2 to 10 ng/ml and a negative DRE, *phi* had greater specificity than total and percent free PSA for prostate cancer detection and thus potential for reduction in unnecessary biopsies (8). In this and other studies, *phi* also correlated with cancer aggressiveness.

Mesothelioma

Mesothelioma is clinically very difficult to diagnose. In fact, radiology reports often differ significantly from surgical and pathology findings, and 20 to 30% of thoracotomy procedures are aborted due to surgical finding of advanced disease beyond radiologic predictions (9).

There are currently no diagnostic tumor markers approved by the FDA for diagnosis of mesothelioma. A Humanitarian Use Device approval was granted by the FDA several years ago for soluble mesothelin-related peptides (SMRPs) as a method to monitor previously diagnosed mesothelioma, but not to diagnose the disease (although some clinicians utilize the serum ELISA to support a new diagnosis). A Humanitarian Use Device approval from the FDA applies to disorders that occur in <4,000 people in the United States annually. This type of approval requires fewer supportive data. It requires data to support that its benefits outweigh its risks, that its risks are not unreasonable, and that nothing comparable is already available to the patient population (10).

Mesothelin is an adhesion protein produced by mesothelium cells. It is encoded by the *MSLN* gene, the mRNA of which produces a preprotein that is cleaved into two fragments: megakaryocyte-potentiating factor and mesothelin. Mesothelin is a protein involved in cellular adhesion (11). SMRPs are measured in human serum with a quantitative ELISA assay. Many studies have been published on mesothelin, but at a level of 2.00 nmol/liter, studies show large ranges for its sensitivity and specificity, ranging from 19 to 68% and 88 to 100%, respectively (9, 11, 12).

NEW DEVELOPMENTS IN TUMOR MARKER DISCOVERY

An active area of research in the field of tumor markers relates to that of exosomes. Exosomes are extracellular vesicles consisting of lipid bilayers surrounding proteins and nucleic acids. All cells produce exosomes, and these vesicles are present in the circulation (13). Exosomes were first described ~30 years ago, but only in the last decade has there been increasing interest in using exosomes to identify new biomarkers for various diseases. Initially, researchers were able to identify significant increases in exosome markers only after diseases had entered advanced stages (14). Recently, however, exosomes have shown promise in application to early detection and diagnosis, using either protein or nucleic acid markers, and sometimes both. Jakobsen et al. were able to demonstrate that exosome markers have a specificity of 76% by studying expression of 30 different proteins using microarrays (15). Madhavan et al. were able to demonstrate 93% specificity in diagnosing pancreatic cancer using five proteins and four microRNAs (16).

Glypican-1 (GPC1) is a membrane-localized protein found in exosomes. It has been shown to be upregulated in cell lines and mouse models of pancreatic carcinoma. Melo et al. (13) focused their recent studies on GPC1-containing exosomes. They used GPC1-specific antibodies and flow cytometry to show that GPC1 vesicles are upregulated in patients with pancreatic carcinoma but not in patients with other pancreatic diseases. Melo et al. concluded that identification and quantification of GPC1 vesicles was a superior test to CA 19-9 for the early diagnosis of pancreatic cancer. The study was completed with small numbers of patients, and thus additional studies are needed. Such findings are promising and warrant future investigation of exosomes as carriers of early cancer biomarkers. These new methods

hold great potential for early detection of disease and can lead to improved patient outcomes.

THE FUTURE OF TUMOR MARKERS

Advancements in knowledge of the human genome and human proteome, improvements in high-throughput nucleic acid and protein analysis, as well as improved bioinformatics capabilities all contribute to a bright future for tumor marker use, improvement, and discovery. New tumor markers that could be used alone or as part of a larger panel of markers are being studied for a variety of applications related to the management of patients with cancer. Hopefully, these new tests will achieve FDA approval in the near future. Goals for future tumor markers include increased sensitivity and specificity to allow greater diagnosis capability with minimally invasive techniques. Tumor markers with increased sensitivity and specificity will allow for earlier detection and treatment of cancer, and therefore better patient care and improved outcomes for those afflicted with this insidious disease.

Malignancies of the Immune System: Use of Immunologic and Molecular Tumor Markers in Classification and Diagnostics

ELAINE S. JAFFE AND MARK RAFFELD

109

Malignancies of the immune system are primarily represented by the malignant lymphomas and a smaller number of nonlymphoid neoplasms that originate from cells involved in antigen presentation and processing. The diagnosis and classification of these tumors have benefited enormously from advances in cellular and molecular immunology, as well as from careful dissection of the molecular genetics of the cancers themselves. Our ability to correctly diagnose tumors of the immune system, which in many instances show little morphological variation, requires the careful application of both immunologic tumor markers as well as molecular (DNA- or RNA-based) tumor markers. Therefore, malignancies of the immune system are not only interesting models of normal immune cells but are also excellent examples of the variety of molecular and immunological approaches for assessing cancers.

The classification of the malignant lymphomas and nonlymphoid tumors of immune cells has undergone significant reappraisal over the past 50 years. Early classification systems of malignant lymphomas, such as the Rappaport classification and the Working Formulation, were based on architectural and cytological characteristics of the neoplastic elements. However, with increasing knowledge of the complexity of the immune system, a more functional approach was sought. The next generation of classification schemes (Kiel, and Lukes and Collins) attempted to integrate immunologic function with morphological parameters, with the premise that each of the lymphomas was an expansion of normal cellular counterparts (1, 2). These classification schemes still relied heavily upon the ability to correlate cytological characteristics of tumor cells with the cytological characteristics of normal counterparts. In practice, this proved to be an extremely difficult endeavor, even for experienced hematopathologists, and it became apparent that a more objective and reproducible classification scheme was needed. The decades from the 1970s through the 1990s saw an explosion of basic information in both cellular and molecular immunology and in cancer genetics. The application of monoclonal antibodies, developed in the course of studying the normal immune system, provided one powerful approach for establishing objective diagnostic criteria, while the development of molecular testing based on rapid advances in the molecular genetic understanding of these tumors provided a second approach. By incorporating these technologies into the diagnostic armamentarium, it became possible to develop a more objective classification scheme that would take into account the molecular and immunologic characterization of the tumors.

In 1994, the International Lymphoma Study Group, a consortium of hematopathologists from the United States and Europe, met and concluded that a classification system should consist of a list of agreed-upon disease entities defined by multiple parameters, rather than being driven by a single overriding principle, such as clinical outcome (Working Formulation) or cellular differentiation (Kiel). For the first time, immunophenotype and molecular genotype were recognized as critical elements in establishing a biologically meaningful classification scheme (3). This breakthrough meeting led to the development of the first modern lymphoma classification system based on biological principles, the REAL classification, and its successor, the current World Health Organization (WHO) classification (Table 1) (4, 5).

A major premise underlying the current classification systems was that lineage must be the starting point for a lymphoma classification. The application of modern immunologic techniques and concepts has permitted the development of a conceptual framework that may be used to decipher the morphological diversity of these neoplasms and has shown the relationship of lymphoid and mononuclear phagocytic neoplasms to the normal immune and hematopoietic systems. The development of monoclonal antibodies reactive with lymphoid, monocytic, and myeloid subsets can be used in the classification, primary diagnosis, and staging of hematopoietic malignancies and as adjunctive tools for immunotherapy in both *in vivo* and *in vitro* settings. In addition, many disease entities, particularly among the B-cell lymphomas, have a highly specific immune profile that can aid greatly in differential diagnosis. Other markers associated with lineage and cellular differentiation help to relate the various lymphoproliferative disorders to distinct stages in the development of the normal immune cells, and they are of particular interest in evaluating lymphoblastic neoplasms and in differentiating germinal-center (GC) from post-GC B-cell neoplasms. Monoclonal antibodies to oncogene or tumor suppressor gene products such as cyclin D1, BCL-2, and p53 have also proved useful in diagnosis and prognostication, and in understanding the pathogenetic mechanisms of lymphomagenesis.

The WHO classification system also recognizes the importance of cytogenetic and correlative molecular genetic

TABLE 1 WHO classification of lymphoid neoplasms (2008)

- Precursor lymphoid neoplasms
  - B-cell lymphoblastic leukemia/lymphoma
  - T-cell lymphoblastic leukemia/lymphoma
  - NK-cell lymphoblastic leukemia/lymphoma
- Mature B-cell neoplasms
  - CLL/SLL
    - Monoclonal B lymphocytosis
  - B-cell prolymphocytic leukemia
  - SMZL
  - HCL
  - LPL
  - α heavy-chain disease
  - γ heavy-chain disease
  - μ heavy-chain disease
  - Plasma cell myeloma
    - Heavy- and light-chain deposition diseases
  - Solitary plasmacytoma of bone
  - Extraosseous plasmacytoma
  - Extranodal MZL of MALT type
  - Nodal MZL
    - Pediatric MZL
  - FL
    - Pediatric FL
    - FL *in situ*
    - Primary intestinal FL
  - Primary cutaneous FL
  - MCL
    - MCL *in situ*
  - DLBCL, not otherwise specified
    - T-cell/histiocyte-rich large B-cell lymphoma
    - Primary DLBCL of the central nervous system
    - Primary cutaneous DLBCL, leg type
    - EBV-positive DLBCL of the elderly (provisional)
  - Primary mediastinal (thymic) large B-cell lymphoma
  - Intravascular large B-cell lymphoma
  - Lymphomatoid granulomatosis
  - DLBCL associated with chronic inflammation
  - ALK-positive DLBCL
  - Plasmablastic lymphoma
  - Primary effusion lymphoma
  - Large B-cell lymphoma arising in HHV-8-associated multicentric Castleman's disease
  - Burkitt's lymphoma
  - B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt's lymphoma
  - B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and CHL
- Mature T-cell and NK-cell neoplasms
  - T-cell prolymphocytic leukemia
  - T-cell large granular lymphocytic leukemia
  - Indolent large granular NK-cell lymphoproliferative disorder
  - Aggressive NK-cell leukemia
  - Fulminant EBV^+ T-cell lymphoproliferative disorder of childhood
  - ATL
  - Extranodal NK/T-cell lymphoma
  - Enteropathy-associated T-cell lymphoma
  - Hepatosplenic T-cell lymphoma
  - Subcutaneous panniculitis-like T-cell lymphoma
  - Mycosis fungoides
  - Sézary syndrome
  - CD30-positive primary cutaneous T-cell lymphoproliferative disease
    - Lymphomatoid papulosis
    - Primary cutaneous ALCL
  - Primary cutaneous γδ T-cell lymphoma
  - Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma (provisional)
  - Primary cutaneous small/medium CD4-positive T-cell lymphoma (provisional)
  - AILT
  - PTL, unspecified
  - ALCL, ALK positive
  - ALCL, ALK negative

abnormalities in contributing to the pathogenesis of particular entities. Many neoplasms possess recurrent cytogenetic abnormalities involving oncogenes or tumor suppressor genes that play key roles in the pathogenesis of particular tumors. In recent years, with advances in sequencing and improved genetic characterization, the number of lymphoid malignancies with specific genetic alterations has expanded significantly. Some of the earliest translocations identified included the t(8;14) translocation and its variants that involve the *MYC* gene in Burkitt's lymphoma (6), the t(11;14) translocation that involves the *CCND1* (*cyclin D1*) gene in mantle cell lymphoma (MCL) (7), and the t(14;18) translocation that involves the *BCL2* gene in the vast majority of follicular lymphomas (FLs) (8). These associations not only validated the morphological component of the classification scheme but also enabled the further development and refinement of categories of lymphomas that were difficult to separate by morphology alone. The continued molecular dissection of lymphomas has further revealed characteristic cytogenetic and molecular genetic abnormalities in mucosa-associated lymphoid tissue (MALT) lymphomas, in anaplastic large-cell lymphomas (ALCLs), and in plasma cell neoplasms, as well as in many other lymphoma subtypes. The development of molecular technologies, particularly fluorescent *in situ* hybridization (FISH) and PCR, has brought molecular diagnostics into the routine clinical laboratory and has enabled molecular genotyping to increasingly become a part of the classification criteria.

MOLECULAR AND IMMUNOLOGIC TESTS UTILIZED IN LYMPHOMA DIAGNOSTICS

Immunologic Approaches

Lymphoid and histiocytic neoplasms can be studied in fluid phase by flow cytometry or in paraffin or frozen sections by immunohistochemistry. Flow cytometry is particularly useful in assessing cell surface markers and has the advantage of being able to provide semiquantitative information regarding antigen density. Furthermore, advances in fluorescent dye chemistry and in laser technology have made the simultaneous detection of multiple antigens routine (9). The disadvantages of flow cytometry are that *in situ* tissue organization is lost and the detection of cytoplasmic and nuclear antigens is technically challenging, requiring permeabilization of the cells during specimen processing. In addition, cell suspensions may not be representative of the pathological process due to fibrosis or abundant stromal elements, and specimens must be processed at the time of procurement, necessitating careful planning when obtaining the sample.

In contrast to flow cytometry, immunohistochemical techniques allow one to visualize the immunologic phenotype in the context of the *in situ* organization and cellular morphology. This approach is useful when one considers that lymphomas are rarely pure populations of neoplastic cells, and that a variety of normal cell types are invariably present. Moreover, in some situations, such as in Hodgkin's disease and T-cell-rich large B-cell lymphomas, the neoplastic cells represent a minority of the cells present. Such minor populations of cells may be difficult to study by flow cytometry but can be easily identified by the combination of immunohistochemistry and morphology.

In recent years, an increasing number of both murine and rabbit monoclonal antibodies have become available for use in paraffin sections, eliminating the need to perform immunohistochemistry on frozen tissue sections (Table 2). The development of these reagents has not occurred by chance, but rather by targeting the antigenic conformations present in fixed tissues (10). Rabbit monoclonal antibodies generally have a much higher affinity than comparable mouse monoclonal antibodies and have shown great promise for diagnostic applications (11, 12).

Paraffin section immunohistochemistry has also been greatly facilitated by the development of heat-induced antigen retrieval techniques (13, 14). Previous antigen retrieval techniques involving chemicals or proteolytic enzymes had relatively limited success in diagnostic immunohistochemistry, beyond their ability to improve intermediate filament staining. Heat-induced antigen retrieval procedures proved to have broad applicability, allowing for the detection of numerous antigens rendered nonreactive during the fixation and paraffin embedding process. The advances in antigen retrieval techniques eliminated the need for the specialized processing at the time of surgical removal and made

TABLE 2 Recommended immunohistochemical panels for lymphoma diagnosis

Diagnostic panel	Antibodies[a]
Reactive hyperplasia	CD20, IgD, CD3, CD5, BCL-2, κ, λ, *CD21*, *CD123*, *CD138*
Small B-cell lymphomas	CD20, CD79a, IgD, CD3, CD5, CD10, CD23, CD21, MIB-1, cyclin D1, BCL-2, BCL-6, MUM-1/IRF4
DLBCL/Burkitt's lymphoma Aggressive B-cell neoplasms	CD20, CD3, CD79a, BCL-2, BCL-6, CD10, MUM-1/IRF4, p53, MIB-1, MYC, EBER
Plasma cell, plasmablastic neoplasms	CD20, CD79a, CD3, κ, λ, and heavy chains, CD56, CD138, MUM-1/IRF-4, ALK, EMA, EBER
CHL	CD20, CD3, CD30, CD15, PAX5, *Oct-2*, *Bob.1*, EBER, LMP-1
NLPHL	CD20, CD3, IgD, OCT-2, CD21, CD57, PD-1
PTL (nodal)	CD20, CD3, CD5, CD4, CD8, *CD2*, *CD7*, CD10, CD21, CD25, CD30, TIA-1, PD-1, ALK, EBER

[a]Antibodies shown in italics can be added as needed in selected cases. Abbreviations: EBER, EBV-encoded RNA; PAX, paired box; LMP, latent membrane protein; OCT, octamer-binding transcription factor; MPO, myeloperoxidase.

it possible for immunophenotyping to be performed on all diagnostic biopsy specimens. There are excellent reviews of both flow cytometry and immunohistochemistry elsewhere in this *Manual* (see chapters 16, 20, and 40).

Molecular Approaches

The molecular tests that are commonly applicable to tumors of immune cells fall into two categories: assays for clonality and molecular cytogenetic assays. Clonality assays are rarely used in nonlymphoid malignancies; however, there are occasions in which they may be useful. The clinically applicable molecular cytogenetic assays include *in situ* hybridization (ISH) studies and PCR-based assays, which are utilized primarily for translocation detection. The principles behind molecular cytogenetic assays are applicable to both lymphoid and nonlymphoid tumors.

Clonality Assays

By far the most common molecular test used in the assessment of hematologic malignancies is clonality testing. Many reactive conditions simulate lymphomas, and it is critical to distinguish between a self-limited benign lymphoid proliferation caused by an immune response to a drug or virus and an uncontrolled neoplastic proliferation. The basis of clonality testing in lymphoid proliferations lies within the unique molecular biology of antigen receptor genes. When progenitor hematopoietic stem cells become committed to either the B- or T-cell lineage, they undergo a structural change in their DNA encoding their respective antigen receptor genes. This structural change is maintained throughout the life of that cell and is inherited in all daughter cells. Likewise, if a neoplastic event occurs in a lymphoid cell possessing a rearranged antigen receptor gene, all daughter cells will inherit the identical rearrangement, creating a tumor-specific molecular marker. Structural changes of antigen receptor genes have traditionally been evaluated using restriction fragment analysis of genomic DNA followed by Southern blotting (15). In this procedure, DNA is digested by restriction enzymes that cut at known sites in the germ line. The restricted DNA is size fractionated, generally by agarose gel electrophoresis. The fractionated DNA is transferred by Southern blotting to a solid nylon or nitrocellulose matrix, and the position (which is proportional to the size) of the fragment containing the antigen receptor gene of interest is visualized by hybridization with a labeled probe that is directed to the antigen receptor gene. Germ line DNA (i.e., DNA that has not undergone rearrangement) generates a single restriction fragment that reflects the distance between the restriction enzyme sites that encompass the probe sequence. However, DNA that has undergone rearrangement will show an altered restriction fragment, different in size from the germ line fragment, reflecting the structural change that has occurred as a result of the rearrangement. Although this procedure is capable of accurately assessing nearly 100% of all clonal B- or T-cell neoplasms, it is time-consuming and requires a relatively large amount of DNA (>20 μg) and is therefore not as well suited as PCR techniques for clinical laboratory testing.

Unlike restriction fragment analysis, the basis of PCR assays for clonality lies within differences in the sizes of the *junctional* regions that are formed during V-J or V-D-J segment recombinations. The biological basis of these size differences lies primarily with the activity of terminal deoxynucleotidyltransferase (TdT) and exonuclease activities that add and delete nucleotides in a nontemplated manner, generating junctional regions of various lengths. Physiologically this process plays a major role in creating antibody diversity, in combination with somatic mutation of the antigen receptor genes. The junctional "repertoire" can be analyzed using consensus primers that span the junctions (V and J region primers). In a reactive polyclonal population of B or T cells, the junctional sequences generated by PCR will vary from one cell to the next, generating many different-sized PCR fragments visualized as a ladder of bands on an ethidium-stained acrylamide gel. In lymphomas, all daughter tumor cells bear the identical rearranged antigen receptor gene containing identical junctional sequences. In this case, PCR will generate a single-sized product visible on the ethidium-stained gel. This product is specific for and a signature of the tumor from which it was generated.

PCR can be performed with 100 ng or less of DNA, is rapid, and is extremely easy to perform. For these reasons, PCR has become the assay of choice in the clinical laboratory to test for clonality. Detection of the resulting PCR fragments is most frequently assessed by gel or capillary electrophoresis. The disadvantage of PCR is that it typically has a much higher false-negativity rate than the genomic Southern blot approach, approximating 20% or more for B-cell clonality and 10% or more for T-cell clonality, depending on the specific method chosen and the primers used. Recently, a large consortium of European laboratories collaborated in a large study designated as BIOMED-II (16). The consortium developed and tested a multiplex system comprising multiple primer pairs designed to lower the false-negativity rate of the commonly used assays for B- and T-cell clonality. These sets of primers were shown to perform extremely well, approaching detection rates of 100% for both B- and T-cell rearrangements. However, in order to reach this high level of diagnostic sensitivity, >31 primers multiplexed in five separate reactions were required for the assessment of immunoglobulin heavy-chain (IGH) gene rearrangements, and 44 primers multiplexed in five separate reactions were required for the assessment of T-cell receptor (TCR) gene rearrangements. Furthermore, these primer sets were validated primarily for freshly isolated DNA and did not perform as well in paraffin tissue, in which DNA may be partially degraded. Nonetheless, this comprehensive study demonstrates that it is possible to attain high levels of diagnostic sensitivity using PCR assays for clonality. The BIOMED-II primers are available through InVivoScribe Technologies (Carlsbad, CA; www.invivoscribe.com).

Clonality testing is rarely used in nonlymphoid malignancies, but there are occasions in which it can be useful. Simple PCR-based approaches for the assessment of clonality in nonlymphoid malignancies are the HUMARA and related assays that exploit X-linked chromosomal inactivation (17). Since the cells comprising a tumor are descendants of a single progenitor cell, the entire population of tumor cells will carry the identical inactivated maternal or paternal X chromosome that was present in the ancestral progenitor. This phenomenon has been known for many years, and the immunologic assessment of the A and B isoforms of the X-linked glucose-6-phosphate dehydrogenase enzyme, with all of its limitations, was the common method for assessing clonality until the development of molecular technologies (18). A molecular genetic feature of X-linked chromosomal inactivation is promoter hypermethylation of genes located on the inactivated chromosome (19). In a monoclonal population of cells, either 100% of the paternal or 100% of the maternal alleles will be hypermethylated, while in a polyclonal population of cells, 50% of the paternal and 50% of the maternal alleles will be hypermethylated, as a result of random X inactivation in the population. The assessment of hypermethylation is performed through the use of

methylation-sensitive restriction enzymes, in combination with PCR. Prior to PCR, the DNA of interest is cut using a methylation-sensitive restriction endonuclease. Subsequently, PCR is performed using primers that encompass the promoter region. The methylated alleles remain uncut and generate a PCR product, while the nonmethylated alleles are cut by the restriction enzyme, which prevents the generation of a PCR product. In order to assess whether both maternal and paternal alleles have been amplified, the promoter chosen must also contain a highly polymorphic site that allows one to distinguish between the two alleles. The complete loss of one allele (maternal or paternal) indicates the presence of a clonal population. Because the X-linked human androgen receptor (HUMARA) gene contains a highly polymorphic sequence in proximity to its promoter, this locus has become the target of choice for X-linked clonality assays (20). The HUMARA assay can be performed on DNA extracted from formalin-fixed, paraffin-embedded tissue, is relatively simple, and is adaptable to the clinical molecular diagnostics laboratory. As for all assays exploiting X inactivation, the primary disadvantage of the HUMARA assay is that it can only be performed in female patients.

Molecular Cytogenetics

ISH

ISH is a powerful technology that allows for *in situ* visualization of specific chromosomal translocations, chromosome copy number, gene copy number, and mRNA expression. Translocations are assessed through the use of DNA probes that recognize regions of chromosomes involved in translocations. These probes fall into two general categories: so-called break-apart probes, which are generally used singly; and fusion probes, which are used in pairs. Break-apart probes are designed to span a breakpoint region of interest. Therefore, if the targeted chromosome is split by a translocation, three signals will appear, one from the normal nontranslocated chromosome and one from each of the two derivative translocated chromosomes. Break-apart probes can provide information that the targeted region is involved in a translocation; they do not provide information identifying the partner chromosome. Break-apart probes are particularly useful when one does not know one translocation partner, or when multiple partners exist, such as for translocations involving the *BCL6* locus on 3q27 (21). Fusion probes, on the other hand, are designed to recognize both chromosomal regions involved in the translocations, so that one can precisely identify both translocation partners (22). In the case of fusion probes, each member of the differentially labeled probe pair hybridizes with its targeted chromosomal region, generating four signals. In cells containing the targeted translocation, two of the signals from each of the chromosomes involved in the translocation fuse into one, and only three signals are seen. In practice, fusion probes are generally labeled in different colors (green and red), so that the fusion signal generally is a mix of the two different probe colors (yellow). Probes are generally labeled with fluorescent dyes (FISH), but chromogens (CISH) have been used successfully as well for some applications. FISH can be performed on metaphase chromosome spreads, but its greatest success in diagnostic pathology has been its adaptation to interphase nuclei in either frozen or fixed tissues (23). FISH has the highest diagnostic sensitivity of any available test for identifying specific chromosomal translocations and numerical chromosome alterations. However, FISH is labor-intensive and is not available in all diagnostic laboratories due to the high cost of the associated equipment.

FISH overcomes some of the limitations of PCR in the assessment of translocations, since large chromosomal regions can be analyzed, greatly reducing the problem of false negatives due to the focal nature of PCR. As previously mentioned, the disadvantages of FISH are that it is technically challenging when applied to tissue sections, is time-consuming, and requires relatively expensive equipment and an experienced practitioner, preferably a cytogeneticist. Nonetheless, when available, FISH is the method of choice to identify most of the lymphoma-specific translocations. Probes for most of the clinically important translocations are available commercially through Vysis, Inc. (Downers Grove, IL).

PCR

PCR of chromosomal breakpoint junctions is also a popular method for identifying translocations because of its rapidity and simplicity. The translocations that occur in lymphoid neoplasms are of two general types, those that result in the deregulation of normal cellular genes without disrupting the coding sequence (type 1) and those that result in the fusion of two normal cellular genes to create a novel chimeric gene product (type 2). The majority of type 1 translocations involve one of the antigen receptor gene loci. These include translocations such as t(8;14) involving the *MYC* gene on chromosome 8 and the *IGH* locus on chromosome 14, t(11;14) involving the *CCND1* locus on chromosome 11 and the *IGH* locus, and t(14;18) involving the *BCL2* gene and the *IGH* locus. In all of these cases, the translocations deregulate the target gene by disrupting its regulatory elements or by placing it under the control of elements of the involved antigen receptor gene. A minority of the type 1 translocations do not involve an antigen receptor gene, such as some of the variant translocations involving the *BCL6* gene on chromosome 3q27. Nonetheless, the result is similar in that the target gene's coding sequence is left intact, but its regulatory elements are altered through the substitution of control elements from the various genes on the partnering chromosomes. Whereas the type 1 translocations leave the coding sequences of the potential oncogenes intact, type 2 translocations occur between two unrelated genes and result in the creation of a novel mRNA and protein encoded by portions of the two fused genes. Typically both genes are transcription factors and the resulting chimeric proteins display highly aberrant transcriptional activities. Representative of the type 2 translocation is the pre-B-cell acute lymphocytic leukemia (ALL) t(12;21) translocation, which fuses the *TEL* gene on chromosome 12 to the *AML1* gene on chromosome 21.

The molecular detection strategies for the two types of translocations differ in that for the type 1 translocations the targeted template is generally the junctional sequence *within the DNA*, while in the type 2 translocations the primers generally target the junctional sequence *within the message (cDNA)* encoding the novel protein. For both types of translocations, a PCR product will be generated only from the tumor cells bearing the junctional DNA or cDNA sequences created by the translocation, which therefore serves as a tumor-specific marker. Detection is generally carried out either by gel or capillary electrophoresis. Alternatively, PCR and detection may be combined in real-time PCR instruments. These instruments monitor the accumulation of product during the PCR reaction using fluorescent detection technologies (24).

The use of PCR to detect type 1 translocations can be highly effective when the breakpoints on the partnering chromosomes are clustered, as occurs with the t(14;18)

translocations in follicle center lymphomas. However, if the breakpoints are instead spread over a larger area, as they are with the t(11;14) translocation in MCLs, this technique will miss many translocations. While DNA-based PCR assays have a very high analytic sensitivity, capable of identifying 1 in 10^6 abnormal cells, these tests have a much lower diagnostic sensitivity than FISH, since each PCR primer set can target only a few hundred base-pair segments of DNA, while an appropriate FISH probe can identify translocations involving all potential breakpoint regions.

Type 2 translocations occur most frequently in pre-B-cell and B-cell lymphoblastic lymphomas/leukemias, but they also occur in some of the mature B- and T-cell lymphomas, including ALCL and MALT lymphoma. These are extremely interesting events from the biological point of view, as they create chimeric proteins that have novel oncogenic activities. For diagnostic purposes, the chimeric RNA serves as the tumor-specific PCR product. Reverse transcription (RT)-PCR assays targeting the chimeric RNA sequences generally have a much higher diagnostic sensitivity than those that target the corresponding chromosomal breakpoint regions because in most cases, gene splicing events create junctions precisely between the exons of the fused genes, even when the breakpoint sequences themselves may be spread diffusely throughout intronic sequences. For example, 75% of ALCLs possess a t(2;5) translocation joining the nucleophosmin gene (*NPM*) on chromosome 5 to the ALCL tyrosine kinase gene (*ALK*) on chromosome 2. The breakpoints are spread throughout intron 4 of the *NPM* gene and within a single intron of the *ALK* gene, which presents difficulties in the design of a simple DNA-based PCR test. However, splicing events in the novel transcript bring exon 4 of *NPM* into contiguity with a 5′ coding exon of *ALK* in all cases. This allows the design of a simple RT-PCR assay, using only a single primer pair, that can reliably identify all of the t(2;5) translocations.

Other Molecular Tests Used in Lymphoma Diagnostics

PCR is also used to identify the presence of viruses that are associated with different lymphoma subtypes. Section J in this *Manual* discusses viral detection assays in more detail. PCR can be especially helpful in detecting viral DNA and in the diagnosis of human T-cell leukemia virus type 1 (HTLV-1)-associated lymphomas; human herpesvirus 8 (HHV-8)-associated pleural effusion lymphomas; and lymphoproliferations associated with Epstein-Barr virus (EBV), such as EBV posttransplant lymphoproliferative disorders, nasal NK/T-cell lymphoma, angioimmunoblastic T-cell lymphoma (AILT), and Burkitt's lymphoma. However, the identification of a viral product by PCR should be correlated with *in situ* or morphological studies since the presence of these viruses is not tumor specific. For example, HHV-8 may also be found in Kaposi's sarcoma and Castleman's disease and EBV may be identified in nonneoplastic immunoproliferative conditions, particularly when immunosuppression is present. Furthermore, it is important to recognize that because of the extremely high sensitivity of PCR-based tests, nonpathological levels of some viruses that are present at low levels, such as EBV, may be detected.

FISH and the related technique CISH are also well suited for identification of mRNA *in situ* and for identifying viruses such as EBV (25). The advantage of CISH is that it can be assessed using an ordinary light microscope. However, it is limited by the number of chromogens available and by the resolution of the technology. CISH can be used as a secondary technique to assess light-chain exclusion, when exclusion cannot be definitively assessed at the protein level. CISH is commonly used in hematopathology laboratories for the identification of EBV infection and has become an important ancillary test for diagnosing cases of NK/T-cell lymphoma, Burkitt's lymphoma, AILT, and other EBV-associated lymphoproliferative disorders, including posttransplant lymphoproliferative disorders.

cDNA microarray studies have recently been utilized to further the classification of lymphomas. Clinically significant subcategories within morphologically homogeneous lymphoma entities, such as diffuse large B-cell lymphoma (DLBCL), chronic lymphocytic leukemia (CLL), and peripheral T-cell lymphoma, have been identified through the use of this technology (26–28). Recently, these techniques have been adapted to allow analysis of gene expression profiling in routinely processed formalin-fixed, paraffin-embedded sections, making application to the routine clinical laboratory possible in the near future (29). cDNA microarray technology is discussed in detail in chapter 2 of this volume.

INTERPRETATION AND APPLICATION OF IMMUNOLOGIC AND MOLECULAR MARKERS IN THE DIAGNOSIS OF TUMORS OF THE IMMUNE SYSTEM

Precursor Lymphoid Neoplasms

Lymphoblastic malignancies (LBL) are neoplasms of precursor T and B lymphocytes. They may present clinically as either lymphoblastic lymphoma or ALL, and morphologically the T- and B-lineage varieties of LBL are indistinguishable. Virtually 100% of these neoplasms are positive for TdT, which can be detected by immunocytochemical techniques using rabbit antisera or murine monoclonal antibodies directed against TdT.

Precursor T-cell LBL most often present as lymphoma, usually with a mediastinal mass, with or without bone marrow involvement and a leukemic phase. They usually have an immature T-cell phenotype that correlates with different stages of intrathymic maturation (Fig. 1). The earliest T-cell-associated antigen with some lineage specificity is CD7. However, it is also expressed in rare cases of acute myeloid leukemia, where it may represent evidence of lineage infidelity, often seen in primitive hematopoietic malignancies. CD3, linked to the T-cell antigen receptor, is expressed in the cytoplasm prior to its presence on the surface and thus may not be revealed by immunofluorescence techniques on living cells (30). In this situation a T-cell LBL may be CD3 positive in tissue sections but negative by routine flow cytometry. However, techniques that permeabilize the cell membrane are available to detect cytoplasmic antigens by flow cytometry. It should be noted that the normal thymocytes encountered in a lymphocyte-rich thymoma would be phenotypically similar to the cells of a T-cell LBL. Immunohistochemical analysis will be necessary to detect the thymic epithelial cells numerous in the former condition.

T-cell lymphoblastic lymphomas are clonal neoplasms, and most have *TCRβ* or *TCRγ* rearrangements (31). About 20% of T-lymphoblastic lymphomas also have *IGH* rearrangements, a phenomenon known as lineage infidelity (32). Lineage infidelity is common in early-lineage T- and B-cell neoplasms but is rare in mature B- and T-cell neoplasms. Therefore, when assessing clonality in lymphoblastic lymphomas, antigen receptor rearrangements cannot be used to assign B- or T-cell lineage. Up to 50% of T-lymphoblastic lymphomas/leukemias have recurrent translocations most

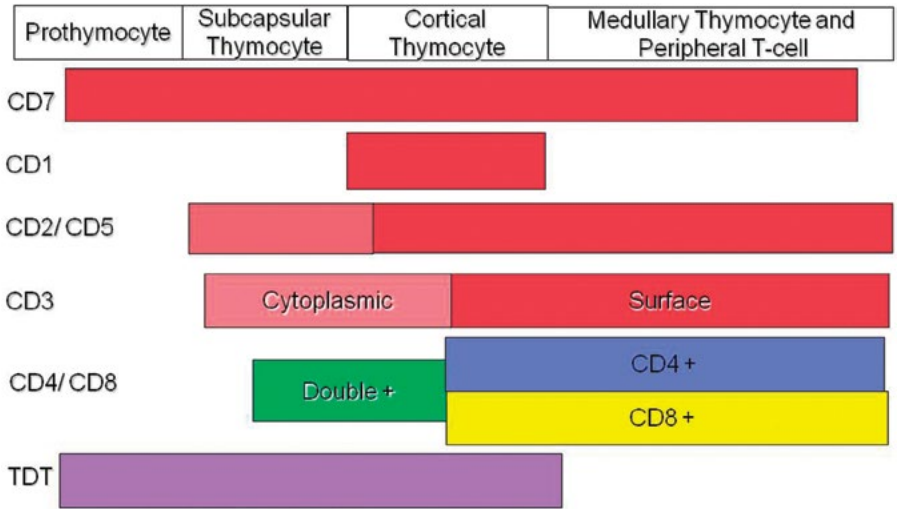

FIGURE 1 Schematic diagram showing stages of T-cell differentiation. Neoplasms can be related to precursor and mature or peripheral T lymphocytes. Antigenic phenotype correlates with maturational stage. Note that CD7 is the earliest T-associated antigen.

frequently involving one of the TCR gene loci (Table 3). These can be detected by FISH and in many cases by PCR.

Precursor B-cell LBL present as leukemia more often than as lymphoma. In cases presenting as lymphoma, common clinical manifestations include skin involvement (often of the scalp or face), lytic bone lesions, or lymphadenopathy. The risk of involvement of the central nervous system is less than for pre-T-cell LBL. Although these precursor B-cell tumors do not normally express immunoglobulin, other markers of B-cell lineage, such as CD19 and CD79a, will be present (Fig. 2) (33). These antigens are expressed at the time of heavy-chain gene rearrangement, usually indicating commitment to the B-cell lineage. In cases of so-called pre-B-cell ALL, the cells contain cytoplasmic μ heavy chains but are still negative for surface immunoglobulin. The CD20 antigen is not acquired until the stage of light-chain gene rearrangement, and it is expressed in ~50% of cases (34). Thus, pre-B-cell LBL are often negative for CD20 in paraffin sections.

All pre-B-cell and B-cell lymphoblastic lymphomas are clonal neoplasms, and the vast majority have *IGH* rearrangements. In some cases *IGH* rearrangements are incomplete, showing only D-to-J segment joining (35). B-cell lymphoblastic lymphomas have an extremely high frequency of lineage infidelity, with 90% of cases having clonal rearrangements of one or more TCR loci (*TCRβ* [35%], *TCRγ* [60%], or *TCRδ* [55%]) (32). About 30% of cases have characteristic chromosomal translocations (Table 3). A high percentage of these involve two nonantigen receptor genes that can be identified by FISH or by RT-PCR.

Both pre-T-cell and pre-B-cell LBL may be negative for the leukocyte common antigen (LCA; CD45). In addition,

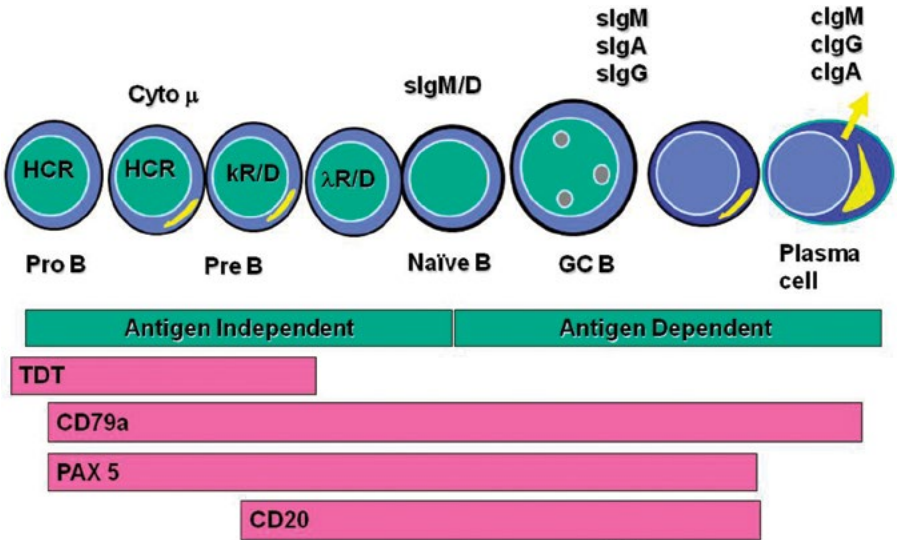

FIGURE 2 Schematic diagram showing stages of B-cell differentiation. Lymphomas can be related to precursor B-cell, mature B-cell, and secretory B-cell (plasma cell) stages of differentiation. Note that CD79a has the broadest range of reactivity, staining precursor, mature, and secretory B cells.

TABLE 3 Chromosomal translocations, involved genes, and detection methods in B- and T-cell lymphomas/leukemias

Translocation	Genes	Tumor[a]	Translocation type	Primary test(s)
B-lymphoblastic leukemias/lymphomas				
t(12;21)(p13;q22)	*TEL-AML1*	B-ALL	2	FISH, RT-PCR
t(1;19)(q23;p13)	*PBX1-E2A*	B-ALL	2	FISH, RT-PCR

[a]Abbreviations: B-ALL, pre-B, B-cell acute lymphoblastic lymphoma/leukemia; MM, multiple myeloma; BL, Burkitt's lymphoma; T-ALL, T-cell lymphoblastic lymphoma/leukemia.
[b]Major cluster region primers identify ~35% of translocations.
[c]RT-PCR to the cyclin D1 mRNA will detect close to 100% of cases.
[d]3q27 partners with various (v) chromosomal partners and loci.
[e]MPS, multiple partner genes.
[f]fv-PTCL, follicular variant panniculitis-like T-cell lymphoma.
[g]c-ALCL, cutaneous ALCL.

TABLE 4 Differential diagnosis of small B-cell lymphomas

Disease	CD5	CD10	CD23	CD43	Cyclin D1	Ig class(es)[a]
FL	−	+	±	−	−	IgM, IgG
MCL	+	−	−	+	+	IgM/IgD
CLL/SLL	+	−	+	+	−	IgM/IgD
LPL	−	−	−	±	−	IgM (c)
MALT	−	−	−	±	−	IgM (c, s)
SMZL	−	−	−	−	−	IgM/IgD
HCL	−	−	−	−	±	IgG

[a]Most commonly expressed heavy chain classes. c, cytoplasmic Ig; s, surface Ig.

they both express CD99, the *mic-2* gene product, in a high proportion of cases. This antigen is expressed in Ewing's sarcoma, a nonlymphoid malignancy presenting in children and young adults, often with lytic bone lesions of the distal extremities. Because of potentially overlapping histological and clinical features, an extensive immunohistochemical panel as well as molecular analysis may be required for accurate differential diagnosis (36).

Mature B-Cell Lymphomas

A variety of malignancies composed of small mature B lymphocytes are recognized in the WHO classification. These include small lymphocytic lymphoma (SLL)/B-cell CLL, FL, MCL, extranodal marginal zone lymphoma (MZL) of MALT type, nodal MZL, splenic MZL (SMZL), and hairy cell leukemia (HCL). In most of these neoplasms, the cells are arrested prior to the secretory stage of B-cell development and express pan-B-cell antigens such as CD19, CD20, and CD22. Evidence of plasmacytoid differentiation is most commonly seen in MZL and is a consistent feature of lymphoplasmacytic lymphoma (LPL). Each of the small B-cell malignancies has a characteristic immunophenotypic signature that is highly useful in differential diagnosis (Table 4).

Monoclonal surface immunoglobulin expression is usually readily detected in frozen sections but is generally not evident in paraffin sections. Even in frozen sections, abundant serum immunoglobulins in the interstitial space may result in high background staining, which can obscure cellular staining and make interpretation difficult. This problem is frequently observed in tissues from patients with polyclonal hypergammaglobulinemia. In paraffin sections, cytoplasmic immunoglobulin can be detected, but is usually most evident in cells showing evidence of plasmacytoid differentiation. Positive staining in the perinuclear space is highly reliable and is usually not subject to technical problems.

The ability of the cells to form follicles correlates with the presence of dendritic reticulum cells (DRCs), which can be identified in frozen and paraffin sections by using monoclonal antibodies reactive with CD21, CD23, CD35, or clusterin. DRCs are numerous in FL and intimately associated with the neoplastic nodules, even in extranodal locations. Staining for DRCs will often enhance a vaguely nodular pattern that is difficult to see in routine histological sections. DRCs are rare in SLL but are present with an irregular, vaguely nodular distribution in MCL.

CD5 is very useful in the subclassification of low-grade B-cell lymphomas. This antigen is found on normal T cells but on few normal B cells. Both SLL and MCL are usually positive for CD5, but it is almost never expressed in true FL. Thus, this antigen is useful in the differential diagnosis of MCL with a vaguely nodular growth pattern versus a true FL. CD5 is also useful in the differential diagnosis of SLL and MCL with lymphomas of MALT. MALT lymphomas arise in extranodal sites (e.g., lung, gastrointestinal tract, and salivary gland) and are composed of small round and small-cleaved (centrocyte-like) cells, which may resemble the cells of SLL and MCL. MALT lymphomas are usually CD5 negative (37). CD23 is very useful in the differential diagnosis of SLL/CLL and MCL, since SLL/CLL is nearly always CD23 positive and MCL nearly always CD23 negative (38). The common ALL (cALL) antigen (CD10) is found much more often in FL than in the other small B-cell lymphomas (39). For unknown reasons, MCL and HCL both express λ light chain much more frequently than do the other B-cell lymphomas, which usually express κ.

Cytogenetic and molecular genetic studies are also extremely valuable in differential diagnosis, and monoclonal

TABLE 5 Evaluation of oncogenes and tumor suppressor genes by immunohistochemistry and molecular diagnostic techniques[a]

Antigen	Disease association	Genetic abnormality	Applicable genetic test(s)	Immunohistochemistry result
BCL-2	FL	t(14;18)	GS, PCR, FISH[b]	+, nonspecific
Cyclin D1	MCL	t(11;14)	GS, PCR, FISH[b]	+, specific[b]
	Multiple myeloma (15%)	t(11;14)	RT-PCR[b] (cyclin D1)	+, specific[b]
p53	Progressed lymphomas	17q deletion mutation	LOH, SSCP, FISH	+, probable[b,c]
	Aggressive lymphomas	Mutation	Sequencing[c]	Mutation
BCL-6	DLBCL (GCB > ABC)	t(3;14)	GS, FISH[b]	+, nonspecific
	3q26 variants	Mutation		
ALK	ALCL	t(2;5)	GS, RT-PCR, FISH[b]	+, specific[b]
		2p23 variants		
BRAF	LCH	V600E mutation	Sequencing	+, ab to mutant protein
	Erdheim-Chester disease			
MYC	Burkitt's lymphoma	t(8;14)	FISH, karyotype	+, but not specific

[a]Abbreviations: GS, genomic Southern blot analysis; SSCP, single-strand conformational polymorphism analysis; ab, antibody.
[b]Method(s) of choice for detection of genetic abnormalities in clinical molecular diagnostics laboratory.
[c]p53 overexpression is generally correlated with the presence of mutation; however, lack of expression is poorly correlated with lack of mutation. Sequencing is required for definitive proof of mutation.

antibodies to oncogene products can be used as surrogate markers in some situations (Table 5). FL is characterized by the t(14;18) translocation that juxtaposes the *BCL2* gene with the *IGH* promoter/enhancer, resulting in BCL-2 overexpression (8). While the translocation results in BCL-2 overexpression, BCL-2 expression, however, is not specific for the translocation, as other low-grade lymphomas express this antiapoptotic protein (40). Thus, while the detection of overexpressed BCL-2 by immunohistochemistry is useful in differentiating FL from follicular hyperplasia, it is not helpful in distinguishing FL from other SLLs. PCR assays targeting the most common breakpoint cluster involved in the t(14;18) translocation can identify up to 65% of cases, while FISH analysis is capable of detecting all cases (41).

The t(11;14) translocation is present in nearly all MCLs (42). This translocation involves the cyclin D1 gene, *CCND1*, resulting in the overexpression of the protein, which is not expressed in nonneoplastic lymphoid cells or in other small lymphocytic neoplasms, with the exception of a small percentage of myeloma cases that have the t(11;14) translocation and HCLs that express very low levels of cyclin D1 (43). A very small subset of MCL cases are identical by gene expression profiling but lack cyclin D1 protein, and are negative for the *CCND1* translocation (44). Recent studies have determined that *CCND2* likely substitutes for *CCND1* in these cases, and a high proportion have translocations involving this gene (45).

The development of new mouse and rabbit monoclonal antibodies to cyclin D1 has greatly improved the detection of these aggressive SLLs, and molecular testing for the translocation is generally not necessary (11). PCR analysis for identification of t(11;14) breakpoint sequences has a relatively low yield unless multiple primer pairs are used, and therefore this method is not widely used. However, RT-PCR targeting the overexpressed cyclin D1 transcripts has been successfully employed in diagnostics (46). This assay exploits the fact that normal lymphocytes and other lymphomas do not express cyclin D1 mRNA, except for a minority of myelomas and HCLs at low levels. FISH assays for the t(11;14) translocation will identify 100% of cases. Recently, cDNA microarray analyses have been performed on cases of MCL (47). While these studies have confirmed the homogeneity of this lymphoma, they have also shown that it is possible to stratify cases and predict survival based on the expression of a set of genes associated with cellular proliferation.

The t(11;18) translocation involving *API2/MLT(MALT)* genes is the most common recurring cytogenetic abnormality in MALT lymphomas of gastrointestinal tract and lung, where it is found in about one-third of all cases (48). However, other less common translocations also occur in MALT lymphomas, including the t(14;18) translocation involving the *IGH* gene and *MALT1* and the t(1;14) translocation involving *BCL10* and *IGH* (49). The t(14;18) translocation preferentially involves non-gastrointestinal tract MALT lymphomas such as those in the lung and ocular adnexa, while the t(1;14) translocation tends to be found in advanced-stage MALT lymphoma. It is of interest that these three translocations perturb two genes (*BCL10* and *MALT1*) that are involved in antigen receptor NF-κB activation (49). The most common of these translocations, t(11;18), can be readily assessed using commercially available FISH probes, or by RT-PCR using published primers to the *API2* and *MALT1* genes.

CLL lacks a characteristic recurrent translocation but displays other cytogenetic abnormalities, including deletions of 13q14, trisomy 12, and deletions of 11q and 17p, which are both associated with a more aggressive clinical course (50). The 13q14 deletion occurs in a very high percentage of CLL cases and results in the consistent loss of genes encoding microRNAs (51). MicroRNAs are small antisense RNAs encoded in the genome that appear to regulate the translation of critical proteins (52). The microRNAs that are deleted at 13q14 are miR15 and miR16, which are regulators of the antiapoptotic BCL-2 protein, implicating the loss of these microRNAs in the abnormally high levels of BCL-2 found in CLL (53). FISH analysis tends to underestimate the frequency of microRNA loss because a significant number of the deletions at 13q14 are small.

Over the past several years there have been a number of studies that have clearly shown that there are two distinct clinicopathological subtypes of CLL that can be distinguished by the presence or absence of IGH mutation, CD38 expression, and ZAP70 expression (28, 54). Nonmutated CLL tends to be CD38 positive and ZAP70 positive. Patients with nonmutated CLL have a 5-year survival of about 40 months, compared to 120 months for their counterparts with ZAP70-negative mutated CLL. Gene microarray studies have confirmed the presence of these two clinicopathological subgroups (55). At present, either mutational analysis or ZAP70 expression by immunohistochemistry or flow cytometry is recommended to distinguish these two CLL subtypes (56).

Tumors of fully differentiated B cells synthesize and secrete immunoglobulin, giving rise to monoclonal immunoglobulin spikes that can be detected by serum immunoelectrophoresis. LPL is the histological counterpart of Waldenström macroglobulinemia. In this disease the cell is arrested between the B lymphocyte and the plasma cell. Class switching from IgM to IgG, IgA, etc., has not yet occurred, and clinically the process resembles a low-grade lymphoma with widespread involvement of lymphoid organs. Recent studies have identified a recurrent translocation in *MYD88* at L265P that is found in a high proportion of cases of Waldenström macroglobulinemia, which appears to be a useful marker to distinguish LPL from other low-grade B-cell neoplasms with plasmacytoid differentiation, especially nodal MZLs (57, 58).

Multiple myeloma, which arises from terminally differentiated B cells, may show monoclonal IgG, IgA, IgM, or IgD, in that order of frequency. The cells at this stage of differentiation lose most B-cell markers, such as CD20, CD19, and CD22. However, CD79a is still found (10). All myelomas have clonally rearranged immunoglobulin genes and express monoclonal immunoglobulin, which is mainly cytoplasmic and can be most readily detected in paraffin sections. Of practical significance, it should be noted that normal and neoplastic plasma cells are CD45 (LCA) negative but are positive for epithelial membrane antigen. The pathologist should be alert to these characteristics in the eventual differential diagnosis of anaplastic carcinoma versus multiple myeloma. Multiple myeloma has several characteristic recurrent translocations (Table 3). Interestingly, many of these result in the overexpression of cyclin D, either directly or indirectly, and it has been proposed that overexpression of cyclin D1 is a common pathogenetic mechanism unifying all of the different translocations (59). FISH is the method of choice for detection of the various translocations.

DLBCL is not a single disease entity but a category that includes both primary aggressive B-cell lymphomas and histologically progressed lymphomas. Because there are as yet no immunophenotypic or morphological features that lead to reliable subclassification of these lymphomas, it was deemed most advisable to retain most morphological

variants of DLBCL in a single category, pending further data and delineation of other entities. Notably, some specific entities have been defined, and these include mediastinal or thymic-B-cell lymphoma, primary effusion lymphomas (HHV-8 associated), and intravascular DLBCL (60–63).

Therefore, it is not unexpected that most cases of DLBCL do not display unique phenotypic profiles but express the mature B-cell characteristics seen in diverse low-grade B-cell tumors. For example, expression of CD10 usually correlates with the presence of the t(14;18) translocation (64). In some cases, the presence of CD5 indicates that the process arose in the background of a small lymphocytic malignancy (SLL/CLL), so-called Richter's syndrome, although *de novo* CD5-positive DLBCLs also exist. p53 is commonly expressed and is often an indication of an acquired *p53* mutation associated with histological progression (65). p53 protein expression also is a poor prognostic marker (66). *BCL6* is expressed in the majority of DLBCL cases, in many instances indicating a derivation from the GC. However, both translocations and mutations of *BCL6* occur frequently as well. While translocations of *BCL6* are clearly important pathogenetically, *BCL6* mutations are a normal physiological event in the GC. Recent data from several laboratories using cDNA microarray studies have begun to identify distinct differences within the DLBCLs (67, 68). Mediastinal B-cell lymphomas have been shown to be quite distinct in their gene expression signature from other DLBCLs and, in fact, have a signature closer to that of Hodgkin's disease (68, 69). "Standard" DLBCL has been shown to comprise two major subgroups: a GCB subgroup, simulating the gene expression signature of GC B cells, and an activated B cell (ABC) subgroup, simulating the signature of activated peripheral B cells (26, 67). The ABC subgroup has been shown to have a significantly worse prognosis than the GCB subgroup, demonstrating that the subclassification has clinical relevance. Pathologists have been able to extract from these data a small panel of genes, amenable to immunohistochemical study, that have been shown to be effective in dividing the GCB group (positive for BCL-6, CD10) from the ABC group positive for IRF4 (interferon regulatory factor 4), detecting the protein referred to as MUM1 (multiple myeloma 1) (70).

It also has been shown that ABC and GCB tumors differ pathogenetically and show consistent differences at the genetic level (71). Indeed, mutations involving *MYD88* were first identified in the ABC subset. Evidence of chronic active B-cell receptor signaling is a feature of the ABC subset (72), a finding that has significant therapeutic significance in the use of new targeted agents such as ibrutinib (73).

A morphological variant of DLBCL is so-called T-cell-rich large B-cell lymphoma. The neoplastic cells comprise <5% of the population in these lymph nodes, with most of the infiltrating cells being reactive polyclonal T cells. Staining of paraffin sections with L-26 is especially helpful in the recognition of T-cell-rich B-cell lymphoma and will highlight the large tumor cells. Cell suspensions prepared from such lymph nodes usually contain >75% T cells (up to 90% or more) and may be erroneously diagnosed as T-cell lymphomas with flow cytometric techniques. In many of these cases, the neoplastic cells resemble the L&H cells of nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL), and a relationship between these entities has been postulated (74). There is as yet no reliable immunohistochemical or molecular test to distinguish these two disease entities, and the diagnosis remains heavily reliant upon clinicopathological parameters.

Another DLBCL variant that has been clearly separated from the vast majority of DLBCLs is the pleural effusion lymphomas associated with HIV infection. Not only do these B-cell lymphomas have the unusual clinical feature of presenting as an effusion, most often without a solid or leukemic phase, but also they have an unusual immunophenotype and contain HHV-8 (62). These lymphomas have a plasmablast-like B-cell phenotype, but paradoxically generally do not display membrane or cytoplasmic immunoglobulin by immunohistochemistry. However, all cases have rearrangement of their immunoglobulin genes as detected by either genomic Southern blotting or PCR. HHV-8 can be easily demonstrated in the tumor cells by specific antibodies to the ORF76 protein or by PCR of involved fluids (75).

Burkitt's lymphoma is a high-grade malignancy that expresses CD20, CD19, and CD22. Surface immunoglobulin is usually of the IgM class, and the cALL antigen (CD10) is nearly always positive. Burkitt's lymphoma can rarely present as acute leukemia. TdT is negative, helping to distinguish Burkitt's lymphoma from LBL, which is always TdT positive. Burkitt's lymphoma is characterized by translocations involving the *MYC* gene (76). Translocations involving *MYC* are best detected by FISH, as the chromosomal breakpoints are not sufficiently clustered to allow simple PCR testing. A monoclonal antibody to the MYC protein is now available for routine immunohistochemistry. While it is highly expressed in cases with a *MYC* translocation, other aggressive lymphomas may also show high levels (77, 78). Burkitt's lymphoma is a highly proliferative tumor, with 100% of the cells in cycle (protein encoded by mindbomb E3 ubiquitin protein ligase 1, or MIB1) and is consistently BCL-2 negative. It is positive for BCL-6, indicating a relationship to the GC. Burkitt's lymphoma also has a characteristic profile by gene expression profiling (79, 80). However, these cases may show overlap with so-called double-hit and triple-hit lymphomas that have *MYC* translocations in conjunction with translocations involving other genes, such as *BCL2* and *BCL6* (81). These double-hit and triple-hit cases have a worse prognosis (82).

Mature T-Cell Neoplasms

Neoplasms of mature or peripheral T-cell origin demonstrate marked cytological heterogeneity. However, in contrast to the case with B-cell lymphomas, cytological features are less useful in defining disease entities. While nearly all cases of peripheral T-cell lymphoma (PTL) possess clonal rearrangements of at least one of the TCR genes, these lymphomas do not display consistent immunophenotypic profiles. In addition, the molecular pathogenesis remains to be defined for most of the T-cell lymphomas. Therefore, at present, clinical parameters play a major role in the classification of T-cell lymphomas, as cytological, immunophenotypic, and molecular features are insufficient to define these neoplasms. As a group they tend to be much more aggressive than B-cell lymphomas (83).

PTL, unspecified, is a category somewhat analogous to DLBCL (84). It is felt to be heterogeneous, and probably contains several yet-to-be-recognized entities. PTLs display a wide morphological spectrum, with cells of diverse sizes and appearances. PTL often has an inflammatory background composed of eosinophils, histiocytes, and plasma cells. This polymorphous cellular composition may lead to difficulty in distinction from classical Hodgkin's lymphoma (CHL). The presence of cytological atypia in the background lymphocytes argues against a diagnosis of CHL. Immunophenotypic markers are also useful in this differential diagnosis.

Immunophenotypic markers for clonality are not readily available in the T-cell system. Therefore, molecular assays for the assessment of clonality are often extremely helpful.

TABLE 6 Immunophenotype in the differential diagnosis of nodal PTLs

Disease	Immunophenotypic features
AILT	$CD10^+$, PD-1 (CD279), mixed CD4/CD8, proliferation of follicular dendritic cells ($CD21^+$ cells), EBV^+ blasts
PTL, unspecified	CD4 > CD8, antigen loss (CD7, CD5, CD2)
ATL	$CD4^+$, $CD25^+$, $CD7^-$, $CD30^{+/-}$, $CD15^-$
ALCL	ALK^+, $CD30^+$, $clusterin^+$, EMA^+, $CD25^+$, $CD4^+$, $CD3^{-/+}$
TCHRLBCL[a]	Large $CD20^+$ blasts in $CD3^+$ background
Reactive	Mixed CD4/CD8, intact architecture, variable CD25, CD30; scattered $CD20^+$

[a]TCHRLBCL, T-cell/histiocyte rich large B-cell lymphoma.

The major subset antigens CD4 and CD8 are not clonal markers analogous to light-chain restriction in the B-cell system. Although most PTLs express only CD4 or CD8, some reactive conditions can also show marked subset restriction, most commonly of the CD4 subset. If a proliferation coexpresses CD4 and CD8 or fails to express either CD4 or CD8, that profile is suggestive of malignancy (85).

Other abnormalities of antigenic phenotype are commonly observed in PTL (Table 6). If a battery of pan-T-cell monoclonal antibodies is used, PTL will often fail to express one or more of the major markers CD7, CD5, CD3, and CD2. The antigen most frequently absent is CD7. However, because this antigen is expressed on only 85% of normal T cells, its absence is not unequivocal evidence of a malignancy. Indeed, some reactive T-cell proliferations will be CD7 negative.

A prominence of postcapillary venules is a feature often noted in PTL. AILT is a specific subtype of PTL characterized by an especially florid proliferation of postcapillary venules (86). The predominant infiltrating cells in AILT are CD4-positive T cells. The neoplastic cells express CD10, programmed death 1 (PD-1; CD279), and CXCR13, suggesting that these tumors originate from T follicular helper (Tfh) cells that normally populate the GC (87, 88). A prominent inflammatory background is present, including polyclonal plasma cells, histiocytes, and eosinophils. A disordered meshwork of CD21-positive reticulum cells distributed around blood vessels is highly characteristic of this lymphoma type (89).

Most cases of AILT show clonal TCRβ or TCRγ gene rearrangement. B cells are variable in frequency and in some cases may be numerous. In addition, some B cells positive for EBV are seen in nearly all cases (90). These EBV-positive cells may be monoclonal as detected by IGH PCR techniques, and in rare cases the EBV-positive B cells may progress to a DLBCL (91). In other rare instances the EBV-positive cells may also simulate Hodgkin's lymphoma morphologically and immunophenotypically (92). It is postulated that the expansion of EBV-positive B cells is secondary to the underlying immunodeficiency so characteristic of this disease. However, EBV-negative B-cell expansions also occur, suggesting that deregulation of B-cell proliferation may be an intrinsic aspect of the disease (93, 94), and likely related to the function of the cells as Tfh. AILT has a characteristic gene expression profile, allowing for inclusion of other forms of T-cell lymphoma with less typical morphological features (95, 96). Recently, recurrent mutations have been identified in AILT and have expanded understanding of its genetic basis (97–99).

Adult T-cell leukemia/lymphoma (ATL) is a unique clinicopathological entity associated with the human retrovirus HTLV-1 (100). The neoplastic cells have a mature T-cell phenotype. They are CD4 positive and strongly express interleukin-2 receptors (CD25). Elevated levels of soluble interleukin-2 receptors may be found in the serum and correlate with disease activity. They have a high proliferative rate with MIB-1, in keeping with the aggressive clinical course. *In vitro* they exhibit suppressor cell function. As with many PTLs, they are CD7 negative. All cases of ATL have clonal *TCR*β and *TCR*γ rearrangements and are associated with clonally integrated HTLV-1 retrovirus. Serologic testing for HTLV-1 as well as the identification of viral genomic sequences by PCR can be of great help in diagnosing this lymphoid neoplasm. However, only a minority of infected patients will develop ATL, and it is important to correlate serologic positivity for HTLV-1 or a positive PCR result with the presence of a clonal T-cell lymphoproliferation. Recurrent translocations are not reported in ATL, but numerical abnormalities and deletions of the long arm of chromosome 6 as assessed by both cytogenetic and loss-of-heterozygosity (LOH) studies are frequent (101).

Extranodal T-cell and NK-cell lymphomas represent a distinctive group and share many histological and immunophenotypic features (102). This observation is in keeping with the close relationship between NK cells and cytotoxic T cells (103). They include intestinal T-cell lymphoma, subcutaneous panniculitis-like T-cell lymphoma, and nasal and extranasal NK/T-cell lymphoma. Most of the extranodal T-cell lymphomas appear to be derived from cytotoxic T cells; they express granzyme B, the cytotoxic-cell-associated granule protein T-cell intracellular antigen 1 (TIA-1; also known as cytotoxic granule-associated RNA binding protein), and perforin (104). CD56, an antigen expressed on NK cells, may also be present, but it is most common in nasal NK/T-cell lymphoma (Table 7). These lymphomas as a group present in and spread to extranodal sites, with infrequent lymph node involvement. They frequently contain extensive necrosis, sometimes associated with angioinvasion. Apoptosis of tumor cells also is prominent, in part related to the cytotoxic features of the neoplastic cells. EBV is universally found in

TABLE 7 Extranodal NK/T-cell lymphomas[a]

Subtype	EBV	CD3	TIA-1	GranB/Per	CD56	TCR	
						Major	Minor
SPTCL	−	+ s	+	+	±	αβ	γδ
EATL	−	+ s	+	+	±	αβ	γδ/NK
Nasal	+	+ c	+	+	+	NK	γδ/αβ?
Hep/spl	−	+ s	+	−	+	γδ	αβ

[a]Abbreviations: SPTCL, subcutaneous panniculitis-like T-cell lymphoma, EATL, enteropathy-associated T-cell lymphoma; Nasal, nasal NK/T-cell lymphoma; Hep/spl, hepatosplenic T-cell lymphoma; GranB/Per, granzyme B/perforin; s, surface CD3; c, cytoplasmic CD3.

nasal and extranasal NK/T-cell lymphoma and may be seen sporadically in intestinal T-cell lymphoma. EBV is generally absent in subcutaneous panniculitis-like T-cell lymphoma. Hepatosplenic T-cell lymphoma also belongs to this broad group of cytotoxic T-cell lymphomas.

Within the extranodal NK/T-cell lymphomas, there is some variation in lineage, a feature that departs from the general principle that lineage is a defining feature of disease entities. For example, nasal NK/T-cell lymphoma is usually of NK-cell derivation, but in rare cases it may be derived from either γδ or αβ T cells. Similarly, intestinal T-cell lymphoma is usually of αβ T-cell derivation, but a minor proportion of cases are derived from γδ T cells.

Nasal NK/T-cell lymphomas express some T-cell-associated antigens but are probably of NK-cell derivation (105). Necrosis is seen in most cases. The midline nasal area is the most common site of involvement, but the disease can also present itself in other extranodal sites. In other sites it is referred to as nasal-type T/NK-cell lymphoma (105). The neoplastic cells generally lack T-cell gene rearrangements. The cells are positive for CD2 and CD7 but negative for surface CD3. However, they usually express CD3ε within the cytoplasm, which can be detected in paraffin sections with both polyclonal and monoclonal antibodies. CD56 is present in virtually all cases. The neoplastic cells are EBV positive, and the EBV genome is monoclonal based on terminal-repeat analysis (106). p53 is overexpressed in nearly all cases, but there have been no confirmatory mutational studies (107). There are few classical cytogenetic studies of these lymphomas, and while numerical abnormalities have been reported, no recurrent translocations have been identified (108). LOH studies show a high frequency of chromosomal loss at 6q, 13q, 11q, and 17p (the site of the p53 gene) (109). Recent studies using spectral karyotyping have identified a cryptic translocation involving Xp21 and 8p23 (110). The genes involved have not been identified.

The hepatosplenic T-cell lymphomas are most often derived from immature γδ T cells (111). The cells express the cytotoxic granule-associated protein TIA-1, but they lack expression of the effector proteins, the granzymes and perforin. This feature may explain the lack of tissue necrosis in these tumors. In addition to expressing TCRγδ, an indication of a γδ cell receptor, the cells are positive for CD56 and either $CD4^-/CD8^-$ or positive for CD8. CD5 is usually absent as well. Recently, it has become possible to detect the antigens associated with the γδ receptor by routine immunohistochemistry, facilitating diagnosis of tumors with a TCRγδ phenotype (112–114). Hepatosplenic T-cell lymphoma, as the name implies, presents with marked hepatosplenomegaly, but occult bone marrow involvement is usually present as well. However, lymph node involvement is absent. This lymphoma is associated with isochromosome 7q and trisomy 8 as consistent cytogenetic abnormalities (115). Interestingly, an identical form of hepatosplenic lymphoma composed of αβ T cells can be encountered in rare cases (116).

A distinctive subtype of T-cell lymphoma is ALCL (117). It can occur at any age but is most common in children and adolescents (118). Although the cells express some T-cell antigens, they usually have a markedly aberrant phenotype, and some cases may appear to be of null cell phenotype (Table 8). However, at the genotypic level, all cases appear to have rearranged TCR genes (119). CD30 is an antigen initially detected on the neoplastic cells of Hodgkin's disease. It is found on Reed-Sternberg (RS) cells, a subset of activated T cells, EBV-infected B cells, and in all cases of ALCL. Other characteristic markers include epithelial membrane antigen (EMA) and clusterin (120). The neoplastic cells also exhibit cytotoxic molecules (121).

Histologically, ALCL most often is composed of large, often lobulated cells that preferentially involve lymph node sinuses, and in the past such lesions were often interpreted as malignant histiocytosis (122). Tissue section immunohistochemistry is helpful in the diagnosis of this entity because the malignant cells may not be numerous and staining for CD30 highlights their sinusoidal distribution. The CD30 antigen can be detected in either paraffin or frozen sections.

ALCL was first recognized based on characteristic histological features (sinusoidal invasion) and a distinctive immunophenotype ($CD30^+$). However, neither sinusoidal invasion nor CD30 positivity proved to be entirely specific. Subsequently, a characteristic cytogenetic abnormality was identified, the t(2;5) translocation, which led to identification of the genes involved in the most common translocation of ALCL (*NPM/ALK*) and insights into the pathogenesis (123, 124). Generation of monoclonal antibodies to the aberrantly expressed ALK can be used diagnostically and has led to improved definition of the diagnostic entity, with important clinical and prognostic implications (125). Utilizing these biological tools, the ultimate histological spectrum of ALCL is both broader and narrower than originally believed. ALK expression can now be considered a defining feature, as ALK-negative cases of ALCL probably represent different entities (126).

In addition to the classical t(2;5) translocation that is found in ~75% of ALCLs, additional variant translocations occur in the remainder of cases (127). All variant translocations involve the *ALK* gene on chromosome 2, but a different partner chromosome. Regardless of the partnering gene involved in the translocation, ALK is activated in all cases and is believed to play a central role in ALCL pathogenesis (128). The diagnosis of ALCL can be assisted by RT-PCR, which will identify the 75% of cases with classical *NPM/ALK* fusion genes, or by FISH, which will detect both classical and variant translocations.

Primary cutaneous ALCL is a different disease and is closely related to lymphomatoid papulosis, a chronic lymphoproliferative disease of the skin (129). These cases do not have a t(2;5) translocation and do not express ALK protein. Notably, although all cases of true ALCL are ALK positive, ALK expression can be detected in other rare entities, such

TABLE 8 Differential diagnosis of ALCL and Hodgkin's disease

Disease	CD30	CD15	LCA	CD3	TIA-1	EMA	Clus	ALK	CD20
ALCL, ALK+	+	−	+	±	+	+	+	+	−
CHL	+	+	−	−	−	−	−	−	±

DLBCL[a]	±	−	+	−	−	±	−	−	+

[a]DLBCL includes T-cell-rich large B-cell lymphoma.

as myofibroblastic tumors, and ALK-positive, CD30-negative large B-cell lymphomas.

Hodgkin's Disease (Hodgkin's Lymphoma)

CHL is an unusual neoplastic disorder because the neoplastic cells represent only a minority of the cells present in the tumor mass. The neoplastic cells, the RS cells and their mononuclear variants, are admixed with normal lymphocytes, histiocytes, eosinophils, neutrophils, and plasma cells. The paucity of RS cells has led to difficulty in their characterization by flow cytometric techniques and has severely impeded the molecular analysis of this neoplasm. The normal lymphocytes within CHL are usually identifiable as T cells, predominantly $CD4^+$. However, the nature of the malignant cell in CHL has taken a long time to unravel.

The tumor cells express CD15, an antigen found in normal granulocytes, histiocytes, and many epithelial cells. They also express the CD30 antigen, first identified on cell lines derived from CHL. LCA (CD45) is frequently absent. The identification of CD20 on at least some of the neoplastic cells led to speculation that CHL was B-cell derived (130). Immunohistochemistry to assess light-chain restriction is also usually not helpful for the assessment of clonality, as the amount of immunoglobulin produced is small, the cells tend to stain nonspecifically, and background staining for immunoglobulin tends to be high. Traditional molecular studies of CHL generally failed to detect clonal *IGH* rearrangements because of the low percentage of tumor cells in the population. The diagnostic sensitivity of IGH PCR is about 2 to 3% tumor cells (of total B cells), and frequently the number of clonal RS cells is below this threshold. However, by enriching RS cells through the use of microdissection techniques, several investigators were able to confirm a clonal B-cell origin in virtually all cases (131, 132). In addition, the cells were shown to have somatic mutations of the IGH genes, indicative of a GC stage of differentiation. Similar to CHL, the nodular lymphocyte-predominant variant (NLPHL) has also been shown to be of B-cell origin; however, because of its distinctive immunophenotypic and clinicopathological characteristics, NLPHL is now considered to be a separate entity (133). There are no characteristic recurrent translocations of significance known in either CHL or in NLPHL, and molecular profiling studies have been difficult to perform due to the difficulty in obtaining pure populations of tumor cells.

NONLYMPHOID TUMORS OF THE IMMUNE SYSTEM: "HISTIOCYTIC" DISORDERS

Normal Histiocytic Subsets

The cells of the histiocytic system consist of two major subsets: the antigen-presenting cells, or dendritic cells; and the antigen-processing cells, or phagocytic cells (134). The follicular DRCs are found in follicles and present antigen to B lymphocytes, but they may not be of hematopoietic origin. They are positive for CD21, CD23, CD35, and clusterin but are CD45 negative. The interdigitating dendritic cells (IDCs) and Langerhans cells (LCs) are bone marrow-derived cells that present antigen to T lymphocytes. LCs are found primarily in the skin but also in other organs. IDCs are found in lymph nodes and other lymphoid organs. Both LCs and IDCs are S100 positive. The relationship between these cells is controversial. Both are CD1a positive, although IDCs show variable expression dependent upon their maturational stage. However, unlike LCs, IDCs do not possess the characteristic Birbeck granule. Fibroblastic reticular cells are involved in transport of cytokines and other mediators (135). In lymph nodes, they ensheathe the postcapillary venules. They are of mesenchymal rather than hematopoietic origin, and they express smooth muscle actin (136).

All of the macrophages of lymph nodes share many enzyme histochemical and immunophenotypic characteristics. They have abundant and diffuse activity for lysosomal enzymes, including acid phosphatase and nonspecific esterase. As stated above, all of these cells can also demonstrate phagocytosis under appropriate conditions. Activity for lysozyme and α1-antitrypsin can be seen in all of the above subtypes but is most prominent in epithelioid histiocytes. Activity for lysozyme decreases abruptly with phagocytosis, presumably because of its loss into lysosomal vacuoles. CD68 is the most useful antigen for detection of macrophages in routine paraffin sections.

A variety of monoclonal antibodies that react with monocytes and macrophages have been derived. Unfortunately, most of these antibodies lack specificity for the mononuclear phagocytic system, and many react with other hematopoietic cells as well: myeloid cells, T cells, or B cells. For example, CD11c is present on monocytes and macrophages and is weak or absent on normal T and B lymphocytes. However, this antigen is found on the cells of HCL (a B-cell lymphoproliferative disorder) and in some cases of B-cell CLL. Cross-reactivities with T cells are present as well. For example, CD4 is found in normal monocytes and macrophages. CD25, in addition to being found on activated T lymphocytes, is found on normal monocytes and macrophages. CD68, strongly positive on histiocytes, also reacts with granulocytic precursors. The CD14 antigen is present on monocytes and macrophages and probably has the greatest specificity for the macrophage lineage among available reagents.

Proliferative Histiocytic Lesions

Proliferative lesions of antigen-presenting cells are relatively rare (137). The principal proliferative lesion of the dendritic cell system is LC histiocytosis (LCH). Recent studies, using the HUMARA method described above, have shown that the cells of LCH are monoclonal, but the disease usually has a self-limited course, especially in older children and adults (138). It may be fatal in infants. The cells of LCH have the characteristics of LCs, including CD1 expression, langerin expression, and Birbeck granules (139). In contrast to normal LCs, the cells also express antigens associated with phagocytic histiocytes, such as CD14 and CD11c. Recently, recurrent mutations of *BRAF* have been identified in a large proportion of cases of LCH, and antibodies to detect the mutant protein may be useful diagnostically (140, 141). Interestingly, Erdheim-Chester disease, another rare histiocytic disorder, also contains *BRAF* mutations (142).

There are rare tumors described that have a derivation from IDCs. These lesions are usually based in lymph nodes and are often associated with an inflammatory background and/or necrosis. There is overlap in histology and phenotype with true histiocytic tumors, and they may have an aggressive clinical course. By contrast, follicular dendritic cell sarcomas usually present with localized lymph node involvement. They may recur locally but usually do not disseminate. These neoplasms are also rare. Rare tumors of fibroblastic reticular cell origin also are seen in lymph nodes. The expression of clusterin, CD21 (DRC sarcomas), S100 (IDC tumors), CD1a (IDC tumors) and actin (fibroblastic reticular cell tumors) can be helpful in distinguishing these three stromal neoplasms of lymph nodes (88, 136). There are no specific cytogenetic abnormalities or molecular tests associated with these tumors.

Malignancies of mononuclear phagocytes include acute monocytic leukemia and histiocytic sarcoma. In rare instances, histiocytic sarcomas may be disseminated, fulfilling criteria for what has been termed in the past "malignant histiocytosis." However, most instances of malignant histiocytosis reported previously represent other entities, such as ALCL (134).

Acute monocytic leukemia relates to a bone marrow-derived monoblast. This malignancy arises in the bone marrow compartment, with secondary involvement of the peripheral blood and usually a markedly elevated leukocyte count. In contrast to acute myeloid leukemia, there is a somewhat higher incidence of involvement of nonhematopoietic sites, with frequent involvement of skin and gingiva.

Histiocytic sarcoma represents a malignancy of the mononuclear phagocytic series at the stage of the fixed-tissue histiocyte. Therefore, the lesions in histiocytic sarcoma represent localized, relatively discrete tumefactions. In addition to the reticuloendothelial system, common sites of involvement include skin and bone. Because there are few, if any, markers with absolute specificity for macrophages, the investigator must rigorously exclude other cell lineages with both immmunophenotypic and molecular means. In the absence of special studies, morphological evidence of phagocytosis by the neoplastic cells, most commonly erythrophagocytosis, had been proposed as a criterion for a derivation from mononuclear phagocytes. However, phagocytosis is inconspicuous in most mononuclear phagocytic malignancies. Moreover, it is not a specific finding and has been described for lymphoid, plasmacytic, and even epithelial tumors. Even if phagocytosis is observed, it is virtually always clinically insignificant. The hemophagocytic syndrome is the most common and clinically significant of the proliferative disorders of macrophages. However, it is not a neoplastic process. It is usually seen in association with immunodeficiency or another hematopoietic malignancy (143, 144). This syndrome appears to be pathogenetically related to an excessive production of cytokines and chemokines capable of stimulating mononuclear phagocytes (145). The cells in hemophagocytic syndromes are morphologically and phenotypically activated macrophages.

CONCLUSIONS

Tumors of the immune system are of interest not only because they represent models of normal immune cells but also because they provide excellent examples of how immunologic and molecular tumor markers may be used in clinical diagnosis. Because the lymphomas simulate normal cellular counterparts, it has been possible to develop modern classification schemes that take advantage of and utilize the large panels of antibodies that were primarily developed to study and characterize normal immune cells. The investigation of the molecular genetic abnormalities found in tumors of the immune system, particularly the translocations that occur in lymphoid neoplasms, has resulted in the discovery of oncogenic classes of genes that have been further exploited for the development of diagnostic testing and tumor classification purposes. The assimilation of both immunologic and molecular approaches has been largely responsible for the current biologically based WHO classification scheme.

The example provided by the WHO classification scheme has not gone unnoticed in the study and classification of other cancers. While many of the other tissues in which cancers arise may not be as complex as the immune system, the classification of nonlymphoid tumors has also benefited from advances in the detection of immunologic and molecular genetics of the tumors. One such example has been the refinements that have occurred in the classification and diagnosis of the so-called small cell tumors of childhood, in which both protein and molecular markers have been used to dissect out the origins and provide the tools to accurately classify these morphologically similar tumors. Small blue cell tumors include neuroblastomas, rhabdomyosarcomas, Ewing's sarcomas, and other rare tumors. Each of these is now known to be associated with characteristic cell surface markers, and tumor-specific translocations. Thus, the same approaches discussed for the lymphomas can be applied to the investigation and classification of these and other cancers. There is little doubt that the next generation of classification schemes developed for both tumors of the immune system and other types of tumors will continue to benefit from and incorporate information from advances in our understanding of the biology of normal cellular counterparts, as well as from the voluminous data being generated from the ongoing molecular dissection of the tumors themselves.

Monitoring of Immunologic Therapies

THERESA L. WHITESIDE

110

Immunologic therapies are becoming increasingly widely utilized. The current interest in these therapies is due to considerable successes in treatment outcomes in a broad spectrum of human diseases targeted for biotherapy, including inheritable or acquired immunodeficiencies, autoimmune diseases, cancer, and persistent infections. Many new biologic agents are available for immune therapy, and antibodies, cytokines, activated or genetically modified immune cells, vaccines, and other immunomodulatory drugs are frequently used either as monotherapies or in combination with conventional therapies such as chemotherapy, radiation, surgery, and even behavior-modifying therapies. In cancer, biotherapies are expected to restore dysfunctional antitumor immune responses, activate immune cells, and help immune cells to reacquire normal homeostasis. In addition, tumors resistant to standard therapies are often sensitive to immune interventions, and this offers a promise of combinatorial therapies to overcome drug resistance.

The selection and use of an immunologic therapy usually requires extensive preclinical evaluations. *In vitro* studies with human cells and *in vivo* experiments with animal models of disease are expected to define the presumed mechanism(s) responsible for its therapeutic activity. Animal models are especially useful for studies of dosages, times, frequencies, and sequences of drug delivery and are essential for evaluating the toxicity of immune therapies and their effects on the disease process and overall survival. A clinical protocol design is frequently based on results of experiments performed in animal models. Translation of preclinical *in vitro* and/or *in vivo* results to a clinical protocol design requires close cooperation and collaboration of the laboratory with clinical personnel.

An equally important requirement for implementation of biotherapy in the clinic is the assessment of its direct and/or indirect *in vivo* effects. For this reason, immunologic monitoring has emerged as an advisable, and more recently as a necessary, adjunct to clinical trials with biologics. In the past, immunologic monitoring fell under the "correlative studies" category. Today, it is often a protocol-mandated requirement, and an immunologic response to therapy might be the primary endpoint. Immune monitoring has become an important part of patient assessment in expectation that immune measures could serve as biomarkers or as surrogate endpoints of clinical responses. A series of recommendations for the development and use of immune biomarkers was formulated by a joint International Society for Biological Therapy of Cancer-Society for Immunotherapy of Cancer, US Food and Drug Administration (FDA), and National Cancer Institute task force (1). This document emphasizes the need for development of reliable immune biomarkers and offers guidelines for how to establish, standardize, and evaluate immune assays to see whether they meet a biomarker designation.

CHALLENGES IN MONITORING OF IMMUNE THERAPIES

The immune system is always ready to respond to "danger signals" that originate within or outside the body (2, 3). However, cancer and chronic persistent infections are characterized by local and systemic immune suppression selectively targeting immune cells responding to tumor antigens and infectious agents, respectively. Thus, the host immune system is dysfunctional with respect to the offender and unable to contain tumor growth or infection (4). Biologic therapies are expected to restore the ability of the immune system to respond by activating immune cells, blocking inhibitory signals, and/or removing or silencing suppressor cells (4). While much has been learned about mechanisms responsible for immune dysfunction in cancer and HIV-1, the complexity of cellular signaling and molecular interactions involved and the cross talk ongoing between immune, endocrine, neural, and hormonal networks complicate the interpretation of immune monitoring results and establishment of reliable correlations with clinical outcome. Complex biological interactions of the various immune system components present a landscape in which therapy-associated effects may not always be readily detectable or measurable.

Immune monitoring itself has been often viewed as a particularly complex and poorly controlled task in comparison to conventional clinically used biochemical assays. Although serial monitoring assays (i.e., the "bulk assays") performed at the population level have been largely replaced by more-accurate single-cell technologies allowing for assessments of immune cells *in situ*, these new sophisticated assays have to be considered and interpreted in the context of immune cell and non-immune cell cross talk. Thus, special expertise may be needed to interpret cellular interactions, and the well-known cellular plasticity of immune cells at

doi:10.1128/9781555818722.ch110

tissue sites might further confuse the results. Nevertheless, recent results from, e.g., clinical trials with antibodies to the checkpoint inhibitors cytotoxic-T-lymphocyte-associated antigen 4 (CTLA-4) and programmed cell death ligand 1 (PD-L1) indicate that beneficial clinical results can be linked to measurably reduced immune suppression, and that selected immunologic characteristics can serve as biomarkers of therapeutic response or overall survival (5, 6). Clearly, recent experience with biotherapy provides many examples of the emerging potential of immunologic markers serving as predictors of outcome or response to therapy (7–9).

CLINICAL TRIALS WITH BIOLOGIC AGENTS

Following preclinical evaluations, a therapeutically promising immunologic agent is introduced to the clinic in the form of a phase I protocol. The design of a phase I study is based on the predicted mechanism of action of this agent, as determined in preclinical *in vitro* and *in vivo* experiments. An investigational new drug application, which contains the results of preclinical and animal safety studies as well as the clinical protocol, is filed with the FDA. Agency approval is necessary for clinical evaluations of any experimental biologic agent. Following a review of the application, the FDA might decline to issue approval for opening of the trial and place the study on hold if additional information or clarifications are needed. Clinical trials involving gene therapy need approval by the Recombinant DNA Advisory Committee of the National Institutes of Health. In addition, institutional approvals from the institutional review board and the biosafety committee have to be obtained prior to opening the trial for patient accrual.

Biologic agents are available as natural or recombinant materials that may have potent immunomodulatory activities. When administered systemically in high doses, they often induce considerable toxicities, as is common, e.g., with cytokines such as interferons or interleukin-2 (IL-2). However, the maximal tolerated dose (MTD) for a given biologic agent is not necessarily the dose that produces the desired biologic or therapeutic effect. In fact, low doses of biologics might have greater or different therapeutic effects than high doses without accompanying toxicity. This observation suggests that in contrast to the case for pharmacologic or chemotherapeutic agents, which are usually characterized by a linear dose-response curve, biologic agents have a distinctive bell-shaped response curve. The optimal biologic dose (OBD) for each biologic agent is thus likely to be different from the MTD and needs to be defined in phase I/II clinical trials in order to preserve and optimize its therapeutic benefits and limit its toxicity. The developmental strategy for a therapeutic agent involves determination of the mechanism-specific OBD, that is, the dose that is optimally effective with tolerable toxicity. A clinical trial designed to determine the OBD is referred to as phase Ib, in contrast to a phase Ia trial, in which only the clinical toxicity of a new biologic agent is defined as the MTD (10). It is important to remember that the OBD may be different from the MTD for a given biologic agent. In addition, the same agent might have quite disparate OBDs for different immunologic characteristics. IL-2, for example, a cytokine approved for therapy of renal cell carcinoma and melanoma, has been used at high doses to activate cytolytic and helper T cells and natural killer cells. More-recent studies show that low-dose IL-2 used as therapy enables expansion and upregulates functions of regulatory T cells (Tregs). Thus, IL-2 at low doses can be used as a tolerogenic agent in, e.g., graft-versus-host disease or posttransplant rejection episodes (11–13).

In general, phase Ib trials are intended to measure the pharmacokinetics and biodistribution of a biologic agent, together with selected immunologic parameters that, on the basis of the postulated immune mechanism, are likely to influence the disease process. For example, in a patient with cancer who is treated with IL-2, one postulated mechanism for antitumor effects might be an upregulation of T-cell and/or NK-cell activity in the peripheral circulation (14). In this case, monitoring of the T-cell or NK-cell activation status, e.g., expression of activation markers CD69 or CD154 (CD40L) on the surface of T cells and activation receptors such as NKp30 or NKp46 on the surface of NK cells in the peripheral blood during therapy, might serve as a surrogate measure for the therapeutic effects of IL-2, and the dose of IL-2 resulting in the maximal upregulation of these markers (as percent positive cells and mean fluorescence intensity) with tolerable toxicity would be selected as the OBD. However, it is now known that IL-2, by binding to cells that express the IL-2 receptor (IL-2Rα; CD25), activates $CD4^{+}CD25^{high}$ Tregs, among other cell subsets (15). Tregs downregulate immune responses, including the antitumor activity of effector T cells, which is clearly an undesirable situation in a patient being treated for cancer (15). Further, newer data suggest that stimulatory versus inhibitory *in vivo* effects of IL-2 may be dose dependent, as indicated above (11–13). Hence, it seems important to define the OBD for IL-2 that promotes immune activation in a patient with cancer. On the other hand, for subjects with autoimmune diseases, the OBD for IL-2-based therapy might be different, as inhibitory effects are a desired endpoint. This type of rationale is likely to apply to immune system-based therapy in general, and therefore the goal of establishing the OBD is a critical component of the developmental strategy for biologic agents and their application to various diseases.

In most phase Ib trials performed to date, surrogate immunologic endpoints are achieved much more easily than clinical responses. During IL-2 therapy for renal cell carcinoma, for example, virtually all patients develop high levels of endogenous NK-cell activity, while only a fraction of these patients achieve objective antitumor responses (16). In other words, surrogate immunologic endpoints selected on the basis of preclinical results do not appear to correlate with clinical responses, possibly because these endpoints seldom reflect the entire spectrum of physiologic mechanisms mediated by a biologic agent. In considering the pleiotropic activities of biologic agents, it appears that no single surrogate endpoint is likely to correlate with their therapeutic effects and thus with a clinical response. On the other hand, it is possible that a panel of carefully selected monitoring assays might provide a clue about the *in vivo* effects of an agent. For this reason, the current approaches to monitoring favor multiparameter analyses employing new high-throughput technologies, including genomics and proteomics. The possibilities for multiparameter testing now extend to immunologic monitoring, allowing evaluations of more than one surrogate endpoint in patients treated with biologic agents to identify those that are clinically meaningful.

In view of the difficulties experienced to date in selecting immunologic endpoints for monitoring of phase Ib trials, it could be anticipated that a direct measure of the dose of a biologic agent inducing the best therapeutic, e.g., antitumor or antiviral, effects would be preferable to the use of surrogate biomarkers. However, practical and ethical considerations rule out the direct approach of determining the best therapeutic dose. Since antitumor response rates for single biologic agents generally range between 10 and 30%, dose-finding studies would require excessively large numbers of patients

and would expose many of them to ineffective doses of the agent tested. For this reason, the goal of phase I trials is to determine the toxicity and to define the promising OBD of a biologic agent, with the caveat that this OBD might relate only to one particular biologic activity of this agent and that it may not relate to its therapeutic activity. In fact, it is not uncommon to see few or even no clinical responses in phase I trials. But having obtained evidence of safety and a lack of toxicity, it is then possible to expand the earlier clinical observations in phase II clinical studies and to begin asking questions about the dose and mechanisms of action of a biologic agent. Ultimately, an agent's therapeutic efficacy has to be determined in large-scale randomized phase III clinical trials in which the placebo arm is compared to the experimental arm. It is encouraging that in recent years several biologic therapeutics, including monoclonal antibodies (MAbs), cytokines, and some vaccines, have reached the stage of being evaluated for efficacy in phase III clinical trials (17–19).

A RATIONALE FOR IMMUNOLOGIC MONITORING OF CLINICAL TRIALS WITH BIOLOGIC AGENTS

"Monitoring" refers to serial specimen acquisition and testing. The rationale for immunologic monitoring in clinical trials with biologics is based on the premise that these agents achieve therapeutic effects as a result of their ability to modify one or more components of the patient's immune system. The expectation is that by serially measuring immune markers, which undergo significant changes relative to their pretherapy baseline levels, it might be possible to define the immunologic mechanisms responsible for biologic and possibly also clinical activity of a biologic agent. In addition, the objective is to determine whether the observed changes in the immunologic phenotype or function correlate with clinical responses, toxicity, resistance to other therapies, or any other phenomena likely to influence the therapeutic outcome.

The first step toward rational immunologic monitoring is the selection of the most informative assay(s). This selection cannot be arbitrary and has to be based on a specific hypothesis. It would be best, of course, to formulate the hypothesis on the basis of preclinical data available to the investigator from personal experience and from the current literature. The investigator is obliged to use judgment and collective experience to address the likely mechanisms responsible for therapeutic effects. But since most biologic agents have multiple biologic effects, more than one hypothesis of action can be postulated. Which of these hypotheses is ultimately selected for testing depends on the individual insights and preferences of the clinical investigator. However, it is not advisable to test too many hypotheses at once, for fear of making the design of a clinical trial too complex and the accompanying monitoring too extensive. There is no way to guarantee that the hypothesis selected for testing in a clinical trial is correct; hence, the selection of a hypothesis is the most crucial aspect of the trial design and has to be formulated only after a complete review of all preclinical data. As such, a clinical trial is not different from any other hypothesis-driven scientific experiment.

The next step of the scientific process calls for a design of an experimental plan in which the proposed hypothesis can be tested in the most satisfactory fashion. This includes the selection of assays to be performed and the frequency of monitoring. For phase I clinical trials, it is prudent to begin by considering a broad array of immunologic effects because the biologic activity of the evaluated biologic agent may be incompletely understood. It may be advantageous at this stage to consider alternative explanations for its biologic and, possibly, therapeutic effects. Hence, the selected assays should be sensitive rather than specific in order to detect biologic effects when they are induced by therapy. In phase II and III clinical trials, it might be possible to narrow down the selection of immunologic assays to those that were observed to reflect biologic activity or to correlate with clinical responses in previous clinical trials. In place of sensitive screening assays, more-specialized specific or confirmatory assays could be introduced at this time to better focus on the mechanisms of activity mediated by the biologic agent. While no well-defined criteria exist for the selection of optimal monitoring assays, a general principle may be defined as follows. The choice of immunologic assays to be used for monitoring of phase I trials has to be based on solid preliminary data derived from relevant animal models of disease as well as *in vitro* experiments with human cells. In phase II and III clinical trials, the choice of assays to be used has to depend on previous results derived from phase I trials.

STRATEGY FOR IMMUNOLOGIC MONITORING: A PRACTICAL GUIDE

The choice of a strategy for immunologic monitoring of clinical trials with biologic agents is neither simple nor straightforward. No single assay or experimental approach is appropriate for all therapeutic interventions. The selection of the "right" monitoring assays requires familiarity with immunologic assays, judgment, and a considerable understanding of the biologic and therapeutic effects induced by the biologic agent used. Therefore, clinical investigators are obliged to make a number of well-informed and practical decisions, each of which is likely to influence the overall quality of monitoring and, hence, the final results of the trial. To facilitate assay selection and use in monitoring of clinical trials, several practical guidelines are given below, with the proviso that these are neither comprehensive nor applicable to all situations.

The frequency of immunologic assays to be performed is an important component of the trial design. Clearly, it is essential to establish a pretherapy baseline and posttherapy values. Beyond that, the number of time points selected for monitoring during the course of therapy depends on the characteristics of the biologic agent administered. For example, it is well known that cytokines usually have rapid and often dramatic effects on the total number and functions of cells in the circulation or on the levels of other cytokines or soluble cytokine receptors in the serum. Thus, with IL-2 administered as a bolus, rapid lymphopenia followed by a rebound in the number of circulating lymphocytes is observed (20). In contrast, when low intravenous doses of IL-2 are given continuously over a period of time, a gradual rise in the number of circulating $CD3^{-}CD56^{+}$ NK cells is observed (21). More-recent data suggest that IL-2 delivery may also increase the frequency of Treg cells in the circulation or tissues and promote activation-induced cell death (22). These initial effects of IL-2 are followed by delayed effects due to the induction of secondary cytokines. The well-known result of high-dose IL-2 therapy, i.e., transient hypotension observed 4 to 8 h after IL-2 bolus administration, is induced by the secondary cytokines tumor necrosis factor alpha (TNF-α) and IL-1β, which are released in response to IL-2 (20). In clinical trials with cytokines, it is important to measure the pharmacokinetics of the cytokine used for therapy as well as the levels of secondary cytokines in serum, which might be responsible for toxicity of the therapy.

A well-described effect of long-term therapy with biologics is the development of antibodies (Abs) to the administered biologic agent (23). Such antidrug Abs do not arise in every patient treated, and they may not appear until weeks or months into therapy or until multiple courses of the drug are administered. However, their presence in the plasma of individuals treated with the biologic agent is an important factor for the outcome of therapy, because they may either neutralize the drug or contribute to the development of immune complex disease. Therefore, it seems reasonable to monitor for the appearance of such Abs during the course of therapy. This requirement is obviously necessary when therapy with anti-idiotypic Abs is considered, e.g., for some patients with malignancies. Such patients may be treated with an anti-idiotypic Ab (Ab2) that is an internal image of the antigen and can include the production of Ab1 and Ab3, both of which are able to bind the antigen. Since Ab3 is therapeutic and Ab1 may not be, the presence and levels of Ab1 and Ab3 in serum are crucial for the interpretation of immunologic as well as clinical responses (24).

Another important consideration is the transient nature of some immune responses. For example, in vaccination protocols for patients with cancer or viral infections, the appearance of antigen-specific effector cells in the circulation may be short-lived after single or even multiple vaccinations. In this case, assays for the detection and frequency of such effector cells have to be performed often and soon after vaccination. With other vaccines, however, the appearance in the peripheral circulation of the effector cells may be delayed, so their frequency will not increase until late into the vaccination regimen. It thus appears that a decision to monitor the immediate versus delayed effects of therapy with any biologic agent has to be made with caution, after considering possible implications of these effects on the interpretation of immunologic and therapeutic results of the trial. The relative complexity and cost of the assay often influence the frequency of monitoring. For this reason, simple, robust assays that can be reliably performed on serially collected, cryopreserved samples are necessary for frequent immunologic monitoring.

A decision to select cellular versus humoral immunologic assays for monitoring is directly related to the mechanism of action proposed for the biologic agent. While it may be difficult to prioritize on the basis of the limited understanding of such mechanisms, the consideration of practical aspects of monitoring can help in reaching a reasonable decision. Limitations in the frequency of phlebotomy or the total blood volume obtained from the patient during treatment are an important consideration. The variability of cell yields, day-to-day assay variability, and problems with the functional activity of cryopreserved effector cells often restrict the use of cellular assays. These assays are more difficult and more costly to perform than serum-based assays. It is advisable to consider serum- or plasma-based (hereafter referred to as serum/plasma) assays first, especially when they can substitute for cellular assays. For example, the levels of cytokines released by activated cells, the enzymatic activity known to be induced by a particular biologic agent (e.g., interferon-induced 2′,5′-adenylate synthetase), and the presence of inhibitors or antagonists of biologic agents (e.g., IL-1ra) or products of activated cell subsets (e.g., soluble cytokine receptors, β_2-microglobulin, or neopterin) can be more readily monitored with serum or plasma than with cells.

The only *in vivo* assay available for measurements of cellular immunity in humans, the skin test for delayed-type hypersensitivity (DTH), is often underutilized or misinterpreted, largely because of difficulties in the recording and interpretation of test results. Yet when performed and read according to the guidelines, a DTH assay remains the best available measure of epitope-specific cell-mediated immunity in patients with immunodeficiencies, particularly when it is combined with a biopsy to confirm the nature of cells infiltrating the skin. Reagents for purified protein derivative, tetanus, *Candida*, and other antigens are commercially available. Other antigens, e.g., tumor-derived purified or synthetic peptides that are not yet commercially available or commercially available viral peptides, can also be used, provided that they have passed the safety requirements. A change in the DTH skin test from unreactive to reactive as a result of biotherapy is a significant result.

Monitoring of numbers or functions of mononuclear cells (MNCs) in peripheral blood during therapy often does not adequately reflect immunologic events that take place at the site of disease. Systemic effects of cytokines and certain other biologic agents are generally distinct from their local or locoregional effects, and monitoring of lesions, tissues, or organs involved in a disease is likely to yield more-informative data than will the same assays performed with cells or cell subsets obtained from the peripheral blood. The obvious difficulty with this strategy is that blood is more readily available than tissues. Only superficial lesions or sites accessible to repeated biopsies can be monitored. Nevertheless, during a clinical trial, it might be feasible to obtain serial biopsies for *in situ* studies, and this opportunity should not be overlooked. An alternative possibility is to obtain body fluids (e.g., pleural fluids and ascites), in addition to peripheral blood, to be able to detect longitudinal changes in organ-associated immune cells or their products relative to those in peripheral circulation. This approach is especially recommended when intracavitary therapy with a biologic agent is considered.

Monitoring of immune functions generally requires considerable cell numbers, fairly large volumes of blood or other body fluids, and facilities to process these samples for cell recovery. Vigorous attempts are being made to miniaturize immunologic assays and to perform them with whole blood. Newer, more sensitive technologies, including molecular assessments, flow cytometry, electrochemiluminescence, and more-sophisticated single-cell assays, that are generally performed on whole blood greatly facilitate monitoring, decreasing the required blood volume and dispensing with blood processing. The concept of bringing immunologic monitoring to the bedside, with only drops of blood needed for each assay, is slowly beginning to emerge. This approach must wait for further technical advances and for strong correlations to be established between immunologic biomarkers and clinical endpoints. Meanwhile, it appears that a profile of several immune measures determined in the course of therapy and analyzed using specially created software can provide useful prognostic information (25). These preliminary results are encouraging, and they indicate that immune profiling is likely to be more widely adopted for monitoring in the near future.

In general, a protocol schema specifies the time points for sample collection. These samples must be recovered from the peripheral blood, body fluids, or tissues and either used fresh or preserved for future monitoring. For studies of pharmacokinetics, a special effort has to be made to collect the specimens at the precisely designated time intervals and to process them in accordance with the experimental protocol to avoid degradation, inactivation, or loss of activity. In the planning of immunologic monitoring, not only the timing of specimen collections but also the nature of anticoagulants needs to be considered. For example, to measure

levels of cytokines in body fluids, plasma rather than serum is preferable, since cytokines tend to be trapped in the clot, with subsequently low levels of cytokines measured in the serum (26). While the separation of serum/plasma or MNCs from the peripheral blood is a routine laboratory procedure, the recovery and fractionation of cells from tissues or body fluids containing normal or malignant tissue cells are time-consuming and require special expertise and considerable effort (27). The use of individual separated subsets of tissue-infiltrating or blood MNCs is not recommended for serial monitoring, mainly because of a need for tissue sampling and large blood volumes. Also, the lack of uniformly acceptable procedures for cell separations and unpredictable yields of cells recovered from tissues hamper the use of cell separation techniques for monitoring. Nevertheless, the advantage of studies performed with highly purified subsets of immune cells obtained from the site of disease is obvious. When it is feasible to obtain a biopsy prior to and after therapy and to recover viable cells for monitoring of cellular functions, or even of cellular phenotypes, investigators are encouraged to incorporate such procedures in a protocol schema.

It is often unclear which immunologic assays can be reliably performed with fresh versus cryopreserved cells. From a practical viewpoint, it would be more convenient to use serially harvested frozen aliquots of serum/plasma or batched cryopreserved immune cells instead of freshly harvested specimens for immunologic monitoring. The ability to reliably cryopreserve immune effector cells for future use in retrospective studies or for batching of serially collected specimens to eliminate the interassay variability is highly desirable. In fact, the only reliable way to determine differences between pretherapy and posttherapy assays is to perform them at the same time. This strategy calls for banking of cryopreserved specimens (batching) and for assays that can be routinely performed with cryopreserved cells. However, certain immunologic assays, especially those that measure cell functions, e.g., cytotoxicity, are best performed with freshly harvested samples. Cryopreservation may introduce artifacts, even when a rate-controlled drop in temperature is implemented. Therefore, each laboratory is obliged to compare fresh and frozen cells to ascertain that a test can be reliably performed with either before attempting to use them for monitoring. Assays that can be reliably performed with frozen cells and batched specimens are the best candidates for monitoring, but in situations that require the use of fresh immune cells, it is essential to determine the interassay variability to be able to distinguish spurious from therapy-induced changes.

Immunologic cellular assays performed with whole blood as opposed to separated MNCs are especially useful for serial monitoring. Their advantages include the ability to measure the phenotype and functions of effector cells without separation from other blood cells and plasma. Separation procedures are likely to modulate and alter functions of effector cells. Since phenotypic markers on immune cells are generally assessed in whole blood by flow cytometry, it would seem to be preferable to also monitor functions of these cells in the same way. At the very least, the correlations between the phenotypic and functional immune parameters might improve under these assay conditions. The disadvantage is that whole-blood assays have to be performed with freshly harvested specimens, thus eliminating the possibility of batching serial samples.

Technical advances and new insights into immunologic mechanisms have led to the recent development of new types of immunoassays. As a result, a clinical investigator generally has a choice between phenotypic versus functional, specific versus nonspecific, and direct versus indirect assays. The range of assays currently available for monitoring predicates that careful consideration needs to be given to selection of the optimal assay. Assay validation is expensive and requires special expertise. Monitoring of patients enrolled in clinical trials should only be performed in laboratories with established quality assurance and quality control (QC) measures that meet the standards for good laboratory practice, as defined by the FDA. It is important for clinical investigators to realize that serial immunologic monitoring of clinical trials is more rigorous and demanding than performing a series of research assays. To monitor trials with credibility, the laboratory has to have methods in place to ensure reliable serial data (see "QC in Immunologic Monitoring" below).

In Table 1, assays that are currently in use for immunologic monitoring are divided into two broad categories: serum/plasma assays and cellular assays (phenotypic and functional). The rationale for utilizing serum/plasma assays for monitoring instead of more technically demanding and expensive cell-based measurements was discussed above. In the same vein, among cellular assays, flow cytometry is faster, more accessible, and frequently more reproducible than most other assays, particularly those involving radioactive labels. In addition to monitoring changes in levels of serum immunoglobulins or specific antibodies by routinely available rate nephelometry or enzyme-linked immunosorbent assays (ELISAs), a spectrum of other assays can be used to obtain a longitudinal serum profile reflecting changes in one or more cellular products. Generally referred to as proteomics, these assays are discussed below. In some cases, soluble products can serve as activation markers for a particular subset of immune cells, such as neopterin for monocytes or soluble IL-2Rα chain (CD25) for T helper cells. Body fluids can be readily frozen and banked to allow batch processing of the planned assays or for future studies.

PHENOTYPIC ASSAYS FOR IMMUNOLOGIC MONITORING

In many trials with biologic agents, a priority is given to cell surface-based phenotype assays, which are generally performed with fresh whole-blood specimens or cells separated from the peripheral blood, body fluids, or tissues. Flow cytometry-based assays are now widely and easily accessible and highly accurate. Vast arrays of labeled MAbs suitable for multicolor and multiparameter flow analyses are commercially available, allowing for measurements of the proportions of various immune cell subsets. Percent changes in these subsets as well as alterations in the activation level of the cells can be readily assessed during immunotherapy. In designing a clinical trial, flow cytometry markers should be judiciously selected.

Selection of Markers

There has been a tendency to indiscriminately include large panels of immunologic markers to monitor changes in the proportions of several MNC subsets induced by therapy. However, phenotypic assays, like all other immunologic assays used for monitoring, should be selected in order to test the hypothesis advanced as part of a clinical trial. Through the skillful selection of marker panels, it is possible to focus on a single population of effector cells or on several phenotypically distinct subsets, on cells expressing activation markers, or on cells that express a particular constellation of adhesion molecules. Various receptors for growth factors and cytokines on the cell surface can further be used

TABLE 1 Immunologic assays currently available for monitoring of phase I/II clinical trials with biologic agents

Assay type and parameter	Sample type
Soluble cellular products	
Immunoglobulin levels	Serum, plasma, body fluids
Cytokine and chemokine levels and pharmacokinetics (ELISA, multiplex format)	Serum, plasma, body fluids
Cytokine receptors and antagonists	Serum, plasma, body fluids
Other lymphocyte surface receptors (e.g., CD8, CD25, soluble Fas, HLA molecules)	Serum, plasma, body fluids
Ligands (Fas ligand, TRAIL[a]) and growth factors	Serum, plasma, body fluids
Enzymes (e.g., 2′,5′-adenylate synthetase and terminal deoxynucleotide transferase)	Serum, plasma, body fluids
Neopterin	Serum, plasma, body fluids
β_2-Microglobulin	Serum, plasma, body fluids
Phenotypic markers	
Proportions of cells	Whole blood, tissue biopsy, body fluids
Absolute cell numbers	Whole blood, tissue biopsy, body fluids
Cellular subpopulations (e.g., MHC-restricted vs. nonrestricted T cells; Th1, Th2, effector, memory, or naive T cells; Tregs), percentages of positive cells	Isolated lymphocytes
Single-cell flow cytometry (e.g., CFC, tetramers)	Isolated lymphocytes
Functional assays	
In vivo DTH skin test	Visual inspection or biopsy
Cytotoxicity (ADCC,[b] activated NK-cell, NK-cell, or T-cell specific)	MNCs or subpopulations of MNCs
Cytokine production (ELISA, ELISPOT), Luminex-based technologies	MNCs or subpopulations of MNCs
Proliferation (e.g., CFSE, [^{3}H]thymidine, Ki-67 metabolic changes)	MNCs or subpopulations of MNCs
Chemotaxis	MNCs or subpopulations of MNCs
Signal transduction (phosphorylated signaling molecules, NF-κB pathway; PI3K pathway, ζ-chain expression)	MNCs or subpopulations of MNCs
Superoxide generation	MNCs or subpopulations of MNCs
Apoptosis assays (annexin V binding, caspase activity, TUNEL, survival protein expression)	MNCs or subpopulations of MNCs

[a]TRAIL, TNF-related apoptosis-inducing ligand.
[b]ADCC, antibody-dependent cellular cytotoxicity.

to assign the cells to subsets and to relate their phenotypes to the functional potential of these cells. Thus, phenotypic analysis is a powerful tool for monitoring the effects of therapy on immune cells, and the selection of markers to be monitored on T, B, and NK cells and monocytes or granulocytes for shifts induced by therapy and based on the predicted mechanism of action of a tested biologic agent can be informative. A combination of activation markers, growth receptors, cytokine or chemokine binding sites, etc., on distinct and identifiable subsets of MNCs provides a powerful tool for their characterization. Whole-blood specimens can be shipped by overnight carriers for flow cytometry analysis without compromising their quality. If multiparameter analysis is considered desirable but not feasible within one's own institution, it may be advisable to make arrangements with a flow facility specializing in immunologic monitoring. This alternative is strongly recommended for the monitoring of multicenter or cooperative group trials.

Percentages versus Absolute Numbers of Immune Cells

Surface phenotypic characteristics of immune cells are often utilized for assessments of their absolute numbers in whole blood. The development of single-platform methods, which are performed entirely on a flow cytometer, has significantly improved the assay precision and accuracy. The most popular technique is based on five-color flow cytometry in the presence of counting beads. The identification of lymphocytes by the surface expression of bright CD45 and low side-scatter signals is followed by the quantification of T-cell subsets based on the expression of CD3, CD4, CD8, and CD56 and performed in parallel with counting of fluorescent beads. The number of labeled cells per microliter of blood is obtained as follows: number of counted cells × concentration of beads/number of beads counted. Absolute numbers of $CD3^+$, $CD4^+$, and $CD8^+$ T cells are frequently decreased in the circulation of patients with advanced malignancies (28). In contrast, the percentages of these cells may not be decreased, suggesting that absolute numbers rather than percentages of lymphocyte subsets should be measured in disease. The usually reported cell percentages are misleading because they do not consider a total white blood cell count, which is frequently altered in patients with advanced diseases, particularly after previously administered therapies.

Neutrophil-to-Lymphocyte Ratio

The neutrophil-to-lymphocyte ratio (NLR) has recently emerged as potentially useful predictive measure of outcome in oncology. When measured prior to therapy, elevated NLR, in addition to elevated total white cell blood count, predicted adverse clinical outcome in patients with

lung, breast, renal, ovarian, and head and neck cancers (29). Further, a high NLR is a significant but not yet validated marker of poor response to chemotherapy (29). These observations fit well with previously reported low lymphocyte counts in patients with cancer (28) and suggest that high pretreatment NLR may be a significant independent predictor of poor cancer-specific survival.

Intracellular Staining for Flow Cytometry

Flow cytometry has been widely used to measure intracytoplasmic markers. This method requires cell permeabilization to allow for access of MAbs used for detection of the cytosol components or molecules residing in cellular compartments. Because this method detects intracytoplasmic proteins, such as granzyme B, perforin, antigen-presenting machinery components, caspases and other enzymes, cytokines, signal transduction molecules, and transcription factors, measured in phenotypically defined cells, it can provide useful information about the activation state of individual cells or subsets of cells and about their functional attributes. In performing these assays, use can be made of quantitative flow cytometry, which allows for quantification of the expression level of each protein. By the use of a mixture of four types of beads with known fluorescence intensities and unlabeled blank beads, a standard curve is generated that expresses the fluorescence intensities of each bead set in terms of molecular equivalents of soluble fluorochrome (MESF) units for every assay. The mean fluorescence intensity of each unknown sample can be transformed into MESF units by use of this calibration curve. This minimizes day-to-day variability, thus providing a stable and standardized method for use in clinical laboratories. The method has been applied to assessment of the individual antigen-presenting machinery component expression in human dendritic cells as well as to quantitation of other intracellular molecules such as the T-cell receptor (TCR)-associated ζ chain in human T lymphocytes (30).

Epitope-Specific T Cells

The frequency of peptide-specific T cells present in mixed lymphocyte populations can be determined based on the use of biotin- or streptavidin-labeled complexes containing the peptide linked to HLA class I molecules (31). These complexes, referred to as tetramers, represent oligomeric complexes of HLA molecules with a peptide, which have an increased avidity for T cells expressing the relevant TCR. When tetramers bind to the TCR on T cells able to recognize the peptide, a strong, easily detectable fluorescent signal is generated that can be measured in a flow cytometer. The specificity of tetramers for peptide-specific T cells, which is considered their greatest asset, cannot be taken for granted, however, as nonspecific binding may occur under unfavorable experimental conditions. Nevertheless, tetramers are currently widely used to monitor changes in the frequency of peptide-specific T cells in lymphocyte populations before and after vaccinations (32). Tetramer analysis provides the frequency of epitope-specific T cells with sensitivity of 1/10,000 but gives no information about their function.

Another category of flow cytometry assays that has recently gained wide acceptance is cytokine flow cytometry (CFC) (33). This is another single-cell assay that allows for quantitation of individual cells positive for a cytokine detectable in permeabilized cells by the use of cytokine-specific MAbs. CFC is performed following a brief (4- to 6-h) coincubation of lymphoid cells with an antigen to induce cytokine expression in antigen-responsive cells. CFC has been used to measure the frequency of T cells able to respond to antigens expressed by infectious agents such as cytomegalovirus, Epstein-Barr virus, and HIV-1; tumor-associated antigens such as MUC-1; or melanoma differentiation antigens. CFC can provide the phenotype of epitope-specific responder cells and defines the frequency of cells poised to secrete but not yet secreting the cytokine accumulating in the Golgi apparatus. Its sensitivity is perhaps a little better than that of tetramers, and it lends itself well to serial monitoring. There is also the possibility for the use of a combination of tetramers with CFC for a cytokine of interest to better define the functional potential of peptide-specific T cells.

Subtyping of T Cells

In trials with biologic agents, especially vaccines, that might alter the process of lymphocyte maturation, differentiation or migration from, e.g., the naive to memory pool or the circulation to target tissues, the use of a panel of surface markers such as CCR7, CD45RO or CD45RA, CD27, and CD28 has been found to be informative. This strategy allows for determination of the percentages of naive, central memory, effector, or terminally differentiated T cells. For example, the frequency of $CD8^+CCR7^+$ T cells in the peripheral circulation of patients with cancer at the time of diagnosis not only discriminated cancer patients from healthy subjects but also predicted disease recurrence (34). After up to 4 years of follow-up, disease-free survival was found to be significantly shorter for patients with a circulating $CD8^+CCR7^+$ T-cell frequency of $<28\%$ at diagnosis compared to patients with higher percentages of these cells (34). This result suggests that the $CD8^+CCR7^+$ T-cell subset might play a role in cancer control, and that a simple blood test at diagnosis could have prognostic value for predicting cancer recurrence.

Measuring Cell Death

Still another type of a flow cytometry assay frequently used today provides means for enumerating cells that have initiated apoptosis, i.e., are able to bind annexin V, have an altered mitochondrial membrane potential, express high levels of caspase-3 activity or a high Bax/Bcl2 ratio, show evidence of DNA fragmentation ($TUNEL^+$ cells [terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling-positive cells]), or have decreased or absent expression of the TCR-associated ζ chain (35). In patients with advanced cancer or with chronic, persistent infections, a considerable proportion of circulating T cells are destined to undergo apoptosis (22), and flow cytometry offers an opportunity to monitor changes in the numbers of these cells before, during, and after immunotherapy. These methods depend on the use of special substrates, chromogens, or MAbs for the detection of proapoptotic or antiapoptotic molecules in the target cell and generally include cell permeabilization as well as a combination of surface and intracellular staining. The availability of reagent kits that are commercially distributed makes measurements of apoptosis relatively simple, with the caveat that freshly harvested cells are required for analyses of annexin binding to cells, as cryopreservation may impair the integrity of cellular membranes.

Multiparameter Flow Cytometry

The ability, using multiparameter flow cytometry, to simultaneously measure numerous (e.g., up to 15 or more) markers on the surface and/or inside the immune cell has greatly expanded opportunities for serial monitoring of therapy-induced changes. It has provided means for following changes in cellular profiles as well as opportunities to measure rare event analysis, including tetramer-based or

cytokine-based detection of peptide-specific T cells. Further, by incorporating calibration beads with different fluorescence intensities, multiparameter flow cytometry has made it feasible to quantitate expression levels of various cellular components. The numerous advantages of flow cytometry have to be counterbalanced by the requirement for special expertise in its performance and in data interpretation. The reproducibility of flow cytometry-based assays is strictly governed by the operator's skills of setting the gates and excluding nonspecific events and is therefore open to considerable subjectivity. However, newer instruments are equipped with automatic compensation strategies facilitating operation. Aside from gating strategies, which can greatly influence results and thus impose a need for a careful and standardized selection of the most appropriate settings, the interpretation of flow cytometry data in serial monitoring requires stringent controls for interassay variability and a great deal of judgment. While daily calibration solves the problem of instrument variability, other challenges exist. For example, some of the lymphocyte subsets encompass only a small proportion of cells in the gate, and to be able to distinguish shifts induced by therapy from daily assay variability, it may be necessary to acquire a large number of cells for such rare event analyses. Changes in the phenotype of effector cells should be interpreted in conjunction with changes observed in functional assays. Specifically, it is important to consider whether changes in function induced during therapy correlate with changes in the number of effector cells or are due to the augmentation of effector function in a small subset of cells. It is also possible that therapy alters both the number and function of effector cells. During therapy, these changes can be dramatic or subtle, and they can simultaneously occur in several subsets of cells. Analyses of these changes and the establishment of correlations between their magnitude and frequency require special statistical approaches, as discussed below. Since alterations in the proportion or absolute number of effector cells and alterations in function may be mediated by entirely different mechanisms (e.g., increased blood vessel permeability and upregulation of NK-cell activity during therapy with IL-2, respectively), it should not be expected that phenotypic and functional data will necessarily correlate with clinical responses. More likely, no significant correlations will be detected, even though significant changes in the immune cell number and/or function may be registered during therapy. This should not be interpreted as evidence that the immune system has no impact on the disease but rather as evidence that despite therapy-mediated immunomodulation, the disease process persists, undoubtedly because of the involvement of factors unrelated to immune system activity.

Immune Score and Monitoring

Phenotypic studies of immune cells need not involve flow cytometry. With the broad availability of excellent Abs, the immunohistochemical evaluation of cells *in situ* is a powerful method for recording therapy-induced changes in the localization, composition, or activation state of infiltrating immune cells. The importance of *in situ* studies cannot be overemphasized. It is well recognized that the tumor microenvironment has a profound impact on immune cells, and the nature, phenotype, localization, and density of immune cells present in the tumor stroma or parenchyma has long been considered to be critical for tumor progression (36). Immune cells accumulating in human tumors have been extensively examined and found to have unique phenotypic and functional characteristics (36). Initially, it was typing of T lymphocytes in human tumors by immunohistochemistry and correlations of $CD8^+$ T-cell infiltrates with prognosis that suggested the role for immune cells as predictors of risk (36). The report on human tumor-infiltrating lymphocytes in colorectal cancer published by Galon and colleagues in 2006 reaffirmed the prognostic significance of tumor-infiltrating T cells (37). Using modern techniques of systems biology and an objective scoring system, these investigators showed that the type, density, and location of immune cells within tumors predicted positive clinical outcome (37). In a series of studies in colorectal cancer, Fridman's group has demonstrated by immunostaining of hundreds of tumor specimens that a strong local immune reaction, including $CD3^+$, $CD8^+$, and memory $CD45RO^+$ T cells, correlates with a favorable prognosis regardless of the local extent of the tumor or the regional lymph node involvement (38). T-cell infiltrates emerged as a stronger independent prognostic factor than the current clinicopathological criteria, which include tumor size, depth of infiltration, differentiation, and nodal status. A number of other laboratories reporting on the nature and cellular composition of immune infiltrates in human tumors have provided additional support to the concept of "immune score" and its role in cancer prognosis. These results have motivated investigators to propose that immune score be considered as a routine part of the standard pathologic examination (39). It is not clear how soon this practice will be embraced by pathologists, pending method standardization and a requirement for automated image analyses. Nevertheless, globally collected data strongly support the merit of the immune score, and it makes sense to evaluate its predictive value, especially in the context of ongoing biotherapy clinical trials. Thus, the immune score emerges as the first immunologic marker of risk in cancer with the potential to be incorporated into prognostically relevant immune classification of human cancer equal to or better than the conventional TNM classification.

Evidence has accumulated indicating that B cells or plasma cells are present in human tumors, especially in breast cancer (40). Recent results validate the B-cell signature as a robust prognostic factor in breast cancer (40). The immunoglobulin κ chain (IGKC) has emerged as a robust immunologic biomarker of prognosis and response to chemotherapy in patients with breast cancer, non-small-cell lung cancer, and colorectal carcinoma (40). The IGKC was microscopically identified as a product of plasma cells present in the tumor stroma and was validated as a prognostic biomarker by RNA- and protein-based expression studies independently performed in thousands of formalin-fixed, paraffin-embedded specimens at 20 centers. Further, the most important feature of IGKC as a biomarker is that it predicts responses to neoadjuvant therapy in breast cancer and thus qualifies as the first immune marker of response to cancer treatment.

FUNCTIONAL ASSAYS IN IMMUNOLOGIC MONITORING

Monitoring the functions of immune effector cells is considered to be necessary, since their phenotypic characteristics may not adequately convey their functional capabilities. Functional assays are usually performed with peripheral blood MNCs and only rarely with effector cells obtained from the site of disease. Thus, functions of "substitute" cells that are easily accessible for monitoring in the circulation are measured instead of those of the effector cells at the sites of disease. This is by far the greatest limitation of monitoring, since systemic effects of biologic agents on immune cells are likely to be different from local or locoregional effects. The surrogate results obtained with peripheral blood lymphocytes

should not be expected to closely reflect the biologic activity of the drug on functions of immune cells *in situ*. Additionally, investigators need to be aware that at any given time point, circulating lymphocytes represent <2% of a total lymphocyte pool, and that the turnover of circulating lymphocytes is responsible for constant changes occurring at the rate determined by the events in the periphery. To overcome these limitations, attempts are being made to study serial tissue biopsies, utilizing immunostaining and/or *in situ* hybridization or reverse transcription-PCR for cellular proteins and/or mRNA coding for the proteins involved in, e.g., cytotoxicity (perforin, granzymes, and TNF), proliferation (growth factors and cytokines), or signal transduction (the ζ chain and protein tyrosine kinases). The field of genomics has greatly facilitated these studies, providing a new set of tools for rapid screening of gene expression, as discussed below. In some cases, it may be possible to recover a limited number of cells from serial biopsies to perform functional studies. Obviously, these studies are very difficult to perform with human tissues, and they are not practical for the monitoring of many patients at multiple time points. Nevertheless, they are extremely valuable because they allow comparisons to be made between local and systemic effects of a biologic agent on immune effector cells and will eventually justify or discredit the common practice of monitoring alterations in cellular functions in the peripheral blood alone.

Antigen-Driven Proliferation

Proliferation of immune cells in response to a biologic agent, an antigen, or a mitogen has been in the monitoring repertoire for a long time. It can be used as a measure of immunocompetence following stimulation with an activating agent and can be performed with banked cryopreserved cells or as a whole-blood assay. In newer, modified versions, it can be nonradioactive. Proliferation assays can require very few cells if performed in Terasaki plates. As discussed above, it is also possible to use a flow cytometer to read the assay and to confirm the phenotype of proliferating cells. Proliferation assays can be used in conjunction with measurements of cytokines and cytotoxicity. These assays are informative, practical, and adjustable to fit the specific trial design or circumstances in a monitoring laboratory. A large variety of proliferation assays, from [^{3}H]thymidine incorporation into cellular DNA to assays based on metabolic changes in proliferating cells, are available, but flow cytometry-based measurements offer special advantages. By using differently labeled responder and stimulator cells, these methods can be adapted to the quantitation of functional responses in individual cells, cell subsets, or entire populations of cells. For example, the proliferative history of fluorescently labeled cells can be established by determining the number of mitoses experienced by these cells. The principle of the method is that the amount of fluorescent dye taken up by the cell is equally partitioned between daughter cells during mitosis and therefore decreased by half at each cell division. Dyes such as carboxyfluorescein diacetate succinimidyl ester (CFSE) diffuse into a cell and are cleaved by intracellular esterases into compounds that are fluorescent and react with amino groups of intracytoplasmic proteins (41). By combining surface marker staining with CFSE, it is possible to monitor a cell or cell subset through successive mitoses and to determine the number of cell divisions. The use of CFSE allows for quantitative resolution of up to eight cell division cycles (41), and by comparing the number of cells that divided with those that did not divide, a precursor frequency as well as the expansion potential of antigen-specific T cells can be calculated with Cell Quest software.

Cytotoxicity Assays

Cytotoxicity measurements have occupied a special place in the monitoring of immune therapies. There is a good rationale for monitoring cytotoxicity in clinical trials with biologics, which often tend to augment this effector function in many different cell types. In oncology protocols, antitumor cytotoxicity, whether mediated by class I major histocompatibility complex (MHC)-restricted antitumor-specific T cells, nonspecific NK cells, monocytes, or FcγR^+ effector cells mediating antibody-dependent cellular cytotoxicity, has been extensively monitored and correlated to outcome. However, tumor progression/regression and metastasis elimination involve multiple mechanisms and cellular interactions, only some of which are mediated by immune cells. Further, the phenomenon known as "epitope spreading" plays an important role in amplification and extension of antitumor responses once the tumor epitope-specific immune activity is induced by biologic therapeutics (32). The process of antitumor cytotoxicity involves not only perforin- or granzyme-mediated lysis, measured *in vitro* by the release of ^{51}Cr from radiolabeled, sensitive targets, but also necrotic or apoptotic cell death. Each of these types of cell death has somewhat different consequences for antitumor immune response, and methods exist that allow for a definition of the mode of cell death. These assays have not yet been used for routine monitoring, and their value as reliable *in vitro* correlates of antitumor immune activity *in vivo* remains to be determined. It is now clear that a classical cytotoxicity assay measuring only the secretory functions of effector cells is not able to adequately reflect the many mechanisms involved in the process of cytotoxicity *in vivo*. It is for this reason that the classical cytotoxicity assay has been largely replaced in monitoring by more-informative, simpler, and cheaper single-cell assays based on multiparameter flow cytometry or image analysis and the enumeration of spots reflecting antigen-specific cytokine production by individual cells (i.e., enzyme-linked immunosorbent spot assay [ELISPOT]). Nevertheless, in some situations, especially when appropriate cellular targets are available, ^{51}Cr-based cytotoxicity may be useful but as a confirmatory rather than monitoring assay. In most viral diseases, the presence of virus-specific cytotoxic T cells is necessary for recovery, and at least one goal of immunotherapy in patients with chronic viral infections is to induce the *in vivo* generation or activation of such virus-specific T cells. Measurements of such responses would be advisable in this case, but the availability of the virus-infected target cells is obligatory for the assay implementation. Also, in a cancer patient immunized with a tumor peptide vaccine in order to induce antigen-specific memory T-cell responses, it might be desirable to monitor for the appearance of tumor-specific cytolytic T lymphocytes (CTLs). Since, however, the number of such cells in the circulation may be very small even after reimmunization, the choice of a specific as well as sensitive assay is critical. The available data indicate that frequencies of single-epitope-specific T cells in non-antigen-primed circulating lymphocyte populations can be as low as 1 in 10^5 to 1 in 10^6. This means that the standard ^{51}Cr-release cytotoxicity assay, even when used after *in vitro* priming of T cells with the relevant peptide, may not be sufficiently sensitive to measure antigen-specific CTL precursors (CTLp). Its sensitivity is estimated to be 1 CTL in 1,000 cells. The frequencies reported in the literature for CTLp specific for some of the well-defined human MHC class I-restricted epitopes in the peripheral circulation of patients with cancer are too low to be detected in classical cytotoxicity assays. Furthermore, cytotoxicity assays measure the activity of the

population of cells and provide no information about the frequency of individual tumor-specific T cells without an additional step of limiting dilution analysis.

The ELISPOT assay for, e.g., T cells that produce gamma interferon or granzyme B when stimulated with a relevant peptide is the assay of choice for monitoring of clinical trials (32). Using synthetic peptides (either individually or as overlapping peptide mixtures) or whole antigens, even cells, total lymphocyte or isolated T-cell subset responses can be assessed either after short-term stimulation or after their expansion during a 10-day culture (cultured ELISPOT). These assays detect different epitope-specific T-cell responses, allowing for the analysis of effector memory T cells and central memory T cells (42). The ELISPOT assay can be used with cryopreserved MNCs and is sufficiently sensitive to detect 1 gamma interferon-secreting T cell among 100,000 plated cells (43). When used with autologous dendritic cells pulsed with cell lysates or individual peptides, for example, the assay can detect not only $CD8^+$ but also $CD4^+$ responses, which is important in view of evidence that $CD4^+$ helper cells play a crucial role in the induction and maintenance of immune responses. The assay can be set up in a variety of formats, allowing for substantial flexibility in the choice of antigen-presenting cells, ratios of responder to stimulator cells, and the use of *in vitro* sensitization for the expansion of antigen-specific T cells (44). ELISPOT assays performed with patients' peripheral blood MNCs without *in vitro* sensitization measure the frequency of epitope-specific precursor cells in the population of responder cells. Like all other assays for the detection of antigen- or peptide-specific T cells, ELISPOT is HLA restricted.

Even with ELISPOT as an assay of choice, monitoring of epitope-specific T-cell cytotoxicity in clinical trials is logistically and practically complex: it requires prior HLA typing of participants and a priori knowledge of the relevant epitope or the use of lysates of cells that express the relevant epitope. To simplify monitoring, non-MHC-restricted cytotoxicity is measured instead to assess lysis mediated by NK cells, activated T cells, NKT cells, monocytes, or granulocytes. The selection of targets (e.g., NK-sensitive K562 versus NK-resistant Daudi cells), length of the assay (4 h for lymphocytes and 18 h for monocytes), and use of targets coated with the target-specific antibody are some of the variables that can be considered.

Cytokine Production and Levels

In addition to proliferation and cytotoxicity, the ability of epitope-sensitized immune cells to produce cytokines or chemokines has been often used as a measure of immunologic activity induced by therapies. Cytokine gene or protein profiling, whether by multiplex immunoassays, microarrays, or proteomics technologies, is especially well suited to evaluations of the functional potential of immune cells in the tumor microenvironment.

The ability to document polarization in the cytokine repertoire or differences in patterns of their production by immune or tumor cells and of relating them to a specific clinical response has tremendous appeal. Also, as systemic and local therapies with cytokines are becoming increasingly common, there is a need for monitoring cytokine levels during therapy in relation to clinical endpoints. Such monitoring has greatly expanded our knowledge of cytokine and chemokine biology and has provided clinically useful information about cytokine involvement in human diseases. In cancer, considered to be a Th2-dominant disease with excess IL-4, IL-5, IL-10, and transforming growth factor beta (TGF-β) production, a therapeutically driven shift back toward the Th1 profile is of interest, as it might correlate with immune and perhaps clinical recovery (45). Indeed, plasma cytokines have been used as prognostic biomarkers in human diseases (46), with individual cytokines emerging as especially promising markers of survival. For example, elevated circulating levels of IL-6 have been associated with decreased survival in patients with cancer. The production of the proinflammatory cytokines IL-1β, IL-6, and TNF-α, all of which facilitate tumor growth, in the tumor microenvironment might be due to STAT3 hyperactivation in both the tumor and immune cells.

Both bioassays and immunoassays are available for assessments of cytokine levels, but only the latter are practical for the monitoring of clinical trials. Body fluids can be frozen and batched for immunoassays. Currently, multiplex-type assays using antibody-coated colored beads for the capture of multiple cytokines in a small (0.5-ml) sample and laser-type detectors to measure the fluorescence intensity of the individual beads have all but replaced traditional ELISAs. Like ELISAs, multiplex cytokine assays are antibody based but have the advantage of providing a profile of 20 to 30 cytokines in a body fluid at a reasonable cost. Assays for Th1- versus Th2-type cytokines, growth-promoting as opposed to inhibitory cytokines, inflammatory cytokines, hematopoietic cytokines, etc., can be selected to profile cytokines associated with a disease process and to assess changes in this profile during or after therapy. A number of problems with the assessment of cytokines in sera exist, including the ability of cytokines to bind to and form complexes with serum proteins and the presence of soluble cytokine receptors or antagonists, natural inhibitors, or anticytokine antibodies (26). Serial, time-course monitoring for cytokines is usually performed with banked serum specimens. Often, samples are banked for extended periods of time before being tested. It has been reported that the length of storage (months, years) in a −80°C freezer profoundly and significantly alters the measured cytokine levels (47). While IL-8 values generally increased after prolonged storage, those for other cytokines tended to decrease, for example. This serves as a reminder that retrospective measurements of cytokines are highly prone to errors resulting from handling of samples, including specimen storage, as also previously emphasized (26). To avoid pitfalls due to long-term storage and sample freezing-thawing, biomarker analyses should be performed with fresh, prospectively collected specimens. The utility of any one cytokine as a candidate biomarker of clinical outcome has to be carefully scrutinized for bias because it is strictly dependent on the sample integrity, rigorous testing, and results interpretation. To be able to accurately assess and interpret alterations of cytokine profiles in biologic fluids, knowledge of cytokine biology is necessary.

Signaling Pathways

In cancer, chronic infections, and certain immunodeficiency diseases, abnormalities in signal transduction have been identified that appear to be responsible for defective functions of immune cells in these diseases (see, e.g., reference 48). Since it might be possible to correct these abnormalities and thus repair immune functions with immunotherapy, monitoring for the presence and extent of signaling defects is indicated, at least before and after such therapy. The TCR-associated ζ chain is one of the key signaling molecules, and its absence or decreased expression in T cells reflects impaired functions (56). Since ζ is also a component of FcγRIII, its lower-than-normal expression in NK cells signifies the presence of signaling defects in these effector cells as well. Today, various components of major signaling

pathways operating in activated immune cells can be measured using Abs specific for phosphorylated proteins by flow cytometry. Commonly, expression of phosphorylated components of the phosphoinositol 3-kinase (PI3K) or mitogen-activated protein kinase pathways, for example, is measured to gauge immune cell activation. Expression of NF-κB or its components and other signaling molecules in MNCs can be measured by Western blotting, but flow cytometry analyses are quantitative and simpler to use for monitoring. Immunostaining *in situ*, which allows for assessment of the signaling molecules in T or NK cells accumulating at the site of disease, is a very useful indirect measure of the functional state of these cells. The expression of signaling molecules in tumor-infiltrating lymphocytes might serve as an important biomarker of survival for patients with cancer, and changes in the mobility of the NF-κB subunits have been related to impaired function of immune cells in some cancers. Thus, monitoring for the expression of signaling molecules in immune cells has biologic as well as clinical significance (35).

Suppressor Cell Functions

Accumulations of $CD4^+Foxp3^+CD25^{high}$ Tregs and myeloid-derived suppressor cells (MDSCs) in human tumors and their increased frequency in the circulation of cancer patients have been widely reported and linked to poor prognosis due to suppression of antitumor responses by the accumulating Tregs (49). However, in colorectal cancer, the presence and density of $Foxp3^+$ Tregs have been reported to predict favorable outcome and better locoregional control of the tumor (49). These conflicting results are based on the prevalent use of Foxp3 transcription factor expression as a marker of human Tregs. However, a comprehensive review of the prognostic significance of $Foxp3^+$ T cells in 16 nonlymphoid cancers suggested that Foxp3 by itself is not a reliable marker of human Tregs and that biologic effects of $Foxp3^+$ Tregs may be regulated by conditions existing at the tumor site. In view of a lack of a definitive phenotypic marker of Tregs, suppressor function remains their only reliable characteristic. Functional assessments of Tregs include (i) coincubation experiments in which responder cells are inhibited in proliferation, cytotoxicity, or cytokine production and (ii) flow cytometry-based detection of surrogate functional markers, such as TGF-β1-associated molecules or IL-10 (50).

MDSC accumulations in the tumor and blood of cancer patients have also been correlated to poor clinical outcome (51). The problems that confound their use as biomarkers of outcome are 2-fold. First, their tremendous phenotypic and functional heterogeneity creates a situation where everyone evaluates a different subset, making it impossible to compare results. Specifically, $HLA\text{-}DR^{neg}Lin^{neg}$ MDSCs present in the human peripheral blood contain cells with monocytic and granulocytic features, which can be subdivided into at least four distinct subsets ($CD33^+$, $CD11b^+$, $CD15^+$, and $CD14^+$) and which differ with respect to mechanisms used for suppression (52). A recently proposed immunophenotyping schema for MDSCs, which utilizes multiparameter flow cytometry, provides a unifying approach to future evaluations of the role these cells play in disease (53). This, however, does not eliminate the second problem of the sensitivity of $CD15^+$ and $CD33^+$ MDSC subsets to cryopreservation (54). Only the frequency of $CD14^+$ and $CD11b^+$ subsets was not significantly decreased after peripheral blood MNC cryopreservation, although their ability to produce reactive oxygen species after *ex vivo* stimulation was lost (54). These findings led to a conclusion that studies of human MDSCs should be performed in fresh blood samples (54). This requirement complicates monitoring of MDSCs in clinical trials and thus their evaluation as potential prognostic biomarkers.

GENOMICS AND PROTEOMICS IN IMMUNOLOGIC MONITORING

Advances in technology now allow for the simultaneous analysis of different genes in cells or tissues by the use of DNA chips or microarrays. Rapid and cost-effective screening for the expression of multiple genes coding for cytokines, activation markers, components of major signaling pathways, etc., offers a powerful new approach to monitoring of cell activation, differentiation, or proliferation in response to biotherapy. The technology involves mRNA extraction from cells or tissues and its subsequent labeling and hybridization to the microarray. The hybridized products are visualized in a phosphorimager and analyzed with software capable of comparing control with test samples to detect differences in the expression of selected genes. In this way, upregulation or downregulation of gene expression in tissues or cells exposed to a biologic agent can be monitored.

Similar to gene arrays, technologies combining two-dimensional PAGE with mass spectrometry allow for simultaneous analysis of many hundreds of proteins in body fluids or tissues. It is expected that pathological changes in tissues or cells are reflected in distinct protein patterns detectable in body fluids or cellular supernatants. Proteomic technologies are able to discriminate between normal and pathological protein patterns and can be used to map protein changes associated with a disease process. The potential of these technologies for capturing distinct protein patterns that could serve as biomarkers or be correlated with clinical responses or prognoses is being actively explored.

Gene and protein profiling, whether by multiplex immunoassays, microarrays, or proteomic detection methods, may be of special importance in relation to cytokine-based therapies. The clinical use of cytokines for therapy of human diseases has been increasing. Discoveries of new cytokines and their availability as recombinant proteins as well as cytokine gene therapies have facilitated the pharmacologic use of cytokines. Systemic or local therapies with these mediators, which induce one another and amplify cytokine circuits, call for careful monitoring of cytokine levels in relation to clinical endpoints. Given the dynamic and rapid progress in cytokine assay development, it appears likely that such monitoring will shortly provide a wealth of clinically useful information about cytokine involvement in human disease.

QC IN IMMUNOLOGIC MONITORING

QC of immunologic assays, particularly cellular assays, is difficult, and QC of serial immunologic measures represents a special challenge. To meet the challenge, a well-designed and rigorously maintained QC program is a requirement in a monitoring laboratory. Such a QC program contains several components, including the definition of standard operating procedures, training of personnel, instrument maintenance, reagent control, review of quality, and proficiency testing. Laboratories performing immunologic monitoring for clinical trials are required to implement their own QC programs to ensure that acceptable data are generated. Currently, no model QC programs exist, but monitoring laboratories are encouraged to follow the good-laboratory practice guidelines defined by various professional groups. A good example is the MIATA program (55). Other proficiency testing programs are becoming available for many

immunologic monitoring assays, and participation in these programs is highly recommended.

An important aspect of serial immunologic monitoring is the documentation of changes from baseline upon treatment. This is possible only when measurements taken over time are assessed accurately. Thus, each assay selected for monitoring has to be vigorously controlled for intra-assay and interassay variability. Also, the reproducibility of the same assay used for individual patients tested at different times has to be ensured (biologic variability).

The process of QC begins with sample collection and processing, which have to be organized to meet the protocol schema and occur at specified times of the day and, presumably, before the next cycle of therapy. Blood samples for immunologic monitoring need to be routinely harvested in the morning to avoid diurnal variability. The flow of specimens and the recording of the collection and arrival times of samples are critical activities in a monitoring laboratory. Although immunologic monitoring assays should be scheduled in advance, times of sample arrival tend to vary. The laboratory is obliged to establish strict guidelines for sample handling and to document problems in accordance with the quality assurance requirements. A precise history of each sample must be maintained. Processing must be uniform and follow standard operating procedures that are available in writing and regularly updated. Frequent checks of reagent quality and equipment performance have to be implemented. The decision to cryopreserve cells or use fresh cells is made prior to the clinical trial and has to be based on preliminary comparative studies using fresh and cryopreserved lots of the same normal MNCs, which need to be performed for every assay. This is a crucial decision for monitoring, because the selection of assays that can be batched (i.e., performed at the same time for all cells collected in the course of the trial) will avoid day-to-day variability and considerably decrease the cost of monitoring.

Regardless of whether cryopreserved or fresh samples are used, standardization of all assays has to be performed prior to the beginning of a clinical trial. The importance of the reproducibility of assays used for longitudinal monitoring cannot be overemphasized. The standardization data are obtained by repeatedly performing the assay with cells obtained from healthy individuals under invariant and previously optimized experimental conditions to establish the mean, median, 80% normal range, and coefficient of variation. The intra-assay variability is also determined. When the standardized assay is ready for monitoring, a set of appropriate controls is selected, and these depend on whether fresh or cryopreserved cells are used. With fresh cells collected at different time points, repeated testing of preserved control samples (e.g., cryopreserved lots of normal MNCs with a predetermined range of reactivity) is necessary to control for day-to-day variability. With fresh cells, it may also be advisable to include fresh control cells obtained from a healthy volunteer. A pool of volunteers repeatedly tested over time can be established for this purpose. A QC program in place will ensure that the values obtained for an individual control sample remain within an acceptable range over time and specify when the assay results are considered out of the normal range. With cryopreserved cells or frozen serum/plasma, it is best to batch and test all serial samples from a patient in one assay. Even in this case, however, it is necessary to control for day-to-day variability to have some assurance that the assay performs equally well for all patients in a protocol. The data obtained from control samples, evaluated in parallel with each patient sample, can help to ensure the validity of the results for a particular day's assay. Whenever universally accepted standards are available (e.g., the World Health Organization standards for cytokines), these should be regularly included in the monitoring of assays. Alternatively, internal controls initially compared with the standards can replace the standards, which are often available in finite quantities, for routine use.

STATISTICAL ANALYSIS OF DATA FROM IMMUNOLOGIC MONITORING

In preparation for final data analysis, the results of immunologic monitoring are "cleaned," i.e., purged of errors made during data entry. We have found it helpful to monitor for such errors at several levels. First, the technologist who performs the test enters the results into the computerized database, after examining the daily controls and finding the assay acceptable. The technologist is least likely to make errors in entering the results of an assay that he or she just performed. Second, prior to the final analysis, a statistician generates summary data sheets, which are screened by the laboratory monitor, often a laboratory supervisor, who is intimately familiar with the assays. All outlier values identified by the computer are checked and verified by the monitor against the laboratory records. Third, all variations from the protocol schema are noted for each patient. It is necessary to confirm that all measurements were made at the time points specified in the original treatment schema. Because of the importance of the timing of samples relative to the treatment, a change in the schedule or dose of therapy or in the sequence of sampling may have profound effects on the results of immunologic monitoring.

The biostatistician performing the analysis of immunologic data should interact closely with the clinical immunologist. The statistician should be consulted with respect to trial design and should be involved in its planning. The statistician's input is vital in determining the number of patients necessary to adequately define an OBD.

Immunologic data are often normalized for analysis with a logarithmic scale. The statistical analysis selected depends on the trial design and hypotheses tested, but since pre- and posttreatment changes are generally measured, the analysis seeks to determine if the changes from baseline are significant. Typically, pretreatment baseline levels are established by computing medians of three pretreatment determinations. Medians are preferable to means, as they are not influenced by extreme data points. Nonparametric tests for differences in posttreatment levels relative to the pretreatment baseline can include tests such as the Wilcoxon signed rank test or analysis of variance with Fisher's protected least-significant-difference method to determine pairwise differences between two specific time points. Comparisons between treatment groups can be accomplished by multiple regression analysis to permit simultaneous contrasts between groups, using a pooled estimate of the variance for all groups. Dose-response analysis utilizes parametric repeated-measure dose-response models that are fitted to posttreatment data, controlling for between-patient differences by including the pretreatment level as a covariate. Repeated-measure analyses are potentially sensitive to occasional extreme data points, and the use of robust fitting methods, which downweigh the influence of extreme data points, is important. The monitoring data are generally presented as a series of time plots, which are adjusted by subtraction of the estimated contribution of each patient's baseline level, so that the plots depict the relationship that would exist if all patients' baseline values were equal to the overall pretreatment average.

ROLE OF THE CLINICAL IMMUNOLOGIST IN IMMUNOLOGIC MONITORING OF CLINICAL TRIALS

The clinical immunologist should play a major role in the design, execution, and analysis of clinical trials that include immunologic monitoring. Many clinicians fail to consult or include the clinical immunologist in the trial design, expecting only to utilize the technical expertise of such an individual. Equally, many clinicians forget that the interpretation of immunologic data is never straightforward and requires special training and considerable experience. The clinical immunologist is likely to be well aware of the preclinical evidence regarding the biologic agent that is being evaluated and can help design a trial based on the agent's mechanism of action. The clinical immunologist can help not only by formulating a correct and rational hypothesis but also by giving advice regarding how best to test this hypothesis by utilizing the assays at hand. The clinician will be best served by working closely with the laboratory staff when monitoring is ongoing, and close daily interactions between the clinical and laboratory teams are necessary for collecting samples and obtaining meaningful data. It is desirable to have the clinical immunologist oversee the performance of assays and be responsible for the QC program in the monitoring laboratory. Equally important responsibilities of the clinical immunologist are the interpretation of results and data analysis, with the latter being performed in conjunction with the statistician. Ongoing discussion between the principal clinical investigator, the immunologist, and the statistician is necessary for the correct analysis and interpretation of immunologic monitoring data.

Immunologic monitoring of clinical trials has entered a new era. Technical developments and molecular insights into interactions of immune cells have expanded the field of opportunities for capturing and analyzing multiple therapy-induced changes in the phenotype and functions of immune cells. The greatest challenge, i.e., relating these changes to clinical endpoints, remains, however, and still requires close and effective teamwork between the clinician, the laboratory immunologist, and biostatistical personnel. Contributions from informatics experts are likely to become equally important. Cooperation and insights provided by each team member will facilitate meaningful monitoring, and the benefits of utilizing combined expertise in all aspects of clinical trials with biologic agents or any other trials monitoring immune responses can be considerable.

Circulating Tumor Cells as an Analytical Tool in the Management of Patients with Cancer

DANIEL C. DANILA, HOWARD I. SCHER, AND MARTIN FLEISHER

111

SHEDDING OF CTC AND THE METASTATIC PROCESS

Circulating tumor cells (CTC), first described in 1869 as cells in the blood identical to those of the cancer itself (1), originate from the primary tumor or metastatic deposits after intravasation through the tumor vasculature by mechanisms that are not completely understood (Fig. 1) (2). Although most CTC die in the circulation, a proportion of them have the ability to spread, seed, and proliferate in distant sites to form secondary metastases (3) (estimated to be 0.05%) or to reestablish in the organ of origin to form new tumors (4), as demonstrated in short-term proliferation experiments (3, 5). First described by Paget in 1889, in his "seed and soil" hypothesis (6), the process of metastatic dissemination is driven by chemokines and integrins specific to the tumor type and by the adhesive interactions of the CTC with the vasculature and extracellular matrix components (4, 7–9). As an example, β4 integrin signaling promotes tumor cell adhesion to the endothelium through ErbB2-mediated vascular endothelial growth factor secretion and has been involved in metastatic development (10). Additionally, CTC have the ability to secrete stem cell-like factors to promote proliferation and self-renewal (11, 12). Microembolic clusters of CTC, isolated by a variety of techniques, are associated with a particularly poor prognosis, which may be related to the enhanced activation of survival pathways by cellular contact and to mechanical capture in the microvasculature, further enabling metastasis formation (13, 14).

As a consequence of vascular spread and the microenvironment, tumor cells can be identified in the bone marrow as disseminated tumor cells (DTC). These DTC are in some cases detected more frequently than CTC found concurrently in the blood, and their detection is associated with an increased risk of tumor recurrence (15–20). DTC can also serve as a reservoir organ of CTC for further dissemination (3, 21, 22). At this time, testing for the presence of DTC is not routinely performed for patients with solid malignancies because of the uncertainty of the information provided by the assay; however, they are performed at diagnosis and serially for patients with leukemias and lymphomas (23).

After seeding a potential metastatic site (24), tumor cells have to adapt to a hypoxic, nutrient-deficient, and low-pH environment (25) in order to remain in a viable yet dormant state for extended periods (16, 26). During disease remission, a dormant heterogeneous tumor cell population may undergo a dedifferentiation process, known as the epithelial-mesenchymal transition (EMT), adapt characteristics of stem cells through reprogramming, or selectively enrich for tumor cells with stem cell-like features (27, 28). Eventually, dormant tumor cells are stimulated by intrinsic mechanisms or by the stroma microenvironment to facilitate active proliferation into visible metastases and to promote invasive features and spread hematogenously as CTC again (28).

MORPHOLOGY AND CHARACTERISTICS OF CTC

The range of CTC phenotypes is postulated to recapitulate the heterogenic range of cells found at metastatic sites, such that they can be a source of tumor for profiling to understand the mechanisms of disease progression and to guide treatment selection in an individual patient at the time that treatment decisions are made. Because CTC are shed into the peripheral circulation from both the primary tumor and multiple heterogeneous metastases, they can represent a spectrum of malignant phenotypes, including tumor-initiating cells with stem cell or stem cell-like properties, the full range of undifferentiated to differentiated phenotypes that lack tumor-initiating capabilities, and cells that have undergone an EMT (29, 30). Therefore, there is no single definition of a CTC; rather, there are specific definitions that relate to particular tumor cell types, which are profiled by physical characteristics, such as size or shape, or by molecular markers.

Importantly, the EMT from an epithelial to a fibroblast-like cell morphology is accompanied by decreased expression of epithelial adhesion molecules (e.g., E-cadherin) and increased expression of mesenchymal molecules (e.g., vimentin and N-cadherin), leading to increased mobility and invasiveness (29, 30) and increases in important cancer stem cell properties (31, 32). The EMT phenotypic change is important not only mechanistically but also from the point of view of CTC detection and characterization, because many capture technologies utilize antibodies to epithelial cell adhesion molecule (EpCAM), which, although commonly expressed on the majority of primary tumor cells, may be downregulated or absent on the subsets of CTC that have undergone EMT (33, 34). Similarly, cells with stem

doi:10.1128/9781555818722.ch111

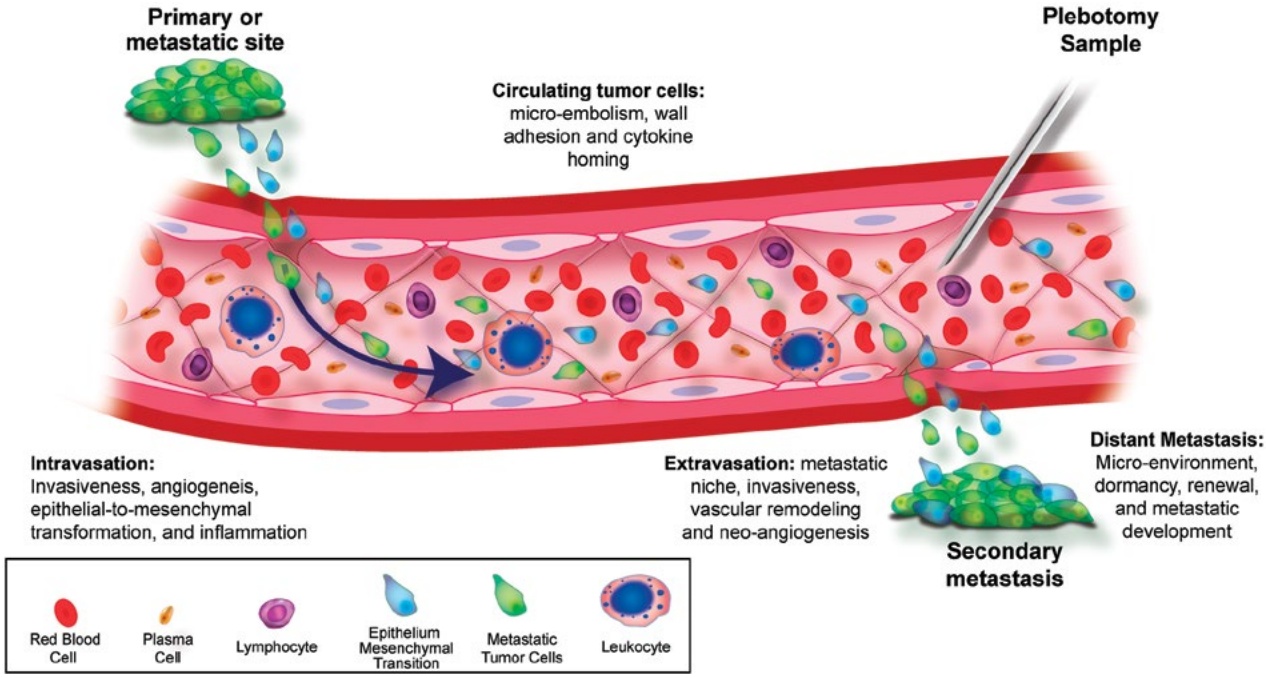

FIGURE 1 CTC in the process of metastatic progression. Tumor cells transition from the primary or metastatic site into the circulation to establish secondary sites. (Reprinted from reference 2 with permission of the publisher.)

cell or stem cell-like properties may also lack EpCAM or cytokeratin expression (35). In addition, DTC in the bone marrow must undergo a reversal of EMT (called MET) to form a solid metastasis. It is therefore possible that cancer cells with a high degree of plasticity to undergo both EMT and MET are the "real" metastasis initiator cells. Different degrees of EMT have been found to occur in solid tumors. Tumor cells with a partial EMT (an "intermediate phenotype" between epithelial and mesenchymal) have shown increased aggressiveness and the ability to survive in suspension as single cells (36).

DETECTION METHODS

CTC are rare in the peripheral blood of patients with a variety of metastatic carcinomas and are currently estimated to account for 1 cell in a billion nucleated cells. In contrast to invasive procedures, such as biopsies, a blood test for CTC or bone marrow aspiration and biopsy for DTC are safe and can be performed with minimal patient discomfort on a repeated basis at low cost (Fig. 2) (37).

Different assays are needed for different contexts of use and different decisions which the test results will be used to inform, whether related to prognosis, prediction, pharmacodynamics, or a measure of patient benefit. For example, these assays may enable a determination of the risk of relapse or the risk of metastasis development or may guide the decision on adjuvant therapy based on posttreatment CTC enumeration.

The definition of a CTC varies with the assay used to isolate, capture, visualize, and/or enumerate cells, and different assays detect different subsets of cells and different biologic determinants in the respective subsets. As such, an individual assay must be evaluated critically from the point of view of which subsets of cells are being captured and/or analyzed, the performance characteristics of the assay that is used for particular types of measurement, and how the results are reported (14, 34, 38, 39).

CellSearch Immunomagnetic Isolation

The CellSearch (Janssen Diagnostics LLC) immunomagnetic isolation technique uses antibodies to EpCAM conjugated to magnetic beads for the immunomagnetic capture of EpCAM-expressing epithelial cells. EpCAM-expressing cells are automatically displayed visually and manually scored as CTC by a trained technologist, based on strict morphologic and immunohistochemical staining characteristics. A captured cell is classified as a CTC if it expresses cytokeratin, displays a nucleus when stained with 4′,6-diamidino-2-phenylindole (DAPI), and is not a white blood cell as determined by a lack of expression of CD45 (40). The results are reported as the number of cells meeting the morphologic and immunohistochemical definition per 7.5 ml of blood, as analytically validated (40) and formally cleared by the FDA as an aid in the monitoring of patients with metastatic breast (41–44), colorectal (45, 46), or prostate (47–49) cancer. Importantly, the number of cells meeting the criteria for CTC is only a small proportion of the EpCAM-positive events displayed (50). Events not counted, for example, include EpCAM-positive cell fragments, cells undergoing apoptosis, necrotic cells, and anucleated cells.

For patients with metastatic prostate cancer, CTC isolated by this method have the biologic determinants unique to prostate cancer, including expression of prostate specific antigen (PSA) and alpha-methylacyl-coenzyme A racemase and prostate-specific genomic abnormalities, such as androgen receptor (AR) gene copy number amplifications, phosphatase and tensin homolog (*PTEN*) deletions, and TMPRSS:ETV fusion products (51, 52). It is underappreciated that the proportion of cells visible in the chamber and meeting the strict criteria defining CTC represents only 1

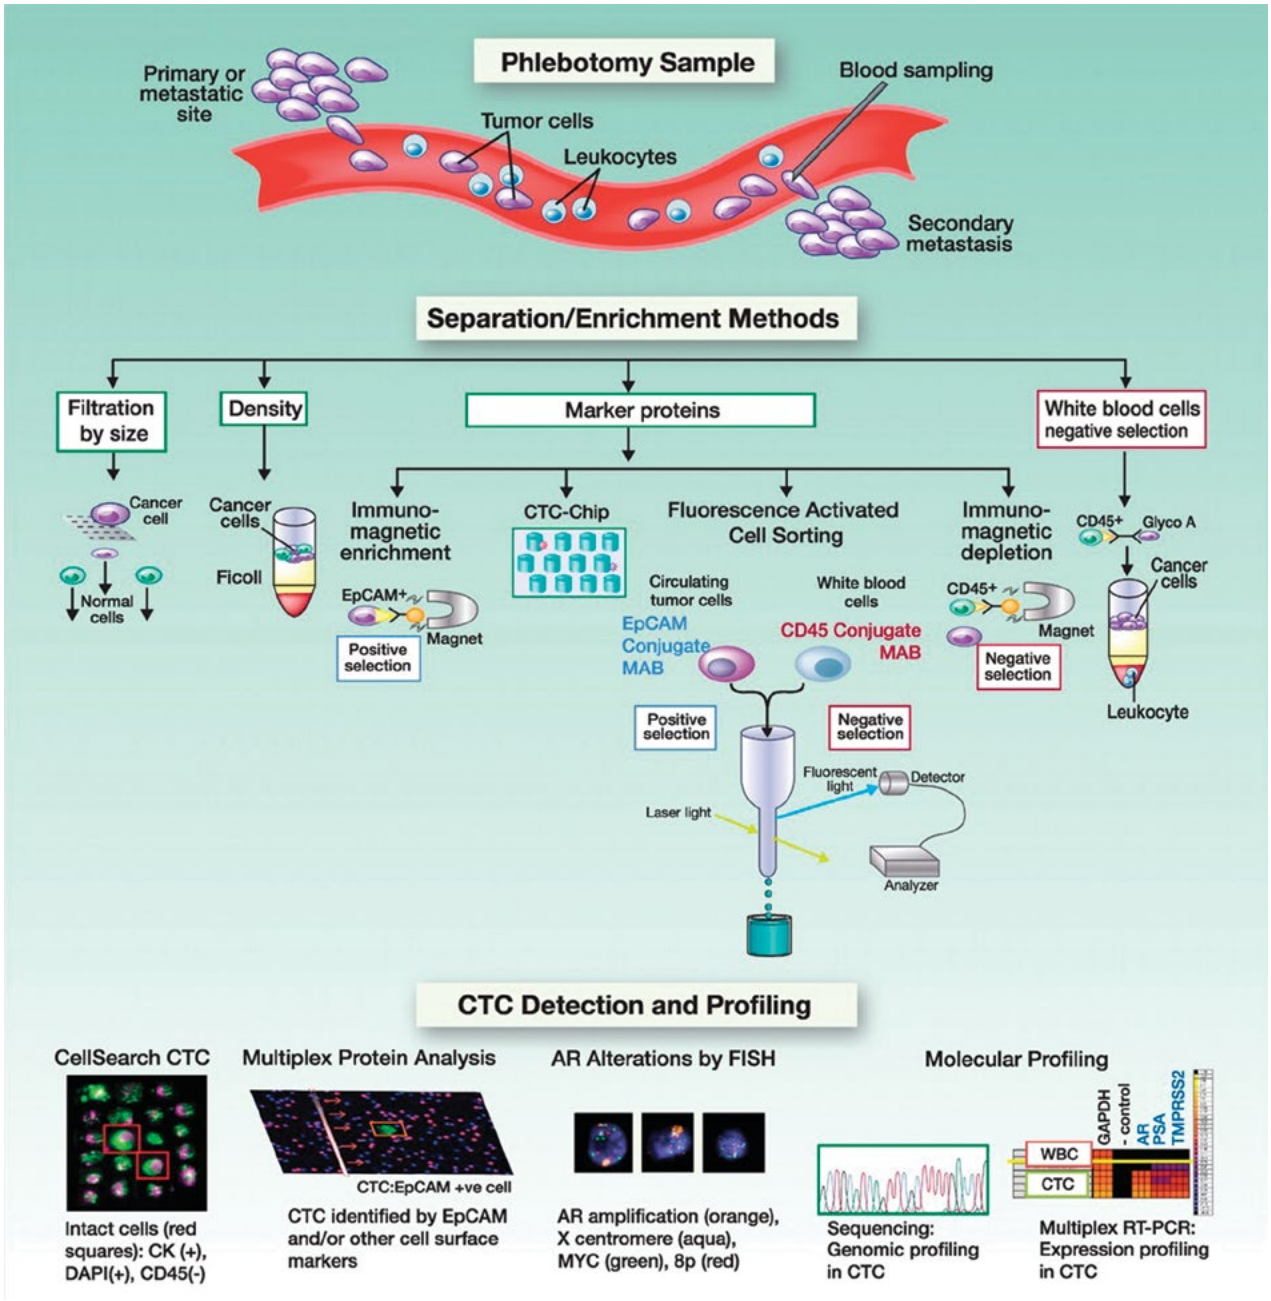

FIGURE 2 CTC in patients with cancer. Sampling of CTC by phlebotomy at the time that treatment is being considered has the potential to provide tumor material for molecular profiling of biomarkers informative of tumor sensitivity to the targeted therapy being considered. FISH, fluorescence *in situ* hybridization. (Reprinted from reference 37 with permission of the publisher.)

to 10% of the cells actually present. The sensitivity of the test can be increased if all $EpCAM^+$ CK^+ $CD45^-$ events are counted, a measurement that is prognostic for survival (50). This finding, however, has not been validated analytically or clinically and is not currently reported routinely.

Because the assay employs positive selection based on immunomagnetic enrichment for tumor cells expressing EpCAM, it is not useful for the isolation of cells from tumors that do not express EpCAM, such as malignant melanoma and renal cell carcinoma. For these tumors, a different "hook" is necessary to capture tumor cells from the circulation. Capture of these cells requires non-EpCAM-based methods, such as negative-depletion strategies that remove leukocytes followed by specific staining of the remaining mononuclear cell fraction with antibodies to markers specific to the tumor under study (11, 12). In an exploratory study of patients with melanoma, the isolation of cells based on the expression of a melanoma-associated chondroitin sulfate proteoglycan allowed the recognition of circulating melanoma cells based on morphology (53).

Flow Cytometry Methods

Flow cytometry methods are used to enrich for more homogeneous and highly purified tumor cell populations separated based on multiple cell surface and intracellular markers. The technique is useful for the evaluation of expression profiles of CTC (54–56), such as the isolation and capture of $EpCAM^+$ $CD45^-$ cells from a mononucleated layer separated from blood through a Ficoll-Hypaque gradient. DAPI is used as a vital stain to exclude permeable and apoptotic cells. Cells isolated by fluorescence-activated cell sorting were shown by multiplex reverse transcription-PCR (RT-PCR) to express tumor-specific mRNAs, indicating that these $EpCAM^+$ events were *bona fide* CTC (37). Another technique uses photoacoustic properties of tumor cells, such as melanoma cells, to enrich for CTC after stimulation by laser light, coupled with flow cytometry for further purification and isolation (57). By isolating CTC with a higher purity, these approaches have the potential to enable in-depth molecular profiling of CTC for a larger cohort of patients, enabling the study of gene signature patterns in the heterogeneous population of CTC. Whole-genome amplification from the cellular events isolated by sorting also enables mutational analyses and studies of copy number alterations at the level of single cells as prognostic and predictive biomarkers (58). Flow cytometry- or fluorescence *in situ* hybridization-based methods to identify sarcoma-specific fusion genes are currently being tested (59–61).

Microfluidic Capture Platforms

Microfluidic capture platforms allow sensitive and selective detection of CTC for enumeration and further molecular profiling at the genomic, transcriptional, and translational levels for CTC isolated from patients with lung, breast, or prostate cancer (5, 14, 62). Reports using this technology have shown CTC isolation and capture rates at points in an illness where the CellSearch assay does not detect cells, such as localized prostate cancer (39). A herringbone configuration designed to create turbulence maximizes gentle cell contact with the surface of the chip while minimizing cell trauma. These platforms allow the isolation and capture of viable cells harboring mutations that predict tumor sensitivity to targeted therapies as well as clinical outcomes, such as the epidermal growth factor receptor T790M activating mutation in non-small-cell lung cancer (63, 64) or the KRAS mutations in colorectal cancer (65). Additional designs stagger obstacles to optimize cell size-dependent flow to increase contact with capture antibody-laden surfaces, where prostate specific membrane antigen-based immunoselection allows enrichment of EpCAM-negative tumor cells (66). Novel generations of this technology allow the isolation of CTC based on inertial focusing-enhanced microfluidic chips or ferrofluidic separation in strategies that are either dependent on or independent of tumor membrane epitopes on CTC from patients with epithelial and nonepithelial cancers, such as lung, prostate, pancreas, and breast cancers and melanoma (67, 68).

Functional Assays

Functional assays allow detection of CTC based on tumor-specific metabolic capabilities. Epithelial immunospot (EPISPOT) assays detect CTC based on the release of full-length CK19 by carcinoma cells of various origins (12). For patients with breast cancer, detection of CK19-releasing cells in blood by EPISPOT assay predicted a lower overall survival rate, and the combination of the EPISPOT and CellSearch assays was the strongest predictor of OS in multivariate regression analysis (69). Tumor antigens mucin 1 and PSA were detected in the majority of patients with metastatic breast and prostate cancers, respectively, whereas the test results were negative for healthy controls or patients with benign prostatic hyperplasia (70). Collagen adhesion matrix assays allow enrichment of CTC based on their ability to ingest and invade connective tissue-like material. Although it is in the initial development phase, this method could allow for a functional separation of more aggressive, invasive types of CTC from patients with prostate or breast cancers (71). Dielectrophoretic array technologies displace blood cells when they pass over microelectrode array configurations designed to separate cells as a function of cell size and electrostatic charges. Cells isolated in this way can be characterized by microscopy or could be analyzed for predictive molecular biomarkers based on relative fluorescence parameters combined with morphology (72–74).

Filtration Assays

Filtration assays capture CTC based on their large size and inflexible biophysical properties relative to those of hematopoietic cells when passed through a porous membrane. Several different pore sizes and shapes have been tested. Advantages of these systems are the ability to perform CTC analysis, including immunocytochemistry, directly on the membrane, as well as the agnostic enrichment of CTC indifferent of EpCAM expression, which allows collection of EMT cells, CTC with stem cell-like features, and circulating cancer-associated macrophage-like cells (75–79). These approaches miss small cells, but in the process of CTC recovery, cancer-associated macrophage-like cell populations have been noted to associate with CTC and provide highly sensitive biomarkers for solid tumors. These tumor-associated giant cells are capable of binding to CTC and facilitate their transport and mobilization through the peripheral circulation of cancer patients (79, 80).

Genome-, Transcription-, and Translation-Based Assays

Genome-, transcription-, and translation-based assays have long been utilized to detect low levels of cancer-specific mRNAs in the mononuclear cell fraction of the blood that are presumed to be from CTC. mRNA for PSA has been tested in the peripheral blood of patients with prostatic cancer (81, 82), and mRNA has been used for detection of CEA, CK, and CD133 in patients with colorectal cancer (83). Additional markers are under investigation for detection of CTC from patients with breast, prostate, lung, melanoma, and head and neck cancers (84–91). An RT-PCR method targeting EWS-FLI-1 or EWS-ERG transcripts was studied for patients with Ewing tumors to detect evidence of occult tumor cells (92). Additional methods isolate CTC from blood by using immunomagnetic methods to preenrich cells for increased detection of tumor-specific mRNAs of breast, prostate, EMT, or stem cell-like cells (93). In some cases, the tumor-specific mRNA detected in the mononuclear cell fraction represents phagocytosed tumor cells in macrophages and does not represent intact tumor cells. To increase the detection sensitivity and tumor-specific molecular profiling of CTC from the blood sample, selection techniques (MagSweeper, AdnaTest, and IsoFlux) have been used to enrich for CTC or to deplete white blood cells before in-depth molecular profiling (68, 94–96).

Agnostic Methods

Agnostic methods to characterize CTC do not enrich for a specific epitope marker or use a physical size-specific capture method; instead, all nucleated blood cells are analyzed

by immunofluorescence and cytometry for tumor-specific markers by use of high-throughput multiparametric imaging systems (Fig. 3) (80). Such technologies have allowed the identification and characterization of tumor cells in relation to their primary tumors in patients with breast, colorectal, and lung cancers (80, 97).

CLINICAL UTILITY OF CTC

Targeted approaches are useful for cohorts of patients with tumors that express the target. A clear unmet need for patients with metastatic cancer is for reliable outcome measures of the clinical benefit at the time of reassessment and treatment selection. Optimal use of these agents for patients with progressive cancer requires new blood-based assays to profile recurrent metastatic disease in a "liquid biopsy" sample to guide treatment selection based on biologic profiles. A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological or pathogenic processes or pharmacologic responses to therapeutic intervention (98). This will ultimately accelerate clinical trials and improve clinical care.

Context of Use

Context of use represents the specific clinical settings in which the results of an assay will be used to inform a medical decision. As drugs are approved for indications, biomarkers are qualified for specific contexts of use as detailed in the FDA Critical Path (99, 100). No single assay can fulfill the requirements for clinical validation or qualification for all contexts of use. The trial designs needed to establish clinical validity and qualification will also differ as a function of which assay, if any, is currently available that addresses the context of use.

The specific contexts of use where qualified biomarkers would influence medical decisions include the following:

1. Detection—use of the biomarker to establish a diagnosis.
2. Prognosis—measuring the probability of a specific clinical outcome, such as recurrence, progression, or survival.
3. Prediction—identifying the chance of response to a specific therapy. Treatment resistance biomarkers define biologic determinants of failure or progression, such as second-site mutations.

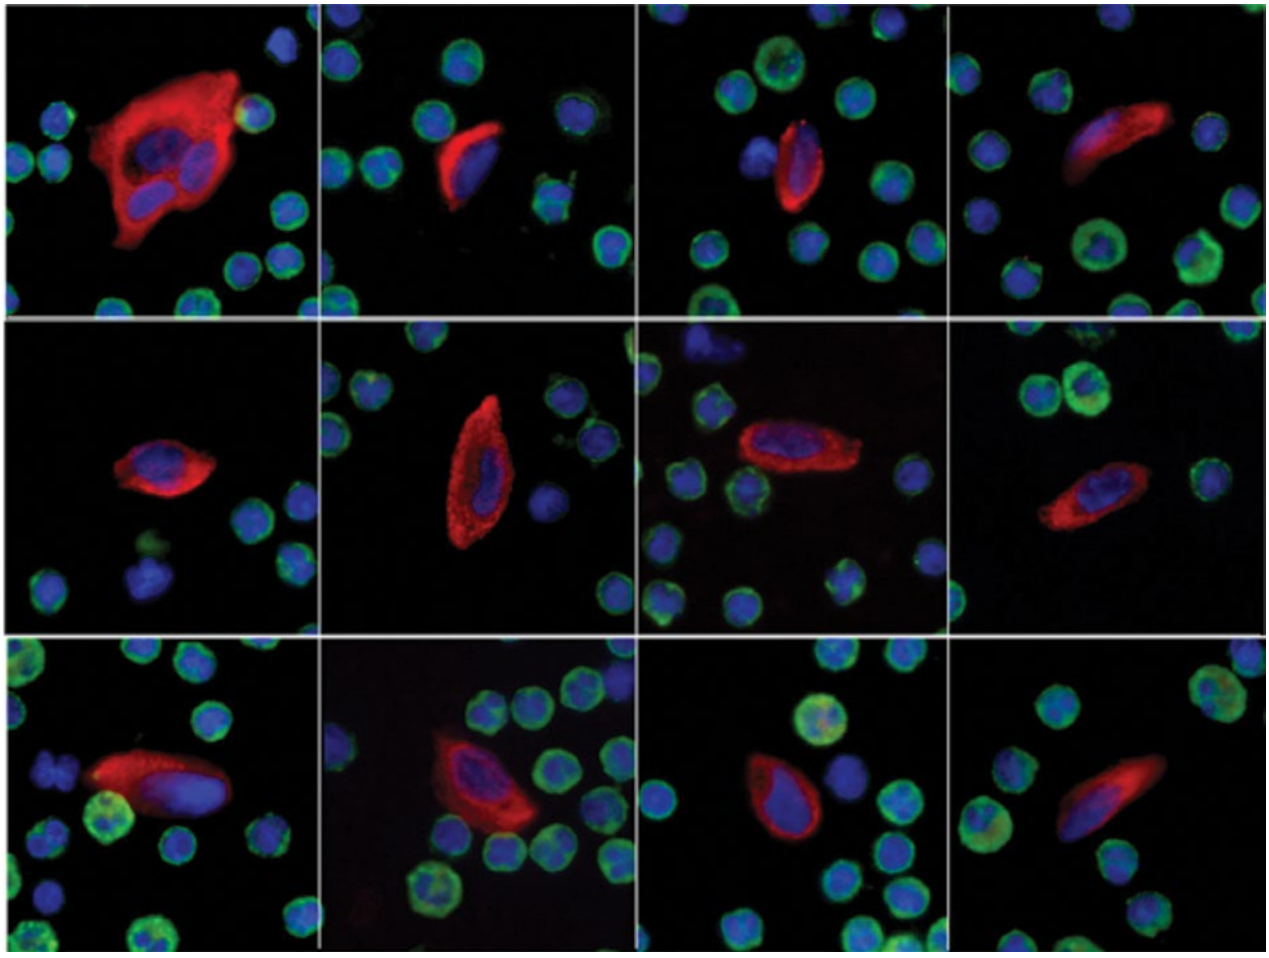

FIGURE 3 Immunofluorescence and cytometry assay by use of high-throughput multiparametric imaging systems for detection of tumor-specific markers in the peripheral blood mononucleated cell fraction for patients with metastatic cancer. Immunostaining for cytokeratin (red) and the nucleus (DAPI; blue) separates morphologically distinct tumor cells from surrounding white blood cells stained by CD45 (green). (Reprinted from reference 80 with permission of the publisher.)

4. Response—response indicator biomarkers demonstrate a pharmacologic or physiologic response to the treatment, which does not necessarily mean that the patient has benefitted from a treatment.
5. Efficacy—efficacy response biomarkers are surrogates for how a patient feels or functions or how long he or she survives and are used to extrapolate the clinical benefit.

Analytical Validation

Analytical validation establishes the performance characteristics of an assay and the range of conditions under which an assay gives reproducible and accurate data. In this process, rigorous performance testing is required to meet Clinical Laboratory Improvement Amendments (CLIA) regulatory requirements. Validation requires a rigorous performance that can be considered in three steps: (i) preanalytical assessment of specimen selection, handling, processing, and storage parameters; (ii) validation of analytical characteristics to meet CLIA regulatory requirements, establishment of the inter- and intra-assay precision, linearity, and analyte recovery, and standardization and development of a comprehensive quality control program; and (iii) assessment of postanalytical parameters requiring data management.

Clinical Qualification

Clinical qualification, distinct from the analytical validation, is the evidentiary process of linking a biomarker with biological processes or clinical endpoints in the context of an intended use to inform a medical decision as described in the FDA Critical Path (99, 100). Because there are more biomarkers than questions, and given the effort and cost to conduct these investigations, it is essential to develop metrics to determine which biomarkers that appear promising warrant prospective testing in large-scale phase III trials to establish qualification.

CTC Enumeration by CellSearch Assay as a Prognosis and Response Indicator Biomarker

CTC enumeration by CellSearch assay as a prognosis and response indicator biomarker was tested in a series of clinical trials of similar design in patients with metastatic breast (41–44), prostate (48, 49), and colorectal (45, 46) cancers about to start a new line of therapy. CTC measured at baseline and at subsequent follow-up visits were used to define patient groups with favorable and unfavorable prognoses based on disease-specific cutoffs (for the favorable group, 4 or fewer CTC per 7.5 ml of blood for breast and prostate cancers and 2 or fewer CTC per 7.5 ml of blood for colorectal cancer). In this context, CTC enumeration was prognostic of median progression-free survival and overall survival (Table 1) (42, 101). Posttreatment CTC enumeration remains prognostic 4, 8, or 12 weeks after initiating treatments in this context (45, 46, 48, 49, 102). These studies resulted in FDA clearance of the CellSearch system to measure CTC as a marker of prognosis in the monitoring of patients with metastatic breast, prostate, and colorectal cancers and as a response indicator biomarker by serial testing for CTC in conjunction with other clinical methods, as described in the 510(K) document (103).

In a head-to-head comparison for patients with metastatic castration-resistant prostate cancer starting a new line of chemotherapy, the posttreatment CTC number was a stronger prognostic factor for survival than a 50% decline in PSA (area under the concentration-time curve for the receiver operating characteristic curve, 0.87 versus 0.62) (48, 49). The discriminatory power of baseline CTC counts for survival was analyzed in a multivariate proportional hazards model with the concordance probability estimate (104). Baseline CTC counts (analyzed with the dichotomous definition of unfavorable versus favorable) had the strongest association with survival time (hazard ratio [HR], 1.58; 95% confidence interval [CI], 1.41 to 1.77) compared to PSA (HR, 1.26; 95% CI, 1.10 to 1.45). Additional baseline factors associated with decreased overall survival included high lactate dehydrogenase levels (HR, 6.44; 95% CI, 4.24 to 9.79) and low hemoglobin levels (HR, 0.72; 95% CI, 0.64 to 0.81).

In a separate analysis, CTC counts were related to survival time as a continuous function by using nonparametric smoothing analysis without a threshold effect (47). This argued against the use of discrete CTC cutoff values in decision-making, a finding confirmed in multiple studies (49).

As a response indicator of treatment outcome, CTC conversion is more associated with survival than is a decline in PSA, as measured at 4, 8, and 12 weeks (48, 49). The most prognostic factors for survival were baseline lactate dehydrogenase levels and the fold change in CTC count from baseline to the follow-up time of measurement (concordance probability estimate, 0.72 to 0.75) (49). A biomarker panel containing CTC number and lactate dehydrogenase levels was demonstrated to be a surrogate for survival at the individual-patient level in a randomized trial with a novel antiandrogen, abiraterone acetate, for patients with metastatic prostate cancer (105). These findings suggest that monitoring the CTC number as early as 4 weeks posttreatment may add clinical data to assist in treatment decisions.

Molecular Characteristics of CTC

Molecular characteristics of CTC observed by PCR-based assays have been tested as prognosis and response indicator biomarkers. The frequency of detection of PSA mRNA in peripheral blood of patients with prostatic cancer correlated with the tumor stage (81, 82). Detection of additional

TABLE 1 Context of use for baseline CTC count as a prognostic biomarker for overall survival for patients with metastatic disease from the Immunicon 38 trials[a]

Type of cancer	Threshold for unfavorable CTC count	No. (%) of patients with unfavorable baseline count	Overall survival based on CTC counts (mo) (mean [95% CI])		Cox HR; log rank *P* value	Reference(s)
			Favorable group	Unfavorable group		
Prostate cancer	<5	219 (43)	21.7 (21.3–>26)	11.5 (9.3–13.7)	3.3; <0.0001	48, 49
Breast cancer	<5	177 (49)	21.9 (20.1–>25)	10.9 (6.4–15.1)	2.45 (1.64–3.65); <0.0001	44
Colorectal cancer	<3	413 (26)	18.5 (15.5–21.2)	9.4 (7.5–11.6)	2.45 (1.77–3.39); <0.0001	45, 46

prostate cancer enriched genes in whole blood collected in PAXgene tubes by a sensitive and analytically validated PCR assay was demonstrated to have predictive value for overall survival in patients with metastatic castration-resistant prostate cancer and was complementary to CellSearch CTC enumeration (91). Detecting CEA, CK19, CK20, and/or CD133 mRNA by RT-PCR was a significant prognostic factor for overall survival (HR, 3.84; 95% CI, 2.41 to 6.22; $P < 0.001$) and disease-free survival (HR, 3.02; 95% CI, 1.83 to 5.00; $P < 0.001$), in particular for patients with Dukes' stage B and C colorectal cancer (83). Serial monitoring by RT-PCR of a multimarker panel for circulating melanoma cells during biochemotherapy may be useful for predicting therapeutic efficacy and disease outcome for patients with metastatic melanoma, although additional studies are necessary (106).

CTC as Biomarkers Predictive of Tumor Sensitivity

As biomarkers predictive of tumor sensitivity, CTC have the potential to provide a snapshot of the molecular makeup of an individual patient's tumor to profile the determinants that predict sensitivity or resistance to treatment at the time of treatment decision. Such a "liquid biopsy" will definitely improve the understanding of tumor growth biology, which can change during the course of disease. Predicting the likelihood that a patient will benefit from a targeted therapy requires a demonstration that the "target" is present in the tumor when treatment is considered. Currently, molecular profiling of heterogeneous tumors is limited by a lack of representative tumor samples in routine clinical practice settings (107).

For prostate cancer, recent reports evaluated alterations in AR at the protein, RNA, and DNA levels (52, 107, 108), IGF-1R expression (109), and TMPRSS2-ETV fusions (52, 94), which have been postulated to increase the likelihood of response to a therapy targeting the specific signaling pathway. AR amplification, although infrequent in primary/diagnostic tumor specimens, is detected in upwards of 50% of castration-resistant lesions (110, 111). AR genomic amplification and copy number gain have been documented for CTC from patients with castration-resistant prostate cancer, with frequencies similar to those reported for late-stage tumors (52, 108).

Detection of a kinase mutation predictive of tumor sensitivity in CTC has potential for clinical application in selecting patients with metastatic colorectal or lung cancer who are most likely to benefit from epidermal growth factor receptor-targeted therapies (64, 112, 113). Combining a microfluidic enrichment system and a mutation assay for KRAS has been proposed to improve the sensitivity of longitudinal tracking of such oncogenic mutational changes, with high success rates (65). The prognostic value of HER2/neu, IGF-1R, and AR splice variants expression in CTC is currently being studied in the context of clinical trials with novel therapies targeting these markers, as a potential tumor sensitivity predictive biomarker, and as a pharmacodynamic measurement for defining the optimal dose, not just the maximum tolerated dose (51, 108, 109, 114).

There are many more potential contexts, and the analytical validation of these assays is ongoing. Although promising, these results still require a rigorous validation across independent cohorts of patients in the appropriate context of proposed use. Since it is not clear which biomarker will be most informative for a medical decision to address a specific context of use, there must be a process for prioritizing biomarker development, first in short efficacy trials in the selected context of use, before beginning full development of a biomarker in large, costly phase III trials.

THE FUTURE OF CTC IN THE CLINIC

Recent work with several tumor types has shown that patients in whom CTC are detected, by use of a variety of different assays, have an inferior prognosis relative to that for patients in whom CTC are not detected and that the "elimination or decrease" of CTC following treatment is associated with improved clinical outcomes (115). The observation in a prostate cancer population that CTC could be detected in patients on hormonal therapy with no measurable PSA suggests that seeding may continue despite seemingly successful therapy and that the continued detection of CTC could provide unique information. Equally intriguing is the potential for the biologic characterization of CTC to provide a profile of an individual patient's tumor that can be used to guide treatment selection, i.e., a liquid biopsy to enable personalized medicine in cases where the potential for point-of-care tests is clear.

The approval of new therapies for patients with cancer based on overall survival requires large cohorts with a lengthy follow-up. Qualified biomarkers for discrete contexts of use have the potential to shorten the drug development process. More significant power to discriminate between low and high risks of a specific outcome could be obtained by combining multiple biomarkers, such as CTC, with additional blood-based as well as radiologic or tissue-based biomarkers, which will ultimately result in a "basket" biomarker meant to influence medical decision-making.

Histocompatibility and Immunogenetics Testing in the 21st Century

QIUHENG ZHANG AND ELAINE F. REED

112

The scope of immunogenetics and histocompatibility testing in transplantation has changed dramatically over the past 50 years. In organ transplantation, outcomes continue to improve as a result of better immunogenetics testing, immune suppression, and patient management; however, acute rejection and chronic rejection remain the biggest obstacles for successful transplantation. Since "crossmatching" was first described by Patel and Terasaki (1), the goal to provide accurate immunological risk assessment for transplant recipients remains unchanged. Histocompatibility and immunogenetics laboratories utilize multiple diagnostic assays to evaluate HLA compatibility between donors and recipients. Furthermore, testing has expanded to include immunogenetics systems other than those using HLA, such as killer immunoglobulin-like receptors (KIR) (2, 3), major histocompatibility complex (MHC) class I chain-related gene A (MICA) (4), angiotensin type 1 receptor (AT1R) (5), and genes encoding cytokines. The application of new state-of-the-art diagnostic tests that inform on the immune status of the transplant recipient has transformed the role of the immunogenetics laboratory from providing tissue-typing and crossmatching services to assessing immunologic risk, donor selection, and presentation of strategies for desensitization and therapeutic intervention. In addition, immunological risk assessment is no longer limited to the pretransplant period but has become increasingly recognized as a noninvasive tool for assessing acute and chronic rejection (6–8).

The MHC, or human leukocyte antigen (HLA), genes are the most polymorphic in the human genome. The highly polymorphic nature of the MHC genes is the foundation of immune responses for both solid-organ transplantation and hematopoietic stem cell transplantation (HSCT). Sanger sequence-based HLA typing has long been considered the "gold standard" for high-resolution typing; however, this method cannot readily distinguish between polymorphisms on the same chromosome (*cis*) or different chromosomes (*trans*), thereby creating ambiguities that are difficult, time-consuming, and expensive to resolve. Recently, a massive parallel sequencing technology, also referred to as next-generation sequencing (NGS), has been developed to sequence the entire HLA gene. Full-length sequencing of a haplotype provides phasing between linked polymorphic sites in both exons and introns, resulting in fewer ambiguities and higher resolution typing results (9, 10). These results will ultimately lead to improved matching and survival. Chapter 113 by Kunkel et al. explains the premises behind various molecular techniques used to differentiate HLA alleles and how to apply one or more of these methods to achieve the degree of typing resolution required for a given clinical application.

Introduced in 1968 by Terasaki (11), the complement-dependent cytotoxicity test became the standard technique for serologic typing, antibody screening, and crossmatching in the 1960s and 1970s. Panel-reactive antibody, or PRA, is used to identify sensitized patients and estimate their likelihood of finding a crossmatch-compatible donor from a panel of healthy blood donors representing the HLA types of the potential organ donor pool. The presence of HLA antibodies at titers sufficient to give a positive cytotoxicity crossmatch has been considered a contraindication for transplantation. Nowadays, cytotoxicity still has an important role in histocompatibility laboratories as a functional assay, and it remains the standard test for antibody crossmatches. Introduction of solid-phase assays in the mid-1990s has allowed for a more comprehensive, sensitive, and cost-effective method for detection of HLA antibodies than the traditional complement-dependent cytotoxicity test. Precise measurement of HLA-specific antibodies permits more accurate risk assessment for patients awaiting transplantation, participating in kidney exchange programs, and undergoing desensitization procedures. Many laboratories have begun to correlate solid-phase test results with cell-based crossmatch test results and have employed this information to develop accurate "virtual" crossmatch predictions to define unacceptable donor HLA antigens for optimizing donor selection for transplantation. A kidney allocation process using calculated PRA (cPRA) was implemented by the United Network for Organ Sharing (UNOS) on 1 October 2009 (12). The cPRA uses the patient's HLA class I and class II antibody specificities to determine the frequency of these unacceptable antigens in the donor population and thereby predicts the probability of a positive crossmatch. A complete review of the patient's sensitization history, including transfusions, pregnancies, and previous transplants, is critically important to accurately define unacceptable HLA antigens for sensitized patients. Increased numbers of unacceptable HLA antigens result in a dramatically diminished potential for receiving organ offers, prolonged wait times, and the death of patients on the wait list.

The demand for organ transplantation has rapidly increased over the past decade. The number of patients on the

doi:10.1128/9781555818722.ch112

wait list at the end of 2014 had risen to over 120,000, while the number of patients receiving deceased-donor transplants remains just over 2,000 annually due to the organ donor shortage. The donor shortage has placed an increased emphasis on attempts to expand live-donor transplants, when possible. However, approximately one-third of kidney transplant candidates who present with a potential living donor(s) will be incompatible owing to blood type or HLA incompatibility. To address this limitation, kidney paired-exchange (KPD) programs have been established to enable kidney transplant candidates with willing but incompatible living donors to join a registry of other incompatible pairs in order to find potentially compatible transplant solutions. To maximize donor-recipient matching and minimize immunologic risk, these multicenter KPD programs use sophisticated algorithms combined with desensitization therapy to identify optimal match potential, with two, three, or more simultaneous complex multiway exchanges. In the United States, KPD has increased dramatically in the past decade (13, 14), from three transplants facilitated in 2000 to 581 in 2013. Clinical protocols using high-dose intravenous immunoglobulin (IVIG) or a combination of IVIG and plasmapheresis with or without rituximab and bortezomib are being used to successfully desensitize and perform transplants on patients who otherwise might have waited years for a compatible deceased-donor organ (15–18). Laboratory support for these innovative clinical protocols is vital and is highly dependent upon timely, complete, and accurate assessment of the levels and specificities of patients' antibodies.

Given that allograft rejection can occur in HLA-identical transplant recipients in the absence of demonstrable donor-specific HLA antibodies, the clinical relevance of non-HLA antibodies is increasingly recognized (19, 20). Non-HLA antibodies can reliably be detected by solid-phase assays (MICA, AT1R, collagen-V, vimentin) and by a flow-crossmatch technique testing for antibodies against donor endothelial progenitors or surrogate endothelial cell lines. In addition, with the advancement of many high-throughput genomics, proteomics, and ProtoArray methods, efforts have been made to understand the mechanisms of graft rejection and identify novel biomarkers for acute rejection, chronic rejection, and tolerance. Five of the chapters in this section focus on the methods that are being used to monitor and evaluate transplant patients. Sikorski and colleagues in chapter 114 compare the various techniques for defining clinically relevant alloantibodies and illustrate the utility of these assays in clinical desensitization protocols, and Jackson and Dale describe current methods for detecting non-HLA antibodies in solid-organ transplantation in chapter 115. In chapter 116, Metes et al. discuss approaches to evaluate cellular sensitization that can be employed in steroid withdrawal protocols and posttransplant monitoring for rejection or tolerance. As summarized by Tan et al. (chapter 117), improved reagents have led to an increased appreciation of the association between complement activation in transplants with poor outcomes (21–23). In addition, the advantages and disadvantages of various reagents to complement used for the diagnosis of different types of rejection in transplants have been discussed. Dadhania et al. (chapter 118) describe molecular and proteomic techniques that permit earlier and more sensitive detection of allograft rejection.

The key factors in predicting survival after bone marrow transplantation or HSCT are the stage of disease and the degree of HLA matching. There is a progressive decrease in survival after HSCT, with each HLA allele mismatch reducing the probability of overall survival at 5 years by approximately 10% (24–26). The availability of suitable donors is problematic for many patients who are candidates for HSCT. The ideal donor for HSCT is an HLA-identical sibling, but only 30% of patients have a suitable matched related donor. Efforts to increase the number of available donors have fostered altruistic donor registries, with more than 50 such registries worldwide. One of the largest registries is the National Marrow Donor Program (NMDP), which presently has more than 10 million typed potential marrow and peripheral blood stem cell donors and more than 185,000 cord blood units. Registry data show that patients receiving transplants from HLA-A, -B, -C, and -DRB1 locus (8/8) allele-matched unrelated donors have outcomes significantly superior to those of patients receiving transplants from donors with one or more mismatches at these loci, while the clinical relevance of matching at the DQB1 locus remains unclear (25). It is estimated that 31 to 75% of patients, depending on ethnic background, are able to find an 8/8 matched unrelated donor in the registry. Recently, retrospective analyses looking at HLA-DPB1 mismatches according to T-cell epitopes showed that nonpermissive mismatches were associated with increased risks of overall mortality, transplant-related mortality, and severe acute graft-versus-host disease (GVHD) compared with permissive mismatches or DPB1 matches (27). Therefore, selecting the best donor, when there are several donors equally matched for HLA-A, -B, -C, and DRB1, may be further narrowed by evaluation of the DPB1 haplotype. Selection of a matched or permissive DPB1 haplotype appears to decrease early nonrelapse mortality but does not impact long-term survival. Alternative sources of stem cells from umbilical cord blood (UCB) serve as a valuable source of hematopoietic stem cells for allogeneic transplantation when a matched sibling or unrelated donor is not available, since UCB requires less stringent HLA matching (28, 29). A major advantage of umbilical cord stem cells is that they can be obtained in less than 4 weeks, which is particularly important for patients with rapidly progressive malignancies. One of the disadvantages of UCB transplantation, however, is that it is associated with a high degree of graft rejection and treatment-related mortality, which appears to be directly associated with UCB cell dose. For transplants with some degree of HLA mismatching, accurate determination of humoral sensitization is required to assess the risk of engraftment failure due to antibody-mediated rejection. The relationship among KIR matching, expression, genotype, and transplantation outcomes has also been an area of intense interest, with rapidly evolving data and insights. In HLA-identical or nearly HLA-identical transplantations, other aspects of KIR physiology may take on a more important role. KIR haplotype A encodes mainly inhibitory receptors and only one activating receptor, while KIR haplotype B encodes more activating receptors. Donors in whom the centromeric B genes were present had a lower rate of relapse and superior rates of survival of acute myeloid leukemia (AML) (2). Compared with homozygous A/A donors, grafts from homozygous centromeric B/B donors resulted in a lower cumulative incidence of relapse. In chapter 119 of this section, Rajalingam et al. focus on the polymorphism of the KIR genes and report that defining KIR alleles and haplotypes is applicable to areas other than HSCT, as KIR genotypes may affect susceptibility to autoimmunity and viral infections.

Graft rejection, disease relapse, and GVHD are major complications after allogeneic HSCT. Short tandem repeats (STRs) are highly polymorphic DNA sequences in the human genome. The basic principle of chimerism detection is based on the differences between donor and recipient

polymorphic genetic markers. Quantitative monitoring of mixed chimerism of self and donor origins after HSCT by STR analysis has become a routine diagnostic tool in the detection of engraftment failure, predicting rejection and disease relapse (30, 31). Baxter-Lowe discusses in chapter 120 the techniques that can be employed to determine both engraftment of donor stem cells and the relative degree of donor-recipient chimerism.

In summary, the following chapters describe the exciting technologies developed during the past 2 decades in histocompatibility and immunogenetics laboratories which advance the care and management of transplant patients using precision-based medicine.

Molecular Methods for Human Leukocyte Antigen Typing: Current Practices and Future Directions

MARK KUNKEL, JAMIE DUKE, DEBORAH FERRIOLA,
CURT LIND, AND DIMITRI MONOS

113

OVERVIEW

The characterization and clinical assessment of the human leukocyte antigen (HLA) genes has undergone significant advances over the last 50 years. As serological methods have given way to more-advanced molecular methods, our understanding of the complexity and polymorphic nature of the HLA genes has been substantially improved. From its basis in serological and cellular testing in the 1960s (antibody and mixed lymphocyte culture) (1–5), through two-dimensional electrophoresis and restriction fragment length polymorphism analysis in the 1970s and '80s (5, 6), the development of PCR in the mid-1980s revolutionized our molecular understanding of the HLA genes. From PCR, methods utilizing sequence-specific oligonucleotide probes (SSOs) and sequence-specific primers (SSPs) provided the means for more directly evaluating the highly variable sequence motifs within the HLA genes (7–10). Subsequently, in the 1990s, Sanger sequence-based typing (SBT) significantly advanced tissue typing and transplantation genetics (11–14) by providing an unprecedented molecular view of HLA polymorphism in the context of exonic variation. Most recently, next-generation sequencing (NGS) appears to definitively address HLA typing complexity, as it provides entire HLA gene characterization and haploid sequence determination.

From the discovery of the first HLA antigen, MAC (by Jean Dausset in the late 1950s) (15), to the rapid discovery of many more antigens throughout the 1960s (16), the scientific community recognized the need for common reagents, tests, methods, and formal naming conventions for the proteins responsible for self/nonself recognition. The first international HLA workshop in 1964 set the stage for identifying reliable, tested antisera for serological typing and established official nomenclature (17). In conjunction with these workshops, mixed lymphocyte culture testing, developed in the 1960s, quickly demonstrated the inadequacy of serological typing alone, as reactivity (and rejection) was often observed between subjects who were serologically identical (18). At the same time, Rolf Zinkernagel and Peter Doherty in the early 1970s discovered (19, 20) that immunologic effector cells, T cells, recognize and respond to a specific antigen only if a peptide from the antigen is presented in the context of an HLA molecule.

The Role and Polymorphic Nature of HLA Genes

Even with a basic cellular and humoral understanding of HLA protein function, the concept of major histocompatibility complex (MHC) restriction, in light of antigen binding and presentation, wasn't fully understood until the HLA protein structure was determined in the late 1980s (21–23). The identification of the HLA protein's antigen-binding pocket explained how allelic polymorphisms within the pocket create the potentially millions of variable antigen specificities from just a few genes. Therefore, the highly polymorphic nature of the HLA genes is largely related to their necessary immune function, where, as receptors for foreign antigens, the HLA proteins must display a vast repertoire of potential antigen-binding conformations. In the late 1980s and 1990s, as molecular methods like SSO, SSP, and SBT were fully developed (7–14), the HLA genes were recognized as some of the most polymorphic in the human genome and formed the basis for the creation of an HLA allele sequence library, whereby all known HLA alleles could be recorded. The very high variability of the HLA genes and their respective proteins interacting with both self and nonself peptides has implications in organ and bone marrow transplantation, autoimmune disease, response to infectious disease, and even response to medications (pharmacogenomics) (24–29).

Organization of the HLA Genes and the Ensuing Protein Structure

The HLA genes are located on the short arm of chromosome 6 within the MHC region, which encodes many immune response proteins (30, 31). Beyond the standard class I (*HLA-A*, *-B*, and *-C*) and class II genes (*HLA-DRB1/3/4/5*, *-DQA1*, *-DQB1*, *-DPA1*, and *-DPB1*) targeted by HLA typing, there are multiple class I and class II "related" or pseudogenes spread across ~3.5 Mb of the MHC (for a complete list, see Table 1).

The class I molecule is a transmembrane protein made up of a single HLA polypeptide heavy chain (encoded by a single MHC gene) that is associated noncovalently with β-microglobulin (a protein encoded by a nonpolymorphic, non-MHC gene) (Fig. 1). For class I proteins, the antigen recognition site (ARS) is encoded by exon 2 (α1 domain) and by exon 3 (α2 domain). Exon 4 encodes a region (α3 domain) that associates with β-microglobulin and is proximal to the cell membrane. Of most importance to tissue typing, exons 2 and 3 are the most polymorphic and encode the peptide-binding domains involved in antigen presentation, which is why traditionally only polymorphisms in exons 2 and 3 were assessed. More recently, class I HLA typing has

doi:10.1128/9781555818722.ch113

TABLE 1 HLA genes, gene fragments, and pseudogenes[a]

Name	Previous equivalents	Molecular characterization
HLA-A	–	Class I α-chain
HLA-B	–	Class I α-chain
HLA-C	–	Class I α-chain
HLA-E	E, '6.2'	Associated with class I 6.2-kb HindIII fragment
HLA-F	F, '5.4'	Associated with class I 5.4-kb HindIII fragment
HLA-G	G, '6.0'	Associated with class I 6.0-kb HindIII fragment
HLA-H	H, AR, '12.4'	Class I pseudogene associated with 5.4-kb HindIII fragment
HLA-J	cda12	Class I pseudogene associated with 5.9-kb HindIII fragment
HLA-K	HLA-70	Class I pseudogene associated with 7.0-kb HindIII fragment
HLA-L	HLA-92	Class I pseudogene associated with 9.2-kb HindIII fragment
HLA-N	HLA-30	Class I gene fragment associated with 1.7-kb HindIII fragment
HLA-P	HLA-90	Class I gene fragment associated with 9.0-kb HindIII fragment
HLA-S	HLA-17	Class I gene fragment associated with 3.0-kb HindIII fragment
HLA-T	HLA-16	Class I gene fragment associated with 16.0-kb HindIII fragment
HLA-U	HLA-21	Class I gene fragment associated with 2.1-kb HindIII fragment
HLA-V	HLA-75	Class I gene fragment associated with 7.5-kb HindIII fragment
HLA-W	HLA-80	Class I gene fragment associated with 8.0-kb HindIII fragment
HLA-X	HLA-X	Class I gene fragment
HLA-Y	HLA-BEL/COQ/DEL	Class I pseudogene
HLA-Z	HLA-Z1	Class I gene fragment located within the HLA class II region
HLA-DRA	DRα	DR α-chain
HLA-DRB1	DRβI, DR1B	DR β1-chain determining specificities of DR1, DR2, DR3, DR4, DR5, etc.
HLA-DRB2	DRβII	Pseudogene with DR β-like sequences
HLA-DRB3	DRβIII, DR3B	DR β3-chain determining DR52 and Dw24, Dw25, Dw26 specificities
HLA-DRB4	DRβIV, DR4B	DR β4-chain determining DR53
HLA-DRB5	DRβIII	DR β5-chain determining DR51
HLA-DRB6	DRBX, DRBσ	DRB pseudogene found on DR1, DR2, and DR10 haplotypes
HLA-DRB7	DRBψ1	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB8	DRBψ2	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB9	M4.2 β exon	DRB pseudogene, isolated fragment
HLA-DQA1	DQα1, DQ1A	DQ α-chain as expressed
HLA-DQB1	DQβ1, DQ1B	DQ β-chain as expressed
HLA-DQA2	DXα, DQ2A	DQ α-chain-related sequence, not known to be expressed
HLA-DQB2	DXβ, DQ2B	DQ β-chain-related sequence, not known to be expressed
HLA-DQB3	DVβ, DQB3	DQ β-chain-related sequence, not known to be expressed
HLA-DOA	DZα, DOα, DNA	DO α-chain
HLA-DOB	DOβ	DO β-chain
HLA-DMA	RING6	DM α-chain
HLA-DMB	RING7	DM β-chain
HLA-DPA1	DPα1, DP1A	DP α-chain as expressed
HLA-DPB1	DPβ1, DP1B	DP β-chain as expressed
HLA-DPA2	DPα2, DP2A	DP α-chain-related pseudogene
HLA-DPB2	DPβ2, DP2B	DP β-chain-related pseudogene
HLA-DPA3	DPA3	DP α-chain-related pseudogene
TAP1	ABCB2, RING4, Y3, PSF1	ABC transporter
TAP2	ABCB3, RING11, Y1, PSF2	ABC transporter
PSMB9	LMP2, RING12	Proteasome-related sequence
PSMB8	LMP7, RING10	Proteasome-related sequence
MICA	MICA, PERB11.1	Class I chain-related gene
MICB	MICB, PERB11.2	Class I chain-related gene
MICC	MICC, PERB11.3	Class I chain-related pseudogene
MICD	MICD, PERB11.4	Class I chain-related pseudogene
MICE	MICE, PERB11.5	Class I chain-related pseudogene

[a]Adapted from reference 35.

expanded to include other exons in high-resolution typing, as exon 4, for example, has been shown to contain polymorphisms that distinguish unique HLA alleles.

The class II molecule is made up of separate α and β protein subunits encoded on separate genes within the MHC that are noncovalently associated posttranslationally (Fig. 1). The ARS is exclusively encoded by exon 2 of both the α- and β-chains (α1 and β1 domains). Exon 3 from both the α- and β-chain (α2 and β2 domains) makes up the region proximal to the cell membrane. Historically, due to its involvement in antigen presentation, only exon 2 of class II proteins was interrogated, but due to known polymorphisms in exon 3, increasingly both exons are included in high-resolution typing.

The Publication of HLA Data

Since 1987, the organization, public accessibility, and distribution of HLA allele data has been provided through the IMGT/HLA database, managed by the Anthony Nolan Research Institute and hosted by the European Bioinformatics Institute (http://www.ebi.ac.uk/ipd/imgt/hla/). Since the introduction of the database, there has been steady growth in the number of alleles, with 14,409 alleles now identified (release 3.23.0, January 2016). The ever increasing number of new alleles, combined with current typing method limitations, poses a challenge to labs that need to identify these alleles for clinical purposes. Identifying new alleles can be costly, time-consuming, and, not infrequently, nearly impossible to do using commercially available products, as the products are often not sufficiently updated to resolve newly described diversity. The immunogenetics community has responded to this challenge by establishing a set of guidelines that determines the extent to which laboratories might resolve HLA ambiguities caused by both the new allele sequence and the unknown phasing of the additional polymorphisms that can lead to additional allele possibilities. These guidelines are based on the frequency of the alleles in a given population and on the polymorphisms located within exons 2 and 3 of class I and exon 2 of class II alleles. Typings that involve common and/or well-documented (CWD) alleles are resolved, while alleles that are extremely rare are not required to be resolved. By definition, "common" alleles are observed at frequencies > 0.001 in reference populations of at least 1,500 individuals and have allele frequency data available. The "well-documented" category includes alleles that have been observed five times in unrelated individuals or have been detected three times via SBT and observed in a specific haplotype in unrelated individuals (32, 33). These guidelines are used for reporting proficiency testing results and have subsequently been adopted by some hematopoietic stem cell donor registries and accreditation organizations. The CWD alleles database is published through a separate consortium and, like the IMGT/HLA database, is also expected to be updated on a regular basis. The most recent publication by this consortium indicates that there are now 1,122 CWD alleles within the HLA-A, -B, -C, -DRB1, -DRB3/4/5, -DQA1, -DQB1, -DPA1, and -DPB1 loci. This represents only 14.3% of the HLA alleles in the IMGT/HLA 3.9.0 database (33).

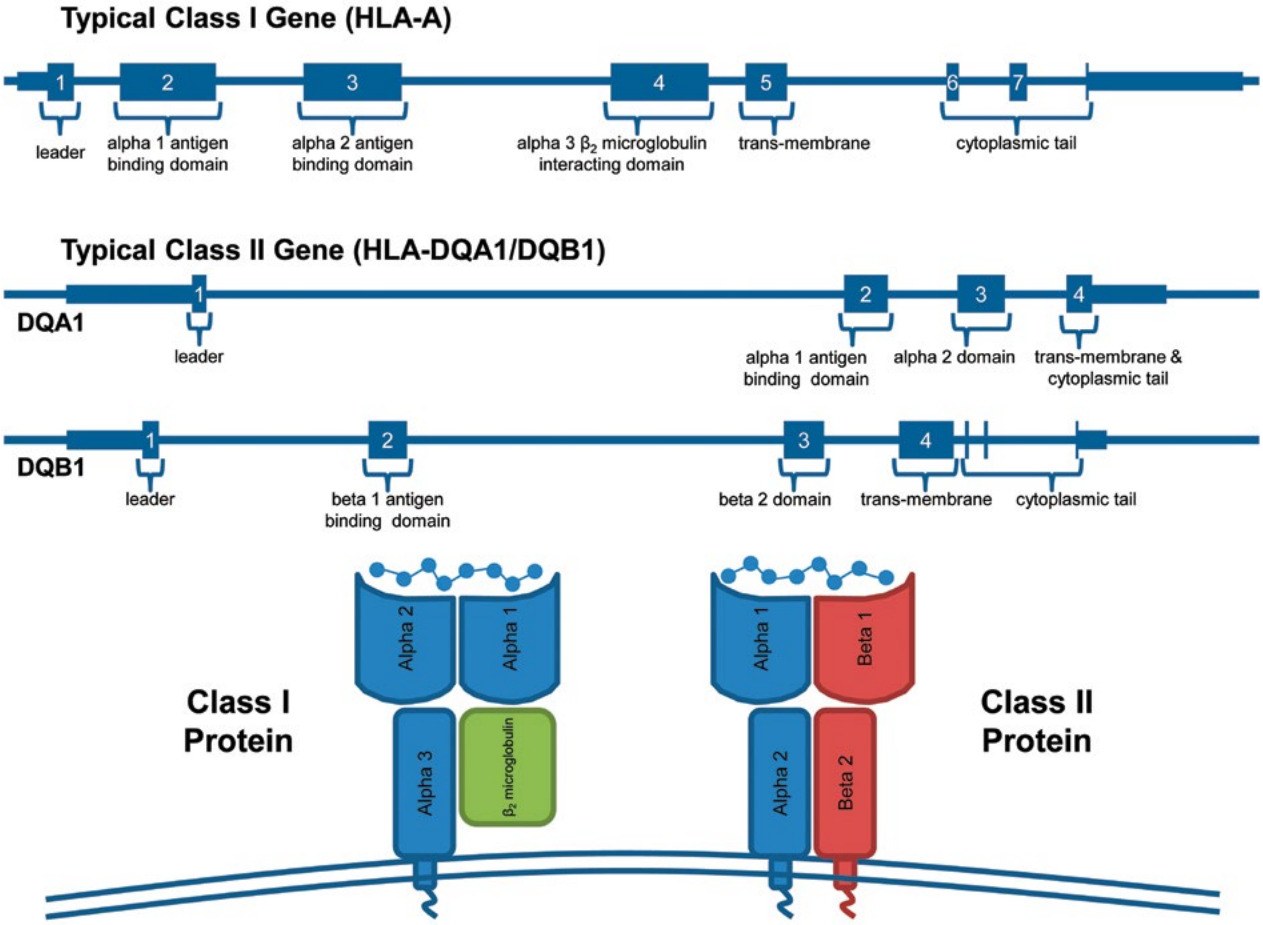

FIGURE 1 Structure of HLA class I and class II genes.

HLA Nomenclature and Recent Changes

The HLA naming convention has undergone substantial iteration, as earlier naming conventions were unable to address the growing numbers and complexity of alleles (e.g., A*02 and B*15 have >100 alleles) (34). At the 15th International Histocompatibility and Immunogenetics Workshop in 2008 (http://ihiws.org/), the WHO Nomenclature Committee for Factors of the HLA System met to determine improvements to the existing nomenclature to address the growing numbers of new alleles being discovered and to reduce naming complexity and confusion (Fig. 2). These changes were implemented in 2010 (35).

Generally, the proposed changes added delimiters (field separators) between each data field in an allele name (e.g., A*01010101 became A*01:01:01:01) to clearly delineate the protein coding and noncoding differences. Three (or more) digit fields are also allowed, providing for allele families that contain >99 alleles. Further changes and details (provided from http://hla.alleles.org) are summarized as follows. The first field following the asterisk in the allele name (**XX**:xx:xx:xx) describes the allele family and generally corresponds to the serological assignment carried by the allotype. HLA typing defined only at the first field is often referred to as low-resolution typing. The second field following the first colon (xx:**XX**:xx:xx) is assigned sequentially as new alleles are determined (e.g., 01, 02, 03 … 101, 102, etc.). Together, these two fields (**XX**:**XX**) indicate one or more nucleotide substitutions that change the HLA protein coding sequence; typing at this level is often referred to as high-resolution typing (the Harmonization of Histocompatibility Typing Terms Working Group recently defined a high-resolution typing result "as a set of alleles that encode the same protein sequence for the region of the HLA molecule called the antigen-binding site and that exclude alleles that are not expressed as cell-surface proteins" [36]). The third field (xx:xx:**XX**:xx) is for designating synonymous nucleotide substitutions within the coding sequence that do not change the amino acids of the protein, while the fourth field (xx:xx:xx:**XX**) identifies sequence polymorphisms in introns, or in the 5′ and 3′ untranslated regions. At the end of the allele name, specific characters have been added (N = null, L = low expression, S = secreted, C = cytoplasm, A = aberrant, Q = questionable) to designate unique characteristics for an allele, such as whether a protein is not expressed (e.g., HLA-A*24:09N) or whether the expression of the protein is unclear (e.g., HLA-A*32:11Q).

HLA TYPING METHODOLOGIES

To meet the growing demand, clinical HLA typing over the past decade has transitioned from a combination of serological and DNA-based methods to a preference for more-direct, faster, more-affordable, and more-informative DNA-based techniques. While serological typing may continue to have a place in clinical or research-based testing in determining the expression of the HLA molecule at the cell surface (a function that DNA-based testing cannot always verify), direct DNA-based typing techniques have all but replaced serological methods in routine HLA typing. This has been driven by advances in commercial HLA typing kits and software using existing SSO, SSP, and SBT methods. With the advent of next-generation and even third-generation sequencing systems, HLA typing is now poised to advance to a level that can truly provide rapid, direct, complete phasing of polymorphic positions throughout an entire gene, with both improved technical performance and reduced overall costs.

DNA-Based Typing Techniques

The most prevalent and well-developed techniques in use today are SSO, SSP, and SBT (Fig. 3). The SSO technique interrogates polymorphic differences using panels of individual DNA oligonucleotide probes that differentially hybridize to the target of interest; the probe either perfectly matches or mismatches the target's polymorphic sites. The hybridization pattern of the oligonucleotides is compared to an expected pattern, based on the sequence database of HLA alleles, and is interpreted as an HLA type. The SSP method uses panels of specific primer sets that overlap polymorphic sites. Perfectly matched primers produce an amplification product, while mismatched primers do not; the pattern of amplification from multiple primer sets determines the HLA allele. In SBT, specific gene regions, usually exons, are amplified and sequenced through a process of polymerase-based extension of specific sequencing primers using fluorescently labeled nucleotides, indicating allelic differences base by base.

Early kits were focused primarily on identifying polymorphisms in exons 2 and 3 of class I genes and exon 2 of class II genes. But as more typings were performed across broader, more ethnically diverse populations, and as more unique HLA alleles were discovered, the ability of these early kits to provide definitive HLA typing decreased. Furthermore, polymorphisms outside of the traditionally tested

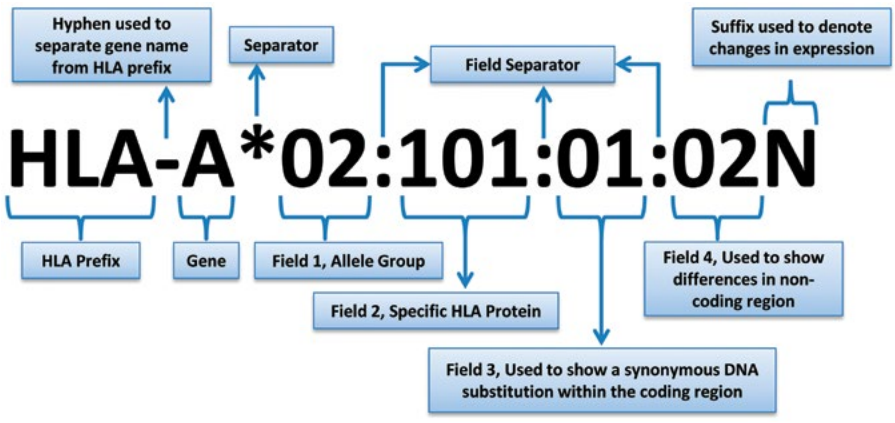

FIGURE 2 HLA nomenclature. Courtesy of Steven G. E. Marsh, Anthony Nolan Research Institute, London, United Kingdom.

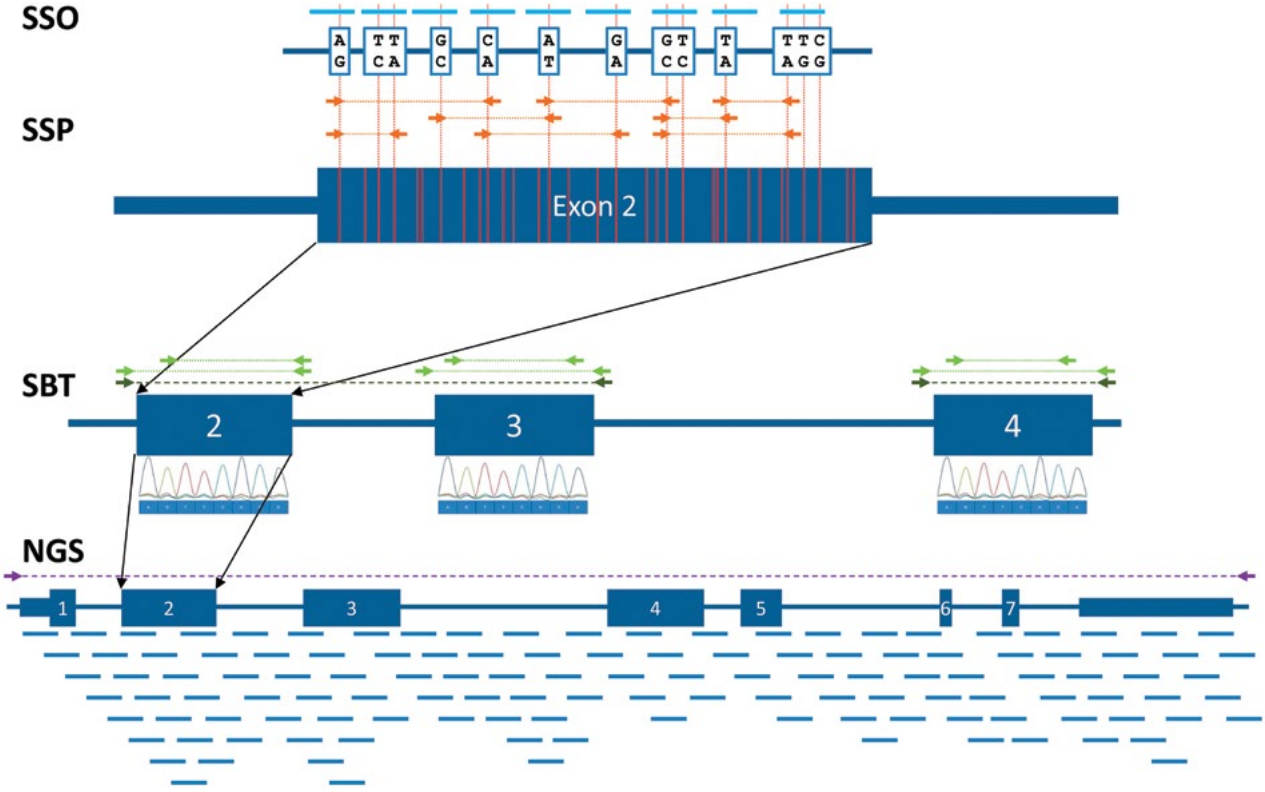

FIGURE 3 Examples of molecular HLA typing techniques and their methods of interrogating the HLA genes. For any given HLA gene (dark blue rectangles), SSOs of ~20 bp (light blue lines) can provide single-nucleotide resolution of haplotype differences (polymorphic differences, red lines in exon 2), but this results in a complex panel of oligonucleotide probes to discern differences between HLA alleles. This probe set is static and therefore cannot adjust to novel alleles. SSPs (orange arrows) can provide haplotype- or allele-specific resolution of nucleotide differences and additionally provide some level of phasing between polymorphic sites. As with SSOs, these oligonucleotide sets are complex and static, limiting their flexibility. SBT provides whole-exon information on the polymorphic content of the HLA allele (amplification primers [dark green] and sequencing primers [light green arrows]) but cannot discern phasing, as this method generally does not rely on allele-specific primers for amplification as a first step. NGS provides whole-gene amplification (amplification primers, purple arrows) and detection of polymorphic content for any HLA allele (known or unknown) and provides significant phasing between polymorphic sites that are within the read lengths of the system being used (usually between 200 and 1,000 bp). This is accomplished through the alignment of thousands of short overlapping reads that are combined to form a single consensus sequence (blue lines).

exons were being described, requiring an expansion into non-ARS regions such as exon 4 for class I and exon 3 for class II. Interrogation of exons that code for transmembrane and intracellular domains was also often required to resolve null alleles that differed only in these exons (e.g., HLA-C*04:09N). Therefore, SSP and SSO kit manufacturers were required to continuously incorporate additional primers and probes to keep up with the growing number of HLA alleles (a problem faced even today). In a further step to provide comprehensive typing, SBT kits began to offer gene amplification with additional sequencing primers (and even allele-specific sequencing primers) as a means to provide expanded coverage of the HLA genes, a practice that is commonplace in SBT kits today.

NGS and Its Potential Impact on HLA Typing

More recently, developments in NGS technology have demonstrated substantial improvements in HLA typing (37–43). Regardless of the platform—Roche 454 GS FLX and GS Junior (Roche Diagnostics, Indianapolis, IN); MiSeq (Illumina, San Diego, CA); Ion Torrent Personal Genome Machine (PGM) (Life Technologies, Thermo Fisher Scientific, Carlsbad, CA), or Pacific Biosciences' (Menlo Park, CA) technology—these systems resolve a number of technological barriers that continue to hamper existing molecular techniques, such as inflexibility in typing and discovering novel alleles and the inability to easily resolve phase ambiguities. While HLA typing by NGS is just now being introduced, it is likely that this new method will transform the way HLA typing is performed in the coming years.

THE PROCESS OF DNA-BASED HLA TYPING

Regardless of the methodology, several processes are required for the implementation of DNA-based HLA typing. Specifically, genomic DNA must be extracted from a sample, the HLA genes amplified, and the resulting products interrogated and analyzed against a library of HLA allele sequences. These processes can be generically broken down into (i) sample preparation, (ii) template amplification,

(iii) interrogation, and (iv) analysis. While template amplification, interrogation, and analysis are often methodology specific, sample preparation is often quite similar and faces similar requirements across all HLA typing methodologies.

Sample Preparation

Genomic DNA should be prepared using well-tested, commercially available DNA preparation kits to ensure consistency of preparation. DNA can be extracted from blood, buccal swabs/brushes, saliva, buffy coat, or blood-spotted filter paper. While ethanol precipitation is generally considered an excellent approach to removing many forms of inhibitors, spin column- and bead-based approaches can provide DNA of sufficient quality and concentration to avoid most problems. The DNA must be free from contaminants that can affect later amplification, hybridization, and sequencing steps (e.g., alcohol, salts, detergents, formaldehyde, and heparin [blood should not be collected in heparinized tubes, and blood samples from patients undergoing heparin therapy and lipemic or hemolyzed samples should not be used]) and should have a 260/280-nm absorbance ratio of ~1.7 to 1.9. Prepared genomic DNA can be used immediately if prepared in nuclease-free water or stored for extended periods at –20°C or lower when properly buffered. Stored DNA should have a concentration of >10 ng/μl and repeated freeze-thaw cycles should be avoided to reduce degradation.

The purity and quality of the genomic and amplified DNA should be validated by spectrophotometric methods. Apart from simple concentration determination (NanoDrop; Thermo Scientific), traditional UV spectrometry can be useful for determining contaminants left over from processing steps, as a number of components (e.g., phenol and chaotropic salts) absorb in the 280-nm and/or 230-nm spectral region. Therefore, visual examination of the absorbance curves can be informative beyond calculating the 260/280-nm ratio. And while the 260/280-nm ratio is useful as a general measure of purity (pure DNA ratio is ~1.8), it is a poor indicator of protein contamination due to its lack of sensitivity (44). Because of potential contaminants, UV methods may not accurately determine concentration. Intercalating dye assays like the Quant-iT PicoGreen dsDNA Assay (Life Technologies) in conjunction with a fluorometer (Qubit; Life Technologies) can provide highly accurate double-stranded DNA concentration determination without interference from potential contaminants. Regardless of the approach, accurate determination of concentration and purity is required for robust assay performance.

Template Amplification

HLA genotyping requires the amplification of the HLA genes by PCR. Depending on the method chosen, the amplification may only include specific exons (exons 2 and 3 of class I genes and exon 2 of class II genes) or may include the entire gene (using multiple amplicons or one single amplicon). Generally, amplification for each HLA locus is performed in a single reaction (one locus per tube) for each sample. Exonic amplification can be performed using standard PCR reagents, while whole-gene amplification generally requires reagents designed for long-range PCR (LR-PCR).

Genotyping

Once DNA is prepared for testing, the process of deriving an HLA genotype can follow several paths depending on the methods and systems installed (described below), the specific need, and the costs involved. While low-resolution typing can typically be obtained with a single test, high-resolution typing is often an iterative process whereby low-resolution testing is followed with additional rounds of high-resolution testing. Historically, low-resolution typing is less costly and higher throughput than high-resolution typing. For bone marrow transplantation, low-resolution typing has been widely used for the initial typing of donors for bone marrow registries, while high-resolution typing is often reserved for bone marrow recipients, is required in selecting final donors for bone marrow transplantation, and, most recently, has also been used for recruitment typing by registries. For solid organ transplantation, low-resolution typing is also performed for donors and recipients, while a second round of high-resolution typing may be required prior to transplantation. This is particularly relevant today as new recombinant single-antigen technology has enabled HLA laboratories to identify anti-HLA antibodies for assessing solid organ transplantation. Therefore, performing allele-level, high-resolution typing can be useful in the context of assessing donor-specific antibodies, as there is now widespread evidence that allele-specific antibodies can impact transplant outcome (45–47).

Analysis

The data generated by the various methods, whether in the form of probe, primer reaction patterns, or sequence information, is typically analyzed with a dedicated software analysis program that accounts for all HLA alleles in the IMGT/HLA database. All software packages available to date use some form of updating service to ensure that the software's internal reference database of known HLA alleles is up to date with the IMGT/HLA database. The level of sophistication, bioinformatics support, and data-handling infrastructure is largely driven by the typing systems being used. SSO- and SSP-based systems have the simplest software requirements and generally require little bioinformatics support, as the amount of raw data is very low and the software automatically converts the raw data (gel images, microparticle fluorescence, and melt curves) into digitized summary data. Interpretation is largely left to the software to assess and determine the HLA alleles present in the sample (or alternative possibilities) based on the presence or absence of assay results (essentially a yes-or-no answer for each probe or primer set). SBT requires significantly more support in terms of both data storage and interpretation of results. Raw sequence reads (electropherograms) are stored and converted by the software into base calls, which are used to determine the presence of specific alleles. With very low noise, robust amplification, and high-quality sequencing, allele calling may produce nonambiguous results. But by the very nature of diploid sequencing, the electropherograms need to be screened visually to determine read quality issues (poor-quality electropherogram), potential contamination issues, miscalled bases (due to low peak height), unexpected homozygosity (from preferential allele amplification), and ambiguous results from unresolvable polymorphism phasing. This review process requires a keen understanding of the biochemistry involved, the operation of the capillary sequencing instrument, and the vagaries of HLA gene sequencing. Therefore, analysis is most often performed by experienced technologists. The introduction of NGS-based HLA typing only increases the bioinformatics support requirements and data analysis needs. NGS systems can generate gigabytes of data per run that need to be processed and supported by well-managed data analysis pipelines. Software packages developed specifically for analyzing HLA NGS data provide automated allele calling but still require manual annotation and review of the results (like SBT).

Review of typing results is critical for detecting problems in the genotyping process and to verify the detection of potential novel alleles. Poor sample quality can result in low or failed amplifications that can skew typing results. Amplification bias, caused by poor primer design, contamination in the reactions, or suboptimal amplification conditions, can lead to spurious typing results even when using commercially available primer sets. A particularly difficult bias arises from imbalanced allele amplification. Due to the complexity of the HLA genes, it is not unusual to have only one of the two alleles present in a sample amplify robustly. This often leads to a strong imbalance in the representation of the two alleles in the amplified material that can mimic a homozygous sample. Imbalances of as much as 90% favoring one allele over the other are not uncommon. Therefore, whichever software is used to analyze the data, the software (and user) must take into account the possibility of allelic imbalance in interpreting the results. While much of the process of analyzing HLA data has been automated, the process of analysis is still sufficiently complex that human oversight and intervention is absolutely required.

REGULATORY OVERSIGHT AND QUALITY CONTROL OF CLINICAL HLA TYPING

Regulatory and Reporting Requirements

Laboratories wanting to establish and perform HLA typing must undergo a process of certification and accreditation. The primary accreditation bodies for HLA typing in the United States are the American Society for Histocompatibility and Immunogenetics (ASHI) and the College of American Pathologists (CAP), while in Europe it is the European Federation for Immunogenetics (EFI). Other countries have chosen to use either ASHI or EFI accreditation. Within the United States, additional accreditation requirements may be imposed by state authorities (e.g., New York or California) in order to perform HLA testing. Organizations like the National Marrow Donor Program and the United Network for Organ Sharing require U.S.-based laboratories to have ASHI or CAP accreditation.

The usual process for accreditation requires that every other year accreditation representatives visit laboratories to physically review procedure documentation (standard operating procedures), quality control and quality assurance practices, and typical typing results (actual patient test records) from organ and bone marrow transplantation testing. These reviews evaluate test results, quality control reports (reagents and instrumentation), maintenance logs, and laboratory staff certifications (training and competency). Generally ASHI and CAP reviews are cycled every other year. In either case, an ASHI reaccreditation application must be filed through online services while a CAP test activity menu is updated online each year. Demonstration of laboratory proficiency is performed through external proficiency testing that can be purchased from CAP or ASHI. This testing service provides blinded sample sets that the laboratory must type accurately in order to pass proficiency.

Quality Control and Quality Assurance

Quality control for HLA typing can be defined as the application of quality processes to ensure correct HLA genotyping, reduce errors, and improve efficiency (driven by standard operating procedures), while quality assurance is the measure of how well those quality control processes are actually working (results from controls, auditing, error correction, and process reviews). Errors in HLA typing can come from multiple sources but are largely driven by people, processes, equipment, or reagents. Validated protocols should be developed, documented, practiced, and updated regularly to reduce errors relating to pipetting mistakes (including cross-contamination), incorrect calculations, and missed steps. The validation process must include rigorous evaluation of the entire process under practical conditions, using both typical and difficult samples to determine the limitations of the assay. Equipment used in any process must be well maintained and checked for performance at least as regularly as specified by the manufacturer. For example, liquid-handling automation must be checked to verify pipetting performance and variance and PCR thermal cyclers must be checked for temperature consistency. Reagent use must be thoroughly documented (with calculations preconfigured for use), and a process should be in place to avoid using expired lots of materials. Negative reactions should be performed to verify that contamination is not present and positive control samples run to verify performance and accuracy over time. The effectiveness of all these quality control processes must also be evaluated over time to ensure that systematic errors are identified and eliminated and that novel errors are reduced as much as possible.

Sample Management and Prevention of Contamination

Barcoding systems for sample tracking and data entry are ideal for avoiding transcription errors and simplifying processing, particularly when samples are stored in 96- or 384-well plates, and when using automation. Irrespective of the size of the laboratory, some degree of automation, whereby manual handling of certain steps and transcription of results is avoided, is strongly recommended and desirable. For large-volume laboratories, the use of liquid-handling automation is absolutely necessary to reduce sample-processing error. Systems from Hamilton (Reno, NV), Tecan (Männedorf, Switzerland), and Beckman Coulter (Brea, CA) have decades of development behind the current commercial products, each with their own advantages and disadvantages (flexibility, capacity, processing speed, operating expense, etc.). While the instruments perform roughly the same function (the automated setup of liquid reagent reactions), the systems have to be assessed in the context of each laboratory's needs and, regardless of the instrument chosen, must be validated for the specific molecular test to be run.

A critical quality control issue is cross-contamination of samples. The possibility of contaminating adjacent samples when loading reactions, removing amplicons for quality control, or even sampling for processing is not trivial. With small reaction volumes and highly sensitive amplification reagents (requiring only nanograms of starting material), even minute droplets of DNA can result in spurious typing. This issue can be partially managed through automated liquid-handling systems. But a thorough quality control program is needed to ensure that samples are clearly and uniquely identified; that processes for selecting, thawing, opening, and plating samples are clear and precise; and that adequate data analysis checks are in place to detect spurious results. Further precautions, such as sequestering the PCR setup process in a separate room from the amplification, cleaning PCR setup surfaces with DNA-degrading cleaners, and performing routine wipe testing to verify lack of contamination, are all required to ensure that erroneous HLA typing results are avoided as much as possible.

CURRENT MOLECULAR METHODS FOR HLA TYPING

Sequence-Specific Oligonucleotide Probes

Principle of the Technology and Its Applications

Typing with SSO probes, commonly referred to as SSO, is a method that uses synthetic oligonucleotides of ~20 to 30 bp to effectively hybridize only to perfectly matched alleles at any given polymorphic site. Large sets of polymorphism-specific oligonucleotides have been designed for each HLA gene to cover a majority of the known HLA alleles. Hybridization conditions are optimized for each oligonucleotide set so that mismatched oligonucleotides do not hybridize efficiently to the target area while perfectly matched oligonucleotides remain stably hybridized.

The original development of the technique in the early 1990s provided a simple test that could easily identify the small number of HLA alleles characterized at that time. PCR primers were developed within conserved regions of the HLA genes with amplification products then bound to a membrane support and denatured to allow the allele-specific oligonucleotides (often labeled with biotin) to hybridize. This "forward" approach of hybridizing the PCR products to the membrane allowed for many samples to be processed on a single membrane, but required the production of the membrane for every sample set.

A simpler method (and the one most commonly used today) was subsequently developed, called reverse SSO (RSSO) typing, in which allele-specific oligonucleotide probes are bound (covalently) to a solid membrane support rather than the amplified products. PCR amplicons, usually labeled using biotin nucleotides, are then denatured and hybridized to the bound probes, washed, and detected by colorimetric or fluorogenic methods. The RSSO method provided a number of advantages, including the ability to preprint membrane strips containing the oligonucleotide probe sets. This allowed vendors to provide test kits ready for detecting amplicons produced by typing laboratories. Today, these membrane strips have largely been replaced by solution-based microparticle assays in which specific capture oligonucleotides are bound to individual microparticles rather than a membrane. In either case, the control of hybridization conditions and the stringency of the washing process greatly affect the pattern of bound versus unbound material and are critical to correctly indicating the alleles present in the sample. SSO typing is still commonly used today (especially in its microparticle form) to provide low-cost, rapid, low- to intermediate-resolution typing.

Strengths and Weaknesses

The primary advantages of SSO typing are its relative simplicity, low cost, and high throughput. RSSO typing based on the Luminex flow cytometry platform enables the interrogation of HLA amplicons by up to 100 or more sequence-specific probes in a single tube. The extent of probe hybridization is measured on the Luminex flow cytometer in an automated manner and through the use of a dedicated software program that translates the probe reaction patterns into HLA genotypes.

Microparticle-based RSSO typing is one of the most widely used methods today but is limited in its resolution. While this method typically delivers low-resolution typing expressed as serological equivalents, it rarely produces unambiguous two-field high-resolution typing, and it requires continual development. As new HLA alleles are discovered, developers of RSSO kits must continually add additional probes and amend the software programs to keep pace with the growing allele library. The technology also suffers from an inability to determine phasing between distal polymorphic sites, leading to unresolved ambiguities. The relatively short oligonucleotide probes can only provide phasing information for polymorphisms underlying the probe, making linkage across an exon difficult, and between exons impossible. For applications like clinical tissue transplantation, where an attempt to reduce ambiguities to an absolute minimum is preferred, an alternative method must be used to supplement the typing results from RSSO (for a summary of strengths and weaknesses, see Table 2).

Analysis of Data and Interpretation of Results

For membrane-based kits, software is now provided to allow automated interpretation of strip results. Membrane strips are either imaged or scanned, allowing the software to automatically detect signals for any specific oligonucleotide on the strip. For the Luminex platform, Luminex-supplied software (and versions of this software modified by each vendor) is provided that detects both the microparticles' fluorescent signature (thereby identifying the specific attached SSO oligonucleotide probe) and the fluorescent hybridization signal generated by the biotinylated HLA PCR product labeled with a streptavidin-phycoerythrin conjugate. The assay result is therefore coordinated with the microparticle signature, and a table of results is created providing oligonucleotide probe identification and allele determination. The software then uses this information to make an HLA genotype call based on expected results from the known oligonucleotide probe set and known HLA alleles. A significant advantage of this system is its real-time determination of assay results (usually within seconds of analyzing a sample). This provides for very rapid downstream analysis of assay results for determination of HLA type.

Troubleshooting and Technical Issues

The Luminex RSSO system is currently the preferred approach for RSSO typing; therefore, this section focuses on troubleshooting specifically for this system. A primary issue for any flow cytometer is proper care and maintenance. Flow cytometers require a sheath buffer for flowing the analytes through the system, and this sheath buffer must be free from contaminants to avoid problems with flow cell clogging and aberrant detection results. Therefore, it is prudent to use the manufacturer's provided sheath buffer. The flow cytometer must also be cleaned regularly, especially after running samples. Failure to do so will result in material trapped within the fluid paths of the system that will obscure results or cause the system to fail entirely.

From an assay perspective, the most critical factor to prevent problems is to ensure proper suspension of the microparticles. Microparticles by nature tend to clump together, and the manufacturer's recommendations for processing the microparticles should be followed. Failing to prepare the microparticles correctly could lead to spurious results and loss of data as clumped microparticles will generally be eliminated from the data set during analysis. As in any hybridization assay, hybridization conditions and reagents must be used and performed exactly as described by the manufacturer. Failure to do so will degrade assay performance or lead to spurious HLA typing results.

Sequence-Specific Priming

Principle of the Technology and Its Applications

Sequence-specific priming relies on the use of primers targeting specific polymorphic sites and has been in use for

TABLE 2 Advantages and disadvantages of molecular methods for HLA typing and of NGS platforms

Methods		Advantages	Disadvantages
Molecular typing methods	(R)SSO	Fast and simple technique Inexpensive Can be performed by hand or with some automation High throughput (SSO); low/high throughput (RSSO)	High frequency of ambiguity Cannot easily identify new alleles Cannot be used for new allele characterization (sequencing) Limited high-resolution typing capability
	SSP	Very fast, simple technique Inexpensive; very little equipment needed Some phasing possible	Not easily automated Cannot easily identify new alleles Ambiguity Kits increase in size as number of alleles in database grows Requires a lot of DNA for full-panel testing
	RT-PCR	Very fast (results in 90 min) Simplified processing (one sample-handling step) Besides the presence/absence of amplicons, analysis accounts for melting temperature features of the particular amplicon	Cannot easily identify new alleles Low throughput (only 1–2 samples per plate) Does not provide high-resolution typing Only one vendor
	SBT	Flexible, from one to dozens of samples per run Accurate, high-resolution typing Robust, validated kits Automatable Can easily handle novel alleles	Takes longer to perform than other methods Relatively expensive (technology is static) Cannot resolve all phasing ambiguities Experienced user required for analysis Low to moderate throughput
	NGS	Single-pass, high-resolution typing Resolves all ambiguities Can be highly automated High throughput	Processing takes 3–5 days Requires complex equipment, skilled technicians Requires batching to be cost-effective Commercial kits are under development Complex data management and analysis Technology development still in flux
NGS platforms	Life Technologies Ion Torrent	Low-cost platform Short run times Semiautomated	Homopolymer inaccuracy contributes to higher error rate
	Illumina MiSeq	Robust sequencing chemistry Least hands-on time Low error rate	Long run time

HLA typing since the early 1990s. In 1995, Bunce et al. (48) developed a comprehensive set of SSPs for all the major HLA genes (A, B, C, DRB1, DRB3, DRB4, DRB5, and DQB1) that could use identical thermal cycling conditions. As with SSOs, most primer sets target exons 2 and 3 of class I genes and exon 2 of class II genes. The basic premise is that one of a pair of unmodified amplification (PCR) primers is designed to overlie a polymorphic site of interest. The primer's 3′ end overlaps the polymorphic site by one to three bases, creating a highly unstable complex when mismatched. A perfectly matched primer pair will produce an amplification product, indicating a positive result, while a mismatched primer pair will not amplify, indicating a negative result. The resulting amplification products are separated and imaged by standard gel electrophoresis or separated by polymer-based capillary separation, allowing HLA typing to be inferred from the pattern of amplification.

Strengths and Weaknesses

The SSP method can be used to provide both low- and high-resolution typing results and can produce results in only 2 to 3 h. This makes it a good choice when immediate results are required, as in the case of deceased donor typing for organ transplantation. Based entirely on standard PCR reagents and gel electrophoresis, the method is also easily accessible and inexpensive to perform. A significant advantage over the SSO method is its ability to provide some phasing information, leading to fewer ambiguities. This is accomplished with PCR primers that overlie polymorphisms on both the

forward and reverse strand, therefore linking the phase of the two polymorphic sites together. Newer kits support preformatted 96-well reaction plates and 96-well gel analysis. More-advanced instruments that can provide capillary-based analysis of the amplicons only simplify this process, albeit for an additional cost.

But the method is not without complication. With primer sets based on known polymorphisms of common HLA alleles, these kits provide limited information in the presence of novel alleles. If the polymorphism that differentiates a novel allele lies within a position targeted by the primers, then the unexpected presence or absence of amplification may indicate the presence of a novel allele. However, like the SSO method, the SSP method does not provide the means to characterize the allele. If there are no primers that target the position differentiating the novel allele, then the allele will go unassigned and may lead to false reporting of the HLA genotype. Therefore, while sufficient for identifying the majority of common alleles, the method does not provide comprehensive coverage of all known and unknown alleles. More problematic is the fact that high-resolution SSP kits can still yield ambiguous results that must be resolved using alternative methods. As the number of allele combinations continues to grow, the ability to resolve ambiguities requires the addition of more and more primer sets, adding to cost and effort. One of the drawbacks of performing high-resolution typing by sequence-specific priming is that the laboratory must maintain a large inventory of kits (as high-resolution kits are most often broken into group-specific assays) that require quality control testing, as many primer sets and even different kits must be independently validated for performance. Yet another constraint of the method is the amount of DNA required. High-resolution typing by SSPs can require hundreds of individual amplification reactions and therefore may require several micrograms of purified DNA. This may limit the method's use when sample availability is restricted. Finally, the amplification requirements to obtain high-resolution typing make this the lowest-throughput method for HLA typing (for a summary of strengths and weaknesses, see Table 2).

Analysis of Data and Interpretation of Results

In the SSP method, a positive reaction is defined as a strong, easily visible, single PCR amplicon of the expected size, while a negative reaction provides no indication of any amplification. Often, kit manufacturers combine an internal control primer set with each allele primer set to provide assurance that amplification conditions were effective and that DNA was added to the well. This control primer set can be targeted to a nonpolymorphic region of the same gene that is being typed and therefore creates no interference with the allele-specific primers. While relatively simple to perform, the manual interpretation of dozens and sometimes hundreds of PCR amplifications quickly becomes burdensome and prone to error. While manufacturers provide visual interpretation tables for determining typings, these worksheets are complex and can be confusing. Therefore, most clinical labs today rely on manufacturer-developed software to interpret the banding patterns expected with any given set of primers.

Troubleshooting and Technical Issues

The consistent amplification of diverse samples as well as the interpretation of the gel electrophoresis result may be complicated by less-than-optimal amplification. A critical quality validation step is the measurement of thermal cycler temperature consistency. Temperature imbalances during cycling can lead to failed reactions and potentially spurious or imbalanced amplification. Therefore, routine (at least quarterly) quality checks of the thermal cyclers are required using calibrated temperature-monitoring equipment that monitors multiple wells in the cycler. Sample quality issues also play a large role in generating spurious results. Impurities accumulated from improperly stored blood or cellular samples can result in reduced amplification efficiency or altered primer behavior. Therefore, the amplification of the internal control must be verified for every reaction. Finally, a clinical laboratory using commercial typing software must make certain to keep the analysis tables or databases used by the software up to date, at least as often as the updates to the IMGT/HLA database. Failure to use updated typing tables or software databases could result in unreported ambiguities.

Real-Time PCR

Principle of the Technology and Its Applications

A relatively new technique for HLA typing was introduced by Linkage Biosciences (South San Francisco, CA) in 2009. Utilizing amplification processes similar to those of the SSP method, allele specificities are evaluated through differences in melting temperature, a predictable physical property. The method utilizes real-time PCR to amplify specific HLA gene regions (overlapping known polymorphic sites) and an intercalating dye to analyze the HLA results, all in the same automated process. This is accomplished through measuring the intercalating dye signal to verify that amplification has occurred and measuring postamplification results through the amplicon's melting curve signature. As the melting temperature of any given amplicon is reached, the double-stranded PCR product denatures and the intercalating dye is released, resulting in a drop in fluorescence. Any differences in base content (different HLA alleles) will cause the amplicon to have a unique melting curve, which is resolvable by the highly precise temperature control provided by the real-time PCR instrument. Linkage Biosciences has spent many years developing its own unique set of SSP assays that can identify the majority of known alleles, including null alleles, at intermediate resolution.

Strengths and Weaknesses

The strengths of real-time PCR HLA typing are the simplicity and speed of the method. Patient DNA is added to reaction buffers and aliquoted into the LinkSeq 96- or 384-well reaction plates. The plates are then sealed and amplified using a standard real-time PCR system. This simplicity translates into the potential for less cross-contamination error due to less sampling handling and reagent transfer.

By performing both amplification and melting curve analysis, the system provides two levels of specificity for positive reactions (endpoint identification of amplification and specific melting curve profile analysis), providing highly accurate results. Overall hands-on and analysis time is purported to be less than 20 min, with a total processing time of just 90 min per sample (one sample per plate). This rapid typing ability is particularly effective for time-critical typing of deceased donors but can also be readily applied to other samples requiring only low-resolution typing. The kits can also be run on several common real-time PCR systems, making the method readily available to many laboratories.

Because the system utilizes melting curve technology with only one manual step and does not require the use of gels or hybridization/washing of probes, it is simple to increase throughput by the addition of standard thermocyclers. Multiple plates can be run in parallel for the amplification step and then transferred to the real-time PCR instrument for a 5-min melting curve analysis. Because the procedure

is straightforward, batching a series of real-time PCR plates takes significantly less effort than running the same number of samples using either SSPs or SSOs. But like the SSO and SSP methods, the company's kits can only account for known HLA alleles. Therefore, this method is not amenable to identifying novel alleles, with spurious results having to be further investigated using other techniques. The system also does not currently provide high-resolution typing, necessitating reflexive testing with alternative methods if high-resolution typing is needed (for a summary of strengths and weaknesses, see Table 2).

Analysis of Data and Interpretation of Results

Analysis of results is automated through the company's SureTyper software. The software is designed to directly accept exported data from supported real-time PCR systems. SureTyper may require specific upgrades to the instrument software for certain models, like Life Technologies' StepOnePlus, which requires software version 2.2 to ensure compatibility. The SureTyper software converts the amplification/melting-curve data into allele calls, which are then used to determine genotype based on expected assay behavior and known IMGT/HLA database alleles. Assay results are provided in a simple +/− format along with the actual allele typing. The software allows manual user intervention and "what if" scenario analysis, providing up to 16 possible allele combination scenarios based on the low-level typing results. Adjusting any result manually forces the software to recalculate its allele calls and provide new scenarios. The software automates the genotype process using embedded allele frequency information and includes some level of linkage analysis between HLA-B and -C, -DRB1 through -DRB3/4/5, and -DRB1 and -DQB1.

Troubleshooting and Technical Issues

All Linkage Biosciences HLA typing kits come with both a negative and positive control. The negative control provides information about contamination of reagents. The positive control is unique in that it both identifies reagent functionality (by producing an amplicon) and provides some measure of sample DNA quality. The positive control is designed to produce a large amplicon that will only amplify optimally with DNA of good integrity (not damaged or fragmented). As with all amplification methods, purity and quality of the DNA sample can impact the quality of the results.

Sequence-Based Typing

Principle of the Technology and Its Applications

Since the advent of Sanger sequencing, SBT has demonstrated itself as a fundamentally improved HLA typing methodology. SBT provides increased flexibility in detecting known and novel alleles and improved accuracy and resolution over SSO and SSP methods with its ability to produce high-resolution typing results (two fields) in a single sequencing reaction. Sequencing in both the forward and reverse directions (bidirectional) for each HLA gene only increases its level of accuracy. Generically, SBT requires two amplification steps: a first amplification that serves to expand the copy number of a particular gene region (exons or an entire gene) and a second amplification to perform the cycle sequencing reactions that produce the fluorescently terminated sequences for subsequent capillary analysis. Historically, the initial process usually amplified only a portion of the HLA gene (exon or exons), while newer strategies generate one or two large amplicons, using long-range PCR to span more of the HLA class I and class II genes. After this initial amplification (and subsequent reaction cleanup), nested primer sets within each gene, specific to one or more exons, are then used for cycle sequencing (e.g., exons 2, 3, and 4 of class I genes). Different kit vendors have developed unique sets of amplification primers that aim to produce balanced amplification for every possible pair of alleles. Designing effective primer sets is quite challenging within the HLA genes, and this critical issue should not be overlooked or minimized, as significant amplification bias can result in spurious typing results.

After initial locus-specific amplification, the PCR reactions are "cleaned" using either a simple enzymatic process (ExoSAP-IT from Affymetrix [Santa Clara, CA], which requires no further purification of the sample) or standard spin preparation- or bead-based kits to remove or inactivate thermal cycling reactants and amplification primers (QIAquick or MinElute spin columns from Qiagen [Venlo, The Netherlands]; Agencourt AMPure XP beads from Beckman Coulter). This cleanup step is essential, as residual PCR reagents (particularly primers) can cause poor sequencing results. The cleaned PCR products are then directly used as a template in subsequent fluorescence-based Sanger sequencing reactions. Sanger sequencing utilizes a method of DNA sequencing called dideoxynucleotide or chain termination sequencing. It is based on the use of 2′,3′-dideoxynucleotides (ddNTPs) in addition to the normal nucleotides (dNTPs) used to synthesize the DNA. These modified nucleotides, when integrated into a sequence, prevent the addition of further nucleotides by DNA polymerase, thus terminating the chain. A sequencing reaction requires the following:

- a template strand to be sequenced (the purified primary PCR product is used as the template)
- forward and reverse sequencing primers (exon specific, used in separate sequencing reactions)
- DNA (Taq) polymerase
- dNTPs: dATP, dCTP, dGTP, and dTTP
- ddNTPs: ddATP, ddCTP, ddGTP, and ddTTP

The concentration of ddNTPs is ~1% of the concentration of dNTPs. The logic behind this ratio is that after DNA polymerase is added, the polymerization will take place and will terminate whenever a ddNTP is incorporated into the growing strand. If the ddNTP is only 1% of the total concentration of dNTP, a whole series of labeled strands of varying length will result. The nucleotide sequence of these fragments is determined using a technique called dye terminator sequencing. In dye terminator sequencing, each of the four dideoxynucleotide chain terminators is labeled with a different dye, each with a unique fluorescent signature. Each terminated fragment has a fluorescent dye on the terminal base that indicates the identity of that base. Once the sequencing reactions are complete, the sequencing products are precipitated with ethanol (to remove unincorporated fluorescent nucleotides), denatured, and loaded onto a sequencer. The sequences of the fluorescently labeled, single-stranded DNA fragments are determined by performing electrophoresis using a capillary genetic analyzer. Briefly, a charge is applied to the sample, which causes the charged DNA fragments to migrate through a polymer-filled capillary and past a detection system (laser and charge-coupled-device [CCD] camera). Smaller fragments migrate faster than larger fragments and thus reach the laser and CCD camera earlier. Each fragment that sequentially passes the laser is one nucleotide longer than the previous fragment. As the fragments pass the laser, the dye attached to the terminal ddNTP is excited and emits

its characteristic wavelength. The CCD camera detects this color, records the fluorescence intensity, and displays the intensity as a colored peak (Fig. 4, top). The color of the peak correlates to the fluorochrome detected, while the peak height correlates to fluorescence intensity (i.e., amount of DNA). It is only the last base in the sequence that is detected since it is the only base to be fluorescently labeled. However, by determining the base at the terminal end of all fragments, the entire DNA sequence can be determined as the pool of fragments, one nucleotide longer than the previous, sequentially reveal their base content (Fig. 4, bottom). The resulting "chromatogram" is used for sequence analysis using specialized genotyping software. In its optimal form, capillary sequencing is performed on an Applied Biosystems (ABI) 3000 series capillary sequencer (Thermo Fisher Scientific).

Strengths and Weaknesses

Sequence-based typing, particularly with the advent of capillary sequencers, is a robust, comprehensive method of determining high resolution HLA typing results, from as few as one to dozens of samples per day. The predominant instrument and sequencing kits from Applied Biosystems provide automated 96/384-well plate handling and sophisticated software to operate the system and collect data. This provides a highly robust and accurate system that is amenable to low and moderate test volumes. Amplification primer sets and related HLA typing software packages provided by commercial vendors have undergone extensive validation testing that confirms both their ability to amplify the region of interest with minimal bias and the ability to derive HLA typing results in a semiautomated fashion.

While Sanger sequencing is considered the gold standard for HLA typing, it has its limitations. Although SBT typically yields higher resolution results than the SSO and SSP methods, it can produce ambiguous results. This is primarily due to the nature of Sanger sequencing itself, whereby both alleles of a given locus are amplified and sequenced together, producing electropherograms that are a combination of the sequences of two alleles present in a sample (heterozygosity). With heterozygous electropherograms, the phase of the polymorphic sites (i.e., which nucleotides are linked together forming an allele) cannot be determined, which is the primary cause of ambiguity in SBT. Ambiguity also arises because of the practice of incompletely sequencing the HLA genes (leaving unsequenced regions that can differentiate one allele from another). Existing SBT kits focus primarily on exons 2, 3, and 4 for class I and exons 2 and 3 for class II. Naturally, alleles that differ (are polymorphic) outside of these sequenced regions cannot be resolved. This requires the reflexive use of alternative technologies like SSO or SSP to resolve these ambiguities. A few companies have developed alternative strategies to provide allele-specific primed sequencing (Abbott Molecular [Des Plaines, IL], Life Technologies, GenDx [Utrecht, The Netherlands], and others) that can help eliminate ambiguities caused by typical heterozygous samples. In this case, allele-specific sequencing primers (similar to SSPs) are used to provide single-allele sequencing results, avoiding *cis*/*trans* effects.

Generally speaking, the process of SBT HLA typing is more complex and time-consuming than either SSO or SSP typing. Primary amplification, cleanup, sequencing reaction setup, and further cleanup steps take a day to perform. Subsequent detection on the capillary sequencer and analysis of results (regardless of the software being used) can take another day. While automation of reaction setup and plate handling by the capillary instrument can help offset the time by reducing hands-on labor, individual sequencing reactions

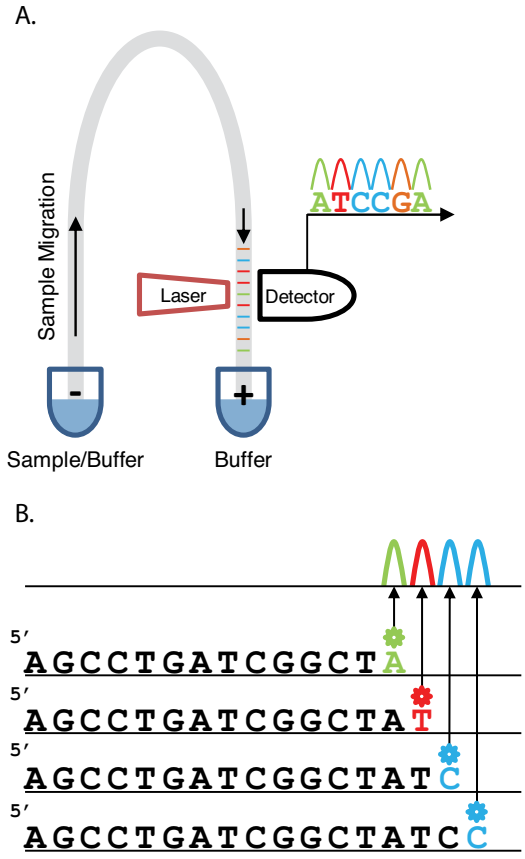

FIGURE 4 (A) Detection of fluorescent terminating nucleotides in a capillary sequencer. (B) Determination of sequence from terminal dideoxy labeling.

are required for each exon in both directions (forward and reverse), making it impossible to type more than four samples on a single 96-well reaction plate. Therefore, SBT is not a rapid methodology and, compared to previously described methods, requires the largest capital expenditure for equipment (for a summary of strengths and weaknesses, see Table 2).

Analysis of Data and Interpretation of Results

HLA typing software is essential for the SBT methodology because the complexity of comparing electropherograms (sequence traces) against a reference library of all HLA alleles makes manual data review impractical. In general, SBT software utilizes HLA sequences published in the IMGT/HLA database, against which sequencing data are compared. This reference set should be updated at least as often as the public updates to the IMGT database itself, and the user should verify this. Each package also provides an automated selection of the most likely candidate alleles from the imported sequencing data. This best match calculation is based on peak calling parameters set by the developers and therefore is not without error. While dedicated software programs facilitate this analysis, manual review of the results is also required because imbalanced allele amplification and poor sequence quality (to name just two issues) can result in incorrect base calls that can confound the HLA typing software's genotype call. Therefore, review of the sequence quality and electropherogram data is crucial to avoid errors.

Individual ABI base quality is measured by a Phred score, a measure of base calling error probability. A Phred score of

30, a common quality cutoff for sequencing, means a base calling error rate of 1 in 1,000 bases, or 99.9% correct base calls. For HLA typing by SBT, bases with Phred scores of <30 should not be used to determine typing results. A second measure of sequence quality is fluorescence intensity/background of each particular trace. Autothresholding found on all ABI sequencing systems adjusts the peak height of each fluorescent channel (base) to normalize the data across the four base channels. But this can lead to artificially high peaks for relatively poor sequencing results, resulting in higher background noise. This high background or "dirty" sequence can lead to incorrect base calling. Finally, all heterozygous positions identified by the sequence traces should be visually confirmed as either indicative of an actual heterozygous position (whether imbalanced or not) or an error. In the case of a suspected error, manually correcting the base call will automatically trigger the reassignment of alleles.

Troubleshooting and Technical Issues

While the abilities of SBT software packages have significantly improved in the last decade, there is still the need for experienced staff in interpreting the eletropherograms and sequencing results. Nonetheless, several issues that can impact automated allele calling should be considered for anyone reviewing SBT HLA typing results.

Amplification bias is a real and complicating factor that can artificially create the absence of heterozygous positions. This can be caused by polymorphic positions underlying primer sites (affecting amplification in an allele-specific manner) but also can be caused simply by difficult-to-amplify regions within the HLA genes (HLA-DQB1 is notorious for allelic imbalance). Despite substantial efforts by vendors developing amplification primer sets, allele bias does occur. Importantly, whether or not bias has occurred cannot be discerned by the results of the amplification step. That is to say, strong amplification is not indicative of balanced amplification any more than poor amplification is indicative of imbalanced amplification.

The quantity of the amplicon can also play a role in the quality of sequencing. Poorly amplified samples will likely generate poor-quality sequencing traces, but this does not mean that sequencing reactions cannot be successful if amplification is weak. Weakly amplifying targets often will sequence with sufficient quality to be HLA typed, if sufficient template is added to the sequencing reaction. Therefore, the issue of whether to sequence weakly performing amplicons is a matter of laboratory preference, quality specifications, and optimization of laboratory costs.

Running a capillary sequencer is generally not a source of problems, so long as the instrument is well maintained and recommended system maintenance is performed on schedule. It is highly recommended that routine system maintenance be performed by a representative of the manufacturer, as indicated in the user manual. From an operational perspective, sequencing quality is generally the first indicator of problems involving the capillary array. Consistently low sequence quality can be caused by either a capillary array that has been used beyond its capacity (the manufacturer stipulates ~150 runs per array), degraded POP6 or POP7 capillary matrix, or both. This problem is different than high background noise. High noise is generally indicative of poor cleanup of the sequencing reactions, leading to free fluorescent nucleotides contaminating the reaction.

Analysis of sequencing results can be highly influenced by the quality and quantity of the input material. In general, a high-quality run will have strong fluorescent signal over background noise, reducing linearly over the course of the run, and have a stable, flat current profile. The electropherogram peaks should be tall, sharp, and nonoverlapping and should not contain artifacts under the peak (from the other bases). Too much DNA loaded into the capillary can cause a truncated (shortened) run with compressed, overlapping peaks. This problem is also identified by an uneven current over the course of the run. Too little DNA caused by poor amplification can lead to peak signals too close to the background noise of the system, leading to poor peak differentiation and thus poor base calling with high inaccuracy. Salt contaminants left over from improper sample processing can elevate the baseline noise, resulting in shorter read lengths and poor-quality reads. A loss of resolution (peak sharpness) can be caused by improper capillary filling or an unexpected sample contaminant (sometimes caused by overloading a spin purification column). Beyond these operational problems, HLA variability can play a direct role in interpreting the electropherogram. In particular, insertions or deletions (indels) within one allele can cause frameshifts that appear as a sudden introduction of overlapping peaks within the electropherogram. Indels, along with difficult-to-sequence regions (regions of high GC content and homopolymers), can present biochemical problems that can also result in overlapping peaks within the electropherogram.

OVERVIEW OF NGS TECHNOLOGIES

Principles of the Technology and Applications

In recent years, new sequencing platforms have been developed that combine novel methods and instrumentation to produce far more sequence than traditional capillary electrophoresis-based Sanger sequencing, at a fraction of the cost. To reflect this advancement, these new methods have been termed next-generation sequencing.

NGS is poised to revolutionize clinical HLA typing by providing the most comprehensive means yet to analyze HLA genes (37–43). The primary advantage of this technology over all other methods is the ability to obtain sequence data from single DNA molecules. Currently, the two most widely used NGS platforms are from Illumina (MiSeq) and Life Technologies (Ion Torrent) (Table 3). It is worth mentioning that the first commercial instrument to be used for HLA typing by NGS was the Roche 454 platform. However, due to a number of limitations, the company decided to withdraw the platform from the market. While the biochemistry of these platforms differs, they are fundamentally similar, as they all combine clonal sequencing with a high level of parallelism. Clonal sequencing is accomplished using methods that enable the isolation of a single DNA molecule, which is subsequently amplified, producing a clonal population of identical DNA fragments. This molecular-level sequencing allows the detection of haploid information directly, resolving many limitations that earlier technologies struggle to resolve. The term "massively parallel" is frequently used to describe NGS technology whereby the simultaneous sequencing of millions of clonal populations is possible.

All NGS workflows consist of the following general steps: template generation, library preparation, clonal amplification, and sequencing.

Template Generation

Within the application of HLA typing, NGS template generation is typically performed by targeted PCR amplification and delivers the specificity and sensitivity required for accurate HLA genotyping. While HLA typing can potentially

TABLE 3 Summary of NGS platform capabilities

Platform	Sequencing chemistry	Library amplification	Read length	Data generation	Run time
Life Technologies Ion Torrent PGM	Ion detection	emPCR	200 or 400 bp	314 Chip: 30–100 Mb 316 Chip: 300 Mb–1 Gb 318 Chip: 600 Mb–2 Gb	314 Chip: 2.3–3.7 h 316 Chip: 3.0–4.9 h 318 Chip: 4.4–7.3 h
Life Technologies Ion Torrent Proton	Ion detection	emPCR	Up to 200 bp	Up to 10 Gb	2–4 h
Illumina MiSeq	Reversible dye terminator	Bridge amplification	1 × 36 bp 2 × 25 bp 2 × 75 bp[a] 2 × 150 bp 2 × 250 bp 2 × 300 bp[a]	500 Mb 800 Mb 3.5 Gb 5.0 Gb (nano: 300 Mb) 8.0 Gb (nano: 500 Mb) 14 Gb	4 h 5.5 h 20 h 24 h (nano: 13 h) 39 h (nano: 22 h) 55 h
Illumina HiSeq 1000	Reversible dye terminator	Bridge amplification	36–101 bp	≤150 Gb	1.5–8.5 days
Illumina HiSeq 2000	Reversible dye terminator	Bridge amplification	36–101 bp	≤300 Gb	2.5–11 days

[a]Uses a version 3 sequencing kit, whereas all other Illumina specs are for version 2 sequencing kits. "nano" indicates the smallest size sequencing chip by Illumina for the MiSeq.

be determined from the sequencing of nonamplified genomic DNA using whole-genome sequencing data, it is not practical to do so. This is primarily due to the low number of reads generated with current technologies for the HLA genes and the absence of adequately tested software analysis tools (see "The Future of HLA Typing" below).

Library Preparation

While library preparation methods vary between platforms, they are conceptually similar in that adaptors are ligated, or integrated through PCR, to the ends of the DNA template. These universal double-stranded DNA adaptors are used throughout the process to capture, amplify, and sequence the DNA. Library preparation is typically performed in one of two ways depending on the size of the DNA region to be sequenced. When the targeted region is relatively small (<500 bases), the regions of interest are amplified using fusion primers that combine or "fuse" region-specific primers with universal adaptor sequences. The resulting PCR amplicon thus incorporates a universal adaptor sequence at its ends. The sequencing approach that uses this type of library preparation method is commonly referred to as amplicon sequencing. For large amplicons (>500 bases in length), an approach called shotgun sequencing is commonly used. In shotgun sequencing, the large PCR amplicon must be fragmented to sizes more appropriate for sequencing on NGS instruments. Breaking large amplicons into smaller fragments is accomplished through nebulization, sonication, or enzymatically. The ends of the fragmented amplicons are then enzymatically blunt-ended (and in some cases 3′ adenylated) in preparation for adaptor ligation. Most, but not all, shotgun sequencing workflows include one or more purification steps to remove enzymes and other reactants between the fragmentation, end repair, and adaptor ligation steps. Purification is typically accomplished with bead-based systems like Beckman Coulter's Agencourt AMPure XP beads. The shotgun approach is typically used for sequencing the full length of HLA genes, while amplicon sequencing characteristically targets specific exons.

Regardless of amplification strategy, a size selection step is necessary to remove adaptors and/or adaptor dimers from the libraries prior to clonal amplification. Failure to remove adaptors and/or adaptor dimers will decrease the availability of library hybridization sites for subsequent clonal amplification due to competitive binding. When using shotgun sequencing, it is also reasonable to specifically select for library sizes that are ideal for clonal amplification on the NGS platforms (500 to 1,200 bp) and for phasing distal polymorphic HLA positions. Commonly used size selection strategies include bead-based technologies such as Beckman Coulter's SPRIselect and Agencourt AMPure XP beads or gel electrophoresis-based technologies like Sage Sciences' (Beverly, MA) Pippin Prep or Life Technologies' E-Gel SizeSelect instruments. Bead-based methods have the advantage of simultaneously concentrating the pools, while electrophoresis-based methods provide better precision.

Indexing

The massively parallel sequencing ability of NGS platforms is best exploited by the sequencing of many samples in a single run through the use of indexed adaptors. An index is a short (6 to 10 bases), unique sequence that is part of the adaptor and is incorporated during library preparation to identify individual samples. These indexes are often referred to as barcodes as they uniquely identify (code) a library. It is the use of indexed adaptors that enables pooling of multiple samples and loci in a single run. There are two primary indexing strategies: indexing by locus or indexing by sample. In the first strategy, a single library is prepared with a unique index for each HLA locus for a single sample. The sequences obtained with this index can then be definitively assigned to a particular locus. The primary benefit of this method is that software programs used to align sequence data and assign HLA genotypes can be aided by this information and can guard against misalignment of reads to an incorrect locus. The second approach, indexing by sample, offers a simplified sample preparation process that also reduces cost. In this approach, amplicons of all loci from a single sample are pooled prior to library preparation; therefore, only one library is prepared per sample. The indexing is simply used to distinguish one sample from the next. This amplicon pooling strategy puts greater pressure on the software programs to accurately identify the source (locus) of the individual reads and align them to the appropriate locus. Given the homology between HLA loci, this approach must be carefully and thoroughly validated.

Quantitation

The concentration of the prepared library must be assessed to ensure that an adequate amount of material is loaded for sequencing. Most importantly, proper library quantitation requires the differentiation of DNA fragments that contain ligated adaptors at both ends from those fragments without adaptors or those that contain only one adaptor (as only those fragments with both adaptors will eventually be sequenced). Most platforms recommend quantitative PCR (qPCR) for library quantitation, as it provides the most accurate assessment of amplifiable material. The qPCR assays can use the ligated adaptor sequence as the priming site for amplification; therefore, only DNA molecules that have successfully incorporated adaptors at both ends will amplify. Nonspecific intercalating fluorescent dyes such as SYBR green are then used to detect the amplification in "real time." Concentration of the library is determined by comparison of fluorescence to that of a standard curve. Currently there are many companies offering qPCR reagents for NGS, such as Kapa Biosystems (Wilmington, MA), Agilent Technologies (Santa Clara, CA), Illumina, and Quanta BioSciences (Gaithersburg, MD). As an alternative, Agilent's Bioanalyzer and TapeStation instruments can determine both size distribution of the library and concentration; however, the concentration measurement from these systems does not accurately represent the library concentration, as it measures all double-stranded DNA that is present and cannot differentiate between completely ligated fragments containing both adaptors and fragments that are missing adaptor sequences.

Clonal Amplification

Each of the NGS technologies described below relies on clonal amplification. However, they do not employ traditional bacterial cloning methods. Instead, they use techniques by which single DNA fragments are isolated and then amplified, producing a population of identical DNA molecules. Clonal amplification can be performed using emulsion PCR (emPCR) (Ion Torrent) or solid-phase amplification on a flow cell (MiSeq).

In emPCR, the DNA library is diluted and stoichiometrically added to capture beads such that a single DNA molecule binds to a single bead. The DNA binds to beads via adaptor sequence with homology to oligonucleotides that are bound to the bead surface. The DNA-bound beads, along with biotinylated primers and other amplification reagents, are placed into an oil emulsion and are shaken in a controlled way such that a single DNA-carrying bead becomes encapsulated in a single micelle droplet. Amplification is thereby performed in isolation within each micelle (microreactor), producing a bead covered with many copies of DNA with identical sequence. After emPCR, the beads are recovered and enriched using streptavidin-coated magnetic microparticles. The DNA-carrying beads are then deposited in a silicon chip (Ion Torrent) possessing microwells in preparation for sequencing. In support of its sequencing systems, Life Technologies has also spent considerable effort in automating the emPCR process. Both semiautomated (Ion OneTouch) and fully automated (Ion Chef) solutions exist that substantially simplify the emPCR and chip-loading process.

Illumina does not use emPCR for clonal amplification; rather, it uses a process called bridge amplification in which DNA fragments are captured onto their chip surface through oligonucleotides prebound at a concentration that allows spatial separation between captured fragments. The capture oligonucleotides also act as amplification primers, priming the DNA fragment for amplification. Repeated cycles of denaturation, annealing to nearby capture oligonucleotides, and extension amplify each fragment, producing localized clonal clusters. These clusters, each produced from different, single DNA fragments, are then sequenced. The clonal generation of clusters is necessary to generate sufficient signals for detecting the sequencing reaction, as a minimum of signal intensity is necessary before it is detected by the camera of the instrument. Using the correct concentration of a particular library is also critical to avoid the overlap of individual clusters on the chip, which can confound the detection of single sequences.

Sequencing

The sequencing methods used by the Ion Torrent and MiSeq platforms are quite different. In Ion Torrent sequencing, following emPCR, DNA-bound beads (Ion Sphere particles) are enriched and loaded into discrete wells on a silicon chip. Nucleotides and polymerases are flowed across the chip in a fixed order, and the incorporation of one nucleotide complementary to the DNA template results in the release of one hydrogen ion. This by-product (H^+) of base incorporation is used to determine sequence. The Ion Torrent detection technology represents a fundamental shift away from fluorescence-based sequencing methodologies, which have been the predominant form of sequencing chemistry for the last 25 years. Using unmodified (i.e., nonfluorescent) nucleotides, the platform's semiconductor chip measures minute changes in pH at the reaction site resulting from the release of the hydrogen ion during base incorporation. The change in pH is proportional to the number of hydrogen ions released, thereby allowing detection of single or multiple base (homopolymer) incorporations. Read lengths on Ion Torrent platforms range from 200 to 400 bases.

Illumina's sequencing method, similar to Sanger sequencing, uses a terminating chemistry in which addition of fluorescently labeled nucleotides is halted following incorporation of a single nucleotide. Unlike Sanger sequencing, however, Illumina's chemistry exclusively uses terminating nucleotides with reversible strand termination. Following fluorescence detection, the dye is cleaved and the terminating 3′ moiety is modified, enabling further nucleotide incorporation. This chemistry may slow the sequencing process, but it provides very accurate base detection, reducing the intrinsic error rate. One of the unique features of the Illumina sequencing chemistry is the simplicity by which both ends of a DNA fragment can be sequenced, commonly referred as "paired-end" sequencing. Single read lengths of 250 to 300 bases are attainable in the paired-end process, producing effective read lengths of 500 to 600 bases and enabling association of paired reads that are distal to each other (depending on insert size). Therefore, fragment sizes up to 1,000 bases can be sequenced on the platform, providing phase information for distant polymorphic positions, a very critical element for eliminating ambiguities in HLA typing.

HLA Gene Coverage Strategies by NGS

Sequencing of the HLA genes has utilized a number of different approaches, from exonic only to whole gene. The choice of approach has largely been driven by the perceived immunologic value versus the complexity, output, and availability of kits to perform the typing. As newer technologies are introduced, more-comprehensive approaches are becoming available to the HLA clinical market.

Exons Only (Amplicon Sequencing)

One of the first methods of HLA typing by NGS, developed by Roche, used short amplicons targeting a limited number

of exons, specifically the exons coding for the ARS. In this protocol, each exon is amplified separately. Non-ARS regions coding exons, introns, and untranslated regions are not sequenced. The primary advantage to this strategy is that the sequence output of the platform is maximally utilized by amplifying and sequencing only those regions that are considered "most relevant." Another advantage to this method is that the universal adaptor sequences can be incorporated through PCR, thereby eliminating the need to fragment DNA and ligate adaptors, as required in LR-PCR shotgun approaches. The disadvantage of the selective exon-only strategy is that ambiguous HLA typing results can be obtained. Non-ARS exons also include polymorphisms, and unless characterized, alleles with otherwise identical sequences will be ambiguously typed. Furthermore, while the sequence obtained within a short amplicon is phased by virtue of its clonal nature, the phase between amplicons is lost. That is, if exons 2 and 3 are amplified separately, it is not possible to phase the sequences from one exon to another unless the intervening intronic sequences are also sequenced and differ between the two alleles. This issue is particularly important, as examples exist of hybrid alleles that have been formed by crossover and exon-shuffling events. For example, discriminating the common alleles B*15:01:01:01 and B*40:01:01 requires the phasing of exon 2 to exon 3 to eliminate the alternative genotype B*40:21 and B*15:212. Therefore, any approach that does not completely sequence the whole gene potentially may generate multiple ambiguities.

A further limitation of this method is that numerous amplifications must be set up for each sample. In an effort to alleviate the burden of preparing numerous reactions, PCR setup has been automated on multiple platforms, including the Fluidigm access array. While the setup of multiple PCRs is simplified through the use of automation, it can be challenging to optimize amplification conditions so that amplification of the numerous exons is equally efficient. Failure to do so leads to nonuniform sequence coverage, which subsequently limits the throughput of the sequencing workflow, as a minimum depth of coverage is necessary for accurate genotype calling.

Whole Gene (Shotgun Sequencing by LR-PCR)

An alternative approach is to sequence the full length of the HLA genes. HLA genes range from 3.2 kb for class I up to 15 kb for class II. While it is possible to amplify the full length of HLA genes through LR-PCR, the current sequence read lengths of second-generation platforms is <1,000 bases. Therefore, in order to sequence the full length of HLA genes, a shotgun sequencing approach is necessary whereby the full gene amplicon is randomly fragmented and sequenced as previously described. The sequences obtained from the fragmented full-gene amplicons are assembled computationally to obtain the full-length sequence of each allele.

Whole Gene (Overlapping Short Amplicon Sequencing)

Yet another approach is a hybrid of the two previously described and is designed to reduce ambiguity through full-gene sequencing while reducing the fragmentation and adaptor ligation steps required of LR-PCR shotgun sequencing. In this approach, numerous amplifications are performed across the full length of the HLA genes with overlapping regions. As each amplicon is designed to overlap its neighbors, it is possible to set the phase from one amplicon to the next given sufficient density of heterozygous positions.

Strengths and Weaknesses of NGS HLA Typing

NGS technology is highly suited for the challenges routinely encountered in HLA genotyping. The two fundamental elements of NGS, clonal sequence and parallelism, can be exploited to develop a typing scheme that delivers high-resolution typing in a single pass. Many of the phase ambiguities encountered in Sanger sequencing are due to the extreme polymorphism of the HLA alleles and the frequently heterozygous nature of our genome. These ambiguities are eliminated by clonal NGS platforms that provide on-phase sequence spanning these regions. In addition, the enormous amount of sequence that can be produced by NGS allows for a new approach to SBT HLA typing that is not limited to a few exons. By expanding the regions that are sequenced, additional ambiguity can be reduced with more-comprehensive data, providing the means to compile a more complete HLA allele library. While current methods of HLA typing have enabled the detection of numerous HLA polymorphisms (14,409 alleles as of January 2016), the majority of these alleles have been only partially sequenced. NGS can be a useful tool for complete characterization of new HLA alleles and for completion of existing, partially sequenced alleles. NGS also offers cost savings when compared to existing high-resolution genotyping methods. Cost savings are achieved primarily through the elimination of reflexive testing (required to resolve ambiguity) and multiplexing (as NGS is highly scalable), allowing many samples to be processed simultaneously in a single run; therefore, the fixed costs can be spread across many samples.

However, as with the introduction of any new technologies, a number of limitations must be considered. NGS-based HLA typing requires a capital investment in equipment. The cost of the sequencer and peripheral equipment can easily exceed $150,000. Another issue is the current limited availability of NGS HLA typing kits. While Roche offers an HLA typing kit based on NGS, the company announced the discontinuation of its 454 sequencing product line by 2016. Meanwhile, a number of commercial vendors have already developed HLA typing products for the two major sequencing platforms including Holotype HLA by Omixon (Budapest, Hungary), MIA FORA by Immucor (Norcross, GA), NGSgo by GenDx (Utrecht, Netherlands), NXType HLA by Thermo Fisher, and TruSight HLA by Illumina.

One of the great challenges in utilizing NGS technology is the analysis of the data. The amount of sequence data produced is immense and therefore requires organized bioinformatics processes and highly sophisticated software programs. Laboratories embarking into NGS are now faced with the need for higher-performance computers and provision for long-term storage of data. Along with expanding bioinformatics requirements, another consideration is the rapid advancement of these technologies as new methods and technologies are continuously being developed, often with different equipment and computational needs. Considering that implementation of any new technology can be costly and time-consuming, laboratories must evaluate the return on this investment to decide if the benefits that NGS offers will translate into better and more cost-effective HLA testing, and to decide at what point in time it makes the most sense to introduce NGS into their workflows (for a summary of strengths and weaknesses, see Table 2).

Current "Clinical" NGS Platforms

The original NGS platforms had throughput capacities that were best suited for high-throughput contract labs but far exceeded the needs of typical clinical HLA labs. Recently, sequencing platform manufacturers have developed

"benchtop" sequencers for the clinical diagnostics market. Illumina's MiSeq and Life Technologies' Ion Torrent PGM systems fall into this category. These smaller versions of the ultra-high-throughput sequencers offer lower per-run cost, shorter sequencing time, and greater ease of use. For targeted applications like HLA typing, these benchtop sequencers are ideal.

Ion Torrent PGM

A primary advantage of the Life Technologies Ion Torrent system is the simplified readout technology provided by the solid-state chip. In contrast to pyrosequencing (Roche 454), none of the complex enzymatic processes and photochemical particles required to generate photoluminescence are required. This directly translates into a much simpler instrument (at much lower cost), as none of the complex and highly sensitive optics of fluorescence-based systems are needed. This also translates into much shorter run times, with sequencing runs taking just a few hours. Additionally, the use of unmodified nucleotides does not result in any chain damage to the growing DNA strand (presumably increasing efficiency). The biochemistry, however, suffers from the same problems as pyrosequencing: the inability to detect homopolymer stretches accurately. Because the sequencing is not terminator based, homopolymer stretches are determined by the proportional proton release from multiple bases added in the same cycle. Taking into account other issues like readout sensitivity, the overall error rate of the system is 1.7%, which is greater than that of the Illumina MiSeq at 0.3% (49). Read lengths are also not as long as for pyrosequencing, with maximum lengths reaching 400 bp. Also, like pyrosequencing, the emPCR process to amplify the template DNA is time-consuming and, in its manual form, difficult. Life Technologies has moderated this problem by introducing semiautomated and now fully automated solutions to the emPCR process (ostensibly alleviating the issue), allowing for the testing of these systems in a clinical environment. The PGM also offers lower per-run costs and shorter sequencing time than the Illumina MiSeq, although the overall time from library preparation to sequencing is comparable between the two systems.

Illumina MiSeq

Illumina's MiSeq has been found to produce the highest-quality sequence data of the existing NGS systems, with reasonable costs and simplified operation. Illumina's reversible terminator sequencing chemistry is very robust and generates accurate base calls. In multiple comparisons between existing systems, Illumina's platform has consistently outperformed all others in terms of sequence quality and low error rate. Also, because Illumina invested heavily in system development, much of the complex chemistry for clonal amplification is performed automatically by the instrument, substantially simplifying the process. From a systems standpoint, the primary disadvantage of the MiSeq system is the relatively long (24 to 39 h, depending on flow cell) run time and onboard data analysis of the instrument. Therefore, the MiSeq is clearly not a system for rapid turnaround of HLA results.

NGS ANALYSIS, INTERPRETATION OF RESULTS, AND TROUBLESHOOTING

After sequencing is completed, the instrument performs base calling on each clonally amplified DNA fragment. The sequence information from each fragment, called a read, is recorded along with the quality scores (the probability of a base calling error quantified using Phred values). Each sequencing platform is unique in how quality scores are calculated and the data storage format used (.sff, .bam). Regardless, all data formats can be converted into the FASTQ format, a standard representation of NGS data, containing entries for each read's haploid DNA sequence and corresponding quality scores (Fig. 5). For paired-end sequencing (Illumina), two FASTQ files are generated, with reads from each end of the DNA fragment placed into separate files and linked through the sequence identifier.

Traditional analysis of NGS data has three main components: (i) alignment of reads to a reference sequence, (ii) identification of variants, and (iii) annotation/interpretation of the identified variants. The first step, alignment, compares the reads to a reference sequence and attempts to locate the proper position of the read, or pairs of reads, given the reference sequence. Typically, the reference sequence selected is a human genome assembly available from a public database (e.g., GRCh37/hg19; UCSC Genome Bioinformatics website [http://genome.ucsc.edu]). After alignment, the variant positions are determined at locations where the aligned sequencing data are different from the reference, and can be either homozygous or heterozygous in nature. In this step, it is important to understand how depth of coverage and the quality score are used to decide whether a position is truly different from the reference. The depth of coverage refers to the number of reads aligned to a given position in the reference sequence (Fig. 6). Aligned bases with lower quality scores indicate lower confidence that the nucleotide call is correct and are down-weighted during variant calling at a given position (with preference given to aligned bases with higher quality scores). A higher number of reads present at a given position (higher depth of coverage) makes it easier to discriminate the signal (actual bases present, high quality scores) from the noise (errors during sequencing, base calling, and alignment, often with lower quality scores) during variant calling. Once the variant positions are identified, these can be fed into various analysis programs for interpretation.

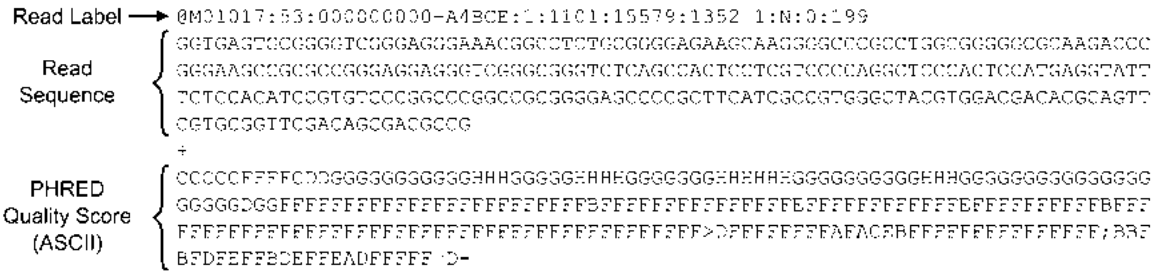

FIGURE 5 NGS read and FASTQ representation.

While it is possible to use a traditional approach to analyze HLA NGS data, methods that rely on alignment against a single reference sequence may be problematic. Widely used alignment programs such as Novoalign, BWA, Bowtie, etc., have limitations or penalties for mapping highly divergent reads to the reference sequence (as would be expected for HLA genes). Given the extreme polymorphism of HLA alleles, it is unlikely that these programs can deliver highly accurate alignment of all HLA alleles. Rather, novel approaches and programs have been developed specifically for HLA sequence data analysis.

Analysis and Interpretation Using Exon-Based and Whole-Gene Strategies

Considering that the two primary methods for sequencing HLA alleles on NGS instruments are the exon-based approach and the whole-gene approach, analysis programs have been developed to match the needs of each sequencing strategy. Exon-based approaches using long reads enable phasing of heterozygous positions within an exon, resolving much of the *cis*/*trans* ambiguity that occurs with the Sanger SBT methodology. However, since exons are amplified separately, these analysis programs cannot resolve all genotyping ambiguities for two reasons: phasing between exons is lost when these regions are amplified separately, and incomplete sequencing of the gene does not allow for resolution of alleles that differ only in regions that have not been included in the amplification strategy (e.g., DRB1*14:01:01/14:54 cannot be resolved without sequencing exon 3). The analysis of the full-length HLA genes is also not without its own challenges. Currently <10% of HLA alleles have been fully sequenced, with the majority of alleles only characterized in regions encoding the ARS (exons 2 and 3 for HLA class I and exon 2 for HLA class II). One of the greatest challenges for developers of analysis programs is accounting for sequence data from the full gene in light of a largely incomplete allele sequence database.

All programs have the capacity to handle NGS data and utilize the IMGT/HLA database genotype assignment, with most of the commercial programs also offering user interfaces that enable the visualization of sequences, coverage, genotype assignment, and mismatch information. While there has been significant development of software programs dedicated to HLA NGS data, these programs continue to evolve alongside the sequencing technology and approaches for HLA template generation. Some of the better-known programs are described below.

Commercial HLA Typing Software Packages

Assign ATF

Assign ATF software (Conexio Genomics, Fremantle, Australia) was developed for use with an exon-based sequencing approach and Roche 454 platform. Assign ATF is similar to the company's Assign software, developed for use in Sanger SBT, and enables the segregation of multiple samples in a single analysis project, providing a graphical user interface for the user to review sequence data and genotype assignment, including mismatch information. Assign ATF also allows manual editing of the data and re-analysis based on user interpretation. While the software has been applied primarily to exon-based sequencing, future versions will

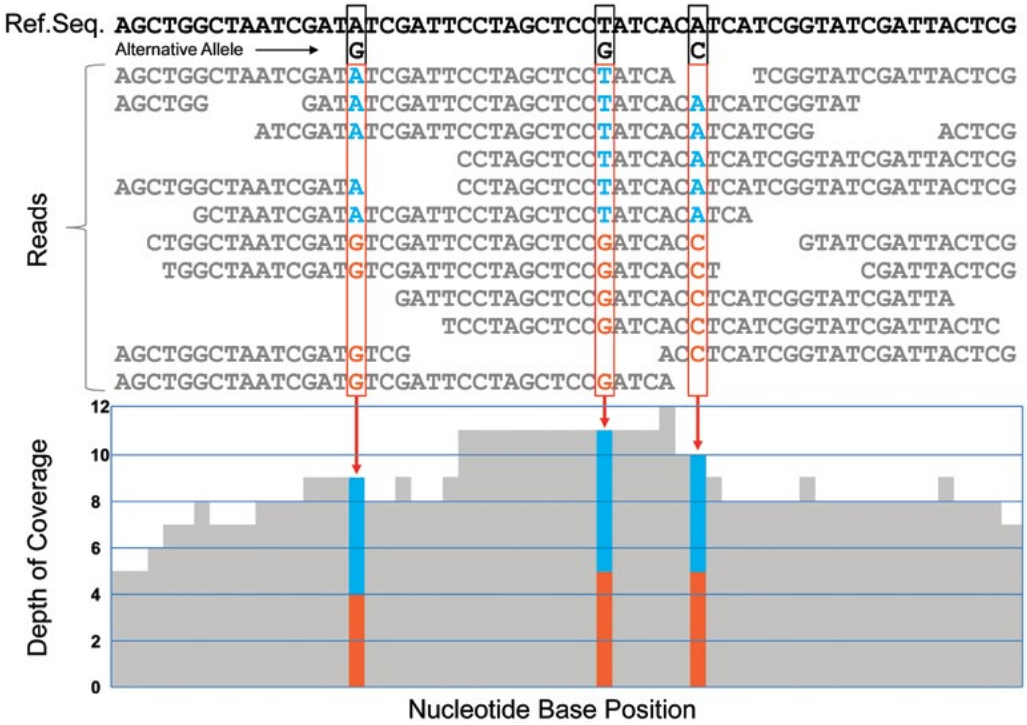

FIGURE 6 Depth of coverage as derived from NGS reads. NGS reads (whether single or paired-end) are aligned to a consensus reference sequence (Ref.Seq.) to form an overlapping, stacked view of the coverage at any given nucleotide position. The number of reads at any given position represents the depth of coverage and is derived by the number of overlapping reads at that nucleotide position. Read depth at polymorphic positions is split between the reference sequence and the alternative allele (blue and orange bars) and indicates allelic representation.

include analysis for full HLA genes with compatibility with additional sequencing platforms.

HLA Twin

HLA Twin (Omixon, Budapest, Hungary) is a highly customizable software program that is able to handle various sequencing platforms (Illumina, Ion Torrent, and Roche 454), gene coverage strategies (exons versus full gene), and data types (targeted, exome, and whole genome). HLA Twin offers two independent genotyping algorithms, a method that aligns the NGS data to the alleles in the IMGT/HLA database, and a second approach using *de novo* assembly of the NGS reads to determine a consensus sequence, which is then compared to the known alleles in IMGT. The combination of the two approaches is a very useful feature that provides a significant degree of confidence for the particular HLA genotyping call. Additional features include the ability to detect novel alleles and their traffic light system to warn users of potential quality issues that may be present in their sample signaling allele imbalance, uneven coverage, exon mismatches, and other statistics. HLA Twin also enables the analysis of mixed data in which sequences from a single sample containing reads from all HLA loci can be parsed to appropriate loci as part of the analysis.

NGSengine

NGSengine (GenDx) has also been developed to handle data from various sequencing platforms (Illumina, Ion Torrent, and Pacific Biosciences) and can analyze data from both exon-based and whole-gene-based sequencing approaches. In an effort to enable full gene alignment of alleles that have not been fully characterized, this software substitutes surrogate sequence for regions not yet characterized, which is obtained from a fully sequenced allele with the fewest differences from the allele in question. After the reads are aligned, the software establishes phase between heterozygous positions. The genotype assignment is based on best-matching alleles and provides mismatch information at the exon and intron level. Additional features include the display of phase across heterozygous positions and the ability to analyze mixed data (multiple loci in a single library). NGSengine also provides statistics about the read length, depth of coverage, and total length of the DNA fragments.

Sequence Pilot

Sequence Pilot (JSI Medical Systems, Ettenheim, Germany) is another commercially available software program for the analysis of HLA NGS data. The SeqNext-HLA module can analyze data from the Illumina, Ion Torrent, and Roche 454 platforms. This program is organized with clinical laboratory operation in mind with the ability to create orders, group files from the same DNA sample, and allow for patient and sample metadata to be stored within the program. This program is able to provide varying precision levels of HLA genotyping, from two-field to full-field resolution, accounting for intronic sequence if provided in the IMGT/HLA database. SeqNext-HLA allows the user to analyze the sequencing data and review, edit, and re-analyze if necessary. Interestingly, while the program was designed for NGS data, it does not provide the user with a view of the sequence read alignment or depth of coverage, but rather displays a simulated electropherogram of the resulting consensus sequence.

Open-Access Software Programs

The development of HLA genotyping programs is not limited to commercial enterprises. Athlates (Broad Institute, Cambridge, MA) is a command line-based application originally developed for HLA genotyping from exome sequencing data. It employs a data-centric approach of identifying reads belonging to HLA genes, assembling the reads into contigs, and creating consensus information for each exon that is compared back to the IMGT/HLA database (with the output of the best pair of alleles that explain the data at each locus identified). Two programs, HLA Caller (an unsupported module for the Genome Analysis Tool Kit, Broad Institute) and SOAP-HLA (Beijing Genomics Institute, Beijing, China), determine HLA genotypes based on alignment of sequencing reads to the human genome. These algorithms are dependent on the accurate alignment of reads and single nucleotide polymorphism determination for making the allele call. While SOAP-HLA works directly with the alignment data, HLA Caller goes one step further in incorporating allele frequencies into its probabilistic algorithm for genotyping. All of the open-access programs listed are restricted to alleles defined in the IMGT/HLA database and cannot handle complicated events, such as allelic imbalance, uncharacterized intronic sequences of alleles, and novel or hybrid alleles, all of which may be encountered in a clinical setting and need to be identified.

The Complexity of HLA Data Analysis—Challenges to Software Programs

All NGS approaches for HLA genotyping have inherent limitations, and the software chosen for analysis should be able to address some, if not all, of the well-known issues with HLA genotyping. Some of the more systematic problems associated with sequencing the HLA genes include nonuniform sequence coverage, allelic imbalance, and coamplification of unintended HLA loci. While it is possible to address these problems during the initial PCR amplification and library preparation steps, the programs should be able to detect events that can lead to incorrect genotype determination. Another event that HLA genotyping programs should be able to detect is the existence of a novel allele. While there are >14,000 known HLA alleles present in the IMGT/HLA database, the number of alleles is increasing rapidly as more sequencing is performed and is only expected to grow as more whole-gene data are characterized. Not only should the programs be able to detect the new alleles that are possible due to novel single nucleotide polymorphisms, but they should also be able to detect and characterize the cases of new alleles that are hybrids of two or more known alleles. Currently, no program is able to handle the detection of hybrid alleles.

THE FUTURE OF HLA TYPING

A plethora of large and small technology companies around the world continue to advance the state of the art in whole- and targeted genome sequencing technologies. Companies like Pacific Biosciences (direct fluorescent sequencing by synthesis) and Oxford Nanopore Technologies (Oxford, United Kingdom) (non-fluorescence, non-polymerase based) are working on more-advanced (true single-molecule) third-generation platforms (Oxford Nanopore has only recently released its first product for commercial evaluation). These third-generation sequencing technologies enable the sequencing of single DNA molecules without the need for clonal amplification and appear promising in regards to supporting more informative HLA typing in the future.

Pacific Biosciences

Pacific Biosciences' technology focuses on using a single, physically anchored DNA polymerase as the driving force

in single-molecule, direct sequencing by synthesis, using fluorescence-tagged, phospholinked nucleotide analogs. This approach allows both the rapid incorporation of nucleotides and very long reads. Initial chemistries produced average read lengths of ~4,500 bp, with newer chemistries today increasing the average to ~10,000 bp (with the longest reads exceeding 30,000 bp). With multi-kilobase reads, ambiguities caused by phasing, even at whole HLA gene distances, can be completely eliminated. A disadvantage of this technology is the Single Molecule Real Time (SMRT) chip itself. Because of the small number of zero-mode waveguides per chip, the system's total output per run (~50 Mbp) is substantially limited. While this level of throughput is insufficient for whole genomes, for targeted approaches, like HLA, this amount of information is entirely sufficient, given the extended read lengths. And while the chemistry suffers from single-pass inaccuracies (median error of ~14%), the base incorporation errors are random and therefore addressable by adequate read depth and appropriate bioinformatics support.

Oxford Nanopore and Similar Nanopore Technologies

Nanopore technology introduces a completely new paradigm in DNA sequencing. Briefly, a single nanoscopic hole (~1 nm) is created in a synthetic membrane within electronically addressable microscopic wells of the application-specific integrated circuit (ASIC) chip, through the addition of a single biological protein nanopore (such as α-hemolysin). A double-stranded DNA template is then prepared by ligating a hairpin to one end and a DNA-unwinding protein at the other. As a single strand of DNA is unwound from the double-stranded target molecule and pulled through the nanopore, an electric potential across the membrane facilitates a unique current signature specific to each type of DNA base as the DNA passes through the pore. These fluctuating electric potentials are then recorded and converted into base calls. The technology enables very long reads, with the additional advantage of simplified sample preparation and reagents. Recent tests of the MinION system demonstrated an average read length of 5.4 kbp, with some reads up to 10 kbp and longer. But the technology is not without problems. Early testing indicates higher error rates than other platforms. The system's low data output (initial chips contain 512 wells, generating only tens of megabases of data per run) and current lack of published data demonstrating the stability, reliability, and accuracy of the technology limit the ability to assess the system's capabilities for HLA typing.

Regardless of current shortcomings, nanopore technology may be a potential sequencing option over the next decade, as a multitude of companies are developing alternative platforms using different nanopore approaches (biological, solid state, and otherwise). Therefore, the technology has the potential to become an extremely inexpensive, very simple, very fast (minutes instead of hours) approach to sequencing any target DNA molecule. From an HLA perspective, this technology has the potential to lead to routine whole-genome sequencing, where HLA typing would naturally result from the overall data.

Alternative Means To Obtain HLA Typing from Whole-Exome or Whole-Genome Sequencing

Besides the approaches described in this chapter for direct HLA typing by NGS, alternative approaches for obtaining HLA typing from whole-exome sequencing (WES) or whole-genome sequencing (WGS) data have recently been attempted (50). Since both WES and WGS data include the HLA sequences, determining the HLA typing from this data is theoretically possible, with the success of these approaches largely dependent on the quality and quantity of the WES or WGS data and the ability of software tools to perform the data analysis.

The challenges associated with HLA genotyping from WGS or WES is inherent to the assay performed. Under the best of circumstances, WES data will be comparable to the exon-based typing strategy, with the known limitations as outlined above [see "Exons Only (Amplicon Sequencing)"] and relatively lower coverage expected for the targeted (HLA) regions. Furthermore, capturing the HLA exons with a standardized set of oligonucleotides for exome sequencing is questionable, since the set of capture oligonucleotides do not change to reflect the increasing diversity (and extensive polymorphism) of the HLA alleles. Therefore, this process may exhibit allelic imbalance or dropouts. So, while WES data may provide sufficient quantity of data, the quality of the sequences remains a challenge. Alternatively, using WGS data (where there is no selection of HLA genomic fragments for sequencing, analogous to shotgun sequencing of the whole HLA genes), the challenge lies in generating a sufficient amount of data to obtain a high enough depth of coverage for accurate HLA genotyping. While WGS is currently cost-prohibitive for HLA typing purposes, it is expected to be possible in the future as NGS technologies are optimized and total throughput increases. But for the foreseeable future (even assuming that throughput is increased and sequencing costs are reduced), it is unlikely that all those who need HLA typing will necessarily have their exome or genome fully sequenced. Therefore, this approach will only be relevant to cases in which WES and WGS data are already available. The computational tools available for WES or WGS HLA analysis, like Omixon's Target HLA, are being tested, and the results suggest that the approach can be successful. However, significant challenges remain, including the considerable time, complexity, and effort for computation and interpretation of results.

REMARKS/CONCLUSIONS

Clinical HLA typing has experienced remarkable technical progress in the last decade that may finally and ultimately resolve several long-standing problems that have hampered HLA testing for the last 60 years. From the inability to determine long-range phasing to the lack of whole-gene information from both coding and noncoding regions to the inability to directly detect novel alleles, HLA typing technologies are poised to rapidly improve our understanding of the role of HLA genes in immune function and transplantation and to provide truly cost-effective, high-volume testing. Equally importantly, these newer technologies can provide high-quality, high-resolution HLA typing for registry donors that will facilitate and expedite organ donor searches while reducing search-related costs. The very fact that non-DNA-based approaches to HLA typing have largely been or are being eliminated from clinical typing laboratories speaks highly of the DNA-based techniques that have replaced antibody- and cell-based screening methods. While SSO and SSP methods will continue to provide simple, economical routine detection of common alleles, methods that can reduce ambiguities and definitively identify HLA alleles will take precedence. This is particularly true when considering the possibility that tissue typing may include even more exons, and possibly introns, in future tissue-matching efforts. Sanger SBT will continue to provide improved high-resolution typing over SSO or SSP methods, but its inability

to resolve phasing ambiguities and its relatively stable and rather high cost will ultimately force its replacement by newer, more advanced sequencing techniques.

With the success of next-generation sequencing platforms and potential advantages of novel third-generation platforms under development, it is clear that single-molecule sequencing may finally resolve all HLA tissue-typing needs. By providing unambiguous, direct haplotype data (within a single gene), the problem of polymorphic phasing is totally eliminated. This is especially true as NGS read lengths continue to increase. By providing whole-gene sequencing, the detection of novel alleles will be facilitated, potentially eliminating all secondary approaches to verify and resolve ambiguities. This whole-gene, full-length allele sequence data will also rapidly improve donor registry databases, providing unprecedented rapidity in evaluating and matching donor and recipient samples.

Even with the current pricing of "personal" sequencing systems, HLA typing by NGS is already possible at costs that are in line with current reimbursement allowances. With sufficient thought and development of the supporting processes, HLA typing by NGS can be both economical and practical. And as NGS continues to advance in technical performance, the ability to apply NGS broadly to clinical HLA typing will only become simpler and more cost-effective for both low- and high-volume laboratories. This is particularly true when considering the interest in HLA typing by leading technology platform companies like Illumina and Thermo Fisher that are actively developing HLA-specific typing kits for their developing platforms. If this trend continues, and if typing by NGS becomes fully supported by these companies, HLA typing will finally advance to the level it has always required but was never quite able to achieve.

Beyond the Molecular Genetics of HLA

While these advanced technologies will provide highly refined approaches for the characterization of HLA genomic sequences, there will remain the need to expand our understanding of the expression of these HLA gene products on the cell surface and the impact of that expression on immune function. Polymorphisms causing alterations in cell surface expression or tissue-to-tissue variability of expression will need to be studied in the context of their significance and impact on tissue transplantation and immune function. For this reason alone, the HLA community should continue to develop new approaches that will match the impressive progress at the genomic level (characterizing genetic variation) with insight into the physiologic relevance and consequences of these genomic differences on HLA protein function.

The authors and volume editors wish to thank Carolyn Katovich Hurley for her excellent review of this chapter and her helpful comments and suggestions.

Evaluation of the Humoral Response in Transplantation

PAUL SIKORSKI, RENATO VEGA, DONNA P. LUCAS, AND
ANDREA A. ZACHARY

114

INTRODUCTION

Relevance of Antibody in Transplantation

Antibodies of the IgG class can damage tissues in a variety of ways, including (i) directly through complement activation, (ii) indirectly through the deposition of immune complexes, and (iii) indirectly through the recruitment of cytotoxic or inflammation-inducing cells. Very high levels of antibody result in hyperacute rejection and graft failure, an outcome that can easily be avoided by the performance of a lymphocyte crossmatch test prior to transplantation. In contrast, clear elucidation of the relevance of donor-reactive antibodies of various strengths and specificities and of antibodies that arise after transplantation has been hampered by inadequate technologies and lack of reimbursement for posttransplant monitoring of antibodies. Nonetheless, a deleterious effect of antibody specific for mismatched donor HLA antigens has been demonstrated for nearly every type of organ and tissue that has been transplanted in sufficient numbers, including hematopoietic stem cells and, possibly, composite tissues. There is overwhelming evidence indicating that anti-HLA antibodies are involved in hyperacute, acute, and chronic rejection of organs (1). In mismatched bone marrow transplants, there is a risk of immunocompetent tissues from sensitized patients producing antibody to recipient tissues as well as a risk of recipients making antidonor antibodies. In theory, antibodies specific for any antigen on transplanted tissue should be capable of damaging the transplant. The best-known antibodies that are injurious to allografts are those specific for antigens of the HLA and ABO systems. Potential deleterious effects of other antibodies are being recognized increasingly. A discussion of those is beyond the scope of this chapter, and the interested reader is directed to two excellent reviews on this topic (2, 3). The focus of this chapter will be HLA-specific antibodies, and we will use the term donor-specific antibody (DSA) to refer to antibody(ies) specific for donor HLA antigens.

There are multiple reasons as to why HLA-specific antibodies are so important to detect and monitor. HLA antigens are present on transplanted tissues (class I [HLA-A, -B, -C] antigens are expressed on most nucleated cells, and class II [HLA-DR, -DQ, -DP] antigen expression, although more limited, is likely to be induced at the time of transplantation or inflammation), most transplants involve some degree of HLA mismatch, HLA antigens provoke one of the strongest immune responses, and recipients may become sensitized to HLA antigens prior to transplantation through transfusion, pregnancy, and possibly environmental agents or after transplantation by the graft itself (*de novo*). The risk represented by HLA-specific antibodies is determined by the characteristics of the antibody, including class, specificity, strength, timing, and course (i.e., whether the antibody is increasing or decreasing), and by the characteristics of the tissue (i.e., the extent and type of antigen expression and the resilience of the tissue to antibody-mediated damage). The level of risk, as measured by timing and extent of damage to the graft, is directly proportional to the antibody titer. Regarding immunoglobulin class, IgG antibodies are established risk factors, the data are ambiguous for IgM antibodies, and there are data suggesting that HLA-specific antibodies of the IgA class are beneficial in transplantation (reviewed in reference 1). It has been clearly demonstrated that antibodies to either HLA class I or class II antigens represent a risk and are capable of producing hyperacute rejection. However, the levels of antigen expression vary among HLA loci. Antigens encoded by the HLA-C, -DP, -DQ, -DRB3 (DRw52), -DRB4 (DRw53), and possibly -DRB5 (DRw51) loci are expressed at much lower levels than those encoded by HLA-A, -B, and -DRB1, and there may be a lower risk of rejection associated with their respective antibodies. However, rejection due to antibodies to HLA-Cw, -DQ, and -DP antigens has been reported, including at least one case of a hyperacute rejection resulting from an antibody to donor Cw (4–7). Antibodies that are present at the time of or that develop after transplantation can damage tissues. In contrast, antibodies that were present only historically appear to represent little risk except in two situations: (i) when the current transplant shares a mismatched antigen with a previous transplant and (ii) when a previous graft was lost to an early immunologic rejection. The course of antibodies over time is also an important indicator of the level of risk. Antibodies that are increasing in strength or expanding in specificity may represent a recent or ongoing sensitization, which may include newly developing antibodies to donor antigen; they are potentially of great risk and can be refractory to treatment. Highly sensitive detection assays available now make the determination of these increases in antibody strength and specificity much easier. Conversely, antibodies that are waning in titer or breadth may reflect an active downregulation of the immune response and may be more responsive to intervention. Differences, among organs

doi:10.1128/9781555818722.ch114

and tissues, in HLA antigen expression, extent of exposure to antibody, and impact on the function of antibody-mediated damage are well known. However, a variety of factors, such as certain cytokines and hormones, which can be released in response to trauma, infection, or certain treatments, can affect antigen expression, which, in turn, can provoke a humoral response and provide increased target for antibody binding.

Goals and Aims

When testing for HLA-specific antibody, a laboratory's goal should be to determine the level of risk to the transplanted organ or tissue. Despite the danger represented by HLA antibody, the risk to the transplant can be overcome, in many cases, through appropriate intervention. The data obtained from tests of HLA-specific antibody provide an opportunity to determine what treatment, if any, will overcome the risk associated with any given transplant. Risk exists in the form of existing antibody or an increased probability of making antibody to donor HLA. The most definitive source of information is the detection and characterization of antibodies both prior to and following transplantation. This includes assessing the antibody characteristics, identified above, that are associated with risk: immunoglobulin class, titer, specificity, and trend. However, even routine screening prior to transplantation represents only a small window in the patient's history, and there is a substantial opportunity for undetected sensitization. Therefore, obtaining information about potentially sensitizing events in the patient's history will increase the accuracy of the assessment of risk. This chapter will deal with the technical aspects of obtaining the information necessary to evaluate humoral sensitization to HLA antigens in transplant patients.

The minimal testing requirements for compliance with the Clinical Laboratory Improvement Act (CLIA) of 1988 can be found in the *Code of Federal Regulations* (8). There has been an ongoing expression of concern, by some, regarding the expense of testing for humoral sensitization. A review of the literature provides extensive evidence of the benefit of such testing in prolonging graft and patient survival and reducing injurious rejection episodes. Treatment protocols designed to overcome sensitization, the single largest barrier to transplantation, are being used worldwide to increase opportunities for transplanting sensitized patients. Antibody testing provides a means of identifying the best candidates for these protocols and monitoring treatment efficacy. Given the high cost of treating rejection, of reduced graft survival, and of alternative treatment when transplants fail, testing for antibodies is a very cost-effective investment.

METHODS

Creating a Patient Profile

Certain patient information is useful for quantifying the risk of rejection, assessing how aggressive a responder a patient is, and interpreting results of antibody tests (9). The applicable information is outlined in Table 1. The table is reasonably self-explanatory and merits only a few additional remarks. Information about previous sensitizing events can be used to achieve a gross assessment of how aggressively a patient responds to exposure to HLA. Patients with a previous graft in place have a source of antigen for maintaining sensitization but may have artificially low levels of antibody because the donor tissue is acting like an "immunologic sponge," removing antibody by adsorption onto the antigens expressed on the tissue or by releasing soluble antigens that bind to the antibody. However, the high sensitivity of the multiplexed bead assays in wide use permit detection of HLA antibody even with a graft in place. Following a recent transfusion, samples should be obtained approximately 2 to 4 weeks posttransfusion to optimize detection of a humoral response. Transfusion histories are extremely difficult to obtain, are often inaccurate, and should be supplemented with information about previous surgeries that might have been occasions for transfusion.

Tests

There are two categories of test used to assess a humoral response, crossmatching and the antibody screen, the latter of which may be further subdivided into screens that simply

TABLE 1 Patient information

Item	Information needed	Relevance
Diagnosis	Specific disease	May indicate the likelihood of auto-antibody
Previous transplants	No. and duration	Extent of immunologic exposure
	Type and date of each	Graft duration, organs at risk
	Present or explanted	Allograft in place may absorb antibody
	HLA phenotype of each	Identify mismatched antigens and repeated mismatches
Pregnancy history	No. of pregnacies	Extent of possible sensitization
	No. of births	Extent of possible sensitization
	Identities of paternal antigens	Specificity of possible sensitization
Transfusions	Yes/no/no. and type	Possible sensitization
	Date of most recent	Identification of sera to be tested
Surgeries	Kind and date of each	Possible source of unrecognized transfusions
Medications	Humanized or chimeric antibodies	Test interference not readily resolved
	Xenoantibodies	Test interference, may be adsorbable
	Cytotoxic drugs	Interference in cell-based assays
Proinflammatory events	Infection	Activation of memory, HLA-specific B cells
	Trauma	
	Transfusion	

test for the presence of antibody and those designed to provide antibody characterization.

Crossmatches

The crossmatch test assesses the presence, in the recipient's serum, of antibody reactive with donor antigens. The most commonly used medium for the antigen is donor lymphocytes, which are readily obtainable and express HLA antigens at high levels, although other cells and tissues have been employed in specialized studies. Complement-dependent cytotoxicity and flow cytometry are the techniques most widely used. The advantages of the crossmatch test are that it measures reactivity with donor antigens directly and can be used to track the trend of antidonor reactivity through serum titration. The disadvantages are that (i) when cellular targets are used, the test does not readily differentiate HLA-specific antibodies from other antibodies that bind to lymphocytes; (ii) multiple therapeutic drugs interfere with the crossmatch test and may render the test uninterpretable; and (iii) donor cells are not always available at the necessary time or in sufficient quantity, although it may be possible to use cells from a surrogate donor, as will be discussed later. In HLA-mismatched transplants that include substantial amounts of immunocompetent tissues, such as transplants of bone marrow and possibly lung and small bowel, a reverse crossmatch involving donor serum and recipient cells may also be appropriate since engrafted tissue from a sensitized donor may produce antibody reactive with recipient HLA. Another antibody-mediated problem, transfusion-related acute lung injury (TRALI), can occur when transfused blood contains a substantial amount of antibody specific for the transfusion recipient's HLA antigens (10). Although a reverse crossmatch might identify such situations, it is more efficient and economical to perform screens of plasma units for the presence of HLA-specific antibody, which is now common practice.

Antibody Screens

An antibody screen is simply a crossmatch or series of crossmatches against cells or antigens from individuals selected to represent, collectively, most HLA antigens. There are three types of panels: antigens pooled from hundreds of individuals (a pooled-antigen panel), phenotype panels consisting of cells or antigens from a series of individuals, and single HLA antigens. Pooled-antigen panel tests are considered "yes/no" tests but can provide information about the extent of and changes in antibody breadth and specificity (11). Phenotype and single-antigen panels provide characterization of antibodies with exquisite sensitivity and specificity. The antibody screen has multiple advantages. It can be performed at any time prior to or following transplantation and, thus, prevent unnecessary donor testing and/or shipment of organs. Screening provides information useful in performing and interpreting a crossmatch, such as which sera represent the array of HLA antibodies that the patient has ever had; which sera might contain interfering antibodies, such as autoantibodies or therapeutic antibodies; what is the most appropriate crossmatch technique; and whether or not a positive crossmatch is due to antibodies to the donor HLA antigens. When performed on sequential samples, antibody screens provide information about trends in antibody activity. Finally, antibody screening provides a means of recognizing when sensitizing events or sample switches might have occurred.

The major disadvantages of the antibody screen are that it neither tests actual donor cells nor defines antibody directly. The high polymorphism of the HLA system mandates the use of panels of 50 to 100 phenotypes to be able to determine HLA specificities reliably. However, it is difficult to characterize sera containing multiple antibodies in tests of phenotype panels since antibodies to three or four common antigens can render a serum panreactive. Tests using single, purified antigen targets resolve this problem to some extent, but these panels come with their own attendant problems. Consideration should be given to utilizing a variety of tests in parallel to elucidate the most accurate antibody profile for a given serum. However, this can be cost-prohibitive, and care must be taken when designing testing protocols to test sera in the most cost-effective manner possible, while maintaining a high standard of patient care in relation to antibody characterization.

Techniques for Testing Antibody

General Principles

There are two categories of techniques differentiated by type of target: (i) those that utilize cells as targets, namely, cytotoxicity and flow cytometry, and (ii) those that utilize soluble HLA molecules bound to a solid matrix. The relevant factors for each type of assay and their advantages and disadvantages are summarized in Tables 2 and 3, discussed below.

TABLE 2 Assay characteristics

Characteristic	Outcome of indicated cell-based assay		Outcome of indicated solid-phase assay		
	Cytotoxicity assay	Flow cytometry	ELISA	Beads on a flow cytometer	Beads on a fluoroanalyzer[a]
Sensitivity	Low to moderate	High	High	High	High
HLA specificity	Low	Low	High	High	High
Isotype determination	IgG/IgM via serum manipulation	Yes	Yes	Yes	Yes
Cost	Low	High	Moderate to high	High	High
Automation	No	Partial	Partial	Partial	Partial
Throughput	Limited	Limited	Moderate	Limited	High

[a]Based on results with the Luminex fluoroanalyzer.

TABLE 3 Advantages and disadvantages of different assays

Category	Characteristic of:		
	Cytotoxicity assay	Flow cytometry	Solid-phase immunoassay
Advantages	No additional training needed Sensitivity can be adjusted Has been in use for 40 yr Inexpensive Uses standard laboratory equipment	Has high sensitivity Can test for different Ig isotypes Can test multiple cell types simultaneously	Has high sensitivity Eliminates most non-HLA reactivity Partial automation is possible Commercially available Readily distinguishes between cI and cII antibodies
Disadvantages	Requires manipulation to differentiate cI and cII antibodies Requires an adequate no. of viable lymphocytes Does not distinguish HLA from non-HLA antibodies Has low sensitivity	Requires expensive equipment Requires an adequate no. of viable lymphocytes Does not distinguish HLA from non-HLA antibodies Software may not interface with a lab's database	May require additional training Expensive Subject to interference from immune complexes, IgM, and some therapeutic reagents Yields relative antibody levels but not antibody strength Provides no control over antigen condition or amount

Complement-Dependent Cytotoxicity

Complement-dependent cytotoxicity (CDC) detects antibody through a secondary process: cell lysis by complement which has been activated by antibodies bound to target cells. It usually consists of a sensitization phase in which target cells and serum are incubated together, followed by addition of complement and a subsequent incubation to allow complement to be activated by bound antibody. Microscopic evaluation following addition of a vital stain permits a gross estimation of the percentage of viable cells. The sensitivity of the assay can be modified by altering incubation times and temperatures, performing washes to remove anticomplementary factors, and adding an antiglobulin reagent to enhance complement activation (12). The test is routinely performed on lymphocytes, which are usually further fractionated into T and B lymphocyte populations. Each test uses cells from a single individual.

Flow Cytometry

Cell-based flow cytometry is an indirect assay that measures the binding of antibody to cells through the use of an antiglobulin labeled with a fluorescent marker. The specificity of the antiglobulin reagent permits identification of the immunoglobulin class of cell-bound antibody. Further characterization of the cells can be achieved by gating on cells defined by physical parameters and staining cells with labeled monoclonal antibodies specific for markers that are unique to certain cell types.

Solid-Phase Immunoassays

Solid-phase immunoassays utilize affinity-purified, soluble HLA antigens isolated from culture fluid or human plasma, solubilized from cell membranes, or synthesized via recombinant technology. Initially performed in an enzyme-linked immunosorbent assay (ELISA) format, they are today most commonly performed as a multiplexed assay with soluble antigens bound to beads differentiated fluorescently. Multiplex bead assays can be performed by two means: standard flow cytometry and Luminex immunoassay (13). In standard flow cytometry, a single dye is incorporated into beads in different concentrations to permit differentiation of beads bearing different antigens or antigen combinations. In the Luminex format, two different dyes, each at 10 different dilutions, are incorporated into beads to provide up to 100 different beads differentiated by color. The beads are examined in a dual-laser fluoroanalyzer, where one laser identifies the particular bead and another detects the presence of antigen-specific antibody through use of a fluorochrome-conjugated antiglobulin.

Advantages and Disadvantages

A few of the major advantages of the cytotoxicity assay stem from its use for over 3 decades; (i) it predicts and can prevent hyperacute and acute antibody-mediated rejection; (ii) all the test variables, factors affecting the test, and quality control requirements have been well characterized; (iii) the test utilizes very small volumes of test materials (1 to 2 μl of serum and 2,000 to 2,500 cells per reaction); and (iv) the assay is relatively inexpensive to run. Multiple serum samples can be tested at multiple dilutions, providing information about antibody titers and trends in one or multiple patients. Despite these advantages, however, the test has many shortcomings. It requires an adequate supply of viable lymphocytes, requires separate tests of T and B lymphocytes and removal of class I-specific antibody to identify class II-specific antibodies, depends on the activity of complement, which is a highly variable and labile reagent, requires adequate amounts of the heterophile antibody found in rabbit serum used routinely as the complement source, is not sufficiently sensitive to detect extremely low levels of antibody, and, most importantly, does not readily differentiate between HLA-specific and other lymphocyte-binding antibodies. Antibodies that may interfere in the assay include autoantibodies, therapeutic antibodies that react with all or some subsets of lymphocytes, and

some anti-Lewis antibodies. Spurious reactions with B lymphocytes have been attributed to antiviral antibodies. A gross evaluation of the class of antibody reactive in the assay is possible through inactivation of IgM with reducing reagents or heat aggregation. However, neither technique will completely abrogate the reactivity of high levels of IgM.

Cell-based flow cytometry provides a high degree of sensitivity, permits simultaneous analysis of multiple cell types without the need for separation of cells, and facilitates determination of immunoglobulin class through the selection of antiglobulin specificity. However, like cytotoxicity tests, it requires an adequate number of viable cells and does not readily differentiate between HLA-specific and other lymphocyte-binding antibodies that either are of human origin or have been humanized. Further, it requires expensive equipment and specialized training and utilizes expensive reagents.

Solid-phase immunoassays using purified HLA antigens combine a high degree of sensitivity and specificity. Solid-phase immunoassays readily distinguish between class I- and class II-specific antibodies by using antigens of only one class in a single test. Further, these assays provide a more refined quantification of reactivity with the different phenotypes by scoring reactions on a continuous scale, which enhances the characterization of antibody specificity. The ability to test against pooled antigens represents a potential for substantial cost savings when sera are tested in batches. Further, beads differentiated by color permit multiple tests to be run in a single assay that uses a very small serum volume. Phenotype assays combine the ability to define specificity with an assessment of relative antibody level. However, although some specificities can be determined in even polyreactive sera, not all specificities can be identified in such sera. Single-antigen panels permit detection and identification of all antibody specificities. The disadvantages of the multiplexed bead assays include a potential need for additional equipment and training, increased reagent cost for some of the assays, and a need for extensive quality control. The high sensitivities of these tests contribute to increased variability and necessitate extensive experience to optimize the interpretation and use of the test results. Nonspecific binding of immunoglobulin may occur when the test serum contains immune complexes or aggregated immunoglobulin, rendering the test invalid. We have found that high levels of IgM antibodies can affect test results, even when an IgG-specific antiglobulin is used (14). We and others have also found that some therapeutic agents can interfere with test results (15). In the past, there has not been a uniform amount of antigen among different beads that are each coated with HLA molecules of one specificity. However, manufacturers have made a great effort to provide a more uniform amount of antigen on each bead. HLA molecules may be distorted upon being bound to a solid matrix, resulting in the loss of some epitopes or the creation of others. Naturally occurring antibodies or antibodies to non-HLA epitopes have been found in nonsensitized males. On the one hand, false-positive reactions due to a non-HLA antibody may prevent a compatible transplant, while a false negative that occurs when an HLA antibody fails to react with a distorted molecule may result in a transplant at increased risk for antibody-mediated rejection (16). Finally, in any assay with computer-generated results, there is a potential for a problem in interfacing with the laboratory's existing database.

It is important to note that cell-based and solid-phase immunoassays are complementary—the former assessing the strength of reactivity with donor cells directly and the latter providing determination of the basis for a crossmatch reaction. A conference of experts that took place in 2012 recognized this and made a strong recommendation to use both types of assays in assessing donor-recipient compatibility (17).

Quality Control

Crossmatching

There are three quality control procedures relevant to the crossmatch test. The first is to ensure that the cells being tested are from the right individual. This can be achieved by performing HLA typing in parallel with crossmatching and using the same cells used for the crossmatch. The second is to identify reactivity due to non-HLA-specific antibodies. Some of these antibodies, namely, autoantibody and therapeutic, lymphocyte-reactive antibodies, can be detected by performing an autologous crossmatch. Finally, use of the crossmatch test to track the course of antibody, including with a serum sample that was previously tested by the same technique as a reference, will provide a measure of variability in sensitivity.

Antibody Screen

Even though a positive control is included in all tests, it usually is not adequate to detect small variations in sensitivity. Such variations may result in a failure to detect antibodies present in levels that are at the border of the test's sensitivity. Inclusion of one or more well-characterized sera, diluted to near their endpoint of reactivity, would provide a means of recognizing this degree of variability.

Cytotoxicity Assay

Information about the cytotoxicity assay and relevant quality control measures is available in an excellent source (18), and we mention here only a few items particularly important in tests of antibody.

Frequently, different lymphocyte subsets are used in the cytotoxicity test because of differences in the levels of expression of various antigens. The test should include controls specific for these subsets to estimate the relative purity of the cell preparation and detect contamination with unwanted cell types. These controls are usually monoclonal antibodies specific for a cell surface marker unique to or predominant in a certain cell type and most often are designed to identify T and B lymphocytes and, occasionally, monocytes.

Addition of an antiglobulin reagent is a frequent modification of the cytotoxicity test used for antibody detection. In these cases, it is important to include a control to validate the presence and efficacy of the antiglobulin reagent. This control should be a serum that activates complement only in the presence of the antiglobulin reagent.

Most nonspecific cell death, (i.e., cell death not mediated by HLA-specific antibody) is detected in the negative-control wells. However, there may be occasions, particularly in the crossmatch test, that warrant additional discrimination. In these cases, the question of whether cell death is mediated by antibody or not can be resolved by running a parallel test using heat-inactivated (56°C for 30 min) complement.

Solid-Phase Immunoassays: Reagents

There are a number of factors that can contribute to variability among test reagent lots, including (i) changes in any component that affects test sensitivity, (ii) variability in the preparation of one or more individual phenotypes, (iii) contamination of or absence of antigen on one or more beads, (iv) changes in a cell line used as a source of antigen, and (v) manufacturing differences in the solid-phase media used. In

turn, these factors can affect the threshold value for a positive test result, the background reactivity of an individual phenotype or single antigen bead, and the ability of an individual phenotype or single antigen bead to yield a positive reaction with specific antibody. Some of this variability can be assessed by testing each lot of reagents with a panel of well-characterized sera that includes sera known to contain HLA-specific antibodies as well as some known to lack such antibodies. In addition, each lot of reagents should be monitored throughout the course of its use to determine if the correct value has been selected as the threshold for a positive reaction and to determine if any individual phenotype demonstrates an inordinate number of reactions that are discordant with the assigned antibody specificity (1). Recent reports have shown that normalizing reactions to the amount of antigen present improves the interpretation of the results. It is likely that this sort of normalization is best conducted by the manufacturer on each lot of reagents rather than by each individual user, providing uniform standardization while minimizing the additional cost.

Solid-Phase Immunoassays: Tests

Tests with pooled antigens provide little or no opportunity for detecting slight variations in test sensitivity or operator error, such as sample switch or dilution error. Inclusion of two or more blind, characterized sera serves as a quality control measure of the test system as well as of testing personnel. The sera should vary in strength to provide a meaningful assessment of test sensitivity and should vary from run to run to serve as meaningful unknowns. Background reactivity may be caused by a variety of factors, including high IgM levels, immune complexes, and certain therapeutic agents, among others. Background reactivity can result in false negatives when it occurs in the negative controls and false positives when it occurs in the test well or bead. The high sensitivity of single-antigen beads appears to make this panel more susceptible to interference and variability. There are commercially available blocking agents designed to reduce nonspecific reactivity. We have found that depletion of IgM by hypotonic dialysis effectively removes or reduces interference, providing increased reactivity with test sera and the positive-control bead (14). Drawbacks to this procedure are that it is time-consuming and can introduce some degree of dilution. Certain patients, notably those undergoing hemapheresis or plasmapheresis, have reduced background reactivity. In such cases, computerized analysis may interpret low values as positive. In assays that use beads, the wash technique must be appropriate and consistent to avoid variable loss of beads. Of course, standard quality assurance measures, particularly instrument calibration, are essential to ensure consistent and reproducible results. Quality control factors relevant to tests of antibody are summarized in Table 4.

TEST VALIDATION

The requirements for validation of laboratory assays are described in detail in the *Code of Federal Regulations* (8). Testing for HLA antibodies is confounded by the complexity of the HLA system, the antibody response to HLA antigens, and the lack of reference antibodies. Therefore, test validation can be prolonged and costly. To optimize evaluation of the assays and the clinical utility of the data generated, there should be an ongoing comparison of the results of various tests; can the crossmatch and antibody screen results for a specimen be reconciled? These comparisons reflect the sensitivity and specificity of the various assays. A frequently asked question is "How many sera need to be tested for validation of an antibody screen assay?" This question is impossible to answer with a number because of the thousands of possible combinations of antibodies that can be present in a specimen. The practical answer is that the validation must

TABLE 4 Quality control

Test/method	Factor	QC measure	Purpose
Crossmatching	Cell identity	Performance of serologic typing simultaneously with XM on cells used in XM	To verify identities of cells used in XM test
	Antibody specificity	Autologous XM	To test for the presence of autoantibody
	Titer	Inclusion of a previously tested serum in the XM	To assess the comparability of test sensitivities when comparing changes in antibody strength
Antibody screen	Test sensitivity	Inclusion of a serum tested at the threshold of reactivity	To detect variation in test sensitivity
Cytotoxicity assay	Cell type	Cell-specific antibody	To assess proportions of cell types in the preparation
	Antiglobulin	Inclusion of an antiglobulin-dependent serum in the test	To verify the addition and efficacy of the antiglobulin reagent
	Nonspecific cell death	Inclusion of inactivated complement	To indicate the occurrence and extent of cell death not due to antibody
Solid-phase immunoassays	Nonspecific binding	Antigen-free matrix (bead or well)	To assess nonspecific binding
	Phenotype validation	Panel of sera containing well-characterized HLA antibody	To determine if beads/wells yield expected reactions
	Variability in sensitivity	Normalization of test serum reactivity to that of a positive control	To normalize for variability in sensitivity

generate enough data for the user to be able to interpret the test results reliably. Some aspects of an assay's performance may be detectable only after extensive testing. Therefore, ongoing evaluation of an assay should continue after sufficient testing has been performed to place the test into clinical use with confidence.

INTERPRETATION

Antibody Screen

The data that may be obtained from antibody screens are the antibody level and the specificity. Positive reactions of a serum with a panel of phenotypes may vary in strength because of differences, among phenotypes, in the numbers of antigens to which the serum contains antibodies and, for cell-based assays, because of normal variability in antigen expression among individuals, among cell types, among antigens, and within an individual from day to day. There are abundant data regarding variability in antigen expression on cells. Class I antigens are expressed at higher levels on B cells than on T cells. Among various loci, HLA-Cw antigens are expressed at lower levels than are HLA-A and -B locus antigens, and antigens encoded by DRB3, -4, and (possibly) -5 loci (DR52, -53, and -51, respectively) are expressed at approximately 15 to 20% of the level of the DRB1-encoded antigens (DR1-18) (19). In tests of pooled antigens, differences in reaction scores obtained with different sera from the same individual reflect differences in the breadths of antibody specificities as well as their strengths. In tests of individual phenotypes, stronger reactions are obtained with phenotypes homozygous for a target antigen or having more than one target antigen. This, in turn, may be useful in verifying antibody specificity. Quantification of the strength of reactivity is more refined in solid-phase immunoassays and flow cytometry than in cytotoxicity testing, and this information may be useful in confirming putative assignments of antibody specificity. Determining the molecular equivalents of soluble fluorochromes (MESFs) for flow cytometric or Luminex results permits comparison of test results from specimen to specimen and day to day. To determine MESFs, a standard calibration curve is created using beads labeled with different, known amounts of a fluorochrome. The MESF value for a test serum is then obtained from the standard curve by interpolating the fluorescent channel values of the serum (20).

Immunoglobulin isotype is most precisely defined in adherence assays that use an isotype-specific antiglobulin. When isotype-specific antiglobulins are used, it is important to verify the reagent specificity, as many "monospecific" reagents have been found to cross-react with other isotypes. In cytotoxicity assays, the immunoglobulin class may be approximated by heating serum (63°C for 10 min) or by adding reducing reagents to inactivate IgM. However, both methods have limited efficacy. Titer determination is easily achieved in cell-based assays by testing a serum at multiple dilutions.

Calculated PRA

A major goal of antibody screening is to be able to assess the breadth and strength of a patient's antibodies and to apply that information to crossmatch prediction. Historically, the measure of breadth was the percent panel-reactive antibody (PRA), which is the percentage of a panel of phenotypes with which a serum gives a positive reaction. Obviously, the numeric value obtained is determined by the panel composition, which does not, necessarily, reflect the frequency of phenotypes in the donor population or the likelihood that an unrelated donor will be incompatible. Many transplant programs now use population frequencies to assess the breadth of sensitization more accurately. In 2009, the United Network for Organ Sharing (UNOS) adopted the use of a calculated PRA (CPRA) that applies an algebraic calculation to determine the percentage of the population that is incompatible (21). The patient data used in the calculation are the donor antigens determined to be unacceptable for transplantation. Using the antibody data gathered for any given patient and by establishing a correlation between antibody strength as determined by solid-phase bead-based assays and crossmatching, a CPRA can be generated to calculate the likelihood of achieving a negative flow-cytometric or cytotoxicity crossmatch result. The value can also be applied by setting a very low threshold to encompass all of a patient's antibodies or to avoid previously mismatched antigens, thus giving the likelihood of finding a donor to which the recipient has no HLA antibody. The calculation can be performed readily using the UNOS CPRA calculator, which can be accessed at https://optn.transplant.hrsa.gov/resources/allocation-calculators/. This program uses frequency data from the U.S. population, accounting for the proportions of different races in the population.

Virtual Crossmatching

CPRA is a statistic applied to determining the likelihood of incompatibility of an unspecified donor in the population, while the virtual crossmatch test is applied to assessing the likelihood that a donor of known HLA phenotype is incompatible. The virtual crossmatch test also uses the specificities of antibodies that are at a strength deemed unacceptable for transplantation. When the threshold is a positive crossmatch, one must identify those antibody specificities that, individually, will yield a positive crossmatch. In situations where a patient has antibodies to multiple antigens of a donor, it is important to make an assessment of the collective strength of those antibodies. Data on the relative strengths of antibodies can be obtained from solid-phase assays by correlating the results of those assays with crossmatch results (22). In establishing these correlations, it is important to take into account the variable amounts of different antigens and, in particular, those antigens with greatly increased amounts in bead assays, namely, HLA-Cw, -DQ, and -DP.

Thus, accurate characterization of the HLA-specific antibodies in a serum may provide the most valuable information for transplant purposes. This information can be used to (i) reduce cold ischemia time by preventing the unnecessary shipment of organs and crossmatch testing of patients incompatible with a specific donor, (ii) avoid incorrectly passing over a sensitized patient by recognizing donors to whom the patient has no antibodies, (iii) determine the clinical relevance of a positive crossmatch by recognizing whether the reactivity is due to HLA-specific antibodies or not, (iv) permit preemptive treatment to avoid antibody-mediated rejection by detecting DSA in levels too low to be detected in the crossmatch test and/or formed *de novo* after transplantation, and (v) facilitate accurate and effective paired-exchange programs. While the utility of cell-based assays, such as cytotoxicity and flow-cytometric crossmatches, should never be overlooked, these virtual crossmatches have taken on a larger role in the laboratory.

Phenotype Panel

Most laboratories today use solid-phase assays rather than cell panels. Therefore, we will not deal with interpretation of data from cell panels here. Rather, the reader is referred to previous editions of this *Manual* for a thorough discussion of

that topic. Interpreting antibody specificity from phenotype panels in solid-phase assays is greatly facilitated by ranking reactions in descending order of strength. An example is shown in Fig. 1. It can be seen that DR52-bearing phenotypes are clustered at the top of the results, with the strongest reactions being phenotypes homozygous for DR52. Below that are phenotypes bearing DR8, an antigen strongly cross-reactive with DR52. Note that below these phenotypes, the reaction strength drops off drastically. However, note also that both of the phenotypes immediately below those with DR8 or DR52 have DR4. While this may be a coincidence, it may suggest the presence of very weak antibody, and one should monitor future serum specimens for possible confirmation of that specificity.

Single-Antigen Panel

Solid-phase immunoassays using purified, single HLA molecules as targets have rapidly become the "go-to" test that identifies specificity readily and is the most sensitive of the types of panels available. The advantage of the single-antigen assays is the ease of analysis and the ability to track antibodies to uncommon antigens or antigens that are difficult to detect on phenotype panels. In particular, antibodies to HLA-Cw and -DP are not detected readily on phenotype panels. Furthermore, in the most broadly sensitized individuals, phenotype panels often are panreactive, making it difficult to characterize all HLA antibodies present. However, the high sensitivity of the single-antigen panel also makes it the most susceptible to interference, run-to-run variability, and problems with conformation of the HLA molecules. Attaching soluble HLA molecules to a solid matrix can result in the distortion of the molecule destroying native epitopes and creating nonnative epitopes. The susceptibility to distortion varies among different antigens. It has been demonstrated that antibodies present in males known to be nonsensitized to HLA can react with distorted HLA molecules (16). Thus, a false-positive reaction may occur due to antibody to a nonnative epitope, and a false-negative reaction can result when a native epitope is lost. Precise information about the quantity of each antigen and the extent to which structural conformation may have been compromised is not readily available for these products. Further, when using single-antigen reagents, the determination of the presence or absence of a particular antibody may rely on only a single reaction. In these cases, a technical failure that involves a key antigen may have serious consequences.

Assigned	Raw Val.	Class II Antigens

FIGURE 1 Results of serum tested on a phenotype panel. The specificity of the antibody can readily be discerned by the clustering of DR52 phenotypes. Note that the three phenotypes bearing DR8, an antigen that strongly cross-reacts with DR52, are interspersed among the DR52-bearing phenotypes. Val., value.

Therefore, single-antigen reagents are probably best used as an adjunct to other antibody tests, in particular when other assays do not provide a clear identification of antibody specificities.

As there is a finite amount of antigen present on each bead, there is also a maximum amount of antibody that can be bound. When a bead is saturated with antibody, it will be difficult to assess the relative strength of the antibody or detect changes in antibody strength over time. In such cases, it is necessary to test sera at a dilution. This provides an additional advantage in that diluting a serum often reduces or eliminates interference. However, one should be cautious about testing sera only at dilution, since newly developing antibodies may go undetected until they reach a certain strength.

Crossmatch Tests

There are two levels of interpretation to be considered in the crossmatch test: whether or not the test result is positive and what the test result means clinically. While it is possible to detect cell death and changes in either optical density or fluorescence, the lack of reference reagents has made it impossible to determine what amount of antibody yields what degree of reactivity in any of the assays used. This is further complicated by test variability within and among assays, among laboratories using the same assay, and among treatment protocols and transplant practices. Therefore, most interpretation is based on clinical outcome. Unfortunately, many of the studies performed to correlate crossmatch results with clinical outcome have not controlled for many of the relevant variables, including the (i) timing of the serum specimen relative to transplantation, (ii) immunoglobulin class of the antibody, (iii) antibody specificity, and (iv) antibody titer. Therefore, the conclusions of these studies are frequently in conflict with each other.

Reactivity strength in cytotoxicity assays is measured on a discontinuous scale in which the percentage of dead cells is grouped into five categories, while flow-cytometric assays are measured on a continuous scale. There are a large number of variables that can affect the assessed strength of reactions in a cell-based assay, including day-to-day variability in test conditions and variability among technologists in assessing reaction strength. When using crossmatch tests to monitor changes in antibody over time, it is useful to include a previously tested serum as a means of assessing variability in test sensitivity. Also having a single technologist read sequential tests will eliminate technologist-to-technologist variability.

Dealing with Interference

Autoantibodies

Among the most common interfering antibodies occurring prior to transplantation are autoantibodies. Many of these antibodies are IgM and can be eliminated by heat inactivation or treatment with reducing agents, such as dithiothreitol. However, these techniques will not completely abrogate reactivity when the antibody is at a high titer and are not compatible with testing using solid-phase assays. More-effective techniques to eliminate IgM, such as chromatography or dialysis (14), or tests that use an isotype-specific conjugate may be necessary in order to achieve a meaningful crossmatch or for accurate interpretation of bead-based, solid-phase assays. However, the large IgM molecule may block IgG binding, rendering the use of an isotype-specific conjugate ineffective. Autoantibodies of the IgG class are less common but do occur and are much more problematic in tests. The removal of these antibodies requires adsorption. Periodically, autoantibodies will be present in an otherwise-healthy-appearing donor. This is suggested when tests of donor cells persistently yield positive reactions in the negative controls of cell-based tests despite consistently good pretest viability. When this is suspected, it is worthwhile to do a donor autocrossmatch for confirmation. The reader is advised that adsorption with cells requires a large volume of cells and can lead to dilution when a small quantity of serum is adsorbed.

Therapeutic Antibodies

Therapeutic antibodies can be problematic in both cell-based and solid-phase assays. When the antibodies are of nonhuman origin, they can be removed by adsorption with magnetic beads coated with a species-specific antiglobulin, or the interference can be overcome by performing flow cytometry with antiglobulin reagents that have been adsorbed to remove reactivity with all but human immunoglobulin. The use of therapeutic humanized antibodies, however, is problematic in cell-based and solid-phase bead-based assays. These antibodies may be reactive in cell-based assays for months after cessation of treatment. In some cases, the target antigen may be removed from the cell surface, abrogating antibody activity. For example, pronase treatment of B cells removes CD20, the target of rituximab. However, pronase is a nonspecific protease that may also destroy or distort HLA molecules on the cell surface (23). When the antibody target cannot be removed, adsorption with cells bearing the target antigen but lacking donor HLA antigens becomes the only recourse. In bead-based antibody detection assays, therapeutic antibodies can cause interference. This interference often can be removed by hypotonic dialysis of the serum to remove the interfering agent. Some agents, such as antithymocyte globulin, can yield a pattern of reactivity that appears HLA specific. If the presence of antithymocyte is not known or taken into account, the test results will be misinterpreted as positive for HLA antibody.

Pronase Treatment of Cells

In the flow-cytometric crossmatch, increased background activity is often seen with B cell targets and has been attributed to the nonspecific binding of IgG to Fc receptors present on B cells. Further, the presence of rituximab (Rituxan), which binds to the CD20 molecule on B cells, renders a B cell crossmatch uninterpretable. Pronase, a nonspecific protease, has been used to resolve both problems. Low levels of pronase have been used to reduce or eliminate Fc receptors, while higher doses have been used to cleave CD20. Pronase also affects HLA molecules in a dose-dependent fashion, and selection of the amount of pronase to use should achieve maximum reduction of background with minimal impact on HLA expression. Higher doses of pronase are necessary to reduce CD20 expression sufficiently, and we have shown a significant impact on HLA expression at these higher levels.

Dealing with Interference in Solid-Phase Immunoassays

While autoantibody and certain therapeutic agents (eculizumab, high-dose intravenous [i.v.] immunoglobulin, bortezomib [15]) have been shown to interfere in solid-phase assays, background reactivity, as indicated by high negative-control or low positive-control values, may occur in the absence of these factors. Such interference may be due to the presence of immune complexes, plastic antibodies, or other as-yet-unidentified factors. Several techniques have been

applied to reducing or eliminating interference, including hypotonic dialysis (14), treatment with a reducing agent, dilution, and the addition of EDTA (24) to serum. Hypotonic dialysis is the most labor-intensive and time-consuming of the procedures, but it is also the only procedure that removes interfering substances. Reducing agents have a greater effect on IgM than on IgG; however, monomeric units of IgM with antigen binding capability may remain, and there is some impact on IgG. The benefit of dilution is based on the possibility of a differential effect on the binding of HLA IgG antibodies and the binding of interfering substances. Finally, the use of EDTA is to eliminate the binding of C1q that may block the binding of the antiglobulin reagent.

Assessment of Antibody Function

Based on the assumption that complement activation is the major way in which antibodies damage allogeneic transplants, modifications of the bead-based assays have been developed to assess the binding of C4d (25) and C1q (26). Both of these assays have been shown to correlate with clinical outcomes (25, 27), and at present, the C1q assay is available commercially from One Lambda, Inc. The C4d assay yields very low mean fluorescent intensity (MFI) values that may limit its use as a diagnostic tool. While the MIF values obtained with the C1q assay are high, some have reported that the test results simply correlate with antibody strength (27, 28), although others have reported negative C1q results with sera that yield high MFI values in the unmodified assay for HLA antibody. Further, while complement-mediated injury may be the most severe aspect of antibody-mediated rejection, it is not the only way in which donor-specific antibodies can lead to graft dysfunction and damage.

Application

Whom To Test

Three groups of patients are at high risk for an adverse effect of HLA-specific antibodies: organ transplant recipients, patients receiving platelet and/or leukocyte support, and patients receiving HLA disparate bone marrow transplants. In the case of bone marrow transplants, both the donor and the recipient should be tested. A fourth group of patients are those at risk for TRALI (see above). Although this is a serious condition and responsible for more than 10% of transfusion-related fatalities, the incidence is low (<0.5% of all patients transfused) and can be averted by having plasma screened for HLA and granulocyte-specific antibodies.

When To Test

Conventional wisdom and federal regulations indicate that testing should be performed at regular intervals prior to transplantation and following sensitizing events. Unfortunately, we do not always know about sensitizing events, and it is becoming increasingly apparent that we have not identified all possible routes of sensitization. Clearly, data from apparently nontransfused patients and evidence of similarities between microbial proteins and HLA antigens indicate that there may be a much broader potential for sensitization or reactivation of a humoral response than has been previously appreciated. Further, inflammation itself may generate a polyclonal B cell activation that results in the production of HLA-specific antibodies (29).

It has been suggested that the low rate of sensitization and increasing waiting times dictate testing only when transplantation is imminent. Most historic data on sensitization are based on cytotoxicity testing. With the increased use of the more sensitive and specific solid-phase immunoassays, it has become increasingly apparent that the percentage of patients sensitized may be grossly underestimated (13). Antibody screening can be performed at a low absolute cost, a cost much lower than that of other components of transplantation. Antibody screening provides information important to selecting patients and sera for and interpreting the results of a crossmatch and can provide advance notice of the presence of factors, such as autoantibody, that may adversely affect interpretation of the crossmatch results.

Special considerations apply to patients being treated in a protocol designed to reduce or eliminate humoral sensitization and will be discussed in a separate section below.

Perhaps one of the greatest and most costly deficiencies of the current standard of practice is the lack of adequate posttransplant testing, which results from the lack of financial reimbursement for such testing. Three factors argue in favor of such testing: (i) there are now treatment protocols that produce a durable elimination of DSA, (ii) assays currently available are sufficiently sensitive to detect antibody before a transplanted organ suffers extensive injury, and (iii) prolonging graft survival by avoiding antibody-mediated rejection not only avoids returning a renal transplant patient to costly dialysis but also avoids increasing the number of patients awaiting transplantation.

How To Test

Good management practices dictate applying the minimal number of protocols, uniformly, to maximize cost saving. Having one or a small number of test protocols does save money in the laboratory, which should mean reduced laboratory charges. However, it is quite possible that this approach extracts a much greater cost in rejection, treatment for rejection, and reduced graft survival. Given the complexity of transplantation, it is probably more cost-effective, overall, to customize testing according to the complexity and emergent nature of the case. For patients that are highly sensitized, one method of posttransplant monitoring involves designing individual testing plans for each recipient. Selection of tests appropriate for monitoring a patient's antibodies (phenotype versus single-antigen or class I and/or class II panels) can be done prior to transplantation. Close monitoring during the immediate posttransplant period is advisable, as the trauma of surgery can provoke an increase or recurrence of DSA. It is wise to monitor and reevaluate the effectiveness of the testing schematic over the course of monitoring. Having a variety of tests available in the lab to monitor antibodies and to determine which tests are needed to provide all the necessary information at the lowest possible cost is advisable.

Monitoring for Desensitization Protocols

Patients with HLA-specific antibody have access to transplantation reduced in proportion to the breadth of their sensitization and, as a group, have poorer graft outcomes. Several treatment protocols have been developed to achieve a long-lasting reduction in or elimination of HLA-specific antibodies. Currently, desensitization protocols can be grouped into two general categories: those that utilize high-dose (1 to 2 g/kg of body mass), pooled i.v. Ig and those that use plasmapheresis combined with low-dose (100 mg/kg) cytomegalovirus (CMV) hyperimmune globulin (CMVIg) or i.v. Ig (29–32). The former is used to eliminate some or all HLA-specific antibodies of patients awaiting either live- or deceased-donor organ transplantation, the latter

is used to downregulate antibodies specific for a particular donor's HLA, and both are used for treating antibody-mediated rejection. Both types of protocol require accurate identification of the patient's HLA-specific antibodies prior to treatment.

The goals of monitoring desensitization are to determine the risk of antibody-mediated rejection, monitor treatment efficacy, and generate information that helps guide and fine-tune treatment (30, 31). The pretreatment evaluation of the patient consists of (i) identifying previous potentially sensitizing events and the response to those events, (ii) creating an immunologic profile of the current transplant (i.e., the number of current mismatches, the number to which the patient has antibody, the immunogenicity of the mismatched antigens, and whether or not they are repeat mismatches), and (iii) determining the specificity and strength of the DSA. High-dose i.v. Ig interferes with tests using antiglobulin reagent. Because this protocol usually treats patients monthly, sera obtained prior to each treatment can be used to monitor treatment efficacy. In the plasmapheresis/i.v. Ig protocol, serum samples should be obtained before and after each treatment, immediately prior to transplantation, and 48 to 72 h after treatment is stopped. The extent of treatment (the number of plasmaphereses and additional immunosuppressants) needed correlates most strongly with the titer of the DSA. Therefore, a crossmatch to assess titer should be performed at a time prior to initiation of treatment that is sufficient to allow any needed adjustments in the treatment schedule. Once treatment is started, tests should be performed to monitor the course of the DSA. A cost- and time-efficient way to do this is to test all sera in a solid-phase immunoassay that uses pooled target antigens to chart the general trend of the antibodies and to monitor the strength of DSA by performing crossmatch or antibody identification tests on selected sera. Plasmapheresis removes many substances from the plasma, and background reactivity in solid-phase and flow-cytometric assays usually decreases during treatment. This should be taken into account when interpreting the results of these assays. There is a certain amount of day-to-day and technologist-to-technologist variability in the CDC crossmatch test. This variability can be minimized to a certain extent by having the same technologist perform all crossmatch tests and by including in each round of testing a reference serum which is a historic serum of the patient and has a known titer. Also, normalization of the data through the use of MESFs and other procedures will facilitate a more meaningful interpretation of test results. The data that should be examined are (i) the overall trend of the DSA titer and (ii) the extent of rebound that occurs between treatments. Once the transplant has been performed, a sample should be obtained 48 to 72 h after treatment is completed to check for DSA rebound. Whenever possible, these patients should have antibody monitoring posttransplantation for a minimum of 3 months and following any potentially sensitizing event.

The Whole Picture: the Assessment of Risk

As the opportunities for reducing antibody and modulating the immune response improve, it will become increasingly important to produce a body of information that provides an assessment of risk to the transplant. Our increasing understanding of the role of the humoral response in transplantation indicates the need for certain types of information. (i) Does the patient have antibody? (ii) If so, what is the specificity, titer, and immunoglobulin class? (iii) Is the antibody increasing or decreasing in strength or breadth? (iv) Has the patient had antibody in the past? (v) Has the patient had potentially sensitizing events? Neither the crossmatch nor the antibody screen alone can answer these questions; the tests are complementary, and both are needed to get an accurate assessment of the patient's humoral immune status. The antibody screen may reveal very low levels of antibody, indicating that a very sensitive crossmatch technique, such as flow cytometry, is appropriate, or conversely, it may demonstrate that the antibody levels are such that this expensive technique is overkill. Even when both antibody screening and crossmatch tests are performed, it may not be possible to obtain an adequate picture of the patient's humoral immunity. In these cases, specialized techniques may be appropriate. While use of such *ad hoc* procedures will add to costs, in many cases and particularly where the information is applied to clinical care, the investment will be well worth it.

Non-Human Leukocyte Antigen Antibodies in Organ Transplantation

ANNETTE M. JACKSON AND BETHANY L. DALE

115

INTRODUCTION

Clinical Relevance of Non-HLA Antibodies in Transplantation

Transplantation can significantly extend the life of patients with end-stage renal disease and provide a lifesaving treatment for patients with failure of other major organs. Extending the long-term survival of these transplanted organs requires a better understanding of the mechanisms of immune injury, including humoral immunity. Alloantibodies were determined early on to be a contraindication to transplantation, but until recently the primary focus has been on HLA-specific antibodies (1). Historically, the lymphocyte crossmatch was the primary tool used to detect HLA antibodies in the sera of transplant recipients and to assess the risk of antibody-mediated rejection posttransplantation. Now, with the advent of solid-phase immunoassays, we can detect HLA antibodies at very low levels and provide a more accurate characterization of their antigen specificities (2).

As our ability to detect and avoid donor-specific HLA antibodies has improved, the contribution of non-HLA antibodies to allograft injury has become more apparent. Multiple reports have described antibody-mediated allograft rejection in the absence of HLA antibodies or following transplantation with HLA-identical grafts (3, 4). In a large collaborative study, sensitized recipients transplanted with HLA-identical sibling allografts were shown to have reduced long-term graft survival compared with their nonsensitized counterparts, revealing the importance of sensitization to antigens other than ABO or HLA in transplantation (5).

Non-HLA Antigens Implicated in Transplantation

Antigens for non-HLA antibodies associated with rejection in renal, heart, and/or lung transplantation include both polymorphic and nonpolymorphic targets (6, 7). Antibodies specific for autoantigens such as collagen, tubulin, agrin, vimentin, myosin, angiotensin II type 1 receptor (AT1R), perlecan, and protein kinase C-ζ have been implicated in acute and/or chronic allograft injury. Many of these autoantigens are intracellular and are presented to the immune system following tissue damage. Exposure in the presence of inflammation (due to infection, an alloimmune response, or surgical injury) is thought to break self-tolerance and provoke the generation of autoantibodies (8–10). Lung recipients with detectable antibodies toward collagen V and Kα1 tubulin are at increased risk for primary graft dysfunction and the development of bronchiolitis obliterans syndrome, a form of chronic rejection in lung transplantation (6, 7). Vimentin- and myosin-specific autoantibodies have been observed in heart recipients with accelerated, chronic vasculopathy. Antibodies specific for membrane proteins AT1R and major histocompatibility complex class I-related chain A (MICA) have been implicated in acute rejection and reduced allograft survival following kidney transplantation. MICA genes are highly polymorphic and located next to HLA-B within the major histocompatibility complex. Approaches combining proteomics and genomics are uncovering additional tissue-specific non-HLA antigens associated with acute and chronic rejection (11–13). Also of interest are non-HLA antigens expressed on the surface of endothelial cells (ECs), the barrier between the recipient's immune system and the transplanted allograft. EC-reactive antibodies have been eluted from rejected kidney allografts and have been associated with acute rejection and graft failure in kidney and heart recipients (14–16). Reports of hyperacute kidney rejections have also been described in kidney recipients with EC-reactive antibody (17, 18).

Non-HLA Antibody: Mechanisms of Allograft Injury

HLA antibodies are efficient activators of complement, eliciting significant tissue damage and amplification of the immune response through the generation of anaphylatoxins (19). Valenzuela and Reed have also shown a role for HLA antibodies in transplant vasculopathy, an indolent form of chronic heart rejection (20). Mechanisms employed by non-HLA antibodies in allograft injury are diverse, likely due to the heterogeneity of the target antigens. In addition, there may be significant differences in the titer and affinity of non-HLA antibodies that are generated from antigens less immunogenic than HLA. The majority of rejections associated with non-HLA antibodies do not correlate with complement activation as measured by C4d positivity in allograft biopsies (15, 18, 21). Le Bas-Bernardet et al. reported that although EC-reactive antibodies are not cytotoxic, they can induce cell apoptosis independent of complement (22). However, non-HLA antibodies may synergize with donor-specific HLA antibodies to accelerate graft injury, to include complement activation (21, 23). EC-reactive antibodies have been shown to induce activation of vascular endothelium, resulting in the increased expression

doi:10.1128/9781555818722.ch115

of adhesion molecules and leukocyte adhesion (14, 24). Antibodies that bind vimentin on the surface of circulating leukocytes induce the release of prothrombotic factors (fibrinogen, thrombin, and platelet-activating factor) that result in platelet activation and increased risk of thrombosis (25). Non-HLA antibodies, such those directed against AT1R, have also been shown to bind as agonists and initiate downstream effects (26).

Multiple platforms have been used to detect non-HLA antibodies in the sera of transplant recipients. Each has advantages and disadvantages; thus, selecting the optimal assay depends on the nature of the investigation or volume of clinical testing.

METHODS

Selecting a Testing Platform

Detection of Antibody to Unknown Non-HLA Targets

Cell-based crossmatch assays using ECs were the first platform used to identify non-HLA antibodies in the sera of transplant recipients. Advantages include the ability to detect antibodies specific for novel antigens, in particular, polymorphic antigens that may differ between cell donors (27). Cell-based methods also allow the antigens to be presented in their native membrane-bound state with the correct post-translational modifications (e.g., glycosylation) (28). However, one must keep in mind that protein expression may not be the same on cells of the same type (e.g., ECs) isolated from different tissues or on cells that have been immortalized or maintained in long-term culture. Importantly, cell-based methods can identify the presence of non-HLA antibodies in the sera, but the antigen specificity of the bound antibodies is not known. Cell-based methods are less sensitive than solid-phase immunoassays, due to lower protein target densities and higher background reactivity with some cell types. The greatest disadvantage may be expression of HLA antigens on all nucleated cells, precluding the ability to detect non-HLA antibodies in the sera of patients broadly sensitized to HLA. Removing HLA antibodies from the serum prior to testing via cell or platelet adsorptions can eliminate this obstacle, but this is a labor-intensive effort.

Discovery strategies utilizing high-density protein arrays or antigen immunoprecipitation coupled with mass spectrometry also provide a means for identifying novel non-HLA targets (11, 12, 16, 29). Methods using mass spectrometry are robust but labor-intensive and are not suitable for routine clinical testing. Protein arrays are amenable to automation but are costly and have disadvantages such as the use of recombinant proteins that lack certain post-translational modifications, the exclusion of membrane-spanning proteins (e.g., AT1R), and a limited ability to identify highly polymorphic antigens.

Detection of Antibody When Non-HLA Targets Are Known

Enzyme-linked immunosorbent assays (ELISAs) or bead-based immunoassays can be purchased or created when the non-HLA target antigen is known (30; https://www.luminexcorp.com/research/reagents-and-accessories/lumavidin-microspheres/). These platforms can be automated and are most amenable to clinical testing. Both have enhanced sensitivity and specificity compared to cell-based strategies. ELISA methods are less sensitive than flow cytometric or Luminex (Austin, TX) bead-based assays; however, they are less expensive and can utilize cell lysates to allow testing of membrane-spanning proteins. The greatest advantage of Luminex bead assays is the ability to perform multiplex analysis of 100 to 500 antigenic targets simultaneously, using very small amounts of serum.

Optimization of Test Platform

The sensitivity of antibody screening assays is dependent on multiple factors, which include antigen density, signal-to-noise ratio, and the methodology used for signal detection. When using cell-based strategies, the purity and quality of the cells at the time of testing may impact antigen density. Surface protein expression may differ on cells with poor viability, after freezing, following long-term culture, or when isolated from older (>24 h) blood samples. Known surface proteins should be assessed at time of testing to ensure that cells are of good quality. These phenotypic markers can also be utilized in flow cytometric assays as gating parameters to assess cell purity and ensure consistency of cells selected for acquisition. Some studies have activated cells, prior to testing, using cytokines such as tumor necrosis factor alpha or gamma interferon to increase antigen expression on the cell surface (14, 22).

The antigen density in commercial solid-phase immunoassays may be fixed, but variables that affect signal-to-noise ratio may allow some optimization. The optimum antibody-to-antigen ratio is important for maximal detection and to avoid prozone effects. This can be optimized by testing different serum quantities and/or testing serial dilutions of the test serum. In addition, the reaction volume, dilution buffer, temperature, and duration of the serum incubation step can enhance or diminish antibody-antigen interactions. Unlike high-affinity monoclonal antibodies that are used in flow cytometric experiments, serum antibodies are polyclonal, containing antibodies of varying affinities and avidities. Affinity describes the strength of the noncovalent interactions (van der Waals, ionic, and hydrophobic) for each antibody and antigenic epitope. Avidity reflects the overall stability or strength of the antibody-antigen interaction and is impacted by antibody affinity and the valence of both the antibody and the antigen. Therefore, optimal conditions may be different when testing for non-HLA antibodies of different isotypes, which may differ in both affinity and valence. For example, it is well established in blood bank literature that IgM binding is enhanced at colder temperatures (4°C) compared to IgG, which binds across a wider temperature range (4 to 22°C).

Antibody detection assays can also be impacted by interfering substances present in some sera. Steric interference from immune complexes, complement bound to the Fc portion of the antibody, or excess serum IgM can decrease sensitivity by blocking or interfering with binding of the secondary detection antibody (31, 32). Serum dilution, EDTA addition, or treatment to deplete IgM using dithiothreitol, heat, or hypotonic dialysis can reduce this type of interference and increase signal detection.

The type of wash buffer used, the wash volume, and the number of wash steps are also important to reduce background and enhance signal. Wash buffers differ with regard to pH, ionic strength, and detergent and/or protein content (33). Complete removal of residual wash fluid between wash steps and prior to the addition of the detection reagents is also important for increasing sensitivity and reproducibility.

Separate blocking reagents may be included in ELISAs and cell-based assays; these are added prior to the detection antibodies to reduce nonspecific protein-protein interactions (33). Solid-phase immunoassays can also be modified, such that antibody-antigen complexes are formed first (using biotin-labeled antigen), and the volume of mixture is

increased and added to an avidin-coated bead or ELISA plate. This modification takes advantage of the high affinity between avidin and biotin and is used to reduce background signals caused by nonspecific binding of serum proteins to the assay matrix.

Finally, the detection strategy can also influence the sensitivity of the assay. Fluorescent or chemiluminescent detection strategies provide greater sensitivity than colorimetric methods. When using fluorochrome-conjugated detection antibodies, select the brightest fluorochrome and minimize spectral overlap to maximize detection sensitivity (34). These secondary antibodies should be tested at different titers/dilutions to determine optimal detection concentration. Utilization of biotin-conjugated detection antibodies with avidin-conjugated fluorochromes can amplify signal intensity and increase sensitivity.

PROCEDURES

EC Crossmatch

Summary

The EC crossmatch allows for the detection of donor-specific non-HLA antibodies present in the sera of transplant candidates. EC precursors (ECPs) are isolated from donor peripheral blood using anti-Tie2 magnetic nanoparticles (http://www.absorber.se/xm-one) and incubated with test serum. Non-HLA antibody bound to the ECP is detected using a fluorochrome-conjugated anti-IgG detection antibody and flow cytometry.

Assay Procedure

1. **Donor ECP preparation:** Isolate peripheral blood mononuclear cells from 40 ml of acid citrate dextrose using a Ficoll-Hypaque gradient separation. Transfer mononuclear cells into a 50-ml conical tube and wash twice (500 × *g*) with 1× phosphate-buffered saline with 5% heat-inactivated fetal calf serum. Incubate donor mononuclear cells with anti-Tie2 magnetic nanoparticles in 1.5-ml volume of wash buffer in a 5-ml polypropylene tube, rotating at 4°C for 30 min. After incubation, place on magnet for 10 min at 18 to 22°C. Remove supernatant containing mononuclear cells, being careful not to dislodge the cells from the magnet. Add 3 ml of wash buffer to $Tie2^+$ cells, briefly vortex, and apply to magnet for an additional 10 min. Remove and discard wash buffer. Resuspend cells in 1 ml of wash buffer and count using a hemocytometer.
2. **Serum preparation:** Heat-inactivate 100 μl of test/control serum at 63°C for 10 min; then spin in an airfuge for 15 min at 100,000 × *g* to remove IgM and/or immune complexes.
3. **Serum incubation:** Pipette 5×10^5 cells into 12- by 75-mm tubes, add 1.0 ml of wash buffer, and centrifuge (500 × *g*). Remove *all* residual wash buffer by blotting or using a vacuum aspirator. Immediately add 50 μl of test/control serum to each appropriate tube. Add 50 μl wash buffer to one tube in lieu of serum to assess autofluorescence. Briefly vortex and incubate cells and sera for 30 min at 18 to 22°C.
4. **Wash:** Wash cells a total of three times using 1 ml of wash buffer (centrifuge at 500 × *g*). Remove *all* residual wash buffer by blotting or using a vacuum aspirator after final wash.
5. **Detection antibody:** Immediately add fluorochrome-conjugated detection antibody and additional antibodies specific for markers used to determine acquisition gate. Incubate for 30 min at 2 to 8°C in the dark.
6. **Wash:** Wash cells a total of three times using 1 ml of *cold* wash buffer (centrifuge at 500 × *g*). Keeping the cells cold will prevent capping of proteins on the cell membrane.
7. **Detection:** Resuspend in 250 μl of cold wash buffer and immediately acquire on calibrated flow cytometer.

ELISA Procedure

Summary

Test serum is added to an ELISA microtiter plate coated with the target non-HLA protein. Non-HLA antibody bound to the plate is detected using an enzyme-conjugated detection antibody and an enzymatic substrate.

Assay Procedure

1. **Serum and standard preparation:** Dilute serum samples with kit-specific sample diluent. This dilution is generally in the range of 1:100 to 1:200. The standard curve dilutions are normally tested in duplicate.
2. **Serum incubation:** Add 50 to 100 μl of diluted test serum and control sera into appropriate microtiter wells in duplicate. The serum incubation time (from 30 min to 2 h or overnight at 4°C) and temperature (4 to 37°C) may vary.
3. **Wash:** Perform three washes with wash buffer. The number of washes and technique may vary depending on test sensitivity.
4. **Detection antibody:** Add diluted enzyme-conjugated detection antibody and incubate. Time (from 30 min to 2 h or overnight at 4°C) and temperature (18 to 37°C) may vary; shaking (200 rpm) is recommended but optional. Additional wash steps may be performed following the second incubation to remove unbound detection antibody.
5. **Enzymatic reaction:** Add enzymatic substrate and incubate at 18 to 22°C for 20 to 30 min. If fluorescent substrate is used, incubate in the dark.
6. **Detection:** Measure the optical density absorption or fluorescence on an appropriate microtiter plate reader.
7. **Interpretation:** If known standards were run, plot the standard curve graph to determine unknown test serum antibody concentration. If only running a semiquantitation assay, perform calculations using the manufacturer's correction factor.

Luminex Assay

Summary

The Luminex assay includes polystyrene beads coated with purified target protein. The beads are incubated with patient sera to identify the presence of target-specific antibodies using flow cytometry principles. *Note: the beads and secondary detection antibody are light sensitive, and all incubations should be performed in the dark.*

Assay Procedure

1. **Serum incubation:** Add control and test serum at the predetermined dilution with the bead set for 30 min at 18 to 22°C with shaking (200 rpm). This can be performed in a filter plate or a V-bottom plate.
2. **Wash:** If using a V-bottom plate, perform a spin-flick method to wash away unbound antibody. If using a filter plate, perform multiple washes using a vacuum

manifold. The number of washes and technique may vary depending on test sensitivity.

3. **Detection antibody:** Add freshly diluted secondary detection antibody to washed plate. Incubate for 30 min at 18 to 22°C with shaking (200 rpm). An additional wash procedure may be performed following the second incubation to remove unbound detection antibody.
4. **Detection**: Acquire data using a Luminex fluorometer. Results are reported as the mean fluorescence intensity (MFI) values.

Validation

Validation studies are important in both research and clinical settings, to evaluate the final testing conditions and determine negative and positive test thresholds. For cell-based assays, a positive control serum/antibody may not be readily available. In these cases, a commercial antibody or serum containing antibodies specific for an alternate surface protein known to be expressed on the cell of interest can be used as an alternative until a panel of non-HLA antibody-positive sera can be generated. For example, to achieve a positive EC crossmatch test, use sera containing HLA antibodies of different strengths but known to yield positive flow cytometric lymphocyte crossmatch with the cell donor. The range for positivity, what designates a weak, moderate, or strongly positive reaction, should be revisited at regular intervals as more data are compiled. When establishing a positive control serum, it is important to use a serum that yields consistent results but is weak enough to detect suboptimal test conditions or reagents. It is also important to secure a large enough quantity of serum so that it can be utilized over an extended period of time.

Next, and most importantly, the threshold for negativity must be determined. Multiple "negative" sera should be tested to determine a range for negative reactions. Negative control sera can be purchased or generated by screening sera obtained from multiple nontransfused healthy males. The establishment of a valid negative threshold range is vital so that weak positive reactions can be distinguished. The negative range should also be monitored over time as more data are compiled.

The reproducibility of the assay is also important; spending time optimizing each step of the assay will enhance test reproducibility. An acceptable range for test variability (% coefficient of variation) must be determined from replicate testing. Comparisons should be made between sera tested in duplicate within the same assay, on separate days, and by different technologists. Initial reproducibility testing should be performed with positive sera or a positive control antibody.

In ELISAs and some bead-based immunoassays, the concentration of an antibody can be estimated through the use of a standard curve (https://tools.thermofisher.com/content/sfs/brochures/TR0057-Read-std-curves.pdf). Standard curves are constructed by testing a positive control antibody against the antigen (standard) serially diluted across a range of relevant concentrations. Standard curves are generated from at least five points, a blank and four standard concentrations. Each standard data point should be monitored for consistency over time and used to reflect assay reproducibility.

Validation studies should include the development of quality control and quality assurance guidelines. These should describe how new reagents will be evaluated and guidelines for monitoring stored reagents to ensure quality for test consistency. Tracking the positive and negative test control values from each test will provide "real-time" monitoring of reagents and test procedures over time. Determination of the proficiency of each technologist performing the test and performing external proficiencies with other laboratories performing the same test through sera exchanges should also be performed. Additional testing guidelines and regulations can be found for the Code of Federal Regulations, 1988 Clinical Laboratory Improvement Amendments (http://www.gpoaccess.gov/cfr/index.html; search for 42CFR493.1278) and American Society for Histocompatibility and Immunogenetics (http://www.ashi-hla.org).

Evaluation of the Cellular Immune Response in Transplantation

DIANA METES, NANCY L. REINSMOEN, AND ADRIANA ZEEVI

116

Solid-organ transplantation has become an increasingly important therapeutic modality for patients with various end-stage diseases. Despite improved immunosuppression protocols, most transplant recipients face a variety of complications. Early posttransplant infection and rejection are the major causes of morbidity and mortality. Drug toxicity, chronic rejection, and malignancies are long-term complications.

Many attempts have been made to develop *in vitro* procedures that can assess the immunological status of the allograft reliably and accurately. Immunological monitoring could, in theory, differentiate rejection from other forms of dysfunction, such as infection or primary nonfunction. Furthermore, the ideal tool would be able to gauge accurately a patient's response to antirejection therapy and might help prevent overimmunosuppression. Immunological monitoring could also be important in predicting long-term graft outcome and thereby identify which recipients could have their immunosuppression therapy markedly reduced without increasing the risk of acute or chronic rejection.

Although there is no one ideal immunological test that can accomplish all of the above, there are a number of tests that can be used together to assess the immunological status of the transplant recipient. The most informative approach appears to be performing sequential analyses using assays that measure different immune functions.

MIXED LYMPHOCYTE CULTURE ASSAY

Concept

The mixed lymphocyte culture assay (MLC) is an *in vitro* test of lymphocytes responding to stimulation by disparate HLA class II molecules, including HLA-DR and -DQ and, to a lesser extent, HLA-DP, which are predominantly expressed on B cells and monocytes of the stimulator cell population. Proliferative reactivity to HLA class I molecules has also been reported to play a role in the overall bulk MLC response. The first description of this assay as a measurement of cellular immunity (1, 2) together with the development of a one-way method of stimulation allowed the correlation of proliferative responses between siblings. The conclusion was that a single genetic locus or region, now known as HLA, controlled the MLC reactivity. The recognition of disparate HLA molecules and the resulting T-cell activation (as measured by MLC) are thought to represent an *in vitro* model of the afferent arm of the *in vitro* allograft reaction.

In MLC, stimulator cells have been inactivated, usually by X irradiation, and can no longer divide. The resulting proliferation of responding cells involves the logarithmic expansion of multiple clones of alloactivated T cells. This expansion can be measured by incorporation of the radioisotope-tritiated thymidine into replicating DNA during the logarithmic phase of cellular expansion, usually on the fifth day of culture. The amount of thymidine incorporated into cellular DNA is then assayed by liquid scintillation spectrophotometry. Exogenous tritiated thymidine added to *in vitro* cultures is incorporated during DNA replication via the salvage pathway, in which free purine bases are formed by hydrolytic degradation of nucleic acid and nucleotides. Exogenous tritiated thymidine is added to cultures for a period of time that is longer than the S phase of the cell cycle but shorter than the cell cycle itself, usually 18 h.

The degree of reactivity observed correlates with the degree of antigenic disparity between responding and stimulating cells. MLC has been used clinically for donor selection, predominantly for bone marrow transplantation. With the more recent application of DNA-based HLA typing methods, MLC is not used for donor selection but more often for monitoring of the recipient's posttransplant donor antigen-specific immune status. The difference between posttransplant and pretransplant antidonor MLC responses can be used to define any changes (increases or decreases). Studies have shown that solid-organ recipients who develop a decreased response (i.e., are hyporesponsive) are at low risk for immunological complications, such as late acute-rejection episodes and chronic rejection. Hyporeactivity is defined as at least a 60% decrease in reactivity of the posttransplant antidonor response compared with that of the pretransplant antidonor response, assuming the response to third-party cells remains unchanged (3, 4).

Procedure

Sample Requirements

For collection of specimens, care must be taken throughout the procedure to ensure a sterile specimen. Usually, 20 to 30 ml of sterile heparinized blood is obtained. The specimen may be saved overnight but should be processed within 24 h

doi:10.1128/9781555818722.ch116

of the phlebotomy. It should be maintained at room temperature even if it is being shipped by overnight carrier. Poor cell yields and poor function may result from temperature conditions that are too cold or too warm.

Materials and Reagents

Lymphocyte separation medium (LSM; catalog no. 17084003; Pharmacia Biotechnologies)

Culture medium: RPMI 1640 with HEPES buffer supplemented with 100 U of penicillin per ml, 100 U of streptomycin (Grand Island Biological catalog no. 380-2400AJ) per ml, 10 U of preservative-free heparin (Monoparin heparin; Accurate Chemical & Scientific Corp. catalog no. A6500) per ml, 2 mM L-glutamine, and 10 to 20% pooled human sera

Pooled human sera: sera from 10 to 20 healthy nontransfused male donors, heat inactivated at 56°C for 30 min (see "Pitfalls and Troubleshooting" below for additional specifications)

[^{3}H]thymidine (New England Nuclear catalog no. NEN-027): specific activity of 6.7 Ci/mM. Commonly used amounts are 0.5 to 1.0 mCi per well.

Hanks balanced salt solution (Grand Island Biological catalog no. 310-4170PJ)

Equipment and Instrumentation

Radiation source (usually gamma-emitting radiation source); alternatively, mitomycin (catalog no. M0503; Sigma)

Laminar flow hoods (Baker 60; The Baker Co., Sanford, Maine)

Liquid scintillation counter (1205 Betaplate; Pharmacia LKB)

Rate freezer (model 70014; CryoMed)

Liquid nitrogen refrigeration unit (model CAIIIL; CryoMed)

Mechanics and Controls

Mononuclear cells are isolated by centrifugation of peripheral blood diluted 1:2 with Hanks balanced salt solution over LSM. Peripheral blood mononuclear cells (PBMC) are removed from the LSM interface, diluted with Hanks balanced salt solution, and then centrifuged at 500 × *g* for 10 min. The supernatant is decanted, and the wash steps are repeated two more times. The cells are resuspended in an exact quantity of complete culture medium. A leukocyte count is done, and viability is determined via dye exclusion. The cell suspension is diluted to a final concentration of 5×10^5 PBMC per ml by using the culture medium. Stimulator cells are inactivated either by irradiation at 1,500 to 3,000 rad or by incubation with mitomycin according to the manufacturer's instructions. With a repeating microliter pipette, stimulator and responder cells are added in triplicate to round-bottom microtiter plates (catalog no. 760-042-05; ICN) such that each well receives 100 μl of stimulator cells (5×10^4 PBMC) and 100 μl of responding cells (5×10^4 PBMC).

A complete culture setup includes the following:

1. Allogeneic cultures containing all possible combinations of responder and stimulator cells, including cells from three control cell donors of known HLA phenotypes
2. Autologous cultures containing the responder and stimulator cells from the same cell donor
3. Control wells containing either responder or stimulator cells alone, with an equal volume of complete culture medium
4. Double irradiation control cultures containing stimulator cells from two different cell donors

The cultures are incubated at 37°C in a humidified atmosphere of 5% CO_2 for 5 days, after which 0.5 to 1.0 μCi of tritiated thymidine is added to each well. The cultures are incubated for an additional 18 h. The culture plates can then be harvested immediately or sealed with pressure-sensitive film and placed in the refrigerator until harvesting. A number of different harvesting machines and counting systems are available: the cells can be harvested onto filter disk sheets, or the samples can be counted in vials or cassettes or directly, without the need for scintillation fluid. The manufacturer's instruction manual should describe the appropriate procedures.

Pitfalls and Troubleshooting

1. **Drugs.** If a patient is taking one of the following drugs, the proliferative response may be compromised: prednisone, busulfan (Myleran), hydroxyurea, cyclophosphamide (Cytoxan), or L-asparaginase.
2. **Serum.** One of the most common sources of technical problems in any cellular procedure is a poor serum source. Each individual lot of a serum source, or preferably, each individual serum unit within the lot should be screened for growth support capabilities and possible HLA antibodies. The screen should include a control response to a pool of allogeneic cells to measure maximum response and an autologous control to ensure low backgrounds. If sporadic high backgrounds are observed, an endotoxin test may be advisable.
3. **Tritiated thymidine.** If low counts per minute are observed, the scintillation counter and the shelf life of tritiated thymidine should be checked. The half-life of the tritium is 12.3 years, but the shelf life of the thymidine is considerably shorter.
4. **Frozen cells.** Cells to be used as responder cells in the cell cultures can be bulk frozen by a step-down procedure at 4, −30, and −70°C before use. However, viability and cell recovery are better if the cells are rate frozen and stored in the vapor phase of a liquid nitrogen storage unit.

The *American Society for Histocompatibility and Immunogenetics Procedure Manual* (5) is an excellent source of additional information and details on cellular methods.

Interpretation

Results are usually expressed as raw counts per minute of tritiated thymidine incorporation. The data may be reduced to allow for easier interpretation and comparability from one test to another. The two most common forms of data reduction are the stimulation index and the relative response. The stimulation index is a simple ratio of the counts per minute for an experimental MLC combination to the counts per minute for the autologous control. The relative response is the ratio of the net counts per minute (after subtraction of the autologous control counts per minute for an allogeneic MLC combination) to the counts per minute for a maximally stimulated or control MLC combination (usually the response to a pool of allogeneic cells), multiplied by 100 to obtain a percentage (5).

MLC VARIATIONS

MTT Method

A nonradioactive alternative to detecting proliferation is a colorimetric (3-4,5-dimethylthiazol-2-yl)-2.5 diphenyl

tetrazolium bromide salt (MTT) reduction assay. This assay detects the activity of a mitochondrial enzyme that is proportional to the number of metabolically active cells present in the culture. The MTT, a yellow aqueous solution, is taken up by the viable cells and reduced in the mitochondria to a purple crystal. After solubilization of these crystals, the reaction product is measured with a spectrophotometer. An increase in the measured optical density parallels an increase in mitochondrial enzyme activity, which reflects an increase in the number of cells. This approach can detect increases in an interleukin 2 (IL-2)-sensitive line, CTLL2O. VanBuskirk et al. (6) have demonstrated that colorimetric detection of IL-2 production correlates well with the radioactive detection of T-cell proliferation and can be used interchangeably with the standard MLC.

RELATED METHODS

T-Cell Precursor Frequency Determination by LDA

The frequency of T-cell precursors is determined by limiting dilution assay (LDA). Limiting numbers of responder cells are cultured with a constant number of stimulator cells and assayed for reactivity (cytotoxicity, proliferation, or cytokine release) against additional stimulator cells. In contrast to MLC, which measures a bulk response, LDA is a quantitative tool. It allows the investigator to estimate the frequency of lymphocytes with a given function and antigen specificity. LDA implies that the lysis is a single-hit process; that is, a single precursor cell will initiate the sequence of events that leads, in the case of cytotoxic precursors, to the eventual lysis of the cell. A frequency can be determined if the lymphocyte population is random; that is, the function of the lymphocyte population is not influenced by the presence of another lymphocyte population. The clear distinction between a response and a lack of that response is imperative. Making this distinction is more difficult in the cytotoxicity assay, where an arbitrary threshold that separates the spontaneous release of ^{51}Cr from the release from the lysed targets is set. The frequency of responding cells is determined by a maximum likelihood estimation by using a computer program (7).

LDA of HTL

Helper T lymphocytes (HTL) are detected by their ability to produce IL-2. The murine IL-2-dependent line CTLL2O is used as the indicator line in this bioassay. Adding CTLL2O cells directly to the micrometer wells is a more sensitive method than removing an aliquot of supernatant and adding it to the CTLL2O cells. Before adding the indicator line, the plates are irradiated to inhibit the responder cells from proliferating and incorporating [^{3}H]thymidine. A low dose of irradiation does not block the continued production of IL-2 by the responding cells. In the absence of IL-2, the CTLL2O cells die rapidly. Therefore, any proliferation detected is due to division of the IL-2-stimulated CTLL2O cells.

Method

LDA can be done on fresh or cryopreserved cells. The cells are prepared as described in "Mixed Lymphocyte Culture Assay." Limiting numbers of PBMC (2×10^4, 1.0×10^4, 0.5×10^4, 0.25×10^4, 0.125×10^4, 0.0625×10^4, and 0.03125×10^4) are cultured in round-bottom microtiter plates with constant numbers (10×10^4) of irradiated (3,000 rad) stimulator cells. When HLA-identical pairs are tested, increased numbers of cells are often used such that the highest concentration is 4×10^4, 6×10^4, 8×10^4, or 10×10^4 cells per well. Multiple wells per dilution are necessary to ensure an accurate assessment of the frequency. Usually, 24 wells per dilution are set up. The culture medium is the same as that used in the MLC protocol. Control wells consist of 24 wells containing irradiated stimulator cells alone (for calculation of background activity), responder cells in medium alone (negative controls), and responder and stimulator cells set up separately against HLA-mismatched third-party cells (positive controls). The plates are incubated for 64 h at 37°C in a 5% CO_2 environment. The plates are irradiated with 2,500 rad. CTLL2O cells (1×10^3) are added in 25 ml of medium. The plates are incubated for 8 h with 1 mCi of [^{3}H]thymidine in 25 ml per well. Cultures are reincubated for 16 h. Cultures are harvested and counted as outlined in the MLC protocol. The wells are considered positive if [^{3}H]thymidine incorporation is greater than the mean plus 3 standard deviations of results for the 24 control wells. The frequency of responding cells is determined by maximum likelihood estimation by using a computer program, and the variance is determined by the use of 95% confidence intervals. Regression analysis is used to generate a straight line. Chi-square analysis is used to show that the data obtained are in accordance with single-hit kinetics. A program that does all the necessary calculations for this analysis is listed in reference 7.

Pitfalls and Troubleshooting

The sensitivity of this assay depends on the condition of the IL-2 indicator cells. The proliferation of the CTLL2O line depends on murine or human IL-2 or murine IL-4, without which the cells will die rapidly. The line should be maintained at a concentration of 1×10^4 to 10×10^4 cells per ml in a solution containing RPMI 1640 (with HEPES), 100 U of penicillin/ml, 100 μg of streptomycin/ml, 2 mM L-glutamine, 1% sodium pyruvate (100 mM solution), 1% minimal essential medium amino acids (50×), 0.5% diluted beta mercaptoethanol (diluted 1:57 with phosphate-buffered saline [PBS]), and 10% pooled human serum culture medium, supplemented with 500 U of IL-2. Great care should be taken to subculture this line every 2 to 3 days.

LDA of CTL

As mentioned before, the major advantage of the LDA is the ability to quantitate a particular T-cell function in an antigen-specific manner. The LDA for cytotoxic T lymphocytes (CTL) requires a longer incubation time than that for HTL since the cytotoxic activity must be generated in the presence of growth factors and alloantigen. Thus, the cultures are incubated for 10 days; IL-2 is added on days 3 and 6. The target cells are labeled with ^{51}Cr, which is taken up by the target cells and linked to internal proteins by endogenous enzymes. The unbound ^{51}Cr is washed away. The targets are added to the LDA wells for 4 h. During this time, CTL lyse the targets and ^{51}Cr leaks out of the cell into the culture supernatant. The amount of ^{51}Cr detected in the culture medium is directly related to the number of target cells lysed by the CTL. Although ^{51}Cr does emit gamma rays, it is more efficient to assay for the Auger rays that are also emitted. The Auger rays have an energy level within the same wavelength range as that of tritium and therefore can be detected by the conventional scintillation counting method. Frequency determinations are done in a manner similar to that used for the HTL precursor (HTLp) method.

Reagents

Phytohemagglutinin (PHA), 28.75 U/ml (catalog no. HA-17; Burroughs Wellcome)

RPMI 1640

Method

Limiting numbers of PBMC (5×10^4 to 0.125×10^4) are cultured in round-bottom microtiter plates with constant numbers (5×10^4) of irradiated (3,000 rad) stimulator cells. Multiple wells per dilution are necessary to ensure an accurate assessment of the frequency. Usually, 24 wells per dilution are set up. The culture medium is the same as that used for the MLC method. IL-2 and additional culture medium are added on days 3 and 6 so that the final concentration is 5 U/ml. Target cells are prepared on day 7 by using unirradiated stimulator cells from the initial priming combination. The cell concentration is adjusted to 10^6 cells per ml, and 1 ml of the cells is placed with 1 ml of PHA in 4 to 6 wells of a 24-well microtiter plate and incubated at 37°C in a humidified atmosphere of 5% CO_2 for 3 days. On day 10, the cultures are assayed for cytotoxicity (or other functional assays are used) against ^{51}Cr-labeled target cells. PHA-stimulated target cells (2×10^6) are labeled with 0.5 mCi of ^{51}Cr for 1.5 h, washed, and adjusted to a concentration of 2×10^4 cells per ml. One hundred microliters of the medium is replaced in the priming cultures with 100 μl of labeled target cells, and the plates are spun at $100 \times g$ for 5 min and incubated for 4 h. Supernatants are harvested and tested for released ^{51}Cr by using either a gamma counter to detect the gamma rays or a beta counter to detect the Auger rays released. Wells are scored as positive by determining that the reactivity observed is significantly (>3 standard deviations) greater than the control background. Wells containing irradiated stimulator cells incubated without responder cells are used as background controls. As for the HTLp method outlined above, the frequency of cytotoxic cells is determined by a maximum likelihood estimation by using a computer program and the variance is determined by the use of 95% confidence intervals. A regression analysis is used to generate a straight line, and chi-square analysis is used to show that the data obtained are in accordance with single-hit kinetics. A program that does all the necessary calculations for this analysis is listed in reference 8.

Variation of LDA of CTL

A variation of the target cell labeling procedure for the cytotoxic limiting dilution analysis has been described by Van Besouw et al. (9). In this approach, the T-cell blast target cells are labeled with europium-diethylenetriaminepentaacetate (Fluka [Buchs, Switzerland] and Sigma Chemicals [St. Louis, MO]). The incubation period to measure cytolysis is the same as that previously described. The supernatant (20 μl) is transferred onto a low-background fluorescent 96-well plate (Fluoroimmunoplate; Nunc, Roskilde, Denmark), and 100 μl of enhancement solution (LKB-Wallac, Turku, Finland) is added to each well. Fluorescence of the released europium is measured in a time-resolved fluorometer (Victor 1420 multilabel counter; LKB-Wallac), and results are expressed in counts per second.

Cell Division and Precursor Frequency Analysis Using Multiparameter CFSE-MLC

The ability to visualize specific peripheral blood cell subpopulations dividing during an *in vitro* response to donor alloantigen (allo-Ag) is extremely useful when monitoring alloimmunity in healthy individuals or transplant patients (10, 11). Flow cytometry can efficiently detect and quantify the phenotype, percentage, and precursor frequency of proliferating cells. The fluorescent dye 5(6)-carboxyfluorescein diacetate succinimidyl ester (CFSE) is used to label intracellular responder cells before placing them in the MLC. CFSE is cell permeant and nonfluorescent until cellular esterases cleave carboxyl groups from the molecule, rendering it nonpermeant and fluorescent. The succinimidyl moiety of CFSE covalently attaches to the cytoplasmic amine groups. The covalently bound CFSE is divided equally between the daughter cells, allowing for resolution of up to eight cell division cycles (12). CFSE can be used with or without additional cell surface and/or intracellular fluorochrome-conjugated monoclonal antibody (MAb) staining. This may allow, over a 5-day cell coculture period, the concomitant assessment of the kinetics of cell proliferation, differentiation status, and function. Various subsets of cells such as peripheral blood $CD4^+$ and $CD8^+$ T cells, B cells, and NK cells can be studied in this manner. Therefore, multiparametric CFSE-MLC may be considered a protocol of choice over the classical MLC or LDA assays when assessing allorecognition. In addition, using Modfit software, the number of cell divisions and of precursor frequencies for a given cell subpopulation can be calculated (10). The procedure outlined below is for testing human cells. Procedures for animal models are described in reference 13.

Procedure

Sample Requirements

The collection requirements are the same as those for the MLC procedure.

Materials and Reagents

The lymphocyte separation medium, culture medium, pooled human sera, and Hanks balanced salt solution are the same as those for the MLC procedure.

CFSE is dissolved in dimethyl sulfoxide to the final concentration determined by the investigator. Aliquots can be stored at −20°C in a desiccator and protected from light for up to 1 year.

Instruments

The Fortessa (BD Biosciences) instrument is used for data acquisition, and FlowJo software (Tree Star, Ashland, OR) and ModFit LT software (Verity Software, USA) are used for data analysis. For cell cocultures, an incubator set at 37°C and 5% CO_2 is needed. Refrigerated centrifuges are used.

Mechanics and Controls

1. **Staining procedure.** The responder cell population (1×10^7 lymphocytes/ml) is resuspended in a prewarmed PBS–0.1% bovine serum albumin (BSA) solution and incubated with 2 μM CFSE for 10 min at room temperature. An equal volume of pooled human sera is added, and the mixture is agitated for 1 min to quench the reaction. Cells are then washed three times in PBS and adjusted to the appropriate working concentration in the culture medium. Alternatively, RPMI 1640 containing 10% pooled human sera can be used for the last two washes.
2. **Culture conditions.** CFSE-labeled bulk PBMC (or sorted lymphocyte subsets) used as responders are incubated in a one-way mixed lymphocyte reaction culture (MLC) with γ-irradiated (2,500 rad) allogeneic stimulator PBMC, labeled with PKH-26 dye (according to the manufacturer's protocol) at a 1:1 ratio (10). The stimulators are labeled to allow their discrimination from the responder cells, which have proliferated and undergone CFSE dilution. The positive and negative controls are the same as those for the MLC. The cells are harvested after 5 days, washed, and surface

stained with the appropriate fluorochrome-labeled MAbs for phenotyping as determined by the investigator (e.g., CD3, CD8, CD45RO, CD62L). Intracellular staining (ICS) can be further performed upon permeabilization to identify transcription factors (e.g., T-bet, GATA-3, RORγt, or FOXP3), granzyme B/perforin, or the cytokine of choice (e.g., gamma interferon [IFN-γ], IL-4, IL-17, IL-10), as described in "ICS and Flow Cytometry" below.

3. **Flow cytometry analysis.** After cleavage, CFSE has a peak excitation of 494 nm and a peak emission of 521 nm, characteristics compatible with fluorescein isothiocyanate (FITC) detection systems. PKH26 is a red fluorochrome and has a peak excitation of 551 nm and peak emission of 567 nm, characteristics compatible with phycoerythrin (PE) detection systems. Six to 8 additional fluorochromes can be added to the panel to complete the 10-color panel. A gate defining live lymphocytes and blasts by forward and side scatter properties is used in all analyses, followed by analysis of $CD3^+$ gate and subsequent exclusion of $PKH\text{-}26^+$ stimulator cell gate. Proliferation of the $CD4^+$ (as $CD8^-$) and $CD8^+$ populations is then quantified by CFSE dilution (% $CFSE^{low}$ cells) and by histogram plots of generations of divided cells as determined by ModFit-LT software (10). Proliferating cells may be also assessed for their memory distribution, type 1 lineage commitment (T-bet), and functional capabilities (IFN-γ, granzyme B/perforin) versus type 2, type 17, or Treg commitment.

Pitfalls and Troubleshooting for CFSE-MLC Assay

As in the MLC, the viability of the cells is crucial in the CFSE-MLC assay. The level of CFSE staining must be determined by titration since too-heavy staining can cause problems with cell viability during culture and compensation during acquisition and analysis. Approximately eight division cycles can be identified before the autofluorescence obscures the peaks. If clear division peaks are not seen, optimal proliferating conditions may not have been obtained. It is helpful to start by setting parameters and culture conditions assaying a response obtained by stimulating with an anti-CD3 MAb or a recall antigen. Once reproducible results are obtained, a response to allogeneic cells can be optimized. Using a dump channel to stain for dead cells (Dead cell stain kit-PB; Invitrogen) and CD14-PB (where PB is Pacific Blue stain) helps lower high background noise.

Troubleshooting for Staining and Data Acquisition

For information on Troubleshooting for Staining and Data Acquisition, see "ICS and Flow Cytometry" below.

Data Analysis and Interpretation

For quantitative assessment of the alloresponse, the number of cells within each CFSE fluorescent peak is determined by analysis of the flow cytometric histogram plots. The number of precursors that divided (P_{div}) is determined by analysis of the number of events comprising the various peaks of daughter cells with identical proliferative histories and extrapolated by dividing by $2n$, where n is the division cycle number. The number of precursors that divided makes up the numerator, and the denominator is the total number of cells (P_{tot}). P_{div} is relatively straightforward to calculate; however, the P_{tot} determination is more complex, and several approaches have been reported. To obtain a precursor frequency, the total number of potentially alloreactive cells, including those plated in culture but not recovered, must be considered as representing P_{tot}. Alternatively, the number of cells recovered may be considered to represent P_{tot}. To obtain a responder frequency, the number of cells that were activated but did not proliferate can be considered to represent P_{tot}. Alternatively, the Modfit Software applies deconvolution algorithms to calculate the precursor frequency of cells that divided, reported as the percentage of the parent population. The investigator decides the method of analysis (10). For quantitative assessment of other functions (i.e., cytokine production), see below.

Graft-Infiltrating Cells—Propagation of Lymphocyte Cultures from Allograft Biopsy Specimens

Concept

In solid-organ transplantation, the histological analysis of allograft biopsy specimens remains the "gold standard" for diagnosing rejection. Although many cell types have been implicated in rejecting allografts, including B cells, macrophages, neutrophils, and eosinophils, it is generally accepted that $CD3^+$ T lymphocytes initiate allograft rejection (14, 15). Both $CD4^+$ (helper) and $CD8^+$ (cytotoxic) T cells are present in the graft and express IL-2 receptor and HLA-DR antigens, suggesting the presence of activated lymphocytes. The phenotype studies provide little information about the functional characteristics and their alloreactive specificity.

Another approach is to learn about the functional characteristics of graft-infiltrating cells through *in vitro* propagation in the presence of IL-2 (16–18). Activation of T cells occurs as a result of recipient allorecognition of donor antigens, which leads to the expression of IL-2 receptors on the activated T cells. The lymphocyte growth assay is straightforward. Biopsy specimen fragments are incubated in tissue culture medium supplemented with 5% human serum and 10 to 30 IU of recombinant IL-2. Lymphocyte growth in cardiac transplant recipients correlates with the histological grade of rejection, and positive growth from histologically negative biopsy specimen fragments is associated with subsequent biopsy-proven rejection (19, 20). A persistent lack of growth from biopsy specimen fragments is associated with an increase in rejection-free cardiac allograft survival. These studies indicate that *in vitro* culturing of lymphocytes from endomyocardial biopsy specimen fragments is clinically useful for the early diagnosis of acute cellular rejection. This conclusion may also apply to other organs. For lung transplant recipients, transbronchial biopsy specimen fragments have been cultured to propagate infiltrating alloreactive T cells. Lymphocyte growth is virtually 100% for biopsy specimen fragments with histological diagnosis of acute rejection or active bronchiolitis obliterans, a form of chronic lung rejection, and fewer than 30% of biopsy specimen fragments with no major abnormalities show growth (21). The presence of activated T cells is indicative of a subsequent rejection episode. Lymphocyte growth from renal transplant biopsy specimen fragments also correlates with acute cellular rejection, and the production of IL-2 by the infiltrating cells is associated with irreversible rejection (22). In liver transplant recipients, more culture lymphocyte growth is associated with rejection and less growth is seen for patients on OKT3 treatment for rejection.

A serious complication of heart transplantation is the development of accelerated graft coronary disease (GCD). Persistent growth from biopsy specimen fragments during the first 3 months posttransplant is associated with a higher risk of GCD. More than 40% of patients whose biopsy specimen fragments persistently grew lymphocytes developed

GCD. In contrast, only 6% with nongrower biopsy specimen fragments had subsequent GCD.

This section outlines the basic approach used to propagate cells from biopsy specimen fragments. Other approaches, such as the use of donor or allogeneic cells as feeder cells, may be used at the discretion of the investigator.

Procedure

Sample Requirements

An endomyocardial (or other tissue) biopsy specimen collected in a jar containing sterile physiological saline

Approximately 10 ml of heparinized blood obtained from the patient

Materials and Reagents

LSM Ficoll-Paque (Pharmacia)

500 ml of RPMI 1640 with L-glutamine (Gibco) plus 12.5 ml of HEPES buffer solution 1 M (Gibco) and 2.8 ml of gentamicin reagent solution (10 mg/ml; Gibco)

Pooled human sera type AB (NormIcera-Plus) (Gemini Bio-Products)

Recombinant IL-2 (Hoffmann La-Roche)

Equipment and Instrumentation

Laminar flow biological safety cabinet (NuAire, Inc.)

Beckman centrifuge (model TJ-6)

Olympus biological microscope (model BHTU)

Forma Scientific water jacket incubator (model 3154)

Cesium-137 Gammacell irradiator

Test Procedure

Autologous feeder cells are separated from recipient blood by LSM centrifugation (see description of the MLC method). The biopsy specimens are placed in a small (35- by 10-mm) sterile petri dish by using a sterile transfer pipette, and with a surgical blade or sterile 20-gauge needles, the biopsy specimens are sectioned into three or four small fragments. Each biopsy specimen fragment is transferred onto a 96-well round- (or flat-) bottom plate that contains 100 μl of IL-2-enriched medium (10 to 30 IU of IL-2 in 5% human serum–RPMI 1640). Autologous feeder cells are irradiated (4,000 rad) and added to each well at a concentration of 0.5×10^6/ml. The biopsy cultures are incubated at 37°C and 5% CO_2. Biopsy cultures are monitored for lymphocyte growth regularly. If the investigator wants to monitor rapid lymphocyte growth as a clinical test for rejection, then the biopsy specimen fragments are incubated in IL-2-enriched medium without autologous feeder cells. This procedure allows the identification of graft-infiltrating cells that emigrate from the tissue to the culture well within 24 to 48 h. In the presence of feeder cells, the earliest report of lymphocyte growth is within 5 to 7 days. Once cell growth is observed, the cultures are split and expanded in culture plates with successively larger wells. The cultures are fed with medium containing IL-2 every other day and with autologous feeder cells once a week. All biopsy-derived cell cultures lacking cell growth are discarded after 3 weeks.

Pitfalls and Troubleshooting

When long-term cultures are required to achieve large numbers of cells, the addition of anti-CD3 monoclonal antibody may help expand the activated population without compromising the specificity. In addition, a cocktail of T-cell growth factors such as IL-2 and IL-4 may enhance the growth of graft-infiltrating cells.

Cytokine Measurements

Concept

The conventional assay of T-cell activation is the measurement of cellular proliferation in response to antigen stimulation. More recently, the determination of the frequency of cytokine-expressing cells has been possible through limiting dilution analysis, intracellular cytokine staining, and the enzyme-linked immunospot (ELISPOT) technique. The CD4 T-helper cell polarization has been subdivided into categories according to their cytokine secretion profiles: Th1 cells that secrete IL-2, IFN-γ, and tumor necrosis factor alpha; Th2 cells that secrete IL-4, IL-5, IL-6, and IL-13; and Th17 cells that may secrete IL-17A, IL-17F, IL-22, and IL-21 (21, 23, 24). Many distinct patterns based on differential quantities of expression within the Th1, Th2, and Th17 phenotypes and mixtures of these phenotypes are associated with graft rejection and acceptance.

ELISPOT Assay

The ELISPOT assay was developed in the laboratories of Peter Heeger and Paul Lehmann (25).

Procedure

Sample Requirements

Human peripheral blood collected in three or four green-top Vacutainer tubes with heparin

Antigens (sources are given in parentheses): alloantigen (donor or third-party spleen cells), mitogens (PHA or concanavalin A), or recall antigens (cytomegalovirus or purified protein derivative)

Materials and Reagents

LSM (Isoprep [Robbins Scientific] or Ficoll-Hypaque)

Culture medium: RPMI 1640 containing antibiotics and glutamine with 10% high-quality fetal bovine serum

Blocking solution: PBS–1% BSA–3 g of BSA (Sigma) added to 300 ml of PBS and allowed to sit for 15 min. Filter through a 0.22-mm-pore-size filter and store at 4°C

PBS-Tween-BSA

Red spots: streptavidin-horseradish peroxidase (Dakoo, Carpenteria, CA) diluted 1:2,000 in PBS-Tween-BSA

Buffer for red substrate: 800 ml of 3-amino-g-ethyl carbazole (AEC) added to 24 ml of AEC buffer

AEC buffer (0.1 M sodium acetate buffer, pH 5.0): 0.2 M acetic acid (11.55 ml of glacial acetic acid per liter of distilled water). Add 148 ml of 0.2 M acetic acid to 352 ml of 0.2 M sodium acetate. Bring volume up to 1 liter with distilled water.

AEC: Add 1 g of AEC (ImmunoPure AEC; Pierce; catalog no. 34004) to 100 ml of DMF (*N*,*N*-dimethylformamide; Fisher Scientific catalog no. BP1160-500) using gloves and a mask and working under a fume hood. Wrap the bottle in foil and store at room temperature.

Antibodies from Pharmingen (San Diego, CA):

- Coating antibody-IFN-γ (clone R46A2) at a final concentration of 2 μg/ml or IL-2 (clone JES6-1A12) at a final concentration of 6 μg/ml
- Secondary detection antibodies-IFN-γ (clone XMG1.2 biotin) at a final concentration of 1 μg/

ml and IL-2 (clone JES6-5H4 biotin) at a final concentration of 2 μg/ml

ELISPOT plates (Fisher Scientific, Millipore, or Cellular Technologies Ltd. [Cleveland, OH] catalog no. M200-50)

Equipment and Instrumentation

Laminar flow hood

Incubator set a 37°C and 5% CO_2

Immunospot 2 analyzer from Cellular Technologies Ltd.

Test Procedure

Day 1. Mark the ELISPOT plate and add 100 μl of coating antibody/well diluted to the appropriate concentration in PBS. Wrap the plate in plastic and incubate it in a humid environment at 4°C overnight.

Day 2. In a sterile laminar flow hood, discard the coating antibody by shaking the inverted plate. Block the plate with a sterile solution of PBS–1% BSA at 150 μl/well and incubate the plate for 1 h at room temperature. Discard the liquid from the plate and wash the plate three times with sterile PBS. Until the assay, keep the plates with 200 μl of PBS/well at room temperature. Peripheral blood lymphocytes isolated from the whole blood are diluted to a concentration of 3 million per ml and are plated at 100 μl/well. Stimulator cells (irradiated or mitomycin C treated) are counted and resuspended at 3 million per ml, and 100 μl is used in each well. When needed, T-cell-depleted antigen-presenting cells can be used to control the background. Mitogens (PHA) at a final concentration of 2 μg/ml and soluble protein antigens at different concentrations (0.1 to 50 μM) are added to the plates (final volume of 200 μl/well). The plates are incubated for 24 h at 37°C with 5% CO_2.

Day 3. The secondary antibody is diluted in PBS-Tween-BSA. Discard the fluid from the wells and wash the wells three times with PBS. After each wash, remove the liquid by tapping the plate onto clean towels. Wash the plate four times with PBS-Tween. Leave the last wash in the plate and incubate the plate for 5 min at room temperature. Discard the liquid and add 100 μl of the second detecting antibody/well. The plate is wrapped and incubated overnight at 4°C in a humid atmosphere or for 4 to 5 h at room temperature.

Day 4. Discard the second antibody and wash the plate three times with PBS-Tween. Add 100 μl of streptavidin-horseradish peroxidase/well and incubate for 90 min at room temperature. Near the end of incubation, prepare the reagent for spot development (AEC in AEC buffer plus 12 μl of 30% H_2O_2). Wash the plate four times in PBS (200 μl/well), and add 200 μl of substrate to each well. The spots should develop in 15 to 40 min. Stop the reaction before the background color becomes too strong by washing the plate four times with distilled water. Dry the plate and keep it covered because the spots are light sensitive and fade if exposed to light. The plate can be kept covered in aluminum foil for counting the next day or stored at room temperature for future analysis. When the plate is fully dry, it can be analyzed with a dissecting microscope or with a computer-assisted image analyzer.

Pitfalls and Troubleshooting

The viability of the responder and stimulator cells is very important. Fresh cells are the best; however, frozen specimens can be used if the recovery is sufficient. The sources of fetal calf serum and antibodies are important for the success of the test. Keeping background staining low is crucial, and it is therefore important to stop the reaction in time. Also, the spontaneous release of cytokines from stimulator cells can be diminished by using T-cell-depleted antigen-presenting cells.

Clinical Significance

The ELISPOT assay has a number of advantages over other techniques. The assay is very sensitive and reproducible, and the detection of the secreted molecule occurs directly at the site of the secreting cells. The ELISPOT assay is 100- to 400-fold more sensitive than the enzyme-linked immunosorbent assay performed on culture supernatants. Since this assay can detect antigen-specific cells at the single-cell level, it is more sensitive than intracellular cytokine staining. The analysis is carried out with the help of an automated image analyzer that detects the spots based on predetermined size, shape, and color density characteristics, making the assay very reproducible. The ELISPOT assay may be used to discriminate between *in vitro*-primed alloreactive cells and naive T cells. Antigen-primed T cells produce cytokines in less than 24 h after stimulation, but naive T cells require 3 to 5 days of stimulation *in vitro* to differentiate into effector cells producing Th1, Th2, or Th17 cytokines. Heeger and colleagues have shown that a high frequency of donor-reactive memory T cells producing IFN-γ pretransplant correlates with an increasing risk of posttransplant acute-rejection episodes in living related-donor kidney transplant recipients (25).

ICS and Flow Cytometry

Multiparametric intracellular cytokine staining (ICS) is a widely used flow cytometry-based method to study and quantify cytokine production by memory T cells, including cytokine production by Ag-specific $CD4^+$ and $CD8^+$ T cells. In the field of transplantation, the method may be used on patients' whole blood for *ex vivo* immune monitoring of global T-cell polarization in response to nonspecific stimulation or T-cell immune quiescence, or to detect T-cell activation. In addition, ICS can be used on *in vitro*-activated T cells in a CFSE-MLC, stimulated with allo-Ag by the direct and/or the indirect presentation pathways, to monitor functional donor-specific T cell hyporesponsiveness or to identify patients with donor-reactive T cells that may be at risk of rejection after organ transplantation (11). This method has the advantage over other methods such as ELISPOT or enzyme-linked immunosorbent assay, which allows the simultaneous detection of transcription factors, cytokine production, and surface phenotype of the same cell. Moreover, due to the tremendous progress in knowledge, instrumentation, and reagent development, the method can accommodate assessment of up to 10 to 12 parameters (fluorochrome combinations) at a time, including staining of 3 or 4 intracellular cytokines such as IFN-γ, IL-10, IL-4, and IL-17 per panel (26–28). Most studies in the past have used Ficoll-separated PBMC as a source of staining material, while recently more laboratories have been using whole-blood-based assays (29, 30). Whole-blood staining allows the generation of large sets of data from small volumes of blood and carries *ex vivo* the cellular and biochemical environment maintaining the immunosuppressive drugs during the *in vitro* stimulation.

Procedure

Sample Requirements

Responder cells may consist of human peripheral blood collected in green-top Vacutainer tubes with heparin. Alter-

natively, PBMC isolated by Ficoll density gradient separation, coculture-propagated lymphocytes, tissue-separated cells, or cells from bronchoalveolar lavage fluid can be also used.

To test the responder global nonspecific T-cell cytokine production, phorbol myristate acetate (PMA; catalog no. P-8139; Sigma) and Ca ionophore A23187 (catalog no. C7522; Sigma) can be used as stimulators.

To test the responder T-cell cytokine production stimulated via direct allo-Ag-specific recognition pathway, irradiated donor (or third-party) PBMC or splenocytes can be used as stimulators.

To test the responder T-cell cytokine production stimulated via indirect allo-Ag-specific recognition pathway, donor-derived (or third-party) allo-Ag cell-free lysates can be used. These can be obtained as previously described (30). Briefly, a known number of donor PBMC or splenocytes are lysed by three cycles of freeze/thawing in Tris-EDTA-based buffer containing 1/5,000 NP-40, 0.1 mM phenylmethylsulfonyl fluoride, 1/200 protease inhibitor mixture (Sigma Chemical Co.) and then centrifuged at 1,000 × *g* for 2 minutes, collected, and further centrifuged for 45 minutes at 14,000 × *g*. The pellet is resuspended in assay medium. The equivalent of 1×10^6 intact cells was added per each 1×10^6 responder cells. The absence of whole intact cells should be confirmed by microscopy.

Materials and Reagents

Chemicals for culture and stimulation of cells: intracellular transport inhibitor brefeldin A (catalog no. B-7651; Sigma). Dissolve in 100% dimethyl sulfoxide.

Directly conjugated monoclonal antibodies: from BD Pharmingen, CD3-V500 (clone SP-34-2; catalog no. 560770), CD4-Texas red (clone RPA-T4; catalog no. 555346), CD45RA-APC (clone HI100; catalog no. 550855), CCR4-PE-Cy-7 (clone 1G1; catalog no. 561034), CCR6-PerCP-Cy5.5 (clone 11A9; catalog no. 561752), IL-4-PE (clone MP4-25D2; catalog no. 554485), IFN-γ-AF700 (clone B27; catalog no. 557995), IL-17-FITC (clone N49-653; catalog no. 560489); from eBioscience, CD62L-AF750 (clone DREG-56; catalog no. 47-0629-42), IL-10-eFluor450 (clone JES3-9D7; catalog no. 48-7108-42); and from BioLegend, CXCR3-BV605 (clone G02H7; catalog no. 353727).

Isotype control antibodies each used at concentrations comparable to those of the antibodies of interest.

Staining buffer fluorescence-activated cell sorter (FACS) medium: Dulbecco's PBS (DPBS) without Mg^{2+} or Ca^{2+}, 1% heat-inactivated fetal calf serum, and 0.1% (wt/vol) sodium azide. Adjust buffer pH to 7.4 to 7.6, filter (0.2 μm), and store at 4°C.

Fixation buffer: 2% (wt/vol) paraformaldehyde. Add paraformaldehyde to DPBS and warm in a 50°C water bath (fume hood) until dissolved (1 to 3 h). Adjust pH to 7.4 to 7.6 and store at 4°C.

Permeabilization buffer: DPBS without Mg^{2+} or Ca^{2+}, 1% heat-inactivated fetal calf serum, 0.1% (wt/vol) sodium azide, and 0.1% (wt/vol) saponin (catalog no. S-7900; Sigma). Adjust pH to 7.4 to 7.6 and filter. Fix and Perm permeabilization kit (Caltag Laboratories, Burlingame, CA) for whole-blood assay.

Ficoll-Hypaque gradient

Human AB serum

V-bottom plates (Costar)

12- by 75-mm Polystyrene round-bottom tubes (catalog no. 352008; BD Falcon)

10× PharmLyse buffer (BD catalog no. 555899)

Tubes for whole-blood stimulation polypropylene culture tubes (VWR catalog no. 82-050-140)

Instruments

Fortessa (BD Biosciences) instrument for data acquisition, FlowJo software (Tree Star, Ashland, OR) for data analysis, and an incubator set at 37°C and 5% CO_2.

Nonspecific Stimulation Test Procedure

Cell culture. Responder PBMC or the cells of interest are plated at 50,000 to 250,000 cells in 96-well V-bottom plates in a final volume of 100 μl of 5% AB RPMI 1640. Cells are cultured with or without PMA (50 ng/ml) and Ca ionophore (1 μg/ml) and brefeldin A (1.5 μg/ml). Incubate cells at 37°C in a humidified 5% CO_2 incubator for 4 h for PBMC cultures.

Whole blood. A 100-μl volume of whole blood is stimulated with PMA (50 ng/ml), Ca ionophore (1 μg/ml), and brefeldin A (1.5 μg/ml). Unstimulated whole blood is cultured with RPMI 1640 alone and brefeldin A. Whole-blood cultures are incubated for 4 to 6 h at 37°C in a humidified 5% CO_2 incubator.

AlloAg-Specific Stimulation Test Procedure

Cell culture. Responder PBMC or the cells of interest are plated at 0.3×10^6 cells in 96-well V-bottom plates in a final volume of 100 μl of 5% AB RPMI 1640. Cells are cocultured with or without 100 μl irradiated T-cell-depleted donor (or third-party) PBMC or splenocytes at 1:1 ratio (direct recognition pathway). Alternatively, 0.3×10^6 responder cells are cocultured with a 100-μl equivalent volume of cell free lysates obtained from 0.3×10^6 intact cells (indirect recognition pathway). Incubate at 37°C in a humidified 5% CO_2 incubator for 15 h, and for the last 4 h of incubation add brefeldin A.

Whole blood. Five hundred microliters of whole blood is stimulated or not with 1×10^6 irradiated donor (or third-party) PBMC or splenocytes (direct pathway) or with the equivalent of cell-free lysates obtained from 1×10^6 intact cells (indirect recognition pathway). Whole-blood cultures are incubated for 15 h at 37°C in a humidified 5% CO_2 incubator, and for the last 4 h of incubation brefeldin A is added. Unstimulated whole blood is cultured with RPMI 1640 alone, and brefeldin A is added for the last 4 h of incubation.

Staining Procedure

PBMC cultures.

1. Centrifuge the plate for 5 min at 1,500 rpm (Beckman TJ-6), quickly flick the supernatants, and blot dry the plate.
2. Wash all wells with 150 μl of FACS medium and recentrifuge. Repeat flick, and blot dry.
3. Surface stain with 10 μl (or the titrated amount) of MAb/well. Place the antibodies in the well and gently resuspend cells 8 to 10 times. Wrap the plate in foil and put it in the refrigerator for at least 20 min.
4. Wash wells with 200 μl of FACS medium and centrifuge for 4 min at 1,500 rpm (Beckman TJ-6).

5. Gently flick out the supernatant and fix cells with 150 μl of 2% paraformaldehyde. Incubate overnight in the refrigerator.
6. Centrifuge plates and blot dry. Add 150 μl of permeabilization buffer to each well.
7. Recentrifuge for 4 min, flick the plate, and repeat once. For the unstained wells, use just 10 μl of permeabilization buffer.
8. Stain with intracellular cytokine antibody for each particular cytokine (10 μl of a 1:10 dilution in permeabilization buffer).
9. Place the plate wrapped in foil at 4°C for 30 min.
10. Wash the plate with 200 μl of FACS medium, and centrifuge for 4 min at 1,500 rpm.
11. Flick the plate, add 200 μl of FACS medium, and transfer cells to labeled flow tubes.

Whole blood.

1. Upon harvest, transfer the stimulated whole blood in flow tubes, and add 1 ml of 1× BD PharmLyse lysing buffer (catalog no. 555899) to each tube at room temperature according to the manufacturer's procedure. Vortex to mix, and add 1 ml more of 1× BD PharmLyse buffer to each tube.
2. Incubate for 15 min at room temperature.
3. Wash the cells in 2 ml flow wash.
4. Add 100 μl flow wash/tube.
5. Do the surface marker staining with fluorochrome-labeled MAbs prior to the intracellular staining for 30 min in the dark.
6. Wash cells with 2 ml flow wash/tube.
7. Fix cells by adding 1% PFA for 30 min at room temperature.
8. Wash cells with 2 ml flow wash/tube.
9. Add 2 ml permeabilization buffer and incubate 5 min at 4°C in the dark.
10. Decant liquid, break up pellets, and add 100 μl permeabilization buffer.
11. To block nonspecific binding of intracellular MAbs, add 10 μl mouse serum to each tube, vortex, and incubate tubes for 10 min at 4°C in the dark.
12. Add the intracellular cytokine-specific antibody (10 μl), and incubate the mixture in the dark at room temperature for 30 min.
13. Wash the samples once in permeabilization buffer.
14. Resuspend the samples in 200 μl of FACS medium and analyze them on a FACScan cytometer within 1 hour.

Data Acquisition

Create compensation tubes for each single color used and one unstained as follows:

1. Add 100 μl of flow wash/tube.
2. Add 1 drop of positive beads/tube.
3. Add MAb, incubate at room temperature for 30 min in the dark.
4. Add 2 ml flow wash, centrifuge at 4°C for 5 min.
5. Resuspend in 200 μl flow wash.

After compensation, the experimental tubes are run for data acquisition.

Data Analysis

- Typical forward and side scatter gates are set for lymphocytes, and $CD3^+$ $CD8^+$ or $CD3^+$ $CD8^-$ ($CD4^+$ cells) gates are set to exclude any dead or contaminating nonlymphoid cells. Subsequent gates should be placed close to each population of cells.
- Fifty thousand events per sample are acquired within the specific gate.
- Two-parameter histograms showing memory distribution, chemokine receptors expression, and cytokine staining are created.
- Quadrant statistics are based on the staining of the negative isotype controls.
- The number of cells staining for each cytokine is expressed as a percentage of $CD8^+$ or $CD8^-$, and the total number of cells is expressed per million PBMC. FlowJo (TreeStar, Ashland, OR) or Diva (BD) software is typically used for data analysis.

Troubleshooting for Staining

Always set aside wells for controls and for unstained cells to use in setting the target cell gates. Appropriate Ig isotype controls should be run with each assay, as well as the nonstimulated samples. Initial fluorochrome-conjugated MAb titration should be done to establish the optimal antibody concentration. After fixation, the plates can be kept overnight at 4°C. This step may also lower nonspecific background staining. The intracellular cytokine antibody should be diluted in permeabilization buffer containing saponin. The best results will be obtained when samples are run using the same number of MAb/tube, MAb clones, and fluorochrome conjugation. It is important to choose the optimal color combination especially for >10 color combination panels to avoid significant spillover between channels, which can be achieved by using Spectra Analyser tools (Biolegend).

Troubleshooting for Data Acquisition

The quality of data is highly influenced by the quality of the reagents and by the instrument type and proper setup. Therefore, it is recommended that reagents always be purchased from the same source and data acquisition be performed on the same instrument when possible, paying attention to the voltage and compensation settings, which need to be recorded and checked before every data acquisition experiment.

Troubleshooting for Data Analysis

Due to the complexity of the ICS protocol, with up to 12 color combinations per panel, and the lack of standardized methods for gating, there is a need for experienced personnel to perform data analysis. It is recommended that the same person perform panel-specific analyses, maintaining the same gating strategy and sequence of plots to detect cell subsets (31). Gates should always be placed uniformly after a proper adjustment of bioexponential scaling. Initiatives such as MyFlowCyt and MIATA may be accessed and consulted in order to troubleshoot and improve data analysis and reporting (32, 33).

Intracellular ATP Synthesis Assay: Immune Cell Function Assay

Recently, a method has been developed to measure the cell-mediated (T-cell, or T-lymphocyte) response directly in whole blood (34). The ImmuKnow assay (Cylex, Inc.) has been used to assess the overall basal immune response and to monitor the efficacy of different immunosuppressive protocols posttransplant (26). This whole-blood assay measures increases in intracellular ATP synthesis by $CD4^+$ cells in response to stimulation with PHA in the presence of immunosuppressive drugs. Most immune cell functions

depend directly or indirectly on the production of ATP, and thus, ATP has been used as a marker of lymphocyte activation (15, 35, 36). Reduced ATP levels directly inhibit the cascade of steps required for lymphocyte function, including the transcription of cytokine mRNA, cytokine production, and lymphocyte proliferation. ATP production precedes the appearance of most cytokines measured.

The immune cell function assay measures ATP synthesis that occurs as a result of stimulation with PHA for 15 to 18 h. Whole blood is also incubated in the absence of stimulant to assess basal ATP activity. Anti-CD4 monoclonal antibody-coated magnetic beads are added to immunoselect out CD4 cells from both the stimulated and nonstimulated wells. After washing of the $CD4^+$ cells on a magnet tray, the cells are lysed to release intracellular ATP. Luminescence reagent (luciferin-luciferase) added to the released ATP produces light. The amount of light measured by a luminometer is proportional to the concentration of ATP. The concentration of ATP (in nanograms per milliliter) is calculated from a calibration curve and compared to ATP level ranges to assess the cell-mediated immune function of the sample. The ImmuKnow assay has been approved by the Food and Drug Administration and is commercially available.

Procedure

Sample Requirements

Whole blood is collected into a specimen collection tube containing sodium heparin and stored and transported at room temperature. The assay must be set up within 30 h of specimen collection. Blood should be stored and transported at room temperature only (18 to 28°C). It is recommended that a normal control sample be drawn and run with each test sample.

Materials and Reagents

The Food and Drug Administration-approved assay kit ImmunoKnow (catalog no. 4400; Cylex, Inc.) contains the following materials and reagents.

- Assay plate and cover: 96-well (12- by 8-well strips) plate coated with an inert substance to prevent nonspecific binding. Store at 2 to 28°C, desiccated in the resealable foil pouch.
- Sample diluent: 25 ml. Store at 2 to 8°C.
- Stimulant: PHA-L, 12.5 μg/ml. Store at 2 to 8°C.
- CD4 Dynabeads (Dynal Biotech A.S.A., Oslo, Norway): magnetic beads coated with mouse monoclonal anti-human CD4, supported in buffered saline with BSA and preservative (6.5 ml). Store at 2 to 8°C.
- Wash buffer: buffered saline with BSA (125 ml). Store at 2 to 8°C.
- Lysis reagent: hypotonic basic solution with detergent (50 ml). Store at 2 to 8°C.
- Calibrator panel: ATP concentrations, 0, 1, 10, 100, and 1,000 ng/ml (0.8 ml each). Store at 2 to 8°C.
- Luminescence reagent: luciferin and luciferase in a buffered solution (33 ml). Store frozen upon receipt at −70°C or lower. Thaw at room temperature (18 to 28°C) only. Mix well after thawing. The reagent may be thawed and refrozen up to four times.
- Measurement plate: 96-well (12 8-well strips) black or white opaque plate (two of each plate). Store at 2 to 28°C in the resealable bag.

Reagent and Equipment Requirements

All reagents should be allowed to come to room temperature before use. Luminescence reagent must not be thawed above room temperature (i.e., do not thaw reagent at 37°C). Reagents should be thoroughly mixed immediately before pipetting.

The microtiter plate shaker must provide an adequate mix to fully resuspend settled blood cells following incubation without visible loss of material from the wells (i.e., no visible splashing should be observed on the assay plate cover). Once an appropriate setting is determined, use this setting throughout the assay. A vacuum pump with a strength of 150 to 200 mm Hg is recommended. If a stronger vacuum is used, care should be taken not to aspirate the Dynabeads during the wash steps.

Equipment and Instrumentation

- Luminometer: The luminometer must be formatted for a 96-well microtiter plate, capable of measuring "glow" luminescence, with a maximum emission of 562 nm, and maintain linearity over a measurement range of 5 decades of light output. A computer with Microsoft Excel version 95, 97, or 2000 is needed to support luminometer function.
- Incubator set at 37°C with a 5% CO_2 humidified atmosphere
- Magnet tray (catalog no. 1050; Cylex, Inc.; also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])
- Cylex immune cell function assay data analysis software (catalog no. 1440; Cylex, Inc.; also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])
- Vacuum aspiration system (catalog no. 1040; Cylex, Inc.) or equivalent (also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])
- Eight-channel aspiration manifold with tubing connector (catalog no. 1070; Cylex, Inc.) or equivalent (also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])
- Miscellaneous equipment: vacuum source, vacuum apparatus with disposable tubing and receiving flask, microtiter plate shaker, Vortex mixer, adjustable pipettes and tips capable of delivering 25- to 1,000-μl volumes, eight-channel multichannel pipette(s) and tips capable of delivering 50- to 200-μl volumes, reagent reservoirs, 12- by 75-mm tubes, and a timer.

Mechanics and Controls

Assay part 1: cell stimulation. Gently invert each control and patient whole-blood specimen several times to ensure uniform distribution of blood cells. Prepare a 1:4 dilution of each whole-blood specimen using sample diluent (e.g., 500 μl of whole blood plus 1.5 μl of sample diluent). Assemble the assay plate according to the worksheet supplied by the manufacturer by using one eight-well strip for each specimen and 25 μl of sample diluent in the first four wells. Dispense 100 μl of each diluted patient specimen into eight appropriately labeled wells, according to the worksheet. Replace the plate cover and shake the plate on a plate shaker for 30 s. Incubate the covered assay plate cover and shake the plate on a plate shaker for 30 s. Incubate the covered, assay plate in a 37°C and 5% CO_2 incubator for 15 to 18 h.

Assay part 2: CD4 cell selection and ATP release. Remove the assay plate from the incubator and shake it on a plate shaker for 3 min. Hand mix by gentle inversion the CD4 Dynabeads, and dispense 50 μl into each well. The magnetic beads must be thoroughly suspended to ensure accurate addition to each well. Cover the plate, shake it on the plate shaker for 15 s, and incubate it for 30 min at room temperature (18 to 28°C). Shake the plate for 15 s halfway through the incubation and again at the end of the incubation. Remove the strips from the assay plate and place them onto the assembled magnet tray. Wait 1 to 2 min for the Dynabeads to collect on the sides of the wells to isolate CD4 cells from the whole blood. Carefully aspirate whole blood from each well by using an eight-channel aspiration manifold attached to a vacuum system. Avoid dislodging the Dynabeads. Wash three times to eliminate residual unbound cells and interfering substances from the wells. Wash with 200 μl of wash buffer in each well, wait 1 min, and then aspirate. After the last wash step, remove the strip holder from the magnet base, shake the strips for 1 min on the plate shaker, and then replace the strip holder on the magnet base. Wait 1 min, and then aspirate.

Dispense 200 μl of lysis reagent into each well. Remove the strip holder from the magnet base and shake the strips on the plate shaker for 5 min. Place the strip holder onto the magnet base and wait 1 to 2 min.

Assay part 3: ATP measurement. If there will be a delay of more than 4 h before proceeding to assay part 3, the strips should be frozen at this time. Remove the strips from the strip holder and place them in the assay plate frame. Seal the strips, place the cover on the assay plate, and freeze at −20°C. Frozen strips are stable for at least 1 month. To continue, remove the plate from the freezer, allow it to come to room temperature (18 to 28°C), place the strips in the strip holder of the magnet tray, and dispense into measurement plates as described below.

The measurement plate should include one strip for each patient and two strips for the calibrator panel. Using a multichannel pipette, transfer 50 μl from each well of the magnet tray to the appropriately labeled wells of the measurement plate. Change pipette tips for each strip. Dispense 50 μl of each calibrator into duplicate wells of the measurement plate according to the worksheet. Using a multichannel pipette, dispense 150 μl of luminescence reagent into each well of the measurement plate. Following the luminometer manufacturer's instructions, read the plate between 3 and 10 min after addition of the luminescence reagent.

Calibration

The amount of ATP present in the cell lysate is calculated from an ATP calibration curve generated in each assay run. Relative light units (RLU) for control and patient samples are obtained from the luminometer and converted into nanograms of ATP per milliliter based on comparable RLU signals in the calibrators.

The RLU data from the luminometer are converted and analyzed using the Cylex immune cell function assay data analysis software. Luminometer RLU values provided in Microsoft Excel or tabular formats can be directly copied and exported into the data analysis software spreadsheet. ATP calibrator concentrations versus RLU values are plotted on a log-log scale, and linear regression analysis generates a calibration curve. To assess the linearity of the curve, each calibrator is reanalyzed by plotting RLU values on the curve and calculating corresponding ATP values. In addition, the correlation coefficient (r^2) of the calibration curve is calculated.

Calculation of Results

Calculate the ATP concentrations for the control and patient specimens by using the Cylex immune cell function assay data analysis software. After RLU values and specimen identification are entered into the spreadsheet and the calibration curve is generated, the following data are calculated and displayed in a report: ATP result for each replicate, average ATP value for replicates, standard deviation for replicates, and coefficient of variance of replicates. The coefficient of variance for stimulated wells must be <20%. If not, an analytical method to identify outlier values must be used and the results must be recalculated. Reported ATP values must be limited to the defined range of the calibrator panel. Samples with ATP values above the highest calibrator are reported as having values of >1,000 ng/ml. Samples with ATP values below the lowest calibrator are reported as having values of <1 ng/ml.

Pitfalls and Troubleshooting: Limitations

All of the following criteria must be met for the assay run to be considered valid:

- The ATP result for the nonstimulated control sample must be ≤60 ng/ml.
- The ATP result for the stimulated control sample must be ≥240 ng/ml.
- The ATP level for the nonstimulated sample must be less than the ATP level for the stimulated sample.

If the specimen meets these criteria, proceed with interpretation of the stimulated sample. If the nonstimulated sample does not meet these criteria, the specimen may have nonspecific production of ATP and the results are not valid. A new specimen should be drawn.

The linearity of the calibration curve must be accepted under the following criteria:

- The calculated value for the 1,000-ng/ml ATP calibrator must be 900 to 1,100 ng/ml (refer to the result in the "Average" column in Table IV of the data analysis software report).
- The calculated value for the 100-ng/ml ATP calibrator must be 85 to 115 ng/ml (refer to the result in the "Average" column in Table IV of the data analysis software report).
- The correlation coefficient (r^2) of the ATP calibration curve must be ≥0.97.

Interpretation of Results

The assessment of the cell-mediated immune response of a specimen is made by comparing the ATP concentration for that specimen to fixed ATP level ranges. The ATP concentration for each specimen is calculated from the calibration curve established for the measurement plate in which the sample was run. Assay standardization is maintained by running the calibrator and a freshly drawn specimen from an apparently healthy individual with each assay run. The cutoffs for the ATP level ranges are 225 and 525 ng/ml (Table 1).

The ATP level ranges for the Cylex immune cell function assay were established by testing 155 apparently healthy adults and 127 transplant recipients with the assay. A cumulative frequency of differences was used to select the ATP levels that give the best balance of results between immunosuppressed and nonimmunosuppressed individuals. Note that this is a qualitative assay, and therefore, the results do not directly quantify the level of immunosuppression. Results of the Cylex immune cell function assay should be used

TABLE 1 Interpretation of PHA-stimulated sample

ATP level (ng/ml)	Result	Interpretation
≤225	Low immune cell response	The patient's circulating immune cells are showing low response to PHA stimulation
226–524	Moderate immune cell response	The patient's circulating immune cells are showing moderate response to PHA stimulation
≥525	Strong immune cell response	The patient's circulating immune cells are showing strong response to PHA stimulation

in conjunction with clinical presentation, medical history, and other clinical indicators when establishing the immune status of a patient.

Expected Values

Freshly drawn whole-blood specimens from 155 apparently healthy adults and 127 transplant recipients were evaluated with the ImmuKnow cell function assay. The distribution of results of the assay for these populations is summarized in Table 2.

The population of apparently healthy adults consisted of 37 (24%) females, 105 (68%) males, and 13 (8%) individuals of unknown gender, and the age range was 20 to 60 years. The ethnicity of the population was as follows: 59% (91) African American, 28% (44) Caucasian, and 13% (20) other or unknown. The population of transplant recipients consisted of 55 (43%) females and 72 (57%) males, and the age range was 20 to 64 years. The ethnicity of the population was as follows: 24% (31) African American, 69% (87) Caucasian, and 7% (9) other or unknown. The organs transplanted included kidneys (59% [75]), livers (34% [43]), pancreases (2% [3]), and multiple organs (5% [6]).

VALIDATION OF NEW CELLULAR ASSAY PROCEDURES

Several of the assays outlined in this chapter are being implemented in the clinical laboratory. A few assays, such as the MLC, have written standards (see the *American Society for Histocompatibility and Immunogenetics Procedure Manual* [5]); however, most immune assays do not. Every new test must be validated before being implemented for patient testing, either by running parallel testing with another laboratory with a validated test procedure or by running known samples that have been tested by another validated method. Validation of a new test usually also includes an external quality assessment through a proficiency testing program. Although many agencies and associations offer programs for this purpose, none are available for the cellular immune assays outlined in this chapter.

When proficiency testing is not available, alternative validation procedures must be implemented, including split-sample and audit sample procedures. The split-sample procedure evaluates imprecision and testing errors. For external verification of test results, 5 to 10 samples are aliquoted and distributed to one or several other laboratories for parallel testing. Internal split-sample procedures test intertechnologist variation and operator-dependent variation. To test intertechnologist variation, samples are split and run by two different technologists. Audit samples, aliquots of control samples that are stored and analyzed periodically over time, assess the imprecision of the assay but not the accuracy. The standard deviation and coefficient of variation are statistics used to determine acceptable thresholds.

Analysis of Patient and Healthy Control Subject Data

Tracking of the daily average of patient data has been used extensively for quality control measures. This technique compares the average of 20 consecutive patient values versus an established patient mean value. Optimal application of this method requires an adequate number of patient values obtained using criteria for exclusion of outlying values likely to be from abnormal subjects. In addition, data from two healthy control subjects run with each assay have been used to detect shifts in method performance. Methods to monitor a daily mean or an average for healthy control subjects have been applied as quality control measures for a number of clinical tests. For methods with small population variation, 10 to 100 results are required for valid quality control.

Analysis of Data from Validation Procedures

The laboratory should define the limits of acceptability for each validated procedure either by analysis of internal quality control data (e.g., a standard deviation from the mean of ±2 or 3) or by use of data in the literature.

Statistical Evaluation of Split-Sample Data

The laboratories involved in evaluation of split-sample data must agree on the criteria for validation, including the test methods, numbers of tests, criteria for determining agreement, and procedures to resolve discrepancies. The statistical procedure to determine agreement between laboratories uses a formula to calculate the confidence interval for the difference between two results.

Statistical Evaluation of Patient and Healthy Control Data

The result values are placed in rank order. The central 68% of all values are selected, and the mean is calculated. If the distribution of values is normal, the low and high values of

TABLE 2 Distribution of results of the Cylex immune cell function assay

ATP level (ng/ml)	Immune cell response	No. (%) of transplant recipients with indicated results	No. (%) of healthy adults with indicated results
≤225	Low	51 (40)	9 (6)
226–524	Moderate	66 (52)	102 (66)
≥525	Strong	10 (8)	44 (28)

the central 68% of all values approximately equal 1 standard deviation below and above the mean. The mean and standard deviation provide measures for comparison with other laboratories, previous data from the same laboratory, and published data.

Proficiency Testing

For every test that is performed, the laboratory must participate in external proficiency testing, when available, to ensure quality of testing. The proficiency test samples must be handled in the same manner as the patient samples; that is, they must be introduced into the laboratory system in the same manner. Testing of the proficiency test samples should be rotated among all technologists who routinely perform the assay in question. The relationship between the results must be defined and evaluated. Corrective action must be initiated if a result is found to be unacceptable when compared to the consensus results. The accuracy for external proficiency testing should be >90%. When no commercial proficiency testing programs are available, parallel testing with another laboratory doing the same test must be done at least every 6 months. In-house proficiency testing should also be performed to assess variability between technologists. This comparison testing should be done at least every 6 months.

Quality Assurance for Cellular Assays

Quality assurance is a comprehensive program to ensure quality results from the initiation of a test through the end of result analysis by conforming to established written policies, monitoring compliance to policies, and documenting corrective actions. Each laboratory must have written policies for the requisition and collection of samples, the volume needed, the type of anticoagulant to be used, labeling, and sample storage and transportation for each test done in the laboratory. The policy must include criteria for sample acceptance or rejection. Each written requisition must match the sample and contain the following information: name of patient, identification number, date and time of sample acquisition, specific testing ordered, and referring facility.

Records of the types of problems encountered in sample acquisition should be kept and monitored for trends. Corrective action should be initiated and documented if problems persist. Compliance with requirements should be 95% or better.

Each laboratory should have a comprehensive procedure manual that details the standard operating procedure for each analysis performed, written in the CLSI format. The procedure manual should be reviewed yearly by the director and all technical staff and signed and dated by the director prior to implementation. Minor corrections can be handwritten but need to include the date of revision and the director's approval.

Quality Control Procedures for Cellular Programs

The laboratory shall define and document quality control measures for each test performed. These measures must include written policies outlining the criteria for accepting or rejecting results, evaluating reagents for consistent quality, and documenting equipment performance. All quality control problems must be addressed. The corrective actions must be documented in writing and reported in the quality assurance report.

Each procedure description must indicate quality control measures employed and how they are used in the interpretation of the results. Acceptable ranges must be established, and corrective actions must be documented when the controls do not fall within these ranges. Results of the test are not reported if the quality control for the test procedure exceeds the acceptable limit.

Each laboratory shall have a written policy for labeling reagents with the name, date received, date prepared or expiration date, date opened, technologist's initials, and storage conditions. Written procedures for quality control for each reagent prior to use are required. Descriptions of specific quality control procedures should include the appropriate method for testing each reagent, which may include titration, parallel testing, and measure of cell growth support, as well as documentation of acceptable performance. The date at which the reagent is put into use must also be documented.

Written protocols must be in place for routine equipment performance checks and scheduled preventative maintenance. All maintenance and results must be documented, and such records must be stored. Tolerance limits for each equipment performance check must be established, and compliance must be documented. When acceptable limits are exceeded, corrective action may include a procedure for troubleshooting, criteria for instrument repair, backup procedures or instruments, and a power failure plan.

CLINICAL APPLICATIONS

Currently, cellular assays are used to define donor antigen-specific hyporeactivity, to investigate the function and specificity of graft-infiltrating cells, and to determine T-cell precursor frequencies. The MLC, cell-mediated lympholysis techniques, and CFSE-MLR are currently used to investigate the development of donor antigen-specific hyporeactivity posttransplant (4, 11). These assays may be useful for identifying patients who are good candidates for discontinuing or tapering immunosuppression therapy on the basis of apparent immunoregulation of response to disparate antigens. The development of donor antigen-specific hyporeactivity, as measured by MLC, correlates with improved late solid-organ transplant outcome, as evidenced by fewer late rejection episodes and fewer graft losses (4). Newer multiparameter flow cytometry-based assays provide investigators with enhanced ability to monitor simultaneously numerous analytes of cell-mediated immunity (e.g., phenotype, proliferation, and cytokine production). In order to generate rigorous, reliable, and reproducible results, proficiency panel programs are in place to help investigators optimize their approach and analyses (10, 11, 30).

Propagation of T lymphocytes from kidney, heart, and liver allografts demonstrates a strong correlation between long-term T cell growth and clinical acute cellular rejection (37). The primed lymphocyte test has been used to investigate the specificity of these graft-infiltrating cells. This technique demonstrates functional characteristics of graft-infiltrating cells and provides information on the activation state of the T-cell infiltrate.

Previous studies have suggested a correlation between CTL precursor (CTLp) frequency and the clinical grade of graft-versus-host disease in recipients of bone marrow from unrelated donors (7, 8). Recipients with CTLp frequencies higher than 1:100,000 tended to have more-severe graft-versus-host disease than those with lower CTLp frequencies. Schwarer et al. (38) compared helper and cytotoxic anti-recipient T-cell frequencies in recipients who had received unrelated-donor bone marrow. They found that the HTLp and CTLp assays provided similar predictive information for outcome; however, the HTLp method is more rapid and less labor-intensive and, thus, may be more useful for donor selection in unrelated-donor bone marrow transplantation.

This approach may be useful in predicting graft-versus-host disease in unrelated-donor bone marrow transplant recipients. More recently, VanBuskirk et al. (6) have described the use of the CTLp assay to identify kidney recipients in whom immunosuppressive therapy can be safely reduced. Their data showed that kidney recipients with low or no frequency of donor-specific CTLp could safely have their immunosuppressive drug load tapered. The frequencies of intracellular IL-2- and IFN-γ-producing cells in normal individuals are similar in whole blood and isolated PBMC. However, in transplant recipients on tacrolimus or cyclosporine (CSA), the frequency of IL-2-producing cells may be significantly inhibited in whole blood while little or no inhibition is observed when the cells are isolated prior to the *in vitro* stimulation (26). In addition, the concentration of tacrolimus in blood does not directly correlate with its inhibitory effect on cytokine production in peripheral T-cell subsets (26). Despite these caveats, monitoring the *in vivo* efficacy of tacrolimus or CSA in suppressing cytokine production in T-cell subsets may further improve the posttransplant management of transplant recipients. This approach can also identify patients who are less susceptible to tacrolimus- or CSA-mediated inhibition and who therefore may need other immunosuppression (26).

The immune function assay (ImmuKnow; Cylex, Inc.) is a Food and Drug Administration-approved assay currently being implemented as a clinical test at many transplant centers. The assay has been used to directly assess the immune system, individualize immunosuppressive therapy, monitor drug tapering, conduct vaccine trials, monitor the efficacy of different immunosuppressive regimens, and distinguish rejection from infections such as hepatitis C virus infection in transplant recipients. A recent multicenter study evaluated the Cylex ImmuKnow assay for the measurement of immune response in immunosuppressed transplant recipients (39). Most immunosuppressive drugs are currently administered on the basis of weight. However, the baseline levels of immune response in patients awaiting transplant vary enormously and are not a function of body weight. The investigators in this multicenter trial found that the level of tacrolimus as measured by the conventional immunoassay did not correlate with the degree of biological immunosuppression by the PHA-induced ATP levels (39). They observed that following transplant, recipients' responses were statistically distributed among three levels of reactivity (low, intermediate, and high) based on this assay. Further, the effectiveness of the immunosuppressive therapy appears to increase with time posttransplant since the number of recipients in the low-response-level category increased despite lower dosing of the drugs. Zeevi et al. demonstrated that responses to recall antigen, alloantigen, and PHA were measurable by lymphoproliferation assays in immunosuppressed transplant recipients but were apparently suppressed when measured by the ATP assay. Furthermore, the Cylex assay provides an objective measure of the net state of a patient's immunosuppression while minimizing the drug therapy (40). A systematic review and meta-analysis of the ImmuKnow test in liver transplantation concluded that this assay is a valid tool for determining the risk of infections but not of rejections in adult liver transplant recipients (41).

CONCLUDING REMARKS

The long-term goals of using the cellular assays described in this chapter are to assess accurately the changing immunological statuses of transplant recipients, to predict long-term graft outcome, and to provide the immune response information needed to individualize immunosuppression therapy. By using methods that measure various immune functions in a serial fashion, an accurate assessment of the recipient's immune status can be obtained. Sequential evaluation of a patient's immune status should be considered in any protocols that incorporate modification of the immunosuppression therapy.

Complement in Transplant Rejection

CARMELA D. TAN, E. RENE RODRIGUEZ, AND WILLIAM M. BALDWIN III

117

Better reagents have led to an increased appreciation of the association between complement activation in transplants and poor outcome (1–4). As diagnostic markers, products of complement activation have two attractive attributes related to the fact that activation of complement proceeds through a series of enzymatic steps resulting in multiple cleavage products. First, each enzymatic step is capable of amplifying the number of molecules that are cleaved. Second, the cleavage process reveals cryptic epitopes that allow the activated products to be distinguished from the unactivated precursors. In addition, activation products from two complement components, namely, C4 and C3, have the unusual property of covalently binding to protein and carbohydrate substrates. All of these properties distinguish complement activation products from some of the molecules that activate complement, such as antibodies. Antibodies themselves are not readily detected in tissue sections because only transient binding of a small number of antibodies to tissue is required to activate exponentially larger amounts of complement.

This chapter examines the advantages and disadvantages of various reagents to complement as applied to the diagnosis of different types of rejection in transplants. In addition, the limitations of complement as a marker of antibody-mediated rejection (AMR) are addressed (5–7).

SELECTION AND INTERPRETATION OF DIAGNOSTIC REAGENTS TO COMPLEMENT IN ALLOTRANSPLANTS

Deposits of Complement in Tissue Biopsy Specimens

Examination of biopsy specimens from organ transplants provides the most direct assessment of pathological processes jeopardizing the transplant. Stains for complement components in the organ transplant offer direct evidence of the location, distribution, and extent of complement activation at the site of injury. The different components of complement that have been used as markers of antibody-mediated rejection in transplants are discussed here in their order of activation by antibodies as shown in Fig. 1.

Polyclonal and Monoclonal Antibodies to C1q

The activation of complement by antibodies is primarily through the classical pathway of complement. Because C1 is the first component of the classical pathway of complement activation, it has long been used as a marker of antibody activation of complement. Polyclonal and monoclonal antibodies are available to detect C1q, the subcomponent of C1 that actually binds to antibodies (Fig. 1). These are frequently applied in renal pathology and dermatopathology to detect immune complexes. There are several drawbacks to C1q as a marker of rejection, however. The most serious drawback relates to sensitivity. In order to bind, one C1q requires at least a pair of IgG antibodies (Fig. 1a). This means that there are actually fewer C1q molecules to detect than IgG molecules. Moreover, the C1q molecules that are bound to antibodies depart when antibodies release from antigen or are shed from a cell surface (Fig. 1c).

In addition to sensitivity, there are theoretical problems of specificity. It is now clear that antibody is not the only ligand that is bound by C1q. C1q can also bind to phosphatidylcholine and sphingomyelin that are exposed on plasma membranes of apoptotic or ischemic cells or to the surface of virally infected cells. The presence of receptors for C1q on endothelial cells raises the possibility that immune complexes containing C1q could result in antigen-independent deposition of C1q on endothelium. However, these reactions are usually less diffuse, and in the case of immune complexes the pattern is usually granular rather than linear.

As predicted by these theoretical considerations, C1q has not proved to be a sensitive marker of antibody-mediated rejection in practice.

Polyclonal and Monoclonal Antibodies to C4d

The tissue-bound split products of C4 are significantly more sensitive than C1q as a marker of antibody-mediated inflammation. Because each activated C1 can enzymatically cleave many C4 molecules, more C4 split products are available to detect. One study found that for each C1 there were about 28 C4b fragments deposited on the cell membrane (8). The covalent binding of C4b and its further split products to tissues results in extended half-lives (Fig. 1c). The result of greater quantities and longer half-lives is that C4b and its further split product C4d are detected more easily than C1q or antibodies in biopsy specimens. Another advantage that results from the enzymatic cleavage of C4 is that neoepitopes are exposed on the split products. Monoclonal antibodies produced to these neoantigens are specific for the activated split product and not the intact precursor.

doi:10.1128/9781555818722.ch117

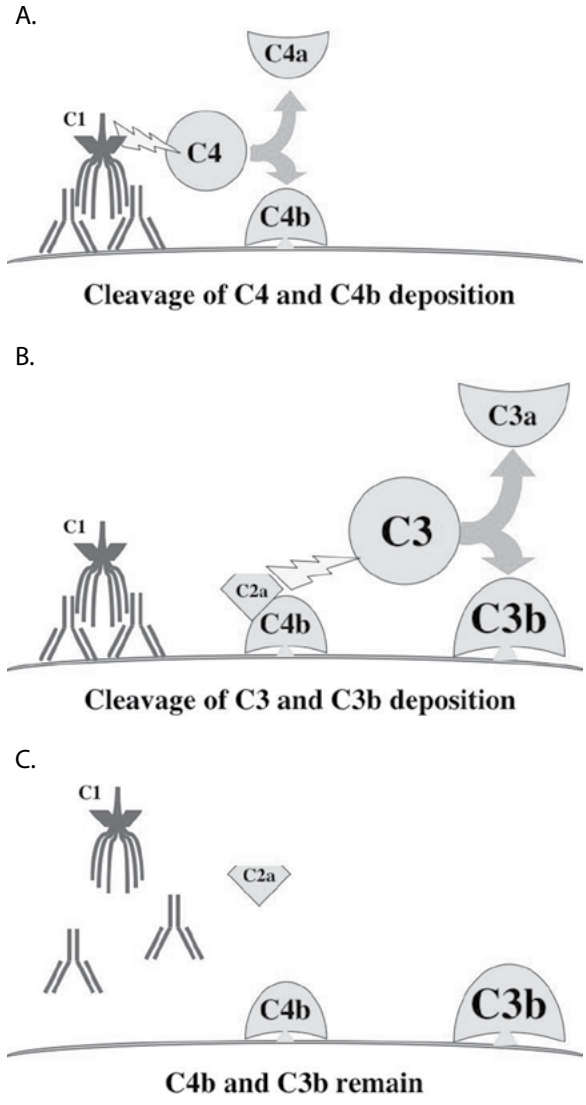

FIGURE 1 Activation of the early complement components by antibodies. (a) A pair of IgG antibodies is bound by C1 through the C1q subcomponent, and the enzymatic C1r and C1s subcomponents are activated to cleave C4 into C4a and C4b. C4b can bind covalently to a membrane protein and provide an anchor for C2, which is then cleaved. (b) The complex of C4bC2a enzymatically cleaves C3 into C3a and C3b. C3b is structurally homologous to C4b and can bind covalently to a membrane protein. (c) The covalently bound split products of C4 and C3 remain attached to the cell membrane after the antibody, C1, and C2a have dissociated from the membrane. The sizes of the symbols for C4b and C3b are intended to reflect the potential for larger quantities of C3 than C4 activation products.

C4d, the final split product of C4, has been the most widely reported marker for humoral immune responses to transplants (1, 2). Therefore, the mechanism that produces C4d is worth reviewing. C4d represents the end product of a regulatory mechanism that evolved to prevent damage to autologous tissues during complement activation. The small C4d fragment results when factor I cleaves C4b twice, once on either side of the covalent bond. Factor I requires a cofactor, such as membrane cofactor protein (MCP; CD46) or complement receptor 1 (CR1), to cleave C4b (Fig. 2). MCP is widely distributed on cells, including leukocytes and vascular endothelial cells. In contrast, CR1 is expressed on erythrocytes and leukocytes, including neutrophils and macrophages. The fluid-phase complement-regulatory protein C4 binding protein (C4bp) can also interact with cell-associated C4b and may also be found in regions of coagulation through its ability to bind to protein S. The rapid enzymatic cleavage of C4b by factor I makes C4d a more stable marker of complement activation than C4b. In fact, the monoclonal antibody used to detect C4d actually detects an epitope expressed on C4b as well as C4d. As a result, both C4d and any remaining C4b are detected by this reagent.

The use of the monoclonal antibodies to C4d has been limited primarily to frozen tissue sections. This limitation has been circumvented by the development of a polyclonal antibody that can be used in formalin-fixed and

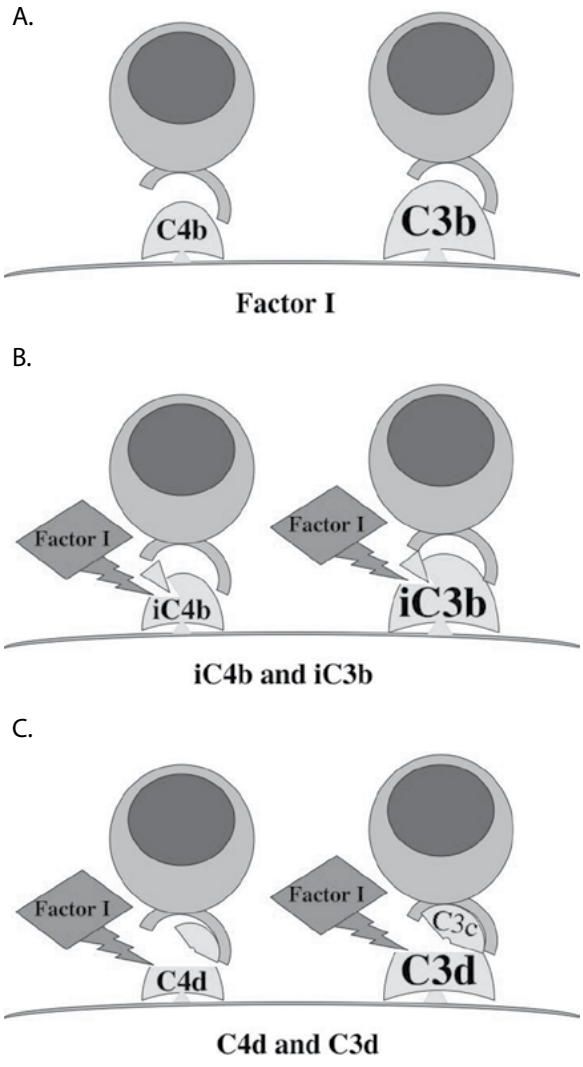

FIGURE 2 Regulation of C4b and C3b by circulating factor I and leukocytes expressing CR1. (a) CR1, which is expressed by leukocytes, associates with C4b or C3b, allowing factor I to cleave C4b and C3b. (b) The first enzymatic cleavage leaves iC4b or iC3b attached to the cell membrane. (c) Factor I then enzymatically cleaves iC4b or iC3b, and C4d and C3d remain covalently bound to the cell membrane. As described for Fig. 1, the sizes of the symbols for C4b and C3b are intended to reflect the potential for larger quantities of C3 than C4 activation products.

paraffin-embedded tissues. The first polyclonal was produced by immunizing a rabbit with a synthetic 15-amino-acid peptide that coincides with a loop segment of C4d that is not shared by the homologous C3d sequence (9). This reagent (available from Biomedica Gruppe, Vienna, Austria, distributed in the United States by Alpco, Salem, NH) has proved to be very useful in the case of biopsy specimens for which no frozen tissue is available. However, detection of C4d in fixed tissues is less sensitive than in frozen sections. In addition, there are difficulties with high background and nonspecific staining of the edges of the biopsy specimens ("edge effects").

The pattern and strength of staining are important for the interpretation of the results (Fig. 3). In biopsy specimens from renal transplants, antibodies to major histocompatibility antigens (HLA in humans) or major blood group antigens are associated with diffuse, linear staining of the peritubular capillaries (2, 10–12). Arterial endothelial cells are variably involved. This pattern may reflect in part the distribution of both the target antigens and the complement regulatory proteins. For example, class II major histocompatibility antigens, such as HLA-DR, are expressed constitutively on capillary and venous endothelium, but not arterial endothelium. However, HLA-DR antigens are upregulated by arterial endothelial cells as well as by tubular epithelial cells in sites of inflammation (13).

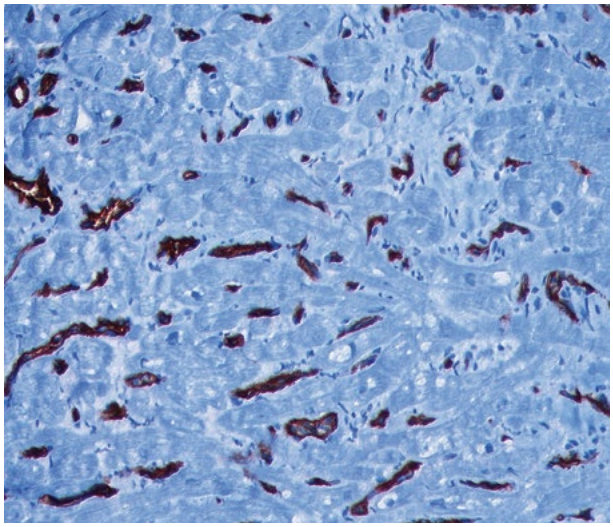

FIGURE 3 C4d staining of a heart transplant biopsy by immunofluorescence (top) and immunohistochemistry (bottom) shows comparable discrete staining of capillaries between myocytes, indicative of antibody-mediated rejection.

Polyclonal and Monoclonal Antibodies to C3 Split Products

Because C3 and C4 are both members of the alpha 2-macroglobulin family (14), the activation and regulation of C3 produce split products that are homologous to C4 split products (Fig. 2). C3d is the final membrane-bound split product of the regulation of C3b by factor I and a cofactor such as factor H, CR1, or MCP. C3d has been compared to C4d as a marker of complement activation (12, 15–18). Like C4d, C3d is covalently bound to tissues. Monoclonal antibodies to C3d are also specific for activated C3 because the epitope recognized is cryptic in uncleaved C3.

There are two major theoretical advantages of C3d as a marker for complement activation. The first advantage is that quantitatively more C3 can be activated than C4 because there is more substrate available and there is an amplification loop that sustains C3 activation. About twice as much C3 as C4 is present normally in the circulation (1.3 and 0.6 mg/ml, respectively), and these levels can be doubled by increased hepatic production in response to acute-phase reactions. In inflammatory sites, macrophages can produce additional C4 and C3. Once C3 is activated by any mechanism, a large supply of C3 is available as a substrate for an amplification loop, in which C3b activates more C3 through factor B.

The second advantage of C3d as a marker is that the split products of C3 have more biological activities than their C4 counterparts. C3b, iC3b, and C3d are the primary ligands for complement receptors 1, 3, and 2 (CR1, CR3, and CR2), respectively. Like CR1, CR3 is expressed on neutrophils, macrophages, and subsets of T lymphocytes. CR2 is part of a major second signaling pathway for antibody production by B lymphocytes. Although C4b is also a ligand for CR1, C4d does not bind CR2 (19). Therefore, the regulation steps for C4b that result in C4d deposition could terminate the complement cascade without activation of C3 or proinflammatory consequences. As a result, cases in which C4d is deposited in the absence of significant activation of C3 would be predicted to be associated with little or no complement-mediated injury (5, 20). In fact, this situation may account for the striking amounts of C4d found in well-functioning major-blood-group-incompatible renal transplants (12, 21, 22). The capacity of renal transplants to function well in the presence of circulating antibodies has been termed "accommodation" (20). The demonstration that C4 is activated indicates that the circulating antibodies do bind to the transplant and initiate activation of complement.

There are practical and theoretical reasons that C4d has been advocated as a better marker for antibody-mediated rejection than C3d. The practical advantage of C4d is that monoclonal and polyclonal antibodies to C4d work well with frozen and formalin-fixed tissue. Interpretation of C3d staining is more problematic with high background staining. In normal kidneys, C3d is also found in the tubular basement membrane and mesangium, particularly in biopsy specimens from older animals or humans.

The theoretical assertion that has been advanced for C4d as a marker for antibody-mediated responses is that it

decreases "false-positive" reactions due to complement activation by the alternative pathway. However, in antibody-mediated immunity, the alternative pathway serves fundamentally as an amplification loop for the classical pathway, and this is one of the reasons that C3 split products can be deposited in larger amounts than C4 split products.

Polyclonal and monoclonal antibodies to other split products of C3 have also been applied in the diagnostic evaluation of tissue biopsy specimens, but these reagents have disadvantages. The intermediate split product, iC3b, has the disadvantage of being short-lived. Moreover, iC3b may be more involved with downregulation of immune responses through its function as the primary ligand for CR3 on T lymphocytes as well as macrophages (reviewed in reference 22).

The use of antibodies to C3c offers even fewer advantages because C3c is the portion of iC3b that is cleaved away to produce C3d (Fig. 2c). As such, C3c does not remain bound to the membrane after being cleaved.

Polyclonal and Monoclonal Antibodies to C5b-C9

The terminal five components of complement attach to each other in succession to form the membrane attack complex (MAC), which increases cell permeability. Polyclonal and monoclonal antibodies have been produced to neoantigens that are created as the complex is formed. The MAC would be the best indicator that enough complement has been activated to exceed the multiple regulatory proteins capable of truncating the complement cascade after C4 or C3 activation. With currently available reagents, however, MAC has proven to be an insensitive indicator (23). This lack of sensitivity is probably related to the fact that MAC is deposited in limited quantities and sublytic amounts of MAC can be cleared rapidly from cell membranes. Regulatory proteins, such as CD59, limit the assembly of MAC on the surface of endothelial cells. Clearance of sublytic amounts of MAC occurs through the endocytic and exocytic response that removes the segments of membrane containing MAC.

Quality Control of Complement Assays Related to Tissue Biopsy Specimens

Quality controls have to be performed on the tissue substrate as well as on the reagents and methods used for the detection of complement. The extremely small tissue samples that are obtained from transplants by percutaneous needle biopsy procedures or bioptomes on catheters can be inadequate quantitatively or qualitatively. The biopsy specimens may provide inadequate amounts of parenchyma or may contain tissue damaged during procurement. Hematoxylin and eosin stains of adjacent tissue sections are useful to control for the quality of the tissue. The use of isotype-matched control antibodies is helpful to determine artifactual staining due to "crushed tissue" or "edge effect." The small size of the transplant biopsy specimens precludes their use as routine controls for the quality or dilution profiles of reagents. Larger specimens from kidneys with deposits of immune complexes can be used to establish optimal dilutions for the primary and secondary antibodies. For this purpose, renal specimens from patients with systemic lupus erythematosus can be useful as positive controls.

Specific Findings in Different Organ Transplants

Detection of activation products of complement is a very useful tool in establishing the diagnosis of AMR and guiding appropriate therapeutic management. The diagnosis of AMR is best made with evidence of histological and immunopathological findings in association with circulating donor-specific antibodies (DSA) and allograft dysfunction. The refinement of these criteria as they pertain to the different solid organ transplants has achieved various degrees of success and consensus, namely because the histopathologic immune response varies in different organs. In general, the presence of histologic alterations and immunopathologic markers for complement activation together with DSA is associated with worse graft survival than the presence of any of these components alone.

Kidney

The deposition of complement split products as a marker of AMR has been most extensively studied in kidney transplants. Recognition of AMR as a cause of graft dysfunction was facilitated by the demonstration of C4d in tissues as a marker of complement-fixing antibodies directed toward the endothelium because antibodies could not be visualized by microscopy in the microvasculature. The 2013 Banff classification of antibody-mediated rejection includes "diffuse or focal C4d staining by IF on frozen sections or any staining by IHC on paraffin sections" as being positive. The immunofluorescence method has been shown to be more sensitive than the immunohistochemical method for C4d staining (24–26). In the interpretation of the C4d stain, it is noteworthy that intrinsic fluorescence of glomerular mesangium and internal elastic lamina of arteries and arterioles is seen with the immunofluorescence method, while artifactual staining of the interstitium, tubular basement membrane, tubular brush border, and plasma in capillaries may be observed in immunohistochemical stains (25). Although C3d correlates with the presence of C4d, staining for C3d added marginal diagnostic value to biopsy specimens that already are positive for C4d and show histologic features of AMR (12). Another study showed no significant correlation of C3d with DSA or graft loss (16). Background staining in the tubular basement membranes may also interfere with accurate interpretation of C3d stains.

Recommendation for C4d staining was first incorporated in the Banff grading system for renal AMR in 2003. Diagnostic criteria for acute AMR include histomorphologic evidence of microvascular injury, C4d deposition in peritubular capillaries, presence of DSA, and allograft dysfunction. A subset of patients with diffuse C4d staining can have microvascular injury and DSA with stable renal function, representing a form of subclinical AMR that appears to be at risk of developing transplant glomerulopathy and graft scarring. The latter histologic changes indicate chronic kidney injury, and a diagnosis of chronic AMR is made if C4d deposition is seen in the presence of these features and DSA (10). Another scenario in which diffuse C4d positivity is commonly seen is in the setting of ABO-incompatible renal transplants with stable function.

Heart

AMR is a well-recognized cause of acute cardiac allograft dysfunction. Immunofluorescence staining, which is considered the gold standard in the evaluation of kidney transplant biopsy specimens, offers a reliable means to evaluate both C4d and C3d in heart biopsy specimens. More importantly, the use of a panel with both C4d and C3d is diagnostically more useful than C4d alone. Concomitant C4d- and C3d-positive staining is significantly correlated with the presence of DSA and cardiac allograft dysfunction (17, 18). Routine C4d and C3d staining of all surveillance biopsy specimens showed that a subset of patients have C4d-only positive

biopsy specimens without evidence of allograft dysfunction, which occurs as single episodes in the majority of cases. It is not clear whether this phenomenon represents subclinical AMR or graft accommodation as seen in ABO-incompatible stable renal allografts (11). Staining of the collagen in the interstitium, endocardium, internal elastic lamina of arteries and arterioles, and myocyte sarcolemma should not be interpreted as positive. Necrotic myocytes, thrombi, and Quilty lesions also exhibit C4d and C3d staining.

Unlike what is recommended for other solid organ transplants, the International Society for Heart and Lung Transplantation working formulation for diagnosis of AMR in heart allografts requires only pathologic evidence of either intravascular macrophages confirmed by CD68 staining or diffuse (>50%) myocardial capillary staining with C4d and/or C3d (27). Most centers utilize immunohistochemical rather than immunofluorescence methods for complement staining in formalin-fixed paraffin-embedded tissue. While C4d staining results using the two methods are comparable, C3d staining by immunohistochemistry has not been standardized, making interpretation less consistent.

Pancreas

The Banff classification of pancreas transplant biopsy requires the presence of histologic evidence of tissue injury, positive C4d staining, and DSA for the diagnosis of acute AMR (28). C4d staining can be seen in interacinar capillaries, interstitial connective tissue, islet capillaries, and small- to medium-sized arteries and veins. However, only C4d deposition in >5% of interacinar capillaries of the pancreatic allograft is correlated with the presence of circulating DSA (29). The presence of C4d staining in interacinar capillaries and DSA has also been shown to correlate with poor graft survival (29, 30). Focal C4d positivity alone is of unknown significance. C3d appears to be less sensitive than C4d as a marker for AMR and does not correlate with DSA. Larger prospective studies are needed to validate these observations and to refine the diagnostic criteria for AMR, which are further hindered by the limited number of surveillance pancreatic biopsies being performed. The feasibility of interpreting biopsy specimens taken from the duodenal segment of a pancreatic graft as a surrogate organ, including evaluation of C4d staining patterns, is beginning to be explored.

Liver

The diagnostic relevance of C4d staining in liver transplantation is not yet clearly established for numerous reasons. Diagnostic criteria for AMR in liver allografts have not been standardized, with only a few cases of reported AMR. The liver allograft is considered quite resistant to AMR, which is thought to be due in part to its capacity to adsorb and neutralize alloantibodies with its large sinusoidal surface area, its ability to secrete soluble HLA molecules, and the presence of Kupffer cells that can phagocytize immune complexes. A major challenge in the interpretation of C4d is the difference in the pattern and sensitivity of C4d staining between immunohistochemical and immunofluorescence methodologies. Most studies have employed immunohistochemical techniques and identified positive staining in portal capillaries and small veins as good markers for AMR (31). Other investigators suggest that diffuse linear C4d staining of sinusoids as detected by immunofluorescence is more reliable. When immunofluorescence and immunohistochemical methods were compared on matched biopsy samples from the same cases, sinusoidal staining was found to be only focal in distribution with much weaker intensity on immunohistochemical staining (32). Nonspecific staining has also been reported in portal tract stroma, internal elastic lamina of arteries, and necrotic hepatocytes. While positive C4d staining is supportive of a diagnosis of AMR, it is also frequently observed in acute cellular rejection, chronic ductopenic rejection, chronic hepatitis, autoimmune hepatitis, and graft-versus-host disease (33).

Lung

AMR in lung transplantation is an infrequent diagnosis, partly because it is not well defined and diagnostic criteria are lacking. Histologic findings of acute lung injury and capillaritis are nonspecific, while C4d deposition is neither a sensitive nor a specific marker of AMR in lung allografts. C4d staining can be seen with acute lung injury patterns, capillary neutrophilic inflammation, high-grade acute cellular rejection, reperfusion injury, and infections (34). In addition, several artifacts make interpretation of C4d staining in the lungs difficult; these include nonspecific staining of vascular and airway elastic fibers, arterial and vein endothelium, peribronchial capillaries, alveolar pneumocytes, hyaline membranes, and macrophage aggregates (35). Only interstitial alveolar capillary staining with C4d is considered positive. A diffuse or multifocal C4d staining is reported as "findings suggestive of AMR," should prompt testing for circulating DSA, and requires clinical correlation to rule out other causes of allograft dysfunction. There is much more limited experience with C3d staining, such that it is currently included only as a secondary antibody panel in the screening for AMR in lung allografts (36).

Small Intestine

Diagnostic criteria for AMR in small intestinal transplantation have not been established. C4d staining currently has not been proven to be of diagnostic utility in small bowel transplantation because of lack of specificity of C4d staining in intestinal mucosa (37, 38).

Composite Tissue Grafts

Compared to other solid organ transplants, composite tissue allografts appear to be less susceptible to AMR. Within the limited experience obtained from the small number of hand and face allotransplantations performed so far, there is no clear evidence that AMR plays an important role in composite tissue grafts because of the lack of detectable DSA, absence of histologic features of microvascular injury, and nonspecific C4d staining (39, 40). The relevance of C4d staining is controversial since it is also observed in inflammatory dermatoses, nonrejecting skin, and mild acute cellular rejection.

Soluble Products of Complement Activation in Serum, Urine, or Bronchoalveolar Lavage Fluid

Activation of the complement cascade produces many split products that do not bind to tissues or that are released from tissues. These fluid-phase products can be detected in plasma, serum, urine, and bronchoalveolar lavage fluids. Enzyme-linked immunosorbent assay kits are available to quantitate soluble split products in fluids (for example, see www.quidel.com/products/product_list.php). C3a, C3c, sC4d, sC3d, and sC5b-8 or -9 are among the most frequently measured soluble complement products. C4a, C3a, and C5a are fluid-phase reactants that are produced by the enzymatic activation of C4, C3, and C5, respectively (Fig. 1b). Regulation of C3b by factor I produces the soluble split product C3c (Fig. 2c). Excess C4b and C3b that fail to bind to protein are hydrolyzed

and can be the source of soluble split products, such as soluble C4d and C3d (sC4d and sC3d). Activation through the amplification loop of the alternative pathway results in the presence of Bb in the plasma. Finally, various forms of MAC that fail to insert into plasma membranes can be detected as soluble C5b-C8 or C5b-C9 (sC5b-8 or -9).

Plasma

Diagnostic tests that require only blood samples are appealing because they are much less invasive than taking biopsy specimens from organ transplants. Theoretically, this approach might also circumvent the sampling error inherent in taking minute pieces of tissue from organs, in which the rejection process may not be diffuse. Finally, avoiding repeated trauma to the transplant could reduce nonspecific inflammation in the organ.

The major disadvantage of testing plasma is the lack of specificity. Many confounding variables can alter the levels of markers in the circulation. In the first decades after transplantation became a successful therapeutic modality, elevated levels of complement split products were detected in the serum as the result of infection as well as rejection (41). More-recent studies have confirmed this finding. One study of patients with renal transplants identified C4b, C4d, C3b, and C3d bound to C-reactive protein in the first days after transplantation (42).

Testing serum can lead to even more sources of artifact. Coagulation enzymes can cleave C3, C4, and C5 and generate excess fragments in a relatively unpredictable fashion (43). Moreover, *ex vivo* activation of complement occurs frequently in samples containing immune complexes, certain drugs, or other contaminants. This is especially true of cryoglobulins, which are barely detectable by other methods. Therefore, it is recommended that samples be collected as EDTA plasma and frozen as soon after centrifugation as possible.

Urine

Urine provides a sample that reflects the inflammatory events in renal transplants more directly. Several reports have indicated that elevated soluble complement split products can be detected in the urine during rejection episodes (23). Obviously, these assays cannot be applied during periods of anuria or oliguria, such as when there is delayed graft function after transplantation. Nonetheless, this is an approach that deserves further investigation.

Bronchoalveolar Lavage Fluids

Currently, most lung transplants are evaluated by periodic bronchoscopic exams that include an infusion and retrieval of saline referred to as bronchoalveolar lavage (usually termed BAL). This procedure is invasive, but the sample is focused on the most susceptible tissue in the transplanted lung. Elevated split products of complement are found during rejection (44). However, the appropriate method of accounting for the effects of dilution have not been established (45).

TYPES OF COMPLEMENT-MEDIATED INJURY IN ALLOTRANSPLANTS

Hyperacute Rejection

Hyperacute rejection is the most unambiguous example of complement-mediated injury to transplants. This type of rejection was first recognized in renal transplants by three groups of investigators between 1966 and 1969 (46–48). This devastatingly rapid type of rejection occurs within minutes to hours after blood flow is restored to the grafted kidney. Immunohistological studies demonstrated that antibodies and complement components were deposited in the transplant. Consequently, hyperacute rejection was quickly attributed to the action of antibodies and complement.

After early reports established a link between antibodies and hyperacute rejection, a "crossmatch test" was devised by Patel and Terasaki to test for the offending antibodies (47). The screening method consisted of mixing leukocytes from the prospective donor with serum from the prospective recipient and then adding a source of complement to demonstrate lysis. After the institution of this test, hyperacute rejection of allografts was almost eliminated.

In hyperacute rejection, complement activation is initiated by large amounts of antibody binding to antigens on the endothelial cells of the transplanted organ. The most characteristic features of hyperacute rejection can be predicted from our knowledge of complement. Prominent inflammatory manifestations of complement activation in hyperacute rejection include (i) recruitment and activation of numerous neutrophils, (ii) disruption of vascular integrity resulting in edema and hemorrhage, and (iii) activation of coagulation leading to fibrin deposition and thrombosis. The relative intensity of these features depends upon the quantities and qualities of the antibodies and their target antigens. Antibodies to both major histocompatibility complex antigens (HLA in humans) and the major blood group antigens (A and B) can cause hyperacute rejection because these antigens are expressed at high concentrations on vascular endothelial cells.

Acute Rejection

Until recently, acute rejection was often cited as an example of pure cell-mediated immunity. This classification was based largely on experimental animal studies, but the vast majority of experimental transplants are performed with young, healthy (even pathogen-free) donor and recipient animals. Unless specifically under study, previous surgical interventions, blood transfusions, trauma, and prolonged ischemia are all avoided or introduced under highly controlled and isolated circumstances. Unfortunately, in clinical transplantation the recipient by definition is suffering from the final stages of organ failure and the organ most often comes from a donor who has died from a traumatic injury. Therefore, the recipient has frequently undergone previous surgical interventions or blood transfusions, the donor has experienced major trauma, and the organ has been subjected to ischemia. All of these variables can affect the function and survival of transplants adversely by increasing the initial recognition of the transplanted organ through complement-mediated processes. More-recent animal experiments have provided evidence to support the clinical observations that complement contributes to the rejection process (49, 50).

Antibodies to major histocompatibility complex antigens can be elicited by previous blood transfusions, pregnancies, or transplants. If this sensitization is below the threshold of the cross-match test used, then hyperacute rejection may be avoided, but the risk of antibody-mediated rejection is increased. Sensitization from previous pregnancies is especially pertinent when a kidney is transplanted to a wife from her husband or to a mother from her child. In these cases, complement deposition can be a prominent feature of the rejection process (51). Obviously, the incidence of antibody-mediated immunity will be related to the composition of the population of patients and the stringency of screening for antibodies before transplantation. In some studies of renal

transplant recipients, a majority of the "steroid-resistant" acute rejections may have an antibody-mediated component. These acute-rejection episodes often occur within the first weeks or months after transplantation in presensitized patients (4). In unsensitized patients, acute-rejection episodes can occur years after transplantation (4, 13, 18).

Chronic Rejection

Chronic loss of graft function is not due solely to immune causes. Instead, the chronic lesions in organ allografts represent repair and remodeling processes that are the final common response to many types of tissue injury. For example, the proliferative vascular lesions that characterize chronic dysfunction of renal and cardiac allografts have some similarities to ordinary arteriosclerosis. The vascular lesions in transplants are generally more extensive and uniform in distribution than ordinary arteriosclerosis, but this may just represent the more widespread injury of the immunologically incompatible tissue. Both types of vascular lesions are currently thought to involve inflammatory processes.

C4d has been associated with chronic rejection in renal transplants. Even in renal transplants, C4d staining often is not strong or diffuse in biopsy specimens with chronic rejection (10). This is not unexpected because the events that initiate chronic repair and remodeling may be resolved and even the covalently bound complement split products can be cleared from the membrane of endothelial cells before the repair processes impair organ function. Moreover, antibodies can initiate vascular changes through mediators independent of complement activation. These include upregulation of adhesion molecules and proliferative signals (52, 53). These changes may be captured by molecular diagnostic techniques (4, 7).

SUMMARY

Complement can be a useful adjunct in diagnosing and directing treatment of rejection, especially for renal and cardiac transplants. Currently, the tissue-associated final split products of C4b and C3b, namely, C4d and C3d, are the most useful markers of antibody-mediated rejection. Both C4d and C3d offer the advantages of being produced in large amounts and binding covalently to tissues. Monoclonal antibodies are available to neoantigens on C4d and C3d that are not accessible in the unactivated precursors. Although these markers have provided significant diagnostic advances for organ transplantation, appropriate interpretation requires additional information, including testing for circulating antibodies to donor antigens and correlation with clinical evidence of graft dysfunction.

Molecular Characterization of Rejection in Solid Organ Transplantation

DARSHANA DADHANIA, TARA K. SIGDEL,
THANGAMANI MUTHUKUMAR, CHOLI HARTONO,
MINNIE M. SARWAL, AND MANIKKAM SUTHANTHIRAN

118

Improved knowledge of the alloimmune repertoire, development and clinical application of new therapies, advances in surgical techniques, and effective infection prophylaxis have helped to transition transplantation from a high-risk experimental therapy to a safe clinical remedy. Nevertheless, diagnostic and therapeutic challenges remain. Here we provide an outline of the immune cascade implicated in allograft rejection, emphasize molecular protocols for characterizing gene expression strengths and patterns and for high-throughput protein and peptide analyses, and summarize molecular correlates of rejection of human kidney, heart, lung, liver, and pancreas allografts.

The immune cascade culminating in allograft rejection is initiated following the physical interaction between the $CD4^+$ T cells and $CD8^+$ T cells of the allograft recipient and antigen-presenting cells (APCs) of donor origin (direct pathway of allorecognition) or APCs of recipient origin (indirect pathway of allorecognition) (1, 2). The allopeptides displayed on the surfaces of APCs impart antigen specificity and provide the antigenic signal. Costimulatory signals are obligatory for plenary T cell activation (3) and result from the physical contacts between cell surface proteins expressed on the T cell surface (e.g., CD2 antigen) and their counterreceptors displayed on APCs. The antigen-experienced and costimulated T cells then secrete cytokines, such as interleukin 2 and gamma interferon, and recruit and educate cytotoxic $CD8^+$ T cells, antibody-forming B cells, and additional proinflammatory cells, and this highly coordinated immune response results in allograft rejection unless it is restrained by immunosuppressive therapy (2, 4, 5). Major histocompatibility complex class I proteins present donor-derived allopeptides to the recipient's $CD8^+$ T cells, whereas major histocompatibility complex class II molecules present the allopeptides to the recipient's $CD4^+$ T cells. Chemokines and adhesion molecules generate the requisite signals for cell trafficking and transmigration of proinflammatory cells into the allograft (6). Toll-like receptors contribute not only by eliciting innate immunity but also by the amplification of acquired immunity directed at the allograft (7).

With knowledge from preclinical studies, investigators have utilized hypothesis-driven approaches to study targeted gene and protein expression patterns associated with acute and chronic rejection of clinical organ allografts. These initial translational studies led the way in refining our knowledge and in further identification of pathways involved in human allograft rejection. Recently, with advances in technology and bioinformatics, we have seen a shift in translational research from a "hypothesis-driven" approach that studied one gene or protein at a time to a "hypothesis-generating" or "discovery-driven" approach, with the aid of "-omic" methods, that allows researchers to investigate several thousands of genes or proteins simultaneously. Ever-evolving bioinformatic tools have helped in examining thousands of genes and proteins for an understanding of diseases at the cellular and organismal levels. Whereas genomic and transcriptomic methods have been tested for some time, new proteomic methods are actively being developed to garner further insights into the allograft rejection process.

MOLECULAR TECHNIQUES FOR CHARACTERIZATION OF GENE EXPRESSION PROFILES OF ALLOGRAFTS

PCR assays, microarrays, and next-generation sequencing (NGS) tools have enabled the characterization of gene expression strengths and patterns of clinical samples and the development of diagnostic and prognostic biomarkers of allograft rejection.

PCR Assay

PCR is a powerful technique for amplifying a short segment of DNA. PCR methodology relies on alternate heating and cooling cycles allowing for the amplification of a segment of the DNA (8). Automation of PCR was made possible with the discovery of the heat-resistant DNA polymerase from the bacterium *Thermus aquaticus* (9). Reverse transcription-PCR (RT-PCR) is an invaluable variant of PCR used for assessing RNA expression. Since RNA polymerase is inactivated by heat and DNA polymerase cannot amplify RNA, the RNA is first converted (reverse transcribed) to cDNA, which is then used as a target/template in the PCR assay.

To study the transcriptome, obtaining high-quality RNA with minimal degradation is a critical first step (10). RNA is unstable and is prone to degradation by RNases. Hence, adequate precautions should be taken to use RNase-free material. RNA degradation can be minimized with the use of commercially available RNA stabilizing reagents, such as RNAlater (11). The purity of RNA can be assessed by several methods. Measuring the ultraviolet absorbance (*A*) at

doi:10.1128/9781555818722.ch118

260 nm, 280 nm, and 230 nm by use of a spectrophotometer is a commonly used method. An A_{260}/A_{280} ratio of 1.8 to 2.2 and an A_{260}/A_{230} ratio of >1.7 suggest the presence of good-quality RNA that is suitable for downstream applications. Agarose or acrylamide gel electrophoresis is another common method for analyzing RNA integrity (12). Samples are loaded into gels, and as an electrical current is applied, nucleic acid fragments are separated on the basis of size. The fragments in the gels are then stained with nonspecific fluorescent dyes, such as ethidium bromide, SYBR Green, and SYBR Gold. RNA quality is assessed by observing the staining intensities of the major rRNA bands and any degradation products. The use of a Bioanalyzer machine (Agilent Technologies) is another technique for assessing RNA samples. It is similar to the gel system, but in a miniature form. The Bioanalyzer instrument determines the "RNA integrity number" by using a proprietary algorithm that considers the entire electrophoretic traces of the RNA to determine the integrity of RNA and then assigns a number from 1 (worst) to 10 (best) (13). Fluorescent dye-based quantification (e.g., using a Qubit fluorometer) is commonly used to quantify RNA abundance. The dyes used in the fluorometer are specific for RNA or DNA. The RNA concentration is quantified by comparing the relative fluorescence intensities of the RNA bands to those of known RNA standards.

A typical PCR mixture to assay RNA expression consists of target cDNA, free nucleotides, sense and antisense oligonucleotide primers, and thermostable DNA polymerase. A segment of the RNA of interest is amplified exponentially in three sequential steps, i.e., denaturation, annealing of the primers, and primer extension, which are repeated with each PCR cycle. The typical length of the PCR product, the amplicon, is about 90 to 150 bp.

Competitive Quantitative PCR Assay

A PCR assay is an endpoint assay, i.e., the presence or absence of the amplified product is typically determined after the final amplification cycle. In a competitive quantitative PCR assay, a competitive DNA fragment is constructed which is similar to the RNA (converted to cDNA) of interest, with the exception of either a mutation at a specific enzyme restriction site or insertion of a small intron or sequence of DNA (14). The concentration of naturally occurring gene transcript is quantified by measuring the ratio of the cDNA band to the band of the specific competitor on gel electrophoresis by using laser densitometry. This approach was successfully used to quantify urinary cell levels of mRNAs for granzyme B and perforin and to demonstrate their utility as biomarkers of acute rejection of kidney allografts (15).

Kinetic (Real-Time) Quantitative PCR Assay

A real-time quantitative PCR assay incorporates the use of a fluorescence signal that is released in "real time" linearly with the amplification process. DNA-binding fluorescent probes, such as TaqMan probes, are used to detect and measure the amplified products (16). The guiding principle for the development of the probes is the transfer of fluorescence resonance energy from the reporter dye to the quencher dye because of close physical proximity in the intact probe. When the probe is degraded, the reporter dye is no longer in close proximity to the quencher dye, which results in the emission of a fluorescence signal. For a real-time TaqMan PCR assay, the reagent mixture contains the gene-specific probe, sense and antisense primers, cDNA, and *Taq* DNA polymerase. The probe is specific for the target mRNA of interest and is designed to be located downstream from one of the primers. As the primer is extended from the 5′ to the 3′ end by *Taq* polymerase, the exonuclease activity of the enzyme degrades the probe and releases the reporter dye from the quencher. This process is repeated with each PCR cycle, and as the fluorescence signal increases, an amplification plot of the change in fluorescence against the cycle number is created in real time. An arbitrary threshold is chosen where the fluorescence signal is increasing linearly (usually 10 times the standard deviation of the baseline), and the cycle number at this point is reported as the cycle threshold (C_T). The C_T value is used to extrapolate the mRNA quantity by using a relative quantification method ($\Delta\Delta C_T$ method) or for absolute quantification of mRNA abundance by using the standard curve method (17).

Absolute Quantification of mRNA Levels by PCR Assay

The Suthanthiran laboratory optimized absolute quantification by developing a universal standard curve method for the absolute quantification of multiple mRNAs. The method involves design and synthesis of a 73-bp mouse amplicon (Bak amplicon) that is used to generate the standard curve in the PCR assay. It is worth noting that the amplification efficiency of the Bak amplicon is similar to the efficiencies of the mRNAs to be quantified, thereby enabling the use of a single rather than multiple gene-specific amplicons in the standard curve method. The amplicon is generated as a PCR product in a thermal cycler (GeneAmp 9600) by using a specific oligonucleotide primer pair (50 μM [each]; accession no. Y13231) (Bak amplicon sense primer, 5′ CCCACATCTGGAGCAGAGTCA 3′ [positions 192 to 212]; and antisense primer, 5′ CAGATGCCATTTTTCAGGTCTTG 3′ [positions 264 to 242]). The final reaction volume is 100 μl and contains 3 μl cDNA, 1.6 μl of 4× deoxynucleoside triphosphates (dNTPs) (10 mM [each]), 10 μl 10× buffer, 1.6 μl AmpliTaq Gold DNA polymerase (5 U/μl), 6.0 μl $MgCl_2$, and 2.0 μl Bak-specific oligonucleotide primer pair. The PCR product is then separated by electrophoresis on a 2% agarose gel, and the amplicon size is confirmed by using pUC mix marker 8 (Crystalgen) as a DNA size standard. The Bak amplicon is then isolated and purified from the gel by use of a QIAquick gel extraction kit (Qiagen). The absolute quantity of the purified amplicon is measured by determining the A_{260} and converted to the number of copies by using the molecular weight of DNA. A stock solution of the Bak amplicon is created by diluting it to a concentration of 10^7 copies/μl. To establish a standard curve for a PCR assay, the stock solution is diluted over 6 orders of magnitude (10^6, 10^5, 10^4, 10^3, 10^2, and 10^1 copies per μl). To run a PCR plate, 2.5 μl of working solution is used in duplicate wells and amplified with the Bak-specific primer pair and a Bak-specific fluorogenic TaqMan probe (5′ 6-carboxyfluorescein-CAGGTGACAAGTGACGGTGGTCTCCA-6-carboxytetramethylrhodamine 3′ [positions 215 to 240]). The C_T values are then plotted against the log of the initial amount of Bak amplicon (2.5×10^6 to 2.5×10^1) to develop the standard curve (18).

Preamplification-Enhanced Real-Time PCR Assay

The median quantity of total RNA obtained from urinary cells in 50 ml of urine from kidney transplant recipients is about 500 ng. This is less than that obtained from blood cells or biopsy tissue. The Suthanthiran laboratory has modified the PCR assay to minimize the amount of RNA required as starting material to quantify the expression of several mRNAs. When RNA is reverse transcribed to cDNA, the volume is adjusted to yield a final concentration

of 1 μg/100 μl. A typical PCR mixture (in duplicate) to assess the expression of a single mRNA uses 5 μl (50 ng) cDNA. Thus, with 500 ng of RNA in a 50-μl volume, only about 10 mRNAs can be quantified. To overcome this limitation of quantity, a preamplification step to the PCR assay is incorporated, and the real-time PCR assay is modified to be a two-step process (19). In the first step, a preamplification reaction mixture is set up in a thermal cycler, with 3 μl (30 ng) cDNA and 7 μl of dNTPs, PCR buffer, *Taq* DNA polymerase, and a panel of (typically 20 to 25 mRNAs) gene-specific oligonucleotide primer pairs of interest. After a 10-cycle (pre)amplification, the PCR product is diluted and used as a stock solution. In the second step, the expression of each of the preamplified mRNAs is measured using quantitative real-time PCR assays. Thus, this two-step process facilitates measurement of a large number of mRNAs (typically 20 to 25 mRNAs) from 3 μl (30 ng) of cDNA.

Microarray Assays

Microarrays are commonly used platforms for the assessment of global gene expression patterns. The steps involved include (i) development of an expression microarray, (ii) hybridization with a labeled unknown cDNA or cRNA, and (iii) quantification and analysis of the signal resulting from the hybridization of the unknown sample to the probes on the microarray. There are two basic types of microarray platforms: arrays that consist of gene-specific cDNA probes and arrays that consist of synthesized oligonucleotide probes.

cDNA Microarray Assays

In cDNA microarray assays, gene-specific probes are selected based on biological relevance. In addition, each array contains negative controls (plant or bacterial genes), positive controls (housekeeping genes), and key controls (genes with a known pattern of expression in the system being studied). The cDNAs are generally prepared in bacterial colonies, amplified using PCR, and subsequently purified using nucleic acid isolation procedures. The cDNA elements are arrayed using a robotic system onto a glass slide coated with a DNA-binding substrate, such as poly-L-lysine or silane (20). The DNA-binding substrate is inactivated following the arraying process. The unknown sample RNA and reference RNA are labeled with different fluorescent markers, such as Cy4 for the unknown sample and Cy5 for the reference sample. The fluorescent markers are linked to one of the nucleotides and incorporated into the samples individually during RT of RNA to cDNA. Unincorporated nucleotides are removed to minimize background noise, and the labeled reference and unknown samples are mixed in a hybridization solution. The mixture is placed on the array and hybridized for 14 to 16 h. The array is then washed and read in a microarray reader. For oligonucleotide arrays, the oligonucleotide probes are synthesized *in vitro* and subsequently arrayed onto the solid support as in cDNA microarrays, or they can be synthesized *in situ* as in the Affymetrix GeneChip system.

The Affymetrix GeneChip system, the most common platform used to perform microarray studies, is unique in that multiple oligonucleotides of 20 to 25 nucleotides (nt) that are complementary to different regions of the same transcript are synthesized *in situ* for each hybridization unit (20). In addition, the hybridization unit contains a mismatched oligonucleotide probe that differs by one nucleotide for each of the target-specific probes. Hence, a hybridization unit for each gene consists of a series of matched and mismatched probes synthesized in a 24- by 24-μm space. mRNA is reverse transcribed to cDNA, which is then transcribed to cRNA by use of T7 RNA polymerase and biotin-labeled CTP and UTP. The biotinylated cRNA is chemically fragmented into fragments of 35 to 200 bases prior to hybridization. The hybridization cocktail is prepared with a buffer solution, control cRNA, and the biotinylated sample cRNA and is later placed on the chip for hybridization. After hybridization, the biotinylated cRNA is fluorescently labeled with streptavidin-phycoerythrin. The array is scanned on an Affymetrix GeneChip scanner and analyzed using various software packages. The detection of the transcript is based on the degree of binding to the perfectly matched (PM) and mismatched (MM) probes in the hybridization unit. The software program calculates a discrimination score [$R = (PM \times MM)/(PM + MM)$] that is then adjusted, ranked, and assigned a *P* value based on nonparametric testing. The determination of whether a transcript is present, marginally present, or absent is based on the *P* value cutoffs set by the operator.

TaqMan Low Density Array

The TaqMan Low Density Array (TLDA) is a commonly used platform for global profiling of microRNAs (miRNAs) (21). It is a real-time PCR-based assay that measures simultaneously the expression of several hundred miRNAs. Each array is a 384-well plate preloaded with TaqMan miRNA gene expression reaction mixtures that include unique miRNA primers and probe in each well and endogenous control snRNAs. The TaqMan miRNA assay uses a stem-loop structured RT primer (22). In contrast to a linear structure, the stem-loop ensures specificity for mature miRNA target. The stem-loop primer binds to the 3′ end of the miRNA target and is reverse transcribed. First-strand cDNA synthesis with stem-loop primer lengthens the miRNA target from its original ~22 nt to >60 nt, allowing binding of forward and reverse primers as well as the hydrolysis probe, as in a standard real-time PCR assay. The novel design, allowing for increase in the length of first-strand cDNA, overcomes the limitations of primer design for miRNAs, as these small ~22-nt RNA species make primer design challenging. The starting amount of RNA can be as low as 1 ng. The workflow consists of reverse-transcribing the RNA with a pool of stem-loop primers, then an optional preamplification reaction, followed by RT-PCR assay, allowing for simultaneous PCR amplification of unique miRNAs in each of the 384 wells.

Next-Generation Sequencing

NGS is a method for determining the primary structure of the genome. The chain termination method, developed by Frederick Sanger in 1977, is considered the gold standard for determining the order of nucleotide bases in a chain of DNA (23). Recently, massively parallel or NGS technologies have emerged. By overcoming the inherent limitations of Sanger sequencing, these NGS methods allow sequencing of the complete genome, transcriptome (the full complement of expressed genes), and known exomes (parts of the genome specifying the sequences of a portion of proteins) in a relatively short time and at a substantially reduced cost (24, 25). The most commonly used platforms for NGS are those developed by Illumina, Inc. The Illumina NGS protocol consists of DNA fragmentation and the addition of 5′ and 3′ universal adapters to the fragmented DNA. The DNA molecules are then immobilized on a glass slide (flow cell). The flow cell surface is coated with single-stranded oligonucleotides that correspond to the sequences of the adapters. DNA is amplified by solid-phase bridge PCR on the flow cell surface, resulting in an array of clonal clusters. These clusters are then sequenced by successively incorporating fluorescently labeled reversible terminators picked one at a time from a mixture of

4 nt (one base per cycle). Each lane of the flow cell is imaged after each cycle for each nucleotide. The sequence is read in real time by four-channel fluorescence scanning, with each signal corresponding to a single nucleotide at a single position. Usually the forward strand of each cluster is read, and the result is called a single-end read. It is also possible and may even be preferable to read both the forward and reverse templates of each cluster, and this is called paired-end reading. Illumina's HiSeq 2500 machine is able to run two flow cells simultaneously. It can generate up to 2 billion reads (8 billion during paired-end reading) per flow cell, with a read length of up to 150 bp. Depth in deep sequencing refers to the average number of times a given nucleotide is represented in sequence reads. For a reliable base call, the base must be read multiple times. The downsides to the speed and accuracy of the machine are a lower accuracy and shorter sequence length than those with traditional Sanger sequencing. Translating the reads into meaningful information is done in three stages: (i) analyzing the images from the sequencers and converting them into sequence reads, (ii) alignment of reads either by *de novo* assembly or by mapping to a reference database, and (iii) using the mapped and unmapped reads in experiments for specific downstream applications. RNA sequencing is an alternative approach for transcriptome analyses using microarrays. The advantages of this method over microarray technology include a higher resolution, discovery of novel transcripts, and identification of allelic expression, alternate splice variants, posttranscriptional mutations, and isoforms.

MOLECULAR CHARACTERIZATION OF HUMAN ALLOGRAFTS

Quantitative PCR assays have been used successfully to characterize acute rejection of allografts and the presence or absence of allograft fibrosis as well as other complications, such as an inflammatory response to BK virus nephropathy (15, 19, 26–36). The use of competitive quantitative PCR assays to measure levels of mRNA in urinary cells and the discovery that urinary cell mRNA levels of perforin and granzyme B are sensitive and specific noninvasive biomarkers of kidney allograft rejection are summarized in the previous edition of this *Manual* (37).

Clinical Application of Real-Time Quantitative PCR To Characterize Allograft Rejection

At present, real-time RT-PCR assays are utilized to measure mRNA abundance not only in renal allografts but also in heart, lung, liver, pancreas, and small intestine allografts (38).

The Clinical Trials in Organ Transplantation 04 (CTOT-04) study was a prospective nonrandomized observational multicenter study to test the hypothesis that the urinary cell mRNA profile is (i) a sensitive and specific noninvasive diagnostic biomarker for the noninvasive diagnosis of biopsy-confirmed acute rejection of renal allografts and (ii) predictive of an acute rejection episode in the near future. The study was conducted at five different clinical centers, with a targeted enrollment of 495 patients, and urine samples were collected on days 3, 7, 15, and 30 and in months 2, 3, 4, 5, 6, 9, and 12. Of the 497 patients who consented to participate, 485 patients provided 4,300 urine specimens for urinary cell mRNA profiling, and this included 298 biopsy-associated urine specimens from 220 patients (18).

Urine cell pellets were prepared at the transplant sites and shipped to the Weill Cornell Medical College Gene Expression Monitoring Core (WCMC GEM). Absolute levels of prespecified mRNAs—mRNAs for perforin, granzyme B, proteinase inhibitor 9, CD103, CD3ε, interferon-inducible protein 10 (IP-10), CXCR3, and transforming growth factor β1—and 18S rRNA were measured using the preamplification-enhanced real-time quantitative PCR assays developed and validated by the WCMC GEM Core (15, 28, 30, 32).

This large-scale study validated that urinary cell levels of 18S rRNA-normalized perforin, granzyme B, CD3ε, and IP-10 were higher in those with acute rejection than in those without acute rejection or those with stable graft function. A 3-gene signature based on 18S rRNA-normalized measures of CD3ε and IP-10 mRNAs and 18S rRNA emerged as the best-fitting parsimonious model and identified the diagnostic signature for acute rejection as follows: $-6.1487 + 0.8534 \log(\text{CD3}\varepsilon/\text{18S rRNA}) + 0.6376 \log(\text{IP-10/18S rRNA}) + 1.6464 \log(\text{18S rRNA})$. Receiver operator characteristic (ROC) curve analysis of the 3-gene signature yielded an area under the curve (AUC) of 0.85 (95% confidence interval [CI], 0.78 to 0.91; $P < 0.0001$), with a sensitivity of 79% and a specificity of 78%, using a cutoff value of -1.213 for the diagnostic signature.

It is important that the mRNA profile diagnostic of acute rejection may differ depending on whether mRNA levels are normalized to 18S rRNA. Such normalization ensures that the differences in mRNA levels observed between rejection and no-rejection cohorts are not due to differences in RNA integrity and RT efficiency.

The CTOT-04 study also identified that the score of the diagnostic signature increases significantly during the posttransplant period in individuals who are destined to develop biopsy-confirmed acute rejection, while it remains flat below the diagnostic cutoff for acute rejection in individuals who have stable function and do not develop acute rejection. Furthermore, the trajectory of the diagnostic signature starts to separate between those with and without acute rejection approximately 120 to 90 days prior to the rejection biopsy and rise above the diagnostic threshold approximately 20 days prior to the clinical diagnosis of acute rejection (Fig. 1).

The Clinical Trials in Organ Transplantation 01 (CTOT-01) study, a separate prospective multicenter observational study designed to investigate the diagnostic accuracy of urinary biomarkers, measured levels of mRNAs and proteins in urine for the diagnosis and prognostication of acute rejection of renal allografts. In this study, 280 patients were enrolled, 250 completed 6 months of follow-up, and 204 completed the study at 24 months. Patients underwent serial urine and blood sampling weekly 4 times, monthly 5 times, and at 12 and 24 months posttransplantation, and a protocol biopsy was performed at 6 months posttransplantation (39).

The CTOT-01 study utilized the urine collection protocol and the preamplification-enhanced real-time quantitative PCR assay that was developed at WCMC. The mRNAs measured included mRNAs for CCR5, CCL5, interleukin-8, CCR1, perforin, granzyme B, IP-10, CXCR3, and CXCL9. Levels of these mRNAs in urinary cells were compared for individuals with acute rejection diagnosis ($n = 24$), suspicion of rejection diagnosis ($n = 21$), infection ($n = 5$), and other findings ($n = 45$). The authors found that urinary cell mRNA levels for granzyme B (AUC = 0.730; $P = 0.004$), perforin (AUC = 0.701; $P = 0.005$), and CXCL9 (AUC = 0.788; $P = 0.0003$), all normalized to 18S rRNA, were associated with an acute rejection diagnosis. In a multivariable model, a combination of CXCL9 mRNA and CXCL9 protein yielded the highest AUC (0.885), with a sensitivity of 82.6% and a specificity of 86.7% for diagnosing acute rejection in the kidney allograft.

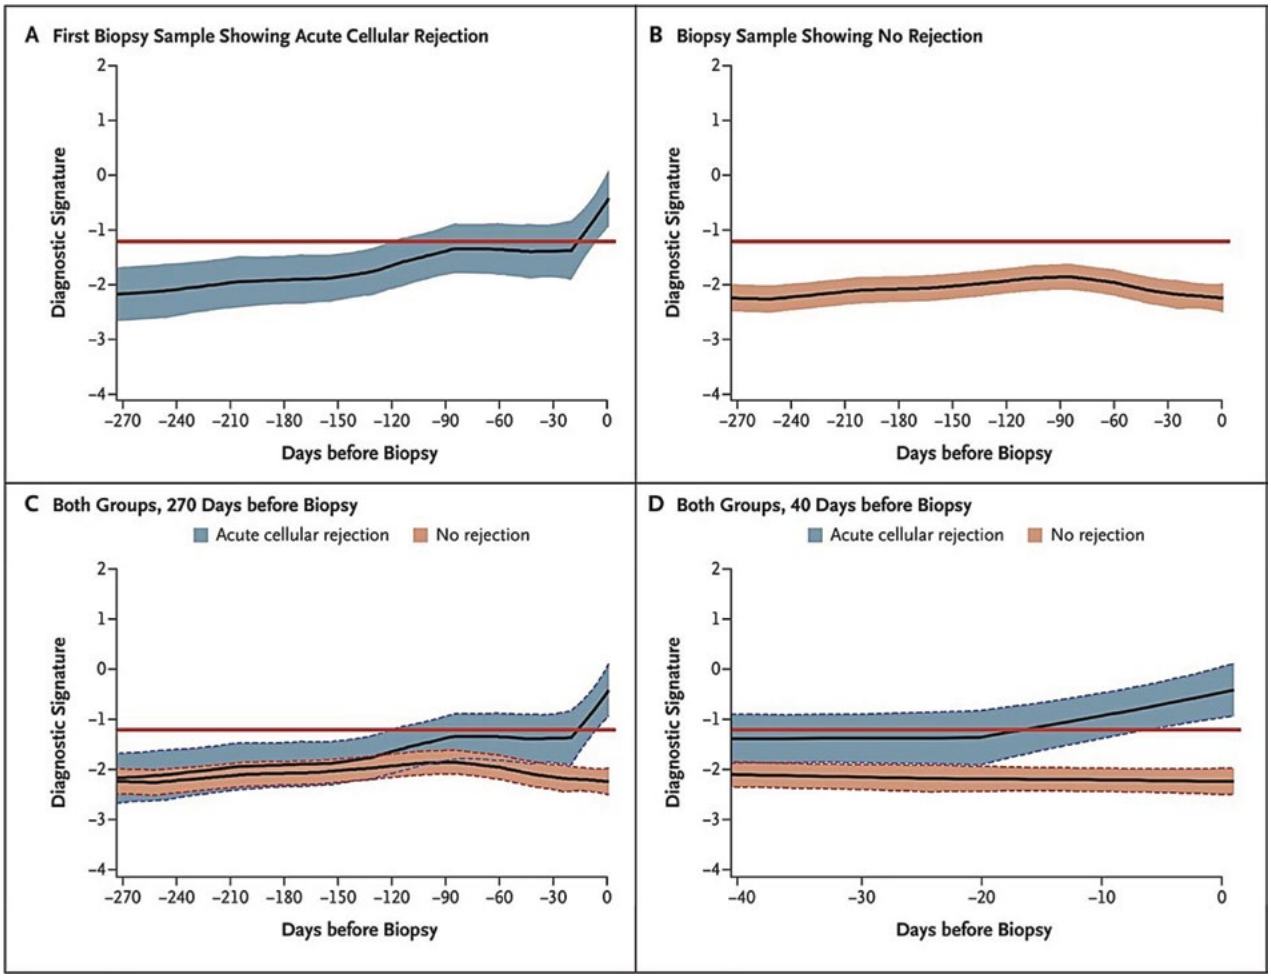

FIGURE 1 CTOT-04 study cohorts and retrospective trajectories of the diagnostic signature. The average within-person retrospective trajectories of the diagnostic signature (i.e., trajectories as a function of the time before biopsy) in urine samples obtained at or before biopsy that passed quality control are shown for the group of 38 patients with first biopsy specimens showing acute cellular rejection (201 urine samples) (A) and the group of 113 patients with specimens showing no rejection (833 urine samples) (B). Only specimens obtained during the first 400 days after transplantation were included. (C) The diagnostic signature remained relatively flat and well below the −1.213 threshold that was diagnostic of acute cellular rejection during the 270 days before biopsy in the group of patients with findings showing no rejection. (D) There was a significant difference in the trajectories between the two groups, with a marked increase in the diagnostic signature during the 20-day period before the first specimen showing acute cellular rejection ($P < 0.001$). In all the panels, the black lines indicate the trajectory, the colored bands indicate the 95% confidence interval, and the red lines indicate the diagnostic threshold. (Reprinted from reference 18 with permission of the publisher.)

Seventy-one samples from the subjects enrolled in the CTOT-01 study were used as an external and independent validation set for the CTOT-04 diagnostic signature. Among the 71 samples, 24 urine samples were from individuals with acute rejection biopsy specimens (from 17 biopsies for cause and 7 protocol biopsies), and 47 urine samples were from individuals with no acute rejection (from 19 biopsies for cause and 28 protocol biopsies). ROC curve analysis of the three-gene (CTOT-04) signature in the validation set yielded an AUC of 0.74 (95% CI, 0.61 to 0.86; $P < 0.0001$) for diagnosis of acute rejection, with a sensitivity of 71% and a specificity of 72%, using the CTOT-04 diagnostic threshold of −1.213 (18).

In addition to serving as diagnostic and prognostic biomarkers, urinary cell mRNA profiles have yielded key insights into the acute rejection process. Existing data from urinary cell mRNA profiling studies suggest the participation of the chemokine signaling pathway (32), costimulatory pathways (26), T cell effector pathways (15), and immune regulatory proteins (19, 30) during an episode of acute rejection in a kidney allograft.

Clinical Application of Microarray Studies To Characterize Allograft Rejection

Interrogation of acute rejection by use of microarrays has helped to elucidate several pathways that are important in acute rejection of solid organ allografts. These studies have also identified prognostic biomarkers of rejection and aided in the development of noninvasive assays for diagnosis of

acute rejection of allografts. Data generated from these studies are also challenging the current diagnostic approach based on histological features alone.

Stanford University has developed a microarray chip, Lymphochip cDNA, containing 28,032 DNA spots representing a large number of selected human genes, to study the rejection of kidney allografts (40). In a study by Sarwal and colleagues, global gene expression profiling of kidney allograft biopsy specimens by use of cDNA microarrays revealed molecular heterogeneity within the acute rejection cohorts. Cluster A (cohort AR-I) demonstrated increased transcripts associated with activated T and B lymphocytes, NK cells, and macrophages; cluster B (cohort AR-II) exhibited increased levels of transcripts associated with the innate immune system, annexin V, and transforming growth factor β1; and cluster C (cohort AR-III) demonstrated increased levels of transcripts associated with cell proliferation and cell cycling (40). Among the acute rejection cohorts, the AR-I cohort was less likely to respond to antirejection therapy and had the highest risk of graft loss. Based on the prominent B cell signature associated with cluster A (AR-I), the authors performed immunostaining for $CD20^+$ cells in kidney biopsy specimens from cases of acute rejection and found that the density of $CD20^+$ cells in the biopsy predicts a poor response to therapy and poor allograft function.

Diagnosis and management of antibody-mediated rejection of kidney allografts remain a challenge and have recently been the focus of many investigations. Microarray analyses of kidney allograft biopsy specimens have provided new insight into the pathways that are upregulated during antibody-mediated rejection. A study of 173 for-cause renal allograft biopsy specimens identified increased expression of endothelial cell-associated transcripts, a group of 119 different transcripts, in the biopsies of patients with acute rejection. The levels of these endothelial cell-associated transcripts were higher in those with antibody-mediated rejection than in those with T cell-mediated rejection (41). Such microarray studies have also questioned the need for positive C4d staining as an absolute requirement for histology diagnosis of antibody-mediated rejection and have facilitated the recent changes in the criteria for diagnosis of acute antibody-mediated rejection.

In an attempt to validate blood gene expression profiles diagnostic of acute rejection across different microarray platforms, Li et al. combined microarray profiles for peripheral blood obtained at the time of for-cause and protocol biopsies from three different platforms: Affymetrix HGU133 Plus 2.0, Agilent, and Lymphochip cDNA (42). From 60 blood samples associated with acute rejection biopsies (AR group) and 62 blood samples associated with normal protocol biopsies in kidney transplant recipients with stable function (stable group), the authors found 32 genes that distinguished the AR group from the stable group, and each gene was present in at least two of the three microarray platforms. These 32 genes were measured in a verification set of 34 samples by use of real-time quantitative PCR, and 15 of the 32 genes (5 previously reported and 10 new genes) distinguished the AR group from the stable group. Among these 10 genes, logistic regression analysis identified 5 genes as the minimal discriminative gene set for the acute rejection diagnosis, and this 5-gene set (DUSP1, PBEF1, PSEN1, MAPK9, and NKTR) was subsequently tested and confirmed to be diagnostic of acute rejection in a single-center training set ($n = 47$). This 5-gene set was later validated with an independent set of 198 biopsy-associated samples obtained from a prospective trial performed at 12 different clinical centers. The 5-gene model distinguished kidney transplant recipients with acute rejection versus stable function with a 91% sensitivity and 94% specificity. The same group measured the 10 genes diagnostic of acute rejection in the kidney transplant recipients in 141 blood samples obtained at the time of biopsy from heart transplant recipients. The samples were split into a discovery set of 32, a validation set for diagnosis of acute rejection ($n = 86$), and a validation set for prediction of acute rejection ($n = 23$) (43). From the 10 genes discovered in kidney transplant recipients, the authors identified a 5-gene signature that was diagnostic of cardiac rejection with 89% accuracy. Furthermore, the measurement of the cardiac 5-gene signature in blood samples obtained 6 months prior to the acute rejection diagnosis predicted the development of biopsy-confirmed acute rejection with an 80% sensitivity.

Microarray studies have also led to the development of noninvasive assay for diagnosis of acute rejection of cardiac allografts. The Cardiac Allograft Rejection Gene Expression Observational (CARGO) study was designed to test the hypothesis that the mRNA profile of peripheral blood mononuclear cells (PBMCs) could discriminate between cardiac rejection with International Society for Heart & Lung Transplantation (ISHLT) grade ≥3A from those with no rejection (ISHLT grade 0) (44). In the CARGO study, the authors designed a custom microarray consisting of 7,370 genes and analyzed mRNA expression patterns of PBMCs from 122 cardiac transplant recipients, 28 with rejection and 94 without rejection. This global gene expression analysis identified 97 genes, and an additional 155 genes were added based on related function and knowledge from the literature. This was followed by diagnostic assay development in which the ability of these genes to distinguish rejection from no rejection in this same cohort was tested using real-time quantitative assays. From this step, 62 genes were found to be informative and many genes were highly correlated. The authors created 20 metagene sets by averaging the gene expression levels of correlated genes and used them in combination with the individual 62 genes to develop a linear discriminant equation that maximized the agreement between the samples and the corresponding biopsy diagnosis. A final equation of 11 genes (5 genes from microarray data and 6 genes based on literature) correctly classified 75% of the samples. This 11-gene signature was tested in two independent sample sets ($n = 63$ and $n = 133$) and was found to accurately diagnose rejection in 84% and 76% and accurately diagnose quiescent (no rejection) in 38% and 41%, respectively.

A prospective randomized multicenter controlled trial compared the use of the 11-gene signature versus endomyocardial biopsies for assessment of cardiac graft function in a cohort of 602 heart transplant recipients. The authors found no difference in the 2-year composite endpoint (14.5% versus 15.3%), consisting of rejection with hemodynamic compromise, graft dysfunction, death, or need for retransplantation, between those monitored using the 11-gene signature and those monitored with endomyocardial biopsies (45). Furthermore, the group monitored with the use of the noninvasive 11-gene signature underwent fewer myocardial biopsies.

The ability to mine data from multiple studies with the use of sophisticated bioinformatic software programs has led to studies focused on identifying a rejection signature that is common across different organs. The Sarwal laboratory performed a meta-analysis of 8 independent data sets obtained from 236 allograft biopsy specimens of different organ types (kidney, lung, heart, and liver) and identified a common rejection module (CRM) consisting of 11 genes (46). The genes associated with CRM, namely, the CD6, CXCL10, CXCL9, brain-abundant membrane-attached signal protein 1

(BASP1), inositol polyphosphate-5-phosphatase (INPP5D), interferon-stimulated exonuclease gene 20 kDa (ISG20), lymphocyte-specific protein tyrosine kinase (LCK), natural killer cell granule protein 7 (NKG7), proteasome subunit beta type 9 (PSMB9), runt-related transcription factor 3 (RUNX3), and TAP1 genes, were also found to be diagnostic of acute rejection in three additional independent data sets consisting of 794 samples. The authors went further and demonstrated that treatment with dasatinib, a potential inhibitor of LCK, and atorvastatin, a modulator of CXCL9 and CXCL10, in an H-2-mismatched mouse heart transplant model resulted in fewer graft-infiltrating cells and reductions in the expression of some of the CRM genes compared to those in controls.

Clinical Application of TaqMan Low-Density Arrays To Characterize Allograft Rejection

miRNAs are recently discovered species of evolutionarily conserved RNA that are not translated into proteins (47). New assays geared towards studies of miRNAs are facilitating the characterization and quantification of miRNAs associated with acute rejection, and these studies may explain the basis for the heterogeneity in the mRNA expression patterns of acutely rejecting allografts.

Sui and colleagues utilized microarray analysis followed by real-time quantitative PCR assay confirmation to study three renal allograft biopsy specimens from patients with acute cellular rejection and three control biopsies from native kidney nephrectomies (48). Twenty miRNAs were differentially expressed (12 downregulated and 8 upregulated).

The Suthanthiran laboratory investigated intragraft expression patterns of miRNAs in seven human kidney grafts (three biopsy specimens showing acute rejection and four with normal results) by using TaqMan low-density arrays containing primers and probes for 365 mature human miRNAs (49). Unsupervised hierarchical clustering and principal component analysis of intragraft miRNA expression patterns correctly differentiated acute rejection from normal biopsy specimens (Fig. 2). There were 17 miRNAs that were differentially expressed ($P < 0.01$) between acute rejection and normal biopsies. Based on their expression patterns and biological relevance, 6 of the 17 differentially expressed miRNAs were evaluated for an independent cohort of 26 kidney graft recipients (9 patients with acute rejection biopsy results and 17 patients with normal biopsies) by use of real-time quantitative PCR assays. In this validation study, five of the six miRNAs were found to be significantly different between patients with acute rejection biopsy results and patients with normal biopsies. As observed in the discovery/training set, intragraft levels of miR-142-5p, miR-155, and miR-223 were higher and the levels of miR-10b, miR-30a-3p, and let-7c were lower in the biopsy specimens showing acute rejection than in those without acute rejection changes. The diagnostic accuracies of intragraft levels of these six miRNAs and four mRNAs (CD3, CD20, NKCC-2, and USAG-1) were evaluated using ROC curve analysis, and the data from ROC curve analysis are summarized in Table 1. Taken together, the data from this study show that (i) miRNAs expressed in high abundance in human PBMCs are present at high levels in acutely rejecting allografts, (ii) a strong positive association exists between intragraft levels of overexpressed miRNAs and mRNAs for T cell CD3 and B cell CD20, and (iii) there is a strong positive relationship between renal tubule-specific NKCC-2 mRNA and the miRNAs miR-30a-3p and miR-10b, expressed in high abundance in human renal tubular epithelial cells. These observations are all consistent with the interpretation that the altered expression of miRNAs during acute rejection is most likely because of the relative proportions of graft-infiltrating immune cells and resident renal parenchymal cells. *In vitro* studies showing that some, but not all, of the differentially expressed miRNAs are also regulated by stimulation raises the possibility that there may be an altered regulation of miRNAs within the cells themselves.

In a recent study of 57 kidney transplant recipients (18 with chronic antibody-mediated rejection, 30 with stable function, and 9 with acute rejection), the level of miR-142-5p in PBMCs was found to be a sensitive and specific biomarker of chronic antibody-mediated rejection (AUC = 0.76; $P = 0.006$) (50).

Future studies focused on the changes in miRNA profiles associated with the course and treatment of acute rejection episodes will improve our understanding of how miRNA profiles can be used to manage transplant recipients and may lead to the development of targeted therapies to improve the long-term function of allografts.

TABLE 1 Diagnostic accuracy of intragraft miRNA/mRNA levels during acute kidney rejection[a]

miRNA or mRNA	Cutoff level	Sensitivity (%)	Specificity (%)	AUC (95% CI)	*P* value
miRNAs					
miR-142-5p	0.11	100	95	0.99 (0.96, 1.02)	<0.0001
miR-155	0.06	100	90	0.98 (0.94, 1.01)	<0.0001
miR-223	0.44	92	90	0.96 (0.90, 1.02)	<0.0001
miR-10b	1.33	100	62	0.83 (0.69, 0.97)	0.002
miR-30a-3p	0.57	67	76	0.79 (0.63, 0.95)	0.007
let-7c	0.64	92	61	0.73 (0.55, 0.92)	0.03
mRNAs					
CD3	4.02	92	86	0.93 (0.85, 1.01)	<0.0001
CD20	1.04	100	80	0.89 (0.77, 1.01)	0.0002
NKCC-2	12.47	67	90	0.77 (0.58, 0.96)	0.01
USA-1	3.04	67	100	0.83 (0.66, 0.99)	0.002

[a]ROC curve analysis was used to determine the optimal cutoff that yields the highest combined sensitivity and specificity. The ratio of miRNA copies to RNU44 copies and the ratio of mRNA copies to 18S rRNA copies were used to perform ROC curve analyses. The levels of the housekeeping miRNA RNU44 and the housekeeping 18S rRNA were not informative individually. The data were obtained from reference 49.

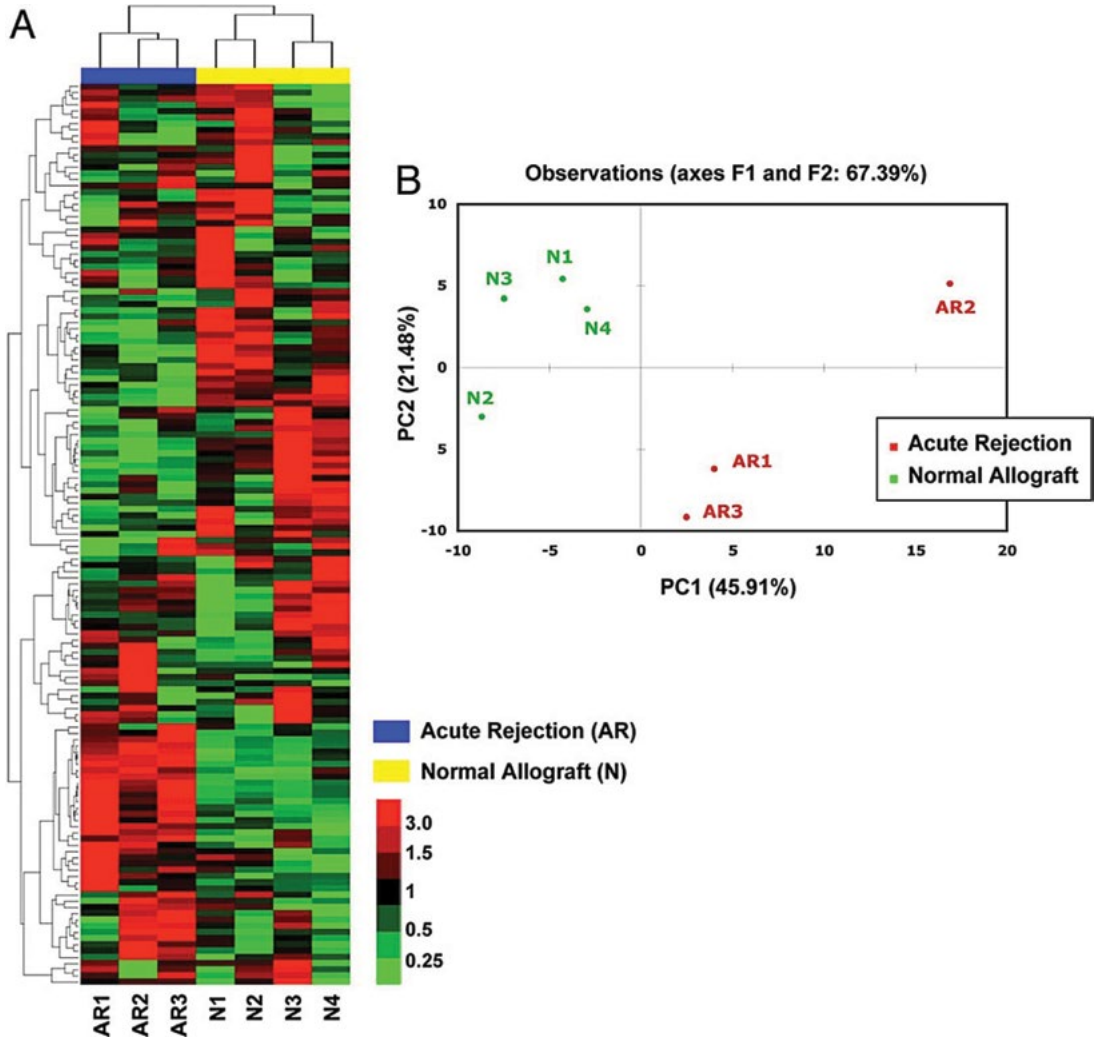

FIGURE 2 Unsupervised hierarchical clustering and principal component analysis of miRNA expression profiles differentiate acute rejection biopsy specimens from normal allograft biopsies of human renal allografts. (A) miRNA expression patterns for seven human kidney allograft biopsy specimens (three with acute rejection [AR] and four with normal allograft biopsy [N]) were examined using TaqMan low-density arrays containing TaqMan probes and primer pairs for 365 human mature miRNAs. A total of 174 ± 7 miRNAs were expressed at a significant level (i.e., C_T of ≥35) in all samples. The biopsy specimens were grouped by unsupervised hierarchical clustering on the basis of similarity in expression patterns, and the degrees of relatedness of the expression patterns of biopsy samples are represented by the dendrogram at the top of the panel. Branch lengths represent the degree of similarity between individual samples (top) or miRNA (left). Two major clusters (top) accurately divided AR biopsy specimens from normal allograft biopsies. Each column corresponds to the expression profile of a renal allograft biopsy, and each row corresponds to a miRNA. The color in each cell reflects the level of expression of the corresponding miRNA in the corresponding sample, relative to its mean level of expression in the entire set of biopsy samples. The increasing intensities of red mean that a specific miRNA has a higher expression in the given sample, and the increasing intensities of green mean that this miRNA has a lower expression. The scale (bottom right) reflects miRNA abundance ratio in a given sample relative to the mean level for all samples. (B) Principal component analysis of seven kidney allograft biopsy specimens based on the expression of 174 small RNAs significantly expressed (i.e., C_T ≥35) in all of the samples. Samples were accurately grouped by PC1, which explained 45.91% of the overall miRNA expression variability, whereas PC2 explained 21.48% of variability and did not classify the samples according to their diagnosis. (Reprinted from reference 49 with permission from the publisher.)

Clinical Application of Sequencing To Characterize Allograft Rejection

Unbiased sequencing of human transcripts can facilitate the identification of novel molecules as well as sequence variants and posttranscriptional modification (PTM) of known transcripts.

A novel bar-coded (multiplexed) sequencing protocol was used successfully for small RNA sequencing of human kidney allograft biopsy specimens, with or without fibrosis. In that study, each RNA sample from human renal allograft biopsies with fibrosis ($n = 4$) and normal ($n = 4$) was labeled using a unique (bar-coded) 3′ adapter, and the pooled RNAs were sequenced (51).

The sequence library contained 2.1 million sequence reads, with ~250,000 unique reads. Reads with miRNA annotation were grouped according to the following three schemes: (i) mature miRNAs with multiple genomic copies were merged into single entries; (ii) reads of mature miRNAs and miRNAs (passenger strands expressed at lower levels), originating from primary miRNA cistronic transcripts, were merged into precursor clusters; and (iii) miRNA reads were grouped by families according to sequence similarities. Among the most abundant miRNAs, miR-21 was more abundant in IFTA (interstitial fibrosis/tubular atrophy) biopsy specimens (2.3-fold increase; false discovery rate of <0.01), while the abundances of miR-30b (3-fold) and miR-30c(2) (2-fold) were higher in normal biopsy specimens (Fig. 3). This differential expression was validated by targeted profiling of an independent cohort of 18 biopsy specimens from 18 patients (10 patients with biopsies showing fibrosis and 8 patients with biopsies showing normal biopsy results).

Importantly, sequencing provided unique information (e.g., nucleotide variations) that could not be gleaned from other platforms. In this first study of miRNA sequencing of human kidney allograft biopsy samples, 33 distinct nucleotide variations that included a single nucleotide polymorphism in miR-196a-2 and RNA editing in the mature sequence of miR-376a/c were identified. Interestingly, variations were noticeably more common in the 3′ end of mature/starred sequences, showing changes compatible with adenylation and uridylation, and these alterations were more frequent in fibrosis samples than in normal biopsy samples.

The application of sequencing to the study of allograft rejection is still in its early stages. Applications of this technique to develop noninvasive biomarkers are limited. Whether the enhanced sensitivity and specificity associated with global sequencing of gene transcripts result in knowledge that explains the clinical heterogeneity and identifies pathways for treatment remains to be resolved fully.

MOLECULAR TECHNIQUES TO CHARACTERIZE THE PROTEOME AND THE PEPTIDOME

The proteome of a cell, an organ, or an organism is defined as the collection of all proteins expressed by the entire genome of the corresponding cell, organ, or organism (52). The publication of the human genome contributed not only to the rapid evolution of molecular profiling and quantification of gene transcripts (mRNA) but also to the identification of protein counterparts of those gene transcripts, with the aid of high-throughput protein profiling and a quantification method termed "proteomics." The central role of proteins in the execution of innumerable biological events makes their analysis on a global scale of prime importance. The traditional one-at-a-time approach utilized tests such as Western blot and immunohistochemistry (IHC), relied on the availability of corresponding antibody, and required relatively larger protein quantities. Currently available proteomic methods help to overcome such issues and provide more analytical strength and capability. Because of this development, the pace of research and our ability to understand molecular mechanisms and to search for more sensitive biomarkers have increased substantially (Fig. 4). Proteomic methods are classified into two types based on how proteins and peptides are prepared for analysis. The first proteomic analysis approach analyzes an unaltered protein or peptide and is called the "top-down" approach. Proteins in a sample are assayed in their intact form by ionization and fragmentation inside a mass spectrometer. This approach does not require proteolytic digestion to generate small peptides. The second approach, the "bottom-up" approach, generates peptides by proteolytically cleaving proteins before they are analyzed by mass spectrometric (MS) methods (53). A list of proteomic analyses and their strengths and weaknesses is given in Table 2.

Proteomic Methods for High-Throughput Protein and Peptide Discovery Biomarker Studies

Gel-Based Methods

Gel-based proteomics utilizes polyacrylamide gels to separate complex protein mixtures of a proteome. There are several gel-based proteomic methods, one of which is traditional one-dimensional SDS-PAGE, which separates proteins in terms of their molecular size. Two-dimensional gel electrophoresis (2DE) was first reported by O'Farrell in 1975 (54) and is a more sophisticated approach to separate proteins, based on their isoelectric points (pIs) as the first dimension of separation and on molecular size-based SDS-PAGE separation in the second. The use of immobilized pH gradient strips contributes to better reproducibility. Two-dimensional difference gel electrophoresis (DIGE) is an advance over conventional 2DE. In this method, two samples are labeled with two different fluorescent dyes (i.e., Cy3 and Cy5) and resolved in a single gel. The assay can be multiplexed in this way, and the ability to use an internal standard is beneficial in terms of gel-to-gel variability and increases reproducibility, with increased statistical confidence (55). In both 2DE and DIGE, the gel is stained and analyzed for significant proteins, and the potential candidates are excised from the gel, digested by

FIGURE 3 miRNA profiles generated by small RNA sequencing. (A) Hierarchical clustering and heat map representation of kidney allograft IFTA biopsy samples (M1, M3, and M4), normal biopsy specimens (M5, M6, M7, and M8), human PBMCs, HDFa cells (primary skin fibroblasts), HEK293 cells (human embryonic kidney cells), and HK2 cells (kidney proximal tubule cells) according to merged miRNA profiles (average linkage, Manhattan distance). miRNAs represented by fewer than 100 reads per sample (average) were collapsed into a single entry ("other mirs"). Brighter shades represent more expression, according to the color scheme shown on the side, in which the numbers correspond to the $\log_2$ values of the normalized read frequencies (e.g., -4 on the scale corresponds to $2^{-4} = 6.25\%$ of all miRNA reads). (B) Multidimensional scaling showing separation of IFTA from normal biopsy specimens by the third factor. (C) MA plot depicting differentially expressed miRNA sequence families, generated using DESeq. miRNA expressed more highly in IFTA samples appear above the horizontal midline. Colored data points represent P values of <0.05 (red points signify false discovery rates of <0.1). (Reprinted from reference 51 with permission of the publisher.)

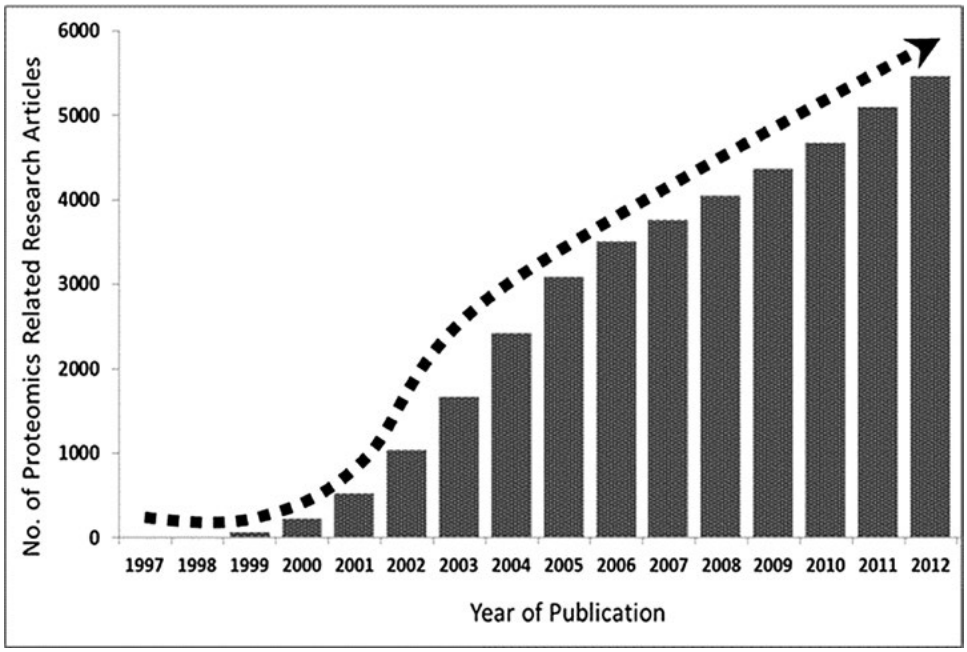

FIGURE 4 Rise in number of published articles on proteomics observed over the last 2 decades. A search of PubMed with the keyword "proteomics" generated a list of research articles and clearly demonstrated a trend of a rise in use of this method for research.

use of proteolytic enzymes (usually trypsin), and analyzed and identified by peptide mass fingerprinting and MS/MS analysis. Since this is a top-down approach and allows for the visualization of intact protein before analysis, this provides an advantage over shotgun proteomics, an approach that does not necessarily provide integrity of the full-length protein. The simple experimental design, the ability to easily assess differential expression or relative abundances of proteins in two biological samples (e.g., samples collected under disease and healthy conditions), and the ease of data analyses are all advantages of the 2DE method. For these reasons, some studies have implemented 2DE-MS in proteomic studies to find markers of rejection. A study published in *Clinical Transplantation* in 2008 used urine samples from healthy control and kidney transplant patients to compare protein preparation methods for biomarker discovery using DIGE (56). Gao et al. (57) and Bañón-Maneus et al. (58) used DIGE to identify proteins as markers of acute and chronic rejection.

Gel-Free Methods

Although gel-based methods such as 2DE and DIGE are useful for assessing proteins in biological samples, they suffer from their inability to resolve proteins with extreme molecular weights and pIs. In addition, these gel-based experiments usually require large sample quantities, have a low-throughput capacity, and are more labor-intensive. Gel-free methods do not use gels but use different methods to analyze the complex proteome in a biological sample.

Capillary Electrophoresis Followed by Mass Spectrometry (CE-MS)

Capillary electrophoresis followed by mass spectrometry (CE-MS) allows for the quick and robust separation of proteins and peptides. In this method, analytes (proteins or peptides) are separated by capillary electrophoresis coupled with mass spectrometry after ionization by either electrospray ionization or matrix-assisted laser desorption ionization. It has applications in basic research in proteomics and quantitative analysis of biomolecules as well as in clinical medicine. Because of low sample consumption and a short analysis time, the CE-MS method provides a powerful alternative for protein and peptide analysis (59). Using urine samples from 29 patients without rejection and 19 with rejection, CE-MS identified distinct urinary biomarkers and patterns in acute rejection or urinary tract infection (60).

Surface-Enhanced Laser Desorption Ionization-Time of Flight Mass Spectrometry

Surface-enhanced laser desorption ionization-time of flight MS (SELDI-TOF MS) combines the strength of different surfaces (reverse phase, anionic exchange, cationic exchange, and immobilized-metal affinity surface) and the use of different binding/washing conditions to resolve a detailed profile of proteins present in the sample. The process involves laser desorption and ionization of proteins from the array surface and detection by TOF MS. This method is limited, however, by the size of the molecules that can be analyzed (>4 kDa to <15 kDa). Because of its commercial availability (Bio-Rad) and available standardized methodology, this platform has been used extensively in biomarker discovery studies, and several studies have been carried out to identify biomarkers for transplantation (61–64).

Liquid Chromatography Coupled with Mass Spectrometry

Liquid chromatography coupled with mass spectrometry (LC-MS) has been used for both top-down and bottom-up approaches. 2D LC separation followed by MS analysis uses strong cation exchange chromatography followed by reverse-phase chromatography. As the name suggests, protein samples are separated by LC before being subjected to MS, by which each fragmented peptide is identified based on its charge and mass (Fig. 5A). Methods based on LC-MS, in general, are able to identify a large number of proteins and peptides in

TABLE 2 Comparison of proteomic methods

Technique	Strengths	Weaknesses	Reference
Gel-based 2DE	Simple experiments and lower cost Easy identification of proteins by Western blotting Ability to analyze full-length proteins	Requirement of larger sample than that for other tests Poor detection of low-abundance proteins Cannot analyze proteins with extreme molecular sizes and pIs Poor reproducibility	54
Gel-based DIGE	Needs smaller sample than 2DE More sensitive than 2DE Lower detection limit and better reproducibility Quantitative and can analyze full-length proteins Can be multiplexed	Requires larger sample than that for LC-MS methods More expensive Cannot analyze proteins with extreme molecular sizes and pIs	97
Gel-free CE-MS and SELDI-TOF MS	Small sample volume Relatively simple procedure	Provides only a signature of peptides and proteins, with difficulty in protein identification	
Gel-free LC-MS (shotgun [no fractionation])	Robust protein identification High throughput compared to other gel-free methods	Suffers from the dynamic range of protein concentration in the sample Exhaustive (once used, samples cannot be revisited)	
Gel-free LC-MS (MudPIT with fractionation)	Very sensitive and easy protein identification Powerful for identifying low-abundance proteins	Suffers from false-positive protein IDs Exhaustive (once used, samples cannot be revisited) Can be very expensive due to the need to analyze multiple fractions from one sample	66
Gel-free LC-MS (top-down approach)	Digestion into peptides is avoided, and protein identification is obtained directly from fragmentation of the intact protein Provides the information for precise identification	More challenging to execute than the bottom-up approach because of the complexity of the data generated and various technical limitations	

biological samples because of their sensitivity and low detection limit (65). In the "bottom-up" approach, protein samples are digested by proteolytic enzymes, such as trypsin, before MS analysis. This kind of strategy is also called "multidimensional protein identification technology" (MudPIT) or shotgun proteomics (66). Fourier transform ion cyclotron resonance (FTICR) MS is another option for the bottom-up approach. It determines the mass-to-charge ratio (m/z) of ions based on the cyclotron frequency of the ions in a fixed magnetic field (67). FTICR MS is particularly beneficial because this method measures peptide and protein masses with a higher accuracy, thereby reducing precursor ion tolerances from the Dalton range to the order of a few subparts per million, reducing the number of peptides initially considered by the peptide spectral matching algorithm. A number of reports on proteomics have reported acute rejection-specific proteins and different transplant injury-specific urine proteins, including those specific for rejection, BK virus nephritis, and chronic allograft injury (68–70).

Top-Down Proteomic Approach with LC-MS

The biggest strength of the bottom-up approach, that it is capable of analyzing hundreds of thousands of peptide fragments to identify parent proteins based on the proteolytic fragments identified, also becomes a weakness because it misses information about the intact protein and its PTM, which is in fact the functioning biological entity. In top-down proteomics (71), proteolytic fragmentation of proteins into peptides is avoided, and detailed information about a protein can be obtained in terms of its exact molecular size and PTMs. However, MS data generated from top-down MS experiments are very complex to interpret because they are different from the data obtained by the bottom-up approach. Because entire sequence coverage is obtained in such experiments, PTMs, N-terminal modifications, and even effects due to single nucleotide polymorphisms need to be considered. Because of its increasing use, more sophisticated software, such as ProSightPC 2.0 (Thermo Scientific), is now available to help researchers in protein identification and analysis (72). Recently, a novel, "middle-down" proteomic approach that utilizes larger proteolytic fragments was introduced. The method uses restricted enzymatic proteolysis using the outer membrane protease T (OmpT) to produce large peptides (>6.3 kDa, on average) for MS-based proteomics (73). A list of studies that have different methodologies for proteomic analyses (gel-based and gel-free) of transplantation specimens is presented in Table 2.

Analysis of PTMs in Biomarker Proteins: A Deeper Look into Disease-Specific Biomarkers

Conventional bottom-up methods usually do not focus on the PTMs of the proteins they identify. PTMs include

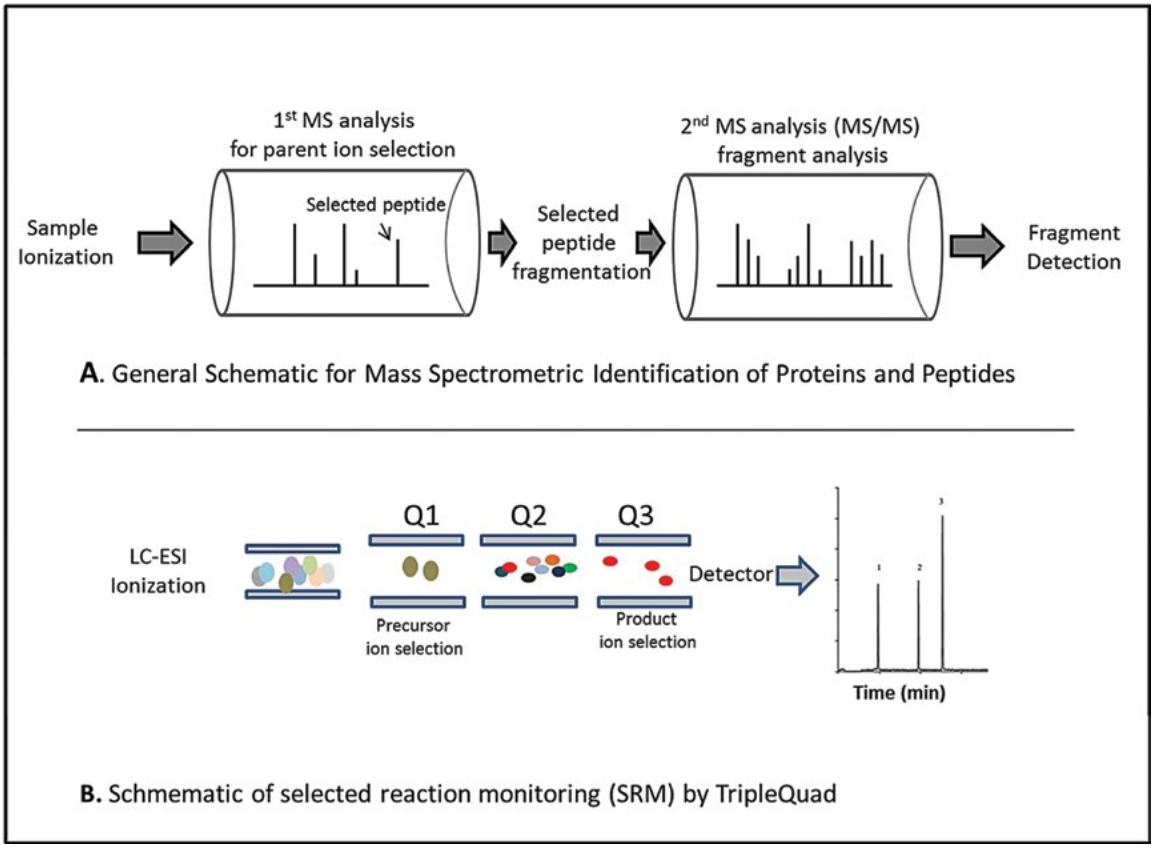

FIGURE 5 MS for proteomic discovery and validation. (A) General schematic for MS identification of proteins and peptides. (B) Schematic of SRM by TripleQuad.

generation of novel protease cleavage sites, isomerization, cross-linking, phosphorylation, nitrosylation, glycosylation, glycation, and hydroxylation, which can be introduced by pathologies and therefore represent potential disease-specific biomarkers (74) as well as novel antigens, as post-translationally modified proteins themselves may be able to activate the immune system (75). The use of recently developed selected reaction monitoring (SRM)-based methods and top-down proteomics makes analysis of PTMs in samples collected from transplant injury and dysfunction possible, which is expected to be a technological feat for biomarker discovery and validation in organ transplantation.

Peptidomics To Screen for "Peptides"

"Peptidomics" is a relatively new term that refers to analysis of the low-molecular-mass proteome, using a technique in which peptides of low molecular mass (<3,000 Da) are analyzed (76). In this method, the low-molecular-mass peptides are isolated, followed by chromatographic separation and MS analysis. Since peptidomic methods identify naturally occurring peptides, this approach also provides invaluable insights into biological processes, such as activation and deactivation of proteases or protease inhibitors. Peptidomic methodologies have been used for the analysis of human samples for the examination of neuropeptides, neurohormones, urothelial cancer, and congenital unilateral ureteropelvic junction in newborns and have been applied to a variety of biofluids, such as blood, cerebrospinal fluid, and urine (77–79). In 2005, Jürgens et al. reported a first-of-its-kind peptidome analysis of urine, using reverse-phase high-pressure liquid chromatography followed by matrix-assisted laser desorption ionization-time of flight analysis (80). More sophistication in peptidomic methods is expected in the future in terms of how to isolate, purify, and analyze the "peptide" fraction. Use of 2,5-dihydroxybenzoic acid for the extraction and purification of small peptides from tissue samples, ranging from cell clusters to brain punches to intact brain regions, was effective for extraction of endogenous peptides from tissue and for long-term preservation of tissue samples and extracts (81). At present, CE-MS (59) and LC-MS are used extensively for peptidomic analysis. A first-of-its-kind report used a novel integrative strategy that utilized peptidomics to identify a 40-peptide panel, including UMOD and collagen peptides, to be acute rejection specific in the urine of kidney transplant patients (82). A list of reports that utilized peptidomics is summarized in Table 2.

Protein Arrays

The ability to print microscopic DNA spots on a solid surface revolutionized DNA microarray technology, but it also evolved to the development of protein microarrays by use of the same biochemical principles, which has greatly facilitated the high-dimensional study of proteins and antibodies (83–85). Currently available protein arrays offer options to measure a large number of proteins or antibodies in a single assay. Protein arrays (Life Technologies) contain approximately 9,500 human antigens to screen for the antibody repertoire against these antigens in the human blood (serum or plasma), and these arrays have been used for the identification of non-HLA antibodies associated with graft

dysfunction and rejection. The current knowledge about non-HLA antibodies in organ transplantation is summarized in recently published reviews (86, 87). Other customized protein/antibody arrays are commercially available from vendors such as RayBiotech (Norcross, GA), Protein Biotechnologies Inc. (Ramona, CA), and Sigma-Aldrich (St. Louis, MO). The application of protein arrays in transplant-related research is summarized in a published review (88).

PROTEIN BIOMARKER VALIDATION PLATFORMS

It is important that a discovery made through any high-throughput method be validated quantitatively on an independent sample set. For a long time, Western blotting was the gold standard not only for protein quantitation but also for the study of PTMs and molecular size estimations. The last decade has seen the evolution of other methodologies for the analysis and quantification of proteins. Similar to how quantitative PCR serves to validate gene expression-related discoveries obtained via microarray platforms, there are two popular methods for quantitative validation for what is discovered through proteomics and peptidomics. These methods are SRM and enzyme-linked immunosorbent assay (ELISA).

Selected Reaction Monitoring

Quantitative proteomic data include the use of $^{16}O/^{18}O$ (89), ICAT (90), and SILAC (91). iTRAQ reagents (Life Technologies) use isobaric labels which, upon fragmentation by MS/MS, give rise to four unique reporter ions (m/z 114 to 117) (92). Second-generation iTRAQ reagents can quantitatively analyze eight samples simultaneously. However, unlike iTRAQ, SRM is a targeted quantitative proteomic method and uses MS to validate the levels of proteins and peptides discovered by high-throughput proteomic and peptidomic methods. This is usually performed by using triple-quadrupole mass spectrometers, a schematic of which is presented in Fig. 5B. In this method, mass-resolving Q1 isolates the precursor, Q2 acts as a collision cell, and Q3 serves for product ion selection. The product ions are detected by an electron multiplier (detector) upon exiting the last quadrupole. Peptides with heavy labels (e.g., D, ^{13}C, or ^{15}N) are used to spike samples to generate a calibration curve, which is often used for the absolute quantification of the peptides being assayed. The ability of this approach to analyze selected peptides quantitatively, with a very low detection limit, makes it the most popular validation platform for proteomic studies (93).

ELISA Validation

ELISA is a popular assay in which the utilized antibody-antigen affinity is used to identify and quantify a substance in the test sample. ELISA is a popular diagnostic tool in medicine. In this method, antigens are first attached to a surface, followed by an antibody linked to an enzyme which acts on a substrate to develop color intensity reflective of the amount of antigen bound to the surface. Because of its simplicity, ELISA has remained a preferred method for validating proteomics-based discoveries (69, 82). Because of the development of better detection systems and with advanced engineering in miniaturizing ELISA plates, new and advanced ELISA platforms are available. One such method involves electrochemiluminescence (ECL) detection, which is highly sensitive. Antibodies, proteins, or peptides can be assayed with the help of ECL. ECL detects analytes with a dynamic range of up to 5 log, which enables the quantification of native levels of biomarker proteins and peptides. Mesoscale Discovery (Rockville, MD) provides this option to researchers through their reagents and kits that can be multiplexed for detection of up to 10 analytes simultaneously (94). This high-throughput analysis of antibodies, proteins, and peptides saves costs and sample volume. The reduced cost and sample volume are very useful, especially for analyzing large sample numbers and when only a limited sample volume is available. Chen et al. utilized publicly available gene expression data sets for screening protein biomarkers for multiple-organ transplants (95). This strategy is summarized in Fig. 6. The use of proteomics and ELISA for discovery and validation of markers in different organ transplants is summarized in previously reported review articles (77, 96).

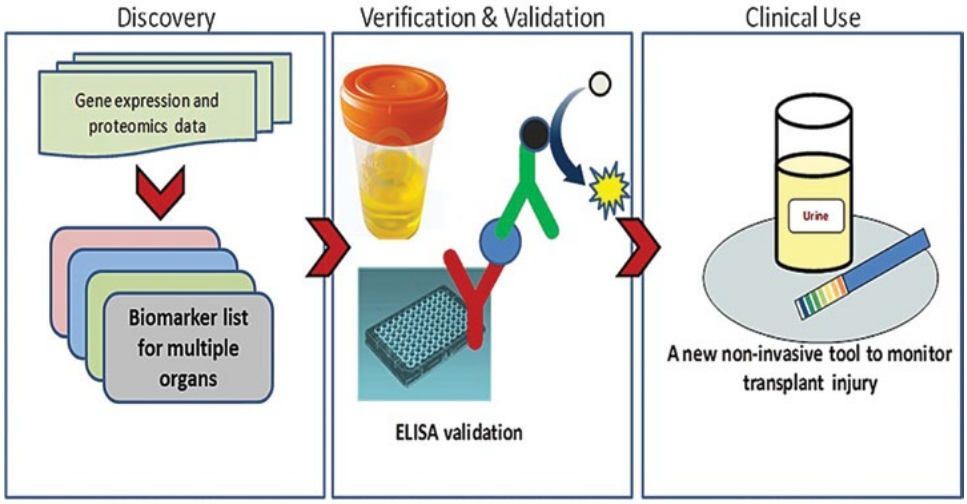

FIGURE 6 Proteomic strategy for biomarker discovery and validation. A strategy that utilizes data sets generated for different organ transplants can be useful for identifying and validating clinically useful protein biomarkers.

CONCLUDING REMARKS

We have presented a summary of molecular profiling methods pertaining to genomics and proteomics in organ transplantation. Whereas nucleic acid-based strategies have proven useful for the detection and quantification of gene expression in the clinic, recent refinements have paved the way for devising noninvasive molecular diagnostic tests for acute rejection of allografts. Protein-, peptide-, and antibody-based methods have further advanced our understanding of underlying molecular mechanisms on the protein level and have provided more potential molecular markers for transplant monitoring. Global expression profiling with technologies such as transcriptome sequencing will add to our knowledge and provide further insights into molecular pathways, and several pathways are likely to be responsible for the rejection process. Future challenges will include sorting through the vast amount of genomic and proteomic data and identifying critical pathways and targetable nodal points. We envision molecular studies to be valuable not only from a diagnostic perspective but also for the development and application of mechanism-based therapeutics. The ultimate objective, personalized medicine for the transplant recipient, is an accomplishable goal.

We are grateful to Deborah Micael and Szu-Chuan Hsieh for their meticulous help in the preparation of the manuscript. We are grateful to our colleagues Ruchuang Ding, Vijay K. Sharma, and Joseph Schwartz for their contributions to gene expression studies in the WCMC GEM laboratory.

The studies from our laboratory were supported in part by awards from the National Institutes of Health (grants R37 AI51652, R01 AI60706, U01 AI 063589, DK083447, and U01 AI63594).

In this focused survey of literature related to molecular correlates of allograft rejection, some of the key and original contributions may not have been cited, and we regret the inadvertent omission.

D.D. and T.S. are co-first authors and M.M.S. and M.S. are co-senior authors of this chapter.

Killer Cell Immunoglobulin-Like Receptors in Clinical Transplantation

RAJA RAJALINGAM, SARAH COOLEY, AND JEROEN VAN BERGEN

119

Both in hematopoietic stem cell transplantation (HSCT) and in solid-organ transplantation (SOT), T and B cell-mediated immunity toward nonshared HLA alleles can have a detrimental outcome. In the past decade, many studies have investigated whether natural killer (NK) cell-mediated immunity might also play a role in clinical transplantation. This work has focused on killer cell immunoglobulin-like receptors (KIRs), as these NK cell receptors interact with HLA class I molecules in an allele-specific manner. In this chapter, we describe the genetics and functions of KIRs and discuss their role in HSCT and SOT.

OVERVIEW OF NK CELLS AND KIRs

NK Cells Contribute to Innate Immunity

NK cells are a subset of lymphocytes representing 10 to 20% of peripheral blood mononuclear cells that contribute to the host defense against virally infected and malignantly transformed cells. NK cells have a highly specific and complex target cell recognition receptor system arbitrated by the integration of signals triggered by a multitude of inhibitory and activating receptors, which trigger cytotoxicity and the secretion of chemokines and cytokines (1). The principal function of NK cells is to respond quickly to infection and tumor transformation, soon after it begins. By such action, NK cells can either terminate infection/transformation without the need for the adaptive immune response or keep it in check until the effector responses of adaptive immunity are brought into play. Because NK cells circulate in a state that can rapidly deliver effector functions, it is critical that they do not attack healthy cells of the body. To prevent such detrimental autoreactivity, NK cells carry inhibitory receptors that engage HLA class I determinants of healthy cells. An essential part of NK cell development is that each functionally competent NK cell expresses at least one inhibitory receptor for a self-HLA class I determinant. As a consequence of this self-tolerance mechanism, NK cells can attack cells in which HLA class I expression is downregulated or otherwise perturbed, common properties of cells that are virally infected or malignantly transformed, a concept originally termed the "missing-self" hypothesis (2) (Fig. 1). Other pathological perturbations of human cell surfaces might also trigger NK cell attack through the activating receptors that recognize either the "induced self" (such as major histocompatibility complex class I chain-related genes MICA and MICB), "altered self" (HLA class I molecule loaded with a foreign peptide), or "nonself" (either pathogen-encoded HLA class I-like molecules or the allogeneic HLA class I molecule). In humans, receptors for the induced self (NKG2D) and allogeneic nonself (KIR2DS1) have been identified, but receptors for the altered self or pathogen-encoded nonself have not.

NK Cell Receptors

Unlike T and B lymphocytes, NK cells do not express receptors that require somatic gene rearrangements to generate receptor diversity and specificity. Instead, NK cells express a wide array of conventional germ line-encoded receptor families with inhibitory or activating functions, including (i) KIRs, (ii) killer cell lectin-like receptors, such as CD94/NKG2, (iii) leukocyte immunoglobulin-like receptors, and (iv) natural cytotoxicity receptors, such as NKp46, NKp44, NKp30, and 2B4. Most of these receptors are expressed in stochastic, variegated combinations of activating and inhibitory receptors, resulting in many subsets of functionally distinct NK cells (3). In addition to receptor-mediated regulation, NK cell functions are enhanced by type I IFNs, interleukin 2 (IL-2), IL-18, and IL-15, which are secreted by dendritic cells and macrophages, as well as pathogen-infected tissue. The integration of signals via inhibitory NK cell receptors, activating NK cell receptors, and cytokine receptors determines the response of an NK cell to a given target. For example, the activating receptor NKG2D is important in the response to acute myeloid leukemia (AML) stem cells, and the expression of class I HLA has been correlated with the relative resistance of some tumors, such as primary pre-B cell acute lymphocytic leukemia (ALL) blasts, to lysis by NK cells.

Killer Cell Immunoglobulin-Like Receptors

KIRs were identified just 2 decades ago and are absent in rodents, so KIR genes likely originated recently, after the split of humans and mice. Fourteen KIRs triggering either inhibition (KIR3DL1 to -3, -2DL1 to -3, -2DL5) or activation (KIR3DS1, -2DS1 to -5), or both (KIR2DL4) have been identified (Fig. 2). HLA-C is the prominent ligand for inhibitory KIRs. Half of the HLA-C allotypes (Cw*02, Cw*04, Cw*05, Cw*06, and Cw*15, collectively called C2) have a lysine residue at position 80 that is recognized

doi:10.1128/9781555818722.ch119

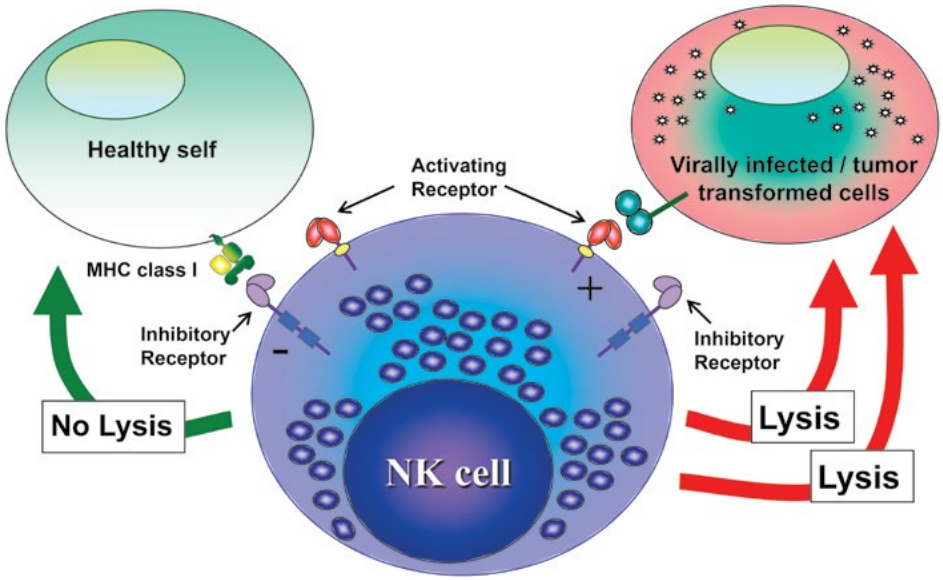

FIGURE 1 NK cell recognition. NK cells are fast-acting effector lymphocytes that provide the first line of defense against an array of viral pathogens by their ability to spontaneously kill infected cells, as well as to rapidly secrete proinflammatory cytokines. Because NK cells circulate in a state that can rapidly deliver effector functions, NK cells express multiple inhibitory receptors that engage specific HLA class I molecules of healthy cells to prevent harmful autoreactivity. By expressing HLA-A, -B, and -C molecules, the healthy cells become resistant to NK cell surveillance. An essential part of NK cell development is that each functionally competent NK cell expresses at least one inhibitory receptor for a self-HLA class I determinant. As a consequence of this self-tolerance mechanism, NK cells can attack cells in which HLA class I expression is downregulated, a common property of cells that are virally infected or malignantly transformed, a phenomenon first described as the missing-self hypothesis. Other pathological perturbations of human cell surfaces might also trigger NK cell attack through the activating receptors that recognize either induced-self (such as MICA and MICB), altered-self (HLA class I molecule loaded with a foreign peptide), or nonself (either pathogen-encoded HLA class I-like molecules or allogeneic HLA class I).

by KIR2DL1. The remaining half of the HLA-C allotypes (Cw*01, Cw*03, Cw*07, and Cw*08, collectively called C1) have an asparagine at position 80 that is bound by KIR2DL2 and -2DL3. In addition to binding C1, KIR2DL2/3 can interact with several C2 allotypes with lower affinity, notably C*05:01 and C*02:02. KIR3DL1 binds to the Bw4 serological epitope, defined by amino acid residues 77 to 83 in the α1 domain, present on 40% of the HLA-B allotypes and certain HLA-A allotypes (HLA-A23, -A24, -A25, and -A32). KIR3DL2 has been shown to recognize certain HLA-A allotypes (HLA-A3 and -A11) loaded with Epstein-Barr virus-derived peptides, as well as HLA-B27 homodimers. The KIR2DL4 receptor probably binds to the trophoblast-specific nonclassical class I molecule HLA-G. The specificities of KIR2DL5 and KIR3DL3 are unknown.

Although the specificities of most inhibitory KIRs have been characterized extensively, very little is known about the ligands for the activating KIRs. Certain activating KIRs are predicted to bind to the same HLA class I ligands as their structurally related inhibitory KIRs. Indeed, the activating receptor KIR2DS1, like KIR2DL1, binds HLA-C2 epitopes. Furthermore, activating receptor KIR3DS1, which differs by less than 10 amino acids from the inhibitory receptor KIR3DL1 in its extracellular Ig domain, may bind to HLA-Bw4. However, KIR2DS2, unlike KIR2DL2, does not seem to bind HLA-C1 epitopes, and KIR2DS3, KIR2DS4, and KIR2DS5 do not have obvious inhibitory receptor counterparts.

KIRs Are Considerably Varied between Individuals

The KIRs are encoded by a family of polymorphic but homologous genes located in the leukocyte receptor complex (LRC), which maps to chromosome 19q13.4 (4). The numbers and types of KIR genes differ substantially between haplotypes (Fig. 3). Nearly 30 distinct KIR haplotypes with distinct gene content have been characterized to date. They are broadly classified into two groups: groups A and B. Group A haplotypes have a fixed gene content comprising KIR3DL3-2DL3-2DP1-2DL1-3DP1-2DL4-3DL1-2DS4-3DL2 but are diversified through allelic polymorphism of the individual genes. In contrast, group B haplotypes have varied gene contents comprising several genes and alleles that are not part of the A haplotype. Particularly, KIR2DS1, -2DS2, -2DS3, -2DS5, -2DL2, -2DL5, and -3DS1 are associated only with group B haplotypes, and thus B haplotypes generally encode more activating KIRs than A haplotypes. The gene contents vary dramatically between group B haplotypes. Only four KIR genes (KIR2DL4, -3DL2, -3DL3, and -3DP1) are present invariably on all KIR haplotypes, and thus they are referred to as framework genes (4). Inheritance of paternal and maternal haplotypes comprising different KIR gene contents generates diversity between humans. For example, homozygotes for group A haplotypes have only 6 or 7 functional KIR genes, while heterozygotes for group A and group B haplotypes may have all 14 functional KIR genes. Group A homozygotes (AA carriers), who

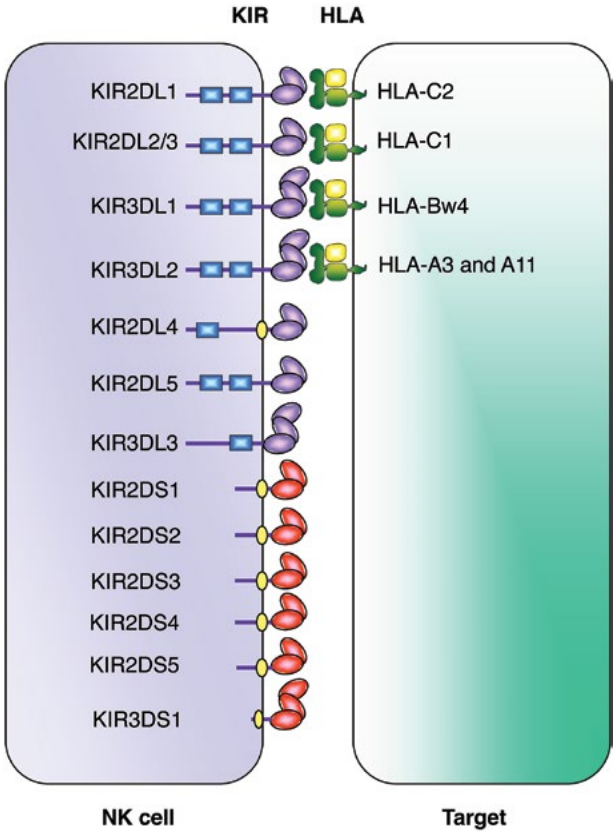

FIGURE 2 Killer cell immunoglobulin-like receptors (KIRs). Fourteen distinct KIRs have been characterized in humans that comprise either two or three (2D or 3D) extracellular Ig-like domains and either a long (L) or short (S) cytoplasmic tail. Six KIRs are activating types, and the remaining KIRs are inhibitory types. The immunoreceptor tyrosine-based inhibition motifs in the cytoplasmic tails of inhibitory KIRs are shown as blue boxes, and positively charged residues in the transmembrane regions of activating KIRs are shown as yellow circles. The inhibitory KIRs bind to distinct HLA class I allotypes, and the ligands for the activating KIRs are not known.

are common in most populations (38% of Asians, 27% of Hispanics, 31% of Caucasians, and 31% of Africans), have a single activating KIR2DS4. Approximately 50% of them were homozygous for the 2DS4 deletion variants, and therefore, 13.4% of human populations do not express any activating KIRs (5).

Nature of KIR Sequence Polymorphism

Each KIR gene exhibits considerable sequence polymorphism in addition to haplotypic diversity. The most abundant allelic polymorphism was reported for KIR3DL1 (6). The KIR3DL2 and -3DL3 framework genes are relatively more polymorphic, while the activating KIR genes are generally conserved. The amino acid substitutions that distinguish the allelic diversity of KIR3DL1 are rich in the region where the receptor contacts the polymorphic HLA-Bw4 ligands (6). The sequence polymorphism of KIR3DL1 is shown to influence their expression, ligand binding, and cytolytic and cytokine secretion functions. Some nucleotide mutations affect the cell surface expression of KIRs. For example, some of the frequently occurring KIR2DS4 sequences have a 22-bp deletion in exon 5, which shifts the reading frame and results in a premature stop codon causing KIR2DS4 to be nonexpressed at the cell surface. Furthermore, chain-terminating frameshift deletions were reported for KIR2DL4. Similarly, sequence variation in the promoter region is associated with the lack of KIR2DL5 expression, and amino acid polymorphism is largely responsible for the intracellular retention of KIR3DL1*004 and -2DL2*004. The synergistic combination of allelic polymorphism and varied gene contents individualizes KIR genotypes to the extent that unrelated individuals almost always have different KIR types. This level of diversity likely reflects a strong pressure from pathogens on the human NK cell response.

Human Populations Differ Substantially in KIR Gene Content Diversity

A stretch of 14 kb enriched with L1 repeats upstream of KIR2DL4 divides the KIR haplotype into halves (4) (Fig. 3). The centromeric half is delimited by KIR3DL3 at the 5′ end and -3DP1 at the 3′ end, while the telomeric half is delimited by -2DL4 at the 5′ end and -3DL2 at the 3′ end. These four framework genes are present on all KIR haplotypes and thus occur in 100% of all populations. In contrast, the existence of the other 12 KIR genes is considerably variable. The inhibitory receptors KIR2DL2 and -2DL3 segregate as alleles of a single locus in the centromeric half. Similarly, inhibitory KIR3DL1 and activating KIR3DS1 behave as alleles of the same locus at the telomeric half. Almost all haplotypes contain these two loci, such that virtually everyone has either -2DL2 or -2DL3 and -3DL1 or -3DS1 within their KIR genome. KIR2DL1, -2DL2, -2DL3, and -2DS2 are specific to the centromeric half, while KIR3DL1, -3DS1, -2DS1, and -2DS4 are specific to the telomeric half. Three KIR genes, -2DL5, -2DS3, and -2DS5, are found in both the centromeric and telomeric locations. For genes within each half, there is significant linkage disequilibrium, but the disequilibrium is much less for genes in the different halves.

Multiple reciprocal recombination events at the center of the KIR complex, between -3DP1 and -2DL4, presumably diversify gene content for KIR haplotypes across individuals and populations. Most of the KIR gene content haplotypes published to date can be explained by the recombination of 10 centromeric and 10 telomeric gene content motifs (7). Recombination events also are reported outside the region between -3DP1 and -2DL4. These are generally nonallelic crossovers generating several unusual haplotypes, including truncated haplotypes that are missing some framework genes or elongated haplotypes that contain duplicated genes. It is important to remark here that the current genotyping methods used to detect the presence and absence of individual KIR genes will not identify the copy number of each KIR gene within a given individual. In recent years, more-advanced typing methods that determine KIR gene copy numbers and that allow allele-level KIR typing have been developed, but these have not yet been implemented in most clinical tissue typing laboratories.

Populations Differ in Their Constellations of KIR-HLA Compound Genotypes

All human populations have both group A and B haplotypes, but their frequencies vary considerably (8). Individuals carrying homozygous group A KIR genotypes (AA genotypes) are common in Northeast Asians (Chinese, Japanese, and Koreans). Conversely, individuals carrying AB/BB genotypes are common in the natives of America, Australia, and India (9). The NK cells from AA-homozygous individuals can express a maximum of four inhibitory KIRs

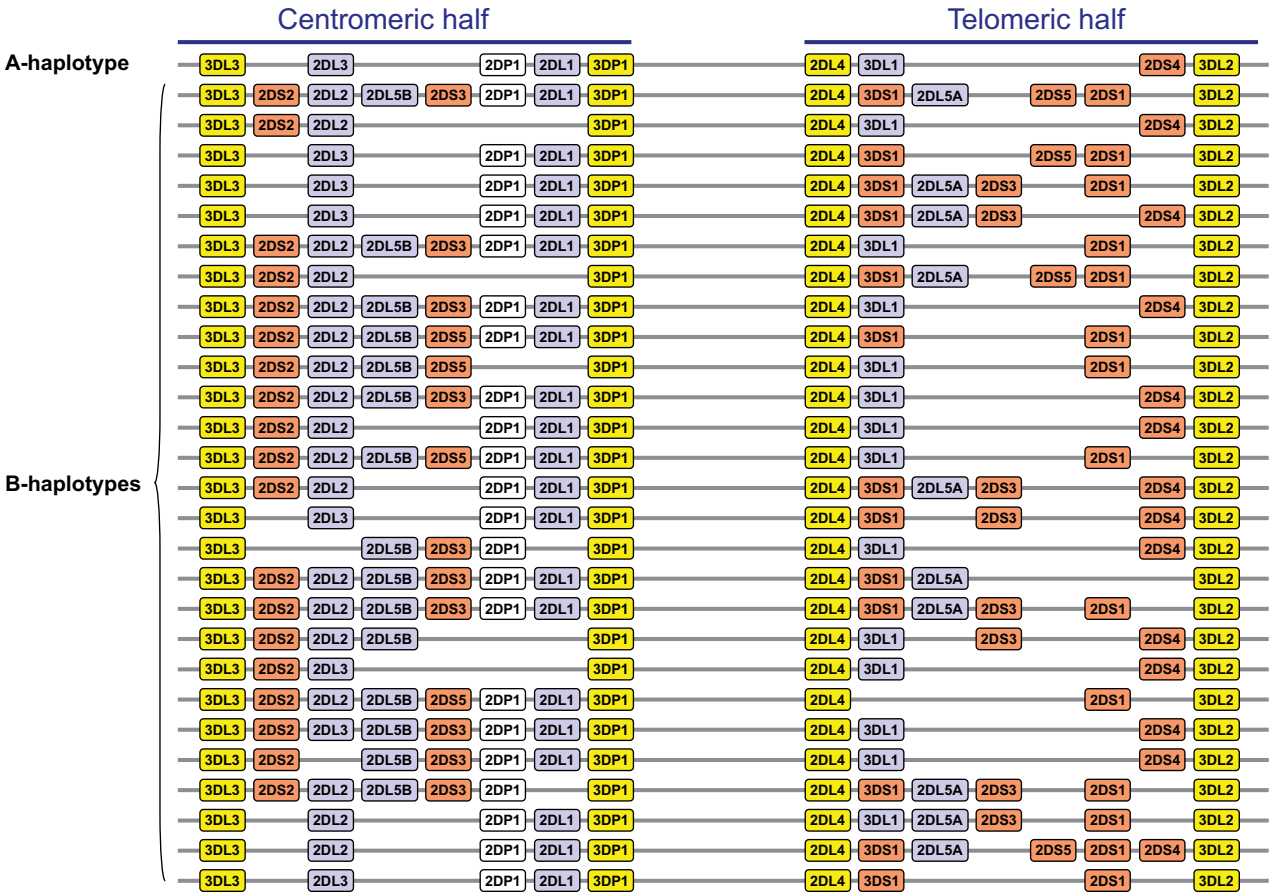

FIGURE 3 KIR haplotypes have varied gene contents. Map of KIR haplotypes as determined by family segregation analyses. The first haplotypes on the top represent the group A KIR haplotype, and the remainder represent the group B haplotype. A stretch of 14 kb enriched with L1 repeats upstream of KIR2DL4 divides the KIR haplotype into halves. The centromeric half is delimited by 3DL3 and 3DP1, while the telomeric half is delimited by 2DL4 and 3DL2. Multiple reciprocal meiotic recombination events between 3DP1 and 2DL4 shuffled the centromeric and telomeric motifs and thus diversified gene content KIR haplotypes across individuals and populations. The framework genes, present in all haplotypes, are shown in yellow, genes encoding activating KIRs are in orange, and those for inhibitory receptors are in blue. KIR2DP1 and -3DP1 are pseudogenes that do not express a receptor.

(KIR2DL1, -2DL3, -3DL1, and -3DL2) and one activating KIR (KIR2DS4). In contrast, individuals carrying AB/BB genotypes can express a maximum of six inhibitory KIRs (KIR2DL1 to -3, -2DL5, -3DL1, and -3DL2) and two to six activating KIRs (KIR3DS1, -2DS1 to -5). The function of the inhibitory KIRs depends on the availability of their specific cognate HLA class I ligands. Given that KIR genes at chromosome 19q13.4 and HLA genes at chromosome 6p21.3 are polymorphic and display significant variations, the independent segregation of these unlinked gene families produces diversity in the number and type of KIR-HLA pairs inherited in individuals (5), which might influence the health and disease status of a given individual. Consistently with this theory, combinations of certain KIR-HLA genes have been associated with diseases as diverse as autoimmunity, infection, cancer, and reproductive failure (10).

Clonal Expression of KIRs and Acquisition of NK Cell Tolerance/Competence/Responsiveness

KIRs are clonally expressed on NK cells, so that each NK cell clone expresses only a portion of the genes within the gene profile (3). Stochastic expression of different combinations of receptors by NK cells results in this repertoire of NK clones with a variety of ligand specificities. Once a given KIR is expressed on an NK cell clone or T cell, it is stably maintained in the progeny of the clone. This pattern of expression appears to be regulated by the methylation of the silent KIR loci.

The majority of NK cells in peripheral blood express at least one inhibitory receptor for self-major histocompatibility complex (MHC) class I and are functionally competent to recognize and eliminate target cells that have downregulated the respective MHC class I ligands (3). However, a subpopulation of NK cells lacks inhibitory receptors for self-MHC class I and is generally hyporesponsive to target cells that are deficient in MHC class I expression (11). In line with this, NK cells from MHC class I-deficient mice and humans, lacking inhibitory receptors for self-MHC class I by definition, are similarly hyporesponsive and defective in target killing (11). Finally, NK cells expressing an activating receptor recognizing a self-ligand are also hyporesponsive (12). Thus, the acquisition of functional competence correlates with the presence of inhibitory and the absence of activating NK cell receptors recognizing self-HLA ligands.

This phenomenon has been referred to as "licensing," "arming/disarming," or "education" (11). NK cell education is not an on-off phenomenon but rather functions like a rheostat. For example, expression of progressively higher numbers of inhibitory KIRs for self-HLA-B and HLA-C molecules is correlated with an increased effector capacity (13). The result is a diverse NK cell repertoire, in which each NK cell has tuned its responsiveness so that the net signaling input from autologous cells is just insufficient to induce activation. This ensures optimum NK cell responsiveness to infected or transformed cells that have upregulated ligands for activating receptors or downregulated ligands for inhibitory receptors.

NK Cell Alloreactivity and Clinical Transplantation

As described above, an NK cell's reactivity pattern is shaped by the interactions between its KIR and autologous HLA, both encoded by highly polymorphic gene families. As a result of this education by autologous HLA, NK cells can respond to allogeneic cells. In an HLA-Cw4+ (C2) individual, for example, an NK cell expressing KIR2DL1 as its only inhibitory receptor depends on KIR2DL1-C2 interactions for self-tolerance, and this NK cell will respond to C1-homozygous (C2-negative) allogeneic cells, as these fail to provide a ligand for KIR2DL1. Had this NK cell been raised in a C1-homozygous individual, however, it would be hyporesponsive and also nonresponsive to C1-homozygous allogeneic cells. A small fraction of the population lacks the KIR2DL1 gene and therefore lacks NK cells with the ability to respond to "missing C2." These considerations make it possible to predict with reasonable accuracy whether NK cells exist in one individual that will attack cells from another individual, based on KIR and HLA class I typing of the former and HLA class I typing of the latter. In the example described above, a KIR-ligand mismatch requires the presence of KIR2DL1 and a C2 HLA-C allele in the responder and the absence of a C2 HLA-C allele from the target. Other KIR-ligand mismatches are based on the interaction between KIR2DL2 or KIR2DL3 and C1, KIR3DL1 and Bw4, and KIR3DL2 and HLA-A3/A11.

Many retrospective studies of SOT and of HSCT have attempted to correlate the results of KIR and HLA genotyping with outcome. This genotyping yields information on the presence or absence of 14 KIR genes and at least 3 HLA-encoded KIR ligands in donors and recipients. For such studies, usually relatively small cohorts (100s of patients) are available for sufficient statistical power, and the typing results have to be analyzed using models that translate such complex outcomes into a smaller number of variables. In most cases, the above-described KIR-ligand mismatch model has been applied, as it reflects current knowledge about NK cell biology and translates the typing outcome into a single binary variable: alloreactivity is either expected (≥1 KIR-ligand mismatch) or not (0 KIR-ligand mismatches). A drawback of this approach is that any potential information on the magnitude of the NK cell alloresponse is lost.

Several variations on this definition of KIR-ligand mismatches have been used in genetic-association studies on transplantation. First, since the phenotype frequencies of the relevant KIRs range from 95 to 100%, taking into account only the HLA genotype of the donor and recipient appears to be sufficient for a reliable prediction of NK cell alloreactivity (14). The "missing KIR ligand" model examines only the responder's KIR and the stimulator's HLA, thereby disregarding the educating impact of the responding party's HLA. Recent evidence suggests that there is a biological foundation for this model as well (15). It is important to note that all transplantations with a KIR-ligand mismatch by definition fall into the "missing KIR-ligand" category and that they may make up such a large fraction of it that it becomes difficult to distinguish between them in statistical analyses.

Another way to analyze the data is to translate the KIR genotyping results into A and B KIR haplotypes. The first studies of this kind classified the individual as either AA or Bx. At the time, it was not possible to distinguish between BB and BA individuals, because A haplotypes are defined by the absence of B haplotype-specific KIR genes (KIR2DL2, KIR2DL5, KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5, and KIR3DS1). More recently, genotyping methods determining KIR copy numbers or KIR alleles have allowed the translation of the genotyping results into AA, AB, and BB. As a meiotic recombination hotspot is located in the center of the locus, just upstream of KIR2DL4, follow-up studies then attempted to map KIR haplotype effects to either the centromeric or the telomeric portion of the haplotypes (centromeric A and B haplotypes [Cen-A, Cen-B] and telomeric A and B haplotypes [Tel-A, Tel-B]).

In the following two sections, the results of the various types of analyses in HSCT and SOT will be discussed. In HSCT, one of the main questions is whether NK cell alloreactivity in the graft-versus-host direction has an impact on the patient's fate after transplantation. Therefore, HSCT studies generally examine the effects of donor KIR and HLA and patient HLA genotypes. In SOT, NK cell alloreactivity in the host-versus-graft direction is most relevant. Solid-organ transplantation studies therefore mostly determine patient KIR and HLA and donor HLA genotypes.

KIRs IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Determination of Donor NK Cell Alloreactivity

NK cells are the first lymphocyte population to reconstitute after HSCT. Engrafted alloreactive NK cells may (i) protect against graft-versus-host disease (GvHD) by depleting host antigen-presenting cells, (ii) facilitate engraftment by production of cytokines and elimination of host immune barriers, (iii) kill residual host tumor to protect against relapse, and (iv) decrease infectious complications. Allogeneic HSCT provides the opportunity to induce NK cell alloreactivity by selecting donors who express inhibitory KIRs for which the donor expresses class I HLA ligand, but the recipient does not express that ligand, thus mimicking missing self. The clinical efficacy of this strategy was first demonstrated in 2002 by the Perugia group, who used predicted KIR-ligand mismatching or incompatibility to select haploidentical donors for HSCT (14). They used donor and recipient HLA typing to predict donor NK cell alloreactivity in the graft-versus-host direction when recipients lacked C2, C1, or Bw4 alleles that were present in the donor. In line with this KIR-ligand mismatch concept, prior to transplantation, *in vitro* graft-versus-host NK cell reactivity was indeed detected in all KIR-ligand-mismatched transplantations (14). A related strategy, referred to as "missing ligand," focuses only on the HLA type of the recipient to assess for KIR ligand absence, where alloreactive potential is based entirely on the number of KIR ligands that the recipient lacks. Initial studies did not include KIR genotyping, as the phenotype frequencies of the relevant KIRs are between 95 and 100%. The incorporation of KIR genotyping has allowed a more accurate prediction of receptor-ligand interactions between donor inhibitory KIRs and their corresponding class I HLA ligands in the recipient. The high degree of allelic polymorphism in the KIR

gene family with associated variability in levels of receptor expression and in the strengths of interactions with different HLA alleles has led to a more recent push to incorporate KIR allelic-level typing into models to predict the magnitude of potential NK cell alloreactivity.

It is important to note that all of these models to predict NK cell alloreactivity assume that they be functionally competent (educated) and present in sufficient numbers to mediate beneficial effects in the recipient. Many groups have demonstrated that despite their high numbers, NK cells reconstituting after HSCT have decreased effector functions, such as CD107a degranulation and IFN-γ production, compared to those in their donors (15). Variables such as stem cell source (umbilical cord blood [UCB], unrelated donors, and siblings), T cell depletion, and graft processing, and the strength of the preparative regimen can affect the kinetics of NK and T cell reconstitution after transplantation, which may have an impact on clinical outcomes. In addition, high levels of stimulation by inflammatory cytokines that are triggered by preparative chemotherapy or GvHD can overcome the rules of NK cell education and receptor-ligand-based determinants of alloreactivity. This may allow graft-versus-host NK cell reactivity in HLA-identical transplants if self-tolerance of donor NK clones expressing KIR for which they lack the ligand is broken in the posttransplant setting, providing a potential rationale for the missing-ligand model.

Role of NK Cells in Hematopoietic Stem Cell Transplantation

The first report of a successful strategy to manipulate NK cell alloreactivity to improve outcome after HSCT came from Velardi's group in Perugia. They demonstrated that patients with AML but not ALL had higher rates of engraftment, less GvHD, and durable remission after T cell-depleted haploidentical transplantation from donors, with graft-versus-host NK cell alloreactivity predicted on the basis of KIR-ligand mismatches deduced from HLA typing results (14). However, in a long-term follow-up of 112 patients, KIR-ligand-mismatched donors were associated with decreased relapse and improved disease-free survival only in patients transplanted while in complete remission (16). Subsequent analyses of the effect of KIR-ligand mismatching and KIR-ligand absence have produced mixed results depending on the clinical setting. In a large cohort of unrelated-donor (URD) transplants, Davies et al. (17) did not observe a benefit to KIR-ligand mismatching, whereas in a T cell-depleted cohort, Giebel et al. (18) demonstrated an association between KIR-ligand mismatching and overall survival. A subsequent study of over 1,500 URD transplants reported higher incidences of GvHD and treatment-related mortality and shorter leukemia-free survival associated with KIR-ligand mismatching (19). In 1,700 URD transplants, Yu et al. reported a beneficial effect of HLA-B and -C mismatches corresponding to recipient KIR ligand absence, but these mismatches did not necessarily correlate with a prediction of donor NK alloreactivity (13). Another large analysis of 2,000 URD transplant recipients found that the absence of one or more KIR ligand in the recipient was associated with less relapse in patients with AML and chronic myeloid leukemia (CML) (20). The effect of KIR-ligand mismatching after transplantation with UCB grafts appears to depend on the intensity of the regimen and the amount of T cell depletion. Willemze et al. (21) reported an association between KIR-ligand mismatching and protection from relapse and improved overall survival, whereas Brunstein et al. (22) observed an increase in acute GvHD and increased risk of death in the presence of KIR-ligand mismatching. The inconsistent benefit reported for KIR-ligand mismatch and KIR-ligand absence strategies is likely related due to key differences among the cohorts, including differences in the stem cell source, conditioning regimen, degree of T cell depletion and type of post-HCT immunosuppression, all of which can affect NK cell development, education, and function.

Donor Selection Based on KIR Genotype

The development of methods to measure the presence or absence of KIR genes to determine the KIR genotype allowed for analysis of the impact of donor and recipient KIRs on outcome after HSCT. In the haploidentical setting, a study of 86 nonmyeloablative, T cell-replete transplants demonstrated protection from relapse and transplant-related mortality as well as improved disease-free survival and overall survival associated with KIR-ligand mismatching or when KIR A/A recipients received grafts from donors with at least one KIR B haplotype. McQueen et al. (23) studied a cohort of HLA-identical sibling transplant recipients, and they observed improved survival in KIR B haplotype recipients receiving grafts from KIR A haplotype donors. Another group reported a beneficial association between donors with the KIR B haplotype genes KIR2DS1, KIR3DS1, and KIR2DL5A and both reduced levels of relapse and improved overall survival after T cell-depleted HLA-matched sibling transplants in 246 patients with AML. In a cohort of 1,087 URD transplants with mixed diseases matched for 9 or 10 HLA loci, donors with KIR3DS1 were associated with reduced acute GvHD and showed increased protection from donors with two copies of the gene (24). The same group published that donors with KIR2DS1 conferred protection from AML relapse but only when the donors expressed at least one copy of HLA-C1 antigens. Cooley et al. demonstrated that patients with AML had reduced relapse and a 30% improvement in disease-free survival after receiving transplants from HLA-matched or -mismatched unrelated donors with at least one B haplotype (25). A subsequent analysis of 1,086 AML and 323 ALL patients evaluated the relative effects of the Cen-B versus Tel-B motifs on transplant outcomes. Donors with Tel-B were associated with relapse protection, whereas donors homozygous for the Cen-B haplotype motif conferred significant reduction in leukemic relapse and improved overall disease-free survival in AML but not in ALL patients.

The general picture emerging from these studies is that the presence of KIR B haplotypes in the donor appears to be beneficial in HSCT and that this effect maps mainly to the centromeric portion of the B haplotype (Cen-B), with a smaller contribution from Tel-B. Therefore, an algorithm was constructed to classify URDs based on KIR genotype in which donors with 0 to 1 KIR B motif were defined as "neutral," donors with ≥2 KIR B motifs were defined as "better," and donors with ≥2 KIR B motifs, including Cen-B/Cen-B, were defined as "best." A publicly available calculator to determine this stratification is available online (http://www.ebi.ac.uk/ipd/kir/donor_b_content.html). A prospective trial incorporating KIR genotyping into unrelated-donor selection for patients with AML facilitated via the National Marrow Donor Program is ongoing. Therefore, it is increasingly accepted that in addition to HLA matching, donor selection for KIR genes is a promising strategy to improve outcome after HCT.

Control of Viral Infection

NK cells play an important role in controlling infections, including those which contribute to morbidity after allogeneic HSCT. Virally infected cells express decreased HLA

and increased stress-induced ligands, which are recognized by NK cell inhibitory and activating receptors, respectively. The KIR genotype of donor NK cells appears to also play an important role in the control of infections after HSCT. A 65% reduction in cytomegalovirus (CMV) reactivation was observed with donors who had more than one activating KIR gene after HLA-matched sibling transplants where both donor and recipient were CMV seropositive. In humans, CMV has been shown to play a unique role in shaping the NK cell receptor repertoire. Recently, it has been proposed that CMV infection may drive the development of a population of $NKG2C^+$ memory-like NK cells (26) in parallel with the $Ly49H^+$ response to murine CMV. These $NKG2C^+$ cells express more self-KIR and have enhanced IFN-γ production after HCST compared to cells from recipients of UCB or allogeneic-sibling transplants who did not reactivate CMV cells. An analysis of KIR repertoires in 200 healthy donors determined that skewing toward expression of self-specific inhibitory KIR was observed only in CMV-seropositive individuals. This observation may be of particular importance in understanding KIR and HLA responses after transplantation. The role of the CMV-induced memory-like NK cells in mediating outcome after HSCT is unknown, but several groups have reported that posttransplant reactivation of CMV is associated with protection against relapse. This supports a model where CMV reactivation early after transplantation may promote expansion of functionally competent $NKG2C^+$ NK cells, which may better mediate antileukemic protection.

Methods To Augment NK Cell-Mediated Benefits after HSCT

Expanded access to KIR genotyping and, increasingly, KIR allelic-level typing is supporting efforts to optimize donor selection to exploit the beneficial effects of NK cells engrafting after allogeneic HSCT. However, many other therapeutic strategies are being perused to be used alone or in conjunction with HSCT. Blockade of inhibitory KIR signaling has been tested using an antibody directed against KIR2DL1, KIR2DL2, and KIR2DL3, which is currently in phase 1 and phase 2 clinical trials (27). Alternatively, enhanced NK cell-mediated antibody-dependent cellular cytotoxicity (ADCC) can be achieved by coating targets with antibodies such as the anti-CD20 agent rituximab to induce signaling via CD16. Autologous NK cells from cancer patients are poor antitumor effectors because they are exposed to cancer-induced immune-suppressive mechanisms (regulatory T cells) and are likely to be inhibited by self-class I HLA ligands. Thus, many groups are testing adoptive transfer of *ex vivo-* or *in vivo*-expanded haploidentical adult NK cells to increase the frequency of alloreactive subsets. Others are testing the manufacture of NK cell products from UCB stem cells or NK cell lines. The safety and clinical efficacy of adoptive haploidentical NK cell infusions given with subcutaneous IL-2 to treat refractory/relapsed AML have been assessed, and complete remissions correlated with *in vivo* NK expansion and higher proportions of circulating (and functional) NK cells.

Although significant heterogeneity in clinical cohorts renders the literature about the beneficial effects of NK cells after HSCT rather confusing, there is a strong consensus that NK cells can play an important role in improving posttransplant outcomes. Many groups are studying the mechanisms of NK cell education and function, defining the effects of the interactions between activating and inhibitory receptors and their ligands and investigating the immunoregulatory roles of NK cells and their interactions with other immune cells. Ultimately, the success of NK cell-based approaches to enhance graft-versus-leukemia and improve outcome after HSCT will require optimization for the specific disease, the type of transplant, donor and recipient immunogenetic factors, and combination with other therapeutic interventions.

KIRs IN SOLID-ORGAN TRANSPLANTATION

Kidney Transplantation

NK cells infiltrate human kidney allografts shortly after transplantation, and this is accompanied by the presence in the blood of NK cells responding to cells from the donor. Yet, when the collaborative transplant study (CTS) examined thousands of kidney transplantations, they detected no effect of KIR-ligand mismatches on graft survival (28). In this case, the presence of KIR-ligand mismatches was derived from HLA typing results, on the usually correct assumption that the corresponding KIR would be present in the patient. Subsequent, often smaller, studies also failed to detect any effect of KIR-ligand mismatches on the occurrence of acute rejection after the reduction of immunosuppression or on acute rejection after kidney transplantation. Taken together, these studies indicated that the presence of KIR-ligand mismatches, predictive of NK cell alloreactivity in the host-versus-graft direction, was not associated with adverse outcome. However, the majority of the transplantations in these studies were incompatible for HLA-A, HLA-B, and/or HLA-DR. Alloreactive T cells may therefore have dominated the allo-immune response, possibly obscuring the negative effects of NK cell-mediated rejection suggested by the mouse experiments. Alternatively, as in the mouse models, NK cell-mediated deletion of graft antigen-presenting cells may have hindered T cells attacking the kidney, thus balancing negative NK cell effects.

In HLA-A-, -B-, and -DR-compatible transplantations, the role of T and B cells in graft rejection is relatively small, potentially revealing detrimental effects of alloreactive NK cells. A retrospective two-center study ($n = 137$) in such HLA-compatible transplantations reported that the presence of KIR-ligand mismatches was associated with a significant reduction in long-term graft survival (29). However, a recent multicenter study by the CTS ($n = 605$) found no such effect (30), not even in separate subset analyses of four larger centers (60 to 80 transplants each). Thus, the consequences of KIR-ligand mismatches in kidney transplantation are currently unclear.

Many studies tested other models, including those with no immediately obvious foundation in NK cell biology (Fig. 4), and reported several, sometimes conflicting, associations. Multiple studies reported an effect of the presence of specific KIR genes in the patient. For example, in one study, KIR2DL1, KIR2DL2/S2, and more inhibitory receptors protected against acute rejection, while in another, KIR2DS5 protected against graft rejection. KIR2DS4, on the other hand, was associated with graft rejection. Another study examined the influence of KIR differences between donor and patient, which may effectively translate into KIR-derived minor antigens on NK cells that might be recognized by T cells in an HLA-restricted fashion. In contrast with the results of studies on HSCT, patient KIR haplotypes (A and B) do not seem to influence graft survival. Finally, the presence HLA-C2 in patients was associated with significantly lower graft survival.

CMV Infection after Kidney Transplantation

Cytomegalovirus infection and reactivation can cause serious complications after kidney transplantation. Patients

carrying at least one KIR B haplotype had a significantly reduced incidence of CMV reactivation/infection (31). This effect mapped to the telomeric end of these B haplotypes, which contains one or more of the following genes: KIR2DS1, KIR3DS1, KIR2DL5A, and KIR2DS5. In the same vein, Hadaya et al. observed an association between the number of patients activating KIR and a reduced incidence of posttransplant CMV infection (32). As most of the ligands for these KIRs are unknown, the mechanistic basis for this association can only be speculated upon. The findings are reminiscent of a study of HSCT in which a 65% reduction in CMV reactivation was observed with donors who had more than one activating KIR gene (33). Also, as in HSCT, in kidney transplantation, CMV infection is also associated with an expansion of $NKG2C^+$ memory-like NK cells (32). In conclusion, KIR B haplotypes may help combat CMV infections in immunosuppressed HSCT and SOT patients, and this effect is likely to involve $NKG2C^+$ NK cells.

Liver Transplantation

In contrast to kidney transplants, liver transplants are not usually matched for HLA. Despite this, graft survival is usually considerably better than for kidneys, suggesting that immune-mediated rejection plays only a minor role in liver transplantation. In line with this, in one study, the presence of KIR-ligand mismatches did not appear to be correlated with graft survival or rejection (34). Yet, another study reported that the presence of HLA-C-based KIR-ligand mismatches was associated with more rejection episodes (35). Several studies investigated the effect of donor HLA-C group 2 (C2), a high-affinity ligand for KIR2DL1. In two of these studies (35, 36), the presence of C2 in the donor was beneficial. However, this trend was not replicated by the CTS (37), and another study reported that donor C2 was associated with more-acute rejection and worse survival (38).

Hepatitis C after Liver Transplantations

In hepatitis C patients with low HCV infectious doses, the presence of KIR2DL3 and a C1 allele is associated with increased HCV clearance (39). This effect is likely to be absent in liver transplantations in HCV-positive patients, as recipient KIR2DL3 is associated with more-aggressive recurrent liver disease (40).

KIR GENOTYPING

Uhrberg et al. developed the first KIR genotyping method in 1997 using sequence-specific-primer-based PCR (PCR-SSP) (41). Since then, various KIR genotyping technologies have been developed using multiplex PCR-SSP (42, 43), real-time PCR assays, sequence-specific oligonucleotide probe hybridization, reverse-sequence-specific oligonucleotide hybridization, matrix-assisted laser desorption ionization–time of flight mass spectrometry, and direct DNA sequencing.

The most commonly used method is SSP analysis, which utilizes gene-specific primers to perform PCR amplification of 16 distinct KIR genes (44). Each primer carries a 3′ residue matching a unique position conserved on all known sequences of a given KIR gene. Primer lengths are adjusted to result in annealing temperatures between 59°C and 67°C to enable PCR amplification of all KIR genes under the same thermal-cycling conditions. An internal positive-control primer specific to a conserved housekeeping gene is coamplified to confirm the success of each PCR.

KIR genotyping is performed in a reaction volume of 15 μl, with a final concentration of 1× PCR buffer II (10 mM Tris-HCl, 50 mM KCl), 200 μM each deoxynucleoside triphosphate (dNTP), 1.0 μM each forward and reverse primer to a given KIR gene, 3.0 mM MgCl2, 0.5 U of AmpliTaq DNA polymerase, and 100 ng of genomic DNA (Applied Biosystems, Foster City, CA). For KIR gene-specific PCRs, an additional set of primers (PIC-F and PIC-R, 0.1 μM each) specific to the polyposis coli gene is included to serve as an internal positive control. For KIR2DS4 subtyping reactions, the internal positive-control primers (GH1F and GH1R, 0.3 μM each) are targeted to human growth hormone gene 1. Thermal cycling is performed using an ABI 9700 GeneAmp PCR system (Applied Biosystems) according to the following conditions: an initial denaturation for 3 min at 95°C and then 5 cycles of 94°C for 20 s, 65°C for 20 s, and 72°C for 90 s; 32 cycles of 94°C for 20 s, 61°C for 20 s, and 72°C for 90 s; and a final extension at 72°C for 10 min. Ten microliters of the PCR-amplified product is electrophoresed on ethidium bromide-prestained 2% agarose gel and examined for the presence and absence of gene-specific PCR products of appropriate sizes.

Under strictly controlled PCR conditions, perfectly matched primer pairs result in the amplification of target sequences (i.e., a positive reaction), while mismatched

primer pairs do not result in amplification (i.e., a negative reaction). Each PCR mixture includes, in addition to KIR gene-specific primers, a positive internal control primer pair which amplifies a 256-bp fragment from a conserved polyposis coli gene. The presence of the 256-bp positive internal control band is used to confirm the success of each PCR. In the presence of a positively typing band, the product of the internal control primer pair may be weak or absent due to the differences in concentrations and melting temperatures between the specific primer pairs and the internal control primer pair. Interpretation of the PCR-SSP typing results is relatively simple and straightforward and is done basically by detecting an amplified product of the correct size by gel electrophoresis. Determine the approximate molecular weight of each PCR product by comparing its mobility against the DNA ladder.

CONCLUSIONS

Taken together, the studies described in this chapter indicate involvement of KIR-HLA interactions in both HSCT and kidney transplantation, most likely mediated by NK cells. These interactions can regulate engraftment and relapse in HSCT, graft survival, and CMV pathology in both HSCT and SOT. However, only in the case of CMV is there a clear consensus between studies: B haplotypes protect both in HSCT and in SOT (45).

Many studies include data from multiple centers, thus increasing statistical power but introducing variation between centers as an additional variable. In HSCT, different transplant centers use different stem cell sources, different conditioning regimens, different degrees of T cell depletion, and different types of post-HCT immunosuppression, all of which can affect NK cell development, education, and function. Increased international standardization of HSCT protocols would greatly facilitate any studies attempting to perform genetic association studies. Another vulnerability of the studies described in this chapter is that they were all retrospective in nature. An exciting development on this front is the prospective trial incorporating KIR genotyping into unrelated-donor selection for patients with AML, facilitated via the National Marrow Donor Program.

Chimerism Testing

LEE ANN BAXTER-LOWE

120

Chimerism testing is routinely used after allogeneic hematopoietic stem cell transplantation (HSCT) to monitor engraftment, detect relapse, identify patients with increased risk for graft-versus-host disease or graft loss, and monitor the effectiveness of therapeutic interventions. Chimerism testing can also be useful in other settings, such as detecting engraftment of donor lymphocytes after organ transplantation and determining sample identity (e.g., investigating suspected sample exchanges).

There are many methods for chimerism testing, but the predominant method for monitoring patients after HSCT measures relative quantities of donor and recipient alleles at loci with short tandem repeats (STR) or variable-number tandem repeats (VNTRs). STR/VNTR loci have alleles that differ in their numbers of tandemly repeated sequence motifs, which are identified by differences in size. The PCR is used to amplify an STR/VNTR locus, and the resultant fluorescently labeled amplicons are separated and quantified using automated capillary electrophoresis instruments. Other methods in use include well-established methods, such as fluorescence *in situ* hybridization (FISH), and novel approaches which take advantage of new technology. This chapter will focus on the use of STR/VNTR methods for HSCT because this represents the majority of chimerism testing conducted in clinical laboratories today. Examples of the alternative methods and other applications will be briefly described.

STR/VNTR METHODS

STR and VNTR alleles differ in number of repeat units and sequence (1). The repeat units can be simple repeats, compound repeats, or complex repeats. Simple repeats have multiple copies of the same sequence motif (Fig. 1), compound repeats have two or more adjacent sequence motifs of the same length but different sequences (an example is AGAT AGAT AGAT TTAA TTAA TTAA), and complex repeats have varied lengths and compositions (an example is AGAT AGAT AGGAT AGAT AGAT TTAACGGCCAT). Although the majority of reference sequences for STR/VNTR loci in the Genome DataBase are simple repeat units, careful sequencing has shown that many of these loci have variability within the repeats (1). The term STR is usually defined as loci with repeat units that are 2 to 6 bp long. These loci are sometimes called microsatellites due to their characteristic banding pattern in DNA centrifugation studies. The term VNTR is usually used to refer to loci with longer repeat units; these loci are sometimes referred to as minisatellites due to their distinctive banding patterns.

DNA Templates

DNA concentration and quality are important factors for STR/VNTR methods because the template influences the amount of PCR product, which in turn can affect several other parameters, including electrophoretic migration of DNA, signal strength, and background fluorescence. For chimerism tests, the amount of genomic DNA in each reaction mixture also affects the sensitivity (i.e., limits of detection) and technical variation (2, 3). Many procedures for chimerism testing recommend 50 to 100 ng template in each reaction mixture, which corresponds to approximately 7,500 to 15,000 cells. A EuroChimerism Consortium reported that under their assay conditions, 10 ng DNA template (equivalent to approximately 1,500 cells) resulted in sensitivities ranging from 0.8 to 1.6% in 90% of tests and showed acceptable technical variation (3). Although they could obtain results using 1 ng of the DNA template, the sensitivity and reproducibility were inferior to those observed for reaction mixtures containing 10 ng DNA. With the 1-ng DNA template, the sensitivity was more likely to be 3 to 5% (3). Although it is technically feasible to generate PCR products using extremely small quantities of DNA, this is not desirable for chimerism testing because sensitivity is affected by the number of cells represented in the reaction. For example, 1 ng genomic DNA represents DNA from approximately 150 cells. If the minority population is 1% of the cells and only 1 ng of the DNA template is added to each reaction mixture, some reactions will not have any detectable signal from the minority population due to sampling variation and stochastic events during PCR.

Each laboratory should establish methods for DNA isolation and acceptance criteria for DNA templates that are appropriate for their procedures and specimens. Acceptance criteria for DNA templates are usually determined using optical density at 260 nm (OD_{260}) and OD_{280} measurements. A EuroChimerism Consortium compared four procedures for isolation of DNA from small samples and reported the best results for an approach using detergents and proteinase K (4). Many labs use commercial kits which have a solid support that binds DNA.

doi:10.1128/9781555818722.ch120

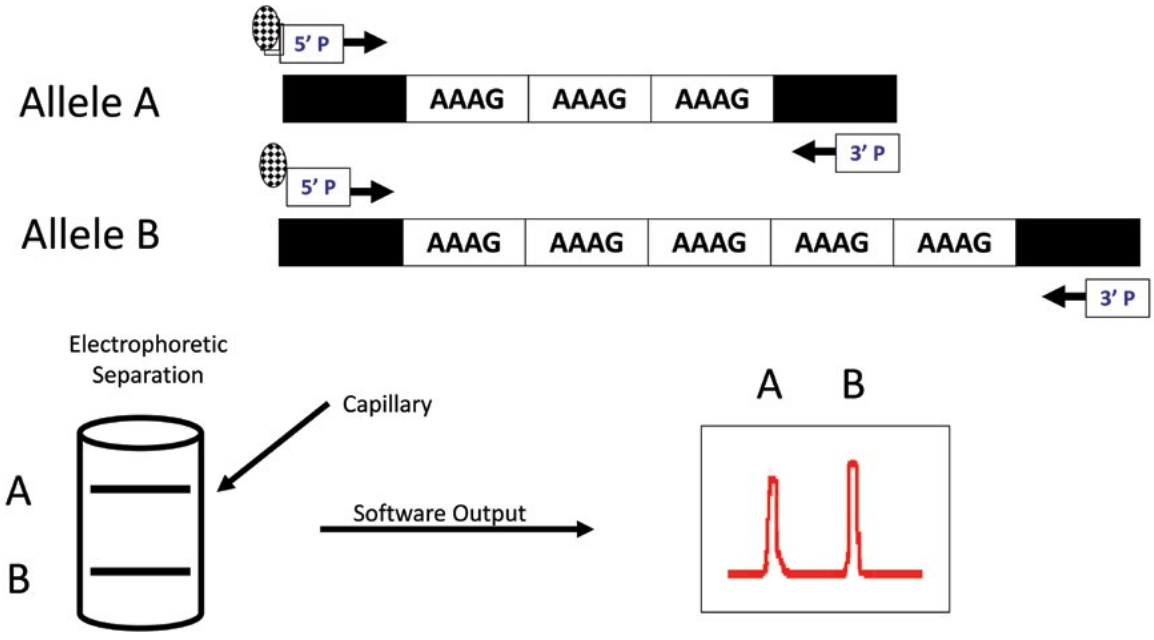

FIGURE 1 STR alleles differ in their lengths due to differences in the numbers of tandemly repeated sequence motifs. This figure shows a simple STR, which is referred to as a tetranucleotide repeat because there are 4 nucleotides in the motif. STRs used for chimerism testing are usually dinucleotide, trinucleotide, tetranucleotide, or pentanucleotide repeats.

Posttransplant specimens are usually peripheral blood or bone marrow. Pretransplant specimens from the donor and recipient are also important to provide control material for posttransplant chimerism assays. If a pretransplant specimen from the recipient is not available, DNA can be isolated from the recipient's hair, nail clippings, and biological material remaining after pathology studies (e.g., paraffin blocks). DNA can be isolated from buccal mucosa or skin, but these sources must be used with caution because contamination with donor lymphocytes is sometimes observed. If donor or recipient DNA is available but extremely limited, whole-genome amplification can be used to generate DNA for control material (5), but this DNA should be used with caution because the use of amplified DNA for the template for STR/VNTR testing has been reported to cause unbalanced reactions, allele dropouts, and allele additions (6).

PCR and Electrophoresis

Multiplex or single primer pairs can be used for PCR. The advantages of multiplex reactions include efficient use of consumables and the opportunity to average the results of several markers in an effort to improve accuracy. However, these advantages are offset by a loss of sensitivity caused by overlapping peaks, limitations in correction for overlapping signals from several different fluorescent dyes, and other factors that influence amplification efficiency. In general, the sensitivity for optimized single reactions is approximately 1%, while multiplex reactions have about 5% sensitivity (3, 7). Since sensitivity is important for determining donor chimerism after HSCT, this chapter will describe methods using a single primer pair in each PCR for measuring donor chimerism.

There is considerable variation in the methods that are used for STR/VNTR-based chimerism testing; most labs either use laboratory-developed tests or adapt commercial kits that were designed for identity (i.e., forensic or parentage) testing (7–10). Panels of PCR primers for 8 to 16 STR/VTNR loci are commonly used, but the loci, primer sequences, and assay conditions are extremely variable. A EuroChimerism Consortium recently proposed a standardized approach for chimerism testing for HSCT which includes methods for preparing DNA templates, primers, and amplification conditions, quality control procedures, criteria for selecting STR markers for each donor-recipient pair, and descriptive nomenclature for reporting the results (3, 4).

STR/VNTR amplicons are detected using capillary electrophoresis capable of resolving single nucleotide differences (e.g., a model 3130XL or 3500 genetic analyzer). The amount of PCR product, injection time, and voltage should be optimized to achieve minimal background fluorescence and strong signals that are not off the scale. Fragment analysis software (e.g., GeneScan/GeneMapper) is used to determine the size and area under the curve for each peak, and data are visualized as a chromatogram (Fig. 2). Each laboratory should establish acceptance criteria, which include signal strength, background fluorescence, and peak resolution. If any peaks are off the scale, it is not possible to accurately determine the relative quantities of each allele.

There are several factors which can adversely affect results, but many problems can easily be prevented or resolved. Signal strength can be improved by changing injection parameters and/or voltage. Fluorescent dyes are susceptible to photobleaching, and signals can be affected if labeled primers or amplicons are exposed to light. This problem can be avoided by ensuring that all fluorescent molecules are protected from light. If this problem is suspected, new reagents (primers) or PCR amplifications (amplicons) should be obtained. Intercapillary bleed-through can cause false-positive signals or confound interpretation of the data. This problem can be prevented by careful instrument setup (e.g., spectral and spatial calibrations). It is best to avoid any possibility of spectral overlap by judicious selection of dyes and primers. Dye-associated peaks caused by template-independent events can confound results when they migrate within the

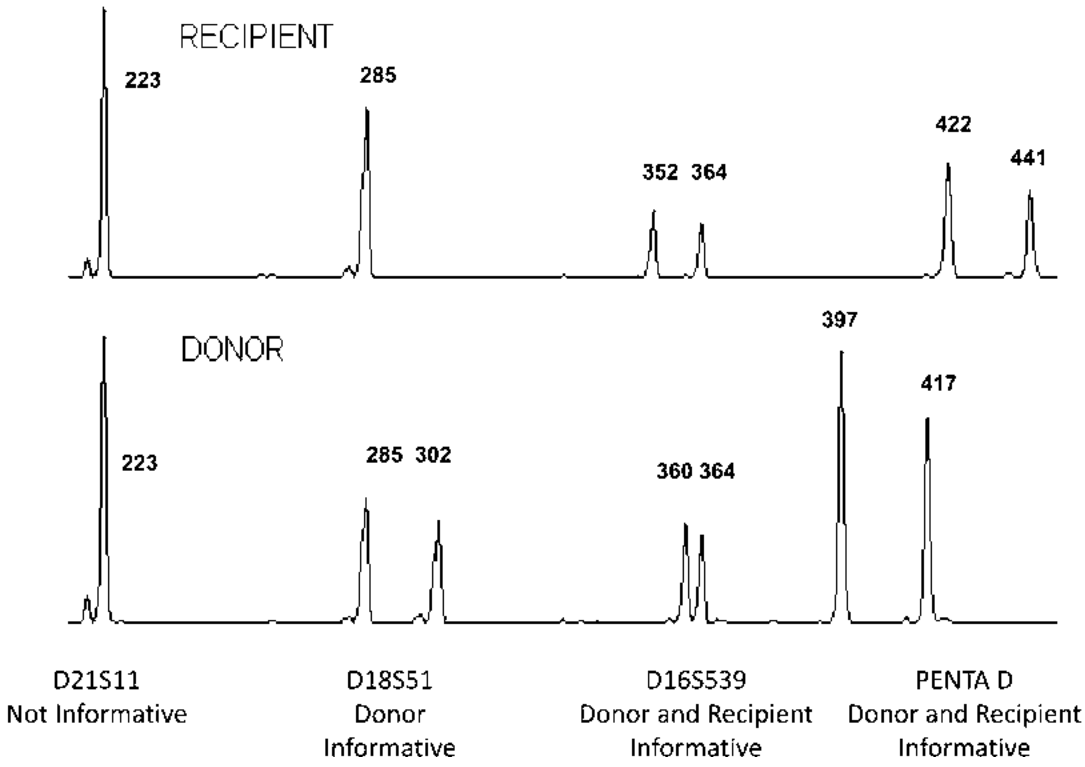

FIGURE 2 Identifying informative STR loci. Electropherograms of a multiplex PCR for four STR loci are shown for an HSCT recipient (top) and donor (bottom). For D21S11, the donor and recipient are homozygous for alleles of the same length (223 bp). For D18S51, the recipient is homozygous for an allele that is 285 bp. The donor shares this allele and has an additional allele that is 302 bp. Thus, D18S51 is a donor-informative locus. For D16S539, the donor and recipient share an allele that is 364 bp, and there are informative alleles for the donor (360 bp) and recipient (352 bp). For Penta D, there are two informative alleles for the recipient (422 and 441 bp) and the donor (394 and 417 bp).

range of STR alleles (11). If this problem occurs, it can be resolved by changing dyes and/or markers. If amplicons appear as split peaks, the DNA polymerase may be adding a single nucleotide to the 3′ ends of amplicons in a template-independent manner. This problem can usually be avoided by including a 30-min incubation at 60°C to allow extra time for the polymerase to catalyze the nontemplate addition of a nucleotide to all amplicons. Another factor that can affect the results is that the templates can slip during DNA synthesis and the resultant PCR products can appear as small peaks surrounding the main peak at intervals corresponding to the size of the repeat unit. This problem can be avoided through locus selection, reaction conditions, and technical factors. If stutter peaks are unavoidable and the area under the peak is used for calculations (see "Donor Chimerism Calculations" below), it is possible to make corrections for overlapping peaks.

Selecting Informative Loci

Loci with at least one allele unique to the donor or recipient are referred to as informative loci. The ideal locus has at least one allele that is informative for the donor and at least one allele that is informative for the recipient (bidirectional informative loci). In Fig. 2, D16S539 and Penta D are bidirectional informative loci. If unique alleles are limited to either the donor or the recipient, the locus is referred to as donor informative or recipient informative, respectively. In Fig. 2, D18S51 is an example of a donor-informative locus. If all alleles are shared, the locus is not informative (D21S11 in Fig. 2).

The likelihood of informative alleles at a particular locus is correlated with the degree of heterozygosity for that locus, not the number of alleles in the population. Thiede et al. compared the frequencies of 27 STR/VNTR markers in 203 recipients and their HLA-matched related donors and reported that Penta E, SE33, D2S1338, and D18S51 were most frequently informative for both recipient and donor (25 to 50% of pairs) (12). A panel of 13 primers was selected by the EuroChimerism Consortium because it provided bidirectional informative alleles for >99% of their donor-recipient pairs (3). Since the heterozygosity index and numbers of alleles for each locus can vary in different racial and ethnic populations, the likelihood of identifying an informative locus using a particular panel of STR/VNTR loci is dependent upon the laboratory's patient population.

To select optimal STR/VNTR loci for posttransplant monitoring, control DNA from the donor and recipient is used to determine the sizes and characteristics (e.g., presence of stutter peaks) of donor and recipient alleles for the lab's panel of STR/VNTR loci (Fig. 2). For this step, multiplex PCR is usually used because it provides efficient use of reagents and resources without compromising the ability to select informative loci. It is desirable to select at least two informative loci for posttransplant testing because averaging the results of multiple loci can increase accuracy. Loci located on different chromosomes are recommended to detect

a loss of heterozygosity which would cause false-negative results (13). The relative sizes of donor and recipient alleles are a very important consideration. If the alleles are within 1 to 3 repeat units in size, analysis can be confounded by stutter peaks, which appear as small peaks surrounding the main peak at intervals corresponding to the size of the repeat unit (see examples in D21S11 and D18S51 in Fig. 2). Stutter peaks are caused by template slippage during DNA synthesis, and the likelihood for stutter peaks is a characteristic of each locus. If possible, loci with stutter peaks that might confound analysis should be avoided. If it is necessary to use loci with stutter peaks, accuracy can be improved by making adjustments for the stutter peaks when the percentage of donor chimerism is calculated.

It is also beneficial to avoid informative loci that have substantial differences in the sizes of alleles because small alleles can be preferentially amplified over larger alleles. For example, Fig. 2 shows that the donor's Penta D 397 allele is amplified more efficiently than the donor's 417 allele. The recipient's 422 allele is amplified more efficiently than the 441 allele. Preferential amplification occurs because amplification efficiency is affected by the amplicon's size and, in some cases, sequence. Technical factors have also been reported to contribute to preferential amplification, including the PCR setup, the amount of template DNA, and the number of cycles used for thermal cycling (3). If there is evidence for preferential amplification of informative alleles, it is possible to correct for differences in amplification efficiency by making adjustments based upon a standard curve consisting of artificial mixtures of donor and recipient DNA (9).

The EuroChimerism Consortium proposed a descriptive nomenclature system for informative alleles named the Recipient-Shared-Donor (RSD) code (14), which incorporates relative allele sizes and the presence of stutter peaks. "D" indicates donor informative, "R" indicates recipient informative, and "S" indicates shared alleles. Alleles with stutter peaks are indicated with the corresponding lowercase letters (i.e., "d," "r," and "s"). Subscripts show the number of nucleotides separating the alleles. For example, $r_8D_{12}S$ is a code for a recipient allele with stutter peaks that is 8 nucleotides smaller than a donor allele that does not have stutter peaks. This donor allele is 12 nucleotides smaller than another allele that is shared.

The optimal informative loci can change during the posttransplant course. For example, if a patient has shown 100% donor chimerism in prior specimens, selecting a locus with an informative recipient allele that is preferentially amplified can improve sensitivity for detecting reemergence of recipient cells. STR/VNTR instability can result in mutations after transplant, particularly if there are malignant cells (13, 15, 16). If this occurs, these loci should be avoided. Loss of heterozygosity can also occur during the posttransplant course, particularly for patients transplanted for hematological malignancy (13). Loci showing loss of heterozygosity cannot be used for determining percentage donor chimerism.

Donor Chimerism Calculations

If the primary data meet the lab's criteria for reporting (e.g., signal strength and background), the areas under each of the informative peaks for the donor and recipient can be used to calculate the percent donor using the equation % donor chimerism = (D1 + D2)/(D1 + D2 + R1 + R2), where D1 and D2 are the areas under each of the donor's informative peaks and R1 and R2 are the areas under each of the recipient's informative peaks. If the donor and recipient share an allele, that allele can be eliminated from the equation. Some laboratories use peak heights rather than area under the peak. Both methods can achieve accurate results. Methods for calculating donor chimerism using many other possible combinations of informative alleles are described elsewhere (3, 8).

Since many factors can affect electrophoresis and sensitivity, it is optimal to include controls using DNA from the donor and recipient in each assay. Donor and recipient DNA is used to confirm alleles, and mixtures of donor and recipient DNA are used to determine sensitivity. The control DNA should have the same concentration as that in unknown samples because sensitivity is influenced by DNA concentration. For example, if an assay that typically achieves 1 to 5% sensitivity with 10 ng genomic DNA template, the mixtures of donor and recipient DNA might be 0%, 1%, 2%, 5%, 95%, 98%, 99%, and 100% donor added in mixtures totaling 10 ng DNA.

In clinics, descriptive terms are often used to describe donor chimerism. Detection of only donor is described as full donor chimerism. Some centers also consider ≥95% donor to be full donor chimerism. Detection of both donor and recipient is termed mixed chimerism. If chimerism is determined for cell lineages and some lineages are only donor while others are only recipient, the term "split chimerism" is used.

Cell Subsets

Determining donor chimerism in cell subsets can provide information that is extremely beneficial for monitoring and managing patients (2, 17–19). Testing of subsets can be used to substantially increase sensitivity. For example, if 8% of T cells are recipient derived, 10% of leukocytes are T cells, and all other cells are donor derived, testing of peripheral blood will show 100% donor because recipient cells represent less than 1% of nucleated cells in peripheral blood. If detection of persistent recipient cells might be critical for optimal management of this patient, sensitivity can be improved by testing a T cell subset where 8% recipient would be readily detected. When subsets that are frequently analyzed are taken into consideration, sensitivity for STR/VNTR-based tests becomes 0.1 to 0.01% of nucleated cells in peripheral blood (20).

Numerous reports have shown that testing of cell subsets can be useful for optimal patient management. For example, engraftment kinetics for T and NK cells has been reported to identify patients at increased risk for rejection and graft-versus-host disease (21–25). For patients that have hematological malignancies, detecting cells in the disease-associated subset can be indicative of impending recurrence, particularly when recipient cells are increasing in longitudinal samples (18–20, 26–29).

Cell subsets are usually isolated using immunomagnetic particles or sorting by flow cytometry to select cells with appropriate CD markers. CD markers that are frequently employed include CD3 (T cells), CD56 (NK cells), and CD19 (B cells). If immunomagnetic particle separation is used, confirming the purity of the subset with analytic flow cytometry can be extremely important to identify preparations that are compromised by contaminating cells (2, 30).

OTHER METHODS

Fluorescence *In Situ* Hybridization

FISH is a long-standing and well-established method that is still used by many laboratories for chimerism testing. Probes for X and Y chromosomes are usually used, but autosomal markers can also be used (31). This method achieves high precision and sensitivity if large numbers of cells are counted

(32). One of the advantages of this method is that it can be used for relatively small numbers of sorted cells, which would be difficult to reliably test using STR/VNTR methods (33); however, sensitivity is compromised if the number of cells that are counted is relatively small.

Quantitative PCR

Conventional real-time PCR methods have also been utilized for chimerism testing but have not achieved widespread use. Many markers have been used for this approach, including single nucleotide polymorphism, HLA, and insertion/deletion mutations (indels) (34–36). Advantages of real-time PCR include excellent sensitivity and avoidance of some of the limitations of STR/VNTR methods. Real-time PCR methods can be very accurate when the minority population is relatively small (<10%). However, technical variation increases when mixed chimerism is in the midrange. The coefficient of variation for real-time PCR methods has been reported to be 30 to 50% (35, 37), in comparison to <5% for STR/VNTR methods (9, 38, 39).

One of the challenges for real-time PCR methods is that they are influenced by relatively small differences in amplification efficiency. A 10% decrease in efficiency over 30 cycles would result in a 4-fold decrease in the estimation of a target sequence. For accurate results, it is important to include controls for amplification efficiency, replicates of each sample to minimize the effects of technical variation in threshold cycle, and calibration curves for the target sequence. Inclusion of these controls for a relatively large number of target sequences can be cumbersome. Although this method has some drawbacks, the high levels of sensitivity are advantageous when it is important to detect extremely low levels of chimerism, such as detection of recipient cells as an indicator for minimal residual disease and determining the presence of microchimerism (18, 19, 40–42).

Droplet digital PCR is a third-generation quantitative PCR method which overcomes many of the drawbacks of conventional real-time PCR methods and provides an absolute measure of target nucleic acid with unrivaled accuracy, precision, and sensitivity (43). Early reports of droplet digital PCR for chimerism testing are very encouraging (44, 45). In this method, target DNA is partitioned into nanodroplets (e.g., emulsion PCR) that contain on average one target molecule. The PCR is performed and each droplet is scored for the presence or absence of an amplicon. Poisson statistics are used to determine the number of copies of the target sequence in the starting material if TaqMan probes are used to differentiate alleles and the relative proportion of each allele can be calculated. Since this method uses endpoint PCR (in contrast to real-time methods), small differences in amplification efficiency do not affect the results and calibration curves are not necessary. Droplet digital PCR overcomes many of the limitations of other methods that are currently in use and has the potential to become a mainstream method for chimerism testing.

Nucleotide Sequencing

Pyrosequencing, which is a rapid and quantitative sequencing method, has been applied to chimerism testing, but early reports showed sensitivity that is inferior to those of STR/VNTR methods (46, 47). Next-generation sequencing technology utilizing pyrosequencing or other platforms is currently being explored for chimerism testing (48, 49). As this technology becomes readily available in clinical laboratories, next-generation sequencing may become an attractive option due to its high sensitivity and accuracy and its potential for lower costs.

Flow Cytometry

There have been several reports showing that flow cytometry using antibodies against proteins that are unique to the donor and recipient can be used for chimerism testing. Major advantages include determining if single cells are of donor or recipient origin, along with fast and convenient analysis of subpopulations. Although these are appealing features, flow cytometry is not widely used for chimerism testing. Antibody reagents that can reliably distinguish cells from a large number of donor/recipient pairs are likely to be one of the limiting factors. Several groups have reported using HLA antibodies, but this approach is not useful when the donor and recipient are HLA matched or there are no reagents to distinguish a small number of HLA mismatches (50, 51). Additionally, many HLA antibodies demonstrate cross-reactivity, which can confound chimerism analysis.

OTHER CLINICAL APPLICATIONS

Chimerism testing is routinely used following HSCT and is sometimes useful in other transplant settings. After solid-organ transplantation, donor microchimerism in peripheral blood has been detected, but the clinical significance is controversial. Some tolerance protocols combine HSCT and solid-organ transplantation and have reported that transient donor chimerism in peripheral blood can be associated with tolerance (52). Detection of donor chimerism can also aid in the assessment of risk for and diagnosis of graft-versus-host disease caused by lymphocytes carried by a solid-organ graft (53). When patients develop malignant disease after transplantation, chimerism testing can be used to determine if the tumor is of donor or recipient origin (15).

Microchimerism is widespread due to maternal-fetal cell exchange (54). Persistent microchimerism has also been reported after blood transfusion (55, 56). Microchimerism that is not caused by transplantation has been implicated in many diseases, including scleroderma, inflammatory bowel disease, Alzheimer disease, allergies, and certain cancers (41). Availability of new technology to aid investigation of microchimerism in health and disease may lead to new discoveries that increase demand for clinical microchimerism testing.

Finally, chimerism tests can also be extremely useful in the laboratory for investigating sample exchanges and confirming the identities of samples sent to the laboratory. For example, chimerism tests can be used to determine if a sample delivered to the laboratory was drawn from the correct individual. It can also be used to investigate suspected sample exchanges within the laboratory.

SUMMARY

Chimerism testing is currently routine for monitoring patients after allogeneic HSCT. Chimerism testing can be useful for other applications, including solid-organ transplantation and diseases associated with microchimerism. Numerous methods for chimerism testing have been reported, but STR/VNTR-based methods currently predominate. It is possible that new technologies that improve sensitivity and accuracy will ultimately supplant current methods.

Clinical Immunology Laboratory Accreditation, Licensure, and Credentials

LINDA COOK AND RONALD J. HARBECK

121

Today's clinical immunology laboratories have emerged from research laboratories as new assays became available to researchers and clinician-scientists. However, in today's hospital and reference laboratory environment, many governmental regulations and professional guidelines mandate defined education levels of individuals who oversee and perform patient testing, recommend test procedures, and define acceptable ordering, result reporting, and billing practices. Among these organizations is the Centers for Medicare and Medicaid Services (CMS), previously known as the Health Care Financing Administration (HCFA). CMS is a federal agency within the U.S. Department of Health and Human Services (DHHS) that administers the Medicare program and works in partnership with state governments to administer Medicaid. CMS also regulates billing practices and has a significant impact on the manner in which laboratories must be structured and managed. Today's successful clinical immunology laboratory practitioners must be knowledgeable about current guidelines and regulations and keep abreast of the constant changes in order to ensure compliance and professionalism in all areas of the laboratory. This chapter provides a broad overview of the major governmental agencies and regulations that impact on clinical laboratory practices. Various agencies and regulations are discussed in this chapter. To assist the reader, a list of their abbreviations is provided. In addition, an extensive list of websites is given in Table 1 to enable the reader to obtain further information regarding specific agencies, regulations, and programs.

REGULATORY ISSUES AND AGENCIES OF THE FEDERAL GOVERNMENT

The Clinical Laboratory Improvement Amendment

In 1965, the U.S. federal government enacted Public Law 89-97, which created Medicare and Medicaid under the Social Security Act of 1939. As a result of this law, the Department of Health, Education and Welfare developed standards for clinical laboratories operating in inpatient and outpatient settings. DHEW appointed The Joint Commission (TJC), formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), to set standards and survey the laboratories for accreditation. However, Congress became concerned that significant problems existed in the quality of laboratory testing for Medicare recipients provided by laboratories engaged in interstate

doi:10.1128/9781555818722.ch21

commerce. Therefore, in 1967, Congress passed the Clinical Laboratory Improvement Amendment (CLIA '67) mandating licensure for laboratories providing testing on more than 100 out-of-state specimens per year in major testing categories such as microbiology, immunology, chemistry, general serology, and hematology. A letter of exemption could be obtained from the CDC for those laboratories receiving fewer than 100 out-of-state specimens per year.

In 1987, the *Wall Street Journal* published an article that again raised concerns among the public about the quality of laboratory testing, especially cytology (1, 2). This prompted Congress and many state health departments to closely review the operations of the nation's clinical laboratories. This review resulted in Congress passing Public Law 100-578 or the Clinical Laboratory Improvement Amendment of 1988 (CLIA '88) (3). In 1992, the final rules for CLIA '88 were published (4, 5, 8). CLIA '88 replaced CLIA '67 and the separate Medicare/Medicaid regulations that were in effect up until this time. CLIA '88 required that all facilities performing examinations on materials obtained from the human body for the purpose of providing information for the diagnosis, prevention, or treatment of any disease or impairment or for the assessment of the health of human beings be subject to CLIA regulations. The sites included in these new regulations were doctor's offices, clinics, health departments, hospitals, and reference laboratories. The primary aim and authority of CLIA is to ensure the accuracy, reliability, and timeliness of test results regardless of where the test was performed. These requirements mandated additional procedures, reviews, and proficiency testing for all laboratories whether or not they were directly associated with a health care institution. Laboratories exempt from CLIA '88 include those that are subject to the rules published and enforced by the Department of Veterans Affairs and by the Department of Defense (for personnel drug surveillance and enforcement purposes). In addition, laboratories licensed by approved state licensure programs, law enforcement agencies that determine the legal status of individuals, laboratories performing forensic testing, and those performing research testing for which the results are not reported for clinical use are also exempt from CLIA '88 regulations.

As part of CMS's (HCFA's) mandates, it is responsible for the administration of the Medicare and Medicaid programs. The Division of Laboratory Services under the Center for Clinical Standards and Quality (CCSQ) is responsible for implementing the CLIA program. It is the responsibility of the Division of Outcomes and Improvement within CMS to ensure that medical laboratories provide quality testing results. This is achieved through a survey and certification program (6). As of January 2016, there were 254,650 laboratories and 122,617 physician office laboratories currently registered with CLIA. The majority of these are located in the United States. Funding of the CLIA program is maintained by user fees collected from these laboratories. There are 10 regional offices located throughout the United States with at least one laboratory consultant in each office who has experience and formal training as a medical technologist and is responsible for ensuring that the laboratories within that region are in compliance with the regulations.

Many medical laboratories may not be directly affected by the CMS surveys. CMS has granted "deemed" status to several organizations. In other words, CMS has the authority to establish and oversee a program that allows private, national accreditation organizations to "deem" that a laboratory is in compliance with Medicare requirements. These organizations include the College of American Pathologists (CAP), The Joint Commission (TJC), the American Association of Blood Banks (AABB), the American Osteopathic Association (AOA), the American Society for Histocompatibility and Immunogenetics (ASHI), and the Commission on Office Laboratory Accreditation (COLA). In addition, two states, Washington and New York, are exempt from CLIA regulations since their programs were found to be equal to or exceed Medicare compliance requirements. As of 2016, 7,796 laboratories had been certified by the CAP while over 3,000 have been certified by TJC.

CLIA has established four categories of testing, i.e., waived, moderate complexity, provider-performed microscopy, and high complexity. The waived tests are those considered simple laboratory examinations and procedures that have insignificant risk of an erroneous result. Laboratories with a certificate of waiver are not subject to inspection for certification. However, it is expected that the laboratory will follow the manufacturer's instructions and perform quality control measures as specified by the manufacturer of the kits in use. CLIA '88 waived tests include those performed in bacteriology, endocrinology, general chemistry, hematology, toxicology and therapeutic drug monitoring (TDM), and urinalysis. The following clinical immunology laboratory tests have been approved as waived tests: HIV-1 and -2 antibodies, influenza virus A/B, Lyme disease antibodies, bladder tumor-associated antigen, and antibodies against *Helicobacter pylori*, Epstein-Barr virus (EBV; infectious mononucleosis), and respiratory syncytial virus (RSV). The FDA maintains a website, which contains frequent updates of waived tests (Table 1). Moreover, waived tests are not completely foolproof. Some waived tests have the potential for serious health impacts if not performed correctly.

For moderate- and high-complexity tests, the FDA evaluates each new commercial test system during the premarket approval process by scoring seven criteria as described in the CLIA regulations. The criteria for categorization include (i) knowledge, (ii) training and experience, (iii) reagent and materials preparation, (iv) characteristics of operational steps, (v) calibration, quality control, and proficiency testing materials, (vi) test system troubleshooting and equipment maintenance, and (vii) interpretation and judgment.

Tests included in the "moderately complex" category require basic scientific and technical knowledge in the various analytical phases of the test. In addition, basic training and experience are required to perform the test. The tests may not be fully automated and may require monitoring, timing, or simple calculations. Independent technical skill decision making or intervention by the analyst may be required. Before the results of a moderately complex test are released, interpretation and judgment may be required by the analyst. There are also requirements for quality control (QC) and quality assurance (QA) processes, for enrollment in a proficiency testing (PT) program, personnel requirements, and accreditation by an approved agency.

The "moderately complex" testing category contains one subcategory of provider-performed microscopy (PPM). Tests included in this category are procedures that utilize a microscope and in which the test specimen is labile or, if testing is delayed, could compromise the accuracy of the results. Some of the tests included in this category are wet mounts, including preparations of vaginal, cervical, or skin specimens, pinworm examinations, microscopic urinalysis, and urinalysis by dipstick or tablet reagent for bilirubin, glucose, hemoglobin, ketones, leukocytes, nitrite, pH, protein, specific gravity, and urobilinogen. Tests included in this category must be performed during a patient's visit only by

licensed physicians, dentists, podiatrists, or mid-level practitioners including nurse practitioners, nurse-midwives, and physician assistants.

The "highly complex" category of tests includes a manual procedure with multiple steps in the sample or reagent processing or automated procedures requiring significant operator intervention. These tests require specialized scientific and technical knowledge as well as appropriate training and experience in order to perform all phases of the analytical process optimally. Reagents used in these tests may be labile and may require special handling or preparation. The operational steps involved in performing highly complex tests may require manual manipulation and monitoring. A high level of troubleshooting ability, decision making, intervention, interpretation, and judgment is required. Many tests performed in the clinical immunology laboratory as well as more than 50 general tests or procedures have been categorized as high complexity. Table 2 provides a list of pertinent Clinical and Laboratory Standards Institute (CLSI) documents that aid immunology laboratories in establishing and reviewing procedures.

CLIA '88 specifies the training required by individuals based on the complexity of the testing. For a laboratory performing moderately complex testing, the directors may include pathologists, medical doctors (M.D.s) doctors of osteopathic medicine (D.O.s), or persons holding a doctoral degree (Ph.D.s) with appropriate laboratory experience and training or individuals with a master's or bachelor's degree in science with appropriate experience and training. For high-complexity laboratories, a pathologist, other M.D., or D.O. with 1 year of laboratory training during residency or 2 years' experience directing or supervising high-complexity testing may direct the laboratory. In addition, the laboratory director may hold an earned doctoral degree in a chemical, physical, biological, or clinical laboratory science from an accredited institution and be certified and continue to be certified by a board approved by DHHS. The current approved boards are listed on the CMS website (Table 1), and they include the following: American Board of Bioanalysis (ABB), ABB public health microbiology certification, American Board of Clinical Chemistry (ABCC), ABCC 24-month Commission on Accreditation in Clinical Chemistry (COMACC) accredited program, American Board of Forensic Toxicology (ABFT) (limited to individuals with a doctoral degree), American Board of Histocompatibility and Immunogenetics (ABHI), American Board of Medical Genetics (ABMG), American Board of Medical Laboratory Immunology (ABMLI), American Board of Medical Microbiology (ABMM), and National Registry of Certified Chemists (NRCC) (limited to individuals with a doctoral degree). These Boards are recognized by federal and state government agencies as a significant component toward meeting licensure requirements to direct clinical laboratories engaged in the diagnosis of human disease. Board certification in some cases is recognized not only by CLIA but also in other states that require licensure, e.g., Florida, Georgia, Hawaii, Louisiana, Montana, Nevada, New York, North Dakota, Rhode Island, Tennessee, and West Virginia.

As of 24 February 2003, an individual may serve as a laboratory director under a grandfather clause with at least 2 years of laboratory training or experience. At the end of the 2 years, such an individual must (i) become board certified, (ii) be serving as a laboratory director and previously qualified on or before 24 February 2003, (iii) be qualified under 14 March 1990 CLIA '67, or (iv) be qualified under state law to direct a laboratory in the state on or before 24 February 2003. In addition to the laboratory director, specific qualifications are required for technical supervisors, general supervisors, clinical consultants, and cytotechnologists.

The CLIA regulations require that the laboratory employ one or more individuals who are qualified by education and either training or experience to perform the responsibilities of a technical supervisor. For the clinical immunology laboratory, the requirements range from board-certified pathologists to a bachelor's degree in science with 4 years of training in high-complexity testing. For histocompatibility

and clinical cytogenetics, individuals must be an M.D., D.O., or Ph.D. with 4 years of training or experience. The CLIA requirements for a general supervisor are to be an M.D. or D.O. or hold a Ph.D. or master's or bachelor's degree in science with 1 year of training or experience in high-complexity testing. Alternatively, the general supervisor must have an associate degree in laboratory science or medical laboratory technology and 2 years of training or experience in high-complexity testing. One should refer to the CMS website for additional requirements on education and training for laboratory directors, supervisors, and testing personnel (Table 1).

Good Laboratory Practices

Clinical laboratories have been increasingly involved with pharmaceutical and diagnostic companies in the evaluation of new drugs or diagnostic products. In the 1970s, the FDA published regulations governing the conduct of the safety tests on regulated products, and these have been updated regularly [*Good Laboratory Practice (GLP) Regulations, 21 CFR Part 58*]. Compliance with these regulations is intended to ensure the quality and integrity of the safety data prior to the marketing and/or clinical testing of the regulated product. Products that must have evidence of safety include human and animal drugs, human biological products, medical devices, and diagnostic products. The regulations address such issues as the protocol, personnel, facilities, equipment, operations, testing, and controls. The FDA conducts regular inspections and data audits to monitor a laboratory's compliance with GLP requirements. This process is rather detailed and thorough. Before undertaking a GLP project, it would be important to consult with a quality assurance professional who has familiarity with GLP regulations. Table 1 lists websites that provide more detailed information on GLP licensing.

Analyte-Specific Reagents

In 1997, the FDA issued a Final Rule regulating "Analyte specific reagents (ASR)" that are sold for clinical diagnostic applications. The latest revision was in 2007 ("Labeling for in vitro diagnostic products," FDA Guidance Document, 21, CFR 809.10, 2007). These products are defined by the FDA as "antibodies, both polyclonal and monoclonal, specific receptor proteins, ligands, nucleic acid sequences, and similar reagents which, through specific binding or chemical reactions with substances in a specimen, are intended for use in a diagnostic application for identification and quantification of an individual chemical substance or ligand in biological specimens" (7) (Table 1). FDA regulations require that manufacturers of ASRs include only a general description concerning the quantity, proportion, or concentration of the product and information about the manufacturer. They are further prohibited from making claims regarding the analytical or clinical performance of the ASR. The FDA has noted that some laboratories have used products or devices that lack FDA clearance and that can be lawfully used only for research or for investigational purposes, outside the context of research or clinical investigations. To address this situation, the FDA issued guidance stating that the manufacturers should not sell "research use only" or "investigational use only" products to laboratories that they know will use the products for nonpermitted purposes such as clinical patient testing, and the manufacturers should halt sales to those laboratories that they discover use the products for nonpermitted purposes, or the manufacturer should comply with FDA requirements for premarket review. This rule made it easier for manufacturers of diagnostic products to develop and market products. The burden of responsibility for the performance of an ASR in an assay thus rests on the clinical laboratory that offers a test using the reagent. Clinical laboratories that use products designated ASRs must be qualified to perform high-complexity testing. This regulation mandates that on each report generated by a clinical laboratory in which an ASR was used, it state, "This test was developed and its performance characteristics determined by (*laboratory name*). It has not been cleared or approved by the U.S. Food and Drug Administration." A laboratory may elect to include additional, clarifying information along with this statement, and the CAP has developed some sample statements to go along with the required statement (7). For example, the following additional statements may be added: (i) "The FDA has determined that such clearance or approval is not necessary"; (ii) "This test is used for clinical purposes. It should not be regarded as investigational or for research"; (iii) "Analyte specific reagents (ASR) are used in many laboratory tests necessary for standard medical care and generally do not require U.S. Food and Drug Administration (FDA) approval or clearance"; and (iv) "This laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 (CLIA) as qualified to perform high-complexity clinical testing. Pursuant to the requirements of CLIA, this laboratory has established and verified the test's accuracy and precision."

Laboratory-Developed Tests

In the context of personalized medicine, diagnostic tests have an increasingly important role in clinical decision making and disease management. However, the FDA is concerned that some LDTs have not been properly validated for their intended use and thus may put patients at risk for a missed or wrong diagnosis or failure to receive appropriate treatment. In 2010, the FDA announced its intention to begin regulating LDTs, and it planned to release a draft guidance in 2011. However, in 2012, those opposed to LDT regulation convinced Congress to pass a law that requires the FDA to give Congress 60 days' notice before issuing a draft guidance on LDTs. Since that time, there has been no activity in Congress to regulate LDTs; however, it is a process that will likely come to fruition in the future.

STATE CERTIFYING PROGRAMS

CMS has recognized certain states as being exempt from their certifying program. These states can carry out their own laboratory surveillance and issue their own certification. These states currently include Washington and New York.

Washington State

In 1989, the Washington State legislature passed the Medical Test Site Licensure law, which allowed the state to regulate clinical laboratory testing. In 1993, Washington's program was judged to be equivalent to that of the CLIA, and it became the first state in the country to be granted deemed status. In 1997 HCFA (CMS) extended Washington State's exempt status under the CLIA program for all laboratories. Washington State retains its regulatory activity at the state level, where it is claimed that the process is more accessible and responsive to local needs.

Washington State surveys the various testing facilities and examines their quality control and patient records, test performance and reporting data, management policies, and quality assurance programs. Although the state does not offer its own proficiency testing program, testing sites must participate in a program that is approved by CMS. The state monitors proficiency test results for acceptability.

New York State

In 1996, New York state received exempt status under the CLIA program for independent and hospital laboratories. Prior to this time, New York became the first state in 1965 to initiate a certification and licensing program for clinical laboratories operating within the state. Since then, the program has been expanded, and now, through the Clinical Laboratory Evaluation Program (CLEP), it monitors the quality of testing from all clinical laboratories and blood banks within the State of New York as well as all out-of-state facilities that accept clinical specimens obtained from within New York State. In very rare situations, an unusual test can be granted an exception and performed in a laboratory without a license. CLEP issues permits on an annual basis to over 1,000 laboratories across the nation and 900 patient service centers in New York State. On a biennial basis, CLEP grants over 3,000 certificates of qualification to individuals to serve as directors/assistant directors of these clinical laboratories and blood banks. The three objectives of the CLEP program are (i) to monitor, improve, and broaden the clinical capabilities of participating laboratories and blood banks; (ii) to provide guidelines, quality control standards, and procedures to be used by permit-holding clinical facilities; and (iii) to expand the clinical and educational background of medical technologists, laboratorians, and other personnel involved in the operation of clinical laboratories through training and remediation programs.

Standards for New York State accreditation can be found on their website (Table 1). To obtain a New York State laboratory permit, the laboratory must complete an application, submit the required fees, designate a laboratory director and assistant directors, if applicable, and obtain Certificates of Qualification (CQ) in all permitted categories for which the laboratory has applied. In addition, the laboratory must successfully participate in two successive New York State proficiency testing (PT) events for all applied categories and subcategories and for all analytes for which New York State proficiency testing is offered, submit standard operating procedures and validation data for Department review and approval, complete a successful on-site inspection, and submit an acceptable plan of correction for any deficiencies cited during the inspection. An out-of-state laboratory seeking a New York State permit shall pay to the NYS Department of Health an on-site survey fee which shall consist of a transportation expense and a *per diem* expense. Details concerning certification of laboratories and tests and a request form for a nonlicensed exemption can be found on their website.

California

The California Department of Public Health, section of Laboratory Field Services (LFS), is responsible for licensing clinical laboratories and personnel, including clinical laboratory scientists (formally titled clinical laboratory technologists), bioanalysts, specialty directors, specialty scientists, and cytotechnologists, through an application process and examination. The program also approves training schools for clinical laboratory personnel, including schools that provide instruction in phlebotomy. LFS also conducts complaint investigations, which may include on-site inspection processes.

California requires all laboratories to participate in proficiency testing programs that have been approved by the California Department of Health Services and the federal government. Other states in which a permit must be obtained, especially if testing is performed in an out-of-state laboratory, include Maryland, Rhode Island, Florida, and Pennsylvania.

ACCREDITATION AND LICENSURE OF LABORATORIES

The CLIA '88 regulations issued by the federal government mandate that all laboratories performing clinical testing must undergo regular inspections by an agency or organization with deemed status, e.g., CAP, TJC, and New York State. These agencies all have detailed requirements, which include acceptable education and training for all personnel, content of procedure manuals, documentation of quality control and preventive maintenance procedures, verification of new procedures, ordering, and result reporting procedures, and many other details that are necessary for documentation of appropriate laboratory practices. The requirements by these agencies are equal to or, in most cases, greater than those mandated by CLIA.

College of American Pathologists

The Laboratory Accreditation Program (LAP) of the CAP has been in existence since 1962. Since that time, it has developed into the world's largest single voluntary clinical laboratory improvement program. The LAP has been granted deemed status by CMS, and it is recognized by the TJC as an equivalent program in TJC-accredited institutions. There are currently over 7,000 laboratories accredited by CAP in the United States and abroad. The focus of the LAP is the use of educational, peer-review inspection processes using teams of laboratory professionals as inspectors. The CAP gives working laboratorians an opportunity to participate in the inspection process. By visiting and inspecting peer laboratories, a significant educational component is added to the accreditation process. The CAP selects a team of inspectors of practicing pathologists, laboratory scientists, and medical technologists who are matched to the laboratory's profile as closely as possible. All aspects of the laboratory's operation are evaluated in this process, from sample acquisition to general laboratory management.

The process of becoming accredited by the CAP begins with the submission of an application. The CAP then forwards to the laboratory "checklists" for each of the laboratory sections. The checklists are developed and approved by CAP committees, and they address each laboratory discipline. There are frequent revisions to the checklists, and most are customized based on the laboratory's activity menu. It is advisable to check the CAP website to review the current checklists. For the immunology laboratory, the checklists that are relevant depend on the menu of tests in the laboratory. They include (i) flow cytometry, (ii) immunology, (iii) general chemistry, and (iv) special chemistry (if such tests as measurement of immunoglobulin and complement levels or electrophoretic techniques are performed), (v) molecular pathology, and (vi) histocompatibility. Since the checklists that are sent to the laboratories are the same ones that the inspectors use during the on-site visit, the laboratory can review all items and address any deficiencies or problem areas prior to their inspection. The major areas that are covered in the checklist include proficiency testing, quality control, and quality improvement (e.g., supervision, procedure manuals, specimen collection and handling, reporting of results, reagents, calibration, controls and standards, instruments and equipment), personnel, physical facilities, and laboratory safety. During the inspection, there are two types of deficiencies that can be noted by the inspectors, phase I and phase II. Phase I deficiencies require a written response indicating that corrective action is taken, while phase II deficiencies require a written response and supporting documentation demonstrating compliance. As of 2006, the CAP conducts unannounced inspections. The

inspection should occur within 90 days of the anniversary date unless it is the laboratory's first inspection.

During the inspection process, the inspectors conduct a thorough inspection of each phase of the laboratory's operation using the checklists as guides. Recently, the CAP implemented the "ROAD" (*R*ead, *O*bserve, *A*sk, *D*iscover) inspection process. This process involves *R*, reading and reviewing documents; *O*, observing laboratory practices, noting if practice deviates from the documented policies or procedures; *A*, asking open-ended, probing questions; and *D*, discovering or following a representative specimen through the lab from collection to reporting.

After the inspection, the inspectors meet with the laboratory staff for a summation conference to review the findings. The inspectors leave a copy of the final summation report, and the laboratory must correct any deficiencies within 30 days and provide any requested documents to the CAP. If the deficiencies are corrected to the satisfaction of the CAP, the laboratory is accredited for a 2-year period. However, the laboratory must conduct a self-inspection at the 1-year mark using the most current checklists.

The Joint Commission

The mission statement for TJC is " To continuously improve health care for the public, in collaboration with other stakeholders, by evaluating health care organizations and inspiring them to excel in providing safe and effective care of the highest quality and value." More than 20,000 health care organizations are accredited by TJC, an independent, not-for-profit organization in the United States and in several foreign countries. TJC began evaluating hospital laboratory services in 1979. In 1995, TJC standards were deemed to be certifiable under CLIA '88. A medical technologist surveyor is assigned to review the laboratory's activities and policies. During the on-site survey, the surveyor looks at administrative, technical, safety, and infection control policies and procedures as well as proficiency testing records. In addition, surveyors meet with laboratory directors and managers to determine their involvement in the operation of the organization. Specifically, they seek information on the communication between the clinical staff, administrators, and other departments, reviewing in-services, evaluating the oversight of the laboratory testing and quality assessment and improvement activities. While visiting each laboratory section, the surveyor reviews section-specific policies and procedures, infection control and safety practices, preventive maintenance, quality control, and proficiency testing results. The surveyor also visits patient care areas to assess the processes for testing, specimen collection, and requesting and reporting of results and blood transfusions.

American Society for Histocompatibility and Immunogenetics

The American Society for Histocompatibility and Immunogenetics (ASHI) has set standards for histocompatibility testing for years. The standards include the following areas: general policies, personnel qualifications, quality assurance, HLA antigens, serological typing (HLA class I and II antigens), mixed leukocyte culture tests, antibody screening, renal transplantation, nonrenal organ transplantation, marrow transplantation, platelet and granulocyte transfusion, disease association, parentage testing, nucleic acid analysis, flow cytometry, and enzyme-linked immunosorbent assays. ASHI maintains these standards and conducts inspections of laboratories for licensing as well as assisting in the certification of technologists and directors. ASHI information is available on their website (Table 1).

Proficiency Testing

A significant ongoing requirement of all accrediting agencies is the regular performance of testing on masked samples. Laboratories must show evidence that they are enrolled and participate in a regular proficiency testing process. Moreover, they must regularly review results and make corrections to problems and errors discovered in the process of the testing. Subsets of tests are "regulated analytes," in which a continuing good performance is necessary in order for the laboratory to be able to bill Medicare and Medicaid for these tests. Regulated tests in the immunology laboratory include a number of assays that are performed by nephelometry (IgG, IgA, IgM, C-reactive protein (CRP), C3, C4, haptoglobin, alpha-1 antitrypsin), venereal disease research laboratory test (VDRL), rapid plasma reagin (RPR), and a few serology tests including alpha-fetoprotein, HIV, HBsAg, anti-HBc, HBeAg rheumatoid factor, quantitative anti-streptolysin O, infectious mononucleosis, rubella, and anti-nuclear antibodies.

Any tests performed by laboratories in which proficiency testing is unavailable must be shown to be performing correctly in some other manner. This may include trading split samples with other laboratories that offer the same test, regular review of clinical appropriateness or correlation, or other strategies. The laboratory director is responsible for reviewing the results for acceptability and taking corrective actions if necessary.

The College of American Pathologists is the proficiency supplier with the largest range of test samples. Details of the surveys available and the analytes contained in each survey are available on the CAP Proficiency website (Table 1). Many other organizations including ASHI, American Association of Bioanalysts, the CDC Model Performance Evaluation Program (MPEP), and certain state programs also supply proficiency materials, e.g., New York. A variety of manufacturers of reagents and instruments also produce proficiency testing or quality control materials in which results from laboratories are compared to each other.

INTERNATIONAL ISSUES AND AGENCIES

While the U.S. medical laboratories are required to follow guidelines established by CLIA, laboratories outside the United States have, in many cases, developed systems for the assessment of quality that follow international standards. One such organization is the International Organization for Standardization (ISO), headquartered in Geneva, Switzerland. ISO is a nongovernmental federation of national standards bodies from over 100 countries worldwide. Established in 1947, the mission of ISO "is to promote the development of standardization and related activities in the world with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technological and economic activity." During the 1970s and 1980s, with an increase in the global economy, companies found extensive variation in the quality of the goods and services that they purchased from sources all over the world. The ISO has developed internationally accepted standards to ensure product quality. In 1987, the ISO published the ISO 9000 series of international standards and guidelines on quality management and quality assurance. For clinical laboratories, document ISO/TC 212, CD 15189 addresses standardization and guidance in the field of laboratory medicine and *in vitro* diagnostic test systems. Currently, ISO 15189 accreditation is offered in 44 countries. Although this is not yet the case in the United States, in some countries it is the standard by which laboratories are reimbursed.

For medical laboratories, ISO 15189 supports the goals of a laboratory that is working to achieve best practices in quality management systems and specifies requirements for competency and quality. It also addresses the continuum of care directly connected with improving patient safety, risk mitigation, and operational efficiency. In addition to the quality management areas discussed in this document, pre- and postanalytical procedures, analytical performance, laboratory safety, reference systems, and quality assurance are included. Certification by the ISO is a voluntary activity. Since the fall of 2008, CAP launched the program based on the ISO 15189:2007 standard (Table 1). This process reinforces the ISO goals and standards while supporting CAP's mission of advocating excellence in the practice of pathology and laboratory medicine. The CAP was also a significant contributor to the development of the ISO 15189 standard. As of April 2014, there were 29 clinical laboratories accredited by CAP ISO 15189.

In addition to the ISO, other nongovernmental organizations are involved in laboratory quality assurance at the international level (9). These include the International Federation of Clinical Chemistry and Laboratory Medicine and the World Health Organization. The IFCC interacts with several international professional organizations involved in laboratory medicine including the International Union of Immunological Societies (IUIS) and the World Association of Societies of Pathology and Laboratory Medicine (WASPALM). Among the national organizations are the Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards [NCCLS]) in the United States and the Institute for Standardization and Documentation in Medical Laboratory (INSTAND) in Germany. Regional organizations include the Asian Pacific and Latin American Federation of Clinical Biochemists. In addition to Germany, many other countries in Europe and several clinical laboratory professional organizations have been actively involved in addressing quality systems and accreditation issues. Among these are the European Communities Confederation of Clinical Chemistry and Laboratory Medicine (10, 11) and External Peer Review Techniques (ExPeRT). Further information about the activities of these organizations can be found on their websites (Table 1).

A peer review system for the accreditation of pathology laboratory services in the United Kingdom was inaugurated in 1992. The Clinical Pathology Accreditation (UK) Ltd (CPA) is a nonprofit company associated with incorporating the Royal College of Pathologists, the Association of Clinical Pathologists, the Association of Clinical Biochemists, and the Institute of Biomedical Science. The operation functions in a manner similar to that of the CAP in the United States. There are Advisory Committees that define and review standards, assess applications, recommend inspectors, and advise on decisions after inspection. Survey teams of voluntary inspectors, each with expertise in the laboratory's specific disciplines, conduct on-site inspections. The inspectors are drawn from practicing pathologists and clinical/biomedical scientists (12).

TABLE 3 Credentialing agencies and programs[a]

Level	Certifying agency or program	Organization	Education level required	Website

[a]See the text for abbreviations.

For a laboratory to become accredited, the process begins with the laboratory assessing itself against the relevant CPA standards, filing an application, and being subjected to an on-site inspection in order to determine compliance with the standards. After the relevant advisory committee has reviewed the inspectors' assessment, a report is sent back to the laboratory. If there are no problems with the on-site inspection of the laboratory, the Board issues a 12-month certificate. If deficiencies are found, accreditation is withheld until the deficiencies have been corrected to the satisfaction of the CPA. When the laboratory has major deficiencies, approval is withheld until the deficiencies have been corrected and reapplication is required. Accreditation is valid for 4 years, with CPA reserving the right to reinspect at any time without notice. There is a requirement for an annual reregistration and a self-declaration stating continuing compliance with the standards. European Federation of Clinical Chemistry and Laboratory Medicine (EFLM) was formed in June 2007 at the Euromedlab Congress in Amsterdam, Netherlands, by the merger of the Forum of European Societies of Clinical Chemistry (FESCC) and the European Communities Confederation of Clinical Chemistry (EC4). In order to better serve the public interest in health care, EFLM connects National Societies of Clinical Chemistry and Laboratory Medicine and provides European leadership in clinical chemistry and laboratory medicine to national professional societies, the diagnostic industry, and governmental and nongovernmental organizations. It also represents the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) in Europe. The Quality and Regulations Committee supports the establishment of effective accreditation schemes and quality management systems in all European countries and liaises with ISO, European Committee for Standardization (CEN), and the European Accreditation body (EA). The Committee currently has two working groups. One focuses on influencing ISO/CEN standards and harmonization of accreditation and on setting European procedures for accreditation. The second working group, the "IVD Directive," focuses on guidance documents in the application of laboratory practices and accreditation.

CREDENTIALING

A number of organizations are involved in issuing credentials or licenses for individuals who demonstrate technical and management skills in clinical immunology. These programs generally include two components, one that establishes guidelines for training programs and another that creates and administers the examination process. It is important for all the individuals involved in clinical immunology laboratory practice to obtain appropriate certification. These programs encourage professionalism for their members and provide core groups of exceptionally qualified leaders in laboratory immunology. A list of professional societies that provide credentialing programs is shown in Table 3.

Validation and Quality Control: General Principles and Application to the Clinical Immunology Laboratory

VIJAYA KNIGHT AND TERRI LEBO

122

Clinical laboratories provide vital services to physicians and patients, public health agencies, and medicolegal entities. Because laboratory test results influence patient care and medical decisions rely on accurate and timely laboratory results, clinical laboratories must ensure that the *right* results are obtained at the *right* time and for the *right* patient. The ability to ensure accuracy of patient results rests on developing a quality program that governs all functional aspects of the clinical laboratory.

Quality, as defined by the Oxford Dictionary, is "a degree of excellence of something," and in the laboratory, it encompasses both internal quality control (IQC) and external quality assessment (EQA). IQC comprises processes that ensure precise and accurate results and focuses on monitoring the day-to-day precision and accuracy of assays, whereas EQA focuses on the comparison of various methods and examination of concordance in testing across a number of facilities. EQA also serves an educational purpose and assists with the evaluation of testing platforms, the comparison of methodologies, and benchmarking a laboratory's performance against peer groups.

Ensuring a quality laboratory from the analytical perspective requires that all assays be validated. This means that they have been thoroughly examined for both robust performance and appropriateness for clinical use. Moreover, it makes sure that there are procedures in place to ensure accurate performance of the assay, as well as detect errors in performance, reagents, or instrumentation as early in the process as possible so as to minimize any impact on patient care. In addition, a well-validated assay also establishes and documents any assay performance limitations, particularly for the more esoteric laboratory-developed tests (LDTs) that are not cleared by federal regulators.

Total quality encompasses all aspects of a clinical laboratory including adequate facilities and infrastructure, trained and qualified personnel, and vendor and instrument qualification and is beyond the scope of this chapter. Additional information regarding total quality programs may be obtained from a number of sources (1, 2). The scope of this chapter is to discuss (i) general guidelines for robust assay validation and quality control and (ii) challenges faced by clinical immunology laboratories performing assays that do not have well-defined guidelines for validation or are LDTs for infrequently encountered immunological disorders.

GUIDELINES FOR ASSAY DEVELOPMENT AND VALIDATION

Guidelines for the development of clinical diagnostic assays are provided by various organizations of which the most widely recognized is the Clinical Laboratory Standards Institute (CLSI). Originally known as National Committee for Clinical Laboratory Standards (NCCLS), the CLSI was started in the 1960s by a group of clinicians and laboratorians with the intention of developing a formal, consensus process for standardization of processes impacting patient care, including laboratory testing. Since then, CLSI has evolved into a global organization that is actively involved in education and global harmonization of standards through collaborative efforts with organizations involved in developing standards and standard material for laboratory testing (see chapter 121). While CLSI guidelines are most commonly used for development and validation of clinical testing, the Centers for Disease Control and Prevention (CDC) (3) and the International Clinical Cytometry Society (ICCS) also provide consensus guidelines for several flow cytometry based assays (4–6). More recently, the International Council for Standardization in Hematology (ICSH) and the ICCS convened a working group to develop comprehensive guidelines on all aspects of development and validation of flow cytometric assays encompassing preanalytical, analytical, and postanalytical stages (7). Additionally, several key publications have emerged to address the development, optimization, and validation of assays for biomarker analysis during immune monitoring studies for new therapeutics that involve challenging methodologies such as flow cytometry, single cell analysis such as the ELISpot and various antibody- and ligand-binding immunoassays, that are also making their way into the arena of diagnostic testing (8–12).

CLASSIFICATION OF ASSAYS

Diagnostic assays may be classified according to their regulatory status or according to their technical performance characteristics. Validation or verification requirements depend on the classification of the assay.

Regulatory Status

For information regarding regulatory status, see http://www.cms.gov/Regulations-and-Guidance/Legislation/CLIA.

doi:10.1128/9781555818722.ch122

FDA-Approved Assays

Food and Drug Administration (FDA)-approved assays have undergone rigorous testing by the kit or device manufacturer, and assay performance characteristics have been defined and deemed acceptable for clinical use. Clinical studies have been conducted to establish the diagnostic utility of the assay, and reference intervals have been established. When a laboratory is considering offering an FDA-approved assay, a *verification* of assay performance characteristics claimed by the manufacturer must be performed (per Clinical Laboratory Improvement Amendments [CLIA] standard 493.1253) (Table 1).

FDA-Approved, Modified Assays

These assays have been approved in their commercially available format for diagnostic testing. Any modification to the assay (e.g., change in volume of a reagent, sample type [plasma versus serum], length of incubation, anticoagulant [EDTA versus heparin], or other parameters) must be *validated* prior to use for diagnostic purposes. It must be noted here that assays for nonstandard body fluids (e.g., pleural fluid, cerebrospinal fluid, and in general, fluids other than blood or urine) are considered FDA-modified assays because nonstandard body fluids are regarded as an alternate matrix and are not interchangeable with serum or plasma (14). For such assays, the effects of the matrix on the performance characteristics of the assay must be evaluated. The criteria to be fulfilled to establish a modified FDA assay as a validated, clinical assay are defined in Table 1.

Lab-Developed Tests

LDTs are prevalent in clinical immunological laboratories and present the greatest challenges for successful validation. In general, the criteria that must be fulfilled to establish an LDT for clinical use are detailed in Table 1 and are similar to those required for an FDA-approved, modified test. However, it must be noted here that depending on the technical nature of the assay, not all validation parameters may be applicable.

Classification According to Performance Characteristics

Diagnostic tests fall into four categories depending on the nature of the result (15): qualitative, quasiquantitative, semiquantitative, and quantitative.

Qualitative Assays

These assays have a binary answer: present/absent, positive/negative, or reactive/nonreactive. While these assays do not provide a numerical value but an absolute descriptive result, they may employ a numerical cutoff value that determines whether a result is positive or negative. Analysis of gene mutations, microbiological assays, infectious disease screening serological tests, flow cytometry tests for leukemia or lymphoma, and the majority of LDTs for the analysis of immune cellular function such as the dihydrorhodamine assay for neutrophil oxidative burst (16) fall into this category.

Quasiquantitative Assays

These assays do not employ a calibration standard but have a continuous response that can be expressed as a numeric value. Examples of quasiquantitative assays include enzyme-linked immunosorbent assays (ELISAs) that employ a single positive control. The absorbance of the test sample is compared with that of the control sample, and a numerical result is calculated as a function of the control sample's absorbance. Flow cytometry assays such as analysis of lymphocyte subsets, DNA content, immunogenicity assays for antidrug antibodies, and functional assays such as lymphocyte proliferation assays also fall into this category (7).

Semiquantitative or Relative Quantitative Assays

Semiquantitative or relative quantitative assays employ calibration standards that do not fully represent the analyte or biomarker. The matrix of the standard may differ from that of the test samples, and a direct quantitative comparison is not possible. While these assays provide a numeric value, this value is often related to a range that describes a qualitative result. Immunological assays for detection of autoantibodies and ligand-binding assays fall into this category, as do flow cytometry-based assays such as CD34 enumeration, which relies on fluorescent calibration beads (7, 15, 17). Precision for semiquantitative assays tends to be much more variable than that of quantitative assays and can be as high as 25% at the upper and lower limits of quantitation for soluble analytes (17) and as high as 45% for flow cytometry-based assays designed to detect rare cell populations (18).

Quantitative Assays

Quantitative assays make use of characterized standards with known numerical values and utilize a regression curve to determine, accurately, the numeric value of an analyte. Reference standards employed in these assays are fully characterized and are representative of the analyte or biomarker. The majority of analytes encountered in chemistry laboratories fall into this category, whereas few immunological assays can truly be considered to be quantitative assays.

TABLE 1 Assay validation or verification requirements per CLIA standard 493.1253

Validation or verification requirement	FDA-cleared, unmodified assays	FDA modified or LDT	Reference document
Accuracy	Required	Required	CLSI EP-12A
Precision	Required	Required	CLSI EP-12A
Reportable range	Required	Required	CLSI MM6-A
Linearity	Required initially and every 6 months thereafter	Required	CLSI EP6-A
Reference interval	Required	Required	CLSI C28-A2
Analytical sensitivity	Not required, verify with 20 results spanning the analytical range	Required	CLSI EP17A
Analytical specificity	Not required	Required	CLSI MM6-A

Based on the nature of the assay, not all assay performance criteria are required to be fulfilled during validation. For instance, an LDT with a qualitative readout will not require studies for linearity, and the limit of detection for a qualitative assay may not be necessary if the result does not depend on a numeric value. Thus, the assay must be fully understood prior to undertaking validation, so that only parameters that are truly representative of the assay's performance are examined and validated.

DEVELOPMENT AND VALIDATION

Validation and quality control of immunological assays can be challenging due to the complex nature of the analyte (autoantibodies, cellular function) as well as the complexity of the analytical methods. Furthermore, in many cases there is little to no standardization of these assays. Assay variability can be introduced at a number of levels, including reagents (antigen preparation, antibody source, cell extract, cells or tissue sources, recombinant or native protein preparations), detection systems (nature of the detection antibody, i.e., monoclonal versus polyclonal; nature of conjugation, i.e., enzyme or fluorophore), variation in method (incubation time, reaction volume, method of readout), and data analysis. Cellular function assays are particularly challenging because they are inherently much more complex than serum-based assays and less robust in their reproducibility. All of these variables influence the assay and must be tested rigorously in order to develop a robust, reproducible, and reliable assay suitable for patient care.

The following section discusses general development and validation guidelines for the four types of assays. The definition of "validation" according to the Oxford Dictionary is to "demonstrate or support the truth or value of..." something. In the context of a clinical diagnostic assay, validation implies the ability of the assay to demonstrate certain predetermined criteria that establish the assay to be "fit-for-purpose." The term "fit-for-purpose" is commonly used in biomarker assay development for therapeutics (15), but similar concepts can be applied to diagnostic testing. The International Organization for Standardization (ISO) defines validation of a method as "the confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled" (19, 20). This concept may be extended to fit-for-purpose validation, whereby the suitability of a diagnostic test must be evaluated scientifically and clinically based on the literature or alternate existing methods. In parallel, an analytical validation plan must be developed describing preset performance criteria for the assay, which if fulfilled, yield results appropriate for diagnostic use. A validation study is then undertaken using suitable clinical samples, and if the performance criteria are met, then the assay is considered fit-for-purpose. Although the relation of a test result to the clinical status of the patient should determine whether the test is fit-for-purpose, clinical information linked to samples is generally not available in most laboratories, making it challenging to perform *clinical* validation of the assay. It is therefore important to evaluate a new test or platform alongside an FDA-approved or predicate method, when available (21), or a method currently employed by the laboratory when considering an alternate method or platform. While these approaches are suitable for FDA-approved kits or methods or when developing an alternate method for a preexisting assay, *de novo*-developed tests are far more challenging since there may be no other method in existence. In such cases, information regarding the suitability of an assay for diagnostic purposes is gathered from prior documented or published research.

Prior to Validation

Prior to commencing test validation, several factors should be taken into consideration. In addition to providing relevant information to the clinician to support diagnosis, a clinical test must be technically feasible and financially viable both for the laboratory and for the patient. Accordingly, the test must be researched thoroughly, and data must be gathered and analyzed prior to commencing validation. Table 2 includes some questions that must be considered prior to test development.

Following an analysis of these factors, if the decision is made to offer the diagnostic test, an optimization protocol must then be developed. The optimization protocol takes into consideration the technical variables that must be examined and optimized before the assay can move into further validation. Optimization protocols are required mainly for LDTs and for modifications of FDA-approved tests. Unmodified FDA-approved tests are performed according to the protocols determined by the manufacturer and should not require any further optimization. The optimization protocol considers variables such as sample type and stability, optimal concentration of reagents (e.g., antibodies for immune assays or flow cytometry), compatible reagents (examination of buffer systems, antibody pairs or combinations), incubation times, substrates, instrumentation, and data processing algorithms.

Depending on the assay or technical platform, there may be other parameters that must be examined and characterized prior to proceeding to validation (e.g., effect of anticoagulant on cellular phenotype or function, sample stability, particularly for cell-based assays, or the effect of transport temperature on the stability of the analyte).

Once all variables are optimized, the assay can proceed to validation as described below. Figure 1 provides a summary of the steps required to develop and validate a test.

TABLE 2 Considerations prior to development or validation studies

1. Clinical considerations
   a. What is the diagnostic value of the test?
   b. Is the test result actionable, and will it influence clinical decisions?
2. Technical considerations
   a. Will Institutional Regulatory Board (IRB) approval be required to develop and validate the test?
   b. On what technical platform will the test be offered?
   c. If the test is a *de novo* lab-developed test, are reagents available?
   d. What quality control parameters must be instituted?
3. Financial considerations
   a. What is the cost of developing the test?
   b. What is the reimbursement for the test?
   c. If the test is to be validated on a new platform, what is the cost of instrumentation?
   d. Is staff available to validate the test?
4. Physician and/or patient interface considerations
   a. How will the test be reported: quantitative, semiquantitative, or qualitative result?
   b. How will results be made available to the physician or patient (laboratory information system interfaces)?

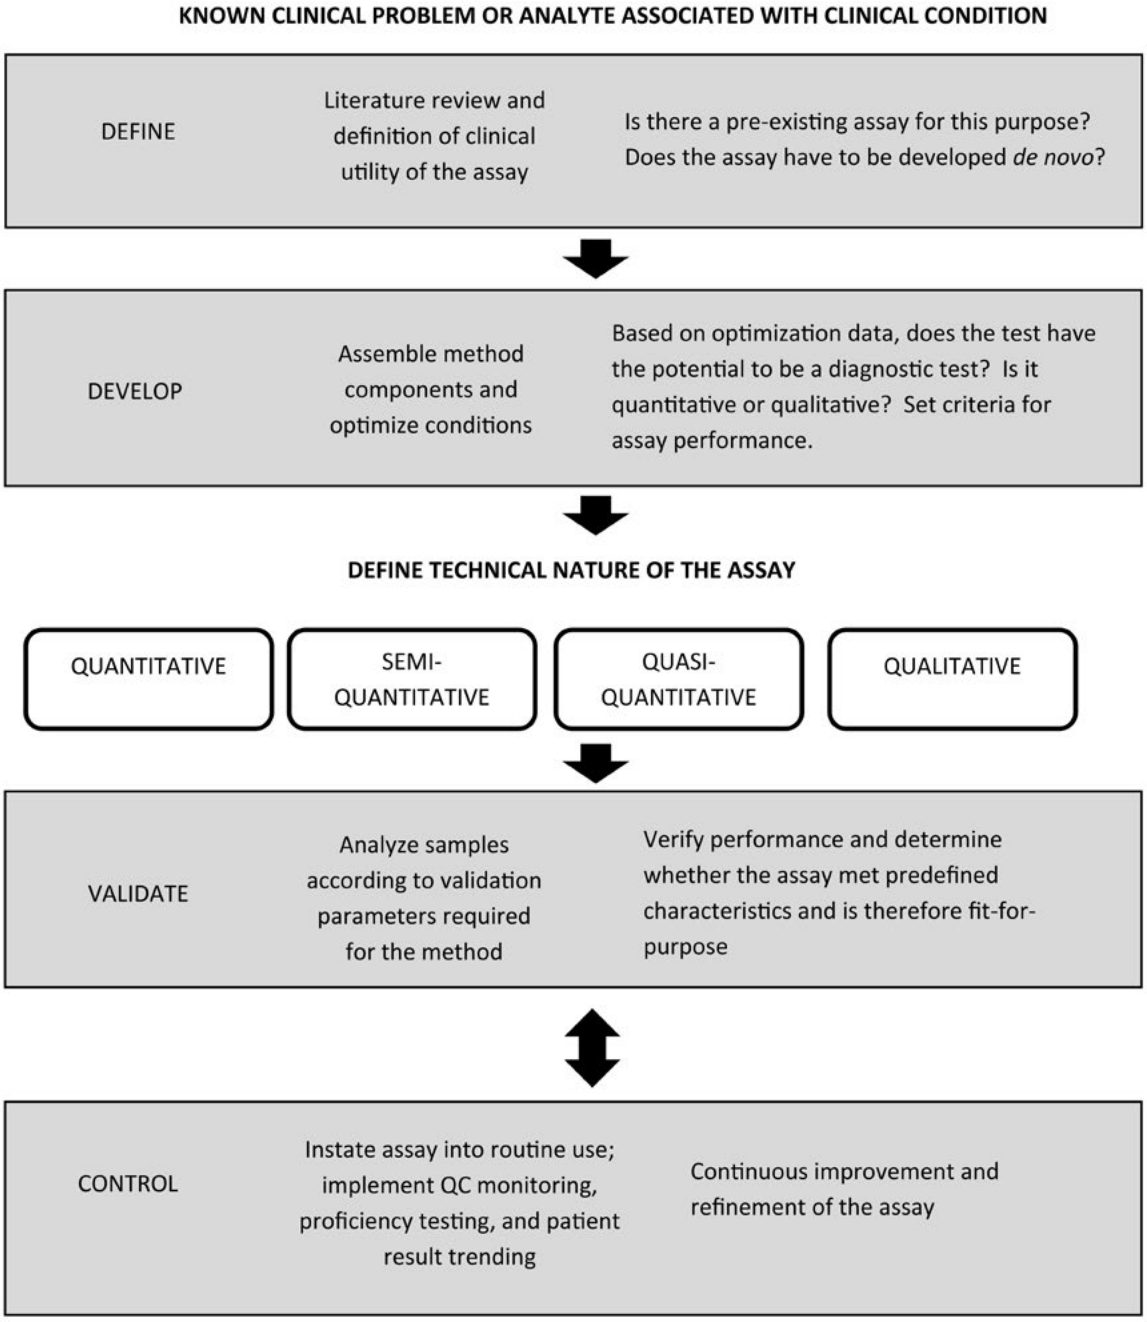

FIGURE 1 Stages in assay development and validation. The flowchart illustrates the four stages of assay development required to scientifically evaluate a potential diagnostic assay, develop and validate the method, and implement continuous quality monitoring of the assay.

Validation Parameters

Validation or verification of an assay determines its performance characteristics. As detailed in Table 1, assay validation examines the accuracy and precision, the analytical range, the limit of detection and linearity, and the analytical sensitivity and specificity of the assay and establishes reference values for diagnostic or clinical monitoring purposes. The following paragraphs examine each of these parameters.

Accuracy

Accuracy is defined as the closeness of agreement to the actual, expected value. *Diagnostic accuracy* of a test refers to the extent of agreement of the test result with the clinical condition associated with the test. When assessing diagnostic accuracy, a relevant patient population must be available. While assessment of diagnostic accuracy is ideal, it is generally beyond the scope of most diagnostic laboratories.

Instead, most laboratories perform studies to demonstrate *agreement* of the diagnostic test with an established method or verify the manufacturer's claims to accuracy using well-characterized samples. To establish agreement, proficiency testing samples, previously assayed patient samples, or reference panels can be used. CLSI EP12-A2 recommends testing at least 50 positive and 50 negative samples for a qualitative assay (22). For quantitative assays, samples chosen to represent the analytical range of the assay are analyzed by the reference method and test method and are compared for agreement using Bland-Altman plots or comparison plots (23; see also www.westgard.com). While these methods are suitable for verification of the manufacturer's claims for a commercially available assay or when comparing a new method with an established method, it is far more challenging to assess accuracy for an LDT. Accuracy for LDTs may be assessed by splitting samples with another laboratory performing the test, by comparing test results with clinical data, or by analyzing previously characterized samples where possible. Flow cytometry- and cell-based functional assays pose additional challenges in that samples utilized in these assays have limited stability and true standard reference material is not available. Furthermore, cellular functions such as lymphocyte proliferative responses to mitogenic or antigenic stimulation can vary widely from person to person and are dependent on seasonal or even diurnal influences. Accordingly, establishing accuracy for such assays can be difficult. Accuracy for flow cytometry assays may be documented by correlation with clinical phenotype where possible. *Analytical accuracy* can be demonstrated by comparison with an alternate methodology (e.g., a protein's phosphorylation status may be detected by flow cytometry or by Western blotting). Such comparisons are not perfect since differences in methodology may affect results. However, laboratories developing esoteric tests must document attempts to assess accuracy and provide reasonable explanations for discrepancies found between methods (7).

Precision

Precision is the ability to obtain the same result on repeated analyses under the same conditions. Precision is expressed as the coefficient of variation (CV) where %CV = SD/mean × 100, where SD is standard deviation. During validation studies, precision of the assay must be analyzed in a single run (intra-assay precision), across multiple runs (interassay precision), and among multiple operators or laboratories (interoperator variability) to determine the total variability of the assay. Qualitative assays with a binary answer do not require precision studies, unless the result is based on a numerical value. In such cases, precision must be examined around the numerical decision point at which a result transitions from negative to positive or normal to abnormal. CLSI EP12-A2 provides detailed guidance on examining precision around a numerical cutoff value for qualitative assays (22). Quantitative assays require examination of at least three levels of the analyte that cover the reportable range of the assay. Twenty replicate values are obtained during a single analytical run for intra-assay precision, whereas 20 values are accumulated over 20 separate analytical runs over several days and involve several operators to estimate inter- and intra-assay precision (25). When validating a commercially available assay, precision (%CV) must correlate with the manufacturer's claim. CLSI EP05-A2 provides further guidance for precision studies for quantitative assays (25).

As with accuracy, defining precision for flow cytometry assays that report a numerical value (percentage of cells) or the ELISpot that is designed to assess cellular function (e.g., cytokine-producing cells) or lymphocyte proliferation assays for antigen-specific responses is challenging. This is because these assays are often developed to detect rare antigen-specific T or B cell populations, which tend to be present in very low numbers and are often close to the detection limit of the assay. Additionally, lymphocyte proliferative responses are known to vary due to biological variation within and between individuals, diurnal variation, and variation due to differences in activation pathways triggered by different stimuli (26). Cell-based assays are inherently less precise than serum-based assays because of greater variability in preparation of cells, stability of samples (27), staining methods, and instrument settings for flow cytometry and assessment of cytokine-positive spots and data analysis for ELISpot assays. Because a flow cytometry result is derived from several thousand individual, simultaneous measurements of cellular parameters such as light scatter and fluorescence, all of which are transformed into numeric values for mean fluorescence or percentages of gated populations, large numbers of replicate samples as for chemistry-based analytes are not required to establish imprecision, nor is it feasible to obtain large numbers of samples with limited stability (28). In general, intra-assay precision studies may be performed with as few as five samples in triplicate within a single run. While a desirable %CV for flow cytometry assays is 10%, precision can be much more variable for less abundant populations. When the frequency of the population is less than 0.1%, as in analysis of low-frequency tetramer-specific T cells or in minimal residual disease, a CV of 20% may be acceptable. Imprecision for functional assays such as the ELISpot assay may be as high as 20 to 25% (18).

The lymphocyte proliferation assay has been widely used as a measure of general immune function and immunological memory. In HIV infection, in particular, loss of lymphocyte responses has been shown to correlate with advancing immune deficiency and has been utilized as a correlate of progression to AIDS (29, 30). The AIDS Clinical Trial Group (ACTG) has therefore established protocols and quality control measures for the lymphocyte proliferation assay in order to establish acceptable parameters for the assay across multiple testing sites (31).

In general, when %CV varies widely, an attempt must be made to analyze larger numbers of samples to develop as stringent precision criteria as possible (7) or to establish that the variability in precision does not have a significant impact on the interpretation of the assay result.

Precision for semiquantitative or quasiquantitative antibody assays can show wide variation as well (10). For instance, immunofluorescence techniques for the detection of autoantibodies can show a variation as high as 20%, or ±2 dilutions when a titer is reported (32), and this is well illustrated by the results of proficiency testing surveys conducted by the College of American Pathologists for autoantibody assays. In many cases, assays that show large variations in precision tend to be semiquantitative in nature, where the result is qualitative. Precision studies should be conducted around the lower discrimination point or medical decision point, particularly at the point where a result transitions from negative to positive, and it is necessary to determine that this wide variation in precision does not impact clinical decisions. It must be noted here that assays with larger imprecision around clinical decision points may require a "grey area" of interpretation, indicating that the numeric cutoff value is not an absolute transition point from a negative to a positive result. Excellent examples of this situation are the interferon gamma release assays that support the diagnosis

of latent tuberculosis infection. Both the ELISpot method (33) and the ELISA method (34) have been shown to have CVs as high as 30% for results at or near the cutoff value for a positive result, whereas imprecision of the assay is much lower for subjects with higher levels of reactivity to tuberculosis antigens. This variability can cause a negative result to turn positive or a positive one to turn negative when the patient's test results are close to the clinical decision point. Because clinical decisions such as isoniazid therapy or the necessity for a chest X ray to rule out tuberculosis may depend on these results, it is advisable to define a "grey area" that encompasses the coefficient of variation around the mean clinical decision point value and recommend repeat testing rather than define an absolute cutoff value, which then defines an absolute, qualitative positive or negative result. Such "indeterminate" result categories are useful for immunological assays when imprecision around the clinical decision point is large.

Measurement of imprecision for cell-based assays includes biologic and clinical variability and must also be considered in light of the clinical interpretation as illustrated earlier. Although cell-based assays tend to be much less precise than serum-based assays, they do provide the physician with useful information. Therefore, it is critical for the physician to consult with the laboratory director regarding the interpretation of such test results and determine whether the results correlate with the patient's clinical information, rather than rely exclusively on a numerical result.

Once interassay, intra-assay, and intraoperator variability is determined, total precision of the assay can be calculated. The precision of the assay can then be used to set acceptable criteria to qualify reagent performance or for acceptable proficiency testing performance.

LoB, LoD, and LoQ

For quantitative, semiquantitative, and qualitative assays that utilize a numeric value to discriminate positive from negative results, it is necessary to determine the lowest concentration of analyte that can be reliably measured by the assay (35). Qualitative assays that yield a binary answer, such as organism identification or confirmation of the expression of a cell surface molecule, do not require these studies.

The three values that are required to establish the lowest reliably measured concentration are (i) limit of blank (LoB), defined as the *highest apparent* concentration of the analyte that can be measured when replicates of a blank sample (vehicle alone) are tested. LoB is determined by the equation $\text{LoB} = \text{mean}_{\text{blank}} + 1.645(\text{SD}_{\text{blank}})$, where $\text{mean}_{\text{blank}}$ is the mean of several replicate measurements of blank (vehicle alone) samples. Limit of detection (LoD) is the *lowest* analyte concentration that can be reliably distinguished from the LoB. LoD is determined by using both the LoB and replicate test samples known to contain a low concentration of the analyte and is defined by the equation $\text{LoD} = \text{LoB} + 1.645(\text{SD}_{\text{low concentration sample}})$. Limit of quantitation (LoQ) is the lowest concentration at which the analyte is reliably detected based on predefined goals or clinical criteria and may equal or be higher than LoD. Further information and studies for the determination of LoD, LoB, and LoQ are defined in CLSI EP17-A (36).

To establish LoB and LoD for soluble analytes, the general recommendation is to use 100 low-positive and 60 negative samples, analyzed over several days (36). While this process is suitable for stable sample types such as serum, it poses problems for cell-based assays such as flow cytometry due to reasons stated earlier, e.g., limited sample stability or unavailability of abnormal samples. LoD is relevant in quasiquantitative flow cytometry assays, where rare populations with dim fluorescence must be detected accurately (e.g., minimal residual disease) or in relative quantitative flow cytometry that employs fluorescent beads as a calibration standard (7). Because of limited sample stability for cell-based assays, it is not possible to analyze several replicates over several days as can be done for soluble analytes. Instead, a limited number of replicates may be analyzed to confirm LoD and LoQ. The ICCS and ICSH guidelines recommend analyzing fewer numbers of samples (e.g., 5 low-positive and negative samples analyzed in 5 replicates over 3 days) (7). LoB is confirmed if 95% of blank replicates fall below the expected low-positive sample value and LoD is confirmed in 95% of the positive samples falling at or above the target value. Other means to establish LoD for flow cytometry-based assays are to use the fluorescence-minus-one (FMO) method, where all antibodies required to identify the population of interest with the exception of the antibody directed against the analyte of interest are included in the assay. This setup can then serve as a blank for the analyte of interest (7).

LoDs for functional cell-based assays such as the ELISpot assay or tetramer analysis by flow cytometry make use of spiking studies to determine the lowest number of antigen-specific cells that can be detected above a background response (18).

Linearity

A quantitative analytical method is said to be linear when the observed value of the analyte from a series of samples with varying concentrations of the analyte is linearly proportional to the true or actual concentration of the analyte in those samples. The linear range of the assay is defined by upper and lower limits of the analytical measurement range that fit a straight line. Assays that measure serum chemistry analytes are generally quantitative and require assessment of linearity when the assay is first initiated and at 6-month intervals thereafter. The general method for linearity assessment requires evaluation of at least five concentrations of the analyte spanning the analytical measurement range and determination of the correlation between the expected versus measured values. It is important to ensure that the matrix of samples used to establish or verify linearity match the matrix of samples used for clinical testing. CLSI EP6-A provides detailed guidance on the establishment and assessment of linearity for quantitative assays (37).

Some immunoassays, such as competitive ELISA, do not have a linear relationship between the instrument response and the analyte concentration. In such cases, the parabolic or sigmoidal curve that describes the mathematical relationship between the instrument's response and the analyte concentration can be transformed into a linear comparison using a four-parameter logistic model (38), allowing test results to then be extrapolated from the linear curve.

Linearity studies for flow cytometry may be performed in the context of both instrument and assay performance. Instrument-specific linearity studies compare the signal detected and the actual fluorescence over an established dynamic range and are performed using hard dyed calibrated beads of known fluorescence intensity. The measured geometric mean fluorescence intensity of the beads is then plotted against the manufacturer's reference values and the linear relationship determined. A coefficient of variation of 1 ($r^2 = 1$) indicates that matched observed and expected data points lie on a straight line. Linearity can vary from instrument to instrument but is generally stable for a

particular instrument and does not have to be checked on a daily basis (39).

Since the vast majority of flow cytometry assays are either qualitative or quasiquantitative, assessment of linearity of the assay is not necessary, except in the case of relative quantitative assays such as the quantitation of surface CD64, recognized as a correlate of sepsis (40, 41). Linearity of the assay can be established using fluorescence calibration beads in which fluorescence intensity is reported in quantitative terms such as molecules of equivalent soluble fluorochrome or antibody binding capacity. The fluorescence intensity of the test sample can then be extrapolated to either molecules of equivalent soluble fluorochrome or antibody binding capacity units from the linear regression curve.

Reference Range or Reference Interval

In order to provide the clinician with information that supports medical decision making, a laboratory test result must be compared with what is considered to be "normal." Determination of the expected normal is the responsibility of clinical laboratories and diagnostic test manufacturers and is termed "reference range" or "reference interval."

Reference intervals are generally defined as the range of values that lie between an established upper and lower limit for the analyte of interest and include the upper and lower limits. However, depending on the type of assay, the reference interval may be a numerical range (quantitative assay), a set of numerical ranges that are assigned to a qualitative result (semi- or quasiquantitative), or simply a qualitative, binary result. In some cases, the reference interval may require only one value (any value above a certain limit is considered abnormal, or values below a certain level are determined to be low). Reference intervals are expected to be characteristic of 95% of healthy subjects (preferably comprising 50% male and 50% female subjects) tested for the particular analyte and should be developed using a clinically relevant population.

CLSI C28-A3c provides detailed guidance on the establishment of reference intervals. Reference intervals do not necessarily have to be established for all analytes. In some cases, national or international consensus determines decision limits (e.g., the reference range for glycated hemoglobin, HbA1c, has been standardized (42) and is accepted and utilized universally). In these cases, the laboratory does not have to establish or even verify the reference interval. Instead, the onus for ensuring accuracy of the reference interval falls to manufacturers of diagnostic kits or instrumentation used to measure the analyte, and the clinical laboratory must ensure the accuracy and precision of the method and implement quality measures to ensure optimal performance of the test. For assays that have an established reference interval, the laboratory *verifies* the interval using at least 20 clinically representative or previously analyzed samples.

Analytes reported as or based on numerical values that do not have established decision limits require the establishment of a reference interval. The recommended method to establish a reference interval is to collect data from 120 samples (from 60 male and 60 female subjects) that are representative of the population normally encountered by the clinical laboratory. In practice, however, it is often not possible for individual clinical laboratories to collect 120 samples. CLSI-C28-A2c recommends, instead, that the laboratory can *verify* the reference interval established elsewhere, for example, in a published study with adequate numbers of subjects. When reference intervals are adopted from published studies, the relevant study or studies must be cited on the laboratory report. Sources for reference interval determination include samples from normal, healthy volunteers. However, patient samples may be used as well, particularly when a reference interval is under verification and not establishment. In some cases, patient samples may be included in the development of a reference interval when they are deemed to be "relatively healthy" as in patients who are undergoing elective surgery or routine health screening or are blood donors.

The accuracy of a reference interval is dependent on the robustness of the method, since analytical variability such as intra-assay and interassay precision, linearity, and sensitivity of performance as well as controls, calibrators, and equipment can all affect the test result and thereby the reference interval. Therefore, for LDTs, parameters such as accuracy, precision, linearity, and limit of detection must be established prior to proceeding to normal range studies. Furthermore, when verifying a reference interval from previously published data, it is critical to ensure that methods and reagents (e.g., antibody clone or fluorophores, antibody concentrations, or buffer systems) are comparable since changes in reagents and methodology can affect test values and therefore the reference interval.

Pediatric reference intervals also pose challenges for the laboratory, since unlike adult samples pediatric samples are not easily available. When possible, efforts should be made to determine the comparability of adult values to pediatric values in a smaller subset of pediatric samples. These data may be acquired from pediatric samples that have undergone routine clinical testing but have values that are considered normal. Reference intervals may also be adapted from published studies and cited on the laboratory report. An alternate is to consider reporting pediatric test results qualitatively, rather than quantitatively, when developing a reference interval is not feasible.

Analytical Sensitivity and Specificity

Analytical sensitivity refers to the ability of a test to detect the smallest concentration of the analyte that can be reliably measured by the assay. Analytical specificity refers to the ability of the assay to accurately measure the particular analyte under consideration, to the exclusion of other analytes. Both these terms relate to the technical aspect of the assay and are not necessarily related to clinical sensitivity and specificity (defined below). It is important to make this distinction because clinical laboratory validation most often refers to sensitivity and specificity relating to the technical performance of the assay.

Clinical (Diagnostic) Sensitivity

Clinical sensitivity is defined as the percentage of subjects with the clinical status as determined by the diagnostic accuracy of the test (in other words, the percentage of subjects with disease who test positive). Sensitivity is calculated as $100 \times$ true positives/(true positives + false negatives) (43). True clinical sensitivity can be calculated only when a study is performed on a relevant clinical population and is often beyond the scope of a clinical laboratory.

Laboratories assess analytical sensitivity instead, which is the ability of the assay to detect low quantities of the analyte and is similar to determining the LoD and LoQ (35). Sensitivity for cell-based assays such as flow cytometry or ELISpot assays is especially challenging to determine and relates to the ability of the assay to identify rare or dimly fluorescent populations. As previously described, sensitivity is assessed by determining the LoD and LoQ of the assay using the FMO approach. In addition, unlabeled samples (whole blood or peripheral blood mononuclear cells) may be spiked with serial dilutions of labeled, fixed cells, and the

lower limit of quantitation can be determined (7). Assay sensitivity for low-frequency populations, such as tetramer-positive cells, can be improved by collecting larger numbers of events on the cytometer. However, this has to be balanced with a practical workflow and the volume of sample available for analysis.

Analytical sensitivity for the ELISpot assay is dependent on the numbers of cells included in the assay. Unlike flow cytometry, increasing the number of cells in the ELISpot assay can lead to lower resolution of individual cytokine-producing spots, making it difficult to obtain an accurate count of antigen-specific cytokine-producing cells. Additionally, since the analytical sensitivity of an ELISpot assay is defined by the denominator or total number of cells per well, a lower number of cells may produce a number of spots similar to that obtained with a higher number of cells but can cause the assay to appear to be less sensitive (18). As with flow cytometry, defining sensitivity of the ELISpot assay must be balanced with optimal numbers of cells for optimal production and resolution of cytokine-producing spots.

Clinical (Diagnostic) Specificity

Clinical specificity of a diagnostic test is the ability to detect true negatives or the number of subjects without disease whose test values are negative. Specificity is calculated as 100 × true negatives/(false positives + true negatives) (43). As with sensitivity, defining clinical or diagnostic specificity of a laboratory test requires a study of the relevant clinical population and is generally not within the scope of most clinical laboratories.

Laboratories instead determine analytical specificity, which is the ability of the assay to detect the analyte to the exclusion of all other analytes or potentially interfering substances. Specificity is often determined by conducting studies to examine the potential for interfering substances to hinder the detection of the analyte. Specificity for serum-based analytes may be determined by spiking hemolyzed, icteric, or lipemic samples with known positive samples or controls. In flow cytometry-based assays, analytical specificity is defined as the ability of the assay to distinguish the cell population or the antigen from all other populations. Strategies that may be employed to demonstrate analytical specificity include (i) use of the FMO approach, (ii) depletion of the cell population of interest with magnetic beads and demonstration of a loss of staining, (iii) use of isotype controls and demonstration of a specific shift over the background fluorescence of the isotype control, or (iv) gating on a population that does not express the molecule of interest as an internal control for specificity (e.g., CD19, a B lymphocyte lineage-specific phosphoglycoprotein, is expressed exclusively on B lymphocytes; therefore, gating on T lymphocytes to demonstrate lack of expression defines specificity of CD19 expression on B lymphocytes). Assay specificity for low-frequency tetramer-positive populations may be determined by using an irrelevant tetramer. Similarly, ELISpot assay specificity for antigen-specific T cell populations may be established by lack of a response to irrelevant peptides along with a positive response to the specific peptide(s) under consideration (18).

QUALITY CONTROL

Once an assay is either verified or validated, it is ready to be put into clinical use. However, prior to including the assay in routine clinical testing, it is necessary to implement quality control procedures. Why control the quality of the assay? Quality control is not merely required to satisfy regulatory requirements but is the means to ensure consistent performance of the assay and detect errors as early as possible, preferably prior to any impact on patient results. As with validation, quality control in the immunology laboratory can be quite challenging due to lack of standardization of control material, quality control guidelines, defined expected values, and the plethora of LDTs that are often exclusively performed in a single laboratory (44). The burden of establishing robust quality control therefore rests with the individual laboratory and requires robust IQC and EQA.

In order to control the quality of an assay, its performance characteristics must be established. This is done at the validation stage, where the accuracy and precision of the assay are established, the LoD is determined, and if a standard curve is used, its performance is documented. Day-to-day quality of the assay can then be assessed by including control material in the assay and monitoring and benchmarking the control values according to the performance characteristics of the assay.

Quality Control Material

Characterized control materials are used to monitor the performance of assays (see www.westgard.com). It is important for control material to be as similar as possible to the clinical samples being tested since differences in sample and control matrices may affect results. Although manufacturers provide control material included in assay kits, this material is often identical to the standards provided for calibration. Any effect on the stability of the standard material may also be observed in the controls, and any changes in the calibration curve may not be detected for a considerable length of time, leading to erroneous results. Controls purchased from another manufacturer or prepared by the laboratory by pooling known positive and negative samples are acceptable alternatives. When pooling known positive or negative samples, it is important to maintain documentation of the samples and original results in order to provide traceability to the origin of the control pool and as a resource to troubleshoot technical issues.

Controls, whether purchased or prepared in the laboratory, must undergo a qualification process prior to being placed in use. Such processes are necessary to document the expected performance of control material such that any changes, e.g., shift or drift trends in values, are detected early and prior to release of patient results. In order to qualify control material, the numeric values of the test material as well as the tolerance limits must be known. The tolerance limits for the control material cannot exceed those established for the assay from precision studies during the validation phase. For example, if the total precision of an assay is ±5%, a control that falls outside these limits is by definition always out of control and therefore invalidates all results. To qualify a control, a minimum of 20 values must be obtained on several independent runs. The recommendation is that 20 values be collected over 2 weeks or 10 working days, and preferably over at least 4 weeks or 20 working days (46). The mean and SD of these values are then utilized to generate a Levey-Jennings (L-J) chart to monitor the assay's performance (see www.westgard.com).

While it is possible to establish controls for stable sample types such as serum, controlling cell-based assays in a similar manner is much more problematic. Functional cellular assays such as lymphocyte proliferation assays for immune competence, neutrophil oxidative burst, or cytokine release assays utilize date-matched samples from healthy volunteers, and the performance of these cells is compared with the test subject's response. For these assays, it is also important to

note that the date-matched control is utilized to control the technical aspects of assay performance, e.g., appropriate distribution of immune cell subsets or a proliferative response to mitogenic or antigenic stimulation, and is therefore only a methodological control. A date-matched control sample's test results may occasionally fall outside the established reference range for the assay. This does not necessarily invalidate the technical performance of the assay since these results may be characteristic of the date-matched control sample and not a reflection of a technical problem with the assay. Maintaining documentation of expected assay results for a pool of donors utilized as date-matched controls can address these situations.

Quality control material for flow cytometry assays is also challenging due to the lack of long-term stability of samples. Stabilized control cells are commercially available for commonly used lymphocyte markers and can be used to monitor instrument and assay performance. However, for the majority of flow cytometry-based LDTs, commercial controls are not available and date-matched normal control samples are generally used to monitor assay performance. An alternative is to use commercially available anti-immunoglobulin-coated beads that have the capacity to bind mouse anti-human labeled antibodies, which can be stained with assay-specific antibody combinations to monitor assay-specific instrument settings and assay performance. However, since beads do not possess the characteristics of live cells and do not react to changes in pH or other reagent parameters as cells would, they are not ideal controls for light scatter settings, nor do they address interference from autofluorescence inherent to certain cell populations.

Tools To Monitor Quality

Levey-Jennings Charts

In the clinical laboratory, the daily documentation and evaluation of quality control is critical for timely detection of errors. The most commonly used method to evaluate quality control is the Levey-Jennings (L-J) control chart. The L-J chart is based on the Shewart control chart, proposed in 1931 by Walter Shewart at the Bell Telephone Laboratories, as a statistics-based graphical representation to monitor industrial manufacturing processes. In 1950, S. Levey and E. R. Jennings adapted this method for the clinical laboratory (48).

The L-J chart provides visual indication of the performance of a laboratory test. The general principle of the L-J chart is that the distance of the observed value from the expected mean value of the control material provides an indication of any perturbation to the test system (48). In practice, control material for which the mean and SD are established is analyzed at an established time during an analytical run (at the beginning, in the middle, and at the end), and the values obtained are plotted on a chart as shown in Fig. 2. The value of the control material for a particular assay run is noted in relation to the mean. The standard L-J chart includes limits at the 1 SD, 2 SD, and 3 SD levels. If the control material shows a Gaussian distribution, 68.2% of the values will be within ±1 SD of the mean, 95.5% of the results will be within ±2 SD of the mean, and 99.7% will be within ±3 SD. Thus, if a control value varies within 1 SD, it is likely due to random chance, and while the laboratory must be aware of a minor shift, it is generally not actionable. However, if a control value falls outside 2 or 3 SD, it is statistically unlikely to be due to random chance and must be investigated. James O. Westgard defined a set of rules, "Westgard rules," to determine whether an analytical run is in control or out of control (49). Figure 2 illustrates the utility of L-J charts to monitor control values and the implementation of Westgard rules to determine whether the analytical run is in or out of control. Several instances of out-of-control runs are indicated. Point A indicates a control value greater than 3 SD from the mean, which must be investigated, and the analytical run must be rejected until troubleshooting has been performed. Points B and C are

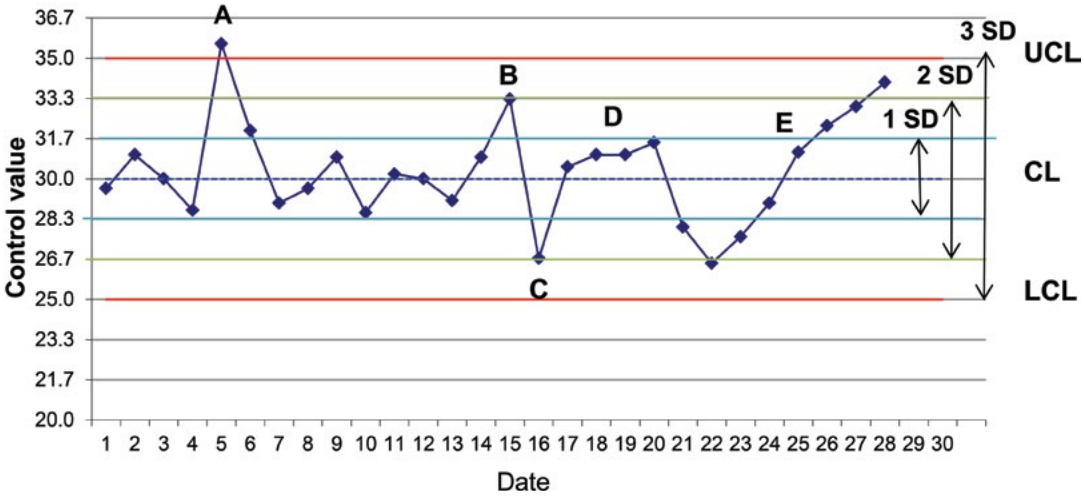

FIGURE 2 Tracking control performance using a Levey-Jennings chart. The chart shows daily values of a hypothetical control with a mean value of 30.0. The upper limit and lower limit of the control are set at +3 SD and −3 SD from the mean value, respectively. The positions of 1 and 2 SD from the mean are indicated. The chart illustrates several instances of out-of-control analytical runs as described by the Westgard rules, indicated by letters A through E: A, violation of 1_{2S} rule (control value exceeds mean + 2 SD); B and C, violation of 2_{2S} rule (two consecutive control values are either plus or minus 2 SD from the mean); D, violation of 4_{1S} rule (four consecutive measurements exceed the mean by 1 SD); E, violation of 7_{T} rule (seven consecutive measurements trend upwards). CL, control limit; UCL, upper control limit; LCL, lower control limit.

consecutive runs where the control value is either +2 SD or −2 SD from the mean and must be investigated. Although the four data points indicated in D are within 1 SD, they all fall on one side of the mean, resulting in a trend requiring investigation. When controls show either a negative or positive trend compared with the mean, assay performance is biased and can potentially affect patient results similarly. Similarly, when the control value consistently trends either upwards (Fig. 2E) or downwards over seven or more consecutive runs, the analytical run must be rejected and troubleshooting of the assay commenced. Detailed use and interpretation of L-J charts and the use of Westgard rules to evaluate an analytical run are available through the Westgard basic QC course (46).

While L-J charts are useful for monitoring quantitative or semiquantitative assays (such as immunoassays for detection of antibodies) when numerical values are known, they are not useful for qualitative and quasiquantitative assays. In these assays, a qualitative positive/negative or known reactive/nonreactive control is analyzed along with test samples to ensure that the assay is performing accurately.

Control material for cell-based assays is particularly challenging due to the limited stability of samples. Flow cytometry assays can be controlled with commercially available stabilized cells. However, only a limited set of surface markers are currently commercially available. In most other assays, a normal control sample is utilized or, in the case of leukemia and lymphoma panels, internal control populations may be employed.

Internal Controls

For some assays, internal controls may be used to verify results and assay performance. For example, when analyzing serum immunoglobulin G (IgG) subclasses, the sum of the concentrations of the four subclasses (IgG_1, IgG_2, IgG_3, and IgG_4) must be equal to total IgG concentration, or when analyzing lymphocyte subsets by flow cytometry, the sum of T, B, and NK (natural killer) cells must be within 5% of the $CD45^+$ lymphocyte population. These internal controls are a good indicator for assay performance and accuracy of test results.

Delta Checks

Delta checks are built into laboratory quality systems to identify discrepant patient results during sequential testing. Delta checks compare current laboratory results to previous results. If the two values differ by predetermined criteria and within a specific time interval, they must be investigated further. Discrepant results may be caused by sample integrity, stability issues, or mislabeling, all of which cannot be detected by QC methods that evaluate assay performance. Discrepant results may also occur due to therapeutic intervention or a genuine change in the patient's clinical status.

Result Trending

For any clinical laboratory, it is necessary to understand the general trend of results for a particular test. Trending patient results can be very informative in detecting potential analytical errors or changes in the patient population. A hypothetical trending chart over the course of 12 months is shown in Fig. 3. The general trend in the laboratory is for negative samples to be at about 90%. During the summer months, a spike in positive samples was observed. Such trends must be investigated to determine if the change was due to an assay error, a change in reagent, shipping conditions during extreme summer temperatures, or a genuine change in patient demographics and epidemiology.

Laboratory result trends also provide valuable information for surveillance programs for communicable diseases. For instance, essential components of HIV surveillance programs include CD4 counts and viral load test results, both of which are used not only to identify cases of HIV, classify disease stage at the time of diagnosis, and monitor disease progression but also to evaluate HIV prevention efforts (3, 50, 13).

AUTOMATED LIQUID-HANDLING SYSTEMS

A number of immunological techniques (ELISA, ELISpot assay, flow cytometry, and cell-based assays such as lymphocyte proliferation assays) have been moved to automated platforms, or liquid-handling robotic systems have been integrated into some of the steps of the assays. Automated liquid-handling systems improve throughput and pipetting accuracy,

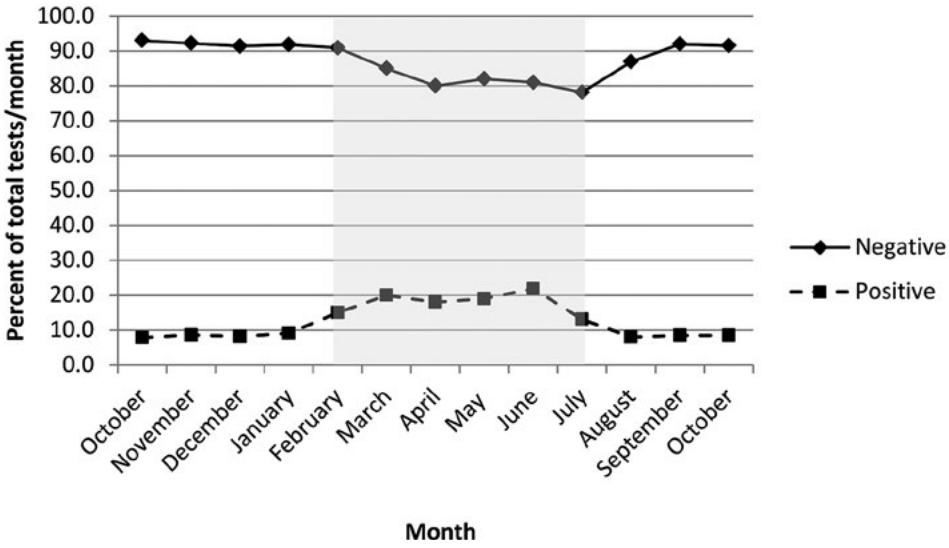

FIGURE 3 Monthly trending of assay results. Assay results were trended over the course of 12 months. The shaded region spanning months March through June shows an abnormally elevated percentage of positive results, which require further investigation.

prevent injuries due to repetitive manual pipetting, and are therefore a significant technical component for the clinical immunology laboratory. Automated systems for serum-based assays such as immunofluorescence assays or ELISA for autoantibodies have been available for a number of years, similar to the automated robotic systems employed in chemistry or molecular laboratories. More recently, liquid-handling systems are being adapted to handle the more complex cell-based assays such ELISpot, lymphocyte proliferation, and flow cytometry assays and are becoming increasingly common in immunological laboratories. It is therefore necessary to implement procedures to initially verify the performance of the instrument relative to its application, as well as establish a quality control program that ensures periodic evaluation of the pipetting accuracy and performance of the instrument.

Validation of an automated liquid-handling system requires evaluation of both the accuracy of the amount of fluid dispensed and the precision or reproducibility of the instrument's performance and, per ISO 17035 guidelines, requires that actual volumes transferred by the automated system be verified and optimized if necessary. The performance of automated liquid-handling systems can be validated and optimized using a number of methods including gravimetric, colorimetric, or fluorometric methods or combinations of these methods for volumes as low as 1 μl. Gravimetric methods, described in ISO 8655-6 (24), utilize weight to confirm the accuracy of dispensed volumes. The uncertainty of gravimetrically verified volumes increases in regions of low humidity and for small volumes (1 μl or lower). In such cases, photometric or fluorimetric methods may be employed (45). Both of these methods employ a linear regression curve generated using a calibrated, verified pipette and compare the instruments' actual to the expected performance (47). The performance of automated liquid handling systems, as with manual pipettes, must be verified periodically. Verification of automated liquid handling systems' performance every 6 months is the generally accepted practice. However, the frequency of a performance check also depends on the frequency of usage, the volume and type of samples handled by the instrument, and the frequency of maintenance or technical troubleshooting procedures.

CONCLUDING REMARKS

Assay validation and quality control, particularly in the area of LDTs, is an evolving process. As an understanding of the differences between chemistry-based and immunological assays continues to develop, guidelines and procedures will continue to be established for esoteric immunological assays to enable laboratories to continue to expand the field of specialized immunological assays that inherently depart from the rigorous, well-established world of chemistry-based testing but are nevertheless key components that aid the diagnosis of immunological disorders. Evolution of immunological testing is and will continue to be a collaborative effort among diagnostics manufacturers, physicians, and directors of clinical immunological laboratories.
