Preface

In the 5 years since the 2011 edition of this book, the molecular diagnostics landscape has changed dramatically. In the 1990s, molecular diagnostics was the domain of only a few reference laboratories; it took almost 20 years for these techniques to make their way into about half of the CLIA high-complexity laboratories in the United States. The full potential of this technology was slow to be realized largely because the methods used by these laboratories were not capable of delivering on-demand results or being conducted at the point of care. Over the past year, with the advent of CLIA-waived molecular testing spurred on by the inexorable force of innovation, molecular diagnostics have become increasingly democratized to the extent that physician office laboratories and sexual health clinics are now performing molecular testing on the premises, often delivering results in minutes or a few hours.

Laboratory professionals may at times find themselves a bit bewildered in this rapidly evolving landscape. Adding to this, enter next-generation sequencing (NGS) technology, as described in several chapters in this book (chapters 2, 3, 5, 6, 10–14, and 53). NGS-based analysis of microbial genomes and populations is in some ways similar to where PCR was in 1987: full of opportunities and challenges. For the first time, identification of the full range of pathogens—viruses, bacteria, fungi, and protozoa—can be addressed by using the same core technology. Microbial population analysis can be carried out at unprecedented depth, opening up the field of metagenomics (chapters 10–14). Whole-genome analysis goes beyond organism identification to predict drug resistance and detect pathogenic determinants. As diagnosticians, it seems likely that as this field evolves, so will our job descriptions. Still, much progress remains to be made before NGS can move beyond its current status as a research tool. NGS systems need to become more automated and less expensive to operate. The analysis of complex data sets provided by these systems needs to be simplified; the interpretation of results cannot require a PhD in bioinformatics for delivery of routine results. However, as complex as it is now, NGS too will eventually become democratized by the integration of workflow automation, improvements in sequencing technology, and information technology (IT).

Speaking of which, IT itself is about to play an increasing role in how and to whom our results are delivered (section X). A rapid molecular result is only as good as the downstream action taken in the treatment and management of patients. As we speak, patients in London, along with providers, are getting "push notifications" of results from their sexual health tests, resulting in a dramatically shortened time to therapy. Cloud-based aggregation of molecular test data is providing snapshots of emerging pathogens and drug resistance in real time by collecting de-identified test data directly from testing platforms. From the respiratory cloud to the digital cloud, we are watching the emergence of a new generation of global surveillance capabilities which will be of enormous public health benefit. Rapid detection technologies are also likely to evolve in the direction of on-demand multiplexing for simultaneous detection of treatment-informing targets. The convergence of rapid molecular assays with improvements in IT to deliver actionable information to health care providers is becoming a reality.

In 2015, the White House announced a $20 million prize for innovative diagnostic tests that will lead to more precise antimicrobial therapeutic decisions. In addition, the United Kingdom has announced the Longitude Prize, a challenge with a £10 million award for developing a point-of-care diagnostic test that also will identify when antibiotics are needed and which one to use. Thus, it seems that the importance of molecular diagnostic testing is finally being appreciated at the highest levels, especially to address the global problem of antimicrobial resistance. Let's not disappoint them.

Novel and Emerging Technologies

Molecular Microbiology: Diagnostic Principles and Practice, 3rd Edition
Edited by David H. Persing et al.

10.1128/9781555819071.ch1

Nucleic Acid Amplification Methods Overview

FREDERICK S. NOLTE AND CARL T. WITTWER

1

The development of the polymerase chain reaction, or PCR, by Saiki et al. (1) was a milestone in biotechnology and heralded the beginning of the modern era of molecular diagnostics. Although PCR is the most widely used nucleic acid amplification strategy, other strategies have been developed, and several have clinical utility. These strategies are based on either signal or target amplification. Examples of each category will be discussed in the sections that follow. These techniques have sensitivity unparalleled in laboratory medicine, have created new opportunities for the clinical laboratory to impact patient care, and have become the new "gold standards" for laboratory diagnosis of many infectious diseases.

SIGNAL AMPLIFICATION TECHNIQUES

In signal amplification methods, the concentration of the probe or target does not increase. The increased analytical sensitivity comes from increasing the concentration of labeled molecules attached to the target nucleic acid. Multiple enzymes, multiple probes, multiple layers of probes, and reduction of background noise have all been used to enhance target detection (2). Target amplification systems generally have greater analytical sensitivity than signal amplification methods, but technological developments, particularly in branched DNA (bDNA) assays, lowered the limits of detection to levels that rivaled those of some earlier target amplification assays (3).

Signal amplification assays have several advantages over target amplification assays. In signal amplification systems, the number of target molecules is not altered, and as a result, the signal is directly proportional to the amount of the target sequence present in the clinical specimen. This reduces concerns about false-positive results due to cross-contamination and simplifies the development of quantitative assays. Since signal amplification systems are not dependent on enzymatic processes to amplify the target sequence, they are not affected by the presence of enzyme inhibitors in clinical specimens. Consequently, less cumbersome nucleic acid extraction methods may be used. Typically, signal amplification systems use either larger probes or more probes than target amplification systems and, consequently, are less susceptible to errors resulting from target sequence heterogeneity. Finally, RNA levels can be measured directly without the synthesis of a cDNA intermediate.

Frederick S. Nolte, Department of Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC 29425. **Carl T. Wittwer,** Department of Pathology, University of Utah Medical School, Salt Lake City, UT 84132.

bDNA

The bDNA signal amplification system is a solid-phase, sandwich hybridization assay incorporating multiple sets of synthetic oligonucleotide probes (4). The key to this technology is the amplifier molecule, a bDNA molecule with 15 identical branches, each of which can bind to three labeled probes.

The bDNA signal amplification system is illustrated in Fig. 1. Multiple target-specific probes are used to capture the target nucleic acid onto the surface of a microtiter well. A second set of target-specific probes also binds to the target and to preamplifier molecules, which in turn bind to up to eight bDNA amplifiers. Three alkaline phosphatase-labeled probes hybridize to each branch of the amplifier. Detection of bound labeled probes is achieved by incubating the complex with dioxetane, an enzyme-triggerable substrate, and measuring the light emission in a luminometer. The resulting signal is directly proportional to the quantity of the target in the sample. The quantity of the target in the sample is determined from an external standard curve.

Nonspecific hybridization of any of the amplification probes and nontarget nucleic acids leads to amplification of the background signal. To reduce potential hybridization to nontarget nucleic acids, isocytidine (isoC) and isoguanosine (isoG) were incorporated into the preamplifier, and labeled probes were used in the third-generation bDNA assays (5). IsoC and isoG form base pairs with each other but not with any of the four naturally occurring bases (6).

The use of isoC- and isoG-containing probes in bDNA assays increases target-specific signal amplification without a concomitant increase in the background signal, thereby greatly enhancing the detection limits without loss of specificity. The detection limit of the third-generation bDNA assay for human immunodeficiency virus type 1 (HIV-1) RNA is 75 copies/ml. bDNA assays for the quantification of hepatitis B virus DNA, hepatitis C virus (HCV) RNA, and HIV-1 RNA are commercially available (Siemens Healthcare Diagnostics, Deerfield, IL). The SiemensVersant 440 analyzer for bDNA assays automates the incubation, washing, reading, and data-processing steps.

Hybrid Capture

The hybrid capture system is a solution hybridization-antibody capture method that uses chemiluminescence

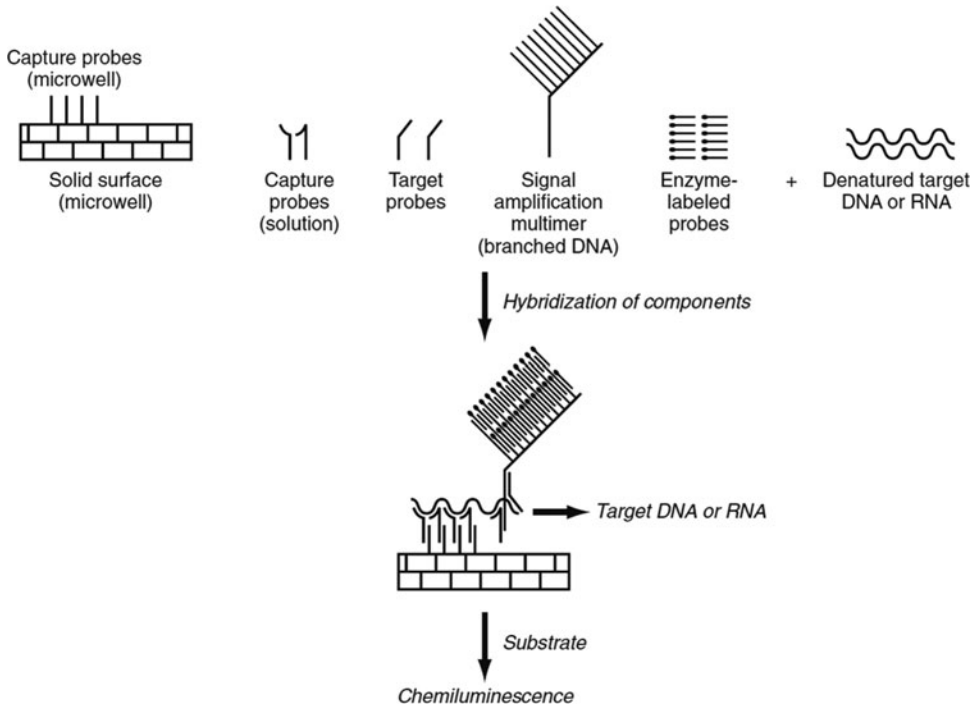

FIGURE 1 Branched DNA signal amplification. Reprinted with permission from reference 70.

detection of hybrid DNA-RNA duplexes (Fig. 2). The target DNA in the specimen is denatured and then hybridized with a specific RNA probe. The DNA-RNA hybrids are captured by antihybrid antibodies that are used to coat the surface of a tube. Alkaline phosphatase-conjugated antihybrid antibodies bind to the immobilized hybrids. The bound antibody conjugate is detected with a chemiluminescent substrate, and the light emitted is measured in a luminometer. Multiple alkaline phosphatase conjugates bind to each hybrid molecule, amplifying the signal. The intensity of the emitted light is proportional to the amount of target DNA in the specimen. Hybrid capture assays for detection of *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and human papillomavirus in clinical specimens are available from Qiagen, Germantown, MD (7). There are manual and automated (rapid capture system) versions of these assays.

Cleavase-Invader Technology

Invader assays (Hologic/Gen-Probe, San Diego, CA) are based on a signal amplification method that relies upon the specific recognition and cleavage of particular DNA structures by cleavase, a member of the FEN-1 family of DNA polymerases. These polymerases will cleave the 5′ single-stranded flap of a branched base-paired duplex. This enzymatic activity likely plays an essential role in the elimination of the complex nucleic acid structures that arise during DNA replication and repair. Since these structures may occur anywhere in a replicating genome, the enzyme recognizes the molecular structure of the substrate without regard to the sequence of the nucleic acids making up the DNA complex (8, 9).

In the invader assays, two probes are designed which hybridize to the target sequence in an overlapping fashion (Fig. 3). Under the proper annealing conditions, the probe oligonucleotide binds to the target sequence. The invader oligonucleotide probe is designed such that it hybridizes upstream of the probe with a region of overlap between the 3′ end of the invader and the 5′ end of the probe. Cleavase cleaves the 5′ end of the probe and releases it. It is in this way that the target sequence acts as a scaffold upon which the proper DNA structure can form. Since the DNA structure necessary to serve as a cleavase substrate will occur only in the presence of the target sequence, the generation of cleavage products indicates the presence of the target. Use of a thermostable cleavase enzyme allows reactions to be run at temperatures high enough for a primer exchange equilibrium to exist. This allows multiple cleavase products to form off of a single target molecule. FRET probes and a second invasive cleavage reaction are used to detect the target-specific products. FDA-cleared assays for detection of pools of high-risk genotypes and types 16 and 18 of human papillomavirus in cervical samples are available from Hologic/Gen-Probe (10, 11).

TARGET AMPLIFICATION TECHNIQUES

All of the target amplification systems share certain fundamental characteristics. They use enzyme-mediated processes, in which a single enzyme or multiple enzymes synthesize copies of a target nucleic acid. In all of these techniques, amplification is initiated by two oligonucleotide primers that bind to complementary sequences on opposite strands of double-stranded targets. These techniques result in the production of millions to billions of copies of the targeted sequence in a matter of minutes to hours, and in each case, the amplification products can serve as templates for subsequent rounds of amplification. Because of this, these techniques are sensitive to contamination with product molecules that can lead to false-positive reactions. The potential for contamination should be adequately addressed before these techniques are used in the clinical laboratory. However, the occurrence of false-positive reactions

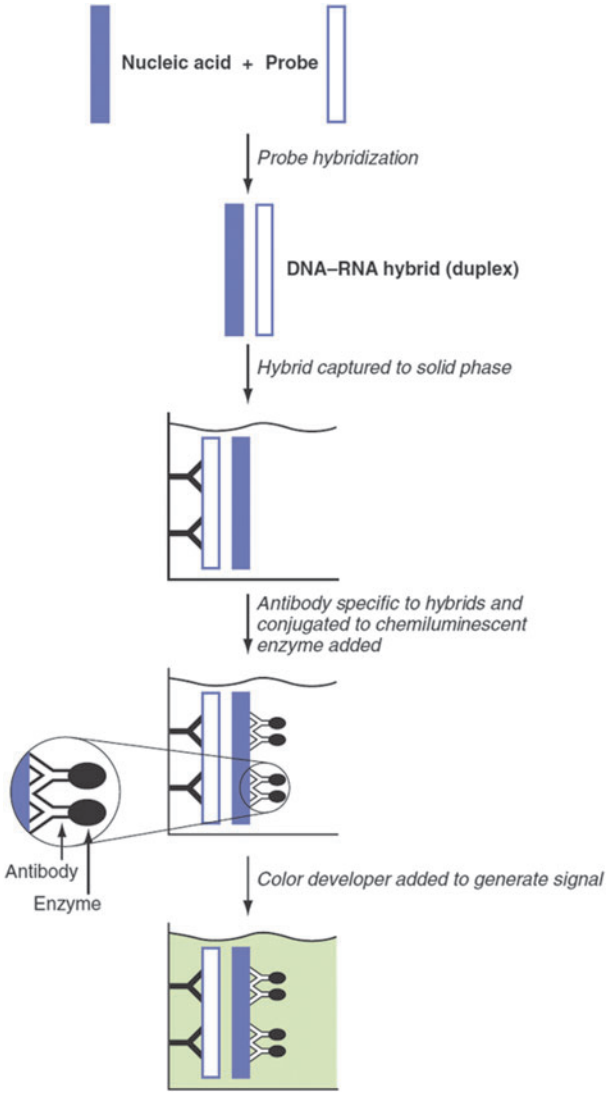

FIGURE 2 Hybrid capture signal amplification. Reprinted with permission from reference 70.

can be reduced through special laboratory design, practices, and workflow (12). In addition, amplification products can be modified by UV light or enzymes into forms that cannot be replicated. For example, if T is replaced with U during the PCR, it can be treated later by an enzyme that degrades U containing carryover products to prevent false-positive reactions (13). The growing use of closed systems where products are not exposed to the environment also helps to greatly reduce the threat of carryover contamination.

PCR

PCR was the first target amplification technique and remains the most popular today, for both research and clinical applications. It deserves such recognition and use because of its simplicity. Kary Mullis received the Nobel Prize in 1993 for its invention. The evolution and development of PCR is covered nicely by many books dedicated to the subject (14–16).

PCR requires a thermostable polymerase, two oligonucleotide primers to select the region to be amplified, a mixture of deoxynucleotide monomers (dNTPs), and template DNA. The polymerase is typically from *Thermus aquaticus*, originally obtained from Yellowstone National Park and later cloned into expression vectors for production. The two primers anneal to opposite DNA strands, typically placed 50 to 1,000 bases apart to select the region to be amplified. Typical reactant concentrations for PCR are shown in Table 1.

PCR is driven by temperature changes. The initial template is denatured or separated by heat (typically 90 to 95°C), lowering the temperature is required for primer annealing (55 to 65°C), and enzyme extension is typically performed at 65 to 75°C. Three-step cycling is performed if all three temperatures are different, although two-step cycling with a combined annealing/extension step is also common in diagnostics. Repeated temperature cycling through denaturation, annealing, and extension accumulates many identical products of defined length (Fig. 4). The products are most commonly detected by agarose gel electrophoresis, hybridization to complementary nucleic acids on solid supports, or probe interaction in solution. For example, if products are sampled during one cycle of PCR and separated on a gel, the process within each cycle can be observed visually (Fig. 5).

The advantages of PCR include simplicity, speed (17), and cost. Basic PCR is off-patent, and most forms of real-time PCR will be off-patent by the time this chapter goes to print. PCR as a process is very similar to bacterial growth. Both processes begin with exponential growth that eventually plateaus (Fig. 6). Growth curves follow a familiar S-curve shape tracking the logistic model of population growth. Although the endpoints of bacterial growth in media and amplification of DNA *in vitro* by PCR are different, they follow the same curve shape. Accurate quantification of the initial template is enabled by controlling denaturation, annealing, and extension by temperature cycling so that each amplification cycle can be measured and overall efficiency calculated.

PCR is clinically used in most laboratory-developed tests and *in vitro* diagnostic tests for infectious diseases. A complete list of all FDA-cleared or -approved nucleic acid amplification tests for detection, quantification, and genotyping of microorganisms can be found at http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm330711.htm.

Reverse Transcriptase-PCR

When the initial template is RNA instead of DNA, an initial conversion of RNA into DNA is necessary for PCR. This conversion is performed by an RNA-dependent DNA polymerase, and the combined process is called reverse transcriptase PCR or RT-PCR. It can be performed in one or two steps. Two-step RT-PCR is typical of most research studies with two different enzymes and conditions optimized for each. One-step RT-PCR is more common for clinical assays where both the reverse transcription and the PCR are performed in a single tube. RT-PCR enables PCR to amplify common RNA targets, including HIV-1, HCV, enterovirus, and many respiratory viruses. The added complexity does require greater care, especially for viral load and other quantification assays. The MIQE guidelines (Minimum Information for Quantitative PCR Experiments) ensure the integrity of the scientific literature, promote consistency between laboratories, and increase

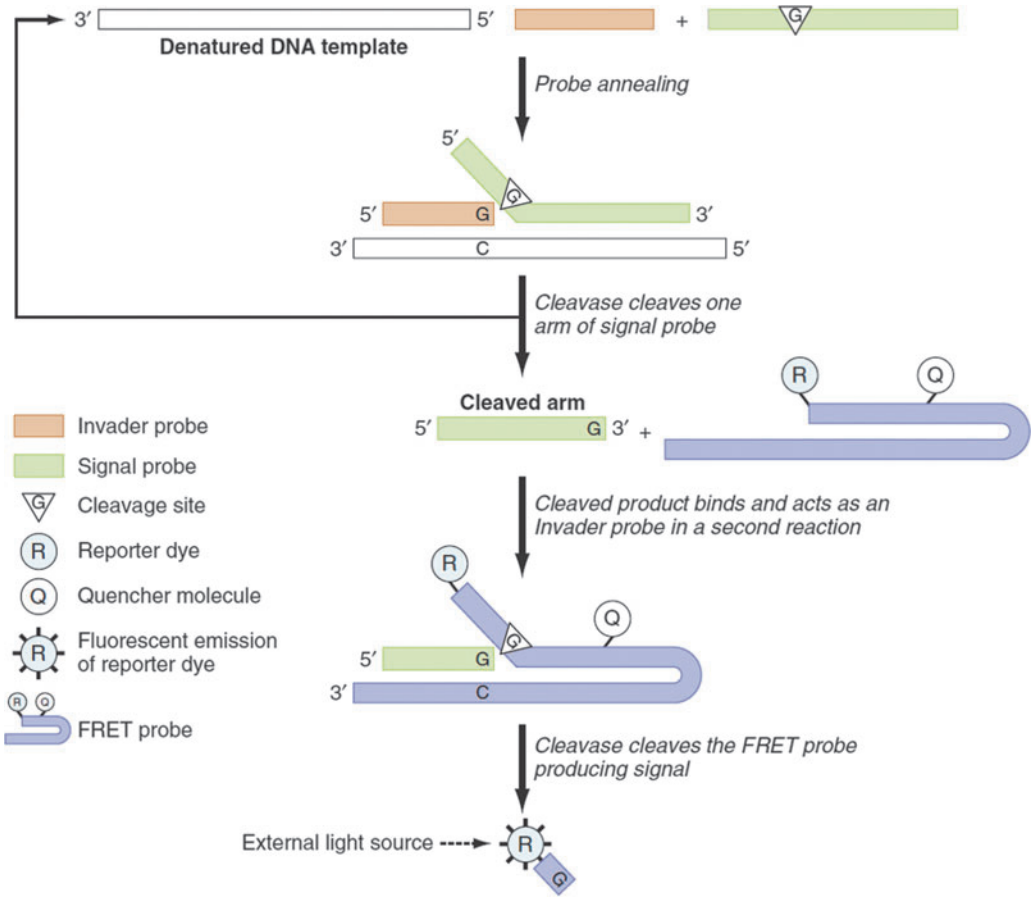

FIGURE 3 Cleavase invader signal amplification. Reprinted with permission from reference 70.

experimental transparency (18). Although written for the research community, these guidelines remain relevant for clinical assays.

Nested PCR

If PCR is followed by a second round of PCR on the products of the first, it is called nested PCR. Typically, both primers in the second PCR are internal to the first, so successful amplification depends on four primers rather than two. However, if one of the primers in the second PCR is the same as the first, it is called "hemi-nested" PCR. The advantage of nested or hemi-nested PCR is a further increase in sensitivity and specificity. The main disadvantage is an increased risk of carryover contamination, and the only nested tests that are FDA-approved are closed-tube real-time systems. The Cepheid MTB/RIF test is hemi-nested and detects *Mycobacterium tuberculosis* and rifampin resistance in <2 h (19). Nested, multiplex panels for respiratory agents (20), positive blood culture bottles (21), and gastrointestinal microbes are also FDA-approved with sample-to-answer results in about an hour and were developed by BioFire Diagnostics, Salt Lake City, UT/bioMérieux, Durham, NC.

Multiplex PCR

When more than one target is amplified by PCR, the process is called "multiplex." Multiplexing can save reagents and sample and is often used when a more complete answer can be obtained by including additional targets. Multiplexing is analyzed by separating products by size on a gel, by spatial separation on a surface or beads, or by probe color in real-time PCR. Real-time PCR is typically limited

TABLE 1 Typical reactant amounts in PCR (10-µl reaction mixture)

Reactant	Type	No. of copies/10 µl
Template DNA	50 ng of human DNA	1.6×10^4
	50 pg of bacterial DNA (3 Mb)	
	0.17 pg of viral DNA (10 kb)	
Polymerase	0.4 U of *Taq*	8.8×10^9
Primers	0.5 µM (each)	3.0×10^{12} (each)
Deoxynucleoside triphosphates	0.2 mM (each)	4.8×10^{15} (total)

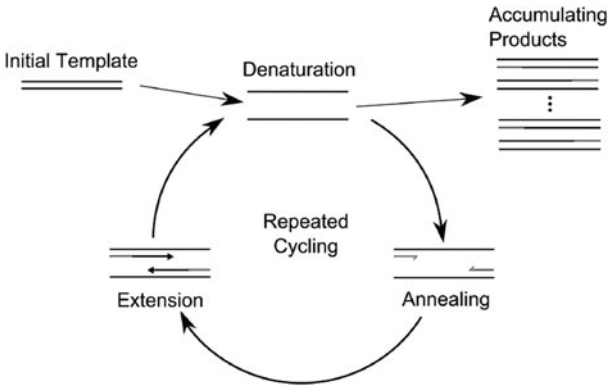

FIGURE 4 The PCR cycle. The initial template DNA is first denatured by heat. The reaction is then cooled to anneal two oligonucleotide primers to opposite strands with their 3′ ends pointed inward. A polymerase then extends each primed template to double the amount of targeted DNA. The cycle is repeated 20 to 40 times through successive steps of denaturation, annealing, and extension, accumulating double-stranded PCR products. Reprinted with permission from reference 16.

to two to six colors, but greater multiplicity is possible by combining color with the melting temperatures of the probes.

One example of multiplexed PCR with clinical utility is for upper respiratory infection. Many viruses and bacteria can cause flu-like illness, and a panel may provide a definitive answer in one multiplexed test. The first multiplexed respiratory panel was FDA-approved in 2008 with 10 viruses (Luminex, Austin, TX). Additional PCR-based respiratory panels are now offered by many companies including Cepheid, Sunnyvale, CA; GenMark Dx, Carlsbad, CA; Nanosphere, Northbrook, IL; Gen-Probe/Hologic, San Diego, CA; and BioFire/biomérieux. BioFire/biomérieux's nested multiplex respiratory panel is most inclusive, with 17 viruses and 3 bacteria (20).

Real-Time PCR

"Real time" implies that data collection and analysis occur as a reaction proceeds. Required reagents for analysis, such as DNA dyes or fluorescent probes, are added to the PCR mixture before amplification. Data are collected during amplification in the same tube and in the same instrument. There are no sample transfers, reagent additions, or gel separations. Real-time PCR is powerful, simple, and rapid and is replacing many conventional techniques in the microbiology laboratory.

Fluorescence is the indicator of choice for real-time PCR. Dyes can be used to monitor double-stranded PCR products, acquiring fluorescence once each cycle (22). If target DNA is present, the fluorescence increases. How soon this rise occurs depends on the initial amount of target DNA. The full power of real-time PCR goes beyond monitoring only once each cycle (23). When fluorescence is monitored as the temperature is changing, melting curves can verify the product amplified and detect sequence variants down to a single base. An example of the data generated from real-time PCR with melting analysis is shown in Fig. 7.

dsDNA Binding Fluorescent Dyes

In research, most real-time PCR is performed with dyes that fluoresce in the presence of double-stranded DNA because of their low cost and convenience (23). However, FDA-approved assays typically use probes instead of dyes. With dyes, any double-stranded product that is formed is detected, including primer dimers and other unintended products. Unless melting analysis of the product is performed, false positives are common (24). Multiplexing is possible by melting temperature discrimination rather than color (25). The mechanism of dye fluorescence during real-time PCR is compared to several probes in Fig. 8.

Hydrolysis (TaqMan) Probes

The most common probes used in FDA-approved real-time PCR assays are hydrolysis probes. If a probe labeled with a

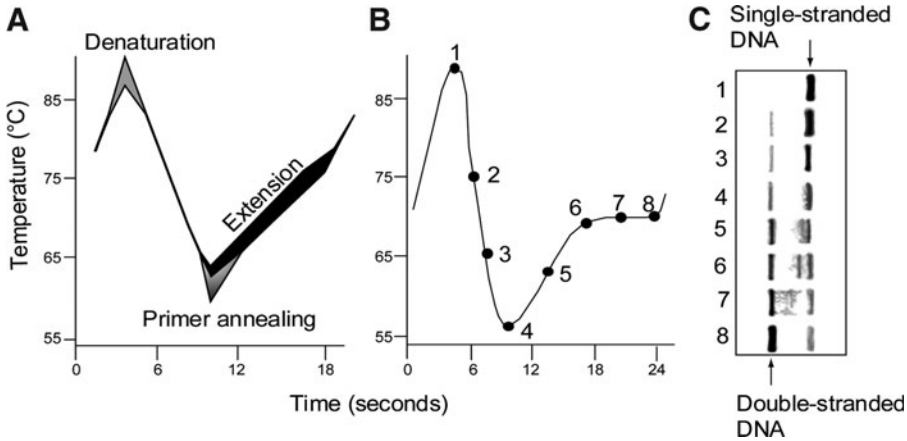

FIGURE 5 Visualization of PCR kinetics. The three phases of PCR (denaturation, annealing, and extension) occur as the temperature is continuously changing (A). Toward the end of PCR the reaction contains single- and double-stranded PCR products. When different points of the cycle are sampled (by snap-cooling the mixture in ice water) (B) and analyzed, the transition from denatured single-stranded DNA to double-stranded DNA is revealed as a continuum (C). Progression of the extension reaction can be followed by additional bands appearing between the single- and double-stranded DNA (time points 5 to 7). Modified with permission from reference 71.

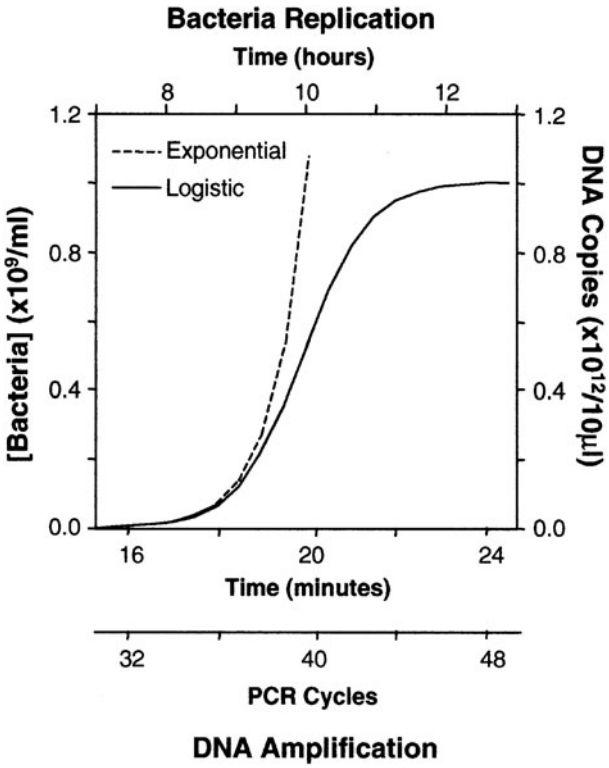

FIGURE 6 Model exponential and logistic curves for bacterial growth and PCR. Doubling times of 20 min and 30 s are assumed for bacteria and PCR, respectively. That is, given the equation $Nt = N_0e^{rt}$, r is 0.0347 min^{-1} for bacteria and 1.386 min^{-1} for PCR. The carrying capacity for bacteria was set at 10^9/ml. Assuming that PCR is primer limited at one-third the primer concentration (Table 1), a carrying capacity of 10^{12} copies of PCR product/10 µl was used. The shapes of the curves for bacteria and DNA are identical, with only the axis scales specific to each method. Starting with a single bacterium, growth plateaus after 11 to 12 h, while PCR takes only 23 min (46 cycles) to amplify a single copy to saturation.

fluorophore and a quencher is hydrolyzed during PCR and the labels are separated, fluorescence will increase. The most frequent implementation uses the 5′-exonuclease activity of a DNA polymerase to hydrolyze the probe and dissociate the labels (26). Another interesting way to hydrolyze fluorescent probes is to produce a DNAzyme during PCR (27). The fluorescence generated by hydrolysis probes is irreversible, and melting analysis is typically not useful. Hydrolysis probes are diagrammed in Fig. 8B.

Dual Hybridization Probes

Hybridization probes change fluorescence on hybridization, usually by fluorescence resonance energy transfer. Two interacting fluorophores are typically placed on adjacent probes (23) so that when they both hybridize, the fluorophores are brought together and energy transfer occurs, changing the color of the emitted fluorescence. Dual hybridization probes were used in the first FDA-approved genetic tests and, along with hydrolysis probes and molecular beacons, are found in many laboratory-developed microbiology tests (28). They are also used in the Roche (Indianapolis, IN) FDA-approved methicillin-resistant *Staphylococcus aureus* (MRSA) test. In contrast to hydrolysis probes, the fluorescence change of hybridization probes is reversible, and melting analysis can be very informative for strain typing and/or antibiotic resistance. Dual hybridization probes are shown in Fig. 8C.

Molecular Beacons

Molecular beacons (hairpin probes) fluoresce when they hybridize to a target (29). A fluorophore and a quencher are present on opposite strands of the stem, typically at the 3′ and 5′ ends of the probe. When the loop hybridizes to the target of interest, the fluorophore and quencher are separated, enhancing fluorescence. Molecular beacons of different colors can be combined with melting temperature for highly multiplexed assays (30). Molecular beacons are used in FDA-approved assays for *M. tuberculosis* and MRSA (Cepheid) and are shown in Fig. 8D.

Scorpion Probes

The fluorescence generated during PCR from self-probing amplicons (31) also depends on separating a fluorophore and a quencher on opposite ends of a hairpin stem. With scorpions, the primer is modified at its 5′ end to include a labeled hairpin similar to a molecular beacon. A blocker prevents copying of the hairpin region during PCR. The hairpin loop is complementary to the primer's extension product, so intramolecular hybridization occurs, replacing one hairpin with another that has a longer stem and is more stable. This separates the fluorophore from the quencher, and fluorescence is increased (Fig. 8E). Scorpion probes are used in FDA-approved assays for group B *Streptococcus* (BD Diagnostics, Franklin Lakes, NJ), *Clostridium difficile* (Focus Diagnostics, Cypress, CA), and some molecular oncology assays.

Dark Quencher Probes

Dark quencher (Pleiades) probes have a minor-groove binder and fluorophore at their 5′ end with a 3′ nonfluorescent quencher. Background fluorescence is very low because hydrophobic attraction between the quencher and minor groove binder ensures efficient quenching, further augmented by the minor groove binder (Fig. 8F). When bound to a target, the fluorophore and quencher are separated, similar to molecular beacons or scorpion primers. The minor groove binder also increases probe stability, making shorter probes possible. Short probes can be an advantage when sequence variation is high. Dark quencher probes are not degraded during PCR and can generate melting curves. Dark quencher probes (ELITech Group, Princeton, NJ) are available as analyte-specific reagents for cytomegalovirus, Epstein-Barr virus, and BK polyomavirus.

Partially Double-Stranded Probes

Partially double-stranded linear probes consist of two complementary oligonucleotides of different length (32). The longer target-specific strand has a 5′ fluorescent label that is effectively quenched by a 3′ quencher on the shorter negative strand (Fig. 8G). When a target is present the longer strand preferentially binds to the target, the shorter strand is displaced, and fluorescence is enhanced. These probes are tolerant to mismatches and are used in FDA-approved assays for HIV-1 and HCV (Abbott Molecular, Des Plaines, IL).

Melting Curve Analysis

Continuous monitoring of PCR (Fig. 9) suggests that hybridization can be followed during temperature cycling

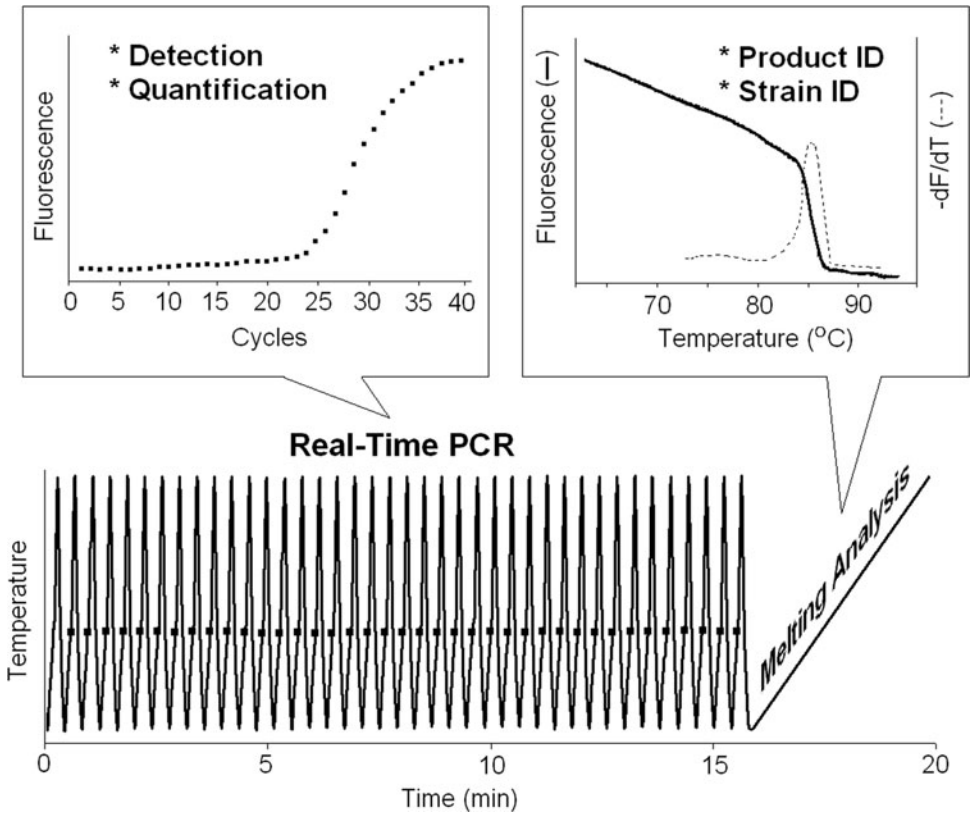

FIGURE 7 Real-time PCR with melting analysis. Detection and quantification are enabled by monitoring fluorescence once each cycle at the end of extension (solid squares). Amplification is immediately followed by melting-curve acquisition. Melting-curve analysis identifies PCR products, microbial strains and sequence alterations by melting temperature. The original melting-curve data (solid line) can also be plotted as a derivative melting curve (dotted line). Reprinted from reference 72 with permission from the American Society of Investigative Pathology and the Association for Molecular Pathology.

with dyes and most probes. Hydrolysis probes are the exception because they are destroyed during signal generation. Instead of monitoring hybridization throughout PCR, a single melting analysis after PCR is typically performed (Fig. 7). The midpoint of melting, called the melting temperature, or T_M, is determined mainly by the GC content and size of the duplex region. DNA melting curve analysis takes advantage of the fluorimeters and temperature control of real-time PCR instruments (17, 23, 24).

Product melting with dyes is useful to confirm PCR specificity by T_M and curve shape. Both T_M and curve shape can be predicted (33). PCR products of >200 bp often have multiple melting domains, and heterozygous products create heteroduplexes, both affecting curve shape. High-resolution melting analysis uses subtle differences in T_M and curve shape for genotyping and mutation scanning (34). Although usually a research technique, high-resolution melting is used in FDA-approved nested, multiplex assays for upper respiratory, blood culture, and gastrointestinal microbes (BioFire/bioMérieux).

Probe melting distinguishes variants only under the probe as opposed to the entire PCR product. For example, single nucleotide variants can be genotyped with hybridization probes because different sequences are revealed by different T_Ms. Irrelevant sequence variants under the probe can be masked by a deletion, mismatch, or universal base (35). Labeled hybridization probes include the dual hybridization probes of Fig. 8C and several single hybridization probes including molecular beacons (Fig. 8D), scorpion primers (Fig. 8E), dark quenchers (Fig. 8F), and partially double-stranded probes (Fig. 8G). Genotyping with labeled hybridization probes is shown in Fig. 10A and B. In parallel to labeled probes, melting and genotyping can also be performed with simple dyes rather than covalent labels. Examples include unlabeled probes (Fig. 10C) and snapback primers (Fig. 10D).

Unlabeled probes have no fluorescent labels but are 3′ blocked with a phosphate or other blocker (36). Unlabeled probes have been used for herpes simplex virus detection and typing (37) and in model studies have distinguished up to 10 variants (34). Similar to scorpion primers, "snapback primers" (Fig. 10D) generate a self-probing amplicon that forms a hairpin (38). Snapback primers achieve probe specificity with only two primers, one of which has a simple 5′ extension without any covalently attached fluorophores. Only amplicon melting is conceptually simpler (Fig. 10E), but the smaller differences between variants usually require high-resolution melting. Melting curves of unlabeled probe and snapback primers show both product and probe melting transitions, providing synergistic information for PCR variant identification (39).

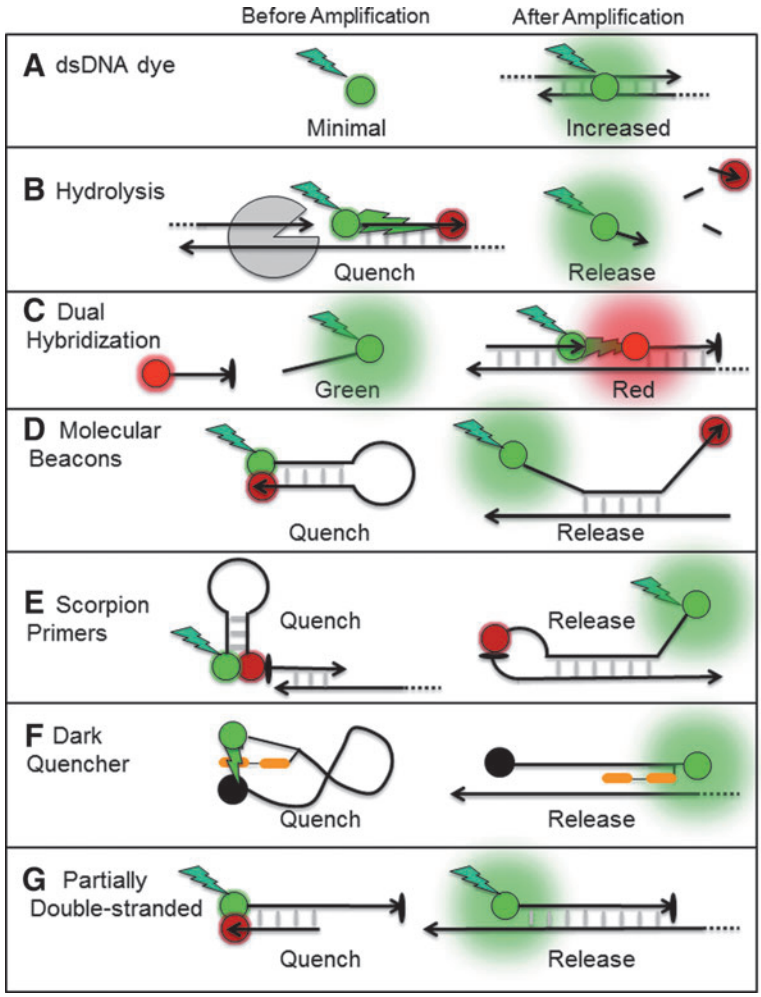

FIGURE 8 Common probes and dyes for real-time PCR. The green lightning bolt is the excitation light. The green circles are fluorophores, the dark red circles are quenchers, and the black circles are dark quenchers. The large hungry gray circle is a polymerase with 5′ to 3′ exonuclease activity. The thin black ovals are blockers, and the orange sausages are minor groove binders. (A) Double-stranded DNA dyes show a significant increase in fluorescence when bound to DNA. (B) Hydrolysis probes are cleaved between a fluorescent reporter and a quencher, resulting in increased fluorescence. (C) Dual hybridization probes change color by resonance energy transfer when hybridized. (D) The molecular beacon hairpin quenches fluorescence until target binding that separates the quencher from the flourophore. (E) Scorpion primers are quenched in the native conformation but increase in fluorescence when the original hairpin loop is hybridized to its extension product. (F) Dark quencher probes are initially quenched by a minor groove binder and the dark quencher. Hybridization to the target releases the fluorescence. (G) The short strand of partially double-stranded probes is displaced in the presence of target, releasing fluorescence from quenching.

Digital PCR

The sensitivity of real-time PCR, defined as a 95% detection rate, cannot be better than three copies per reaction because of variable partitioning of templates into any particular reaction (18). Digital PCR, however, uses partitioning to its advantage by running many PCRs with an average copy number typically between 0 and 1 (40). Each reaction is either positive or negative. Digital PCR can precisely determine the number of copies of a template (or variant) present at less than one copy per reaction if enough reactions are performed. Instruments that divide microliter PCR volumes into hundreds or millions of nanoliter to picoliter partitions on microfluidic chips or droplets are now available, promising highly sensitive and precise quantification. Digital MIQE guidelines defining the minimal information for publication of quantitative digital PCR experiments emphasize the unique requirements of digital PCR (41). The main uses of digital PCR in microbiology are (i) absolute quantification of reference materials, (ii) quantification of rare variants, for example, the emergence of a drug-resistant variant, and (iii) viral load testing.

Because digital PCR does not depend on a standard curve for absolute quantification, it is an ideal method to establish quantitative reference materials. For example, the U.S. National Institute of Standards and Technology produced a standard reference material for cytomegalovirus quantification by digital PCR (42), and many more are

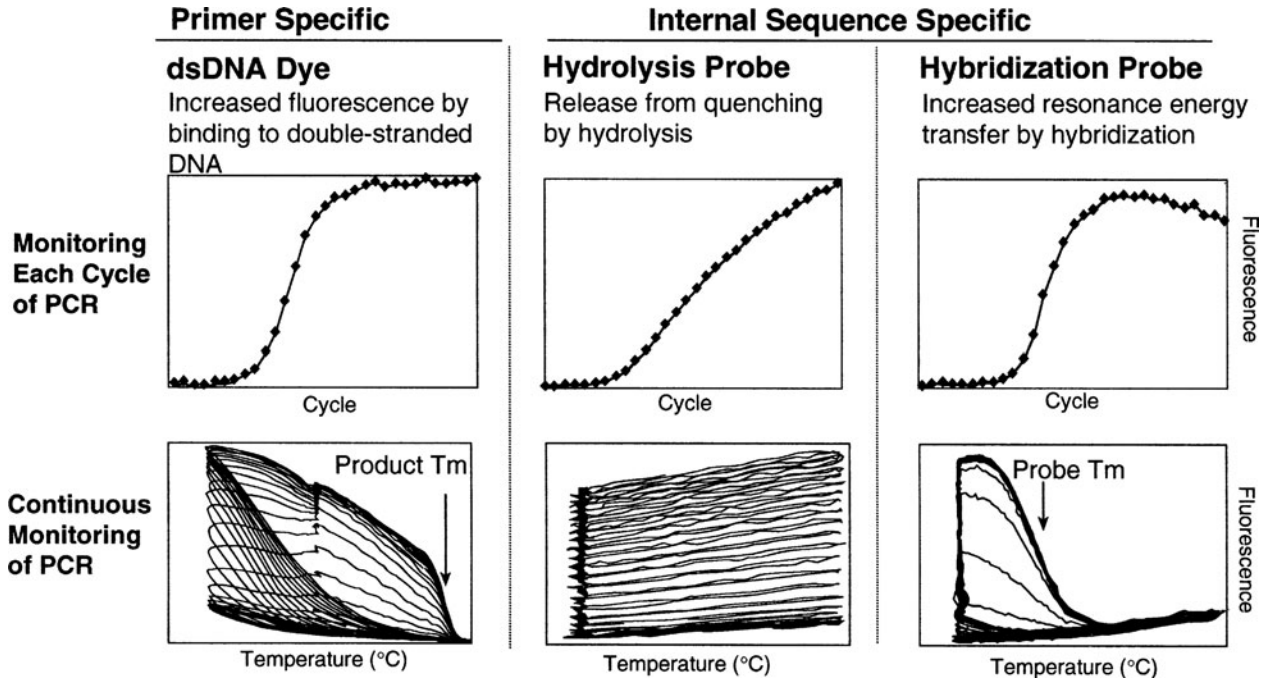

FIGURE 9 Typical real-time PCR amplifications monitored with SYBR Green I, hydrolysis probes, and hybridization probes. Both once-per-cycle and continuously monitored displays are shown. Note the hybridization information inherent in reactions monitored with SYBR Green I and hybridization probes.

likely to follow. Please see the chapter on digital PCR in this book for more details on the methods and clinical applications.

Detecting a small percentage of drug-resistant microbes in a population, or heteroresistance, is challenging by conventional methods. Digital PCR was successfully applied to heteroresistance in M. *tuberculosis*, targeting variants in four genes associated with isoniazid, rifampin, fluoroquinolone, and aminoglycoside resistance (43). Variants were detected at 0.01%, much more sensitive than real-time PCR or sequencing. Similar studies in HIV-1, HCV, and other viruses and bacteria are sure to follow.

Digital PCR for viral load testing has been compared to real-time PCR in several studies. In addition to the more common chip and droplet systems, novel rotational systems provide greater dynamic range, as demonstrated for HIV-1 and HCV (44). The proportion of chromosomally integrated human herpesvirus type 6 (HHV-6) to genomic DNA was precisely determined by digital PCR to prevent misdiagnosis and unnecessary treatment of active HHV-6 (45). Two studies comparing digital to real-time PCR for viral load testing of cytomegalovirus concluded that although there are theoretical advantages to digital PCR, practically clinical results are similar (46, 47).

Transcription-Based Amplification Methods

Nucleic acid sequence-based amplification (NASBA) and transcription-mediated amplification (TMA) are both isothermal RNA amplification methods modeled after retroviral replication (48–50). These methods are similar in that the RNA target is reverse transcribed into cDNA and then RNA copies are synthesized with an RNA polymerase. NASBA uses avian myeloblastosis virus RT, RNase H, and T7 bacteriophage RNA polymerase, whereas TMA uses an RT enzyme with endogenous RNase H activity and T7 RNA polymerase.

Amplification involves the synthesis of cDNA from the RNA target with a primer containing the T7 RNA polymerase promoter sequence (Fig. 11). The RNase H then degrades the initial strand of target RNA in the RNA-cDNA hybrid. The second primer then binds to the cDNA and is extended by the DNA polymerase activity of the RT, resulting in the formation of double-stranded DNA containing the T7 RNA polymerase promoter. The RNA polymerase then generates multiple copies of single-stranded, antisense RNA. These RNA product molecules reenter the cycle, with subsequent formation of more double-stranded cDNA molecules that can serve as templates for more RNA synthesis. A 10^9-fold amplification of the target RNA can be achieved in less than 2 h by this method.

The single-stranded RNA products of TMA in the Hologic/Gen-Probe tests are detected by the hybridization protection assay. Oligonucleotide probes are labeled with modified acridinium esters with either fast or slow chemiluminescence kinetics so that signals from two hybridization reactions can be analyzed simultaneously in the same tube. The probes are added after amplification and hybridize to the amplicons. A selection reagent is then added which differentiates between hydridized and unhybridized probes by inactivating the label on the unhybridized probes. The NASBA products in the bioMérieux tests are detected by hybridization with probes that are added after amplification, labeled with tris (2,2′-bispyridine)ruthenium and detected by electrochemiluminescence. NASBA has also been used with molecular beacons to create a homogeneous, kinetic amplification system similar to real-time PCR (51).

Transcription-based amplification systems have several strengths, including no requirement for a thermal cycler,

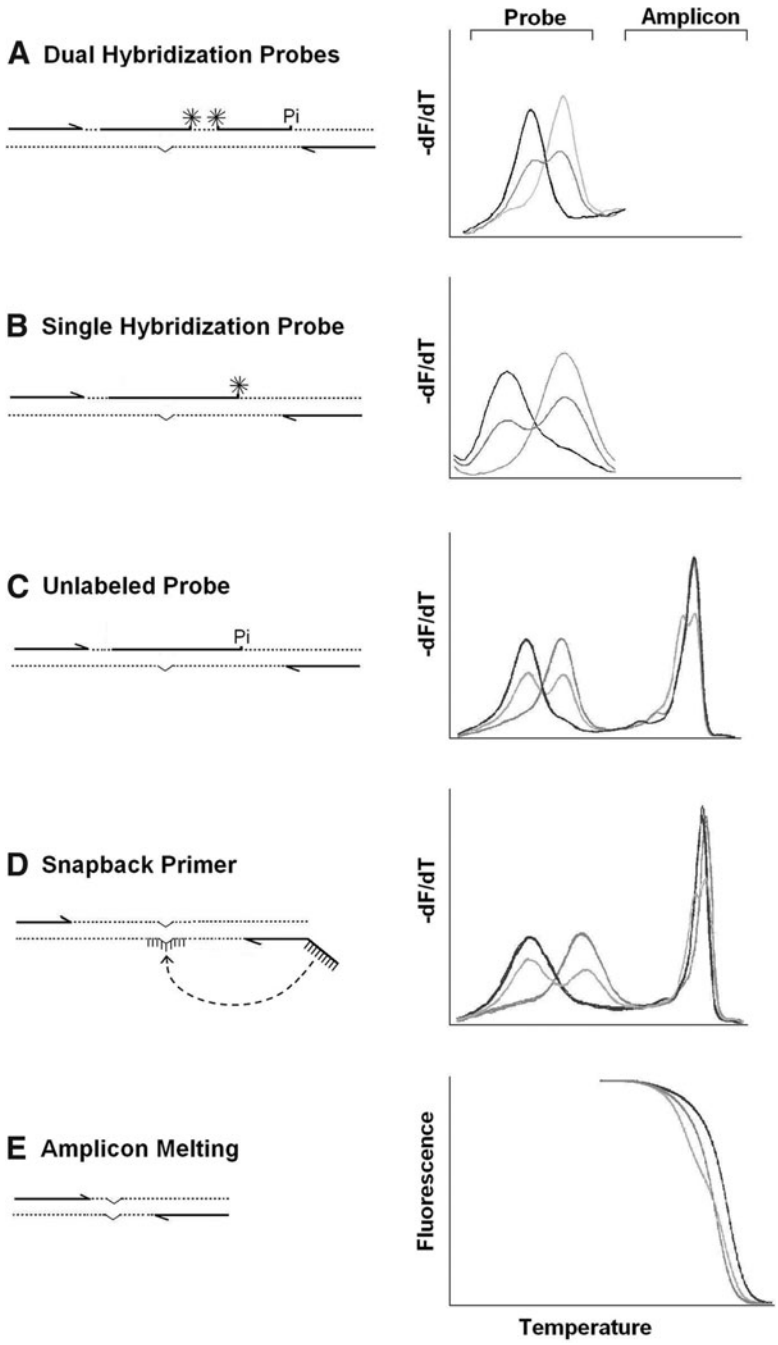

FIGURE 10 Variant typing by melting analysis. Primer and probe designs are shown on the left with typical data on the right. Dual (A) and single (B) hybridization probes use covalent fluorescent labels (asterisks), and typing is solely derived from the probe signal. Single hybridization probes discussed here include molecular beacons, scorpion primers, dark quencher probes, and partially double-stranded probes. Unlabeled probes (C) and snapback primers (D) require no covalent labels because fluorescence is provided by a dye that binds to dsDNA. With unlabeled probes and snapback primers, both probe and PCR product melting transitions are observed and can contribute to typing. Any free 3′ ends on the probes are terminated with a phosphate (Pi) or other blocker to prevent probe extension by the polymerase. The snapback primer (D) incorporates an unlabeled probe into the 5′ end of one primer, generating a self-probing amplicon that forms a hairpin. In panel E, no probe is present, but typing of the PCR product is still possible by high-resolution melting. High-resolution melting identifies heterozygotes by a change in curve shape and distinguishes homozygotes by T_m.

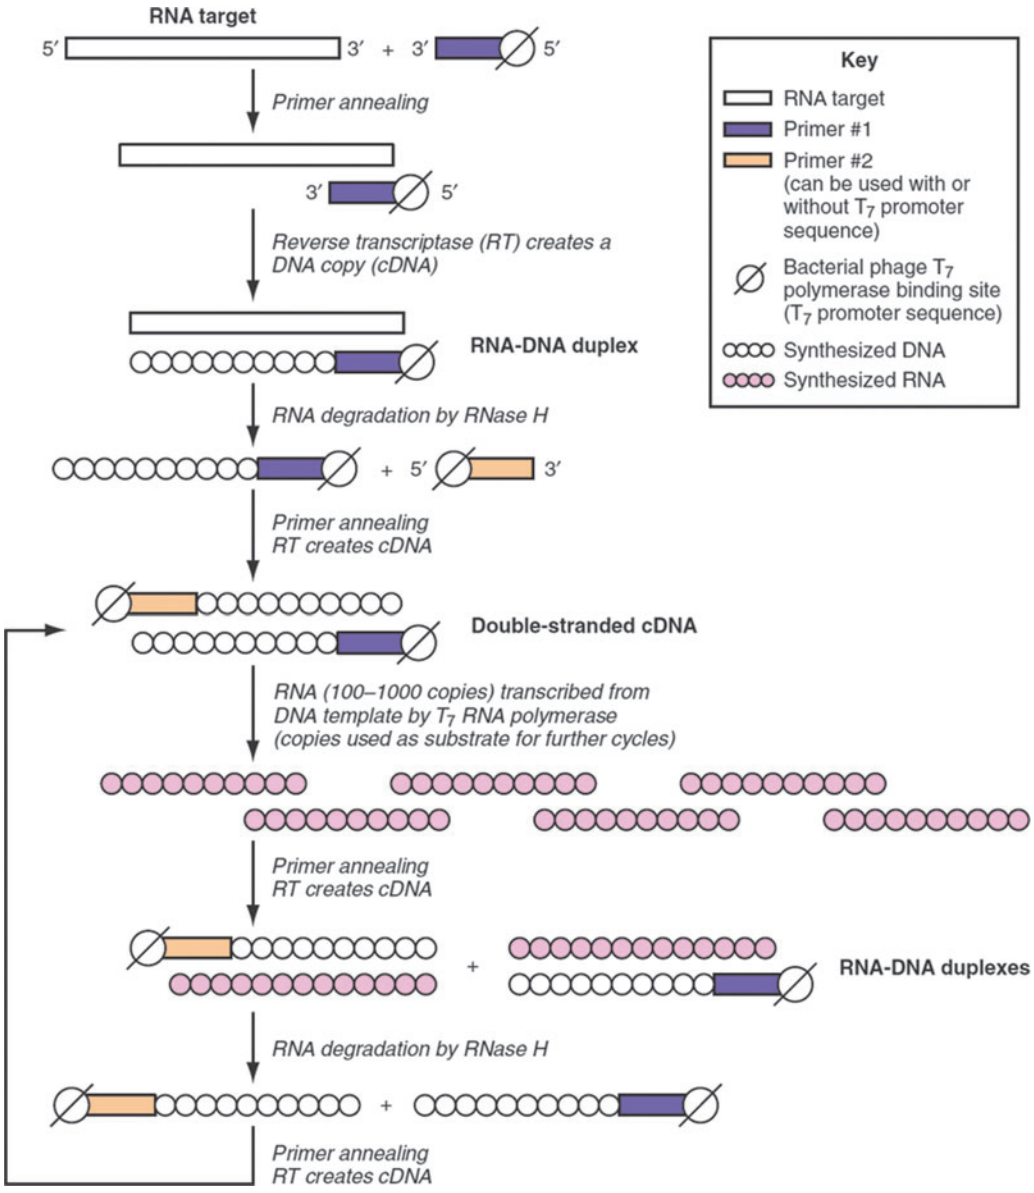

FIGURE 11 Transcription-based target amplification. NASBA and TMA are examples of transcription-based amplification systems. Reprinted with permission from reference 70.

rapid kinetics, and a single-stranded RNA product that does not require denaturation prior to detection. Also, single-tube clinical assays and a labile RNA product may help minimize contamination risks. Limitations include the poor performance with DNA targets and concerns about the stability of complex multienzyme systems. Hologic/Gen-Probe has developed FDA-cleared, TMA-based assays for detection of *M. tuberculosis*, *C. trachomatis*, *N. gonorrhoeae*, human papillomavirus, and *Trichomonas vaginalis*. NASBA-based kits (bioMérieux) for the detection and quantification of HIV-1 RNA and detection of enterovirus and MRSA were developed but are no longer commercially available. A basic NASBA kit is also available for the development of other applications defined by the user. In its latest iteration, NucliSens EasyQ, NASBA is coupled with molecular beacons for real-time amplification and detection of target nucleic acids (52).

Strand Displacement Amplification

Strand displacement amplification (SDA) is an isothermal template amplification technique that can be used to detect trace amounts of DNA or RNA of a particular sequence. SDA, as it was first described, was a conceptually straightforward amplification process with some technical limitations (53). Since its initial description, however, it has evolved into a highly versatile tool that is technically simple to perform but conceptually complex. SDA is the intellectual property of BD Diagnostics.

In its current iteration, SDA occurs in two discrete phases: target generation and exponential target amplification (54). Both are illustrated in Fig. 12. In the target generation phase, a double-stranded DNA target is denatured and hybridized to two different primer pairs, designated as bumper and amplification primers. The amplification primers include the single-stranded restriction endonuclease

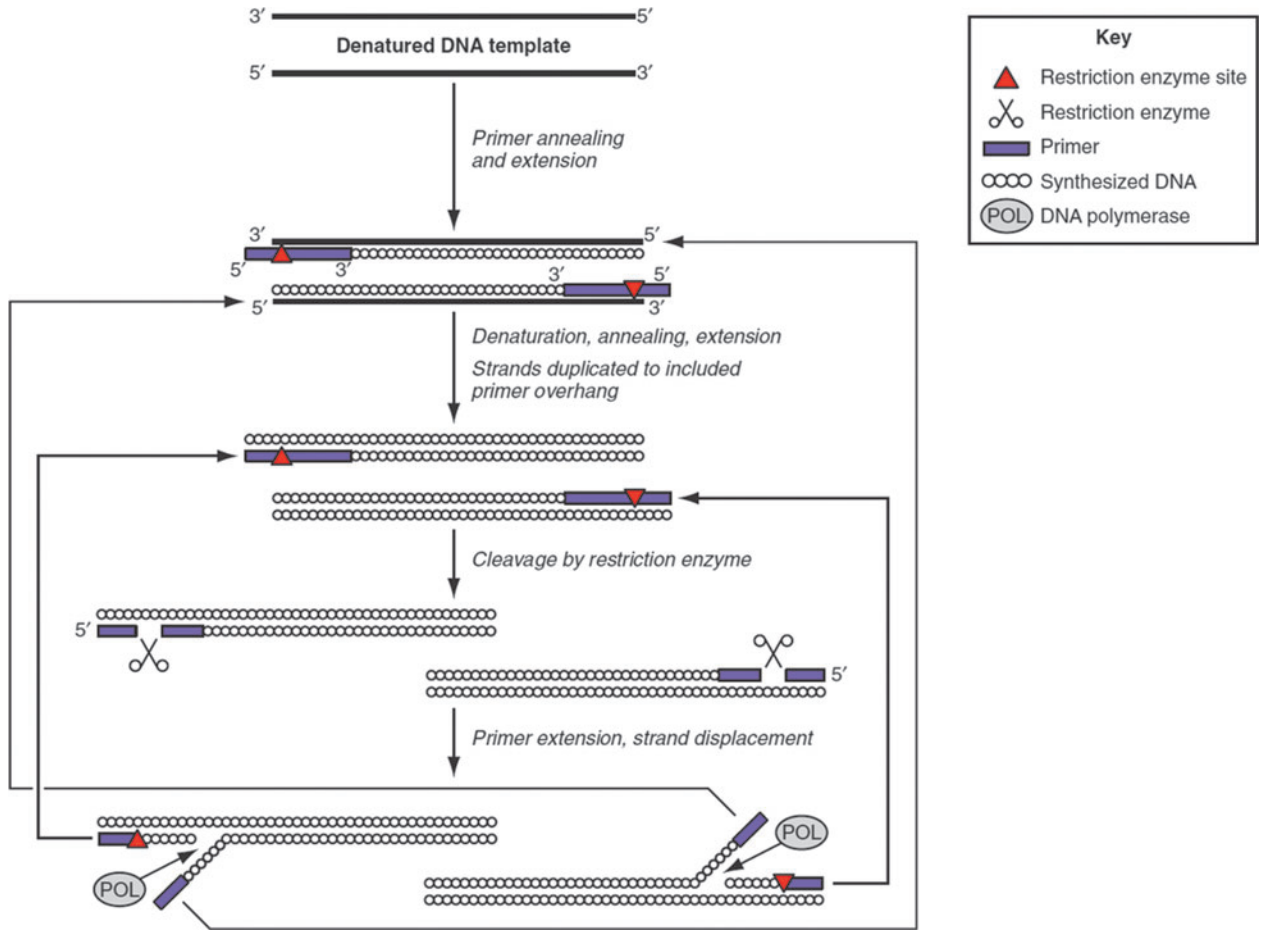

FIGURE 12 Strand displacement target amplification. The process is shown for only one strand of a double-stranded DNA target, but amplification occurs on both strands simultaneously. Reprinted with permission from reference 70.

enzyme sequence for BsoB1 located at the 5′ end of the target binding sequence. The bumper primers are shorter and anneal to the target DNA just upstream of the region to be amplified. In the presence of BsoB1, an exonuclease-free DNA polymerase, and a dNTP mixture consisting of dUTP, dATP, dGTP, and thiolated dCTP (C_s), simultaneous extension products of both the bumper and amplification primers are generated. This process displaces the amplification primer products, which are available for hybridization with the opposite-strand products with the opposite-strand bumper and amplification primers.

The simultaneous extension of opposite-strand primers produces strands complementary to the product formed by extension of the first amplification primer with C_s incorporated into the BsoB1 cleavage site. This product enters the exponential target amplification phase of the reaction. The BsoB1 enzyme recognizes the double-stranded site, but because one strand contains C_s, it is nicked rather than cleaved by the enzyme. The DNA polymerase then binds to the nicked site and begins synthesis of a new strand while simultaneously displacing the downstream strand. This step re-creates the double-stranded species with the hemimodified restriction endonuclease recognition sequence, and the iterative nicking and displacement process repeats. The displaced strands are capable of binding to opposite-strand primers, which produces exponential amplification of the target sequences.

These single-stranded products also bind to detector probes for real-time detection. The detector probes are single-stranded DNA molecules with fluorescein and rhodamine labels. The region between the labels includes a stem-loop structure. The loop contains the recognition site for the BsoB1 enzyme. The target-specific sequences are located 3′ of the rhodamine label. In the absence of a specific target, the stem-loop structure is maintained with the fluorescein and rhodamine labels in close proximity. The net effect is that very little emission for the fluorescein is detected after excitation. After SDA, the probe is converted to a double-stranded species, which is cleaved by BsoB1. The cleavage causes physical separation of the fluorescein and rhodamine labels, which results in an increase in emission from the fluorescein label.

SDA has a reported sensitivity high enough to detect as few as 10 to 50 copies of a target molecule (53). By using a primer set designed to amplify a repetitive sequence with 10 copies in the *M. tuberculosis* genome, the assay is sensitive enough to detect 1 to 5 genome copies from the bacterium. SDA has also been adapted to quantify RNA by adding an RT step (RT-SDA). In this case, a primer hybridizes to the target RNA and an RT synthesizes a cDNA molecule. This cDNA can then serve as a template for

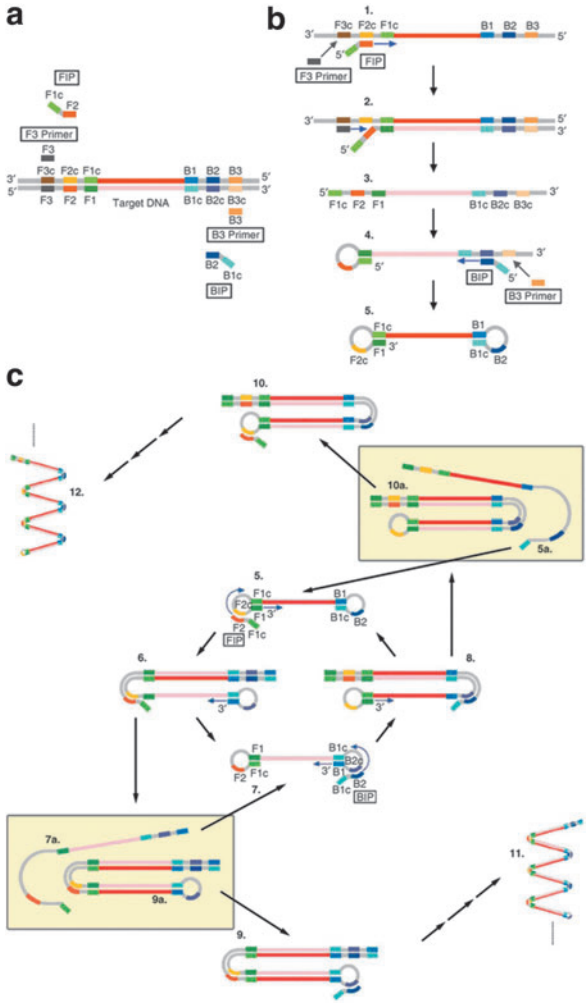

FIGURE 13 (a) Primer design of the LAMP reaction. For ease of explanation, six distinct regions are designated on the target DNA, labeled F3, F2, F1, B1c, B2c, and B3 from the 5′ end. Because c represents a complementary sequence, the F1c sequence is complementary to the F1 sequence. Two inner primers (FIP and BIP) and outer primers (F3 and B3) are used in the LAMP method. FIP (BIP) is a hybrid primer consisting of the F1c (B1c) sequence and the F2 (B2) sequence. (b) Starting structure producing step. DNA synthesis initiated from FIP proceeds as follows. The F2 region anneals to the F2c region on the target DNA and initiates the elongation. DNA amplification proceeds with BIP in a similar manner. The F3 primer anneals to the F3c region on the target DNA, and strand displacement DNA synthesis takes place. The DNA strand elongated from FIP is replaced and released. The released single strand forms a loop structure at its 3′ end (structure 3). DNA synthesis proceeds with the single-strand DNA as the template, and BIP and B3 primer, in the same manner as described earlier, to generate structure 5, which possesses the loop structure at both ends (dumbbell-like structure). (c) Cycling amplification step. Using self-structure as the template, self-primed DNA synthesis is initiated from the 3′ end F1 region, and the elongation starts from FIP annealing to the single strand of the F2c region in the loop structure. Passing through several steps, structure 7 is generated, which is complementary to structure 5, and structure 5 is produced from structure 8 in a reaction similar to that which led from structures 5 to 7. Structures 9 and 10 are produced from structures 6 and 8, respectively, and more elongated structures (11, 12) are also produced. Reprinted with permission from reference 57.

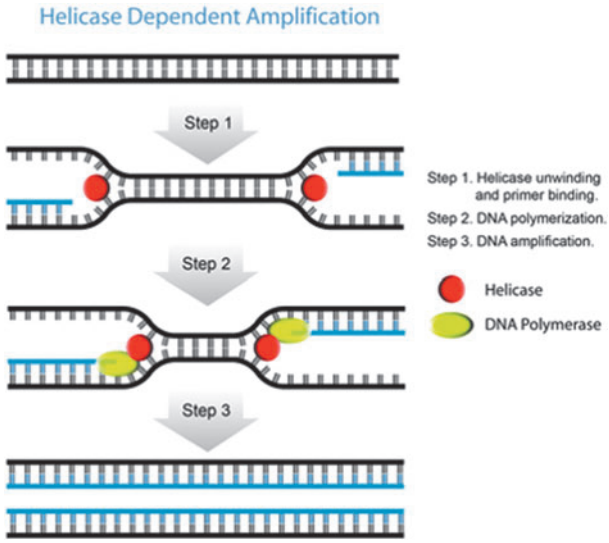

FIGURE 14 HDA amplifies target sequences using two sequence-specific primers flanking the fragment to be amplified and a mixture of enzymes for DNA strand separation and polymerization. In the first step of the HDA reaction, the helicase enzyme loads on to the template and traverses along the target DNA, disrupting the hydrogen bonds linking the two strands. Exposure of the single-stranded target region by helicase allows primers to anneal. The DNA polymerase then extends the 3′ ends of each primer using free deoxynucleotides (dNTPs) to produce two DNA replicates. The two replicated DNAs independently enter the next cycle of HDA, resulting in exponential amplification of the target sequence. Reprinted from http://www.biohelix.com/HDA_mechanism.asp.

primer incorporation and strand displacement. The products of this strand displacement then feed into the amplification scheme described above. RT-SDA has been used for the determination of HIV-1 viral load (55). FDA-cleared tests using SDA for the direct detection of C. *trachomatis*, N. *gonorrhoeae*, and HSV types 1 and 2 in urogenital specimens are available from BD Diagnostics. These assays can be run on either a semiautomated (ProbeTec) or fully automated (Viper) system.

The main advantage of SDA is that it is an isothermal process that, unlike PCR, can be performed at a single temperature after initial target denaturation. This eliminates the need for expensive thermal cyclers. Furthermore, samples can be subjected to SDA in a single tube, with amplification times varying from 30 min to 2 h. The main disadvantage of SDA lies in the fact that, unlike temperatures at which PCR is performed, the relatively low temperature at which SDA is carried out (52.5°C) can result in nonspecific primer hybridization to sequences found in complex mixtures such as genomic DNA. Hence, when the target is in low abundance compared to background DNA, nonspecific amplification products can swamp the system, decreasing the sensitivity of the technique. However, the use of organic solvents to increase stringency at low temperatures and the recent introduction of more thermostable polymerases capable of strand displacement have alleviated much of this problem.

Loop-Mediated Amplification

Loop-mediated amplification (LAMP) is an isothermal method that relies on autocycling strand displacement

DNA synthesis by *Bst* DNA polymerase and a set of four to six primers (56). Two inner and two outer primers define the target sequence, and an additional set of loop primers is added to increase the sensitivity of the reaction. The final products of the LAMP reaction are DNA molecules with a cauliflower-like structure of multiple loops consisting of repeats of the target sequence (Fig. 13) (57). The products can be analyzed in real time by monitoring of the turbidity in the reaction tube resulting from production of magnesium pyrophosphate precipitate during the DNA amplification. Amplification products can also be visualized in agarose gels after electrophoresis and staining with ethidium bromide or SYBR Green I.

LAMP has been used successfully in a number of laboratory-developed assays to detect DNA and RNA viruses (58–61) and diagnose mycobacterial infections (62). Since LAMP is an isothermal process and positive reactions can be detected by simple turbidity measurements or visualized directly with the naked eye, it requires no expensive equipment. These attributes make it an attractive technology for resource-poor settings and field use (63). However, primer design for LAMP is more complex than for PCR, with specialized training and software required for its design. Meridian Bioscience, Inc., Cincinnati, OH, has licensed LAMP technology from Eiken Chemical Company, Ltd., Tokyo, Japan, for the development of infectious disease diagnostics in the United States. Meridian currently has FDA-cleared tests for detection of *C. difficile*, *Mycoplasma pneumoniae*, group A and B beta-hemolytic streptococci, and *Bordetella pertussis* (64).

Helicase-Dependent Amplification

Helicase-dependent amplification (HDA) is an isothermal process developed by BioHelix, Beverly, MA, that uses helicase to separate dsDNA and generate single-stranded templates for primer hybridization and subsequent extension by a DNA polymerase (65). As the helicase unwinds dsDNA enzymatically, the initial heat denaturation and subsequent thermocycling steps required by PCR can all be omitted. In HDA, strands of dsDNA are separated by the DNA helicase and the ssDNA is coated with ssDNA-binding proteins. Two sequence-specific primers hybridize to each border of the target sequence, and a DNA polymerase extends the primers annealed to the target sequence to produce dsDNA. The two newly synthesized products are used as substrates by the helicase in the next round of amplification. Thus, a simultaneous chain reaction proceeds, resulting in exponential amplification of the selected target sequence (Fig. 14).

HDA is compatible with multiple detection technologies including qualitative and quantitative fluorescent technologies and with instruments designed for real-time PCR (66). Furthermore, HDA has shown potential for the development of simple, portable DNA diagnostic devices to be used in the field or at the point of care (67–69). FDA-cleared tests for detection of HSV type 1 and type 2, *C. difficile*, and group A and B beta-hemolytic streptococci based on HDA are available from Quidel (San Diego, CA).

FUTURE DIRECTIONS

Amplification methods and the probes that allow detection and quantification of nucleic acids are becoming faster, easier, and less expensive. Multiplexing and nesting extract more information, and better assay design provides greater clinical relevance. These trends will continue in the future. Entirely new amplification methods and probes will be created that may displace existing methods in some applications. Digital PCR and high-resolution melting will find greater use in clinical assays. Targeted amplification as presented here is currently being challenged by broad-spectrum mass spectroscopy and massively parallel sequencing. The needs of central clinical labs (cost efficiency and batching) will continue to clash with the ideals of rapid turnaround near the patient. No one knows the future, but it is exciting to be part of the process.

Application of Identification of Bacteria by DNA Target Sequencing in a Clinical Microbiology Laboratory

KARISSA D. CULBREATH, KEITH E. SIMMON, AND CATHY A. PETTI

2

The identification of bacteria has traditionally been based upon the phenotypic properties of microorganisms grown in pure culture under optimal conditions. While useful in most circumstances, the physiological characteristics of bacteria are mutable and not always consistent within a given species. Phenotypic identification can, moreover, be tedious, subjective, and inconclusive when conflicting results are obtained. Even with the aid of semiautomated or automated instruments, these methods are still limited in that they cannot fully characterize all bacterial isolates, and the phenotype of an isolate may not be predictable (1, 2). We are beginning to appreciate the growing diversity of bacteria and the complexities in the evolution of a bacterial species. Similarly, we now more fully realize that the physiological properties of bacteria vary from the dynamic interplay between their environmental and ecological niches and their human hosts. With growing numbers of immunocompromised hosts who are susceptible to unusual infections, the distinction between environmental, colonizing, and clinically relevant bacteria is not always clear. Hence, commonly encountered bacteria with unusual physiological properties and the emergence of novel bacterial pathogens with unknown or poorly defined phenotypes pose significant challenges to clinical microbiologists. These challenges underscore the importance of characterizing bacteria by methods that are independent of a microorganism's biochemical characteristics.

Nucleic acid sequencing of various bacterial genes and other DNA targets has been used for determining the phylogeny of bacteria and for their identification (3) and aid in the description of novel organisms. With advances in technology, this approach has moved from research to the clinical laboratory. Even with newer technologies such as matrix-assisted laser deadsorption time-of-flight (MALDI-TOF) mass spectrometry gaining more widespread use in the clinical laboratory, DNA target sequencing remains the "gold standard" in bacterial identification. Compared to conventional methods, DNA target sequencing holds the advantage of speed, accuracy, and growth-independent identification (4–8). Once performed by using more laborious methods, nucleic acid sequencing can now be accomplished using high-throughput automated instrumentation. A brief overview of nucleic acid sequencing is shown in Fig. 1.

The rRNA genes (sometimes referred to as rDNA) and their intergenic regions found in bacteria are commonly used for prokaryotic phylogenetic studies (9). The small-subunit rRNA molecule is a fragment with a sedimentation coefficient of 16S and is encoded by an ~1,500-bp gene. The large-subunit rRNA contains 23S and 5S molecules. Partial sequencing of the 16S rRNA gene, with amplification of the first 500 bp, is usually used for bacterial identification in the clinical laboratory, including anaerobes and mycobacteria (1, 5, 10–15). Because it is commonplace to include a 16S rRNA sequence with the description of a new species and it is the most frequently used target for clinical and environmental metagenomic studies, the 16S rRNA databases cover more species than other targets. Most sequences that have been deposited in publicly available databases correspond to this region of the 16S rRNA gene. Using this method, researchers have discovered pathogenic bacteria such as *Tropheryma whipplei* and *Bartonella bacilliformis* (16, 17).

The 16S rRNA molecule contains alternating regions of sequence conservation and heterogeneity (Fig. 2), making it well suited as a target for sequence analysis (18). The conserved regions are ideal primer targets for amplification of this gene from all bacterial species. Regions of DNA sequence diversity between these conserved regions provide sequence polymorphisms that serve as "signatures" unique to a genus or species. The sequence obtained is compared to a database containing sequences of known microorganisms. The number of similar nucleotide bases between sequences is used to calculate the percent identity and ascertain the identification of the microorganism. While this strategy is adequate for the identification of many bacterial species, the degree of divergence observed within the 16S rRNA molecule may not be sufficient to distinguish some closely related species (19). Criteria for identification of bacteria to the genus or species level were initially determined empirically and differed from laboratory to laboratory. Only recently have standardized criteria been developed for use by clinical laboratories (20).

Karissa D. Culbreath, Department of Pathology, University of New Mexico Health Sciences Center, and TriCore Reference Laboratories, Albuquerque, NM 87102. **Keith E. Simmon,** Department of Biomedical Informatics, University of Utah, Salt Lake City, UT 84108. **Cathy A. Petti,** HealthSpring Global, Inc. Bradenton, FL 34209.

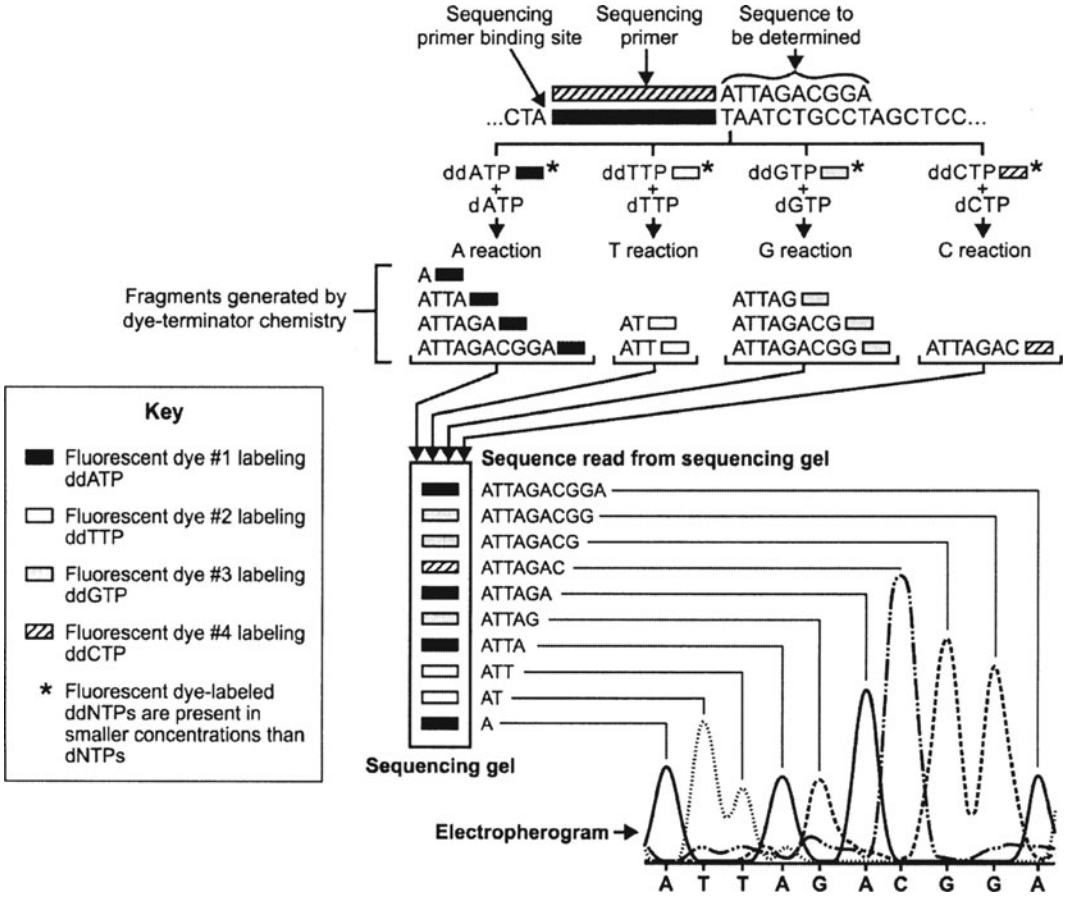

FIGURE 1 Dye-terminator cycle sequencing of amplified 16S rRNA gene. Purified PCR amplicon, sequencing primer, and limited concentrations of dideoxynucleotide triphosphates (ddNTPs) into which four fluorescent dyes have been incorporated are mixed with unlabeled deoxynucleotides (dNTPs). Synthesis terminates whenever a ddNTP instead of a dNTP is incorporated into a new strand. Strands of various lengths are synthesized and labeled as the terminal ddNTP is incorporated into the strand. Accumulated fragments are separated according to size by electrophoresis. During electrophoresis, labeled products are visualized by fluorescence, with each of the four fluorescent dyes indicating which of the terminal ddNTPs have been incorporated. Combining the terminal ddNTP information with the fragment size allows the determination of sequence information. Reprinted from reference 58 with permission from the publisher.

Other DNA targets have been used to better separate closely related species. These include *rpoB* (beta subunit of RNA polymerase), *sodA* (manganese-dependent superoxide dismutase), *gyrA* or *gyrB* (gyrase A or B), *tuf* (elongation factor Tu), *recA*, *secA*, and heat shock proteins (21–27). The utility of each target varies depending on the microorganism. Similar to the 16S rRNA gene, these alternative DNA targets have conserved regions flanking variable regions that can be used to differentiate closely related bacterial species. It should be noted that primers to the conserved regions are not universal to all bacteria, and targets should be selected based on the microorganism of

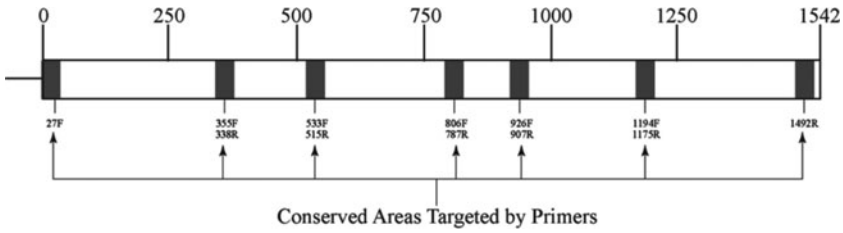

FIGURE 2 Schematic for 16S rRNA located on the small ribosomal subunit (30S). Arrows indicate the conserved regions that serve as primer targets for PCR amplification and DNA sequencing of bacteria.

interest. Databases for these alternative DNA targets are not as well populated as for the 16S rRNA gene, but the number of reference sequences is increasing rapidly. Use of DNA sequence information from more than one locus may be useful to distinguish some closely related species.

The routine use of sequencing can greatly enhance the ability of the clinical microbiology laboratory to identify bacteria on many levels. Once bacteria from a pure culture are isolated, the turnaround time for obtaining a sequence can be less than 24 h. When applied to fastidious, slow-growing, or biochemically inert microorganisms, such as anaerobes and *Nocardia* spp., the time required for microorganism identification can be decreased from weeks to within one day. In some cases, sequencing may be performed directly from a clinical specimen or from instrument flagged bottles, reducing the need for growth of individual colonies. Because sequence-based identification can replace the performance of many time-consuming and labor-intensive biochemical reactions, the average time spent per specimen is also dramatically reduced, allowing laboratory technologists more time to accomplish other necessary tasks. This is especially important in the current environment, in which there is a growing shortage of well-trained medical technologists. In our experience, sequence-based identification has decreased the personnel needed by at least one full-time-equivalent certified medical technologist.

Even in cases in which sequence-based identification is unable to provide a definitive answer, sequencing results can provide information on the isolate's phylogenetic relationship to more commonly known bacteria. Relatedness trees provide the clinician with more information about the microorganism's ecological and taxonomical niches than with conventional methods alone. One challenge of conventional biochemical identification and MALDI-TOF is the need for viable organisms under specific culture conditions, cultivation media, and sample preparation to achieve optimal identification. Sequencing overcomes this challenge in that it does not require viable or culturable organisms for identification. As our understanding of the role of the microbiome is increased, the role of non-cultivable organisms in specific medical conditions is becomingly increasingly important. Unlike MALDI-TOF or biochemical-based methods, sequencing data have less sample-to-sample and lab-to-lab variability, providing the opportunity for information to be exchanged between researchers and laboratories. Portability of unambiguous sequence data is important for furthering our understanding of the genetic relationship of microorganisms from a regional, national, and global perspective and defining their biological relevance.

Importantly, DNA target sequencing can serve as an adjunctive tool to conventional and MALDI-TOF-based identification methods. When MALDI-TOF libraries are insufficient to identify unusual or rarely encountered organisms, sequencing can act as a confirmatory or reference method for identifying such pathogens. We recommend that laboratories develop algorithm screening for microorganisms that can be identified by conventional methods with only a subset of isolates referred for 16S rRNA gene sequencing. For many bacteria, conventional testing, including MALDI-TOF, is less expensive, quicker, and more convenient than sequence-based methods. Conventional testing remains a cost-efficient and relatively accurate method to identify most microorganisms associated with clinical disease. Indeed, for microorganisms that share a high percent identity with 16S rRNA sequencing, simple and rapid biochemical tests can help differentiate between species and provide the definitive identification (Table 1). Of consideration in the routine use of DNA target sequencing is the need for technical expertise and its cost. Microbiologists who are less familiar with molecular techniques may find the transition to a molecular platform difficult. However, this technology is well received in the laboratory because it possesses high-throughput capabilities and many options for user-friendly software.

In addition to the use of sequencing in the identification of bacteria from pure colonies, direct amplification and sequencing from clinical specimens have become important diagnostic tools. Viable microorganisms may not

TABLE 1 Select microorganisms with indistinguishable 16S rRNA gene sequences and suggested supplemental phenotypic tests

Microorganism(s)	Phenotypic tests for species resolution
Bacillus anthracis and *Bacillus cereus*	Motility, hemolysis on blood agar, penicillin sensitivity Refer suspected *B. anthracis* isolates to Laboratory Response Network
Bordetella pertussis, *Bordetella parapertussis*, and *Bordetella bronchiseptica*	Urease, catalase, oxidase, motility, citrate
Campylobacter coli and *Campylobacter jejuni*	Hippurate hydrolysis, MALDI-TOF
Clostridium botulinum and *Clostridium sporogenes*	Refer to Laboratory Response Network for botulinum toxin testing in suspected cases
Escherichia coli and *Shigella* spp.	Spot indole, motility, lactose fermentation MALDI-TOF does not provide good species-level resolution
Streptococcus pneumoniae and *Streptococcus mitis*	Bile solubility
Pseudomonas spp.	For *Pseudomonas fluorescens* group, rule out *Pseudomonas aeruginosa* by phenotypic tests if necessary
Yersinia pestis and *Yersinia pseudotuberculosis*	Motility, refer suspected *Y. pestis* isolates to Laboratory Response Network

be available from a specimen due to low organism burden, previous antibiotic treatment, or the presence of highly fastidious organisms that do not grow well in routine culture conditions, such as *Coxiella burnetii*, *T. whipplei*, and *Bartonella quintana*. Additionally, sequencing can be performed from formalin-fixed paraffin embedded (FFPE) specimens—a performance characteristic with high value when the entire specimen is placed in formalin and not sent to the microbiology laboratory for culture.

Next-generation sequencing (NGS) has expanded our understanding of the microbial community in various tissue and body sites. The role of the microbiome has informed our understanding of disease pathogenesis and health outcomes. DNA target sequencing has become a helpful companion to NGS through characterization of the individual organisms that are identified in microbial communities. This is especially important because NGS identifies organisms that are difficult to culture or are noncultivable. Additionally, DNA target sequencing is not limited to monomicrobial infections. Although not as robust as NGS, in combination with various software algorithms, multiple microorganisms can be differentiated from mixed microbial populations identified using DNA target sequencing.

Caution with result interpretation is extremely important when performing amplification and 16S rRNA sequencing directly from clinical specimens. While the increased sensitivity of sequencing for detection of a pathogen is of value in the setting of previous antibiotic treatment or low organism burden, there is also a risk for increased detection of potential contaminants such as *Propionibacterium acnes* or coagulase-negative *Staphylococcus* species. Distinguishing between true infection and contamination is a challenge, and laboratories should make efforts to correlate sequencing results with Gram-stain or other clinical information prior to reporting results. Another challenge of sequencing directly from specimens is that multiple organisms may be detected from sources that historically were associated with monomicrobial infections. However, recent studies have demonstrated the important role of microbial communities in the pathogenesis of infection, and hence, identification of multiple pathogens from clinical specimens through DNA target sequencing will enhance our understanding of human disease and health.

METHODS: GENERAL CONSIDERATIONS

DNA Preparation

In this chapter, we address the preparation of DNA from pure culture, clinical specimens, and FFPE tissues. When starting from culture, the starting material can be either a broth culture (including positive blood culture or liquid AFB culture broth) or colonies on solid media. Centrifugation and washing the cells with sterile water or phosphate-buffered saline are recommended to dilute media because the composition of the media can affect the fidelity of the PCR. Preparation methods range from simple cell lysis to a robust DNA purification. The method of choice is usually influenced by the laboratory workflow and the spectrum of microorganisms that are being analyzed. For example, Gram-negative bacilli such as *Escherichia coli* may require no prelysis step, and cells may be directly added to the PCR, where the elevated 94°C denaturation step is sufficient to lyse the bacteria.

For methods that do not purify the DNA, the concentration of inocula is an important consideration to prevent PCR inhibition. For tissue, body fluid, or FFPE specimens, additional DNA purification steps should be performed to remove cellular debris. In fresh samples, body fluid specimens may go directly to DNA extraction, but tissue requires grinding of the sample prior to DNA extraction. For FFPE tissues, deparaffinization must be performed prior to DNA extraction. It should be taken into consideration that the process of formalin fixing and subsequent deparaffinization damages DNA and may inhibit the amplification of the target for sequencing. An internal control such as β-actin may be used to asses the PCR efficiency in these tissues.

Amplification and Sequencing

The selection of PCR reagents and enzymes should be influenced by laboratory workflow, the anticipated size of the generated amplicon, convenience, and considerations of contamination control. When amplification is performed directly from pure culture, contamination control via uracil *N*-glycosylase is not critical. For laboratories that cannot adequately separate the sample preparation and amplification areas, use of uracil *N*-glycosylase is strongly recommended. In clinical laboratories, the first 500 bp of the 16S rRNA gene is the most common portion of the gene used for identification. The 16S rRNA 500-bp fragment will identify most microorganisms and can be bidirectionally sequenced with a single forward and reverse primer. To reduce costs, some laboratories have favored the use of only the forward or reverse sequence. While more expensive, use of both forward and reverse strands allows evaluation of the impact of copy variants that can be present within a single 16S rRNA genome for many bacterial pathogens (28, 29). Table 2 provides information about several versions of primers targeting similar regions of the 500-bp region. PCR conditions and cycling times are influenced by amplification reagents and available instrumentation. For example, Applied Biosystems offers two versions of the MicroSeq 500-bp kit. One version controls for contamination with use of dUTP instead of dTTP and requires ~2 h to complete the PCR step. Their second version amplifies the gene in ~45 min by use of a "fast

TABLE 2 Frequently used primer sequences for gene sequence-based identification of bacteria

Gene target	Primer name	Orientation	Sequence (5′ to 3′)
16S rRNA	4F	Sense	TTGGAGAGTTTGATCCTGGCTC
16S rRNA	27F	Sense	AGAGTTTGATCMTGGCTCAG
16S rRNA	534R	Antisense	TACCGCGGCTGCTGGCAC
16S rRNA	801R	Antisense	GGCGTGGACTTCCAGGGTATCT

kit." Preparation of the PCR for sequencing can be performed by using shrimp alkaline phosphatase and exonuclease I or by affinity matrixes such as magnetic beads or column purification. (Note that when uracil *N*-glycosylase is included in the PCR, enzymatic purification will not be adequate.)

The alternative sequencing targets, *sodA*, *hsp*65, and *rpoB*, are used when the 16S rRNA gene does not provide sufficient discrimination. The *rpoB* gene is often used as an alternative target to 16S for routine sequencing of bacterial isolates. Of particular value is that it is generally a monocopy gene, reducing the challenges that arise with multiple copies of 16S rRNA in a bacterial genome. Additionally, the *rpoB* gene reflects more accurately DNA-DNA hybridization than has been described in the 16S rRNA gene. The *rpoB* gene and other alternative targets have been demonstrated to be effective in providing resolution within groups of closely related bacteria and may refine phylogenetic identification of bacterial genera. However, the use of targets other than the 16S rRNA gene is limited due to the lack of standardization in the development of kits and databases specific to those targets.

Several methods exist for inferring DNA sequence data such as pyrosequencing, mass spectrometry, a massively parallel sequence often referred to as next-generation sequencing or NGS, and the most common method, capillary electrophoresis. Data from capillary electrophoresis are viewed as electropherograms, which contain the sequence and quality information. The Phred score or quality value (QV) is a score for each base call that estimates the probability that the base was correctly called. For example, a QV of 10 indicates a 10% probability that the error was called incorrectly, and a QV of 20 indicates a 1% probability of error. It is important to realize that multiple copies of the 16S rRNA gene often exist in a bacterial genome, and sequence differences between copies can affect the ability to analyze the sequence.

Controls

Controls are useful for monitoring DNA preparation (extraction), amplification, and sequencing steps. A negative control and a positive control should be incorporated at the DNA preparation step. The DNA preparation negative control should be the same solution that serves as the starting material for the isolates to be analyzed. For the DNA preparation positive control, an uncommon isolate that is not a human pathogen is recommended. A second set of positive and negative controls should be added at the amplification step to monitor the components of the PCR. The positive control at this step should be purified DNA devoid of inhibitors and also an uncommon microorganism that is different from the DNA preparation control. Sterile water is recommended for the negative control. Sequencing controls are not critical to the process but can be helpful in monitoring sequencing reagents in cases of a complete sequencing run failure. A plasmid, pGEM, is often provided in sequencing kits and is a suitable control to monitor this step.

Interpretation of Results

Definitions

The "percent identity" for a sequence is defined as the percentage of nucleotide bases between the query and reference sequence that are identical in the aligned region. "Percent separation" indicates the distance between the query and subject sequence and is simply 100% minus the percent identity. These two values are usually used when establishing criteria for microorganism identification. It is also important to consider the query coverage when using programs like BLAST. The query coverage represents the percentage of the query sequence used to generate the alignment, which is the query length aligned / query length.

Interpretation

Because of the inherent issues with any database, it is advisable for laboratory personnel to review more than just the first few references from a BLAST search to analyze for possible aberrant references. At least the first 20 matches should be reviewed to detect any outlying or erroneous references. Whenever there is a question, the origin of a reference sequence should be examined to assess its validity, which can be based on several parameters such as derivation of the sequence (type strain, peer-reviewed publication, and year) and whether the species is formally recognized by DSMZ or other reputable collections. As a general practice, for viable, cultivable microorganisms, sequencing results should always be correlated with colony morphology prior to reporting a final result to avert laboratory errors.

SEQUENCING SOFTWARE

Sequence analysis and sequence alignment are two core tasks addressed by software. Many platforms are available for sequence analysis, which consist of manual and automated editing of the electropherograms, and consensus generation when more than one overlapping sequence fragment is generated from a sample. Sequence alignment is used to compare the edit query sequences to a reference database. Sequence alignment may be incorporated into products that allow sequence editing, but these two tasks are often split among software packages. In this chapter we provide software resources that mainly target Sanger-based sequencing, since this is the most common form of sequencing used on pure culture. Other chapters in this book specifically address NGS applications. In some cases the software is agnostic in regard to the method by which the sequence was generated.

Software for sequence analyses includes MicroSeq (Life Technologies, Grand Island, NY) SmartGene (SmartGene, Lausanne, Switzerland), RipSeq (Isentio, Palo Alto, CA), DNA Baser Assembler (Heracle Software, Germany), SeqMan (DNASTAR, Inc., Madison, WI), Geneious (Biomatters, Auckland, New Zealand), and CLC Workbench (CLC Bio, Aarhus, Denmark). In general, these applications provide a graphical view of the electropherogram with the text sequence underneath. The interface can be used to edit base calls with ambiguity or bases with low quality scores. Settings based on sequence quality values can also be used to automatically trim the sequence or resolve base conflicts between two sequencing fragments. The speed at which a sequence can be identified is influenced by a number of parameters, including whether the alignment is performed locally or on a server, the number of reference sequences in the database, the settings that are used to seed an alignment, and the number of processors used to run the alignment. Ultimately, the choice of software will be influenced by the number of expected sequences that will be analyzed in any given run and the

cost of the software. There are many commercial and free options available to analyze sequence data.

Sequence comparison or alignment to a reference database is performed after generating a high-quality consensus sequence. Common sequence alignment algorithms for sequence alignment include BLAST and Needleman-Wunsch. BLAST is one of the most popular sequence alignment programs. It allows the query sequence or subject sequence to align to its partner. BLAST is provided as an aligner in SmartGene, RipSeq, Geneious, and CLC Workbench. BLAST can also be accessed directly on NCBI using NCBI references as the reference database. In Geneious and the CLC Workbench, the NCBI BLAST web server is accessed when performing searches to NCBI databases. Alternatively, a custom database can be set up to run BLAST locally. SmartGene and Isentio are web-based software, and BLAST is performed on their servers with maintained databases. BLAST can also be set up locally and used with custom local databases. This is performed via the command line interface, so it may not be suitable for labs without a sufficient IT or bioinformatics infrastructure.

MicroSeq performs an alignment using the Needleman-Wunsch algorithm. Needleman-Wunsch differs from BLAST in that it is a global rather than local alignment and is typically slower than BLAST. The query sequence is aligned end-to-end, so both the reference and query sequence should contain the same region or the alignment values will be compromised.

An additional tool for sequence comparison is the RDP classifier (http://rdp.cme.msu.edu/) (30). The RDP classifier uses sequences (commonly referred to as kmers; e.g., 8-mers) of a length of 8 bp to determine the relationship to reference sequences. Unlike an alignment program, where a sequence is compared directly to a subject sequence, the RDP classifier requires that a database have an overlying taxonomic structure that describes how the references are related. The classifier is then trained on the database. The taxonomic lineage of the query sequence is determined from its kmer content. In this approach, the taxonomic lineage is reported rather than the top reference hit, a feature that may be helpful for placing novel organisms into the appropriate taxonomic location. Routine use of the RDP classifier for the identification of microorganisms in the clinical microbiology laboratory may be limited by the fact that the default database reports sequences only to the genus level. SmartGene, MicroSeq, and Isentio provide complete packages for microorganism identification that include tools for sequence analysis and sequence alignment with reference databases suited for microorganism identification to the species level. Such packages are sufficient for clinical laboratories to perform organism identification.

Database Selection

Both proprietary, commercially available, and free access, public reference databases exist for sequence comparison. A summary of the strengths and limitations of these databases is provided in Table 3. Databases that are available to the public include GenBank (http://www.ncbi.nlm.nih.gov/Genbank/), European Molecular Biology Laboratory (EMBL) Nucleotide Sequence Database (http://www.ebi.ac.uk/embl//), DNA Data Bank of Japan (DDBJ) (http://www.ddbj.nig.ac.jp/), Ribosomal Database Project (RDP) (31) (http://rdp.cme.msu.edu/), Greengenes (32) (http://greengenes.secondgenome.com/), and Silva (33) (http://www.arb-silva.de/). GenBank, EMBL, and DDBJ form the International Nucleotide Sequence Collaboration (INSC), in which data are exchanged on a daily basis. In general, public databases contain many more sequences (e.g., RDP-II, Release 10, contains >700,000 aligned 16S rRNA sequences). However, the user should be aware that public reference sequences might contain errors with potentially poor quality sequences, inaccurate terminology, and outdated nomenclature.

The DNA target of interest will influence the choice of database. Some of the databases mentioned above only collect and curate data from ribosomal sequences. For example, the RDP database consists of small-ribosomal subunit (SSU) sequences for bacteria and large-ribosomal subunit (LSU) sequences for fungi; the Silva database contains LSU and SSU sequences for eukaryotic, bacterial, and archaeal sequences; and Greengenes contains bacterial/archaeal SSU sequences. These databases all draw from publicly available data from the International Nucleotide Sequence Collaboration and have different levels of curation, quality filtering, and database size. Silva and RDP offer a set of tools to query sequences on their servers. Greengenes references are downloaded by the user and must be used locally. Greengenes 16S rRNA sequences are clustered at different identity cutoffs, which provide a non-redundant dataset with each sequence representing an "operational taxonomic unit." Ribosomal sequences, or more specifically SSU sequences, offer the most species coverage in public databases and have been used extensively as phylogenetic markers. For alternative genetic markers, curated datasets are less common, and institutions may need to sequence the references internally to create a suitable clinical reference set.

The quantity and quality of reference sequences in a database are important to determine when making a selec-

TABLE 3 Comparison of features of various nucleotide sequence databases[a]

Database	Fee for use?	Database size (no. of sequences)	Comprehensive phylogenetic analysis	Creation of private sequence database	Automatic creation of searchable clinical isolate database	Use of flagging of questionable reference sequences	Quality control	Updates
SmartGene (v.3.2.3)	Yes	~130,000	Yes	Yes	Yes	Yes	Partial	Weekly
MicroSeq (v1.4.3)	Yes	~2,000	Yes	Yes	No	No	All type strains	Periodically
RIDOM	No	~250	Yes	No	No	No	All type strains	Periodically
RDP-II	No	>700,000	Yes	Yes	Yes	No	Partial	Monthly
GenBank	No	>700,000	No	No	No	No	No	Daily

[a]Modified from reference 48 with permission.

tion. Proprietary databases include SmartGene, Isentio, and MicroSeq. These databases contain 16S rRNA sequences for bacteria. Unlike other databases that contain mostly type strains, MicroSeq consists entirely of culture collection strains that may reflect the wider genetic variability within a species. MicroSeq has been evaluated by a number of investigators for identification of a wide breadth of bacteria (34). However, there are fewer sequences in the database, and it has been shown to lack some clinically important organisms (34).

SmartGene and Isentio build reference databases from sequence data in the public domain, using profile-based filters to exclude non-useful sequences and annotations. The SmartGene 16S rDNA database contains approximately 500,000 sequences, as of September 2014, and is updated by SmartGene on a daily basis. This approach accommodates species variability, including recently described organisms. All sequences included in the SmartGene databases have a link to their original source. SmartGene also has several datasets that have been created through collaborations with academic institutions, and SmartGene allows users to report suspected errors in sequence annotation, which can then be flagged for correction or removal. As targets other than 16S rRNA are being more widely used, databases have begun to incorporate these additional sequences. For example, SmartGene has additional databases for the *rpoB* sequence for bacteria and provides services to add user-specified targets. Isentio also provides alternative DNA targets in their database. Few studies have been undertaken to systematically compare the strengths and limitations of these proprietary databases (35). The choice of reference database ultimately depends on numerous factors, such as laboratory budget, computer skill level of the technologists, and personal preference for the various features unique to each product.

Criteria for Microorganism Identification

General Considerations

Sequences should be reviewed for read length and length of alignment. For sequencing of the first 500 bp of the 16S rRNA gene, at least 300 bp should be aligned with the database reference sequences to ensure that areas of sequence variability are captured. When the number of aligned base pairs is <300, the quality of the sequence should be questioned, and proper alignment with the reference sequence should be reviewed. Improper alignment may occur due to the presence of ambiguous base pairs, in which case manual alignment may rectify the issue. Ideally, the forward and reverse strands will form a consensus sequence. The Clinical and Laboratory Standards Institute (CLSI) has published standards for result analysis and interpretation (20). This document addresses criteria for identification of a bacteria, mycobacteria, and fungi to the genus and species levels for clinical microbiology laboratories. For most bacteria, except for aerobic actinomycetes and mycobacteria, ≥99.0% identity with an acceptable reference sequence is required for species identification, and ≥97.0% identity is required for genus identification. When the identity score is <97.0% but ≥95.0%, the microorganism cannot be identified to the genus or species level but can be reported as most closely related to a genus. For isolates that share less than 95% identity with a reference sequence, the reference database may be insufficient and/or the isolate may represent a novel species. The cutoff for species identification may vary if alternative targets are used for sequencing depending on the level of shared sequence identity in the target. These general guidelines should certainly be considered in the context of the clinical scenario and microorganism phenotype. The guideline is a pragmatic approach for implementing DNA target sequencing in clinical laboratories and attempts to develop a uniform standard for laboratory specialists to identify microorganisms. The guideline does not reflect strict taxonomical classifications since microbial taxonomy remains an evolving field and the concept of species is largely unresolved.

Staphylococcus spp. and Related Gram-Positive Cocci

Although identification of *Staphylococcus aureus* is usually straightforward with conventional testing, difficult to identify *S. aureus* isolates are occasionally encountered. The 16S rRNA target can identify *S. aureus*, *Staphylococcus warneri*, and *Staphylococcus lugdunensis*. For many other coagulase-negative *Staphylococcus* spp. such as *Staphylococcus epidermidis*, *Staphylococcus capitis*, *Staphylococcus caprae*, *Staphylococcus schleiferi*, and *Staphylococcus intermedius*, the use of alternative targets such as sodA provides better resolution to the species level (36). *Staphylococcus saprophyticus* and *Staphylococcus xylosus*, both of which are novobiocin resistant, may not be differentiated using 16S rRNA, and use of *tuf* or *rpoB* genes would be better for this purpose (24, 37–39). The importance of identifying these species of coagulase-negative staphylococci to the species level lies in their different antibiotic susceptibility profiles and potential differences in virulence. Increased resistance to glycopeptides has emerged in species such as *S. epidermidis*, *Staphylococcus haemolyticus*, and *S. lugdunensis* associated with native valve endocarditis (40). While beyond the scope of this chapter, it is noted that *rpoB* gene mutation analysis can also provide information on rifampin resistance in *Staphylococcus* spp. (24, 41). For other staphylococcus-like microorganisms, such as *Micrococcus* spp., *Kocuria* spp., and *Kytococcus* spp., 16S rRNA provides adequate resolution to the species level.

Streptococcus spp. and *Streptococcus*-Like Microorganisms

Identification of streptoccoci to the species level can be challenging, even using conventional methods, given the prominent role of horizontal gene transfer in this genus. 16S *Streptococcus pyogenes* and *Streptococcus agalactiae* as well as the former "nutritionally variant streptococci," *Abiotrophia* spp. and *Granulicatella* spp., are easily identified by using 16S rRNA as the gene target. However, there is no single gene target to reliably identify beta-hemolytic streptococci of Lancefield group C and G (42). For viridans group streptococci, resolution to the genus level with the 16S rRNA target is usually possible, but there is limited resolution to the species level; *rpoA* has been demonstrated to provide better species resolution for the viridans group streptococcus (25, 43, 44). *Streptococcus cristatus*, *Streptococcus oralis*, and members of the *Streptococcus anginosus* group are exceptions, with 16S rRNA providing sufficient resolution to the species level (45, 46).

Enterococci are usually resolvable to the species level, but a high level (>99.0%) of shared identity may be seen between the *Enterococcus* species *Enterococcus faecium* and *Enterococcus durans*, *Enterococcus hirae*, or *Enterococcus azikeevi* (47). *Enterococcus casseliflavus* and *Enterococcus flavescens* share a similarly high percent identity, and it is

now believed that they represent a single species, *E. casseliflavus* (48).

Anaerobes

DNA target sequencing is still the most accurate method of anaerobic identification, especially since databases from conventional methods often are not current and do not reflect the tremendous genetic diversity within anaerobic taxa. More accurate identification is highly relevant clinically because antimicrobial resistance is increasing. Determining the optimal percent identity to identify an anaerobic isolate is difficult due in large part to evolving taxonomical classifications and uncertainty about the taxonomical significance of genetic heterogeneity. 16S rRNA gene sequence provides resolution to the species level for many anaerobic Gram-negative bacilli, such as *Bacteroides* spp., *Parabacteroides* spp., *Porphyromonas* spp., *Prevotella* spp., *Veillonella* spp., *Anaerobiospirillum* spp., *Bilophila* spp., *Desulfovibrio* spp., *Tissierella* spp., and *Tannerella* spp. (49–51). Speciation of *Fusobacterium* spp. may be limited using the 16S gene, and *rpoB* may be the preferred target for this genus (52). The 16S rRNA gene sequence remains the preferred target for many Gram-positive anaerobes as well, including *Bifidobacterium* spp., *Eubacterium* spp., *Eggerthella* spp., *P. acnes*, *Finegoldia magna*, *Parvimonas micra*, *Peptostreptococcus anaerobius*, *Peptoniphilus asaccharolyticus*, and *Anaerococcus* spp. (53, 54). For *Clostridium* spp., resolution to the species level is typically good, with the notable exceptions of *Clostridium botulinum* and *Clostridium sporogenes*, which often cluster together. Testing for botulinum toxin is necessary for definitive identification.

Gram-Negative Bacilli: Enterics, Nonfermenters, and *Campylobacterales*

Many species in the family *Enterobacteriaceae* can be identified by use of the 16S rRNA gene target. However, use of automated identification methods is in many cases quicker and more convenient without compromising accuracy. When 16S rRNA fails to provide adequate identification, *rpoB*, *gyrB*, *tuf*, or F-ATPase beta-subunit (*atpD*) genes can provide better resolution (55, 56). The utility of 16S rRNA sequencing depends on the genera of the organisms in question. For example, the genera *Proteus*, *Providencia*, *Morganella*, *Xenorhabdus*, *Cedecea*, *Edwardsiella*, and *Hafnia* demonstrate good separation. On the other hand, *E. coli* and *Shigella* spp. cannot be distinguished based on 16S rRNA sequencing because genetically, they can be considered the same species. *Aeromonas* species cannot be reliably identified using the 16S gene, and resolution to the species level can be achieved by sequencing the *gyrB* or *rpoD* gene (57, 58).

Classification of microorganisms belonging to the genera *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Pantoea* based on phenotypic characteristics does not correlate well with phylogenetic classification using the 16S rRNA region. Our understanding of their taxonomic relationship is still evolving, and conventional methods of identification may be more helpful at this time. *Citrobacter freundii*, *Enterobacter aerogenes*, and *Pantoea agglomerans* may cluster closely together, as can *Citrobacter koseri* and some *Salmonella* spp. Identification of *Klebsiella* spp. and *Raoultella* spp. to the species level is usually limited, but *Klebsiella oxytoca* is well separated from the *Klebsiella pneumoniae* group (*K. pneumoniae*, *Klebsiella milletis*, and *Klebsiella granulomatis*) (59). Slightly different criteria should be applied to interpreting sequencing results for these microorganisms. The cutoff for species identification should be raised to 99.5% with separation of >0.5% between species. For sequence identities of ≥97.0% but with poor separation between genera, it may be necessary to report all closely related genera. However, species of different genera from the *Enterobacteriaceae* family typically share between 97 and 99% 16S rRNA gene sequence identity. Alternative targets such as *rpoB* or *gyrB* may be more useful for providing greater resolution to the species level for *Klebsiella* spp., but shared sequence identity may still be observed with the *rpoB* target between newly classified groups of *Enterobacter* species (shared identity ranges from 88 to 100%) (60).

For the glucose-nonfermenting Gram-negative bacilli, 16S rRNA gene target sequencing is a valuable tool because many such microorganisms are difficult to separate phenotypically. Resolution to the species level is well attainable for species of *Stenotrophomonas*, *Pasteurella*, *Moraxella*, *Achromobacter*, *Alcaligenes*, *Actinobacillus*, *Aggregatibacter*, *Oligella*, *Ralstonia*, *Pandoraea*, *Eikenella*, and *Kingella*. Identification to the species level using 16S rRNA is attainable for most *Burkholderia* spp., and greater resolution of the *Burkholderia cepacia* complex can be achieved by sequencing the *recA* gene (61). For *Haemophilus* spp., the 16S rRNA sequence does not allow for adequate speciation because *Haemophilus influenzae* can cluster with *Haemophilus haemolyticus* or *Haemophilus aegyptius*. While phylogeneic relationships of *Haemophilus* and *Aggregatibacter* are continuing to be evaluated, multitarget sequencing may be required for the most accurate identification (62).

For *Acinetobacter* spp., resolution may be to only the genus level with the 16S rRNA gene and to groups using the *rpoB* gene (63). If *Acinetobacter baumannii* needs to be excluded, MALDI-TOF is not able to distinguish *A. baumanii* from other related *Acinetobacter* species; phenotypic tests (growth at 42°C and acid production from lactose) are helpful. For *Pseudomonas* spp., *Pseudomonas aeruginosa* can usually be discerned, but other members may only be classifiable to groups, e.g., *Pseudomonas fluorescens*, *Pseudomonas stutzeri*, and the *Pseudomonas alcaligenes* group. The *Bordetella* species *Bordetella pertussis*, *Bordetella parapertussis*, and *Bordetella bronchiseptica* share >99% sequence identity, and therefore resolution is usually limited to the genus level only (64). Phenotypic tests or use of *recA* sequence analysis can provide resolution to the species level (65). *Legionella* spp. are adequately identified to the genus level by 16S rRNA sequencing, but resolution to the species level requires additional targets such as *mip* or *rpoB* (66).

Neisseria meningitidis is not well demarcated from *Neisseria lactamica*, *Neisseria cinerea*, or *Neisseria gonorrhoeae* using the 16S rRNA target. Laboratories should be aware that there are a great number of *N. meningitidis* reference sequences in databases, such that they can obscure the presence of other *Neisseria* spp. that appear much lower on the list of matches but that are closely related as well. Misidentification of commensal *Neisseria* species as *N. meningitidis* has also occurred with MALDI-TOF (67). A fragment of the 50S ribosomal protein L6 (*rplF*) gene has been demonstrated to distinguish between *Neisseria* species (68). *Bartonella* spp. can be identified to the genus level and, in some cases, to the species level. For *Rhizobium*, *Agrobacterium*, *Brucella*, and *Ochrobactrum* spp., 16S rRNA analysis can provide resolution to the genus level, but *recA* or *gyrB* can better provide resolution to the species level (69).

Campylobacter coli and *Campylobacter jejuni* cannot be differentiated by 16S rRNA sequencing. We have found

that phenotypic methods such as hippurate hydrolysis or MALDI-TOF are valuable for differentiating these two species. Other *Campylobacter* spp. can frequently be identified to the species level with 16S rRNA sequence analysis. *Helicobacter* spp. and *Arcobacter* spp. can usually be resolved to the species level with the 16S rRNA target. Other targets, such as *hsp60* and *atpA*, have been shown to give better resolution of *Campylobacter*, *Helicobacter*, and *Arcobacter* to the species level (70).

Coryneform Gram-Positive Bacilli

Once believed to largely represent a skin contaminant when isolated in culture, coryneform bacteria are now recognized as important pathogens, especially in immunocompromised patients. Identification of a clinically significant coryneform organism is important, because some have characteristic antimicrobial susceptibility patterns, with some well known for multidrug resistance (71). As mentioned previously, copy variants of the 16S rRNA may be seen more frequently in coryneform bacteria, creating the appearance of mixed bases in the sequencing data. With proper manual editing, a consensus sequence can usually be reached. Identification to the species level can be achieved for most coryneform bacteria, including *Actinobaculum* spp., *Arcanobacterium* spp., *Brevibacterium* spp., *Gardnerella vaginalis*, *Rothia* spp., and *Dermabacter hominis* (1). For the genus *Corynebacterium*, resolution to the species level is good for some members, but there is poor separation between *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*, between *Corynebacterium pseudodiphtheriticum* and *Corynebacterium propinquum*, and among *Corynebacterium amycolatum*, *Corynebacterium xerosis*, and *Corynebacterium freneyi* (72). Due to the lack of resolution between species in this genus, the *rpoB* gene may be the preferred sequence to resolve to the species level (73). For *Actinomyces* spp., there is good resolution to the species level except for *Actinomyces meyeri*, *Actinomyces odontolyticus*, and *Actinomyces lingae*, which cluster as a group (12). Alternative targets such as *rpoB*, *atpA*, or *metG* may be necessary to resolve the *Actinomyces* spp. to the species level (74).

Nocardia spp. and Other Aerobic Actinomycetes

In general, ≥99.6% sequence identity in the 16S rRNA is sufficient to identify an organism to the genus and species level for *Nocardia* spp. and other aerobic actinomycetes, provided that there is at least 0.4% separation between different species. Between 99.0 and 99.5% identity, an organism can be identified to the genus level. A sequence identity of ≥95% but <99.0% is insufficient to definitively identify an aerobic actinomycete to the genus level, but the organism may be reported as "most closely related" to the genus in question.

Many *Nocardia* spp. can be identified to the species level using the 16S rRNA target, including *Nocardia beijingensis*, *Nocardia brasiliensis*, *Nocardia farcinica*, *Nocardia otitidiscaviarum*, and *Nocardia kruczakiae*. For better resolution to the species level, *secA*, *rpoB*, and *gryB* have been used successfully (21, 75, 76). In laboratories where the technology and expertise are available, multilocus sequence analysis using a combination of these genes may be the optimal approach (77). For other aerobic actinomycetes, including *Actinomadura* spp., *Gordonia* spp., *Rhodococcus* spp., and *Tsukamurella* spp., 16S rRNA is an appropriate target to resolve an organism to the species level. *Streptomyces* spp. can frequently only be resolved to the genus level, which is usually sufficient for clinical purposes (15).

Bioterrorism Agents and Other Microorganisms

For agents of bioterrorism, i.e., *Bacillus anthracis*, *Brucella* spp., *Clostridium botulinum*, *Francisella tularensis*, and *Yersinia pestis*, 16S rRNA sequencing has varying utility. There is poor separation between *Bacillus anthracis*, *Bacillus cereus*, and *Bacillus thuringiensis*; between *C. botulinum* and *C. sporogenes*; and between *Y. pestis* and *Yersinia pseudotuberculosis*. *F. tularensis* and *Brucella* spp. are conveniently identified with the 16S rRNA target. In any suspected cases, the isolate should immediately be referred to the nearest Laboratory Response Network laboratory (http://www.bt.cdc.gov/lrn).

We have found 16S rRNA sequencing to be valuable in identifying other bacteria worth mentioning. *Streptobacillus moniliformis* is easily identified, and in nearly all cases we have been able to extract a patient history of rat exposure. *Mycoplasma hominis* has been identified from various body sites, including soft tissue, abdominal fluid, and cerebrospinal fluid. In many cases growth of a faint haze of microorganism is seen on sheep blood agar during routine culture. Sequencing can confirm the organism identity more quickly than most phenotypic assays for identifying *M. hominis*.

Detection of Organisms from Primary Specimens

The utility of 16S sequencing has expanded beyond sequencing from isolated colonies to sequencing from the primary clinical specimen. In cases where organisms are slow growing, require specific cultivation environments, or are noncultivable, direct sequencing provides the only means of identification of the pathogen. Sequencing can also be applied from direct specimen for more timely results for slowly growing microorganisms. Direct sequencing of whole blood to identify *Borrelia* spp. is a tool to aide in the diagnosis of tick-borne relapsing fever, particularly in cases of low spirochetemia (78). Causes of culture-negative endocarditis can be ascertained through sequencing of infected valves, particularly for *B. quintana* and *C. burnetii* (79). In cases of direct sequencing of clinical specimens, the 16S gene is likely the best target to sequence since there are more well-characterized databases to query for organism identification.

Novel Organism Identification

One of the valuable applications of DNA target sequencing is in the identification of novel organisms. Currently, the 16S rRNA gene is the benchmark for novel organism identification; however, because sequencing technologies are evolving, interrogation of additional targets has expanded the opportunity to identify novel organisms. The *International Journal of Systematic and Evolutionary Microbiology* (*IJSEM*) is the journal responsible for the taxonomy, nomenclature, identification, and characterization of all microorganisms. The journal requires that upon proposing a new organism, authors provide evidence that type strain sequences are deposited in recognized culture collections in two different countries. Additional guidelines for the description of a new taxon are available at http://ijs.sgmjournals.org. Sequencing a single locus such as the 16S gene to identify a novel species has limitations, and

sequencing of the entire 16S gene, use of multilocus sequencing, and whole-genome sequencing will likely become the gold standards for novel organism identification and taxonomy assignment (80).

REPORTING RESULTS

In most cases, a result can be reported as genus and species provided that the sequencing results have met established criteria. For microorganisms with more than one top-scoring match, it is possible to report all top matches, using a slash mark in between, for example, "*Neisseria meningitidis/Neisseria lactamica*." When the top references do not separate well enough, it may also be necessary to report that the second most closely related species could not be ruled out, or adjunctive phenotypic testing may be able to provide resolution to species. Occasionally isolates will be identified as a bacterial species that is completely novel to the laboratory and clinician. If the laboratory information system permits, it would be highly informative to clinicians for the laboratory to provide a phylogenetic representation of the microorganism. This way, the most closely related bacteria are demonstrated, facilitating clinical decision making (Fig. 3).

CONCLUSION

Molecular studies have enhanced our knowledge about the taxonomical diversity among bacteria and have improved our ability to conduct surveillance of emerging pathogens. Numerous pathogens once believed to be rare clinical isolates or even contaminants are now being identified more precisely by nucleic acid sequencing and recognized as being clinically relevant. Our taxonomical understanding continues to evolve along with our understanding of their clinical correlates.

Although sandwiched between the widely attainable and inexpensive option of MALDI-TOF and the broadly applicable option of NGS, DNA target sequencing remains an important part of the clinical microbiology toolbox. As conventional identification methods, including MALDI-TOF, increase the numbers of microorganisms in their databases, the role of 16S rRNA sequencing has shifted from routine to use as a reference method or as a method to identify novel or uncultivable pathogens. Application of 16S rRNA sequencing has defined the etiologic agent for various culture-negative infections, such as meningitis, brain abscess, septic arthritis, endocarditis, and sepsis. Although MALDI-TOF has emerged as a routine tool for identification of microorganisms from culture-dependent methods, it continues to rely on sequencing to confirm identification of newly identified organisms.

Sequencing remains a powerful tool in clinical diagnostic laboratories, and its data is portable and transferable. The technology is culture independent, enabling direct detection of microorganisms from clinical specimens—a valuable tool particularly for patients on antecedent antimicrobial therapy. Software has been developed to tease apart mixed sequences and perform multiplex sequencing reactions in the same tube. Evolution of routine Sanger sequencing to newer sequencing applications will allow us to gain insight into the contribution of previously unidentified organisms including complex microbial communities contributing to human health and disease. These sequencing-based innovations combined with improvements in cost, automation, and ease of use will accelerate the ap-

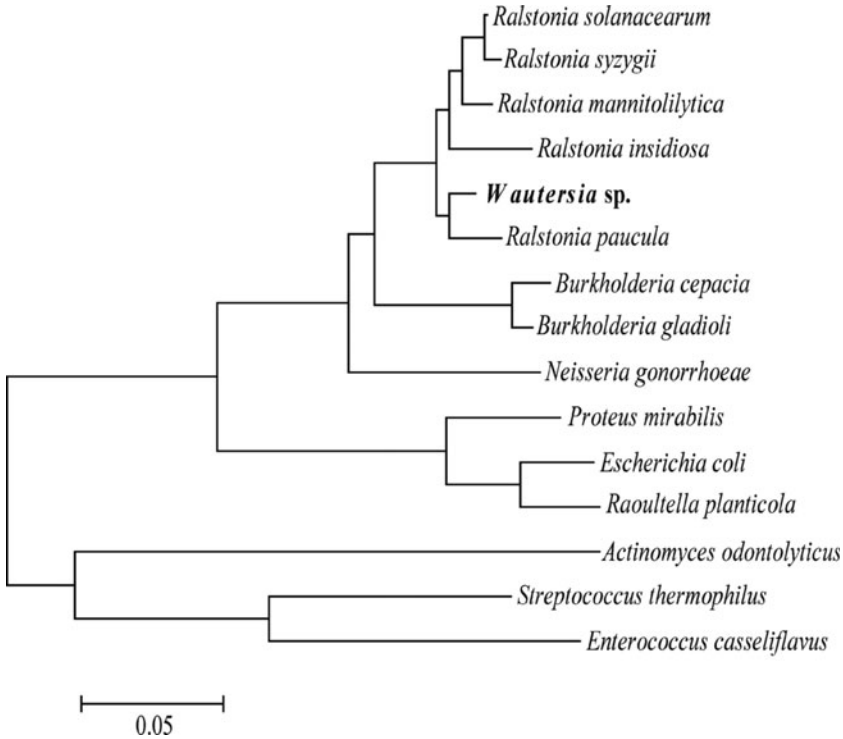

FIGURE 3 Phylogenetic representation of an unusual clinical isolate, such as this *Wautersia* sp., can provide useful information to the clinician if included with the patient results.

plication of sequence analysis for clinical microbiology laboratories.

Microbial Whole-Genome Sequencing: Applications in Clinical Microbiology and Public Health

M. E. TÖRÖK AND S. J. PEACOCK

3

The genomic era of bacteriology began in 1995 when the first bacterial genome (*Haemophilus influenzae*) was sequenced using the Sanger sequencing method (1). A decade later, the introduction of high-throughput or next-generation sequencing (NGS) technologies allowed sequencing of bacterial genomes to be performed in days rather than months or years (2). These newer technologies use different processes but rely on a combination of template preparation, sequencing and imaging, and genome alignment and assembly methods (3). The major advantages of NGS over Sanger sequencing are speed of sequencing combined with lower costs (4). The ability to readily sequence the whole genome of microorganisms has enabled the performance of large-scale comparative and evolutionary studies that were unimaginable even a few years ago (5–9). Furthermore, the development of rapid benchtop sequencing platforms (10) that are able to sequence a microbial genome in a day makes them increasingly appropriate for introduction into the diagnostic microbiology laboratory environment (11). This chapter will briefly review the currently available NGS technologies and platforms, followed by an in-depth review of the potential clinical applications of whole-genome sequencing (WGS) in the microbiology laboratory. We will also present the challenges for implementation of WGS in the clinical setting and consider some future directions.

THE CURRENT DIAGNOSTIC MICROBIOLOGY PARADIGM

Clinical microbiology is a laboratory discipline that primarily focuses on the detection and characterization of pathogens that cause disease in humans (diagnostic microbiology) (12, 13). The laboratory also has a secondary function: the surveillance and monitoring of infectious diseases (public health microbiology). This is particularly important for detecting outbreaks of infection and the emergence and spread of new pathogens or highly drug-resistant or virulent organisms. Bacterial pathogens account for a large proportion of the global burden of infectious diseases, and the majority of samples submitted to the microbiology laboratory for investigation fall into this category.

Culture, Identification, and Antimicrobial Susceptibility Testing of Bacterial Pathogens

Clinical specimens are submitted to the laboratory and cultured to detect pathogens, which then undergo identification using a variety of methods. These include colonial appearance and morphology, Gram staining and microscopy, and biochemical tests which may be performed at the bench or using an automated platform such as the Vitek 2 system (Biomérieux, Marcy l'Etoile, France) or BD Phoenix (Becton Dickinson, Oxford, England). Antimicrobial susceptibility testing is performed in parallel to identify drugs to which the isolate is susceptible and resistant and to enable appropriate treatment. Recently, matrix-assisted laser desorption ionization–time of flight mass spectroscopy, a method that can rapidly identify many bacterial pathogens within a few minutes at low cost (14), has been introduced into many diagnostic microbiology laboratories. However, although it has many advantages over more traditional identification methods, it cannot reliably distinguish certain species (e.g., *Escherichia coli* and *Shigella sonnei*), and does not provide antimicrobial susceptibility data.

Epidemiological Typing and Detection of Virulence Determinants

In the context of suspected outbreaks of infection, bacterial isolates collected from infected patients undergo epidemiological typing to determine their degree of relatedness. For certain organisms such as carbapenem-resistant *Enterobacteriaceae* or multidrug-resistant or extensively drug-resistant tuberculosis, additional antimicrobial susceptibility testing is required, usually at a reference laboratory. For other species such *Staphylococcus aureus* and group A streptococci, testing for virulence determinants such as toxins may also be performed. The time taken to provide a final result (turnaround time) increases with the number of tests performed on the bacterial isolate. This can sometimes be

M. E. Török and S. J. Peacock, University of Cambridge, Department of Medicine, Cambridge, CB2 0SP, United Kingdom; Cambridge University Hospitals NHS Foundation Trust, Cambridge, CB2 0QQ, United Kingdom; Public Health England, Clinical Microbiology and Public Health Laboratory, Cambridge, CB2 0QW, United Kingdom; Wellcome Trust Sanger Institute, Hinxton, CB10 1SA, United Kingdom.

too long to guide initial patient management, particularly for samples that require reference laboratory testing. The complexity of the current diagnostic microbiology paradigm is illustrated in Fig. 1.

Identification of Other Pathogens

Similar principles apply to the identification of other pathogens including fungi, viruses, and parasites, although the tests that are performed may differ. Fungi are cultured on specialist media and undergo identification and antifungal susceptibility testing in a diagnostic or reference laboratory. The diagnosis of viral infections is predominantly based on molecular diagnostics directed at detection of virus antigens or nucleic acids using amplification methods. Parasites are usually diagnosed by microscopy or molecular methods. This review will focus primarily on the clinical applications of NGS in the diagnosis and management of bacterial and viral pathogens, to reflect applications that are likely to be adopted first into day-to-day clinical practice. However, because the technology is pathogen agnostic, it could potentially be applied to other pathogens.

NGS TECHNOLOGIES AND PLATFORMS

Sequencing technologies include a number of methods that involve template preparation, sequencing, and imaging and data analysis (3). The type of data produced by each platform (e.g., length of DNA sequence read and depth of coverage) depends on the unique combination of methods for these steps and can present challenges when comparing data quality and costs between platforms.

Template Preparation

There are two methods for preparing templates for NGS reactions: clonally amplified templates arising from single DNA molecules and single DNA molecule templates (3). Current methods are based on randomly shearing genomic DNA from which templates are created. The template is then attached or immobilized to a solid surface or support, which enables thousands or millions of sequencing reactions to be performed simultaneously. The two most common methods for clonal amplification are emulsion PCR (15) and solid-phase amplification (16) (Fig. 2). Although clonally amplified methods offer some advantages over

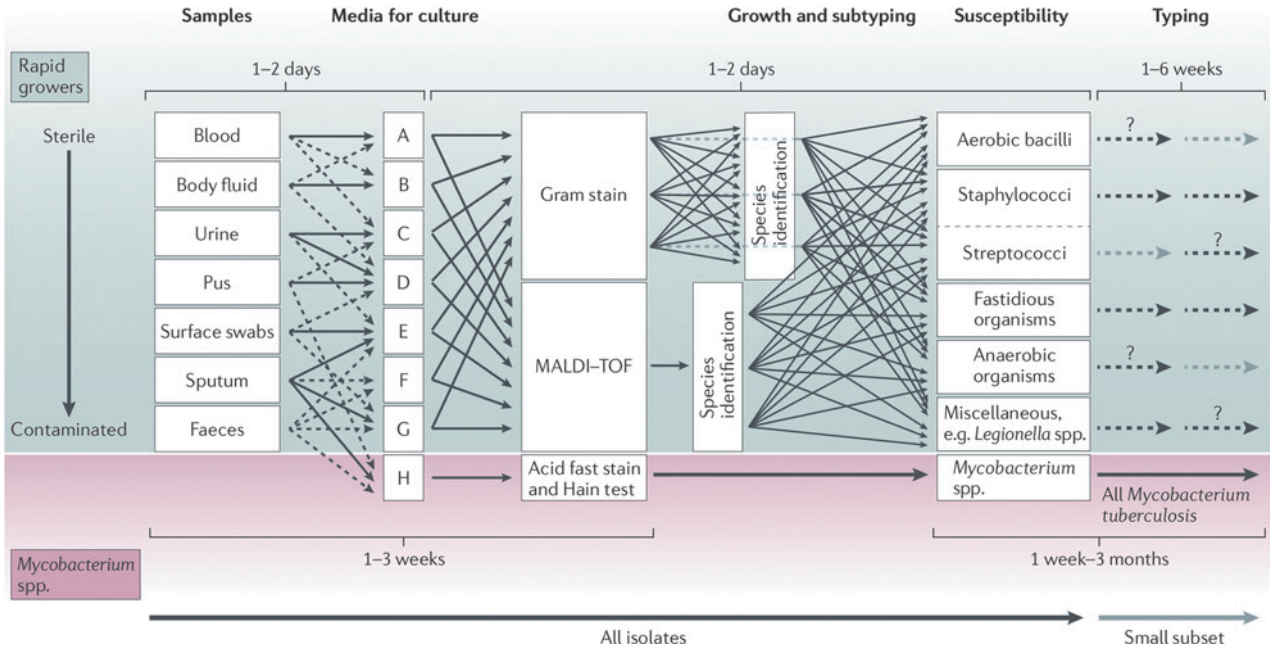

FIGURE 1 The current diagnostic microbiology processes for bacterial pathogens. A schematic representation of the current workflow for processing samples for bacterial pathogens is presented, showing high complexity and a typical timescale of a few weeks to a few months. The schematic is an approximation that highlights the principal steps in the workflow; it is not intended to be a comprehensive or precise description. Samples that are likely to be normally sterile are often cultured on a rich medium that will support the growth of any culturable organism. Samples that are contaminated with colonizing flora present a challenge for growing the infecting pathogen. Many types of culture media (referred to as selective media) are used to favor the growth of the suspected pathogen; this approach is particularly important for culturing pathogens from feces. Boxes A to H arbitrarily represent the many different media for culture. Medium H represents a medium designed for growing mycobacteria that have specific growth requirements. When an organism is growing, the morphological appearance and density of growth are properties that need specialist knowledge for deciding whether it is likely to be pathogenic. The likely pathogens are then processed through a complex pathway that has many contingencies to determine species and antimicrobial susceptibility. Broadly, there are two approaches. One approach uses matrix-assisted laser desorption ionization–time of flight mass spectrometry for species identification before setting up susceptibility testing. The other uses Gram staining followed by biochemical testing to determine species; susceptibility testing is often set up simultaneously with biochemical tests. Categorization of pathogens into groups of species is needed to choose the appropriate susceptibility-testing panel. Finally, depending on the species and perceived likelihood of an outbreak, a small subset of isolates may be chosen for further investigation using a wide range of typing tests that are often only provided by reference laboratories. The dashed lines and question marks are positioned arbitrarily to indicate that the further investigation is varied and happens in only a small number of cases. FIGURE 2 NGS platforms. The schematic shows the main high-throughput sequencing platforms available to microbiologists today and the associated sample preparation and template amplification procedures. PGM, personal genome machine. (Reprinted from reference 10 with permission.)

bacterial cloning, some of the protocols are cumbersome and require large amounts of starting genomic DNA (3 to 20 μg). Furthermore, AT-rich and GC-rich target sequences may show amplification bias in product yield, which can result in their under-representation in genome alignments and assemblies. The preparation of single DNA molecule templates is more straightforward by comparison because it requires less starting material (1 μg DNA) and does not require PCR (which can introduce mutations that may be falsely interpreted as sequence variants). Single-molecule templates are immobilized on solid supports using one of three approaches: immobilization by a primer, a template, or a polymerase.

Sequencing and Imaging

There are fundamental differences in sequencing of clonally amplified and single-molecule templates (3). Clonal amplification results in a population of identical templates, each of which has undergone the sequencing reaction. Upon imaging, the observed signal is a consensus of the nucleotides or probes added to the identical templates for a given cycle. This places a greater emphasis on the

efficiency of the addition process, and incomplete extension of the template ensemble results in dephasing (i.e., the growing primers move out of synchronicity for any given cycle). Signal dephasing increases fluorescence noise, causing base-calling errors and shorter reads. In contrast, dephasing is not an issue with single-molecule templates, so the requirement for cycle efficiency is relaxed. Single molecules, however, are susceptible to multiple nucleotide or probe additions in any given cycle. Here, deletion errors will occur owing to quenching effects between adjacent dye molecules or no signal will be detected because of the incorporation of dark nucleotides or probes (i.e., those that do not contain a fluorescent signal).

A number of sequencing and imaging methods are available; these include cyclic reversible termination, sequencing by ligation, single nucleotide addition, and single-molecule real-time sequencing. A brief description of these methods is given below, but they are comprehensively reviewed elsewhere (3).

Cyclic reversible termination uses reversible terminators in a cyclic method that comprises nucleotide incorporation, fluorescent imaging, and cleavage (2). In the first step, a DNA polymerase, bound to the primed template, adds or incorporates just one fluorescently modified nucleotide, which represents the complement of the template base. The termination of DNA synthesis after the addition of a single nucleotide is an important feature of cyclic reversible termination. Following incorporation, the remaining unincorporated nucleotides are washed away. Imaging is then performed to determine the identity of the incorporated nucleotide. This is followed by a cleavage step, which removes the terminating/inhibiting group and the fluorescent dye. Additional washing is performed before starting the next incorporation step. This technology is used by the Illumina sequencing platforms, which currently dominate the NGS market.

Sequencing by ligation is another cyclic method that differs from cyclic reversible termination in its use of DNA ligase and either one-base-encoded probes or two-base-encoded probes (17, 18). In its simplest form, a fluorescently labeled probe hybridizes to its complementary sequence adjacent to the primed template. DNA ligase is then added to join the dye-labeled probe to the primer. Nonligated probes are washed away, followed by fluorescence imaging to determine the identity of the ligated probe. The cycle can be repeated either by using cleavable probes to remove the fluorescent dye and regenerate a 5′-PO4 group for subsequent ligation cycles, or by removing and hybridizing a new primer to the template. This technology has been commercialized by Life/APG and is called the support oligonucleotide ligation detection, or SOLiD, system.

Single nucleotide addition, also known as pyrosequencing, is a nonelectrophoretic, bioluminescence method that measures the release of inorganic pyrophosphate by proportionally converting it into visible light using a series of enzymatic reactions (19, 20). Unlike other sequencing approaches that use modified nucleotides to terminate DNA synthesis, the pyrosequencing method manipulates DNA polymerase by the single addition of a deoxynucleoside triphosphate (dNTP) in limiting amounts. Upon incorporation of the complementary dNTP, DNA polymerase extends the primer and pauses. DNA synthesis is reinitiated following the addition of the next complementary dNTP in the dispensing cycle. The order and intensity of the light peaks are recorded as flowgrams, which reveal the underlying DNA sequence. This technology was commercialized by 454 Life Sciences (Branford, Connecticut, USA) and is now less popular than the Illumina platforms. The last addition to the market of second-generation sequencing instruments is the Ion Torrent, manufactured by Life Technologies (Paisley, United Kingdom). This device is based on a technique similar to 454 Life Sciences, but it senses the incorporation of a nucleotide electrically by using a small, sensitive complementary metal-oxide semiconductor–compatible pH meter (21). Instead of detecting the incorporation of a nucleotide through a fluorescent dye, the generation of a hydrogen atom, which is released each time a nucleotide is added into the growing strand, is probed. The pH meter chip replaces the camera and fluorescent molecules in the 454 device and permits cheaper sequencing through lower reagent and device costs.

Single-molecule real-time sequencing involves imaging the continuous incorporation of dye-labeled nucleotides during DNA synthesis (22). The first NGS instrument, developed by Pacific Biosciences (Menlo Park, California, USA), is referred to as single-molecule real-time sequencing and has been available since 2011. Single-molecule real-time sequencing is based on a chip pioneered by Levene et al. (23) that contains an array of zero-mode waveguides. A single DNA polymerase is attached to the bottom of the well, and the zero-mode waveguides create an illuminated volume that is small enough to allow observation of the incorporation of a single nucleotide. Each time a nucleotide is added to the DNA at the bottom of the well, the dye is detected before being cleaved off and diffusing away. Although the devices are very expensive, they are ideal for *de novo* sequencing of unknown genomes due to their long read lengths of 8 kbp. They even permit the quantification of methylation, DNA damage, and other epigenetic information.

Another NGS technique that has been gaining much attention recently is based on nanopores (24, 25). The first detection of DNA using the biological nanopore α-hemolysin was accomplished in 1996 by John Kasianowicz et al. (26). The nanopore was incorporated into a phospholipid bilayer, which separated two reservoirs filled with a KCl solution. Using two electrodes placed on opposite sides of the bilayer, an electrical potential can be applied, causing an ionic current. DNA, which is negatively charged, can therefore be forced to translocate through the nanopore by applying a positive potential to the electrode on the opposite side of the membrane. The translocation velocity varies, depending on parameters such as the electrical potential, the type of nanopore, and whether the DNA is single-stranded or double-stranded (27). Oxford Nanopore Technologies (Oxford, United Kingdom) is developing a device based on an array of biological nanopores (28, 29). A commercial launch has not yet been disclosed, but if the technology is coupled with a device that enables reliable decoding of long sequences with an acceptable error rate, it could change the current landscape of DNA sequencing.

Genome Alignment and Assembly

After NGS reads have been generated they are aligned to a known reference sequence or assembled *de novo*. The decision to use either strategy depends on the biological application as well as cost, effort, and time considerations. For example, identifying and cataloguing genetic variation in multiple strains of highly related genomes are best

achieved by mapping to a previously sequenced reference genome. This enables phylogenetic and epidemiological analysis (5–9) and is of clinical utility when investigating outbreaks of infection in hospital (30–35) and community settings (33, 36–41). Single-nucleotide variants can be easily identified, although validation of these findings may be required, for example, by visually examining the raw sequence data and checking its alignment to the reference genome.

There are, however, some limitations to the alignment approach. First, there needs to be a previously sequenced reference genome to which others are mapped. Second, there may be difficulties in mapping within repetitive regions of the reference genome or if there are no corresponding areas in the reference genome, e.g., as a result of gaps in the reference genome or the presence of structural variants. The latter problem may be resolved to some extent with mate pair reads (i.e., reads that are generated from sequencing from both ends of a DNA fragment). *De novo* assemblies are usually performed for genomes that are relatively small compared with the human genome such as bacteria, viruses, or fungi, either when the organism identity is unknown (e.g., a new or emerging pathogen) or when no previously sequenced reference genome is available. One strategy to improve the quality of alignment or assembly is to increase the coverage (i.e., the number of times a nucleotide is read during the sequencing process). An alternative strategy is to combine sequence read data generated by different NGS platforms, e.g., Roche 454 and Illumina, which has been shown to improve *de novo* assemblies of microbial genomes (42).

An overview of NGS technologies, instrument performance and costs, pros and cons, and recommendations for biological applications is presented in Table 1. The rapid pace of technological advances in the field means that this information is likely to become outdated.

CLINICAL AND RESEARCH APPLICATIONS OF NGS

The main driver for platform development has been the sequencing of human genomes to catalogue single-nucleotide variants and their association with phenotypic differences, with the eventual goal of personalized genomics for medical purposes. To this end, the United Kingdom government has committed to sequence 100,000 human genomes (43), and similar initiatives are ongoing in other countries, e.g., the Cancer Genome Atlas (44) and the 1000 Genomes project (45). Although not the primary intended audience, diagnostic and public health microbiology can derive major benefit from these technical developments. This includes large-scale projects such as the 100K Foodborne Pathogen Genome Project, an international collaboration to sequence 100,000 bacterial genomes with a view to addressing issues relating to food-borne infectious diseases (46).

The clinical applications of genomics in microbiology can be divided into two categories: those that require a bacterial isolate (e.g., bacterial typing, outbreak investigation, and surveillance and determination of resistance and virulence determinants) and those that can be applied directly to clinical samples (e.g., metagenomics and population profiling). In the following sections we will discuss the background literature that will inform current and future applications of NGS in clinical microbiology and public health.

Global Evolutionary Studies

In recent years WGS has been used to examine the evolution and spread of medically important bacterial pathogens at local, national, and international levels. Although many of these were conducted as research studies, they have been crucial in preparing the ground for clinical sequencing and generating databases of reference genomes. The first paper to demonstrate this was a study by Harris and colleagues (5), who sequenced 63 methicillin-resistant *S. aureus* (MRSA) ST239 isolates: a global collection of 43 MRSA isolates collected between 1982 and 2003, and a local collection of 20 MRSA isolates from a hospital in Thailand. Using this approach they were able to demonstrate intercontinental spread of MRSA isolates as well as evidence of local, intra-hospital transmission of MRSA. A second study, by McAdam and colleagues, examined 87 hospital-associated MRSA isolates (including 60 epidemic MRSA 16 [EMRSA-16] and 27 additional clonal complex 30 isolates collected from three continents over a 53-year period (47). They found that the three major pandemic clones to originate from the clonal complex 30 lineage had a common ancestor about 100 years ago and that EMRSA had emerged about 35 years ago. Genome-wide analysis revealed molecular correlates of hospital- or community-associated pandemics represented by mobile genetic elements and nonsynonymous mutations affecting antibiotic resistance and virulence. Phylogeographic analysis indicated that EMRSA-16 spread within the United Kingdom by transmission from hospitals in large population centers in London and Glasgow to regional health care settings.

A third study, by Holden and colleagues, examined the emergence and spread of another epidemic clone, EMRSA-15, which was first detected in the United Kingdom in the early 1990s (48). They sequenced 193 MRSA ST22 isolates from 15 countries collected between 1990 and 2009 and found that the current pandemic population of EMRSA-15 descended from a health care–associated MRSA epidemic that spread throughout England in the 1980s. Furthermore, the emergence of fluoroquinolone resistance in this EMRSA-15 subclone in the English Midlands during the mid-1980s may have played a role in triggering the pandemic spread. Using comparative genomic analysis, they identified the genetic basis of 99.8% of the antimicrobial resistance phenotypes of the isolate collection, highlighting the potential of pathogen genome sequencing as a diagnostic tool. They also documented the genetic changes associated with adaptation to the hospital environment and with increasing drug resistance over time, and how MRSA evolution may have been influenced by differences in antibiotic use between countries. Collectively, these studies have provided new insights into the emergence and spread of epidemic MRSA clones and the factors that may have contributed to their epidemiological success.

WGS has also been applied to the epidemiological analysis of important enteric pathogens such as *Vibrio cholerae*, *Salmonella enterica* serovar Typhi (*S.* Typhi), *S. sonnei*, and *Clostridium difficile*. *V. cholerae* is a globally important pathogen that causes 3 to 5 million reported cases of cholera every year. Historically, seven cholera pandemics have been recognized, with recent outbreaks in Zimbabwe and Haiti being included in the seventh pandemic. Only isolates in serogroup O1 (consisting of the classical and El Tor biotypes) and serogroup O139 can cause epidemic cholera. The first six cholera pandemics were caused by

TABLE 1 Comparison of NGS platforms[a]

Machine	Manufacturer	Chemistry	Avg read length	Run time	Output range	Advantages	Disadvantages
GS FLX Titanium XL+	Roche	Pyrosequencing	700 bp	23 hours	0.7	Long read lengths	Appreciable hands-on time High reagent costs High error rate in homopolymers

[a]Adapted from reference 10.

the classical biotype, but the El Tor biotype has subsequently spread globally. Standard epidemiological typing methods have relied on subgenomic regions, which are less discriminatory than WGS data. A recent study examined the phylogeny of 154 geographically and temporally diverse *V. cholerae* isolates and found that the seventh pandemic had spread from the Bay of Bengal in three separate but overlapping waves, with a common ancestor in the 1950s as shown in Fig. 3 (6). Furthermore, the acquisition of the SXT element (an integrating and conjugating

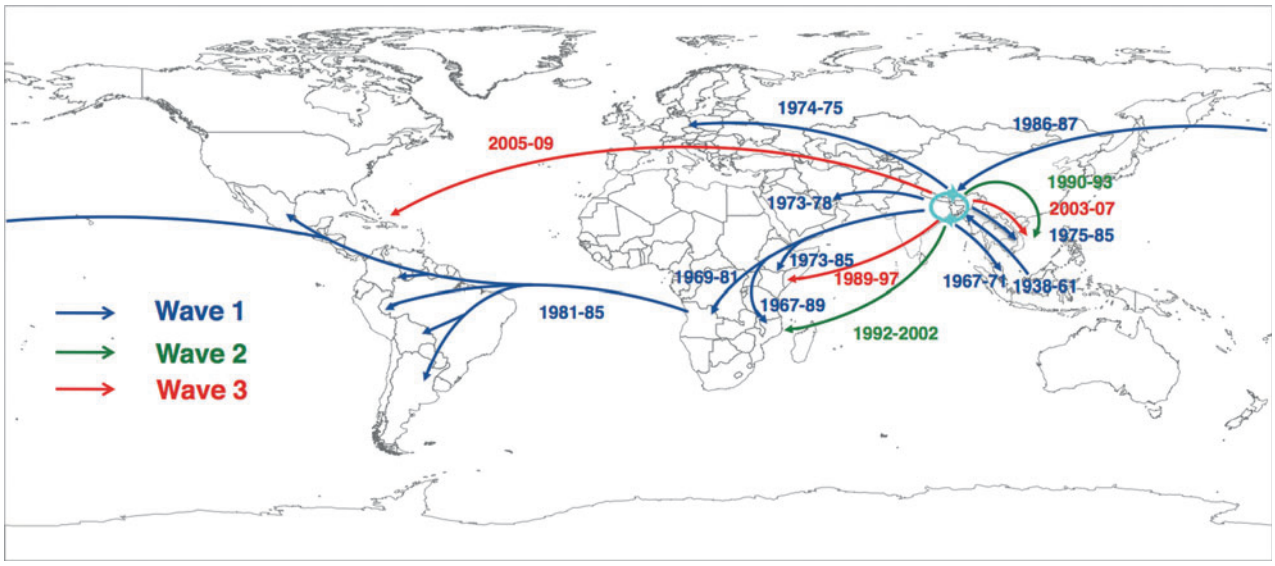

FIGURE 3 Global spread of the seventh cholera pandemic. Transmission events inferred for the seventh-pandemic phylogenetic tree, drawn on a global map. The date ranges shown for transmission events are taken from the BEAST analysis and represent the median values for the most recent common ancestor of the transmitted strains (later bound) and the most recent common ancestor of the transmitted strains and their closest relative from the source location (earlier bound). (Reprinted from reference 6 with permission.)

element that encodes resistance to sulfamethoxazole, trimethoprim, chloramphenicol, and streptomycin) appears to have shaped the pandemic spread.

S. Typhi is the major cause of enteric fever, which is estimated to affect 16 million people per year, and accounts for 500,000 to 600,000 deaths per year. Chloramphenicol-resistant *S.* Typhi was first reported in 1950 (49), and by the 1970s multidrug-resistant strains (resistant to chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole) had been reported (50). Multidrug resistance in *S.* Typhi is almost exclusively conferred by IncHI1 plasmids carrying antimicrobial resistance genes (51). The first study to examine genome variation and evolution in *S.* Typhi using WGS sequenced 19 *S.* Typhi isolates from 11 countries collected between 1916 and 2000 (52). Comparative analysis showed little evidence of selection, antigenic variation, or recombination between isolates, which was notable when compared to patterns observed among other human bacterial pathogens. Only 3 *S.* Typhi genes contained more than 6 single-nucleotide polymorphisms (SNPs), and 16 genes contained independent nonsynonymous SNPs in the same or neighboring amino acids. The scarcity of evidence for antigenic variation in *S.* Typhi suggested that this pathogen was not under strong selective pressure from the human immune system. If human carriers provide the main reservoir for *S.* Typhi, this could account for the patterns of genetic drift and lack of recombination or gene acquisition observed, because the human reservoir is likely to be small and physiologically isolated. Furthermore, adaptive mutations arising during symptomatic typhoid infections may have no fitness advantage in the carrier state and may therefore not persist in the long-term *S.* Typhi population.

S. sonnei is another globally important enteric pathogen, which causes outbreaks of bacterial dysentery. Historically, this has been associated with outbreaks in developed countries but is emerging as a problem in the developing world, where it appears to be replacing *Shigella flexneri* as a cause of dysentery. Holt and colleagues sequenced 132 globally distributed *S. sonnei* isolates collected between 1943 and 2008 (7). Phylogenetic analysis revealed that the current *S. sonnei* population descended from a common ancestor that existed less than 500 years ago and diversified into several lineages with unique characteristics. The majority of this diversification appears to have taken place in Europe and then disseminated to other continents through pandemic spread of multidrug-resistant clones.

In contrast to the above, *C. difficile* is an enteric pathogen that is the most common cause of antibiotic-associated diarrhea (53). The emergence of an epidemic strain, designated *C. difficile* 027/BI/NAP1, was associated with nosocomial outbreaks and high morbidity and mortality (54). This fluoroquinoline-resistant strain was previously uncommon, and the reasons underlying its evolutionary success were unknown. To investigate this, He and colleagues sequenced a global collection of 151 *C. difficile* 027/BI/NAP1 isolates from hospital patients between 1985 and 2010 (8). They found not one, but two distinct epidemic lineages (designated FQR1 and FQR2) that had both emerged in North America but showed different patterns of global spread. The FQR2 lineage, in particular, had spread more widely and caused outbreaks in the United Kingdom, continental Europe, and Australia.

Mycobacterium tuberculosis is a globally important pathogen causing 8.6 million cases of tuberculosis (TB) and 1.3 million deaths in 2012 (55). In common with other crowd diseases, *M. tuberculosis* is believed to have emerged about 10,000 years ago during the Neolithic demographic transition. However, recent studies suggest an earlier origin. Comas and colleagues explored the evolutionary history of *M. tuberculosis* (9) by sequencing a global collection of 259 isolates of *M. tuberculosis* complex representing all seven lineages. They found that *M. tuberculosis* complex emerged about 70,000 years ago, accompanied migrations of anatomically modern humans out of Africa, and expanded as a consequence of increases in human population density. A second study examined the evolution of drug resistance in

M. tuberculosis (56). Using 116 new and 7 previously sequenced genomes, Farhat and colleagues reconstructed a phylogeny and identified targets of convergent evolution using a simple statistical test. They identified all of a set of 11 known drug resistance determinants, as well as 39 genes and intergenic regions newly associated with resistance. These regions encoded pathways of cell wall biosynthesis, transcriptional regulation, and DNA repair—mutations that could directly confer resistance or compensate for fitness costs associated with resistance.

Collectively, these studies demonstrate the superiority of WGS over current typing methods for investigating the global spread of bacterial pathogens, particularly those that are highly clonal in nature. In addition, WGS can provide information about antibiotic resistance mutations/genes and virulence determinants that may help to explain the evolutionary success of particular epidemic or pandemic lineages.

Outbreak Investigation

The major application of WGS in clinical microbiology and public health is likely to be the investigation and management of suspected outbreaks of infection, in both hospital and community settings. Early recognition and confirmation of outbreaks can result in rapid implementation of appropriate infection control and/or public health measures and thus potentially bring the outbreak to a close more quickly. Conversely, being able to refute an outbreak (57) may be reassuring to clinicians and allow de-escalation of infection control measures, which can be time-consuming and expensive. Over the past few years a number of studies have demonstrated the potential utility of this approach for pathogens such as *E. coli* (41), MRSA (30, 34), *Klebsiella pneumoniae* (31), *Acinetobacter baumannii* (58), *Enterococcus faecium* (35), *Enterobacter cloacae* (35), *Pseudomonas aeruginosa* (59), *C. difficile* (33, 60), *M. tuberculosis* (37, 61), *Mycobacterium abscessus* (32), viruses (62–64), and fungi (65). Most of these studies were conducted retrospectively and did not influence immediate clinical management, although a few were conducted in real time (34, 41). As clinical microbiology laboratories become more adept at sequencing and bioinformatic analysis becomes automated, it is likely that WGS will replace conventional typing methods and provide clinically actionable data for outbreak investigation and management.

One of the earliest and most high-profile examples of the use of WGS was during the investigation of an outbreak of *E. coli* 0104:H4, which affected more than 3,000 people in Germany in 2011 (41). This outbreak was characterized by a number of unusual features, namely a high incidence in adults (particularly in females) and the hemolytic-uremic syndrome. Rohde and colleagues sequenced a sample obtained from a patient involved in the outbreak using a rapid benchtop sequencing platform, the Ion Torrent PGM. Sequence data were released into the public domain on day 3 and rapidly analyzed by bioinformaticians on four continents. By 24 hours after the release of the sequence data the genome had been assembled, and 2 days after its dissemination it had been assigned to an existing sequence type. Five days after the release of the sequence data, strain-specific diagnostic primer sequences had been designed and released. In less than a week, this study revealed that the outbreak strain belonged to an enteroaggregative *E. coli* lineage that had acquired genes for Shiga toxin 2 and for antibiotic resistance, illustrating the potential power of open source genomic analysis to investigate outbreaks of emerging infectious diseases.

A second study published simultaneously used third-generation single-molecule real-time DNA sequencing (using the PacBio platform) to determine the complete genome sequence of the German strain, as well as the genome sequences of seven diarrhea-associated enteroaggregative *E. coli* serotype O104:H4 strains from Africa and four enteroaggregative *E. coli* reference strains belonging to other serotypes (66). Genome-wide comparisons were performed using these enteroaggregative *E. coli* genomes, as well as those of 40 previously sequenced *E. coli* isolates. The investigators found that the enteroaggregative *E. coli* O104:H4 strains were closely related and formed a distinct clade among *E. coli* and enteroaggregative *E. coli* strains. The German outbreak strain contained a prophage encoding Shiga toxin 2 and a distinct set of additional antibiotic resistance and virulence factors, suggesting that horizontal genetic exchange preceded the emergence of this strain.

One of the first studies to demonstrate the potential utility of WGS in nosocomial outbreak investigations was conducted by Köser and colleagues in the United Kingdom (30). The investigators retrospectively investigated an MRSA outbreak in a neonatal intensive care unit by sequencing 14 MRSA isolates: 7 from infants on the unit and 7 from control patients located elsewhere in the hospital. Phylogenetic analysis revealed a cluster of outbreak strains that were clearly separated from the control isolates and detected a previously unsuspected transmission event between two of the control patients. The investigators also created an artificial "resistome" of antibiotic resistance genes and demonstrated concordance between genotypic and phenotypic antimicrobial susceptibility results, thus highlighting another potential use for WGS. A second study, by Harris and colleagues, applied WGS during the course of a suspected ongoing MRSA outbreak in neonates (34). In this study, the investigators sequenced MRSA isolates from 12 infants who were admitted to the special care baby unit over a 6-month period. These were found to be a novel MRSA strain (ST2371) that carried the gene for Panton-Valentine leukocidin. Sequencing of additional MRSA isolates with the same antibiotic susceptibility profile identified 24 cases that were epidemiologically linked, indicating spread between infants on the special care baby unit, mothers on the postnatal ward, and family members in the community. A new case, which occurred 64 days after the previous case, prompted screening of health care workers on the unit. One person was found to be carrying the outbreak strain, and no further cases were detected after they were successfully decolonized. The epidemiology and phylogeny of this outbreak are illustrated in Fig. 4. Of note, this was the first study to demonstrate the feasibility of using WGS in real time to investigate and manage a nosocomial infection outbreak.

K. pneumoniae is an important nosocomial pathogen in intensive care units, particularly among immunocompromised patients. In recent years *K. pneumoniae* strains resistant to carbapenems have emerged and spread worldwide. In 2011, the U.S. National Institutes of Health experienced an outbreak of carbapenem-resistant *K. pneumoniae* that affected 18 patients, 11 of whom died (31). Snitkin and colleagues sequenced *K. pneumoniae* isolates from the affected patients and found that the outbreak was monoclonal despite a 3-week gap between the index case and subsequent cases. They identified at least three independent transmission events from the index case, resulting in

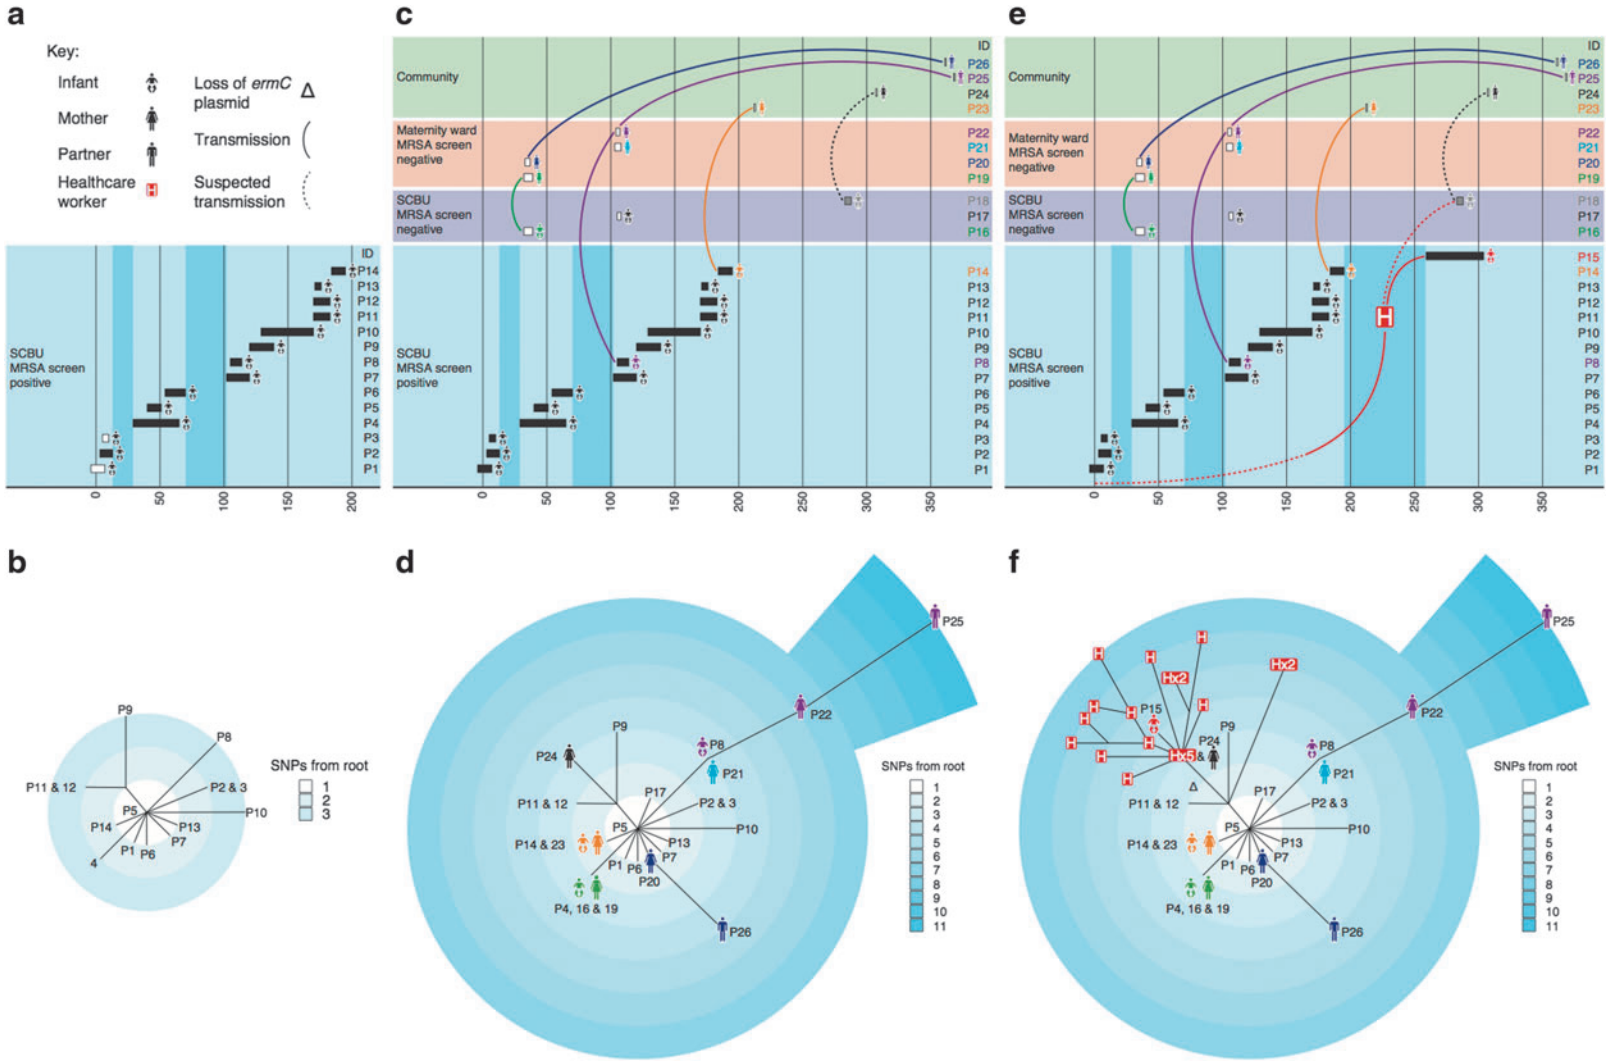

FIGURE 4 Epidemiology and phylogeny of a neonatal MRSA ST2371 outbreak. (a) Epidemiological map of 14 infants (patients 1 to 14) on the special care baby unit (SCBU). Boxes shown for infants in the SCBU in panel a represent duration of hospital stay (black boxes show infants included by the infection-control investigation and white boxes show infants excluded by the infection-control team). Gray vertical blocks in panels a, c, and e show the time periods on the SCBU when there were no known carriers of MRSA. (b) Phylogenetic tree based on WGS of MRSA isolates from patients 1 to 14. (c) Epidemiological map of patients 1 to 14 and 10 other patients (patients 16, 17, and 19 to 26) with linked MRSA infection detected in the community. The colored lines link members of the same family. (d) Phylogenetic tree based on WGS of MRSA isolates from patients 1 to14 and patients 16, 17, and 19 to 26. (e) Epidemiological map of all cases of MRSA identified by WGS and one patient (patient 18) suspected of being linked to the outbreak but for whom no MRSA colonization was detected. (f) Phylogenetic tree of all cases of MRSA in the outbreak. Twenty individual MRSA colonies from a staff member are shown in red boxes, with multiple colonies from the staff member shown in parentheses. MRSA, methicillin-resistant *Staphylococcus aureus*; SCBU, special care baby unit; SNP, single-nucleotide polymorphism; P, patient. Note: Out-group was the sequence type 22 reference genome. (Reprinted from reference 34 with permission.)

two major clusters of colonized patients. One patient could be linked to a contaminated ventilator. They also identified putative resistance mutations in isolates that had become resistant to colistin.

A number of other studies have used WGS to investigate nosocomial outbreaks caused by a variety of pathogens including multidrug-resistant *A. baumannii* (58), vancomycin-resistant *E. faecium* (35, 67), carbapenem-resistant *E. cloacae* (35), and *P. aeruginosa* (59). WGS has also been used to investigate *Legionella pneumophila* outbreaks both retrospectively (39) and in real time (68). More recently, WGS has been applied to the investigation of a milk-borne outbreak of *Campylobacter jejuni* (69) and a food-borne outbreak of *Listeria monocytogenes* (70). In all of these studies the investigators were able to distinguish outbreak from nonoutbreak strains and to delineate probable transmission pathways.

A similar approach has been applied to the investigation of *C. difficile* cases in health care and community settings. A study by Eyre and colleagues sequenced 1,223 isolates from symptomatic patients with *C. difficile* infection between 2007 and 2011 (33). Thirty-five percent of isolates had no more than two single-nucleotide variants between them, which was considered to be consistent with transmission. Of these, 38% had ward contact with another patient (admitted to the same ward at the same time), 2% may have acquired the organism from the ward environment (ward contamination), 9% had hospital contact (admitted on different hospital wards at the same time), and 6% had both ward contamination and hospital contact. In terms of community contact opportunities, 10% of patients were registered at the same general practice and 11% lived in the same postal code district. The remaining 36% had no evidence of hospital or community contact. Forty-five percent of isolates had more than 10 single-nucleotide variants from previous cases, representing transmission from sources other than symptomatic cases included in the study. These findings suggest that *C. difficile* transmission arises from genetically diverse sources, which may include asymptomatic patients and/or the environment. The use of WGS for *C. difficile* could, therefore, be targeted to investigate cases that are epidemiologically linked with a view to preventing further spread, and also to monitor performance of institutional infection control programs. A second study by the same group considered the role of asymptomatic carriage in the transmission of *C. difficile* (60). Of the 227 patients recruited, 132 provided one or more stool samples; 18 were culture positive for *C. difficile*, and 13 carried toxigenic strains. Several plausible cases of transmission to asymptomatic carriers were identified, but there was no clear evidence of onward transmission from an asymptomatic case in this small study.

In developed countries, tuberculosis control programs use genotyping (e.g., IS6110 RFLP or MIRU-VNTR [Mycobacterial Interspersed Repetitive Units-Variable Number of Tandem Repeats] typing) to identify clusters of patients affected with the same strain, to target contact tracing of associated cases with active disease or latent infection. The first study to compare WGS with traditional genotyping methods for TB outbreak investigation was conducted by Schürch and colleagues in the Netherlands (36). They sequenced *M. tuberculosis* isolates from 3 of 104 patients involved in the Harlingen outbreak between 2001 and 2008 and compared these to the results obtained by IS6110 RFLP typing. WGS proved highly discriminatory and enabled them to identify transmission chains within the Harlingen outbreak that were not apparent by conventional typing.

A second, larger study by Gardy and colleagues investigated a 3-year TB outbreak in Canada (37). Sequencing of 32 outbreak isolates and four historical controls revealed two genetically distinct lineages with identical MIRU-VNTR genotypes. Integration of phylogenetic and social network analysis revealed several transmission events, including some involving "super-spreaders." Both lineages descended from a common ancestor that had been present in the community prior to the outbreak, suggesting a social rather than a genetic reason for spread. Further epidemiological investigation indicated that the outbreak coincided with increased crack cocaine use in the community.

A third study, conducted by Walker and colleagues in the United Kingdom, aimed to estimate the genetic diversity of *M. tuberculosis* strains in the Midlands and to determine how this might be used to investigate outbreaks (61). They sequenced 390 *M. tuberculosis* isolates from 254 patients and characterized them into four groups: cross sectional, longitudinal, household, and community. They measured pair-wise nucleotide differences within hosts and between hosts in household outbreaks. The estimated rate of change in DNA sequence was 0.5 SNPs per genome per year, and divergence was rarely higher than five SNPs in 3 years. Ninety-six percent of paired isolates from individuals and households differed by five or fewer SNPs. More than five SNPs separated none of the epidemiologically linked patients, 15% of the possibly linked patients, and 17% of the unlinked patients. Phylogenetic analysis suggested that super-spreaders were present in two community clusters. Other studies have confirmed the utility of WGS in TB outbreak investigation in different settings (38, 71, 72). Collectively, the findings of these studies indicate that WGS can be used to distinguish patients who are in a recent TB transmission chain from those who are not and have substantial implications for contact tracing, particularly in complex transmission settings or where epidemiological data are incomplete.

M. abscessus is a major respiratory pathogen, particularly in patients with cystic fibrosis, in whom it can lead to rapid decline in lung function and may preclude transplantation. Three subspecies have been recognized—*M. abscessus* subsp. *abscessus*, *M. abscessus* subsp. *massiliense*, and *M. abscessus* subsp. *bolletti*—but these are not usually distinguished in the clinical microbiology laboratory. Previous studies have suggested that *M. abscessus* was acquired from the environment and that there was limited evidence for person-to-person transmission. A recent study by Bryant and colleagues has challenged this view (32). The investigators sequenced 168 *M. abscessus* isolates from 31 adults attending a cystic fibrosis unit in the United Kingdom between 2007 and 2011. Phylogenetic analysis revealed two clustered outbreaks of near-identical isolates of *M. abscessus* subsp. *massiliense* that differed by less than 10 SNPs, suggesting patient-to-patient transmission. Furthermore, there was evidence of transmission of acquired drug resistance mutations between individuals, some of whom had not been exposed to the antibiotics to which their isolate was resistant. An epidemiological investigation identified numerous opportunities for cross-infection between patients within the hospital setting, but environmental sampling for *M. abscessus* was negative. Thus, WGS revealed transmission of multidrug-resistant *M. abscessus* strains between patients with cystic fibrosis despite standard infection control measures. This study has led to changes in

infection prevention and control guidance for *M. abscessus* in the United Kingdom.

WGS has been applied to the epidemiological analysis of the influenza AH1N1/09 pandemic in the United States and the United Kingdom. Nelson and colleagues undertook a large-scale phylogeographic analysis of viruses sampled in three locations in the United States to determine if there were different epidemiological patterns between the spring and autumn waves of the pandemic (73). Between March and July 2009 no specific viral lineage dominated in Texas, whereas outbreaks in Milwaukee and New York State were each dominated by a different viral lineage. By August 2009 a single viral lineage (the dominant lineage in New York during the spring wave) had also become dominant in all three locations. Baillie and colleagues sequenced 153 pandemic influenza H1N1/09 strains—127 from the first wave and 26 from the second wave (74). The investigators found that the United Kingdom epidemic was composed of many cocirculating lineages, at least 13 of which were exclusively or predominantly United Kingdom clusters. The estimated divergence times of two of the clusters predated the detection of influenza H1N1/09 in the United Kingdom, suggesting that the virus was already circulating before the first clinical case was reported. Two United Kingdom clusters contained similar sequences in the first and second waves of infection, suggesting persistent transmission in the community. These studies shed light on the changing epidemiology of influenza strains and highlight a potential role for WGS influenza surveillance, which could be used to inform vaccine design.

WGS has also been applied to the investigation of outbreaks of viral infections in hospital and community settings, including norovirus (62), hepatitis A virus (63), West Nile virus (WNV) (64), and Middle Eastern respiratory syndrome (MERS) coronavirus. Norovirus is a leading cause of viral gastroenteritis worldwide and is associated with outbreaks of infection in health care and community settings. Kundu and colleagues investigated a cluster of norovirus infections that occurred in children undergoing bone marrow transplantation at a United Kingdom hospital in 2010 (62). Thirteen complementary DNA samples from five patients were amplified and sequenced using the Roche 454 platform and assembled *de novo*. Phylogenetic analysis indicated that two of the three patients on the same ward had closely related viruses, indicating the possibility of cross-infection despite protective isolation. Analysis of deep sequencing data established the likely direction of nosocomial transmission.

Hepatitis A virus is a common cause of acute viral hepatitis and usually causes a self-limited infection. Infection in children is usually asymptomatic but can, rarely, result in fulminant liver failure. Vaughan and colleagues investigated a hepatitis A virus outbreak in five children, two of whom developed acute liver failure and died (63). Samples were obtained and sequenced from the two fatal cases and two asymptomatic cases in one household and from a symptomatic case in another household. Both households were infected with hepatitis A virus subtype 1A, but the infecting strains in the two households were different. Interestingly, the strain recovered from the asymptomatic household contact was nearly identical to the strain causing acute liver failure.

WNV is an arbovirus infection transmitted by mosquitoes, and may be asymptomatic or cause a febrile illness, meningitis, or encephalitis. Since 2010, WNV has caused a number of large epidemic outbreaks in Europe. Barzon and colleagues used WGS to investigate cases of WNV infection associated with an ongoing outbreak in northern Italy (64). Analysis of six WNV sequences obtained from clinical samples in 2013 indicated a new strain of WNV lineage 2, which was similar to strains circulating in Greece and Hungary. They also sequenced a WNV strain from a blood donor collected during the 2012 outbreak, which was found to be WNV lineage 1. Thus, WGS identified two strains of WNV that were cocirculating in northern Italy in 2012 to 2013.

In September 2012 the WHO reported the first cases of MERS (75). Whole-genome sequencing identified a novel human coronavirus, which was isolated from the sputum of a patient who died of pneumonia and renal failure in a hospital in Saudi Arabia (76). Since then MERS coronavirus has been reported from several countries and associated with person-to-person transmission in a hospital setting (77). As of June 2014, 699 laboratory-confirmed cases of MERS coronavirus and 209 deaths had been reported to WHO (78).

Finally, WGS has also been used to investigate an outbreak of fungal infections caused by *Exserohilum rostratum* (65) and *Apophysomyces trapeziformis* (79). In the first study, *E. rostratum* caused an outbreak of fungal meningitis and other infections that were associated with contaminated methylprednisolone injections. The investigators sequenced 22 isolates of *E. rostratum* from 19 patients, 6 isolates from contaminated vials, and 7 isolates unrelated to the outbreak. All 28 isolates associated with the outbreak were closely related, with a total of eight SNPs between them and no more than two SNPs between any of the two outbreak genomes. In contrast, the control isolates showed considerable genetic variability, and the closest isolate was >100,000 SNPs distant from the outbreak isolates. In the second study, 13 patients in 6 hospitals developed mucormycosis after sustaining tornado-related injuries (79). Sequencing of 11 isolates showed that 4 strains infected the patients. Clonally related isolates did not cluster geographically but were scattered throughout the tornado path, the two predominant clones causing infections in patients living closest to the touch-down site of the tornado.

Collectively, these studies indicate the clinical utility of using rapid microbial WGS for the investigation of suspected outbreaks in hospital and community settings. It is likely that this technology will supplant conventional epidemiological typing methods in the future, but significant challenges remain. As WGS becomes faster and cheaper, the key barrier to implementation into routine clinical care is the lack of automated sequence data analysis tools for the common human pathogens. In addition, although large genomic databases that provide a genomic context exist for some common pathogens, these are not always readily accessible for comparison of genome sequences generated during outbreak investigations.

Detection and Surveillance of Antimicrobial Resistance

WGS can be used to detect drug resistance mutations and acquired genes and to elucidate mechanisms of resistance. Several studies have compared phenotypic antimicrobial susceptibility testing with genotypic predictions by WGS for a variety of pathogens (80–82). These have shown good concordance between phenotypic and genotypic susceptibility results that are well within the limits set by the U.S. FDA for marketing approval (<1.5% for a very major

discrepancy and <3% for a major discrepancy). For most common bacterial pathogens, however, phenotypic antimicrobial susceptibility testing is rapid and inexpensive and is likely to remain the first-line testing method for some time to come.

There are specific clinical scenarios where rapid WGS could play a role in the detection of antibiotic resistance. The first is when phenotypic drug susceptibility testing is too slow to guide initial patient management. A prime example is *M. tuberculosis*, for which drug susceptibility testing can takes weeks to months, particularly for multidrug-resistant or extensively drug-resistant isolates for which a wider panel of drugs are tested. Molecular tests exist but only target the most common mutations for a limited number of drugs. A study by Köser and colleagues used WGS to investigate a case of extensively drug-resistant tuberculosis (83). They detected evidence of mixed infection with two Beijing strains and were able to demonstrate concordance between genotypic and phenotypic susceptibility testing. Furthermore, they were able to detect resistance mutations for additional agents that were not routinely tested for in the reference laboratory. WGS therefore shows great promise not just for epidemiological typing of *M. tuberculosis* isolates, but also for clinical management of infection caused by highly drug-resistant isolates. Caveats include the fact that genotype-phenotype associations have not been determined for all drugs and that current technology may be not be able to detect mutations that are present at 1% or less in the total population unless deep sequencing is performed (that is, the genome is sequenced many times over).

Another potential application is where elucidation of the resistance mechanism is important for infection control purposes. One example is linezolid-resistant *E. faecium*, when determination of the basis of resistance (mutation versus plasmid-mediated resistance) may influence the decision to implement enhanced infection control measures (84). A second example is carbapenem-resistant *Enterobacteriaceae*, which may be caused by carbapenemase production (which requires enhanced infection control) or by a combination of resistance mechanisms (e.g., extended-spectrum β-lactamase production plus porin loss) (35, 85). It is important to note that these resistance mechanisms are currently detected using multiplex PCR or array technologies, so WGS is unlikely to be cost-effective if only used for the detection of known resistance mechanisms.

WGS can also be used to study the emergence of antibiotic resistance in real time under a variety of conditions (86). Toprak and colleagues developed a microbial cultivation system capable of maintaining a constant antibiotic pressure and then monitored the evolution of resistance in *E. coli* to trimethoprim, chloramphenicol, and doxycycline over 20 days (87). Resistance levels increased dramatically, with parallel populations showing similar phenotypic trajectories. WGS of the evolved strains identified mutations both specific to individual drugs and shared in resistance to multiple drugs.

Safi and colleagues used WGS to study the evolution of ethambutol resistance in *M. tuberculosis* (88). Both epidemiological and laboratory evidence suggests that mutations in the *embCAB* operon are responsible for resistance to ethambutol. *M. tuberculosis* isolates with a range of ethambutol MICs were selected and cultured. Ethambutol MICs were determined using the 7H10 agar proportion method and by the BACTEC 460TB method. Isolation of genomic DNA and PCR were performed, and *Rv3806c*, *Rv3792*, *embC*, and *embB* mRNA expression levels were measured by quantitative real-time PCR. Direct Sanger sequencing of PCR products was performed on an ABI 3100 Genetic Analyzer. Mutations in decaprenylphosphoryl-β-D-arabinose biosynthetic and utilization pathway genes *Rv3806c*, *Rv3792*, *embB*, and *embC* accumulated to produce a wide range of ethambutol that depended on mutation type and number.

In addition to elucidating the mechanisms of resistance, WGS also has a role in determining the rate at which resistance emerges. For example, Ford and colleagues reported that lineage 2 *M. tuberculosis* strains acquired rifampicin resistance more rapidly than lineage 4 strains (89). WGS has also established some of the genetic factors that have facilitated the spread of drug-resistant *M. tuberculosis*. For example, WGS has identified mutations in the α- and β-subunits of the RNA polymerase that alleviate fitness costs of resistance to rifampicin (90). These compensatory mutations are widespread in multidrug-resistant *M. tuberculosis* complex strains in high-incidence countries and are associated with ongoing transmission (91). WGS has also highlighted the importance of antimicrobial resistance in the evolution and spread of microbial pathogens, as discussed previously. For example, the emergence of fluoroquinolone resistance preceded the global spread of the MRSA ST22 strain (48) and the *C. difficile* 027/BI/NAP1 strain (8).

Development of Novel Antibiotics

WGS has been used to develop a novel antibiotic for the treatment of *M. tuberculosis*. In 2005, 454 pyrosequencing was used to identify the F0 subunit of a mycobacterial ATP synthase (92), which resulted in the development of the novel TB drug bedaquiline (93). This has enabled researchers to sequence this gene in a genetically diverse collection of reference isolates to ensure that it is conserved among all *M. tuberculosis* complex lineages (94). This represents an important step in drug development and will allow pharmaceutical companies to confirm the presence of a drug in a large bacterial population prior to investing in clinical trials of new agents. The early elucidation of drug resistance mechanisms also has implications for clinical trial design because it may enable the detection of resistance mechanisms that raise the MIC of a drug, but it may be overcome by using higher doses. It may also detect cross-resistance between different antibiotic classes, e.g., bedaquiline and clofazimine (95), which would then not be used in combination.

Microbiome Analysis

One of the most powerful applications of NGS has been its role in understanding the complex diversity of the human microbiome. We are only just beginning to understand what constitutes normal and abnormal flora in the gut, respiratory tract, urinary tract, vagina, skin, and wounds (96, 97). Gut microbiome analyses are also providing new insights into the pathogenesis of inflammatory conditions such as Crohn's disease (98). A further possibility is the ability to monitor changes in microbial populations during treatment, which might provide useful prognostic information. For example, a study of the human gut microbiome in bone marrow transplant recipients found that postantibiotic overgrowth with vancomycin-resistant enterococci was associated with a higher risk of bacterial sepsis from this organism (99). For further information on metagenomics please see chapters 10 to 14.

Viral WGS for Genotyping and Resistance Monitoring

WGS has the potential to improve the clinical management of viral infections such as human immunodeficiency virus (HIV). Since its introduction in the 1990s, highly active antiretroviral therapy has transformed HIV infection from a rapidly fatal disease into a treatable condition with near-normal life span and quality of life (100, 101). One of the key principles of antiretroviral therapy is to select a combination drug regimen to which the virus is susceptible and which suppresses HIV viral replication below the limit of detection for as long as possible. Current clinical practice involves examining regions of the viral genome for mutations that confer resistance to antiretroviral drugs and using this information to guide treatment decisions, both at initiation of therapy and when treatment failure/resistance occurs (102, 103). WGS provides detailed information on the entire viral genome, rather than just the parts of the genome coding for drug resistance. It can also simultaneously provide information on regions that are used to genotype viruses, thus providing genotyping and drug resistance data in one step, in a rapid and potentially cost-effective manner. As directly acting antivirals are introduced for other infections such as hepatitis C and hepatitis B, it seems likely that WGS will be used to guide therapy in these conditions.

CONSIDERATIONS FOR IMPLEMENTATION OF WGS INTO CLINICAL PRACTICE

A number of challenges remain before WGS can be implemented into routine clinical practice (11). Sequencing platforms are under constant development and refinement, and the choice of platform will depend upon their relative advantages and disadvantages for their intended use. Reassuringly, an evaluation of three sequencing platforms used in an investigation of an MRSA outbreak gave clinically comparable results (104). A second consideration is how best to design a WGS service. The current paradigm of clinical microbiology involves detection and antimicrobial susceptibility testing at a local diagnostic laboratory followed by referral of specimens to reference laboratories for further specialist testing. However, numerous studies have demonstrated the feasibility of performing WGS in clinical microbiology laboratories, reducing the delays incurred by transporting specimens to a centralized laboratory, and generating sequence data more rapidly. An additional consideration is whether to use the infrastructure and expertise that already exists, for example in clinical genetics laboratories in the United Kingdom. Standard operating procedures are required for DNA extraction, library preparation, sequencing and data handling, storage, and reporting. These procedures need to be validated locally and undergo internal control and external quality assurance. The laboratory should be accredited by the relevant authorities to perform WGS to ensure that the information produced is robust and fit for its purpose.

The production of billions of NGS reads has also challenged the infrastructure of existing information technology systems in terms of data transfer, storage and quality control, computational analysis to align or assemble read data, and laboratory information management systems for sample tracking and process management. Advances in bioinformatics are ongoing, and improvements are needed if these systems are to keep pace with the continuing developments in NGS technologies. A major limitation to the implementation of WGS into routine clinical practice is the lack of automated data interpretation tools to enable rapid analysis and reporting of clinically relevant findings from genome sequence data. Furthermore, there is a need for large open-access genomic databases against which to compare sequenced isolates, a problem that was highlighted by a study that sequenced all isolates processed in a diagnostic laboratory over the course of one day (105). An additional challenge is the integration of clinical and genomic data, which will need to be stored securely but also be accessible to relevant individuals, e.g., clinicians, infection control teams, and public health officials. This potentially raises ethical issues with respect to the collection and storage of such information with individual patient consent, as well as potential concerns about breaches in patient confidentiality if clinical data are not held securely.

THE FUTURE OF GENOMICS IN CLINICAL MICROBIOLOGY

There are several situations where sequencing directly from a clinical sample would simplify and/or improve diagnostic microbiology. This includes fastidious or slow-growing bacterial species, which can be difficult and labor-intensive to isolate. Culture-based approaches are also of limited value if the patient has received antibiotic therapy prior to sample collection or is infected by nonculturable organisms. New developments in sample preparation are required that facilitate direct sample sequencing, which is currently difficult because of a low copy number of the bacterial target of interest combined with contamination with other flora and human DNA.

The use of single-cell genomics is emerging as a strategy for the investigation of microbial communities and uncultured organisms (106). A study by Raghunathan and colleagues provided proof-of-principle that DNA from a single bacterium could be sequenced (107). Single-cell sequencing has already provided draft genome sequences of major bacterial taxa that were not previously available in databases. Single-cell genomics can also be combined with metagenomics to provide an inventory of the microbial community and genetic linkages of sequences in a single organism (108).

Our understanding of microbial diversity in health and disease is currently rudimentary, but human microbiome analysis may ultimately become a part of patient management. Furthermore, the influence of host genetics on the susceptibility and outcome of infectious diseases has been established for certain pathogens, e.g., *M. tuberculosis*, HIV, and hepatitis C virus. Parallel investigation of host and bacterial genomics may improve our understanding of host-pathogen interactions and patient management.

Digital PCR and Its Potential Application to Microbiology

JIM F. HUGGETT, JEREMY A. GARSON, AND ALEXANDRA S. WHALE

4

A digital PCR (dPCR) takes a PCR and subdivides it across a large number of smaller reactions, termed partitions, so that a number of the partitions contain no template molecules. Many of the ideas that underpin dPCR were described in the late 1980s and early 1990s (1) and applied at that time using conventional or nested PCR. However, the procedure originally required partitioning of a single sample using individual tubes or a 96-well plate, followed by amplicon detection by agarose gel electrophoresis. This initial format represented a very unwieldy technique and an inefficient use of time and resources.

The term "digital PCR" was coined by Vogelstein and Kinzler (2). They used dPCR to improve the ability of PCR to detect rare mutations in a sample predominated by wild-type sequence. The partitioning in this study essentially reduced the wild type/mutant ratio, thus improving the assay sensitivity by reducing the effect of competition from the wild type sequence (this is described in more detail in reference 3). Partitioning was performed using the same 96-well plate approach that had been described almost a decade earlier. Consequently, at that time, dPCR offered the potential of a powerful experimental method to quantify and detect DNA molecules, but it was not practical for routine use in an applied diagnostic setting.

The advent of real-time quantitative PCR (qPCR) (4) offered a far simpler method for quantification that had the added benefit of being automated, requiring no subsequent handling postamplification to determine whether any target sequence had been detected. Uptake of qPCR rapidly rendered the complex, inefficient, and reagent-hungry original dPCR method obsolete. qPCR continued to advance in many areas of clinical and biological research, including microbiology.

The use of qPCR for clinical (both communicable and noncommunicable diseases) applications was, arguably, led by the virologists with monitoring of viral loads used to guide treatment in numerous viral diseases (5–7) (see chapters 1 and 30 through 32 of this volume). This was followed by applications in bacterial infectious disease (see chapter 1 and sections II, III, and V), hand in hand with the development of fully automated "black box" qPCR point-of-care instrumentation developed to reduce the requirement for expert scientists to perform the assays (8, 9) (see sections VIII and X).

While qPCR-based methods have been making considerable inroads into research and applied diagnostic microbiology, dPCR has been experiencing something of a renaissance. This has been made possible by technical advances in microfluidic engineering and emulsion chemistries that have enabled partitioning across thousands to millions of nanoliter and subnanoliter partitions (10). With these technological advances, dPCR is being increasingly applied in a variety of research areas including microbiology because it is able to offer more precise measurement (11) and, when sample volumes are matched, higher sensitivity (12, 13) than qPCR. The data generated are more reproducible than with qPCR, with a more predictable variance, thus making power calculations simpler (11, 14) and sources of random error easier to determine (15).

These characteristics make dPCR a potentially valuable tool for microbial research and offer an independent means of quantifying calibrators for other methods (16) such as qPCR and next-generation sequencing. It also provides opportunities for translation to clinical laboratory analysis, potentially offering more accurate and reproducible detection and quantification for the diagnosis and monitoring of infectious diseases. In this chapter we describe how dPCR is performed and discuss some of the most common formats and sources of error. In addition, we discuss how it has been applied in molecular microbiology and how it has the potential to advance pathogen measurement in the context of disease.

SPECIFIC EXPERIMENTAL CONSIDERATIONS FOR dPCR

For dPCR to be performed, a PCR must be distributed across a large number of partitions. The resurgence of dPCR over the last 5 or so years has largely been due to the development of instruments that have simplified this partitioning. The current instruments can be split into two categories depending on how they partition the reaction, either by using nanofluidic solid partitions or water-in-oil emulsions. Details of the current commercially available instruments can be found in Table 1. The choice of machine will inevitably depend on a range of factors. For those

TABLE 1 Details of the currently available dPCR instruments

Instrument (company)	Analyzed reaction vol[a]	No. reactions per run	Partition no./reaction	Partition vol	Run duration[b]	
Biomark (Fluidigm)	4.6 µl (12-panel array)	12	765	~4 nl	Chip loading	<10 min
					PCR	~120 min
	0.65 µl (48-panel array)	48	770	~1 nl	Chip loading	<40 min
					PCR	~120 min
QX200 (Biorad)	Up to 18 out of 20 µl	96	Up to ~20,000	~0.85 nl	Droplet generation	<2 min (per eight samples)
					PCR	~120 min
					Droplet reading	<10 min (per eight samples)
RainDrop (Raindance)	Full recovery mode: 25–50 µl	8	4,500,000–9,000,000	~5 pl	Droplet generation	20–30 min
					PCR	~180 min
					Droplet reading	<240 min
	1M read mode: 5 µl	8	~1,000,000	~5 pl	Droplet generation	20–30 min
					PCR	~180 min
					Droplet reading	<120 min
QuantStudio 3D Digital PCR System (Thermofisher)	14.5 µl	24 chips	Up to 20,000	~0.865 nl	Chip loading	<4 min (per chip)
					PCR	~2.5 hours
					Chip reading	~1 min (per chip)
Constellation dPCR platform (Formulatrix)	2.2 µl	96-well plate	496	~4 nl	Plate priming	<12 min
					PCR	~60 min
					Plate reading	<12 min

[b]This does not include reaction setup but does include instrument-specific pre- and postmanipulation.

who are familiar with qPCR, some technical considerations that set dPCR instruments apart are described in the following subsections.

Number of Partitions

Partition number is a key factor because it determines the dynamic range of the instrument. Those with fewer partitions will still enable precise quantification, but this may require dilution of the sample to ensure that the template concentration is not too high. Such dilution also requires prior knowledge of the sample concentration and may require initial analysis of the sample to determine whether, and how much, dilution is needed. When measuring rare mutations, the partition number also determines the sensitivity. Consequently, increased partitions enable greater dilution, thereby increasing the ratio of rare mutants to wild type in those partitions that contain the mutant sequence.

Reaction Volume

Reaction volume is an important consideration because, unlike qPCR, only a proportion of the reaction that is loaded into the instrument ends up being analyzed. This is because there is a dead volume associated with partition loading and/or selecting the partitions to be included in the analysis. Consequently, experiments need to be designed to account for this dead volume wastage. Additionally, unlike qPCR, most dPCR instruments are not readily scalable, which limits the volume of sample that can be analyzed in any one reaction. This can be compensated for somewhat by performing multiple reactions, but such an approach may require committing considerable amounts of sample to dead volume as well as additional costs associated with increased reagent use. Current instruments that offer >10,000 partitions per reaction all have variable reaction volumes because the number of partitions generated and analyzed varies from run to run. This is a unique concept for dPCR because other PCR methods usually perform replicate, control, and calibration reactions with the same reaction volume.

Protocol Steps

All of the current dPCR instruments require an initial step to partition the reaction. Depending on the partitioning format, this can comprise priming or loading a chip or generating water-in-oil emulsions. Whichever format is chosen, this step adds time. There is currently only one instrument that offers real-time analysis and an amplification plot of each reaction; this is clearly not crucial, but it is a useful tool to have when interpreting data, with the added benefit that data analysis is automated requiring no post-reaction manipulation. For the majority of dPCR instruments a subsequent end-point analysis step is required after the PCR. Compared to qPCR, this also increases the time needed to perform the reaction, and this varies between instruments (Table 1).

QUANTIFICATION BY dPCR

One of the key metrics for dPCR is the average number of template copies per partition (also termed lambda, λ). Where λ is low (<0.1 copies per partition) the majority of positive partitions contain a single molecule only, and their number is roughly equivalent to the estimated copies (Fig. 1a). This principle can be used to measure multiple

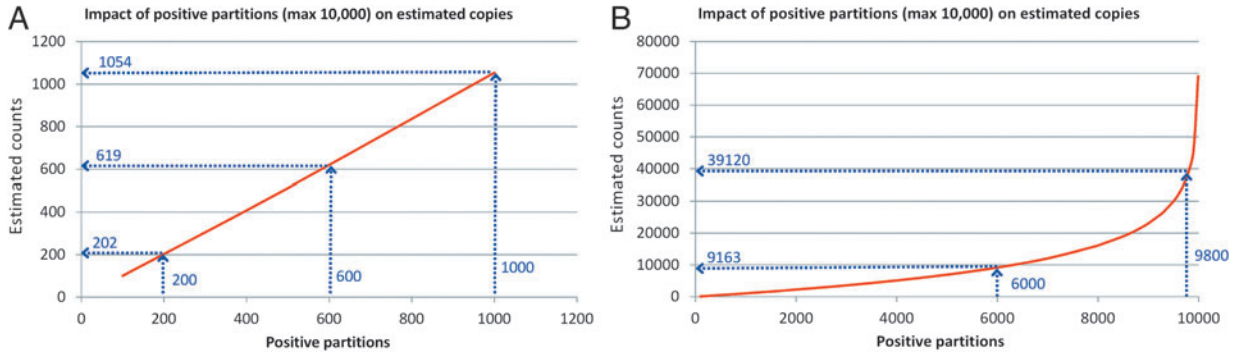

FIGURE 1 Influence of the number of positive partitions on the estimated copy calculations. Graph demonstrating the linear relationship between the number of positive partitions and estimated copies (red line) when a total of 10,000 partitions are measured. (A) When λ is low (<0.1), the number of positive partitions is almost equal to the number of molecules (blue dashed lines). (B) As λ increases, the total number of estimated copies exceeds the number of positive partitions (blue dashed lines), so the dynamic range is greater than the total number of partitions.

targets (multiplexing) using probes with different amounts of the same fluorophore (17), thus increasing the number of targets that can be measured in a single reaction (18). This unique aspect of dPCR is only practical if the instrument has very large numbers of partitions because the vast majority must contain no template to ensure that those that do only contain a single molecule.

As λ increases, the number of positive partitions containing more than one molecule also increases (Fig. 1b). This leads to a potential problem because dPCR only measures partitions as positive or negative. While negative partitions are assumed to contain no template (molecular dropout is discussed in more detail below), there is currently no physical means of precisely establishing whether a positive partition contains one or more template molecules, a fact that is crucial for accurate quantification. To compensate for this, the random distribution of the template DNA can be used and λ can be estimated using equation 1:

$$\lambda = -\ln\left(1 - \frac{k}{n}\right) \quad (1)$$

where k is the number of positive partitions and n is the total number of partitions. As well as providing a precise estimation of the template concentration, this signifies that the dynamic range of any dPCR instrument is greater than the number of partitions used to perform the reaction (Fig. 1b).

Because dPCR simply counts positive and negative reactions, the output is potentially more reproducible than with qPCR. Furthermore, dPCR does not require a calibration curve to provide a numeric value for the measurement. Together, these facts give dPCR a substantial advantage over qPCR that may facilitate more reproducible measurements between laboratories.

Without the application of a common calibration standard, qPCR results generated by different laboratories may vary greatly (19). This establishes the need for reference materials in the field of applied molecular measurement when performing qPCR. With the support of international WHO reference materials, quantification of viral load for pathogens such as HIV and the hepatitis viruses using qPCR revolutionized clinical analysis with increasing agreement between laboratories. Despite this there may be residual interlaboratory differences, and physicians should be cautious when comparing results from different laboratories. This is, in part, likely to be due to the challenges associated with the reproducibility of qPCR. Furthermore, WHO reference materials are not available for all pathogens.

While dPCR does not require a calibration curve to assign a quantitative value, we cannot agree with the assertion of some users that dPCR is "calibration-free." This is because instrument calibration is crucial to determine factors such as thermal profile and partition size, which may differ between instruments (or the same instrument over time) and must be monitored. Although relatively robust, dPCR remains susceptible to sources of error that may impact on measurement accuracy, and thus calibrators may still be needed to compensate for this.

SOURCES OF ERROR

When discussing quantification error, the following points should be considered. First, error comes in two guises: fixed and random. Random error is the component that varies with replicate measurements and determines variance, standard deviation, and precision. Fixed error is the component that leads to bias, which leads to deviation from the true value. Second, a given technique will be susceptible to intrinsic (linked to the technique in question) and extrinsic (linked to factors that affect the result but not due to the technique) error.

While the advantages of a novel approach frequently focus on the intrinsic benefits of the technique in question, the extrinsic factors must also be considered in any discussion about applications and potential translation to routine practice. This is particularly pertinent for molecular methods since extrinsic factors including sample storage and extraction are frequently ignored while paradoxically being the main source of error in the measurement.

Variance

As with any measurement method, dPCR provides a value that can be influenced by both variance and bias. When measuring the quantity of a given DNA molecule by qPCR, variance is dependent on both the addition of the template to the reaction as well as "noise" intrinsic to the

qPCR, which is influenced by factors such as optimization and PCR efficiency. Notably, the intrinsic variance of a given qPCR reaction can vary considerably depending on a variety of factors including primers, platform, level of optimization, etc. Where dPCR differs is that the intrinsic noise is more fixed because it follows a random distribution which is used by the Poisson calculation to estimate the numbers of copies (11, 14).

dPCR also differs from qPCR in how precision is influenced by the template concentration being measured. A considerable strength of a well-optimized qPCR is that it offers a similar variance as a proportion of the mean across a wide dynamic range: i.e., the error is homoscedastic in the logarithmic scale. The variance of dPCR differs because it is dependent upon the λ (Fig. 2), which means that for the most precise measurement, the sample needs to be at or diluted to a concentration that is approximately 1.5 to 1.6 copies per partition (20), and thus for the most precise measurements some idea of the concentration of the sample is needed prior to analysis.

As with qPCR, dPCR is susceptible to variance associated with the addition of template to the reaction as well as "upstream" extrinsic factors required to sample and prepare the template for analysis. These upstream factors are frequently the predominant source of variance for both qPCR (21) and dPCR (15). Consequently, experiments should be performed which reflect this by replicating steps including sampling and extraction to more accurately estimate the variance associated with the whole procedure required to analyze the sample in question.

Bias

One of the major problems associated with qPCR is that it is prone to bias. The output (the quantification cycle, Cq [22], formerly designated Ct or Cp) is an arbitrary metric dependent upon a host of factors including instrument, threshold level, plastic ware, choice of probe chemistry, and batch of reagents to name but a few. Most methods applying qPCR to quantify microbial abundance compare the unknown sample to a calibration curve to convert the Cq to DNA or RNA copies.

The problem with applying calibration curves is that they can give very precise but potentially highly biased results because accurate quantification of the calibrator is difficult and/or choosing a calibrator that is readily commutable to the sample being analyzed is very challenging. Consequently, laboratories can differ widely in the magnitude of the measurements (19). This may hamper research into aspects such as the dynamics of a given infection and can impair comparisons between data generated by different laboratories.

One of the major potential benefits of dPCR is that it does not require a calibration curve to provide a quantitative result. While this is a clear advantage, dPCR is not infallible and will be susceptible to bias that may in cases require calibration in some form. Because volume is crucial to dPCR, it is essential that instrument manufacturers accurately define both the volume and volume variance of their partitions. Other than such volume-related issues, there are few routes for a well-optimized and specific dPCR reaction to overestimate the quantity. As with any method, contamination could have such an impact, but the only other route to overestimation of dsDNA is if the strands become denatured and populate two different partitions. Consequently, there could potentially be a 2-fold overestimation bias (23).

The potential for dPCR to underestimate the abundance of a target is arguably a more prominent source of bias. dPCR may be less susceptible to certain inhibitors than qPCR (24, 25). However, molecular dropout, where a molecule is present but does not amplify, is known to occur (26), and inhibition remains a potential problem and must be considered and controlled for, especially where a sample is reported as negative for a given pathogen. Internal positive controls are therefore likely to be as important for dPCR when used diagnostically as they are for qPCR.

Underestimation may also occur if some of the assumptions applied when performing dPCR are not met. dPCR is dependent upon random distribution of template across partitions. If, for example, template molecules are linked *in cis*, they will not distribute randomly because they will colocalize in the same partition. Because there is no current way to quantify the number of molecules present in a

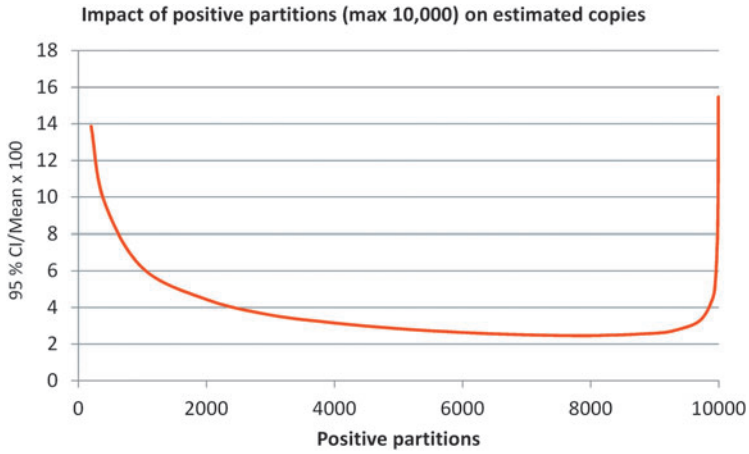

FIGURE 2 Influence of the number of positive partitions on precision. Graph demonstrating the correlation between the precision and the proportion of positive partitions observed. At very low or high λ, the precision is reduced. The highest precision is observed when $1.5 < \lambda < 1.6$, where the number of positive partitions is between 7,700 and 8,000. Graph calculated using Ucount (https://dna.utah.edu/ucount/uc.html).

given partition, they will be treated as a single molecule, and with equation 1 the true number will be underestimated. This could be rectified by separating the linked sequences using methods such restriction digestion or sonication.

Many other extrinsic sources of bias that must be considered when performing qPCR equally affect dPCR. For example, if an extraction only recovers a small proportion of the sample, or the sample is degraded, then dPCR will not be able to accurately measure the amount of nucleic acid originally present within the sample. Where microbial, or patient, gene expression is being measured by targeting RNA, or an RNA virus is of interest, then the target must be converted to complementary DNA (cDNA) using reverse transcription (RT) that can be both variable and biased (27). The implications of the effects of extrinsic factors such as extraction and RT on dPCR and the need for calibration are discussed in more detail below.

dPCR can be used to measure single nucleotide polymorphisms (SNPs), for example, in the detection of drug-resistant *Mycobacterium tuberculosis* mutations (28). A PCR-based SNP assay is usually performed with universal primers that amplify both the wild type and mutant sequences with the specificity being conferred by a probe for either the wild type or mutant variant. While dPCR partitioning can improve sensitivity to rare mutations, the presence of wild type sequences within the sample can lead to two signal populations being observed: one containing the amplification of the mutant sequence and a second containing the amplification of the wild type sequence due to probe cross-reactivity leading to a reduced signal amplitude (Fig. 3a). If these two populations are not clearly separated, an overestimation of the mutant sequence could occur depending on where the threshold is set; consequently, wild-type-only controls are crucial in the experimental design. In such situations it may be preferable to perform such analyses in duplex (measuring both wild type and mutant sequences concomitantly using different fluorophores) and visualize the results using a two-dimensional plot. This would allow the user to determine which partitions contain mutant, wild type, or both sequences (Fig. 3b).

The measurement of rare variants is also heavily dependent upon template concentration; for example, to detect a mutant SNP present at 0.1% of the population, at least 1,000 copies must be added to the reaction. This may seem obvious, but it is an important consideration where the pathogen in question may be at a low level and a potential resistance genotype may be missed due to insufficient sampling. A further consideration to compound this matter is the fidelity of the DNA polymerase. At some point, the frequency of the mutant sequence in the sample will be lower than the error rate at which the polymerase introduces the specific mutant SNP into the wild type sequence, thereby contributing to reduced sensitivity if it is defined or specificity if it is not.

When a partition contains both wild type and mutant SNP sequences, a phenomenon we call "partition-specific competitive PCR" occurs. When the primers are universal, they amplify both sequences within the partition, resulting in roughly half of each. This results in a reduced amount of template for each probe to bind to, leading to a reduced signal output (Fig. 3c). This may not be cause for concern for many samples if the thresholds can be set to separate the different populations. However, high-concentration samples may be more difficult to analyze because a number of partitions contain more than one copy of the two sequences. If, for example, a partition contains five copies of the wild type and one copy of the mutant sequences, then the wild type sequence may outcompete the mutant sequence entirely, resulting in almost no mutant signal. In such cases, the partitions containing both sequences may resemble an arc across the two-dimensional plot, causing difficulty in selecting the correct position for the thresholds (Fig. 3c). In such situations, it may be appropriate to

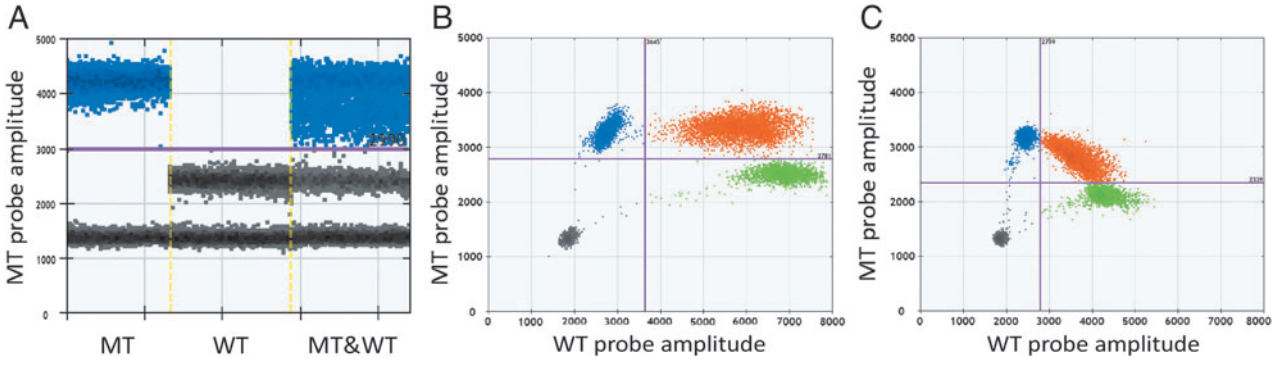

FIGURE 3 Detection of single nucleotide polymorphisms using droplet dPCR. Example of graphs produced with the QuantaSoft Software from the QX200 Droplet Digital PCR System (Bio-Rad). The horizontal and vertical pink lines represent the thresholds between negative and positive droplets. (A) One-dimensional plot illustrating positive and negative droplets using a uniplex reaction containing a mutant-specific probe only. The mutant-only sample (MT) gives two distinct droplet populations: positive (blue droplets) and negative (gray droplets). The presence of the wild type sequence in the wild type-only sample (WT) and mixed sample (MT & WT) generates a second population of droplets that falls between the negative and positive droplets due to the probe binding with lower affinity to the wild type sequence. (B) Two-dimensional plot of the mixed sample shown in (A) with a duplex reaction containing both the mutant and wild type probes. Each droplet has both a mutant and wild type signal, so four possible outcomes are observed: MT only (blue), WT only (green), MT & WT (orange), and negative (gray). (C) Two-dimensional plot of a mixed sample showing partition-specific competitive PCR. Droplets containing both MT and WT sequences (orange) merge with the MT only (blue) and WT only (green) droplets to form an "arc" across the plot with reduced amplitude of one or both signals, thus making confident positioning of the thresholds difficult.

perform dilutions to reduce the effect of partition-specific competitive PCR.

THE ABILITY OF dPCR TO PERFORM ACCURATE QUANTIFICATION

A comprehensive description of the sources of bias and variance will provide a better understanding of the accuracy of dPCR. However, the groundswell of interest that accompanies a novel method frequently comes with much hype and inflated expectations. The speculated ability of dPCR to provide an "absolute" measure of DNA quantity is of note because the vast majority of other molecular methods used in clinical and biological quantitative measurement (e.g., qPCR, enzyme-linked immunosorbent assay) are made relative to some kind of calibrator. Part of the problem with current molecular quantification is defining what that calibrator should be so that laboratories' performance can be readily compared in a manner that is appropriate (or commutable) to the sample being analyzed.

dPCR has caught the interest of the metrology community and national measurement institutes including the European Commission's Joint Research Center, the Korean Research Institute of Standards and Science, LGC in the UK, the National Institute of Biology in Slovenia, the National Institute of Metrology in China, the National Institute of Standards and Controls in the United States, the National Measurement Institute in Australia, and TÜBİTAK National Metrology Institute in Turkey. This is because dPCR offers measurement that counts individual molecules without being compared to a calibrator. It is the national measurement institutes that have made major contributions to some of the initial research performed on dPCR. To date, research into the technique has focused on defining the actual performance of the method and critically evaluating emerging dogmas.

This has included demonstrating with purified DNA that dPCR quantification can be precise and linear (12) and that primers targeting different regions of the same molecule can perform with very good agreement (12, 16, 29). When measuring purified DNA, dPCR can offer improved precision which facilitates smaller-fold change measurements and thus finer discriminations (26).

When compared to orthogonal methods such as spectrophotometry (the only other readily available molecular method that does not require comparison to a calibrator) or methods like qPCR, which are frequently calibrated using spectrophotometry, the agreement with dPCR is frequently reported to be within 2-fold (12, 29). dPCR has also been demonstrated to perform with good agreement to other orthogonal methods such as isotope dilution mass spectrometry (30). Taken together this suggests that when measuring a purified DNA molecule, the estimated quantity that is reported is likely to be close to the "real" value, and dPCR can therefore be regarded as accurate. More focused research has been performed to improve the accuracy of dPCR to better understand partition volume and error (31, 32), with further discussion on how to determine the impact of partition volume associated error (3, 33).

While dPCR may currently offer the most accurate method to measure a small quantity of a specific DNA sequence in a complex background, some key factors must be considered when it is applied to microbial analysis. First, dPCR, like any PCR reaction, measures an amplicon. This typically follows qPCR design parameters and thus is usually <100 bp long. Any link between this measurement and that of the microbial genome being measured must make the fairly substantial assumption that a 100-bp molecule is representative of a genome in the kilobase (viral), megabase (bacterial), or >10 Mb (fungal, parasite) range. This assumption has generally proved adequate for established applications using qPCR, and we have shown that dPCR can demonstrate good agreement with next-generation sequencing methods for metagenomics analysis (34, 35). However, because neither PCR nor next-generation sequencing requires intact large-molecular-weight genomic DNA, it can be difficult to know whether the measured DNA is from an intact genome or a degraded fragment, which may mean different things; it is important to appreciate that the detection of such small genomic fragments provides no direct evidence of viability or infectivity of a given microbe.

POTENTIAL APPLICATIONS OF dPCR TO MICROBIAL RESEARCH AND DIAGNOSTICS

In the short term, the biggest impact the technique of dPCR will have on microbial analysis is likely to be within research rather than clinical diagnostics. The growth in research applying dPCR has either capitalized on the advanced features of dPCR to investigate a specific question or compared dPCR to alternative methods. The latter is done either to specifically evaluate dPCR performance or to apply it as an additional method to back up findings generated by other techniques.

dPCR has been applied in a number of infectious disease settings. The improved precision of dPCR has been demonstrated in DNA viral quantification of human cytomegalovirus (hCMV) (36, 37), HIV LTR circles, and total HIV DNA (38, 39). dPCR has also been used to measure chromosomally integrated human herpesvirus 6 (40, 41).

Where clinical sensitivity has been compared in viral analysis, dPCR has been reported as worse than qPCR for hCMV (36) and hepatitis B virus (42). Digital technologies have also been applied to isothermal methods such as loop-mediated isothermal amplification for measuring hCMV (25) and recombinase polymerase chain reaction in the analysis of methicillin-resistant *Staphylococcus aureus* (43).

Identification of methicillin-resistant *S. aureus* using dPCR has also been directly compared with in-house qPCR and near-patient PCR-based instruments (44). Unlike the above viral comparisons, the authors concluded that dPCR performed with comparable sensitivity and specificity to the other methods, which are routinely applied clinically. Clinical application of dPCR to the analysis of other pathogenic bacteria has included detection of ocular *Chlamydia trachomatis* infections (45). *C. trachomatis* is one of the few bacterial pathogens for which molecular diagnosis has been the gold standard for detection in sexually transmitted infection for some time.

Roberts et al. compared dPCR with the Roche Amplicor CT/NG test as a diagnostic test for the cause of trachoma due to *C. trachomatis* infections, concluding that the former was an effective diagnostic technology suitable for both research and clinical use in the application (45). The same group used dPCR to demonstrate that there was no association with plasmid abundance and severity of ocular *C. trachomatis* infection, suggesting that dPCR did not concur with many of the qPCR reports (46).

The application of dPCR has also been assessed for the analysis of anthrax to enumerate chromosomal and virulence plasmid copies (47), and the authors reported that dPCR was in good agreement with direct sequencing. Pholwat et al. used dPCR to investigate mixed genotypes of *M. tuberculosis* to quantify heteroresistance and compared this to the agar proportion method, reporting good agreement between the methods (28). They reported that the dPCR approach was more sensitive than qPCR or Sanger sequencing; notably, they performed this dPCR with 384-well plates, demonstrating that a dPCR instrument is not essential to perform the method.

The measurement of RNA expression or RNA viral genomes is less well documented, but possible applications of RT-dPCR have been described in hand, foot, and mouth disease (48) and for measuring variant sequences in hepatitis C infections (49). A multivolume dPCR instrument has also been used to measure HIV and HCV viral load (50). Additionally, dPCR measurement of patient HLA-DR mRNA expression as a surrogate marker of sepsis has been reported as a more accurate alternative to RT-qPCR (51).

As previously mentioned, a further challenge to RNA measurement is the potential bias attributable to the RT step required to convert the RNA to cDNA. Historically, RT-qPCR has depended on the qPCR as a measurement of performance, and conversion efficiencies of RNA to cDNA were not extensively evaluated. Essentially, as long as the quantification was linear and maximal sensitivity was not essential, RT enzymes were generally assumed suitable and conversion efficiencies were not routinely considered, despite some evidence of wide differences (27).

dPCR will place the RT step under a higher level of scrutiny because different enzymes and primers convert RNA to cDNA with different efficiencies. This will lead to a different number of positive partitions when measuring the same template, and there is the potential for wide disagreement between different approaches (13). Consequently, early application of RT-dPCR needs to be approached with caution, and calibration to compensate for the associated bias may be a key consideration. The measurement of positive partitions associated with dPCR will enable RT-dPCR to evaluate conversion efficiencies of reverse transcriptase and most suitable priming strategies in a much simpler and informative manner than with qPCR; this could assist manufacturers in the development of more effective and reproducible formats.

Calibration may also be needed where different laboratories perform different procedures to prepare a sample for analysis. Because these steps can add both bias and variance, this may impact the final dPCR result and compromise reproducibility. As with reverse transcriptases, dPCR provides a simple method for interrogating specific extrinsic factors, such as the nucleic acid extraction method, in an "absolute" manner.

CONSIDERATIONS FOR THE FUTURE

dPCR is a powerful research tool that enables a number of unique measurements with high sensitivity and precision. In turn, it could push the frontiers of molecular microbiology by improving our understanding of microbial dynamics through potentially accurate quantification of DNA and associated mutations. However, while its sister technique qPCR has contributed a huge amount to clinical and biological research, including molecular microbiology, the technique has also led to much error due to its incorrect application (52) and difficulties associated with reproducibility, which were discussed above.

Such error is partly due to poor reporting of the basic details of experimental design and procedures in publications that apply the method, which has meant experiments may be very difficult to repeat. To rectify this, the Minimum Information for the Publication of Quantitative Real Time PCR Experiments, or MIQE, guidelines were published in 2009 (22), providing guidance on how to perform the methods and also a key set of experimental factors that should be described in a paper. This was followed in 2012 by the publication of the digital MIQE guidelines (53) to support the reproducible application of dPCR and increase the impact and, ultimately, the likelihood that findings can be translated into routine clinical applications.

Where dPCR may have an advantage in molecular diagnosis is that the final measurement of the DNA and its calibration are simpler. Thus, when applying dPCR to detect and quantify pathogens, detect mutations, or investigate linkage, not only may the method offer improved accuracy, but it could make it easier for two different laboratories measuring the same sample to get the same result. Furthermore, the simplicity of the dPCR output count will potentially make routine application simpler for the wider community of clinical scientists.

While dPCR may have considerable potential for routine clinical diagnostic applications, the reality is that instrument complexity and cost are likely to delay uptake. In the short term dPCR will have, and is having, a useful role in the value assigning of calibration materials needed for the other more common methods including qPCR (16, 54, 55).

Those who expound the benefits of dPCR must remember that comparisons that demonstrate improved performance with, for example, a clinically applied qPCR in a single laboratory are not considering a major factor that allows qPCR to be successfully applied clinically: namely, reproducibility. Until formal studies comparing interlaboratory performance of dPCR are undertaken, it will not be possible to provide a true assessment of dPCR as a diagnostic method.

CONCLUSION

The potential role of dPCR in diagnostic, predictive, or prognostic monitoring of microorganisms is now becoming apparent. dPCR has the potential to overcome one of the major shortfalls of other measurement techniques: "absolute" quantification without the need for calibration curves, thereby reducing measurement bias and potentially improving intra- and interlaboratory reproducibility. With the appropriate use of controls and continued development of the instrumentation, dPCR could improve microbial measurement and monitoring so that accurate routine molecular quantification may be facilitated.

We are grateful to Fluidigm, Biorad, Raindance, Thermo Fisher, and Formulatrix for their assistance with Table 1. We are grateful to Dr. Carole Foy for her critical review of the manuscript. The work described in this manuscript was funded by the European Metrology Research Programme (EMRP) joint research project (HLT08) "InfectMet" (http://infectmet.lgcgroup.com), which is jointly funded by the EMRP participating countries within EURAMET and the European Union.

Massively Parallel DNA Sequencing and Microbiology

ULF GYLLENSTEN, RUSSELL HIGUCHI, AND DAVID PERSING

5

Recent, dramatic increases in the throughput of DNA sequencing instruments provide opportunities for microbiology research that previously were limited to large genome centers. In sequencing the human genome, what once took years and hundreds of instruments and workers to complete can now be done in days on just one instrument. Moreover, such increases in throughput are likely to continue over the next few years. Here we review the different platforms for massively parallel sequencing (also called next-generation sequencing, or NGS) and compare those that are currently most popular. As evidenced by other chapters of this book, some of the exciting applications of NGS for microbiology research are the abilities to accurately deduce microbial population structure (also known as metagenomics), discover new pathogens, detect rare pathogens within a complex background, and elucidate the dynamics of drug resistance—even when culture of the microorganisms is impossible. These new technologies are directly applicable to and have significant ramifications for both research and clinical microbiology.

OVERVIEW OF METHODS

Most earlier generations of sequencing systems were based on slab or capillary gel electrophoresis of a nested series of DNA fragments produced by specifically primed, *in vitro* DNA polymerase reactions, i.e., Sanger sequencing (1). The sequencing templates for these reactions were prepared either by molecular cloning or PCR. Per sequencing instrument, up to a microtiter plate's worth of templates (96 or 384) could be run at one time using a corresponding array of capillary gels.

Many, but not all, of the technologies for massively parallel sequencing also use molecular cloning, not in bacterial hosts but by using limiting-dilution of DNA followed by the isolated PCR amplification of single DNA molecules. This is done in a highly parallel, automated, and high-throughput fashion with millions of such amplified templates being produced in a short time. The two most popular massively parallel DNA sequencing systems accomplish this clonal amplification in two ways, using either emulsion PCR (2, 3) or bridge PCR (4, 5), as described in more detail below. The two systems are the Illumina system (www.illumina.com) (6) and the Thermo-Fisher/Life Technologies Ion Torrent and Ion Proton system (http://www.lifetechnologies.com). In contrast to these methods, the sequencing technology of Pacific Biosciences (RS II) is based on sequencing of single native DNA molecules with no prior amplification (http://www.pacificbiosciences.com).

The sequencing reactions in earlier-generation systems were performed in microtiter plates, and the results were visualized after resolution of the nested DNA fragments upon gel electrophoresis. Massively parallel sequencing platforms perform reactions on millions of templates that are isolated from one another on nanometer-scale arrays. For each isolated template the sequence-specific incorporations of nucleotides are followed on a cycle (of incorporation)-by-cycle basis. The isolation and following of the sequencing reactions upon the array differ among the different platforms, as do the sequencing chemistries. In all these new platforms, the fact that hundreds of thousands to millions of reactions are followed in parallel accounts for the many orders of magnitude increase in sequence throughput per instrument.

As in earlier genome sequencing efforts, "shotgun sequencing" of randomly fragmented DNA and assembly of the sequences using the overlap between randomly distributed sequences into increasingly larger sequence "contigs" are required (7, 8). As before, this is handled by algorithms encoded in software. Particular challenges for such software in massively parallel sequencing include shorter read lengths for some of the technologies and therefore increased uncertainty with regard to the specificity of the overlaps, the higher error rates inherent in the sequencing methods employed, and the sheer number of sequence reads that need to be handled.

In this chapter, steps that are similar and shared in common among the massively parallel sequencing platforms will be described first. Following this, the differences among them and the advantages and disadvantages of each will be examined. Last, there will be a brief description of an application of NGS to metagenomic research.

METHODS BASED ON THE AMPLIFICATION OF SINGLE MOLECULES

A method for isolating and amplifying single DNA molecules in a thin, polyacrylamide gel layer was described in

Russell Higuchi and David Persing, Cepheid, 904 Caribbean Dr., Sunnyvale, CA 94089. **Ulf Gyllensten,** Uppsala University, Department of Immunology, Genetics and Pathology, Science of Life Laboratory Uppsala, Biomedical Center, Box 815, SE-751 08 Uppsala, Sweden.

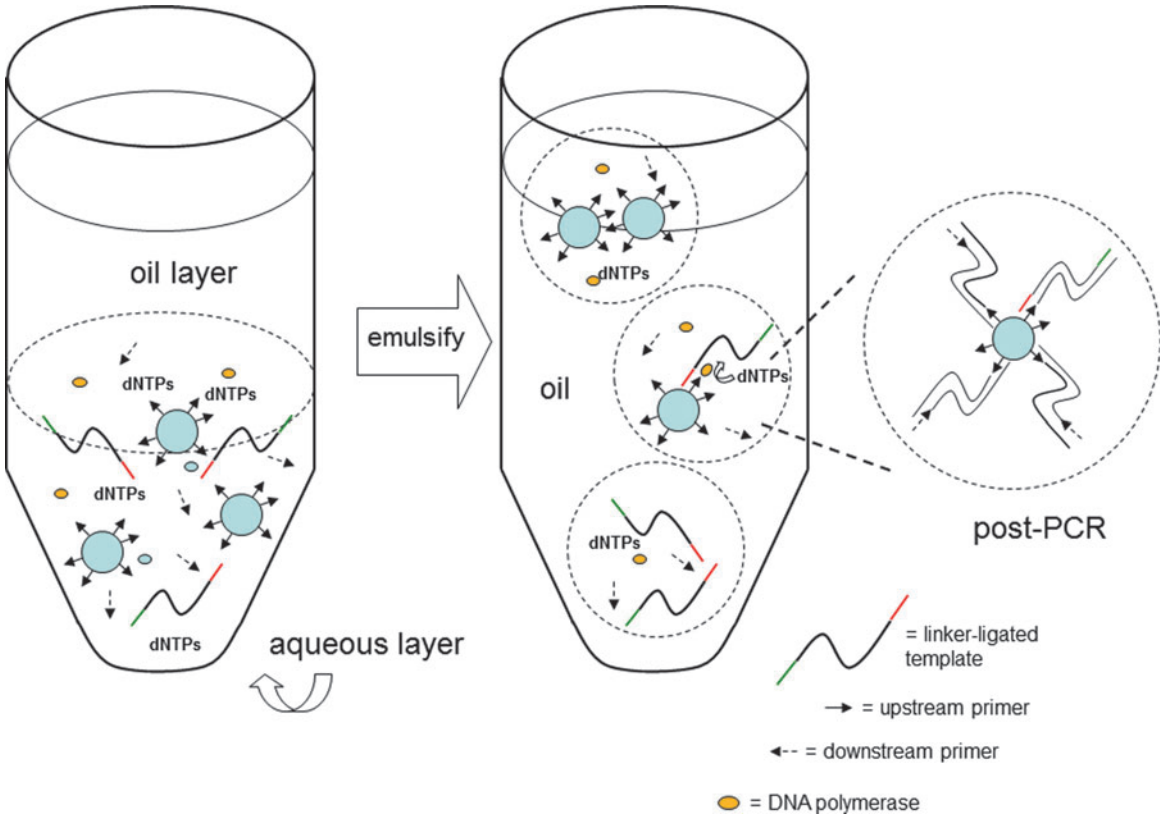

FIGURE 1 Emulsion PCR for single-molecule amplification. A two-phase (aqueous and oil) system in which PCR components are included in the aqueus phase. Also included are capture beads upon which one of the two PCR primers is attached. In the Ion Torrent system these beads are magnetic to facilitate their subsequent capture and washing. With vigorous agitation, emulsification takes place such that millions of tiny water droplets form in the oil. The concentration of DNA templates, beads, and water droplets is such that the frequency of there being one bead and one DNA template in one droplet is optimized. In this case, an amplicon attached to the bead as shown will form. Other possibilities include a droplet with neither bead nor template or a droplet with only a bead or a template (shown). In these cases no amplification can occur. The possibility of multiple templates and/or beads per droplet, which results in amplification, is minimized as much as possible by concentration. Multiple templates per droplet usually result in a mixed sequence read from the capture bead and are ultimately filtered out in software.

1999 (9). DNA molecules were diluted into the gel before it was formed, as were appropriate amounts of the ingredients for PCR—that is, primers, DNA polymerase, deoxynucleoside triphosphates (dNTPs), and the appropriate salts and buffer. The gel was subjected to thermocycling such that the individual template molecules were amplified. Because of the gel, the products of the amplification were localized to within a small area surrounding the initial template and formed molecular colonies, or "polonies," that generally did not overlap one another because of the level of dilution of the initial template molecules. Nonetheless, millions of such polonies could be contained in the area of a microscope slide. The gel-based polony method has been used to support high-throughput sequencing (10) using a scanning, fluorescence microscope but not in a commercially available system.

Another method of isolating and amplifying single DNA molecules is called emulsion PCR (2, 3), in which an oil-water emulsion is formed. As shown in Fig. 1, the aqueous phase contains the reagents for PCR, including primers matching the ends of template fragments (see "DNA Fragment Libraries" section, below) and the DNA template. Also present are beads to which are attached "capture" oligonucleotides. When emulsified with an excess of oil using controlled, vigorous agitation, aqueous droplets are formed that comprise millions of nanoscale "microreactors" in which PCR can take place. The DNA template and beads are dilute enough, and the number of microreactors large enough that if a microreactor contains both a template molecule and a capture bead, there is likely to be only one of each, ensuring that the amplification that takes place is clonal and that the clone will be captured on a single bead. Emulsion PCR is used in the 454 system (11) and the Ion systems.

Although originally used as a means of amplifying DNA on a solid phase irrespective of the number of starting template molecules, "bridge PCR" (4, 5) has been adapted to single molecule amplification in the Illumina system (Fig. 2). In bridge PCR both PCR primers are attached via the 5′ end to a solid support at sufficient density that a templated, 3′ extension can, after the template is denatured off, bend back and anneal to the reverse primer and allow extension off of that primer. The end result is that both strands are attached to the solid support in increasing numbers as PCR proceeds. In the Illumina system the solid support is a glass slide. The template molecules are flowed over the slide at low enough concentration that the primer extensions arise from a single template in a

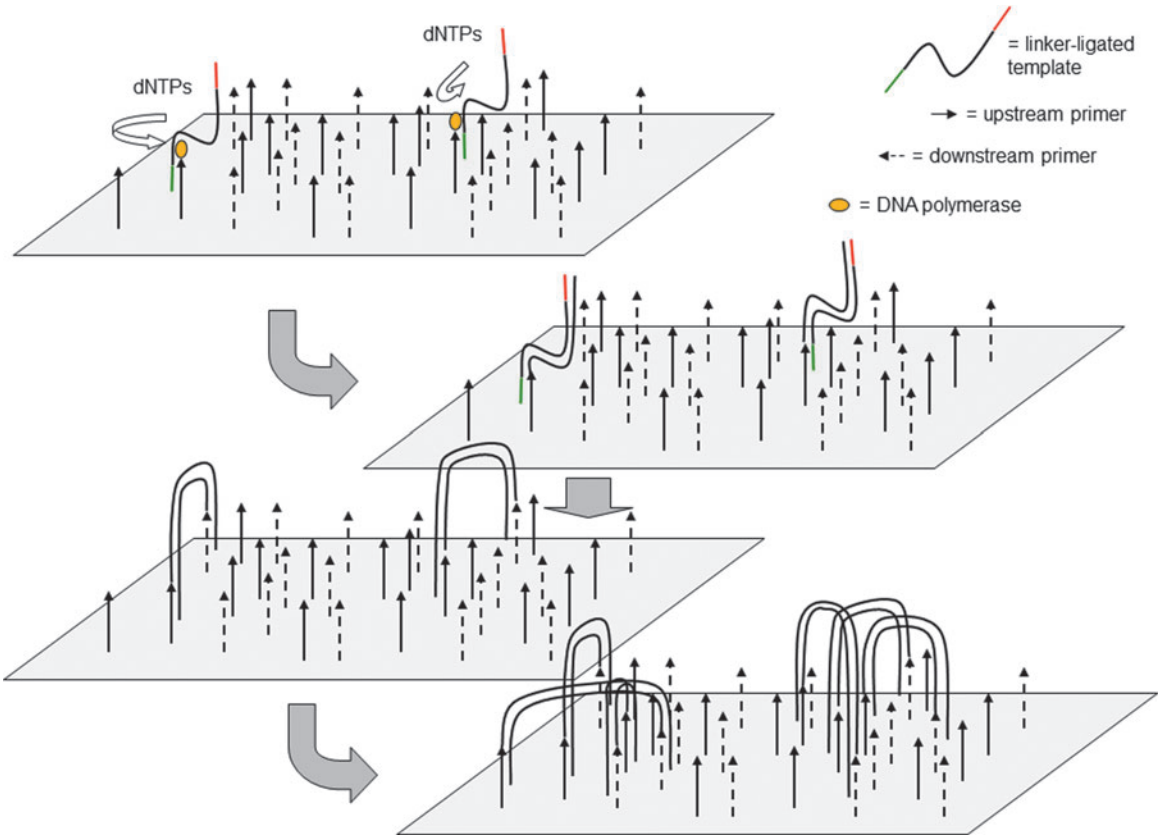

FIGURE 2 A representation of single-molecule, bridge PCR. Immobilized on a microscope slide are a high density of both forward and reverse primers with the 3′ ends free. Single DNA template molecules are flowed over the slide and captured by the PCR primers as shown. Rounds of replication and denaturation through thermocycling are allowed such that 3′ ends of primer extensions can anneal and reanneal to reverse primers, each time being copied again. The original template strands get released to solution in this process but are washed away. All the copies of the original template strand stay localized as shown.

localized, nanoscale area (referred to by Illumina as a "cluster"), usually not overlapping with another such area. For the purpose of this discussion, such single-molecule amplifications will be referred to as "clonal PCR," and the aggregate amplification product, however isolated and imaged in two-dimensional space, will be referred to as a "polony."

For the standard Illumina technology, the arraying of polonies on the surface of a glass slide is an inherent property of the bridge PCR used to originate them. In contrast, the Ion Torrent/Proton systems strive to capture single beads carrying amplified single DNA molecules from the emulsion PCR in single, nanoscale, indexed wells (Fig. 3). For both systems, careful titration of the number of seed molecules or beads relative to the slide or chip surface area is required to achieve an optimum density of enough polonies to maximize sequence throughput but not create overlapping (and thus unreadable) polonies. All of the above schemes require the appropriate modification of the ends of DNA fragments to be amplified, captured, and sequenced, as described in the next section.

DNA FRAGMENT LIBRARIES

"Library" is the term applied to a collection of DNA fragments—frequently obtained via random, physical shearing to facilitate sequence assembly by overlap—that form the basis for a sequencing run. Individual fragment molecules from these libraries are the single molecules that are either directly sequenced or amplified before sequencing as described in the previous section. For genomic sequencing, three types of DNA libraries are used: the fragment library, the paired-end library, and the mate-pair library. The standard fragment library is typically used in obtaining most of the unassembled sequences in whole-genome sequencing. Fragmentation is achieved by nebulization or sonication to a certain mean fragment size. After suitable "blunting" of the ends of the sheared double-stranded DNA molecules, DNA adapters are then ligated on. These provide universal, forward or reverse primer annealing sites for clonal PCR and subsequent sequencing. Unligated adapters are removed, and fragments of a size range appropriate for clonal PCR are isolated by gel purification. This sizing increases the percentage of meaningful sequencing reads.

More recently, an enzymatic means of performing DNA fragmentation and end sequence modification for library construction has been developed that requires fewer manipulations and is more efficient in its use of input DNA. The Nextera method uses an engineered transposase complex, referred to as a transposasome, that performs "tagmentation," that is, the simultaneous cleavage of high-molecular-weight DNA at somewhat random locations around 300 bp apart, and adapter sequence addition to the ends of the resultant fragments (12). Low-cycle PCR with

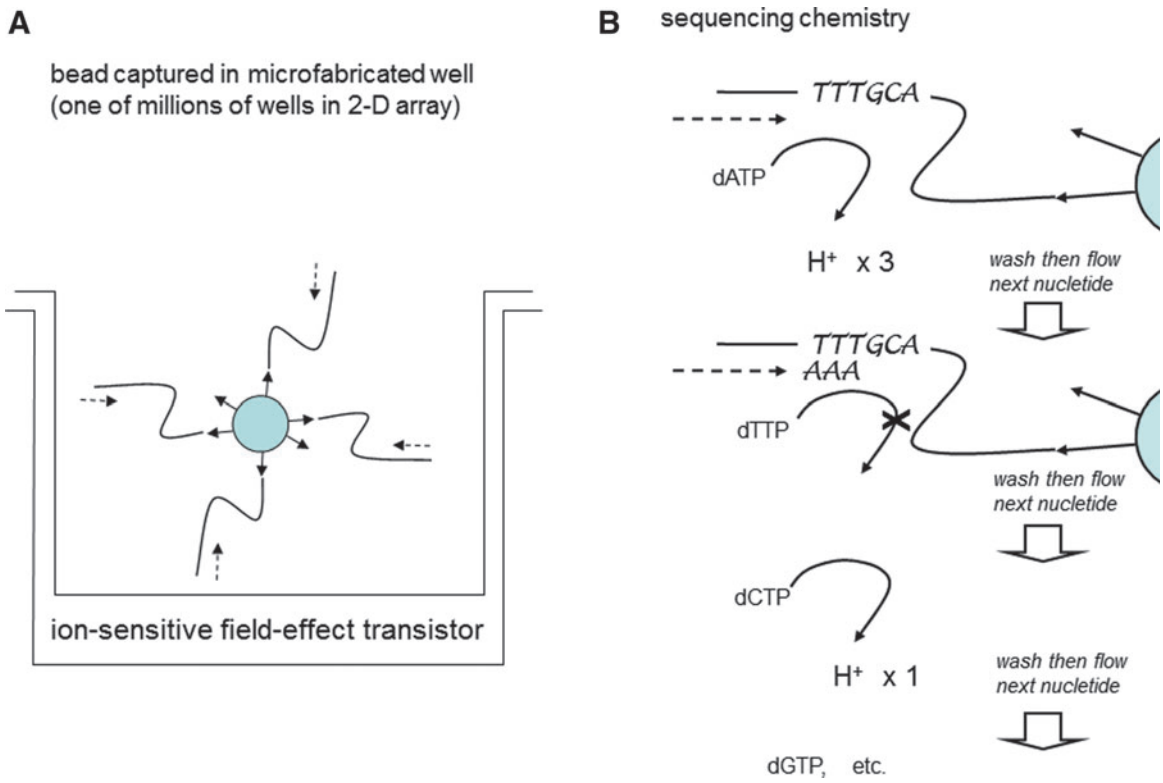

FIGURE 3 The capture of beads carrying amplicon and sequencing chemistry: Ion Torrent system. (A) A single bead in a single well of the array of wells on the sequencing chip. The beads—enriched for those that are carrying amplified template—are deposited in the chip wells by a short centrifugation step. The density of capture beads is adjusted such that there are more wells than capture beads and most wells with capture beads contain only one bead. Shown attached to the beads are single-stranded amplicon templates extended from a primer attached to the bead. Annealed to each template is a sequencing primer. (B) A closeup of the bead shows the sequencing chemistry employed. Sequencing reagents are flowed over the filled plate, including one of the four dNTPs at a time. For each incorporated nucleotide molecule, a hydrogen ion (H^+) is released. The sum of all such incorporations over all template molecules is recorded by the ion-sensitive field-effect transistor fabricated into the bottom of the well. The nucleotides are not modified or terminated such that if the template contains, for example, three sequential deoxyribosyladenines, three dTTP molecules are incorporated and three hydrogen ions are released. This is recorded as three times the signal as a single incorporation. If there is no base in the template complementary to the currently flowed dNTP, no signal is generated.

primers targeting the adapters amplifies the library to a level suitable for use.

The paired-end and mate-pair libraries both localize within the genome and subsequently facilitate the sequencing of the two end sequences of a larger DNA fragment. While paired-end sequencing involves determining the sequence of two ends of a fragment about 200 to 400 bp long, mate-pair sequencing involves sequences that are several kilobases apart. Although increasing steadily, current sequence read lengths for the Illumina and Ion Torrent systems—between 100 and 400 nucleotides (nt)—place limits on how large sequence contigs can be made using overlap assembly. Knowing that two sequences derive from the ends of the same large molecule of defined length allows the assembly of larger sequence contigs, particularly when the overlap assembly is interrupted by a repeated sequence. For the Illumina system, bridge PCR inherently captures both ends of a single molecule in a single polony; use of appropriate adapters and sequencing primers allows both ends to be sequenced.

Paired-end sequencing uses a larger bridge amplicon than normal sequencing—up to about the limit possible for efficient bridge PCR, which is around 300 bp. In mate-pair sequencing, DNA fragments of 2 to 10 kb are generated, end-repaired—with biotin labeled nucleotides—and circularized by ligation. Noncircularized DNA is removed by exonuclease digestion. The remaining circular DNA is then fragmented, and the fragments containing the ends that have been biotin-labeled during end repair and have become joined during ligation are affinity purified. Thus, the libraries consist of short fragments made up of two DNA segments that were originally separated by several kilobases.

Protocols have also been developed to obtain the longer sequence reads that to a large extent would obviate the need for paired-end and mate-pair libraries. This includes the Moleculo protocol, which can be used together with the Illumina technology (13). This method sequence-tags shorter reads from long (around 10 kb) PCRs to create "synthetic" long-read libraries. Longer reads are an inherent feature of Pacific Biosciences RS II single-molecule sequencing (see below) and the Oxford Nanopore technology (not yet on the market; http://www.nanoporetech.com). Long-range mapping technologies such as Irys (http://www.bionanogenomics.com) and Argus (http://opgen.com/) have been developed that are based on the location of sequence motifs (such as restriction enzyme sites) in very long single DNA molecules (100 kb and more).

These represent complementary technologies that are useful to bridge long highly complex repetitive regions.

PRE-ENRICHMENT OF PARTICULAR GENES AND "BARCODING"

In many instances, determining entire genome sequences is not required. Then one can take advantage of the massive throughput of NGS and direct it to multiple samples in parallel. This is facilitated by pre-enrichment of the desired target sequences before sequencing and by sequence tagging or barcoding DNA fragments arising from individual samples as described below.

In deep sequencing, the "bandwidth" of the sequencing experiment is focused only on certain key, subgenomic sequences such that low-level mutations in subpopulations of cells can be identified. This focus also allows the comparison of these subgenomic sequences among many individual organisms at once. The term "deep sequencing" was originally applied to the Sanger sequencing of up to thousands of bacterial clones of, say, a region of the 16s ribosomal gene but was most rapidly adopted once high-throughput *in vitro* molecular cloning and sequencing, that is, NGS, became available.

The most straightforward way to accomplish the enrichment of particular sequences is by using PCR. At first, multiplex PCR was limited in the number of amplicons that could be addressed, which was at most a few dozen (14). Subsequently, by limiting the number of cycles in PCR (low-cycle PCR), replication bias among amplicons, which would over- and underrepresent some sequences in the library, was prevented. Also, combinatorial methods of oligo synthesis were employed which allow the facile creation of primer sets with hundreds or even thousands of different targets. Examples of such multiplex PCR are in the Ion AmpliSeq human exome sequencing kit, which is based on multiplex PCR of 294,000 primer pairs across 12 primer pools (http://tools.lifetechnologies.com). The primers also feature proprietary modifications that allow their subsequent removal because they would interfere with the sequencing process. Another method of using primers to enrich specific target sequences is used by Illumina and called the TrueSeq targeted or enrichment system and features target-specific primer extension and ligation followed by PCR to 5′ and 3′ generic extensions of the targeting primers.

Larger subgenomic regions can be enriched by sequence-specific capture on microarrays of probes or through solution hybridization to probes on beads (15–18). The ability to make many different probes in a facile manner on microarrays is exploited to be able to select large fractions of the genome for enrichment. In the case of solution hybridization to probes on beads, probes are first made on a microarray, amplified and linked to an RNA polymerase promoter, and transcribed into single-stranded, biotinylated RNA. The biotinylated RNA is then coupled to streptavidin magnetic beads. Such enrichments have been demonstrated to work with good efficiencies such that the majority of the recovered sequences are those desired, even from genomes of high sequence complexity. These kinds of enrichments have been performed both prior to and after library preparation.

Since all the systems feature added adapter sequences to facilitate priming of the sequencing reactions, it is also possible to add immediately downstream of the primer annealing sequence a short identifier tag or barcode sequence (19). Such adapter sequences with unique barcodes can be added to individual DNA samples; when read out during a sequencing reaction, the barcode can identify the sample. This allows the pooling of multiple samples, which simplifies sample preparation, particularly for the systems employing emulsion PCR and bead capture. A four-base code in theory would be adequate for 256 samples, although the impact of a misread of the barcode—the result of which is the misassignment of a sequence read—needs to be considered.

SEQUENCING CHEMISTRIES

The sequencing chemistries applied to the two-dimensionally arrayed templates include either generation of light (through fluorescence or luminescence) in response to the incorporation of specific single nucleotides by polymerases (Illumina, Pacific Biosciences) or release of a proton in connection with the incorporation (Ion system). The light-generating reactions are followed in two-dimensional space and time using imaging, and the proton releasing reactions using pH change in a microfabricated well/detector. Fluidic systems deliver nucleotides and other reagents as well as wash away unincorporated nucleotides in a laminar flow over the arrayed polonies. This is repeated in cycles to build up the template DNA sequence. The Illumina system uses a terminated nucleotide much as Sanger sequencing does, but as a complete rather than partial block to further extension until the terminator is removed. A sequencing cycle consists of the flow of reagents for DNA polymerization (dNTPs, polymerase, sequencing primer, etc.) over the arrayed templates (Fig. 4). The four dNTPs are reversibly blocked to further extension as well as fluorescently labeled, each dNTP with a fluorophore of distinguishable wavelength. A color charge-coupled-device image of the two-dimensional array records for each polony (also known as cluster) the color, and hence identity, of the base incorporated. For optimal signal to background, a scanning laser microscope is used to generate the image (this is the most time-consuming part of the process). The block is then removed in a subsequent flow, and the cycle begins again. Read lengths in the range of 2×150–300 nt (paired end) are achieved.

The Ion Torrent/Ion Proton sequencing chemistry is based on incorporation of native nucleotides and the release of a proton (H^+) for each molecule of nucleotide incorporated (20). The pH change induced by the release of such protons is detected at the bottom of the nanowell and converted to an electric signal. By flowing each of four nucleotides in succession over the array of wells (separated by washes) and monitoring the proton release in individual wells in relation to the order of bases introduced, the template sequence can be determined (Fig. 3). There will be proton release in a given well when, say, dATP is flowed only if the next base in the template is deoxyribosylthymine. Since native, nonterminated nucleotides are used, multiple incorporations of a single base occur in response to homopolymer runs in the template. These are seen as a proportionately larger electronic signal in response to a release of proportionately more protons. In this way, homopolymer runs of two, three, four and so on bases can be discerned, although the accuracy of discriminating among longer runs is diminished as the relative increase in signal declines. Read lengths in the range of 200 to 400 nt are achieved.

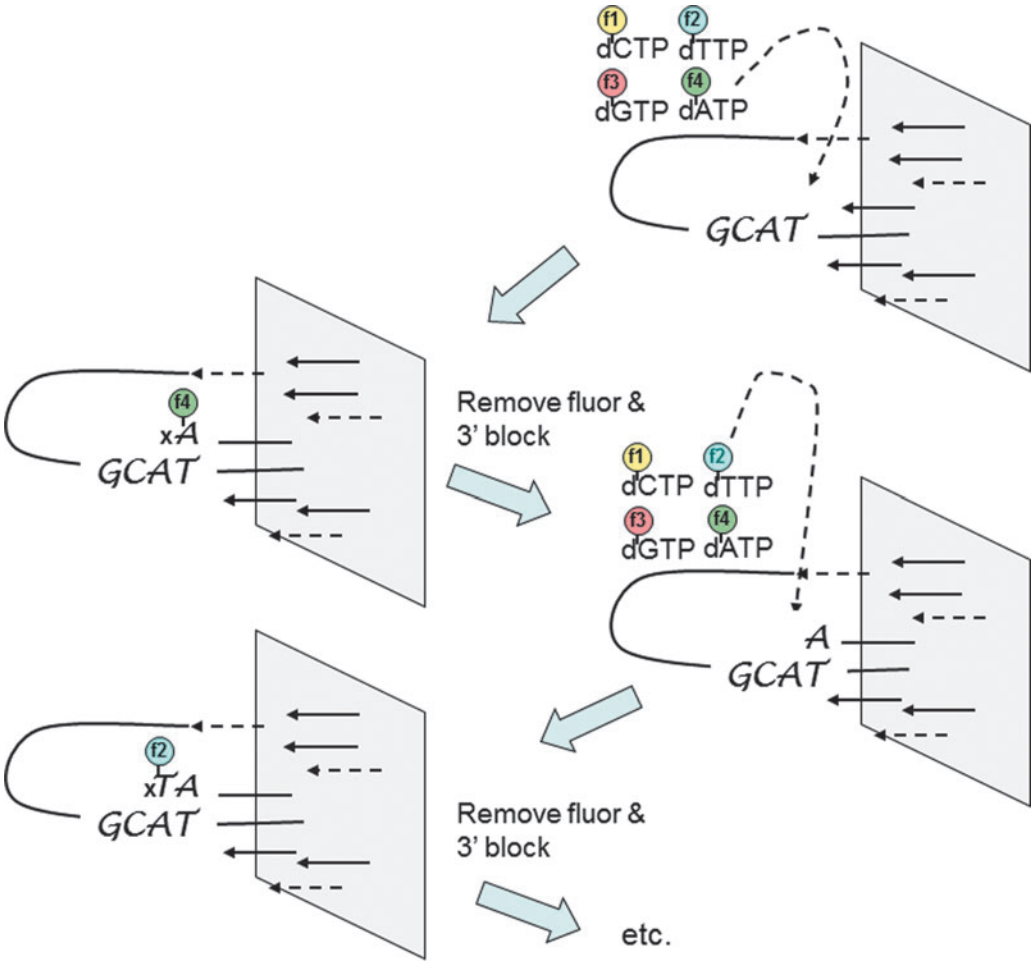

FIGURE 4 Illumina sequencing chemistry. Different fluorophore-labeled nucleotides (f1 through f4) with blocked 3′ termini are added specifically to the end of a primer one at a time. After each addition the fluorophore color is recorded by the imaging system, the block and fluorophore are removed, and the next addition is made.

SINGLE-MOLECULE, LONG-READ DNA SEQUENCING TECHNOLOGY

As in other systems, the Pacific Biosciences RS II technology distributes upon a two-dimensional array (the bottom surface of the "SMRT cell") massive numbers of individual "sequencing-by-synthesis" reactions that are followed in parallel in real time. In contrast to the Illumina and Ion Torrent/Proton systems, the Pacific Biosciences RS II technology is based on such reactions performed upon single, long, native DNA molecules (21). This is possible through the use of several proprietary technologies, including the zero-mode waveguide, which allows for monitoring of the incorporation of individual nucleotides by a single DNA polymerase molecule (Fig. 5). The microfabricated zero-mode waveguide confines the single polymerase molecule and DNA template within a nanometer-scale hole in an aluminum film deposited on a silica substrate. There are 150,000 such wells in the SMRT cell. This well is smaller in all dimensions than the wavelength of the illuminating laser light, such that only light generated very close to the bottom of the well is detected, e.g., the light generated from the incorporation of a specific, modified dNTP. Thus, interference from background light and from unincorporated nucleotides is greatly reduced. Each of the four dNTPs is labeled with a different color fluorescent dye. Colocalization of the incorporating dNTP and the polymerase/template complex in the well results in readable fluorescence of a specific color attributable to the specific incoming base. Completion of the incorporation reaction results in cleavage of the fluorescence tag and its diffusion away from the polymerase such that it will not interfere with the detection of the next, incoming dNTP.

In the RS II system, DNA libraries are generated by fragmenting DNA to a chosen size between 2,000 and 40,000 bp, repairing the ends, and ligating on oligonucleotides to generate circular DNA molecules. The advantage of circular DNA templates is that by using a polymerase with the ability to both displace preexisting complementary DNA and synthesize a new strand of complementary DNA (displacement synthesis), the same sequence can be "read" many times, providing an error correction mechanism that can produce a sequence with 99.999% accuracy, which is higher than the previous "gold-standard" Sanger sequencing method. These circular sequencing templates (SMRT bells) are mixed with DNA polymerase in such a proportion that on average one DNA polymerase is bound to each DNA template. The polymerase/template mix is

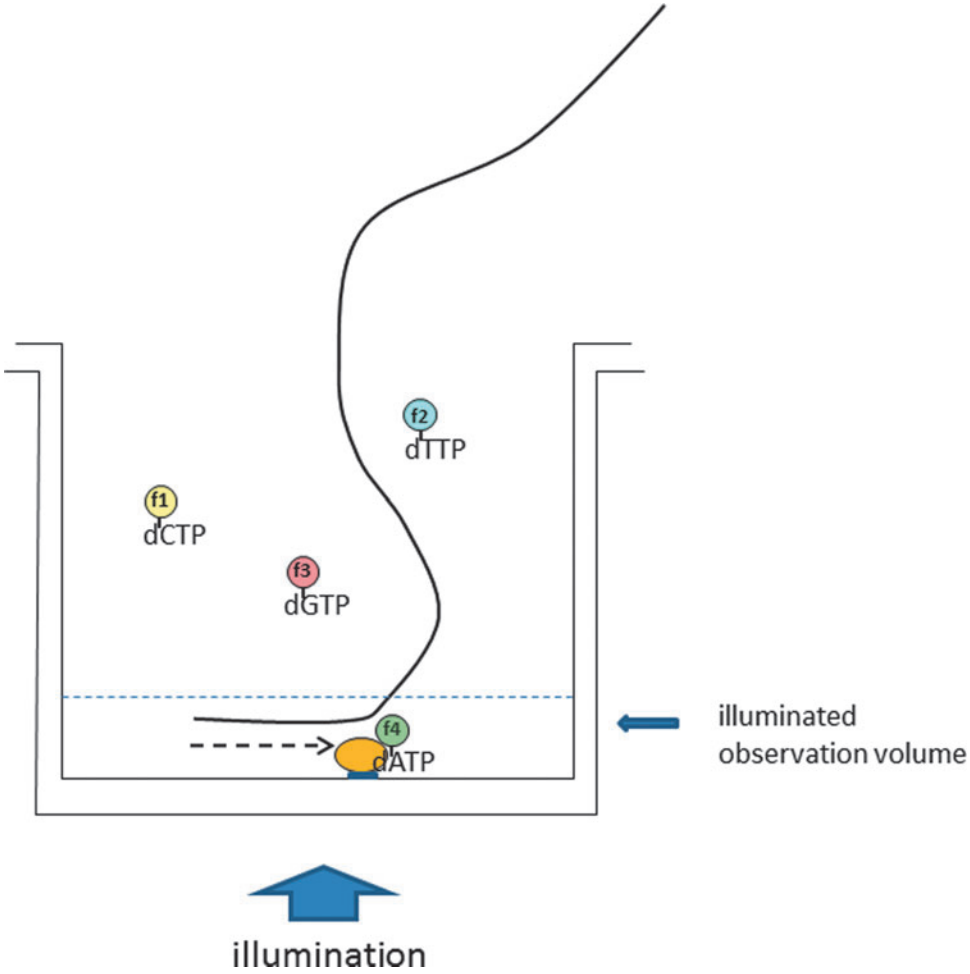

FIGURE 5 Single-molecule sequencing: the Pacific Biosciences system. Shown is a single, microfabricated nanowell with a light-transmitting bottom and with dimensions smaller than the wavelengths of light used to illuminate the well. This results in a "zero mode waveguide" with a narrow zone of illumination as shown. The nanowell has a single DNA polymerase molecule attached to its bottom within this zone. When overlaid with a solution of prepared DNA templates (also known as a library) at a suitable concentration, the polymerase is able to capture and bind a single primer-template molecule, as shown. Present in the solution are the four dNTPs, each labeled with a different color of fluorescent dye as shown and mostly outside the zone of illumination. Also shown is one of the four dNTPs bound to the polymerase-template-primer complex. This is the next base to be incorporated opposite its complementary base. The fluorescent tag is bound long enough for its presence and color to be detected. Subsequently, completion of the incorporation reaction results in cleavage of the fluorescence tag and its diffusion away from the polymerase such that it will not interfere with the detection of the next, incoming dNTP.

then loaded onto a SMRT cell in such a way that each well should contain on average one DNA template/one polymerase molecule. The polymerase is bound to the bottom of the well, and DNA sequencing is initiated by flowing the cell with the four fluorescent nucleotides and monitoring their incorporation as described above. Templates with, by chance, multiple bound polymerases give a "mixed" sequence read which can be discriminated from a valid read. When using passive loading of the polymerase/DNA template to the SMRT cell, the number of wells with a single (as opposed to multiple) polymerase/DNA template complex follows the Poisson distribution. This results in a maximum of about 50,000 wells with a readable DNA sequence. Systems for active loading of the SMRT cells are under development and will significantly increase the number of wells containing a single polymerase/DNA template complex. All 150,000 wells are followed in parallel to generate sequence reads of 2,000 to 40,000 nt in 0.5 to 2 hours.

In contrast to the other massively parallel sequencing technologies, the RS II technology can be used to sequence very long individual DNA strands (see discussion below). The reaction proceeds as long as there are nucleotides available and the DNA polymerase is active.

COMPARISON OF NGS PLATFORMS

The Illumina technology currently dominates the market. Illumina provides a range of instruments with different throughput, sequencing run times, and read lengths. The

larger Illumina instrument (HiSeq) runs flow cells containing eight independent lanes. An individual sample can be run on each lane in parallel with others. The Illumina system, since it does not use emulsion PCR and beads, has a less cumbersome and time-consuming protocol for preparing samples for the sequencing run than does Ion Torrent's system. Although the shearing, adapter ligating, and sizing of input DNA required for genomic library creation are a day's worth of intensive work for all the systems, the creation of a two-dimensional array of polonies takes less than 30 minutes of hands-on time in the Illumina system.

Illumina has recently introduced a novel development of its sequencing technology, initially only implemented in a system called HiSeq X Ten. The throughput of this instrumentation has been increased dramatically using dual-surface imaging (using both sides in a flow cell) enabled by a two-camera, four-sensor, epifluorescence system with a novel scanning technology. Also, the HiSeq X Ten uses a patterned flow cell with billions of ordered nanowells that allows the generation of sequencing clusters in an ordered arrangement, which increases the density of clusters and thus the sequence reads. Although initially dedicated to whole human genome DNA sequencing, this technology is likely to become available for a wider range of applications and enables terabases of DNA to be determined in a single instrument run.

The Ion Torrent/Ion Proton system has lower sequence throughput but is suited to projects in microbiology because of the rapid generation of data. Although the library preparation involves the somewhat cumbersome emulsion PCR, this can now be partly automated. The sequencing time is relatively short, involving only a couple of hours on the instrument, as opposed to days on the Illumina platform. Because the imaging systems of the Illumina system require a scanning microscope, completing the image takes considerable time per cycle. The entire time for a run on the larger HiSeq instruments amounts to between 1 and 6 days, depending on the throughput required. The smaller MiSeq has a run time of about 5 to 55 hours. The Ion system's read length is on par with the Illumina system's, up to about 400 bp per fragment. Methods for emulsion PCR-free library preparations are under way (Avalanche). One weakness of the Ion Torrent/Proton system has been the higher error rate in homopolymer nucleotide stretches. This has been largely corrected with successive updates in chemistry and software.

The Pacific Biosciences RS II system is unique in that it does not require amplification of the original DNA template. Prior amplification has a number of advantages, in particular, reducing the ambiguity and complexity of the sequence analysis, but it also may result in biases due to differences in amplification efficiency of individual targets. Also, without amplification, DNA modifications such as methylations, which would not be copied and would be lost in amplification, can be studied. This is because the average time it takes for incorporation of a base opposite to a modified base is significantly longer and can vary depending on the specific modification (22). It is also the only commercially available system that allows for very long DNA strands to be sequenced, dramatically extending the length of a sequence read beyond that obtained even by Sanger sequencing. Such long reads of up to 40,000 bases result in more efficient assembly of contigs both because of certainty of overlap and because of the ability to span short interspersed repeat sequences that otherwise prevent unambiguous sequence assembly. The simple procedure for library preparation and the very short time on the instrument also position the RS II system as overall the fastest sequencing technology for small or medium size genomes. This includes the faster turnaround time for the software to assemble microbial genomes. The drawback of the RS II system is the relatively low throughput (presently about 1 Gb per SMRT cell) and the per-nucleotide high error rate. The latter, however, can be handled effectively with sufficient coverage, since errors are random relative to nucleotide position and type. Also, improvement in loading efficiency and polymerase performance is projected to triple the sequence throughput in the coming year, making this technology also suitable for medium size genomes. See the section below on application of the RS II system to microbiology.

APPLICATION OF LONG-READ SEQUENCING TECHNOLOGY TO MICROBIOLOGY

The ability to exhaustively analyze nucleotide sequence content (base by base, single molecule by single molecule), even for sequences present in very low abundance, means that deep sequencing is an ideal tool for pathogen discovery and for evaluating the population structure of complicated mixtures of bacterial and viral organisms. The most economically feasible way to perform deep sequencing is by targeting subgenomic sequence elements, such as 16S ribosomal DNA. 16S ribosomal DNA is highly conserved among species in general, allowing it to be targeted, yet variable enough that it can distinguish even closely related species. However, the throughput and read lengths of NGS have increased to the point where the assembly of viruses, plasmids, and even whole bacterial genomes from complex populations of genomes has become feasible. Here and in general, deep sequencing has used computational algorithms and electronic subtraction to make sense of the massive amounts of data generated by each run. Such computer-intensive approaches represent the general trajectory of this technology in the future.

The Pacific Biosciences RS II long-read sequencing technology provides unique opportunities for generating complete genome sequences with no gaps. The sequence throughput per SMRT cell is ideal for sequencing microbial genomes with sufficient coverage. Also, the technology has a short turnaround time, making it suitable for clinical applications. For example, sequencing of the complete genome of multiresistant bacteria can be performed in 2 days, from DNA extraction to delivery of a complete microbial genome (Ulf Gyllensten, unpublished). Also, the long sequence read length provides advantages in metagenomic sequencing, since individual reads can encompass the entire genomic sequence of viruses or plasmids, increasing the accuracy of a genome assembly. An example of the application of this technology is the study by Conlan et al. (23). They isolated a repertoire of carbapenemase-encoding *Enterobacteriaceae*, including *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Escherichia coli*, *Enterobacter cloacae*, *Citrobacter freundii*, and *Pantoea* species. Long-read genome sequencing using the RS II system resulted in full genome, end-to-end assembly and revealed that these organisms carry the carbapenem resistance genes on a wide array of different plasmids. They found evidence of horizontal transfer of carbapenemase-encoding plasmids between *K. pneumoniae*, *E. cloacae*, and *C. freundii* in the hospital environment. By enabling full plasmid identification, their

data challenge assumptions about horizontal gene transfer events within patients and identify possible connections between patients and the hospital environment. In addition, they identified a new carbapenemase-encoding plasmid of potentially high clinical impact carried by *K. pneumoniae*, *E. coli*, *E. cloacae*, and *Pantoea* species in unrelated patients and in the hospital environment. Because plasmid sequences contain complexities such as repeats and mobile genetic elements, previous attempts to sequence them with short-read technology have not been able to discriminate and resolve plasmid from chromosomal genes.

CONCLUDING REMARKS

Massively parallel sequencing technologies have continued to make remarkable advances. The cost of sequencing has come down steadily and at a faster rate than Moore's law, which is used to predict the cost versus performance of computer chips and which promises a doubling in speed at the same cost every two years. The complexity of the technology has also been reduced, making it available to individual laboratories as well as core facilities. In addition, advances in computational support have made the systems faster and easier to use. The systems have also been made easier to use by integrating sample preparation with the automated steps of the sequencing reactions themselves. A major breakthrough has been the emergence of technologies that enable very long, contiguous stretches of DNA to be read. At present only one such technology, that of Pacific Biosciences, is available, but several others are in development and are likely to come to fruition in coming years. A promising development is the use of molecular (or nano-) pores for sequencing. This technology infers a DNA sequence based on the rate of passage of individual or groups of nucleotides as the whole DNA molecule passes through the pore. In principle such a sequencing technology could be much faster, simpler, and more economical than current NGS. One implementation of nanopore sequencing (Oxford Nanopore) has been made available for early testing, but initial results indicate that it requires further improvement. Overall, given the rapid rate of technology development and the decrease in cost and time, massively parallel sequencing is likely to eventually become the method of first choice for accurate identification of bacterial and viral infections both in experimental science and clinical microbiology, replacing most of the current laboratory methods.

Next-Generation Sequencing

CHARLES CHIU AND STEVE MILLER

6

Next-generation sequencing (NGS), otherwise known as deep or massively parallel sequencing, refers to the technological advances in DNA sequencing instrumentation that enable the generation of hundreds of thousands to millions of sequence reads per run. Sequencing of the human genome, which was once a >10-year endeavor by the NIH at the cost of approximately $3 billion (1), can now be done routinely on a single instrument. Rapid advances in technology led to the first-ever FDA clearance of an NGS instrument, the Illumina MiSeq, in 2014 (2), and the development of rapid, miniaturized sequencing devices such as the Oxford Nanopore are ongoing (3). The applications of NGS are wide-ranging and include (i) whole-genome sequencing, (ii) pathogen discovery, (iii) metagenomic/microbiome analyses, (iv) transcriptome profiling, and (vi) infectious disease diagnosis. Here we will focus on NGS technology and the last three applications, because the first two topics are described in detail elsewhere.

OVERVIEW OF NEXT-GENERATION SEQUENCING METHODS

Prior to the 1980s, Sanger sequencing, based on slab or capillary gel electrophoresis of individual DNA fragments (4), was the only available sequencing technology. The technique was laborious, with a turnaround time of 6 to 24 h, and capacity was limited to the sequencing of fragments in 96 or 384 microtiter wells at a time. The approach taken by NGS technologies, on the other hand, is based on preparation of a "library" of DNA fragments to be sequenced (5). The library is typically produced by the clonal amplification of millions of amplified DNA templates at a time, followed by some method to determine the sequences in a massively parallel fashion. The first available NGS system was the Roche 454 pyrosequencing instrument (6), followed by the emergence of "second-generation" systems (7, 8), including the Illumina (formerly known as Solexa) HiSeq/MiSeq/NextSeq, ABI SOLiD, Life Technologies Ion Torrent, and the PacBio RX system. Currently, the Illumina instruments are used in most published NGS studies, including those in the microbiological field, although new "third-generation" platforms, such as those based on nanopore sequencing (9), are now available and being increasingly used.

Charles Chiu and Steve Miller, Department of Laboratory Medicine, University of California, San Francisco, San Francisco, CA 94107.

Roche 454 Pyrosequencing and SOLiD Sequencing

Both the Roche 454 instrument and SOLiD systems isolate and amplify single DNA molecules to construct a library for sequencing by a process known as emulsion PCR (Fig. 1A) (10). Emulsification of an oil-water interface leads to the formation of droplets, with each droplet, referred to as a microreactor, containing a bead that is covalently bound to a single DNA template. PCR amplification is then performed across the surface of the bead to generate clonally amplified fragments. For Roche 454 pyrosequencing, the beads are then deposited into individual wells on picotiter plates, and sequencing reagents containing DNA polymerase are added into the wells (Fig. 1A, left). As the complementary strand is synthesized by nucleotide incorporation, pyrophosphate release produces a fluorescent signal that can be recorded by a CCD (charge coupled device) camera for base calling. For SOLiD, after emulsion PCR, the 3′ ends of the DNA template on the bead are modified to permit chemical linkage to the surface of a glass slide (Fig. 1A, middle). When sequencing reagents containing DNA ligase are flowed over the slide, a fluorescent signal is generated that is captured by a CCD camera for base calling. Roche 454 pyrosequencing is classified as sequencing-by-synthesis, because the sequence is being read concurrently with synthesis of the complementary strand by incorporation of fluorescent-labeled nucleotides (11), whereas SOLiD sequencing is classified as sequencing-by-ligation, because sequencing is determined according to the selective mismatch sensitivity of DNA ligase to fluorescently labeled probes (12).

Ion Torrent Sequencing

For the Ion Torrent, which similar to the Roche 454 uses a sequencing-by-synthesis approach, a semiconductor chip is used to detect hydrogen ions released during DNA polymerization (Fig. 1A, right). A library is prepared by emulsion PCR, and amplified fragments are coupled to beads that are individually deposited in sequencing wells. Nucleotides are then added to the chip, with each of the four bases (A, C, T, and G) being introduced one at a time in a predetermined order. As each nucleotide is incorporated during strand synthesis, a hydrogen ion is released that alters the pH value. Changes in pH are converted and measured in voltage values, which are directly proportional to the number of nucleotides that are incorporated during each cycle.

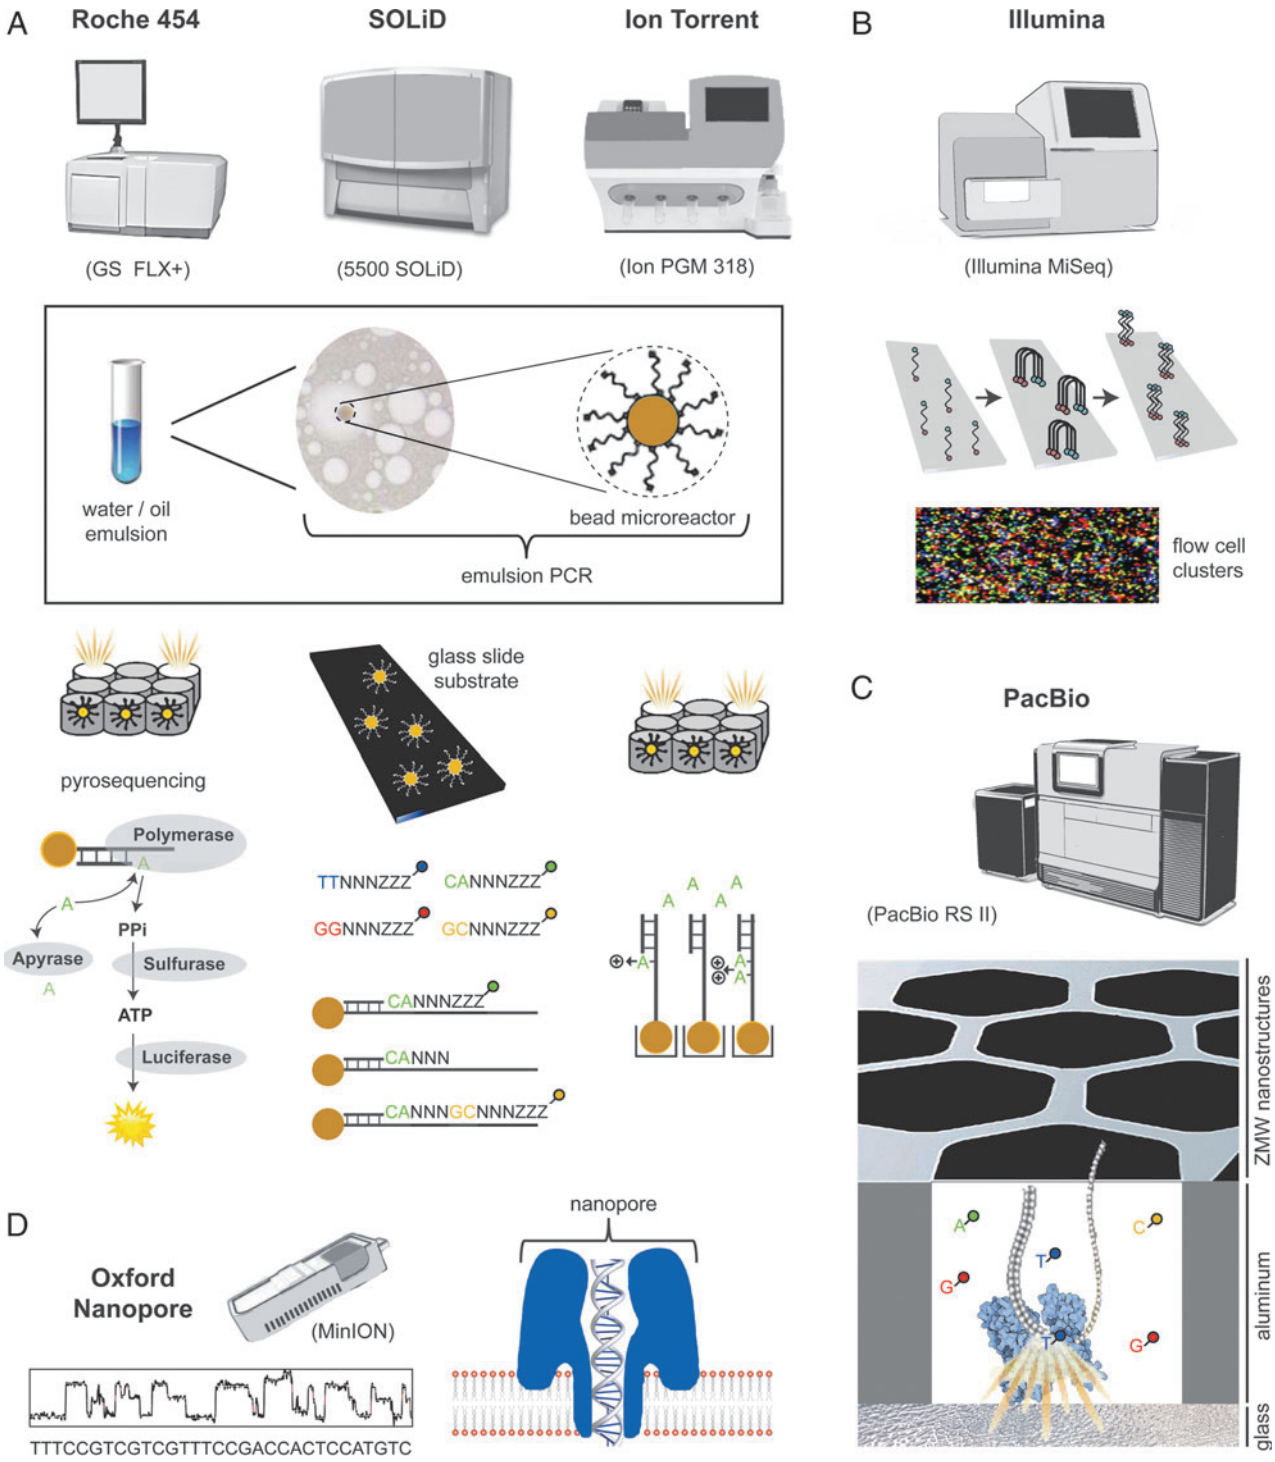

FIGURE 1 Sequencing methods for currently available NGS platforms. (A) The sequencers manufactured by Roche/454 (left), SOLiD (middle), and Ion Torrent (right) all use bead-based emulsion PCR (rectangular inset) in the library generation process, followed by different approaches to fluorescent-based sequencing. (B) Illumina sequencing involves library generation on a flow cell via a sequencing-by-synthesis approach and the imaging of millions of fluorescent flow cell clusters. (C) PacBio sequencing is performed by a DNA polymerase enzyme affixed to a glass substrate in a zero-mode waveguide nanostructure. Each nanostructure generates an individual sequence. (D) Nanopore sequencing, as performed by the Oxford Nanopore MinION instrument, leverages the voltage conductance changes (left) that occur in response to passage of DNA through a nanopore (right), a protein in the lipid-bilayer membrane containing a single hole that allows a single molecule of DNA to pass through.

Illumina Sequencing

The library preparation is simpler than emulsion PCR for Illumina sequencing (Fig. 1B). Two unique primers (adaptors) are attached to the ends of each DNA fragment by ligation, PCR, or transposon switching (Nextera technology) and then affixed to the surface of a flow cell in the form of hairpin loops. "Bridge amplification" using PCR is then performed on the flow cell surface by denaturing the 3′ end of the DNA fragment and replicating the complementary strand. Successive rounds of replication and denaturation by PCR thermocycling result in the generation of thousands of copies of clonally amplified fragments in a tightly circumscribed cluster. Sequencing reagents, including DNA polymerase and a sequencing primer, are then passaged across the flow cell. For each cycle, a single fluorescently labeled nucleotide containing a reversible terminator is added to the complementary strand within each individual cluster in a sequencing-by-synthesis approach. After CCD imaging, cleavage of the fluorescent label permits the next nucleotide to be added. The number of cycles producing the final read length is specified in advance, and sequencing can also be done from both ends (paired-end sequencing) using a second primer to the newly synthesized DNA strand.

PacBio Sequencing

In PacBio single-molecule real-time sequencing technology, individual molecules of DNA template are affixed to the bottom surface of the chip in an optical waveguide called a zero-mode waveguide (Fig. 1C). The zero-mode waveguide creates an illuminated volume within which to observe the incorporation of single nucleotides of DNA. The four nucleotide bases are labeled with different fluorescent dyes and added simultaneously to synthesize the complementary DNA strand. During nucleotide incorporation, the fluorescent tag is cleaved off and a base call is made according to the corresponding fluorescence of the dye (sequencing-by-synthesis). Each single-molecule real-time cell contains approximately 150,000 zero-mode waveguides (13).

Nanopore Sequencing

The sequencers manufactured by Oxford Nanopore use arrays of specialized nanopores that allow a single DNA molecule to pass through at a typical rate of 30 bases per second (range of 0 to 250 bases per second) (14). Current versions of the Oxford Nanopore MinION sequencer, a miniaturized device about the size of a USB stick, contain arrays of 512 nanopores (15), although greater capacity can be achieved with instruments in development including the GridION and PromethION. The current passing through the pores changes in response to the different nucleotide bases as they pass through (Fig. 1D), allowing the sequence to be determined without synthesis, ligation, or other enzymatic steps. Library preparation is simple, but the rate at which a nanopore can capture and sequence a diffusing DNA molecule is limited by concentration, thus requiring relatively high input concentrations of target DNA. At present, error rates in practice are high compared to the more mature sequencing-by-synthesis methods (20 to 40%) (16), but quality consensus sequences can be generated given adequate sequencing coverage.

DIFFERENCES BETWEEN NGS PLATFORMS

Table 1 shows a comparison of the different NGS technologies. The choice of which NGS platform is best suited for any particular application depends on a number of factors including cost, sequencing read lengths, sequencing depth (number of reads per clinical sample) and coverage, and sequencing quality.

Cost

The costs of sequencing have decreased significantly in recent years. Nevertheless, an NGS run is still typically at least an order of magnitude more expensive than that of conventional microbiological assays. Often samples must be individually barcoded and pooled into single runs to decrease costs. As the costs continue to decrease, however, increasing consideration should be given to the cost attractiveness of NGS relative to other recent technologies such as mass spectrometry and microarrays.

Read Length

Longer read lengths are more desirable than shorter read lengths for many applications. For example, in pathogen discovery, longer read lengths facilitate detection of sequences from highly divergent microorganisms such as novel emerging viruses that may be only identifiable on the basis of weak homology in their translated amino acid, rather than nucleotide sequence (17). For metagenomic sequencing, longer reads can also be more accurately classified according to their origin (e.g., human, virus, bacteria, fungus, or parasite), because they are more likely to be uniquely identifying than shorter reads. In addition, longer reads can provide genomic scaffolds that are critical in the *de novo* assembly (joining together of individual reads on the basis of overlapping sequences) of novel microbial genomes for which there is no closely related reference in the database (18). Indeed, many *de novo* assembly approaches combine two technologies: one technology that employs longer but fewer reads (e.g., PacBio, Oxford Nanopore) to enable genomic scaffolding and another technology that employs many more short reads (e.g., Illumina) that can be subsequently mapped onto those scaffolds (3, 19).

Sequencing Depth and Coverage

Sequencing depth and coverage are important parameters for many NGS applications. As a rule of thumb, at least 20× coverage of the genome is generally thought to be needed for accurate *de novo* assembly of a novel organism from short NGS reads (20). In metagenomic "needle-in-a-haystack" applications, a minimum sequencing depth is needed to detect sequences from a target pathogen with high sensitivity amidst a large number of human or animal host background reads (21). The required depth depends on the relative copy number of microbial versus host nucleic acid in the library, with acellular fluids such as serum/plasma, cerebrospinal fluid, and respiratory secretions typically requiring much less sequencing depth at a given level of sensitivity than tissue samples, for which host background sequences are predominant.

Sequencing Quality

Some technologies, such as Roche 454 and Ion Torrent, have difficulty sequencing long homopolymers (22, 23). Other technologies, such as PacBio and Oxford Nanopore, have inherently low individual sequence quality. The low, per-read sequencing quality can be compensated for in PacBio by resequencing the same fragment multiple times

TABLE 1 Comparison of NGS platforms

Platform	Sequencing method	Instrument	Typical read lengths	Accuracy	Throughput (reads per run)	Run time	Instrument cost	Sequencing cost	Key advantages	Key disadvantages
454 Roche	Pyrosequencing	GS FLX+	Up to 700 bp	99.9%	Up to 1 million	20 h	++	+++	Long reads; fast run times	Low throughput; homopolymer errors
SOLiD	Sequencing by ligation	5500 SOLiD	35–50 bp	99.9%	1.0–1.5 billion	1–2 weeks	++++	+	Low cost per base	Very short reads; slow
Ion Torrent	Ion semiconductor	Ion PGM 318	100–200 bp	98.0%	4–5.5 million	2 h	++	++	Fast run times	Homopolymer errors
		Ion Proton I	200–400 bp	98.0%	60–80 million	8 h	+++	++	Fast run times	Homopolymer errors
Illumina	Sequencing by synthesis	HiSeq 2500	50–300 bp	98.0%	0.6–4 billion[b]	6 h to 11 days[b]	++++	+	Highest yield; low cost per base	Instrumentation expensive
		MiSeq	50–300 bp	98.0%	20–30 million	6–40 h	++	+	FDA cleared; low cost per base	Lower throughput
		NextSeq	50–300 bp	98.0%	Up to 800 billion	6–40 h	+++	+	Intermediate yields; low cost per base	Lower throughput
PacBio	Single-molecule real-time (SMRT)	PacBio RSII	10–15 kb	87% or >99.9%[c]	50,000	2 h	++++	+	Long read	Instrumentation expensive
Oxford Nanopore	Nanopore sequencing	MinION	100 bp–10 kb	60–80% or >99%[c]	10,000–50,000	6 h[d]	+	?	Real-time sequencing; portable; long reads	High error rate; low throughput
Sanger[a]	Chain terminator	3730xl	400–900 bp	99.9%	N/A	2 h	++	++++	Long reads; fast run times	Lowest throughput

[a]Not an NGS method; included for purposes of comparison.
[b]Dependent on whether run is rapid-mode or standard-mode.
[c]Individual read or consensus read accuracy.
[d]Can be run until sufficient data are collected; lifetime of flow cell currently 24 to 48 h.

to generate consensus reads (24), while Oxford Nanopore relies on having redundant coverage to compensate for the high error rates (75). The sequencing quality can also vary with length. For example, the quality of Illumina reads deteriorate gradually toward the end of the read (25).

OTHER NGS CONSIDERATIONS

Sample Selection

The NGS approach in microbiology is compatible with a wide range of samples, including clinical human, animal, and even environmental samples, and the choice of sample type is highly dependent on availability and the desired application. When applying unbiased metagenomic techniques that do not rely on specific primers or probes, acellular fluids are preferable to tissues because they have much less host background (21). Metagenomic detection of pathogens is generally less sensitive in whole blood, for example, than in acellular serum or plasma samples. When available, freshly frozen samples are generally superior in quality for NGS applications than formalin-fixed, paraffin-embedded samples or samples allowed to sit at room temperature or 4°C, due to the risk of nucleic acid degradation (26). For applications involving labile RNA such as detection of RNA viruses or transcriptome profiling of mRNA, the use of stabilization reagents at initial sample collection (e.g., PaxGene tubes) should be considered (27). For applications such as infectious disease diagnostics, analysis of more sterile samples such as blood or cerebrospinal fluid is preferred given the increased likelihood of finding a sole causative agent (17), as well as the difficulty in bioinformatics analysis and interpretation of more complex, "environmental" microbial samples such as stool (21). On the other hand, metagenomic and microbiome analyses typically require the presence of a diverse polymicrobial community, such as those found in stool or respiratory secretions. These analyses may not be meaningful for more sterile samples such as blood or cerebrospinal fluid, for which a virome (28), but probably not bacteriome, exists in the healthy state.

For diagnostic NGS, several other considerations need to be taken into account. Collection of noninvasive samples (e.g., sweat, saliva, stool, and urine) is easier than collection of blood or tissue biopsy samples. However, any detected association with NGS is much stronger if made from invasive samples such as tissue biopsy, especially if there is concurrent pathology such as inflammation. Another key consideration is whether to focus on sequencing of library DNA or cDNA generated from RNA. RNA-based NGS is obviously required for RNA virus detection or mRNA transcriptome profiling. For bacterial, fungal, or parasitic identification by 16S/18S rRNA (see below) (29), it may also be preferable to detect transcribed rRNA molecules rather than the rRNA genes to maximize sensitivity, because 10^4 to 10^5 rRNA molecules can be present per microbial cell versus only 1 to 10 copies of the rRNA gene (30). It is also worth noting that RNA-based NGS detection is still capable of detecting DNA-based organisms such as DNA viruses and bacteria by detection of their corresponding host or pathogen mRNA transcripts, respectively. However, RNA is significantly more labile than DNA, and NGS libraries constructed from RNA are also more prone to contamination from exogenous bacterial rRNA from laboratory reagents and the environment (31), which can confound interpretation of the sequencing results.

Disease and Host

Most NGS applications in microbiology are based on direct detection and/or sequencing of microbes. Thus, acute diseases such as febrile illness, which can be associated with high titers of the causative agent (32), are generally more amenable to NGS analysis than chronic diseases. In chronic diseases such as cancer or chronic autoimmune disease, NGS for pathogen detection and discovery relies on the infectious agent still being present at detectable levels in tissue at the time of clinical sample collection. NGS studies in animals can also be more problematic than those in humans, especially if the genome of the animal or a close relative has not yet been sequenced, precluding computational host subtraction approaches to simplify the data analysis (see below).

Sample Preparation Methods

Clinical and environmental samples for NGS are prepared in a series of steps beginning with nucleic acid extraction followed by library preparation (+/− sample barcoding) and loading onto the instrument for sequencing (Fig. 2, left). Initial sample preparation and nucleic acid extraction methods vary depending on the assay type, sample matrix, and pathogen type being detected. Methods to reduce host background or enrich for microbial sequences include ultracentrifugation, nuclease treatment (either pre- or postextraction), and probe-based enrichment. Ultracentrifugation allows for enrichment of virus-like particles, enhancing viral detection (33, 34). Treatment with DNase or RNase will enrich for RNA or DNA targets, respectively, and can substantially reduce host background (33, 34). Probe-based enrichment can be performed using a panel of targets to recover specific organisms from low-titer samples (35).

Sample Barcoding

To multiplex analysis of specimens in a single NGS assay, each sample can be barcoded by adding a short oligonucleotide tag 6 to 12 base pairs (bp) in length to each end of the DNA molecule. Barcoded libraries are then mixed and sequences classified bioinformatically based on the sequenced barcode. To reduce barcode switching, the barcodes are designed to be different by more than one base pair change in a single sequencing run. The use of Hamming code-based designs can preserve minimal distance (in number of base pair changes) between barcodes, and also enable error correction (36). Separate barcodes can be attached to each end of the sequencing target (dual-index barcoding), and barcodes can be rotated over time, reducing the risk of carryover contamination.

Library Preparation Methods

Once the samples have been prepared and nucleic acid extracted, the library is constructed. Each instrument method requires an optimal input amount, which can be generated by preamplification. The final library is generated using emulsion PCR or sequencing adaptor ligation specific to each method (Fig. 1). Library quality control is performed by determining the concentration and size distribution using capillary electrophoresis or real-time PCR. Individually prepared libraries with different barcodes can be pooled for sequencing on a single run, depending on the desired number of sequences per sample.

Contamination

Due to the high sensitivity offered by sequencing large numbers of reads, NGS approaches are extremely vulnerable to

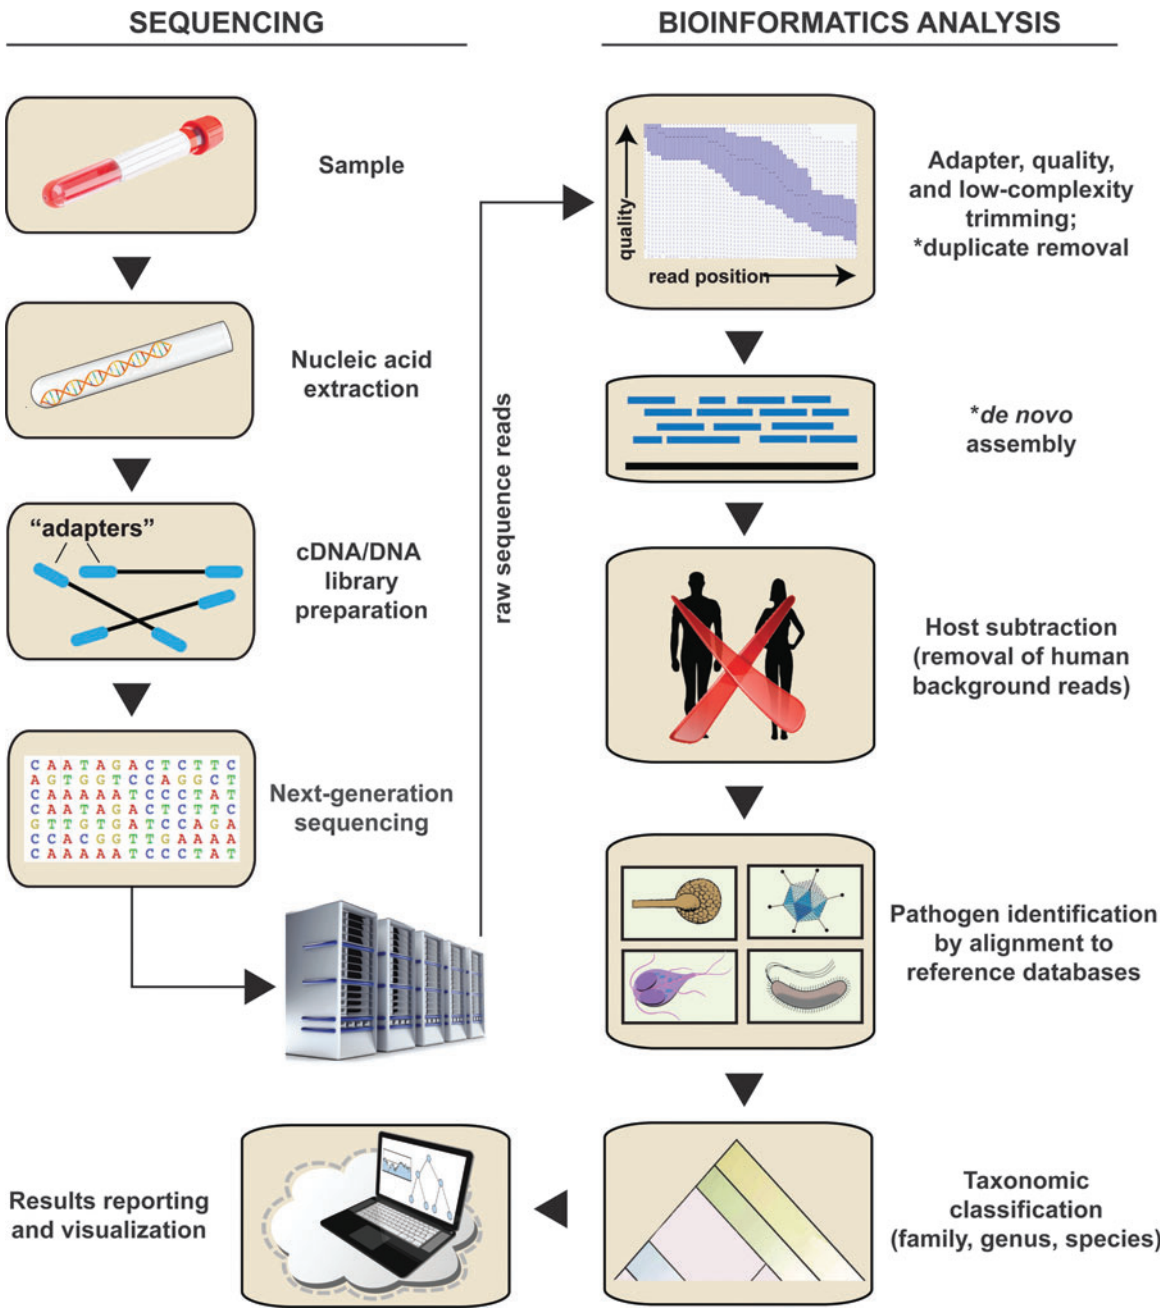

FIGURE 2 Schematic overview of an NGS pipeline. Sample processing for NGS involves a stepwise process of nucleic acid extraction, library preparation, and sequencing on a dedicated instrument (left). Following generation of raw data, bioinformatics analysis of metagenomic or microbial NGS data includes preprocessing, *de novo* assembly, host subtraction, pathogen identification, taxonomic classification, and results reporting/visualization (right). The asterisks denote optional steps in the procedure.

contamination (31). There are multiple points where contaminating organisms or nucleic acid may be introduced into the system, including sample collection, sample processing, and on the sequencing instrument. NGS traditionally requires handling of libraries in an open environment with multiple steps, so amplified material may cross-contaminate samples prepared simultaneously or during subsequent sequencing runs. Reagents used for NGS analysis may be contaminated with microbial nucleic acid, because it is difficult to completely remove DNA from recombinant enzymes. Even commonly used supplies can harbor microbial contamination, such as silica-based DNA purification columns containing what is now thought to be an algal virus (37). Instrument carryover can also occur and is seen both within a run and between runs. Finally, cross-contamination of barcoded samples that are multiplexed in a single run can occur, especially if an individual sample contains a high titer of a specific microbial agent, reads from which can "spill over" into adjacent barcoded samples. This can be mitigated, but perhaps not eliminated entirely, with the use of dual-indexed barcodes at both ends of library amplicons. Thus, careful handling, unidirectional

sample flow, proper quality control, and careful measurements of levels of background contamination are necessary to reduce the risk of false-positive identifications using NGS.

Quality control of NGS reagents is yet another key step to minimize false-positive identifications, particularly with low-input samples having minimal titers of target nucleic acid. Despite efforts to produce ultra-pure reagents (38), there will likely never be assurances that reagents are truly nucleic acid–free. Thus, each new lot of reagents should always be tested with negative controls, and laboratories need to understand the expected frequency and distribution of reagent-derived contaminating sequences and establish appropriate threshold levels of detection to avoid false-positive calls. Common laboratory water supplies often contain bacterial DNA from organisms such as environmental *Burkholderia* and *Ralstonia* species (39, 40), making it difficult to distinguish a true positive identification from background levels of contamination. Also, aerosolized nucleic acid has the potential to contaminate sample hoods and can become a major component of libraries prepared in the hood, requiring extensive cleaning. For certain NGS applications such as pathogen discovery and clinical detection of unusual or unexpected agents, it may be desirable to confirm the results using different extraction methods or reagents or even running the NGS assay in separate laboratories. Confirmation using an orthogonal method such as specific PCR testing from the original sample may also be necessary to exclude the possibility of contamination.

NGS BIOINFORMATICS WORKFLOWS

The sheer number of NGS reads generated by existing instruments and rapid increases in sequencing capacity pose a major computational challenge for analysis of NGS data. A number of bioinformatics software choices are now available, both commercial and open source. For the most part, some degree of computational expertise is needed to take full advantage of these algorithms and workflows, although user-friendly options for NGS analysis exist, such as Geneious (41) and Galaxy (42). Although the details can vary significantly, a computational pipeline for processing and analyzing NGS data follows a general schema (Fig. 2, right). First, sequencing reads are preprocessed by trimming of adapter, low-quality, and low-complexity sequences, with optional removal of duplicate reads. With the exception of host transcriptome profiling using RNA-Seq (43, 44), which deals with alignment and classification of human mRNA genes and isoforms (see below), the next step is to computationally subtract background host sequences (45). For human clinical samples, NGS reads are aligned to the human genome and then removed from the dataset, which decreases the number of remaining reads that need to be analyzed using more computationally intensive downstream algorithms. Next, microbial sequences are identified by alignment to pathogen-specific reference databases such as the National Center for Biotechnology Information (NCBI) bacterial or viral RefSeq databases. Specialized applications such as 16S rRNA sequencing for microbiome analysis classify reads on the basis of alignments to the rRNA gene sequences in the Ribosomal Database Project database (46). Recent advances in the speed and efficiency of alignment algorithms have even made simultaneous alignment to all nucleotide sequences in the NCBI nucleotide (NT) database, including all of GenBank NT (~160 gigabases of sequence as of February 2014; ftp://ftp.ncbi.nlm.nih.gov/genbank/release.notes/), computationally feasible (21).

In addition to sequence alignment, either *de novo*, seed-based, or mapped (using a discrete reference) assembly can be performed to join NGS reads together into contiguous sequences (contigs) and recover partial or even full genomes (47). With metagenomic data, the use of an ensemble method that partitions the data beforehand and combines the use of multiple assembly algorithms may be preferable to maximize contig lengths (48). Translated nucleotide alignment to a protein database or remote homology detection using hidden Markov models (49) can be useful in identifying sequences corresponding to highly divergent pathogens, such as novel viruses. Finally, for NGS applications such as infectious disease diagnosis, precise taxonomic classification of reads to the species level is a necessary step in the analysis (50–52). For example, it is often clinically relevant to be able to distinguish *Staphylococcus* species (e.g., *Staphylococcus aureus* versus coagulase-negative staphylococci) or influenza subtypes (e.g., influenza A [H3N2] versus 2009 pandemic influenza A [H1N1]).

Especially for clinical applications, the development of visualization tools and cloud-computing-compatible platforms will be critical in providing interpretation and context to the NGS data analysis. Software that is user-friendly and produces results that are understandable by microbiologists who lack bioinformatics expertise is greatly needed to enable communication of accurate NGS results to clinicians. A key aspect of NGS for clinical microbiology laboratories will also be not only standardization of the bioinformatics analysis workflows but also standardization of the reference databases. There is currently no consensus as to what standard reference databases will be needed for microbial NGS applications and who would be responsible for developing and maintaining such a database. Nevertheless, working groups consisting of the FDA, NCBI, CDC, and other institutions have been formed to discuss and implement standardized microbial reference databases for NGS (75) as part of a larger effort to ensure the quality of next-generation sequencing in clinical laboratory practice (53).

NGS APPLICATIONS

Amplicon Sequencing

NGS is suitable for sequencing of PCR amplicons in a massively parallel fashion. Applications include determination of minority sequence variants or viral quasispecies and targeted metagenomic analysis. NGS analysis of specific amplicons can deconvolve multiple species in mixed infections, allowing each component to be recognized, whereas Sanger sequencing requires the majority sequence to comprise at least 75% of the total.

Universal Bacterial Identification by 16S PCR

Although the 16S small rRNA gene is found in all bacteria and is highly conserved, the presence of hypervariable regions in the gene sequence allows it to be useful for specific diagnostic identification to the genus and even species level (54). The 16S rRNA gene is 1.5 kB in length and consists of nine hypervariable regions flanked by highly conserved regions. Universal bacterial primers targeting

the conserved regions enable amplification and subsequent sequencing of the hypervariable regions.

A clinically validated assay based on 16S rRNA PCR followed by NGS has been shown to be useful for universal diagnostic identification of bacterial pathogens directly from clinical samples (55). This approach has the advantage of not relying on "gold-standard" culture-based identification, which requires that organisms are capable of growing and replicating *in vitro*. Such an assay based on 16S rRNA PCR would be able to detect fastidious or slow-growing organisms or those rendered nonviable by prior antibiotic treatment or processing (e.g., formalin-fixed paraffin-embedded tissue samples). With the sequencing depth provided by NGS, the presence of even low-titer microorganisms in a highly diverse, polymicrobial sample can potentially be identified. The 16S rRNA gene is also used in most environmental metagenomic studies (56), because it can reveal the phylogenetic relationships among complex bacterial populations at very high resolution. Other targets in bacteria that have been used for these applications include the 23S gene and the intergenic spacer region located between 16S and 23S (57).

UNIVERSAL EUKARYOTIC IDENTIFICATION BY 18S AND/OR ITS PCR

Analogous to the 16S rRNA gene in bacteria, eukaryotic microorganisms that lack a backbone (nonchordate eukaryotes) such as fungi and parasites are identifiable on the basis of 18S or 28S rRNA sequences (58). For fungi, the internal transcribed spacer (ITS) regions can also be used. The hypervariable regions within these sequences can be used to classify fungi and parasites to the species level, and NGS can be readily used for metagenomic analysis as well as provide high sensitivity for detecting low-titer organisms in mixed infections. Because the 18S and 28S rRNA genes are also found in high-order eukaryotes such as animals and humans, inadvertent host background amplification can be significant, generally requiring higher sequencing depths for successful microbial identification.

Pathogen versus Commensal

Many microorganisms are commensals that colonize various body niches of their host and are only associated with disease in the setting of invasion. For instance, fungi such as *Malassezia* spp. and bacteria such as *Staphylococcus* spp. and *Propionibacterium acnes* colonize the skin of healthy adults (59). Therefore, the presence of microbial sequences from nonsterile body sites needs to be interpreted in the context of the infectious disease being studied. A positive detection from a sterile body site is more likely to be associated with true infection but requires differentiation from potential contamination. Also, microbial nucleic acid does not necessarily indicate the presence of live microorganisms but could simply indicate prior colonization. Assessment of the patient's symptoms and clinical presentation, along with the sequencing results, is necessary to determine the pathogenic significance of any microorganisms detected by NGS analysis.

METAGENOMIC AND MICROBIOME ANALYSES

Metagenomic sequencing is targeted (e.g., 16S) or shotgun sequencing of clinical or environmental samples and is now being largely performed by NGS given the depth of coverage that can be achieved. The microbiome, the totality of microorganisms that reside in diverse niches of the human body (60), can be assayed using metagenomic sequencing. The Human Microbiome Project, started in 2008, used 16S sequencing to profile microbial communities at different body sites and thus characterize the baseline microbiome responsible for the maintenance of human health (61). 16S metagenomic or microbiome sequencing can now be routinely performed using customized workflows such as QIIME to classify reads into operational taxonomic units and assess sample diversity (62). Similarly, 18S/ITS or shotgun metagenomic sequencing can be done to analyze fungi for high-resolution species identification and overall profiling of complex microbial communities.

TRANSCRIPTOME PROFILING

Transcriptome profiling by NGS, otherwise known as RNA-Seq, has many applications to microbiology. Transcriptome profiling by NGS is the sequencing of all of the mRNA molecules from either the host or the microorganism to obtain a global view of the gene expression pattern in a clinical sample (43, 44). For full coverage of the human transcriptome, approximately 30 to 50 million short reads are needed. Previously, only microarrays were available to conduct comprehensive gene expression analyses. By transcriptome analyses of the human host response to infection, microarray-based methods have proven effective in the diagnosis of staphylococcal bacteremia (63), active versus latent tuberculosis (64), and acute respiratory infections such as influenza (65). RNA-Seq using NGS has been shown to be more sensitive for detection of low-abundance transcripts, with a broader dynamic range in detecting fold-changes in gene expression at the cost of greater complexity of analysis and current lack of standardization (66, 67).

Transcriptome profiling of the microorganism is also possible, either in pure experimental cultures *in vitro* or directly from clinical samples (68). The data from mRNA gene expression is compared to that from the DNA genome. Microbial transcriptional profiling may yield insights into the overall activity of the organisms (latent versus active metabolism), growth characteristics (aerobic versus anaerobic growth), or expression of resistance and virulence elements.

INFECTIOUS DISEASE DIAGNOSTICS

There is much excitement about the potential of NGS to cause a paradigm shift in microbiology by complementing or even replacing existing diagnostic tests in the clinical laboratory. Metagenomic NGS in particular is promising for diagnosis because this unbiased approach does not target any individual microbial agent but, rather, identifies any and all potential pathogens simultaneously on the basis of sequence homology (17, 21). The capacity of metagenomic NGS to generate clinically actionable data was recently demonstrated in its use to diagnose a case of neuroleptospirosis in a critically ill child that had eluded all conventional diagnostic testing for 4 months (69). Once the diagnosis was made, appropriate targeted therapy resulted in a prompt recovery and cure.

However, translation of NGS assays from research tools for microbial characterization, pathogen discovery, and

epidemiological investigation to actionable clinical diagnostic tests introduces a number of new challenges. Reproducibly generating acceptable libraries from a variety of specimen types that vary by orders of magnitude in human and microbial nucleic acid content is difficult and currently requires multiple parallel strategies. Samples with low organism loads may require pathogen enrichment or amplification, while tissues with high human DNA content may need host subtraction techniques. Each additional step must be controlled for quality and has the potential to introduce contamination, so it is preferable to minimize processing steps where possible. To date, we are unaware of any universal library preparation protocol that can be used to detect all pathogen types in clinical samples with high sensitivity and specificity. One potential workaround is to bias the detection for specific pathogens using a targeted probe enrichment or amplification panel approach followed by NGS instead of relying on shotgun metagenomic NGS for diagnosis (35).

Even with technical hurdles cleared, it remains to be seen whether NGS allows for improved efficiency when compared to conventional clinical diagnostic testing. Certainly the promise of enhanced breadth of detection and genomic characterization is compelling, since it could allow for more personalized medicine and individualized treatment regimens. NGS-based analysis of the host transcriptome response using RNA-Seq may provide complementary information that can be used to guide or modify the approach to patient management and treatment. Furthermore, many studies are now describing how the human microbiome and pathogen genotype influence disease progression, but our knowledge in this area is far from complete. However, we expect that ongoing findings and insights from NGS in microbiology will enable a more comprehensive perspective regarding health and disease states and eventually lead to treatments targeted to specific aberrations in the host and microbial genomic profile.

CLINICAL VALIDATION

Clinical validation of a metagenomic or targeted NGS assay is a substantial undertaking, designed to demonstrate acceptable performance characteristics for an essentially unlimited number of pathogen targets and sequence variants. The assay should be shown to be significantly robust with valid limits of detection, accuracy, specificity, and reproducibility (70). Here, the traditional approach to single-analyte validation fails, because it is impossible to confirm the presence or absence of all possible organisms using standard reference methods. Instead, a validation approach that aims to identify and reduce potential sources of error in the test may be a practical alternative. For infectious disease NGS, this can be done using representative pathogen types in clinical matrices of interest, along with a thorough analytic evaluation to identify error-prone steps and introduce specific quality controls designed to detect errors when they occur. Controlling for sources of contamination is particularly important and should be addressed in the workflow and implementation of routine internal and external controls. Additionally, the NGS data analysis pipeline and reference databases will need to be separately validated. Establishment of curated standard reference databases will likely to be needed, in parallel with the use of additional bioinformatics analysis and review steps to identify misannotated or incomplete database entries. Finally, the reports must be interpretable by clinical microbiologists, be understandable to treating physicians, and provide clinically relevant and actionable results.

REGULATORY AND OTHER CONSIDERATIONS

Currently, no NGS assays for infectious disease diagnosis have been approved by the FDA, though clinical laboratories are starting to offer them as laboratory-developed tests. Proposed regulatory changes initiated by the FDA would likely establish a mechanism for review of newly developed NGS assays, and additional requirements may be instituted in the future to ensure that these clinical tests are safe and efficacious (71). While clinical laboratories are familiar with the requirements under the Clinical Laboratory Improvement Amendments for test validation, quality control, and proficiency testing, they do not typically establish *de novo* clinical utility for these assays. Indeed, the clinical trial design, outcome measures, and statistical confidence needed to demonstrate clinical utility are unknown. It will likely take a coordinated effort between academia and industry as well as stepwise guidance by the FDA to bring NGS for infectious disease to regulatory approval.

The validation of bioinformatics pipelines and databases is another challenge that is beginning to be addressed, but a suitable solution is not yet available. Analysis tools are being continually refined for speed and accuracy, but there is no standardized method to compare them or benchmark their performance. Curated databases typically have a limited number of microorganisms represented, and large public databases such as NCBI NT contain many misannotated sequences that could lead to erroneous results and interpretation (72). Curated 16S ribosomal databases are available for bacterial amplicon sequencing, but databases for other targets and whole-genome sequences are less well characterized. On the other hand, if a standardized reference database is successfully established, it is possible that it can be used as a sole comparator to establish the performance of an NGS assay, forgoing the need for traditional confirmation by orthogonal testing. Given the risk of contamination with metagenomic NGS, multisite evaluation would likely be a requirement for regulatory approval. Development of a panel of representative microorganisms that would function as microbial reference standards, under way at National Institute of Standards and Technology, would also likely be needed for NGS validation (73).

Due to the complexity and data storage requirements for high-throughput NGS analysis, cloud computing and remote storage are attractive options. However, demonstrating HIPAA (Health Insurance Portability and Accountability Act) compliance may be difficult, and there is a risk of data loss during transfer or storage. Most clinical laboratories are unfamiliar with the establishment or maintenance of large computational servers and databases, and the requirements for remote systems are not always clear. The use of bioinformatics tools for NGS analysis and interpretation of results are also not part of the routine skill set of most microbiology laboratories, so simpler graphical visualization interfaces and additional training in bioinformatics may be needed to enable these tests to be more broadly accessible to laboratory personnel. Standards will need to be established for the storage of clinical and technical metadata in addition to the sequence data. Finally, advances in health information technology and electronic medical records software will be required to determine how best to incorporate NGS information into the patient medical record.

CONCLUSIONS AND PERSPECTIVE

NGS assays hold great promise for the broad identification and genomic characterization of infectious disease pathogens. A variety of NGS technologies are now available, each with specific advantages and disadvantages. Sequencing assays incorporating pathogen detection, microbiome analysis, and host transcriptome profiling may lead to more personalized treatment approaches in the future. Several technical hurdles remain to be overcome prior to routine use, including optimal library preparation techniques for different microorganism and sample types, choice of bioinformatics pipelines, and suitable reference databases for comparison. The pathologic significance of microbial detection requires interpretation within the clinical context and may need additional confirmatory testing, particularly for detection of unexpected and/or novel agents. A multifaceted approach involving clinical and research laboratories, bioinformatics scientists, biotechnology companies, and regulatory agencies will likely be needed to take advantage of the large and complex sequence datasets that are currently generated by NGS analysis.

Pathogen Discovery

EFREM S. LIM AND DAVID WANG

7

There are many clinical syndromes that pose diagnostic conundrums. Despite clinical symptoms consistent with an infectious etiology, many of these cases are negative by all clinical diagnostic assays. Specimens from such cases are ideal substrates for pathogen discovery efforts, which entail a range of additional technical methods beyond those routinely used in the diagnostic laboratory. Furthermore, the number of emerging infectious diseases has greatly increased in the last 2 decades. Many emerging infectious diseases originate from cross-species transmissions from animals to humans. Recent environmental and ecological changes are leading to a greater frequency of human and wildlife interactions that catalyze pathogen emergence. Furthermore, globalization and improvements to travel have made it easier for infectious diseases to spread rapidly. Therefore, there is an urgent need to identify novel pathogens in a rapid and efficient manner. Thus, pathogen discovery is a critical component of modern public health care.

The goal of this chapter is to review methods and approaches to identify novel microbial agents with an emphasis on viral discovery. We will illustrate this with examples of pathogens noted for their discovery method (Table 1) and highlight new trends in the field that have been driven by next-generation sequencing (NGS).

PATHOGEN DISCOVERY TECHNIQUES

Over the last few decades, pathogen discovery methods have evolved dramatically, largely driven by significant technological breakthroughs. Traditionally, pathogen discovery involved culturing the pathogen in animals or in cell cultures. For example, poliovirus was isolated by passaging the virus through rabbits, guinea pigs, mice, and monkeys in 1908 (1). Culture remains an important component of viral discovery efforts as exemplified by the isolation of Middle East respiratory syndrome (MERS) coronavirus after passaging in LLC-MK2 and Vero cells (2). However, not all pathogens can be cultured under standard laboratory conditions. Therefore, many culture-independent methods have been developed to complement traditional approaches. These methods can be used directly on clinical specimens or in many cases in conjunction with culture-based approaches to significantly speed up the identification process and increase its accuracy.

Efrem S. Lim and David Wang, Department of Molecular Microbiology and Pathology & Immunology, Washington University, Saint Louis, MO 63110.

IMMUNOSCREENING

One of the early milestones in pathogen discovery methodology was the application of immunoscreening, which utilizes antibody screening against a cDNA library derived from the infected specimen to identify pathogens. While this method has not been used as widely in recent years, it is worth noting its approach in several seminal discoveries tracing back to 1989 with the discovery of hepatitis C virus (initially named non-A, non-B hepatitis virus) (3). Hepatitis C virus is an enveloped RNA virus that encodes a 9.6-kb single-stranded positive-sense RNA genome. It is estimated that up to 150 million people worldwide are chronically infected with hepatitis C virus, accounting for more than 350,000 hepatitis C-related deaths each year. Previous efforts leading up to the study failed to identify specific viral antigens or antibodies to the non-A, non-B hepatitis agent. The primary hypothesis that led to this approach was that the levels of viral antigen were below the detection limit of standard immunological methods at that time. Therefore, a random cDNA library was constructed from infectious material whereby efficient cDNA expression could be driven by the vector. The library was screened for clones that expressed cDNA-encoded polypeptides that cross-reacted with sera from a patient with chronic non-A, non-B hepatitis. This led to the identification of a single positive clone (clone 5-1-1) out of approximately one million libraries. Additional biochemical experiments supported that clone 5-1-1 was derived from the genome of the etiologic agent, and this led to the sequencing and identification of hepatitis C virus. Immunoscreening was also used subsequently in the identification of Norwalk virus and GB virus C (4, 5).

REPRESENTATIONAL DIFFERENCE ANALYSIS

Representational difference analysis uses subtractive DNA hybridization coupled to PCR amplification to identify genomic or cDNA sequences that differ between two samples (6). Developed in 1993, this method was originally used for genome studies and was shown to be able to detect a single copy of adenoviral DNA in human tissue. Representational difference analysis was used in the identification of human herpesvirus 8, also called Kaposi's sarcoma-associated herpesvirus, in Kaposi's sarcoma (7). Human herpesvirus 8 is a large double-stranded DNA virus that encodes an approximately 165-kb genome. Seroprevalence rates of human herpesvirus 8 range from 20 to 80% in

TABLE 1 Summary of molecular approaches to pathogen discovery

Pathogen discovery method	Human pathogen(s) identified	Reference(s)
Immunoscreening	Hepatitis C virus, Norwalk virus, GB virus C	3–5
Representational difference analysis	Human herpesvirus 8	7
Random arbitrary primer binding PCR (RAP-PCR)	Human metapneumovirus	35
DNase-SISPA	Parvovirus 4	41
DNA microarray	SARS-coronavirus	42
Virus discovery cDNA-AFLP (VIDISCA)	Human coronavirus NL63	53
Direct high-throughput sequencing	Human bocavirus, KI polyomavirus, WU polyomavirus	40, 57, 58
Next-generation sequencing	Merkel cell polyomavirus, MERS-coronavirus, Heartland virus, Bas-Congo virus	2, 62, 66, 69

African and Mediterranean regions but are lower (<10%) in the United States and Northern Europe (8). Kaposi's sarcoma is the most common neoplasm in AIDS patients. To identify the pathogen, Kaposi's sarcoma tissue and tissue from a nondiseased site were analyzed. Nucleic acid from the diseased samples was PCR amplified and ligated to a specific priming sequence adaptor. The DNA was then hybridized to an excess of nucleic acid from the normal nondiseased sample that lacked the priming sequence adaptor. Doing this blocked homologous nucleic acid fragments from the subsequent PCR amplification step, thus enriching for DNA fragments that are unique to the diseased sample. As a result, four unique PCR bands were identified. Subsequent cloning and sequencing led to the identification of a novel herpesvirus. While successful in this instance, a major technical limitation is that it is difficult to obtain a well-matched negative control for the specimen of interest, and frequently, the amplified differences between the samples reflect differences in host gene expression rather than foreign microbial sequences.

TAXON-SPECIFIC CONSENSUS/ DEGENERATE PCR

Since its advent in the 1980s, PCR has become a common method for microbial detection. Once the genome sequence for a given microbe is available, it is a straightforward endeavor to design primers that detect the target microbe. Application of PCR to highly conserved regions of microbes has enabled the identification of many novel bacteria, fungi, and viruses. For bacteria and fungal detection, universal loci (e.g., 16S, 18S, or ITS) can be targeted. However, because there is no universally conserved site in viruses, primers must be designed to detect any given specific taxon (viral family or genus) of interest.

BACTERIAL IDENTIFICATION BY 16S PCR

Bacterial pathogens can be difficult to routinely culture. Hence, sequencing-based bacterial identification has emerged as an attractive strategy. Ribosomal gene sequences are commonly used for bacterial pathogen identification and phylogenetic analyses. The 16S small ribosomal subunit (16S rRNA) gene is widely used because the gene is ubiquitous to all bacteria. As applied to pathogen discovery, pioneering studies by Relman et al. in the early 1990s led to the identification of *Bartonella* as the cause of bacillary angiomatosis and *Tropheryma whipplei* as the etiologic agent of Whipple's disease (9, 10).

Use of the 16S locus has expanded in recent years beyond discovery of novel taxa to studies of bacterial populations. In addition, its clock-like rate of evolution supports robust phylogenetic resolution (11). The 16S rRNA gene is approximately 1.5 kb long and contains nine hypervariable regions, each flanked by highly conserved regions. Universal bacterial primers designed to the conserved regions are used to amplify the hypervariable regions. A sequence from one or more hypervariable regions, such as the V2 and V3 region, is sufficient to distinguish genus and species taxa (11, 12). Analysis of the entire 16S gene sequence can even distinguish between strains. Sequences are compared to curated 16S reference databases such as the Ribosomal Database Project, EzTaxon, and Silva (13–15). One caveat is that intracellular polymorphisms can exist from multiple copies of 16S rRNA gene in the genome (16). Other alternative genes used for molecular identification include the 23S rRNA and the intergenic spacer region between 16S and 23S (17). However, these sequence regions are longer, and variations are generally marked by insertions and deletions (18).

FUNGAL IDENTIFICATION BY CONSENSUS PCR

Despite being found in almost all habitats on Earth, it is estimated that more than 90% of *Fungi* have yet to be identified (19). Sequencing-based identification of fungal pathogens is particularly beneficial for its fast workflow. Standard microbiological tests can take more than a week because fungal organisms can be slow-growing. Initially, a mitochondrial locus for the cytochrome oxidase I (COI) gene was used for fungal classification. COI has been shown to accurately resolve *Ascomycota*, *Penicillium*, and *Neohumicola* species (20, 21). However, COI is less effective in other fungal genera such as *Aspergillus*, *Basidiomycota*, and *Fusarium* due to higher amplification failures from "universal" primer mismatches and because the gene can be present in multiple copies in some species (22). These multiple gene copies often vary in length and sequences, making its use phylogenetically ambiguous. In fact, some fungal clades such as *Neocallimastigomycota* lack mitochondria altogether (23). Hence, use of nuclear rRNA gene sequences has since been favored in fungal identification.

Two internal transcribed spacer (ITS) regions of the nuclear rRNA genes are most commonly used and are the fungal typing loci recommended by the Fungal Barcoding Consortium (24). The first region, called ITS1, lies between 18S and 5.8S rRNA genes, and the second region, called ITS2, lies between the 5.8S and 28S rRNA genes. ITS regions have a high PCR amplification success rate, and their sequences are able to discriminate between species taxa across the 17 major fungal lineages (21, 24). This has been applied in metagenomic studies that analyze the fungal community at the mouth, skin, and mucosal sites (25, 26). However, some disease-causing fungi such as *Candida* and *Malassezia* species can be commonly found on mucosal surfaces and the skin of healthy adults (26–28). It is believed that they represent low-level commensals and that they cause disease when they are able to establish an outgrowth niche such as when there is physical disruption at the site, antibiotic treatment, or host immunosuppression (29).

VIRAL IDENTIFICATION BY CONSENSUS PCR

The first example of viral discovery using conserved PCR primers was during the emergence of hantavirus pulmonary syndrome in 1993 (30). Initial serologic tests cross-reacted with known hantaviruses, suggesting infection by a virus in that family. Based on this information, conserved PCR primers derived from known hantavirus genomes were designed and used to interrogate specimens from the patients. Subsequent analysis of the amplicons yielded sequences phylogenetically distinct from the known hantaviruses. This virus was demonstrated to be the causal agent and was ultimately named *Sin Nombre hantavirus*. There have since been many additional novel viruses identified by consensus PCR approaches. Due to the broad utility of this approach, various computational strategies for design of consensus PCR primers for novel virus identification have been described (31, 32).

PCR screening for novel viruses using primers designed to conserved features of viral families offers a powerful approach to virus identification, provided there is adequate rationale to select a given candidate viral family or taxon to test. In the absence of a logical set of candidates to screen, it is typically not feasible to target every viral family individually, which would be prohibitively laborious, time-intensive, and reagent-intensive. Therefore, the development of methods in which nucleic acids could be amplified in the absence of primers designed to a specific target sequence has played a critical role in the latest methods for virus discovery. These sequence-independent amplification methods are capable of increasing the quantity of an unknown agent to detectable levels. In addition, various postamplification detection strategies have been devised to "visualize" the products of interest, which include gel electrophoresis-based differential display approaches (e.g., VIDISCA), hybridization to pan viral microarrays, and high-throughput mass sequencing.

RAP-PCR

In 2001, random arbitrary primer binding PCR (RAP-PCR) was adapted for pathogen discovery. This method was initially used in biochemical studies to compare genomic fingerprints between polymorphic genomes (33, 34). Generic primers are used in a PCR reaction performed initially under low stringency conditions, followed by high-stringency PCR amplification. The initial low-stringency conditions accommodate more mismatches during primer annealing, while the high-stringency conditions selectively amplify the PCR products. PCR products are then analyzed by gel electrophoresis to visualize the genomic fingerprint. In this way, differences in genomic content between samples such as those derived from pathogen infection can be distinguished as unique bands in the genomic fingerprints. This method was used in the identification of human metapneumovirus, a negative single-stranded RNA virus encoding an approximately 13-kb genome, in 2001 (35). RAP-PCR analysis was performed on cell culture that was infected with the virus and compared to a control culture. By cloning the unique PCR bands, the authors obtained sequences spanning different regions of the genome and were able to verify that the virus isolate was distinct from known members of the *Paramyxoviridae* family. Human metapneumovirus has since been detected worldwide and found to cause acute respiratory illness in infants, older adults, and patients with underlying chronic conditions (36, 37). Human metapneumovirus infections can be typically detected in infants from around 6 months of life onward, and the seroprevalence rate of human metapneumovirus is 100% by 5 years of age (35, 38).

DNASE-SISPA

Another approach, known as sequence-independent single primer amplification (SISPA), involves the ligation of a common primer binding sequence to both ends of cDNA molecules, which can then be amplified with a cognate primer (39). A refinement of this approach, called DNase-SISPA, involves the treatment of samples with DNase prior to nucleic acid extraction (40). The theory behind DNase-SISPA is that the DNase should degrade host DNA, but viral nucleic acid should be protected by the protein capsid and for some viruses also by the lipid viral envelope. Therefore, nucleic acids that survive the DNase treatment step should be enriched for sequences of viral origin. In the initial description of the method, the extracted nucleic acid was digested using restriction enzymes, and the resulting restriction fragments were then subjected to SISPA. The SISPA products were visualized by gel electrophoresis, and prominent bands were sequenced. Amplicons derived from novel bovine parvoviruses were identified in this initial proof of concept. Subsequently, DNase-SISPA has been used to identify novel viruses from human plasma (parvovirus 4 and two TTV-like anelloviruses) (41). Parvovirus 4 has since been detected in human serum in multiple studies, but its role in human disease is not currently known.

DNA MICROARRAY

In 2002, the first large-scale DNA microarray for pathogen discovery was developed (42). Prior to this, DNA microarrays were used primarily to measure gene expression or changes in genomic content in a massively parallel DNA hybridization assay. Pathogens often share stretches of nucleotide sequences that are conserved among members of the same taxa. These sequences are usually constrained by strong purifying selection to maintain an essential molecular function. For example, the untranslated regions of picornaviruses involved in transcription regulation are highly conserved across genera. Capitalizing on such features, the DNA microarray was designed to capture novel pathogens

by maximizing cross-hybridization to highly conserved sequences (42). A defined collection of pathogen-derived 70-mer oligonucleotide probes were printed onto a solid-surface microarray. In principle, the number of probes can vary up to several hundred thousand probes per slide. Multiple probes were often designed for each pathogen of interest for redundancy, and repetitive elements are avoided during probe design because they might reduce the specificity of the probes. Next, viral nucleic acid from the target specimen was randomly PCR amplified, fluorescently labeled, and hybridized to the probe microarray. The microarray was then visualized to quantify the probe signal intensities. This generated a hybridization profile specific for features that were conserved among viral families and genera. In certain cases, the microarray was also able to distinguish between serotypes (42).

Microarray-based pathogen discovery was applied in the identification of severe acute respiratory syndrome (SARS) coronavirus during the global outbreak of SARS in 2003 (43, 44). SARS coronavirus is a single, positive-stranded RNA virus with an approximately 29.7-kb genome. During the global epidemic, 8,098 probable SARS cases were identified across 29 countries (45). The mortality of SARS coronavirus ranged from 10 to 50% depending on age (46). Oropharyngeal specimens collected from a patient with SARS were used to inoculate cell cultures, following which, total nucleic acid extracted from the viral culture was hybridized to a virus microarray. The hybridization profile indicated that the virus was a novel member of the *Coronaviridae* family. The hybridized viral sequences were also directly recovered from the microarray and sequenced to validate the findings.

A significant advantage to the DNA microarray is the use of much longer oligonucleotide probes compared to primer lengths used in conventional PCR assays. This meant that a higher sequence divergence over the length of the probes could be tolerated during hybridization. For example, the Virochip DNA microarray identified a divergent human metapneumovirus subtype 1B that eluded clinical diagnosis in a reported case of a patient with respiratory illness (47). The microarray showed a hybridization pattern consistent with human metapneumovirus infection. However, results from four out of five clinically validated reverse transcription PCR (RT-PCR) assays for human metapneumovirus were negative. Subsequent sequencing of the virus genome revealed mutations in the regions targeted by the RT-PCR assay primers. Several pan-microbial microarrays have since been developed to detect a variety of microbial agents. These include a pathogen microarray for tropical and emerging infectious agents and biothreat agents called RPM-TEI (48) and broad-spectrum microarrays called the GreeneChip series designed to detect viruses, pathogenic bacteria, fungi, and protozoa (49, 50). A broad-spectrum microarray called the pan-microbial detection array was designed to detect viruses, bacteria, and plasmids (51).

VIDISCA

In 2004, virus discovery cDNA-AFLP (VIDISCA) was first described (52). VIDISCA was adapted from a technique called cDNA amplified restriction fragment polymorphism (cDNA-AFLP). The general rationale for this method is that an unknown pathogen should yield a unique banding profile after PCR amplification compared to a specimen where the pathogen is absent. This technique differs from RAP-PCR, which does not involve the use of restriction enzymes. Viral nucleic acid extracted from the specimen is converted to cDNA and digested with one or more restriction enzymes. The restriction fragments are ligated to specific adaptors corresponding to the overhang ends of the restriction sites. The ligated fragments are selectively amplified by primers designed to the adaptor-overhang region with a single specified nucleotide added. Varying the primers used at each end makes it possible for up to 16 primer combinations to be used in the selective amplification to reduce the complexity of the amplicons. This was done on a positive and negative specimen. The amplicons are then separated by gel electrophoresis and compared to the negative specimen to distinguish background amplicons.

VIDISCA was first applied in the discovery of human coronavirus NL63 (53). Virus from the clinical sample of an infant with acute respiratory disease was passaged in LLC-MK2 cell cultures. VIDISCA was performed on supernatant from infected LLC-MK2 cells and compared to uninfected LLC-MK2 cells. Several unique fragments were identified and found to be sequences of a divergent coronavirus. Using a combination of cDNA library, 5′ and 3′ rapid amplification of cDNA ends, the complete genome of human coronavirus NL63 was resolved. An advantage of VIDISCA is its reproducibility, because the method relies on digestion by specific restriction enzymes. VIDISCA has since been adapted to be used in conjunction with NGS. Adaptors containing the Roche-454 "universal tail" sequences are ligated to DNA fragments during VIDISCA and directly amplified in the emulsion PCR for 454 sequencing (54).

DIRECT HIGH-THROUGHPUT SEQUENCING

The previous sequencing-based methods all relied upon some form of enrichment or differential display to be able to select microbial sequences from the large background of host nucleic acid with a limited extent of sequencing. As the throughput of traditional Sanger sequencing increased due to the Human Genome Sequencing project, it became feasible to attempt direct sequencing of clinical specimens to identify the viruses present.

Meyerson and colleagues conducted the first proof of principle experiment to demonstrate that extensive sequencing of nucleic acids in a specimen in conjunction with computational subtraction could be used to detect pathogens (55). They examined a tissue specimen from a case of posttransplant lymphoproliferative disorder, knowing that most such cases are caused by Epstein-Barr virus. A cDNA library with 27,840 sequences was generated, and each sequence was compared to the human genome to identify sequences of human origin. These sequences were then eliminated from further consideration in a process termed "transcript filtering." The remaining sequences that did not match human genomic sequences were postulated to be derived from microbial organisms present in the sample. From this library, 10 sequences that did not match any human sequences but had similarity to Epstein-Barr virus were identified. Furthermore, these sequences could only be amplified from Epstein-Barr virus-infected tissues and not from controls, thus showing the potential power of mass sequencing strategies.

The discovery of human bocavirus (HBoV) marked the first discovery of a novel virus by direct high-throughput

sequencing of clinical specimens (40). In this study, pools of respiratory samples were ultracentrifuged, filtered, and DNase treated to produce samples for analysis that were highly enriched for intact viral particles (in which the genome is protected from DNase treatment) and to minimize the amount of other contaminating DNAs. In contrast to the discovery of human metapneumovirus, in which primers were arbitrarily chosen for amplification, a random PCR amplification strategy was used for amplification in the human bocavirus study. The amplified products were then cloned, and ~300 to 500 clones were sequenced without any effort to identify specific amplicons. In this analysis, 20% of the sequences showed similarity to viral sequences, the majority of which were derived from known viruses. However, some of the sequences had only limited similarity to viruses in the *Parvoviridae* family and, more specifically, the genus *Bocavirus*. The respiratory samples that were initially pooled together for sequencing analysis were independently screened by PCR for the presence of the novel bocavirus, and two tested positive. Further PCR screening of other pediatric respiratory specimens revealed that HBoV could be detected in 3.1% of the samples. The potential role of human bocavirus in respiratory disease and gastroenteritis has been investigated in numerous subsequent studies. These epidemiologic and seroepidemiologic analyses have determined incidence rates of bocavirus between 2.7 and 19% (in respiratory secretions) and seroprevalence rates of 94.7 to 98.3% in healthy adults (56). Other notable viruses identified using direct Sanger sequencing include KI polyomavirus and WU polyomavirus (57, 58).

NGS

While the principle of pathogen identification by direct sequencing had clearly been established by high-throughput Sanger sequencing, the advent of NGS, by lowering the cost of sequencing by multiple orders of magnitude, revolutionized the field of pathogen discovery. NGS provided the depth of sequencing to directly find the metaphoric needle in a haystack. The first NGS platform (454, Roche) was initially the primary platform used for pathogen discovery. As NGS technologies have evolved, most current efforts now primarily use the Illumina platform, although studies using other technologies such as Ion Torrent have also been described. Because of the significant impact of NGS on this field, we will briefly summarize key aspects of these platforms below (Table 2).

454 ROCHE

454 Roche sequencing is based on detecting pyrophosphate release, hence it is also known as pyrosequencing (59). Approximately 1 million sequencing reads are obtained from each 454 sequencing run, with an average read length of 450 bp. DNA library fragments are constructed with two different adaptors on each end. A single DNA fragment is immobilized onto a bead within a water-in-oil emulsion droplet and undergoes amplification across the surface of the bead (referred to as emulsion PCR). Each template-amplified bead is then deposited into individual wells of a PicoTiter plate in a manner in which each well holds only a single bead. Sequencing reagents are subsequently added across the plate in a predetermined order. As one or more nucleotides are incorporated into the complementary strand, a chemiluminescent signal is emitted during the pyrophosphate release. The chemiluminescent signal is recorded by a camera for base-calling. This allows sequences to be recorded at each bead location on the PicoTiter plate. The chemiluminescent signal intensity is proportional to the number of identical bases incorporated. A limitation to 454 pyrosequencing has been its inability to resolve long stretches of homopolymers, a stretch of a single base repeated consecutively. This occurs when the homopolymer length is incorrectly called from the signal intensity. Several algorithms have been developed to correct homopolymer-based errors in 454 sequencing data (60, 61).

The discovery of Merkel cell polyomavirus as the causative agent of Merkel cell carcinoma was one of the first successes of pathogen discovery by 454 sequencing (62). Merkel cell carcinoma is a rare, but aggressive, neuroendocrine cancer that is associated with immunosuppressed individuals (63). The cDNA from four Merkel cell carcinomas was pyrosequenced using a 454 platform. Human-derived sequencing reads were first removed, and then the remaining reads were aligned to known viral genomes. Out of approximately 400,000 sequencing reads, three sequencing reads were identified that had shared similarity to known polyomaviruses. This led to sequencing of the complete genome of Merkel cell polyomavirus by primer walking. Using a combination of PCR and Southern hybridization assays, Merkel cell polyomavirus infection was found to be associated with Merkel cell carcinoma. The authors also demonstrated that Merkel cell polyomavirus DNA was clonally integrated into the genome of carcinoma cells. Since then, Merkel cell polyomavirus has been shown to be in most Merkel cell carcinoma specimens (64, 65).

Subsequently, 454 sequencing has been used directly to identify viruses from clinical samples and from cultured samples. A few examples demonstrating the diversity of virus types and hosts include MERS-coronavirus, a virus associated with respiratory disease (2); Heartland virus, a novel phlebovirus identified in a patient with severe febrile illness (66); Lloviu virus, a filovirus from a pathogenic out-

TABLE 2 Comparison of NGS platforms

Instrument	GS FLX+	HiSeq 2500	MiSeq v2	Ion Proton I	Ion PGM 318	PacBio RS II
Platform	454 Roche	Illumina	Illumina	Ion Torrent	Ion Torrent	PacBio
Sequencing technology	Pyrosequencing	Illumina sequencing	Illumina sequencing	Ion semiconductor sequencing	Ion semiconductor sequencing	SMRT cell sequencing
Average sequencing reads per run	1 million	4 billion	22 million	60 million	4 million	47,000
Average read length	450 bp	125 bp	300 bp	200 bp	400 bp	10 kb
Run time	23 hours	6 days	55 hours	4 hours	8 hours	10 hours

break in bats in Europe (67); and Rosavirus 2, a picornavirus in fecal samples from children in The Gambia (68).

ILLUMINA

Illumina sequencing technology is also based on sequencing by synthesis. The DNA library is ligated with two unique adaptors at each end of the DNA fragment and attached to the surface of a flow cell. The DNA fragment undergoes solid-phase amplification in place on the flow cell through a process called bridge amplification, yielding a cluster of thousands of copies of a DNA fragment at each spot on the flow cell. Sequencing reagents are added to the flow cell that includes a sequencing primer that anneals to an adaptor at one end and nucleotides. Each nucleotide is labeled with a different fluorescent dye. During each sequencing cycle, a single nucleotide is incorporated into the complementary strand, and an image of the fluorescent signal is recorded indicating the corresponding nucleotide. However, DNA synthesis stops after incorporation of a single nucleotide because the fluorescent label on the nucleotide also acts as a reversible terminator. After imaging, the fluorescent label is enzymatically cleaved off to allow incorporation of a labeled nucleotide in the next cycle. This step-by-step sequencing proceeds from one end of the DNA strand for a specified number of cycles. In paired-end sequencing, both ends of the DNA fragment are sequenced.

Illumina libraries are often constructed with a slight overlap to facilitate downstream assembly analyses. For example, a 225-bp fragment will have a 25-bp overlap in the middle when 2 × 125-bp paired-end sequencing is performed. Thus, the insert fragment length can influence the number of useful base sequences. Illumina offers the HiSeq and MiSeq sequencing systems. The HiSeq platform offers considerably more reads than the MiSeq platform, but the HiSeq read length is shorter than MiSeq. Currently, the typical output of an Illumina HiSeq run is 4 billion pairs of reads, while a MiSeq run gives 22 million pairs of reads. Paired-end reads obtained from the Illumina HiSeq 2500 and MiSeq are 2 × 125 bp and 2 × 300 bp, respectively.

One of the earliest applications of Illumina sequencing technology in pathogen discovery was in the identification of a novel rhabdovirus associated with an acute hemorrhagic fever outbreak in the Democratic Republic of Congo (69). Three human cases presented with an abrupt disease onset, high fever, bloody vomiting, and diarrhea. Two of the patients died within 3 days. Initially, RNA extracted from a sera specimen from the lone survivor was sequenced on the 454 Roche platform. However, only a single candidate read out of 4,536 sequencing reads was identified, as it showed limited similarity to known rhabdoviruses. Thus, the RNA was subsequently sequenced to a greater depth on an Illumina HiSeq platform that yielded a total of 140 million sequencing reads. Ninety-eight percent of the novel rhabdovirus genome was assembled with at least 10-fold coverage across the genome. The viral load of Bas-Congo virus, the novel rhabdovirus, in the patient's serum was 1.09×10^6 RNA copies/ml. Additionally, serological assays indicated that an asymptomatic primary health care provider to the patient had developed neutralizing antibodies against Bas-Congo virus. Thus, Bas-Congo virus was identified as an emerging human pathogen associated with acute hemorrhagic fever. Other examples of novel pathogens discovered by Illumina sequencing include avian bornavirus, a virus associated with proventricular dilatation disease of parrots (70); and Theiler's disease-associated virus, a new pegivirus associated with equine hepatitis (71).

OTHER NGS PLATFORMS

Other recent NGS sequencing platforms on the market include Ion Torrent from Life Technologies and PacBio from Pacific Biosciences. Ion Torrent platforms use a semiconductor chip to detect hydrogen ions during DNA polymerization. Similar to 454 sequencing, nucleotides are added to the chip in a predetermined order. As each nucleotide is incorporated during strand synthesis, a hydrogen ion is released that alters the pH value. Changes in pH are then converted to and measured in voltage values. The changes in pH, and hence voltage, are proportional to the number of nucleotides that are incorporated. Currently, Ion Torrent offers sequencing reagent kits for 200-bp and 400-bp read length configurations. The number of sequencing reads obtained per run can be varied based on the type of chip used. Options range from half a million reads to more than 60 million reads per chip.

PacBio sequencing technology is based on a single-molecule, real-time (SMRT) DNA sequencing system. Individual molecules of DNA template are fixed to the bottom of a chip in an optical waveguide called a zero-mode waveguide, together with a single DNA polymerase enzyme. Each zero-mode waveguide is a nanophotonic structure that creates an individual illuminated observation area. The four nucleotide bases are labeled with different fluorescent dyes. During nucleotide incorporation, the fluorescent tag is cleaved and detected in the zero-mode waveguide, allowing the base to be called accordingly. Each SMRT cell is embedded with 150,000 zero-mode waveguides, and the average sequencing read length can be up to 10 kb.

PARAMETERS DRIVING THE CHOICE OF NGS PLATFORM

Amid the myriad sequencing platforms currently available, new NGS sequencing platforms will undoubtedly continue to emerge in the coming years with rapid advances in technology. However, certain instruments are ideally suited for specific applications such as detection of single nucleotide polymorphisms, *de novo* genome assembly, and metagenomic studies. Some of the key considerations in deciding on the NGS approach to use are sequencing cost, number of reads desired, and sequencing read length.

1. Sequencing costs have dropped tremendously in recent years, outpacing the exponential predictions of Moore's Law (72). Nonetheless, sequencing costs are nontrivial. While the cost per base is many orders of magnitude lower than with traditional Sanger sequencing, NGS platforms have a fixed cost per "run," so in many cases multiple samples are pooled to optimize cost-efficiency. For reference, 454 Roche sequencing costs approximately 100 times less than Sanger sequencing per megabase of DNA. However, Illumina sequencing costs approximately 100 times less than 454 Roche sequencing per megabase. This is partly because Illumina sequencing costs are averaged across a much higher number of sequencing reads.

2. The sequencing depth necessary to detect microbial sequences present in a specimen depends on the relative copy number of the microbe compared to the host nucleic acid. For samples that are relatively poor in host sequences (e.g., respiratory secretions), sequencing of as little as 10^2 to 10^3 reads may suffice for detection. By contrast, a tissue specimen, which contains the entire human genome and transcriptome, may require much greater sequencing depth (>10^7 reads).
3. Read length is an important parameter in the detection of divergent sequences from individual reads. For sequences that do not share nucleotide similarity, translation to amino acids is often necessary to identify the read as microbial in origin. Longer reads enable alignments of longer stretches of amino acids, thereby increasing the probability of detection of divergent microbes. Naturally short reads may be assembled into longer contigs, but the assembly process also poses its own challenges. The average read length from the 454 FLX Titanium is 450 bp, while the read length from Illumina is 2 × 125 bp (HiSeq) or 2 × 300 bp (MiSeq) through paired-end sequencing. However, the average read length of the PacBio RS II platform is 10 kb.

NGS BIOINFORMATICS WORKFLOWS

While increased sequencing capacity and decreased costs of sequencing have been a boon for the field of pathogen discovery, it has also raised significant computational challenges in the processing and analysis of the resulting sequencing data. A number of bioinformatics workflows have been developed to identify viruses from high-throughput sequencing datasets (73–79; www.pathseek.eu). The general approach can be summarized in three stages. First, sequencing reads are preprocessed for quality control such as trimming low-quality and adaptor sequences. Next, host sequences are subtracted from the dataset. For instance, for a human specimen, sequencing reads that map to a human reference genome are removed. This is done to reduce the amount of sequencing data because the subsequent downstream analyses are often computationally intensive. Finally, sequencing reads are aligned to a virus database to identify virus sequences using algorithms such as BLAST. Other workflows have additional features such as detecting viral integration sites in VirusFinder (76). Pathoscope uses Bayesian statistics to assign a posterior probability to the matching hits (77). Additionally, SURPI supports a cloud-compatible workflow (78), and MetaVir can be accessed through a web server (79). A bioinformatics workflow is also being developed by the PATHSEEK consortium with the goal to provide a diagnostic assessment within 48 hours from clinical samples sequenced by NGS (www.pathseek.eu).

METAGENOMICS

Beyond the identification of individual, novel microbes that may be pathogens, the advent of NGS has made it possible to define entire microbial communities that occupy a given biologic niche. Multi-institutional consortiums such as the European Metagenomics of the Human Intestinal Tract (MetaHIT) and the U.S. Human Microbiome Project (HMP) have made significant efforts to characterize the human microbial communities (80, 81). These metagenomics studies show that healthy individuals harbor a tremendous diversity of bacterial microbes that is highly variable over time and across populations (82, 83). However, while the specific bacterial lineages can vary between individuals, the profile of enzyme gene functions encoded by the bacterial community is highly similar between individuals (84). Thus, it has been proposed that the microbial community's functional gene composition might be associated with altered physiological states (85). In support of this model, the pathogenesis of some diseases has been linked to the imbalance of the commensal microbial community, rather than invasion by specific microbial agents. In Crohn's disease, a form of inflammatory bowel disease, microbial dysbiosis is consistently observed, where the proportion of *Proteobacteria* increases concomitant with a decrease in *Firmacutes* (86). Additionally, bacterial dysbiosis mediated by a high-fat diet has been shown to accelerate intestinal tumor progression (87). Taken together, the complex ecological community of commensal microbes can influence human health, and this concept presents a new model of microbial pathogenesis beyond the traditional "one microbe, one disease" paradigm. As another example of this concept, a recent intriguing observation emerged from a study of the enteric virome of simian immunodeficiency virus-infected macaques. In this study, significant expansion of the enteric virome (predominantly an increase in picornaviruses and adenoviruses) was observed specifically in pathogen simian immunodeficiency virus-infected monkeys as compared to controls (88). Whether similar changes in the enteric virome are seen in HIV-infected humans remains to be determined.

NGS has become an attractive tool for bacterial community profiling because short 16S gene amplicons (less than 500 bp) can be easily sequenced within the standard read lengths of most sequencing platforms. 16S sequencing was used to profile the microbial communities of different niches such as the mouth, skin, vagina, gut, and lung in the human microbiome project (81, 89). Metagenomic workflows such as QIIME perform high-throughput analyses on sequencing datasets to assign operational taxonomic units and estimate sample diversity (90). A complementary metagenomic profiling approach is to analyze the microbial community using clade-specific marker genes. Rather than sequencing 16S gene amplicons, shotgun sequences from the microbial community are mapped to a curated catalog of clade-specific marker sequences using classifiers such as MetaPhlAn (91). This approach is able to measure species-level relative abundance of bacterial and archaeal microbes. Likewise, NGS has been adapted to interrogate entire fungal communities using high-throughput ITS sequencing (25, 92).

CHALLENGES OF PATHOGEN DISCOVERY

The advent of NGS has dramatically increased the rate of detection of novel microbial sequences. With the tremendous sequencing depth achievable with current technology, it is possible to detect microbial nucleic acids that are present at a frequency of less than 1 per 10^8. However, this also poses significant challenges in interpretation of the biological significance of these discoveries. One key point to address is the criteria for establishing a causal link between the newly detected agent and disease. Traditionally, this has relied on Koch's postulates, which have been revised over the past decades (93–95). This issue is beyond the

scope of this review. However, the focus of those approaches is to distinguish pathogens from nonpathogenic infections. Additional challenges faced in this molecular era include the potential for contamination artifacts. Contamination may arise at any point from initial sample collection through the end of the computational analysis pipeline. We will provide several examples to illustrate the pitfalls that may arise from inadequate control of contamination.

LABORATORY CONTAMINATION

Xenotropic murine leukemia virus-related virus (XMRV) illustrates the confusion that can arise when the discovery of a *bona fide* novel virus is incorrectly associated with a disease. XMRV was initially linked to human prostate cancer and subsequently to chronic fatigue syndrome. Mutations in the ribonuclease L gene were previously linked to prostate cancer (96). Using a pan-viral DNA microarray approach, XMRV was identified in tissue samples from prostate cancer patients (97). Subsequently, XMRV was detected in the blood of patients with chronic fatigue syndrome (98, 99). However, nearly all follow-up studies failed to detect the association of XMRV with these diseases (100). The origin of XMRV was traced to a prostate cancer cell line that had been xenografted in a mouse, where XMRV emerged from a unique recombination event between two endogenous murine retroviruses (101). Thus, XMRV was shown to be a laboratory-derived contamination that had no association with human prostate cancer and chronic fatigue syndrome (100, 102). This highlights the importance of interpreting disease association with the newly identified novel pathogens and the need for controls that can detect contamination especially in highly sensitive discovery techniques.

REAGENT CONTAMINATION

During the course of the XMRV controversy, multiple labs identified similar murine retrovirus-derived sequences that were present in standard molecular biology reagent preparations such as commercial reverse transcriptase (103, 104). Another example of reagent contamination emerged following the discovery of a novel circovirus-parvovirus hybrid DNA virus called National Institutes of Health Chongqing virus (NIH-CQV), putatively identified in sera specimens from patients with non-A-E hepatitis (105). The discovery had significant implications because up to 20% of acute hepatitis cases have an unknown etiology (106). The cDNA from pooled sera of patients with non-A-E hepatitis was deep-sequenced. Bioinformatics analyses identified a 3.7-kb contig that shared limited identity with known parvoviruses. The complete genome of NIH-CQV was subsequently verified in eight overlapping PCR fragments. Additionally, genetic heterogeneity was detected in the NGS data and inferred to represent intrapatient quasispecies. Using quantitative PCR and serological assays, the authors concluded that NIH-CQV was highly prevalent in patients with non-A-E hepatitis. However, NIH-CQV has since been shown to be a reagent contaminant of nucleic acid extraction spin columns (107, 108). NIH-CQV could be detected by PCR in mock extractions of water eluted from the silica column. Importantly, samples that were previously positive for NIH-CQV subsequently tested negative when they were reextracted using other vendor kits and platforms. Further analyses indicated that NIH-CQV sequences could be detected in NGS metagenomic data from marine environmental samples. Therefore, the origin of NIH-CQV has been proposed to be an inadvertent contamination of silica during spin column manufacture (107).

METAGENOMICS LIMITATIONS

Microbial contamination during specimen sampling can also significantly influence metagenomic studies that survey taxonomic distributions and frequencies (109, 110). Samples with low microbial biomass, such as spinal fluid, blood, and lung specimens, are particularly prone to these effects (111). Serial 10-fold dilutions of a pure *Salmonella bongori* culture were sequenced at three research institutions and analyzed to compare the effect of limiting sample dilution on bacterial community composition analyses. While the bacterial taxonomic profiles were generally similar among the three sites, some bacterial genera were only detected in a site-specific manner, indicating that contaminants could vary between laboratories. Importantly, the proportion of bacterial contaminants was dominant in samples at increasing dilutions. These observations were consistent in bacterial 16S amplicon sequencing and shotgun sequencing. Thus, as NGS becomes more widely accessible, studies should include added precaution to minimize contamination.

CONCLUSIONS

Significant advances have been made in the methodologies for pathogen discovery. NGS has changed the face of pathogen discovery by providing a high-throughput cost-effective approach. As this technology becomes more widely accessible and new innovative methods are developed over the coming years, it is important to emphasize the value of good practices in microbiology sterile techniques. This can have significant implications when the disease causation is established. Thus, the field of molecular diagnostics is poised to offer the first clues to many unsolved clinical syndromes. Moreover, the improved technologies have enabled the field to develop more nuanced concepts of microbial pathogenesis.

Matrix-Assisted Laser Desorption Ionization-Time of Flight Mass Spectrometry for Microbial Identification in Clinical Microbiology

ALEX VAN BELKUM, VICTORIA GIRARD, MAUD ARSAC, AND ROBIN PATEL

8

After several decades of limited progress, the practice of clinical microbiology is beginning to evolve on a more rapid scale. The introduction of immunological methods in the 1970s was followed by the introduction of automated biochemistry-based identification systems, automated antimicrobial susceptibility testing systems, and automated blood culture instruments in the 1980s and 1990s, and thereafter by the gradual adoption of nucleic acid amplification tests over the past 25 years. Today, there is an accelerated pace of introduction of novel technologies into clinical microbiology laboratories (1). Easy-to-use panel-based molecular testing and automated workflow are in the process of being adopted. Workflow optimization is being facilitated by the introduction of automated equipment, with rapid identification of microbial pathogens being a key component (2). A revolutionary new entry, matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS), has been introduced into clinical microbiology laboratories over the past 5 years as a tool for microbial identification (3–5). The quality of MALDI-TOF MS with respect to bacterial identification already seems to surpass that of more classical growth-based technologies (6). The reason for the rapid adoption of this technology is that it is simple, high speed, cost-effective, and at least as good as, if not better than, conventional identification strategies. Sometimes the combination of classical technologies such as Gram staining with MS is advocated, but most people agree that MS will be able to function as a stand-alone technology for bacterial identification (7).

MS methods can be fairly easily standardized, and although in some cases culture conditions may affect the nature and overall quality of the mass spectra (8), this is the exception rather than the rule and has not hindered the development of spectral databases and dedicated identification assays. Results can be obtained in as few as 6 min, and identifications are very reproducible (5). The technology has been broadly adopted, and many laboratories around the world use MALDI-TOF MS as their main microbial identification strategy. Given this success and the availability of many good reviews on the topic, this chapter does not aim to provide a detailed description of MALDI-TOF MS as such. Instead, this chapter aims to summarize some of the major developments surrounding the use of MALDI-TOF MS in clinical microbiology with a focus on the recently performed comparative studies (MALDI-TOF MS versus other technologies) and multicenter evaluations.

Alex van Belkum, Victoria Girard, and Maud Arsac, bioMérieux SA, R&D Microbiology, 3 Route de Port Michaud, 38390 La Balme Les Grottes, France. **Robin Patel,** Mayo Clinic, Division of Clinical Microbiology, Division of Infectious Diseases, Rochester, MN 55905.

SAMPLE PREPARATION

A key component of MALDI-TOF MS is sample processing. DNA testing using MS has been proposed and commercially developed (9), but in most current clinical microbiology applications of MALDI-TOF MS, the focus is on the evaluation of protein rather than nucleic acid spectra. For this purpose, the only requirement is to have a relatively pure bacterial, mycobacterial, or fungal culture with a sufficient number of cells, typically at least 10^5 microbial cells per sample for most species, to generate useful spectra and microbial identification. When cultures have grown on a commercial agar medium, simply picking a colony and transferring the biomass to a MALDI-TOF MS sample plate suffices in most cases, although spectra may differ depending on culture media used and the age of the colony. Adding a small amount of a chemical matrix (α-cyano-4-hydroxycinnaminic acid or others) needed for ionization of the biomaterial is all that is required for processing most bacteria.

For some bacterial and fungal species, the addition of a simple preparatory on-plate extraction step with formic acid can improve the diagnostic outcome. This has been demonstrated particularly for the *Corynebacterium* species and Gram-positive cocci of the species *Streptococcus mitis* and *Streptococcus dysgalactiae* using a commercially available MALDI-TOF MS system (10). The on-plate formic acid preparation or a more formal formic acid–ethanol extraction approach is generally required to analyze fungal cells (11, 12). For yeasts, this is typically performed using the aforementioned on-plate formic acid strategy (13). Molds may require formal protein extraction prior to being placed on the sample plate. Likewise, bacteria grown in liquid media (e.g., in blood culture bottles) need preparatory treatment to purify the bacterial cells free from other contents

present in the liquid. For this purpose, a variety of methods have been used. Whereas the accuracy of bacterial species identification of MALDI-TOF MS is usually over 96%, in the case of positive blood culture bottles, this percentage may drop depending on the bacterial species in the sample. Some commercial systems are available, but in-house lysis-filtration and lysis-centrifugation methods have been proposed (14–16). These methods have been claimed to be economical and time-saving compared with the more classical methodologies, especially when coupled with rapid antimicrobial susceptibility testing (17). Some very impressive results have been reported for the mycobacteria, a particularly cumbersome group of organisms when the processing of bacteria grown in liquid or solid media is involved (18). When handling potentially hazardous organisms, such as *Brucella melitensis*, work with live organisms should be exclusively performed in biological safety cabinets.

Sample processing is more cumbersome if analyses are performed directly from clinical specimens. Even detection and identification of bacteria from positive blood culture media may require adaptation of the laboratory workflow to enhance reliability. Several studies have documented good results while using a variety of sample preparation methods where selective lysis of host cells seems to be a common experimental theme. For the postculture detection of blood-borne pathogens, PCR methods have also been developed, but the results of such molecular methods are similar to those of mostly cheaper MS analyses (19). The sensitivity of the MALDI-TOF MS methods ranges between 80 and 90%, so there still is room for improvement (20, 21), which will be primarily sought in the preanalytical steps.

Urine specimens are the only clinical specimens that regularly contain the requisite 10^5 or more cells compatible with direct microbial detection in clinical specimens, although these samples may contain mixed species (22, 23). A recent study reported a successful complementation of urine flow cytometry with MALDI-TOF MS where the combination of the results obtained with both methods provided actionable data (24). However, the method failed in some instances of mixed infection. To address this issue, proposed solutions that seem to work quite well involve the adaptation of interpretative software (25). In addition, focus has been on the development of sample preparation methods that improve the sensitivity by eliminating contaminating and potentially MS-confounding compounds (such as human defensin proteins, phosphate crystals, and leukocytes). Protocols involving differential centrifugation (26), short preincubation of urine sediments on agar-based growth media (27), and diafiltration (28) have all shown their analytical utility.

Interestingly, organisms from completely different phyla can be analyzed by MALDI-TOF MS: a recent paper clearly showed that ticks of a variety of species and origins can be differentiated (29). Work on larvae, cell lines, mosquitoes, and midges has been published as well (30, 31). We expect soon to see even more widely differing applications in all fields of medical, environmental, pathological, chemical, and toxicological diagnostics.

MICROBIAL IDENTIFICATION

Once samples have been processed and the sample plate has been put in the mass spectrometer, the process is highly automated, with the end result being a report indicating top matches and confidence in the proposed identifications. Generally speaking, MALDI-TOF MS yields identifications that are as good as, if not better than, currently available biochemical and nucleic acid–based identification systems for both bacteria and yeast. In some instances, such as the case of nontypeable *Haemophilus influenzae* versus *Haemophilus haemolyticus*, MALDI-TOF MS supplements classical taxonomy. Whereas classical microbiologic techniques may have difficulty distinguishing the two, MALDI-TOF MS has been shown to provide a means to identify both organisms (32). Similar data were obtained for identification of *Bacteroides* spp. and *Streptococcus* spp. including *Streptococcus pneumoniae* (using the VITEK MS system), with MALDI-TOF MS being as good as classical testing with regard to sensitivity and with enhanced specificity (33–35). In addition, applications were developed for microbial species as diverse as *Leptospira* spp. (36), *Mycobacteria* spp. (37), and *Propionibacterium* spp. (38) (see Fig. 1).

The current commercially available systems cover a broad array of species, and as databases and strategies expand, the spectrum continues to broaden. For example, although select agents have historically not been adequately addressed, using appropriately constructed databases, including Bruker's Security-Relevant Library, *Brucella* species, *Francisella* species, and *Burkholderia pseudomallei/mallei* may be identified (39, 40). It has also been shown that detection and identification of *Bacillus anthracis* may be reliably performed using 2.5×10^6 spores (41). For fungi, MALDI-TOF MS has added significantly to the reliable identification of these organisms (42–44). Increasingly, commercial databases are being expanded to include the majority of the clinically relevant fungal species (45, 46) and will be expanded to include additional species that are currently hard to identify by phenotypic methods as well (such as the *Nocardiae*; see Fig. 2 and Fig. 3). Obviously, MALDI-TOF MS is not a panacea. When taxonomy is not clear, MS may have issues with correct microbial identification. Examples include the differentiation between *Escherichia coli* and *Shigella* species and the correct identification of several streptococcal species.

ANTIMICROBIAL SUSCEPTIBILITY TESTING AND BACTERIAL TYPING

To date, commercial MALDI-TOF MS offerings in clinical microbiology have been solely focused on microbial identification. However, there are other applications that have the potential for impact on clinical patient management. Among these are strain-typing and antimicrobial susceptibility testing; the latter was recently reviewed by several authors (47, 48). Methods may be simple; in some cases the combination of MALDI-TOF MS and automated antimicrobial susceptibility testing facilitated a better workflow for the timely management of positive blood cultures (4, 49–51). Alternatively, four major types of assays can be envisioned: (i) detection of antibiotic modification or degradation based on changes in mass of the antibiotic, (ii) detection of proteomic changes in resistant versus susceptible bacterial species in the absence or presence of the antimicrobial compounds, (iii) semiquantitation of intracellular or extracellular antibiotics, and (iv) detection of modified antibiotic target sites (52). Practical examples have been recently published. For example, detection of specific β-lactamase activities (53–55), including carbapenemases (56), assessing the susceptibility of *Candida* species and *Aspergillus* species to caspofungin (57), and simple and straightforward testing for ampicillin resistance among *E.*

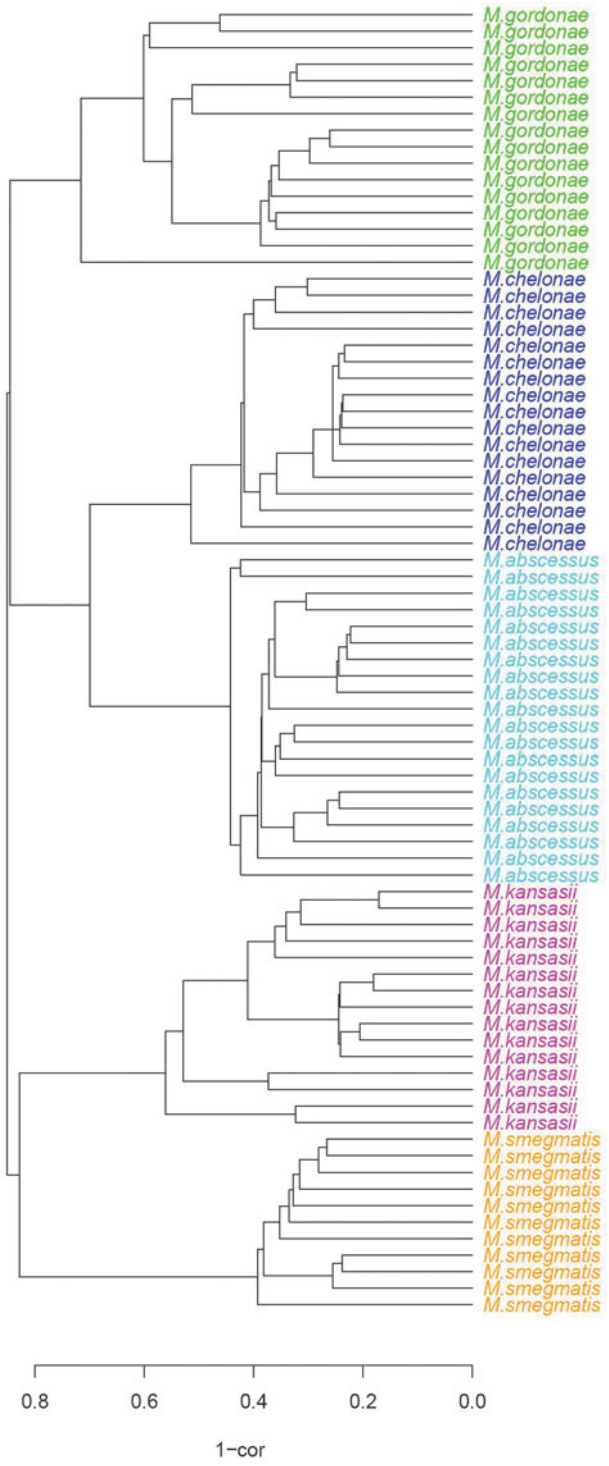

FIGURE 1 Dendrogram (Spearman correlation dissimilarity index, single linkage criteria) based on the MALDI-TOF MS spectra of some strains of *Mycobacterium* species used for the VITEK MS knowledge base creation. For each strain, replicate measurements were summarized into a prototype spectrum by retaining only the peaks found in 50% or more of the spectra. *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium smegmatis*, *Mycobacterium gordonae*, and *Mycobacterium kansasii* are clearly separated by MALDI-TOF MS.

coli strains (58) have been convincingly demonstrated. Details can be found in several good reviews on the subject (59, 60).

Bacterial strain-typing can also be performed using MALDI-TOF MS (61). While identification assays usually focus on those peaks that are universally conserved among all isolates from within a microbial species, high-resolution typing within a species relies on comparison of peaks that are unique to an isolate. It has been suggested that MALDI-TOF MS–based typing may be quicker than molecular typing for investigation of *Acinetobacter baumannii* outbreaks (62). Also, clonal lineages of *Staphylococcus aureus* can be identified on the basis of MALDI-TOF MS analysis of point mutations in stress and ribosomal proteins, as can *E. coli* pathotypes (63–66). Interestingly, MALDI-TOF MS can also be used to track plasmids (67). This allows for the investigation of infectious outbreaks related to horizontal plasmid transfer rather than local spreading of bacterial strains. Additional studies into reproducibility and robustness of these analyses are eagerly awaited, and methods for data interpretation are yet to be described. Again, there are currently no commercial offerings for this type of analysis, but there is proof of principle with regard to the MALDI-TOF MS–based typing procedures. It remains to be shown whether this sort of typing procedure will be competitive with nucleic acid sequencing–based approaches.

MOLECULAR DIAGNOSTICS INCLUDING MS ANALYSES

To date, MALDI-TOF MS has been primarily used for proteomic analyses. The two main distributors of MALDI-TOF mass spectrometers, Bruker (Bremen, Germany) and bioMérieux (Marcy l'Etoile,France), have a significant installed customer base, and the method is increasingly popular among clinical microbiologists. However, MS procedures can also be used for the characterization of DNA molecules, especially PCR-amplified DNA fragments. Many papers have been published, primarily ones that use electrospray ionization (ESI) MS applications rather than the current MALDI-TOF strategies (68, 69). Such methods have proven useful to demonstrate microbial diversity that goes beyond the resolution of MALDI-TOF MS and have been shown to be particularly capable of detecting genetic variability after DNA amplification. However, only a single such commercial system, using ESI MS, has been demonstrated to have potential utility for routine clinical microbiology applications. The Ibis PLEX-ID system (currently renamed the IRIDICA system, marketed by Abbott) was demonstrated as a useful tool for bacterial detection and identification (70). Since the system first amplifies DNA and then characterizes the amplified material, the approach is compatible with direct analyses of clinical samples without the time-consuming cultivation step required for "classical" microbiological MALDI-TOF MS. So the sequence of events is DNA purification from a clinical sample, targeted amplification of this genetic material, ESI MS, and finally, using sophisticated mathematical algorithms, identification of pathogens. Although the method is costly and may be relatively difficult to adapt for routine use in all but high-throughput microbiology laboratories, the strategy holds promise as demonstrated in recent literature.

Detection of potential bioterrorism-relevant organisms using ESI MS has been studied in detail, and reports show good sensitivity and applicability in a variety of matrices (70). Among clinically relevant fungal species, *Aspergillus*

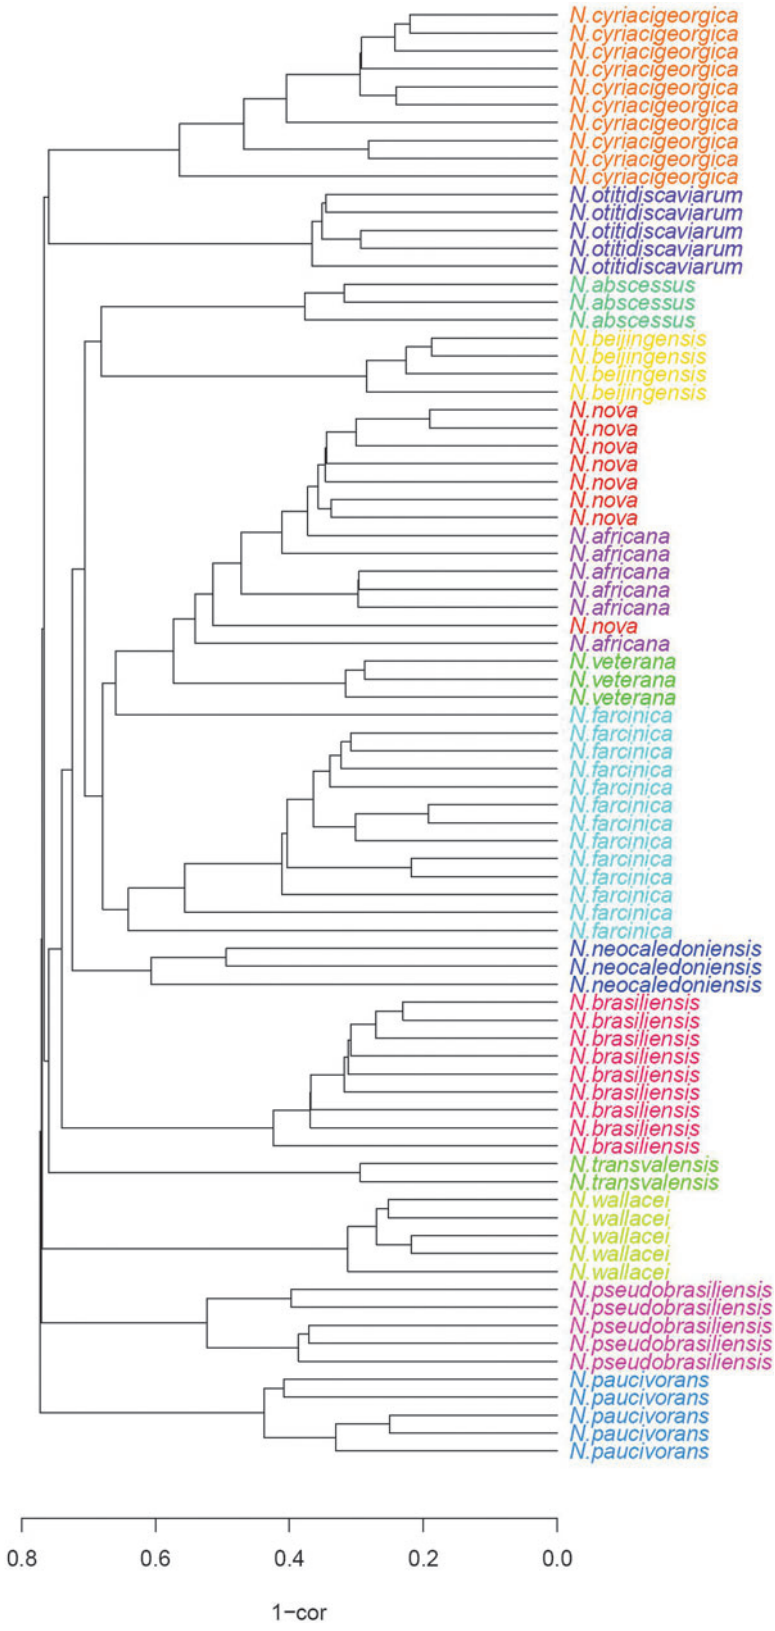

FIGURE 2 Dendrogram (Spearman correlation dissimilarity index, single linkage criteria) based on the MALDI-TOF MS spectra for strains of *Nocardia* spp. used for the VITEK MS knowledge base creation. For each strain, replicate measurements were summarized into a prototype spectrum by retaining only the peaks found in 50% or more of the spectra. Most *Nocardia* spp. are clearly separated by MALDI-TOF MS except *Nocardia nova* and *Nocardia africana*, at least with the VITEK MS system.

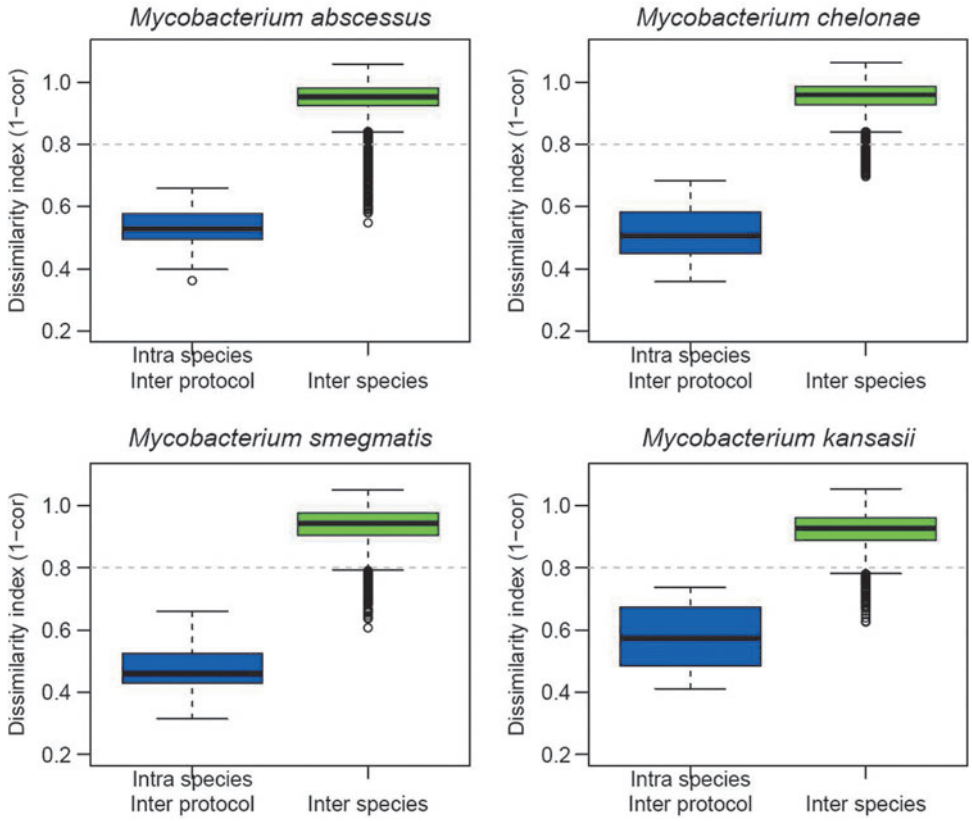

FIGURE 3 Distribution of intraspecies pairwise dissimilarity compared to interspecies pairwise dissimilarity based on the MALDI-TOF MS spectra of some species of *Mycobacterium* used for the VITEK MS knowledge base creation. For each strain, replicate measurements were summarized into a prototype spectrum by retaining only the peaks found in 50% or more of the spectra. For intraspecies pairwise dissimilarity, prototype spectra obtained from liquid cultures were compared to prototype spectra obtained from solid, agar-based cultures. For interspecies pairwise dissimilarity, prototypes from one species were compared to those from all other species. Despite the variability observed in spectral patterns in response to culture conditions, the intraspecific variability of spectra was found smaller than the interspecies variability.

fumigatus and *Candida albicans* showed sensitivities of 94.4 and 99.2%, respectively (71). Similar performance was demonstrated for the detection and characterization of other bacterial species (72), even when working directly from clinical specimens (73). Because of the initial PCR amplification step, the method is also compatible with the detection of viruses, a capability that is still quite cumbersome with the MALDI-TOF MS approach (74). Compared to alternative viral detection assays (including fluorescent antibody staining or other commercial PCR systems), the ESI MS assays performed very well (75). The method is also well suited for further typing of microbial pathogens including the detection of specific virulence or resistance genes (76). In conclusion, the use of ESI MS may very well complement the more classical MALDI-TOF MS assays, although it remains to be seen whether ESI MS–based sequence identification will be supplanted by (next-generation) enzymatic DNA sequencing.

CLINICAL IMPACT

Applications in the field of mass spectrometry need to be cost effective and provide added value in the clinical care of patients (77, 78). In this regard, clinical evaluations have recently appeared in the international literature. Preliminary studies in the United States have demonstrated the added value of MALDI-TOF MS–mediated identification of bacterial isolates from patients with recurrent bacteremia (79). Such individual analyses are important, but longitudinal studies on the overall effect of rapid diagnostics in changing patients' morbidity and mortality are required to more clearly document medical value. A Dutch study on the effect of faster identification of bacterial species in positive blood cultures demonstrated that identification via MALDI-TOF MS reduced the time to identification by more than a day (80); this was confirmed in a subsequent Swiss study (81). This resulted in a significant increase in the number of patients receiving appropriate antibiotic therapy: 64.0% in the control group versus 75.3% in the MALDI-TOF MS group ($P < 0.01$) (82). There was no demonstrable effect on morbidity and mortality, but the study was notably small. Also, results may differ in settings where the prevalence of multiresistant microorganisms is greater. A report from Belgium showed an 11% therapy change based on MALDI-TOF MS results and also proposed that MALDI-TOF MS was helpful in defining contamination rather than real infection in septic patients (83). When a Swiss study compared the impact of Gram staining versus

MALDI-TOF MS on the management of bacteremia caused by Gram-negative organisms, the outcome was optimistic (81). In 35% of cases of infection, MALDI-TOF MS affected the spectrum of prescribed antibiotics. MALDI-TOF MS was more frequently the basis of de-escalation of antibiotic treatment than Gram staining, although it has to be pointed out that all of the current studies were performed in settings where antimicrobial stewardship programs were already vigorously implemented before the study. As yet there are no data on precise assessment of the effect of rapid MALDI-TOF MS on morbidity and mortality.

COMPARATIVE AND TECHNICAL MULTICENTER STUDIES

When a new technology is introduced, its various iterations are compared to "gold standard" assays using side-by-side evaluations. In all comparisons performed thus far, MALDI-TOF MS has turned out to be at least as good as the reference standard method. In many cases, MALDI-TOF MS has outperformed classical testing (see, for instance, reference 84; there are many other papers showing similar results). Currently, the MALDI-TOF MS market is dominated by two commercial vendors: bioMérieux, offering the VITEK MS, VITEK MS RUO, and VITEK MS Plus systems (France), and Bruker Daltonics, marketing the MALDI Biotyper and MALDI Biotyper CA systems (Germany). Accordingly, most comparisons of performance have been done with these two brands. One of these comparative studies was published in early 2012 and evaluated identification of nonfermenting Gram-negative bacilli from cultures of patients with cystic fibrosis (85), a study that was recently complemented by an additional one analyzing Gram-negative rods from a similar patient cohort (86). In the first study, species-level identification was not significantly different between the two MS methods. However, the MALDI Biotyper system required more extractions in order to generate interpretable spectra. The second study demonstrated agreement with 16S rRNA sequencing of 96.6, 90.1, and 93.6% for the Bruker Biotyper, VITEK MS systems using Saramis version 4.09, and VITEK MS with the Knowledge Base version 2.0, respectively (86). A similar study on yeasts was recently published by a combined team from Rome and Milan, Italy. Again, using the clinical databases of the two systems, no significant difference was found for correct species identification (87). The studies showed that open database extension, as can be done with both systems, improved results.

A third study performed in Brussels, Belgium, was the first where routine application of the two systems was compared. More than 1,000 isolates were tested using the MALDI Biotyper and the premarket version of the VITEK MS Plus system; spectra were interpreted using three databases (88). Among 986 routine isolates identified to the species level, 93% were correctly identified by the Biotyper and Vitek MS databases. Neither system was able to discriminate between *E. coli* and *Shigella* species. The performance of the Saramis database, which is available as an open database for the VITEK MS system, was globally poorer. A multicenter study employing a single type of instrument confirmed the reproducibility of the technology for identification of *Brucella* species, as did a multicenter study on yeast in 10 Korean hospitals (89, 90).

Finally, a recent study from Seattle compared the diagnostic performance of the two systems in combination with two simplified protein extraction protocols including vortexing with silica beads in the presence of ethanol for identification of *Mycobacterium* species (91). The commercial Bruker database was augmented with an in-house database composed of clinical *Mycobacterium* strains. The 198 isolates tested were correctly identified to the species level in 94.9% of cases using the augmented database and in 94.4% of cases using the bioMérieux system. Notably, only 79.3% were identified to the species level using the nonaugmented Bruker database; if a lower identification score threshold of ≥1.700 was applied, the identification percentage increased to 93.9% using the nonaugmented database. For mycobacteria, as for any other pathogenic bacterial species, sample preparation is key, and inactivation protocols for processing such samples outside of a biosafety level 3 environment are important (92).

Quality verification of diagnostic equipment and assays is within the domain of the U.S. FDA. To be able to apply for FDA approval of a test system, external validation studies are important (93, 94). For the VITEK MS system the performance of such studies included over 6,000 clinical bacterial isolates, among which about 180 different species were identified. This led to FDA approval for the identification of these species in clinical laboratories. This leaves open the question of how to adequately validate databases covering thousands of different species. However, overall, the commercially available systems work well and provide clinically actionable data. There are differences between systems and databases, but on the whole, the choice between the systems will likely depend on specific workflow needs, laboratory information system connectivity requirements, and unique characteristics of the purchasing laboratories or, on the other hand, the qualities or shortcomings of the manufacturers.

CONCLUSIONS AND FUTURE PERSPECTIVE

Clearly, MALDI-TOF MS is here to stay, although, of course, many studies are also focusing on the potential usefulness of next-generation MS tools (95). For the coming decade, the MALDI-TOF technology will continue to prevail and dominate the microbial identification market while applications in the domain of viral detection and identification are currently being developed as well (96). DNA whole-genome sequencing is currently identified as a potentially invasive technology covering the same domain, and it holds the potential to, in the end, take away market share because of its ability to identify resistance mechanisms, epidemiologically important genetic polymorphisms, and virulence traits as well as provide identification, all in the same assay. However, the simplicity, speed, and low cost of MALDI-TOF MS, including its convenient sample handling, will not be easily challenged by next-generation sequencing technologies in the very near future. While it is possible that sequencing may ultimately replace certain MALDI-TOF MS applications, this will only occur when the process is significantly simplified from a processing and timing standpoint and when the cost is much reduced. Today, MALDI-TOF is state of the art, and it is important to further enrich the MALDI-TOF MS field with innovative diagnostic applications.

Multiplex Technologies

KEVIN ALBY AND MELISSA B. MILLER

9

It is well appreciated that the adoption of molecular methods by clinical laboratories has revolutionized the identification of microbial isolates, detection of pathogens directly from clinical specimens, and methods for monitoring response to antiviral therapy. As discussed in chapter 1 of this volume, hybridization and amplification technologies continue to mature and enable new diagnostic applications, particularly as the ability to multiplex has become a reality. Multiplexing allows for the simultaneous detection of more than one target, whether it is a pathogen and internal control, multiple pathogens, pathogen and resistance determinants, or pathogen and host sequences. Multiplex detection performed on a single specimen allows laboratories to expand the breadth of their testing menu while improving efficiency and decreasing reagent and personnel costs. This chapter will review the multiplex technologies with potential diagnostic applications, including multiplexed hybridization and amplification and microarrays. Although the ultimate multiplexing technology could be considered next-generation sequencing, this technology and its applications are discussed in chapters 5 and 6 and section II.

MULTIPLEX HYBRIDIZATION

Nucleic acid probes have long been used for culture confirmation as well as direct detection of organisms from clinical material. Applying this technology in a multiplexed manner allows for the expansion of clinical applications. Probes are single-stranded oligonucleotides that can vary in size from 20 base pairs (bp) to a few kilobases but are generally less than 50 bp. Probe specificity is defined by the nucleic acid sequence of the probe. Typical probe targets include genomic DNA or RNA, mRNA, or rRNA. Probe detection occurs by hybridization, or annealing, of a labeled probe to a target sequence which has been released by lysis of the organism. Hybridization generally uses stringent conditions (i.e., high temperature, low salt) to promote the highest specificity, often allowing even a single base pair change to be detected. Following hybridization, the probe-target hybrids are generally either isolated and detected using a luminometer or viewed using fluorescent microscopy.

Hybridization can occur in liquid phase or in solid phase. In liquid-phase hybridization, both the probe and the target are free in solution to interact, allowing for more rapid annealing and thus shorter assay times. Disadvantages of liquid-phase hybridization include a requirement for relatively pure target nucleic acid, and interference from related but not identical target nucleic acid sequence can affect detection (1). In contrast, solid-phase hybridization uses solid media such as nitrocellulose, nylon membrane, or glass slide to immobilize the target nucleic acids. Labeled probes are then added to the solid support, allowing for detection of the nucleic acid sequence of interest. The format can also be reversed such that the probe is immobilized on a solid surface and target sequences are added in solution. This reversed format allows for the detection of multiple analytes from a single specimen preparation or the detection of multiple polymorphisms in a single amplicon generated using consensus primers for amplification (i.e., hepatitis C and human papillomavirus genotyping, resistance detection in *Mycobacterium tuberculosis*). Examples of multiplexed hybridization detection include *in situ* hybridization (ISH) and microarrays, the latter of which will be discussed under a separate heading.

Probes used for ISH can be either DNA or RNA and are typically short (15 to 30 bp), which allows for easier penetration and access to the target site. Lysis of cellular membranes and proteins must occur to allow permeation and hybridization of the probe. Both colorimetric and fluorescent ISH probes have been described; common fluorescent labels include fluorescein, rhodamine, their derivatives, and cyanine dyes (1). A powerful application of ISH is the use of multiple probes tagged with different fluorophores for the simultaneous detection of multiple organisms in a single specimen or the simultaneous detection of an etiologic agent and immunohistologic markers. Advantages of ISH applications in histopathology are that the host tissue response can be evaluated, and the exact cells displaying a specific morphotype can be probed for suspected etiologic agent(s). Disadvantages include autofluorescence exhibited by some microorganisms (including *Pseudomonas*, *Legionella*, many yeasts, and molds), highly probe-sequence-dependent specificity and reliability, insufficient penetration of sample material, secondary structure of target sequence, low target content, and photobleaching (2).

For direct identification of microbial organisms in patient samples or cultures, peptide nucleic acid fluorescent ISH (PNA-FISH) has been described. PNA probes have a neutral peptide-like backbone, as opposed to the negatively charged sugar phosphate backbone found in DNA

Kevin Alby, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA 19104. **Melissa B. Miller,** Department of Pathology and Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, NC 27599.

probes (3). However, like DNA probes, PNA probes still hybridize to DNA and RNA in a sequence-specific manner and can be labeled fluorescently for ease of detection. Reported advantages of PNA probes include stronger and faster hybridization, ability to discriminate 1-bp differences, resistance to nucleases and proteases, survival under stringent conditions that allow for access to regions with secondary structure, and increased hydrophobicity that allows for penetration of cell membranes during ISH (3). PNA-FISH allows for multiplexed detection directly from positive blood culture bottles since different fluorophores can be used to identify different target sequences. Commercially available PNA-FISH tests for multiplexed detection and differentiation of microorganisms from positive blood cultures include *Staphylococcus aureus*/coagulase-negative staphylococci, *Enterococcus faecalis*/other enterococci, *Escherichia coli*/*Pseudomonas aeruginosa*/*Klebsiella pneumoniae*, and *Candida albicans* or *Candida parapsilosis*/*Candida tropicalis*/*Candida glabrata* or *Candida krusei* (AdvanDx, Inc., Woburn, MA) (4).

MULTPLEX SIGNAL AMPLIFICATION

Another methodology that is used for the multiplex detection of nucleic acid sequences in clinical specimens is signal amplification. This technique is unique in that the signal, as opposed to the target (as in PCR), is amplified. Due to the amplification of the signal generated from hybridization, signal amplification is more sensitive than nonamplified direct detection but is generally not as sensitive as target amplification methods. However, there seems to be less risk of contamination with signal amplification than with target amplification techniques.

Although signal amplification methods have been available for over a decade (see chapter 1) and have been used clinically for quantification of a variety of viruses, their use in multiplex detection is relatively new. The introduction of gold nanoparticle technology has allowed sensitive detection of nucleic acids and proteins without the need for target amplification (Nanosphere, Northbrook, IL). However, for the most sensitive detection, either culture amplification or target amplification should occur prior to signal amplification. The most common clinical application of multiplex signal amplification (in the absence of target amplification) is detection and differentiation of organisms and resistance determinants from positive blood cultures (Verigene System, Nanosphere). Since the organism is amplified by culture, target amplification is not needed prior to detection by signal amplification. Target sequences from lysed organisms are hybridized on a microarray by capture oligonucleotides (Fig. 1). A gold nanoparticle (13 to 20 nm) with sequence-specific probes is subsequently hybridized via specific mediator oligonucleotides. The end result is hybridization of the target sequence to a gold nanoparticle on a microarray spot. The nanoparticles are then coated with silver, which increases their size (0.5 to 1 um) and their reflectivity. Optical analysis of LED light scatter is used to detect signal from hybridized spots on the microarray and generate test results (5).

Commercially available tests using multiplex signal amplification without the need for target amplification include the Gram-positive blood culture test and Gram-negative blood culture test; a yeast blood culture test is in development. The Gram-positive blood culture test includes targets to detect staphylococcal, streptococcal, and enterococcal species, as well as *Listeria* spp. and resistance determinants *mecA*, *vanA*, and *vanB*. The Gram-negative blood culture test detects *E. coli*, *K. pneumoniae*, *Klebsiella oxytoca*, *P. aeruginosa*, *Acinetobacter* spp., *Citrobacter* spp., *Enterobacter* spp., *Proteus* spp., and select resistance genes for extended spectrum beta-lactamases (CTX-M) and carbapenemases (IMP, KPC, NDM, OXA and VIM).

MULTIPLEX AMPLIFICATION

With careful planning and design, it is possible to create sets of primers that can be run in the same amplification reaction together or multiplexed. By multiplexing, the user

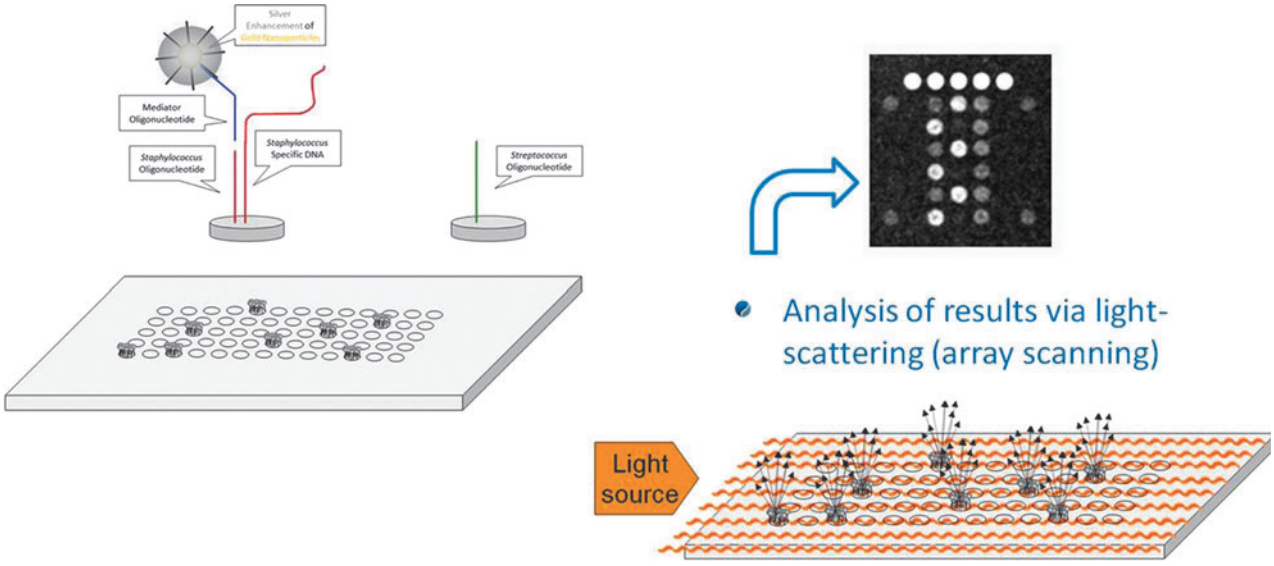

FIGURE 1 Signal amplification and hybridization. This diagram depicts the detection of *Staphylococcus*-specific DNA using gold nanoparticles followed by signal amplification. The targeted DNA is hybridized to a specific oligonucleotide on an array. A mediator oligonucleotide is bound to a gold nanoparticle and then hybridizes at the specific array site. Following silver-based signal amplification, light scattering is detected at each of the array locations. Image provided by courtesy of Nanosphere.

is able to amplify and detect multiple targets from one nucleic acid sample in one reaction vessel. As discussed in chapter 1, there are numerous amplification and detection methods that also apply to multiplex reactions. Multiplex detection methods essentially fall into two broad categories: endpoint detection, where only the final products are analyzed (either by composition or hybridization), and real-time detection, where the products are evaluated throughout the reaction.

Endpoint Detection by Composition

There are two predominant methods for endpoint detection of multiplex PCR: composition based and hybridization based, though within each category there are a variety of specific methods. The most basic of multiplex reactions uses different primer sets that generate amplicons of different, but predictable, sizes that can be resolved using standard gel electrophoresis. Gel electrophoresis utilizes the fact that DNA is negatively charged and will migrate away from a positive source within an electric field. In this case the DNA has to move through a matrix of gel, typically made of agarose. Larger molecules have a more difficult time moving through the gel matrix, and their movement in the assay is impeded. Smaller amplicons have an easier time moving through the gel, and this is demonstrated by increased migration away from the field source. In this way, the composition of the product directly influences the result. The PCR products are stained using dyes such as ethidium bromide or SYBR Green, often within the gel itself, and can be visualized using UV or blue light. This method is useful when looking for only a few targets and can be implemented without special thermocyclers or other equipment beyond what is typically used for PCR in a laboratory. This approach is limited by the number of amplicons that can be reliably resolved, and quantitative analysis may be difficult.

SYBR Green is also commonly used in a different type of endpoint analysis: melting curve analysis. Since SYBR Green is most fluorescent when intercalated within double-stranded DNA (6), seeing a reduction in fluorescence while increasing the temperature applied to the PCR product indicates the point at which the two strands of the product disassociate. By manipulating the plot that is generated, typically by applying a negative first derivative, a characteristic peak(s) can be derived, equating to the melting point of the product (6). Importantly, the melting point of the product is directly related to the G/C content (6). Therefore, even products of similar sizes can be resolved as long as their G/C content is sufficiently different.

Another more sophisticated method of composition-based endpoint detection is using mass spectrometry (MS) to analyze the end products of a PCR reaction. Under the names Ibis Biosensor, PLEX-ID, and IRIDICA, PCR is followed by electrospray ionization with mass spectrometry (ESI-MS) (Abbott Molecular, Des Plaines, IL). In ESI-MS, the molecule of interest, the PCR product in the case of PCR ESI-MS, is introduced to the mass spectrometer via ESI (Fig. 2). In this method the sample must first be nebulized, which is achieved by introducing the product to a high electric field at the tip of a capillary tube. Eventually, the electrostatic forces overwhelm the surface tension, and an electrically charged droplet is released from the tip into the surrounding chamber. This droplet contains multiple ionic species. As the droplet travels through the gas in the surrounding chamber, solvent evaporation

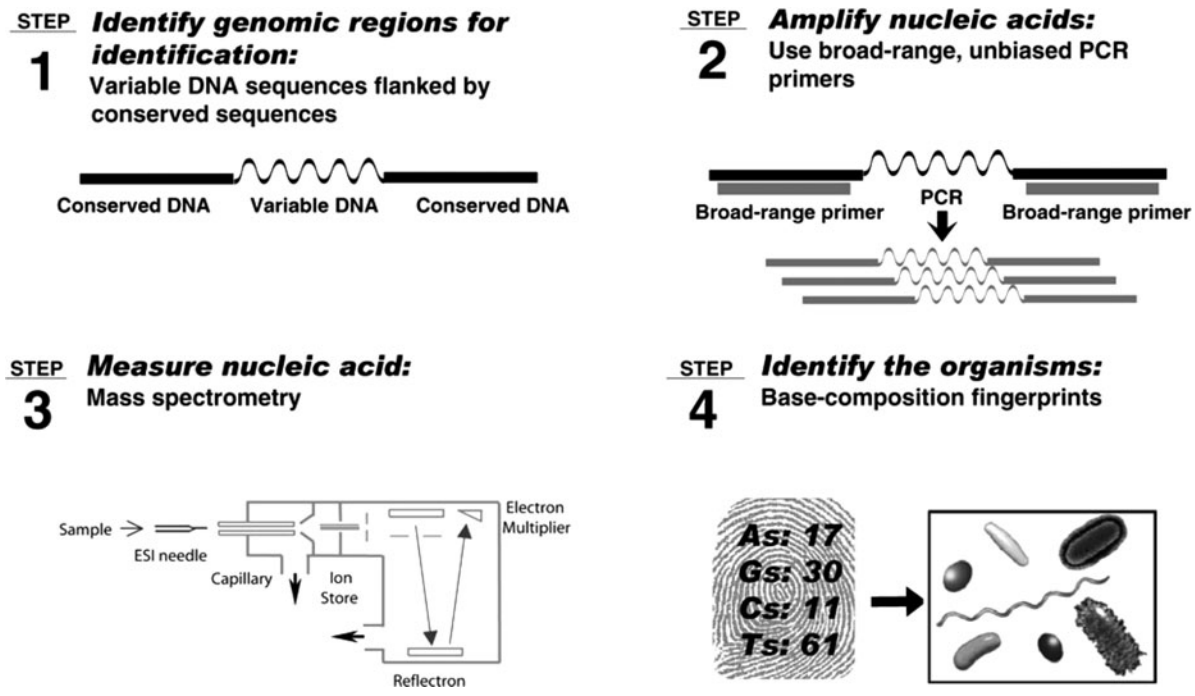

FIGURE 2 PCR electrospray ionization with mass spectrometry. Genetic regions of interest are first identified (step 1). Broad primers near the region of interest are utilized to amplify that region (step 2). The products of these reactions are measured using mass spectrometry (step 3). The sample is introduced via an ionization needle into a capillary, where the solvent is stripped away. Ions are then introduced into a chamber, where they are detected via an electron multiplier. The size of the ions is directly related to the base composition of the PCR product (step 4), which is utilized to determine the identity of the target.

and shear forces result in the release of individual ions (7). In the case of PCR ESI-MS, these ions are components of a single-stranded species. These ions are then introduced into a spectrometer and a mass is determined. Each mass is associated with a unique combination of nucleotides such that for any one mass, the base composition (but not sequence order) is known. By combining multiple primer sets, one can reliably determine the identity of an unknown target with a few different reactions (8).

The iPLEX MassArray system by Sequenom (San Diego, CA) is another system that utilizes MS as a method for detection of a PCR reaction. In the case of the iPLEX, a number of single-base extension PCRs are performed and then analyzed using matrix-assisted desorption ionization–time of flight MS. One of the keys for analysis on this instrument is the utilization of mass-modified terminating nucleotides that allow for the location of the incorporation of these specific nucleotides to be determined. Matrix-assisted desorption ionization–time of flight MS is becoming more common in the diagnostic microbiology laboratory for its ability to discriminate protein profiles of different microorganisms (see chapter 8). The technology used in the iPLEX is similar to that used for identification of organisms except that the starting product is nucleic acid as opposed to bacterial or fungal cellular proteins. After being mixed with an organic matrix to aid in energy distribution, laser energy is utilized to ionize the sample. These ions are then organized in an electric field before release into a drift tube. Ions with a lower mass/charge ratio move faster through the tube, while ions with larger ratios move more slowly. A detector at the end of the tube registers the frequency of ions at any one mass/charge ratio. This technology has been shown to be an effective method of phylogenetic investigation (9) and has potential applications for not only outbreak investigation but pathogen discovery as well.

Methods such as PCR ESI-MS and iPLEX MassArray have the potential to change molecular diagnostics by providing an approach that has limited bias. The question that remains is will these technologies remain restricted to those with the financial resources and expertise, much like next-generation sequencing currently is, or will these technologies become more useful for routine diagnostic laboratories? The ability to assess the composition of dozens of products simultaneously, however, makes these technologies attractive platforms for future development and ensures that they will be ones to monitor in the coming years.

Endpoint Detection by Hybridization

One common way of detecting PCR products while increasing the specificity is to utilize a nucleic acid probe. This probe binds to a complementary sequence internal to the PCR product and can be detected via a variety of methods. While this was initially done using radiolabeled probes, the most common way today is to use different fluorescent probes for each target. The use of fluorescently labeled probes has allowed for the development of real-time monitoring strategies (see below and chapter 1). Many commercial multiplex platforms use target amplification followed by array-based detection in which probes are fixed to a substrate and their spatial location determines their identity. The Nanosphere Verigene system currently has amplification assays for the detection of respiratory and enteric pathogens that use a printed array on a glass slide. The amplified products hybridize to complementary oligonucleotides at specific locations on a glass slide. Secondary mediator probes hybridize to the captured target and allow for further hybridization with the gold nanoparticle signal probes. The Genmark eSensor (Carlsbad, CA) has assays to detect respiratory viruses, distinguish hepatitis C virus genotypes, and identify cystic fibrosis mutations. This platform uses an electrochemical array to identify products. The products of a multiplex PCR reaction are labeled with iron-containing probes. The labeled products then pass through a flow cell over gold electrodes which contain complementary oligonucleotides. If the target of that oligonucleotide is present in the sample, then the ferric probe allows for the completion of an electronic circuit, the position of which determines the identity of the target. The FilmArray system (BioFire Diagnostics, Salt Lake City, UT) combines multiplex and nested PCR with melting curve analysis in their multiplex arrays for respiratory and gastrointestinal pathogens as well as blood culture identification. After nucleic acid purification, an initial large volume massively multiplexed reaction occurs. This reaction mixture is then diluted into wells, where a second-stage single-plex reaction takes place. Each well has a predetermined secondary reaction, such that the presence of a positive signal specifically identifies the target. Additionally, the products of this second, nested reaction are analyzed via melting curve analysis to further increase specificity. Suspension (or liquid)–based arrays where the probe is attached to a specific-sized bead and analyzed via flow cytometry are also available commercially (see "Microarray Technologies" below).

Array-based detection methods greatly expand the number of targets that can be discriminated in a single amplification reaction beyond what can be determined using other methods of endpoint detection such as gel electrophoresis. This has allowed for the development of syndromic panels for infectious disease for conditions such as respiratory infections and gastroenteritis (10–12). Using a syndromic-based approach greatly reduces the diagnostic bias compared to single-plex reactions, though because these methods are still looking for specific targets, they are more biased than methods such as next-generation sequencing or PCR ESI-MS. Because these panels may detect anywhere from 14 to 22 targets, additional measures must be taken to ensure the sensitivity and specificity of the reactions for all analytes. This can be achieved in a number of ways including using multiple reactions for the same target since the product discrimination step is no longer rate limiting. Additionally, since array-based detection of amplified products is an endpoint method, no information is available until the process is complete, which limits the ability to perform these assays rapidly without sacrificing the number of cycles performed in the amplification step. A drawback of some array-based detection technologies is that they require the handling of amplified material in the laboratory, increasing the likelihood of contamination. This typically translates to a need for staff with specialized training and expertise to run these assays while limiting contamination. More assays are being developed like the FilmArray and Verigene, which do not require pre-extraction or manipulation of postamplification material and are more applicable to implementation in laboratories with limited molecular experience.

Real-Time Detection

Hydrolysis probe– or Taqman-based chemistry is at the heart of many real-time detection methods. In hydrolysis probe–based real-time methods, a probe is designed that is

internal to the primers of the target of interest and contains a 5′ fluorophore and a 3′ quencher. See Tables 1 and 2 for common fluorophores and quenchers used in these reactions (13). The advantages of hydrolysis probe–based real-time PCR are its facile adaptation to multiplexing and utility in reporting styles. As long as nonoverlapping fluorophores are used, multiple targets can be queried in the same reaction. This can either be additional targets amplified using different primers or different targets of a variable region amplified by a set of common primers. The assay can provide a positive/negative readout based on whether or not the fluorescent signal crosses a predetermined threshold. This threshold is typically set using control or other known material, and it represents the amount of fluorescence that needs to be generated for a reaction to be considered positive. Different thresholds can be set for different targets in the same reaction to allow for more stringent determination of some analytes (e.g., process or internal control). Finally, results can be reported semiquantitatively using the cycle threshold value because, in general, specimens with lower cycle threshold values start with more template DNA than those with high cycle threshold values. This can be particularly useful in multiplex reactions to determine the relative abundance of the different targets compared to one another.

Many commercial and laboratory-developed multiplex assays use real-time hydrolysis probes, though they all have similar strengths and weaknesses. These assays are easy to design and relatively simple to implement since many molecular laboratories already have the necessary equipment. Since the detection step occurs during the reaction, there is no need to have additional equipment such as that needed for mass spectrometry or array-based detection of multiplex products. These assays can also be performed and resulted quickly since there are no additional steps after the reaction is set up. Finally, real-time detection allows the evolution of the reaction itself to be queried. This can play an important role in discerning falsely positive or negative results, which is not possible with endpoint detection methods. The main problem with hydrolysis probe–based real-time detection is that it is limited by the number of unique emission wavelengths that can be read by the spectrophotometer. In most cases this limits the number of members of the multiplex reaction to between 2 and 6 (13). This limits not only the number of targets that can be queried in any one reaction, but introduces challenges in assay design because there is typically no room for the redundancy seen with array-based detection methods. Thus, targets must be chosen carefully for each assay.

In addition to being a method of endpoint detection, melting curve analysis can also provide real-time results. The LightCycler instrument (Roche Diagnostics, Indianapolis, IN) has multiple assays, both laboratory- and commercially developed, that utilize this technology. The CE-marked SeptiFast test is one example that can detect eight different Gram-negative bacteria, six different Gram-positive bacteria, and six different fungi from a whole-blood sample in a few hours, with modest performance compared to blood culture (14).

Scalable transcriptional analysis routine (STAR) combines PCR with real-time capillary electrophoresis. The Modaplex (also ICEplex) system by PrimeraDx (QIAGEN, Mansfield, MA) has several research-use-only kits available including assays for sexually transmitted infections and a viral panel designed for transplant recipients. For a STAR experiment, each target of interest has primers that generate a fluorescently labeled product. Each target must have a size variation of at least 5 nucleotides for the product to be distinctly resolved. After each round of PCR, a small aliquot of the reaction is removed and subjected to capillary electrophoresis. The area under each target on the electropherogram is used to reconstruct amplification curves. These reconstructed curves can then be treated similarly to real-time PCR curves for the determination of a cycle threshold or even quantification. Studies have shown that using STAR for the quantification of gene transcripts is equivalent to either TaqMan or SYBR Green–based methods with increased signal generation (15). STAR has a number of additional advantages over traditional real-time PCR including increased tolerance of amplicon size (up to 1,000 bp). Additionally, because STAR uses incorporation of a fluorescent primer, the system eliminates the need for a probe and allows for quantitation based on the presence of the product, not a byproduct of the reaction as with hydrolysis probes (16).

Multiplex detection of amplified products has a number of benefits. Multiplexing allows for more targets to be queried using the same amount of input specimen or nucleic acid, which is ideal for situations where volume is limited due to specimen type. Multiplexing also reduces a component of sample bias since all of the targets in the reaction query the same input nucleic acids. This can be especially valuable when looking for things such as polymorphisms or other small nucleotide changes. The expansion of methods of detection such as arrays and STAR has allowed for the development of massively multiplexed reactions with dozens of primer sets used in a single reaction capable of being discriminated from each other. One major drawback to multiplex reactions, however, is that oftentimes these methods are less specific and/or less sensitive than corresponding single-plex reactions. This primarily is due to sacrifices made in either primer design or reaction conditions to allow multiple sets of primers to work simultaneously, albeit at different efficiencies. Additionally, even though massively multiplexed platforms are playing a larger role in diagnostic testing, they still represent a biased approach. Whether an unbiased approach such as next-generation

sequencing is capable of matching the speed and value of multiplex amplification reactions remains to be seen. Until it does, however, multiplex amplification will remain a staple of diagnostic laboratories.

MICROARRAY TECHNOLOGIES

Similar to the PCR revolution, hybridization array technologies have transformed the complex analysis of transcriptomes, genomes, and proteomes in the research setting and have begun to modernize multiplex detection in the clinical diagnostic arena. Simply defined, an array is a collection of macroscopic or microscopic features that can be probed with target molecules to produce either qualitative or quantitative data. Though other arrays exist, such as protein arrays (17, 18), the focus of this section is DNA-based hybridization array technology.

Microarrays can be distinguished based on characteristics such as the nature of the probe, the type of solid surface support used, and the methodology of feature addressing or target detection. This section reviews the methodologies of cDNA, oligonucleotide, and suspension bead arrays. In each of these methodologies, the probe refers to the DNA sequence bound to the solid surface support in the microarray, whereas the target is the "unknown" sequence of interest. In general terms, the probes are synthesized and immobilized as discrete features, or spots. Each feature contains millions of identical probes. The target is labeled fluorescently and subsequently hybridized to the probe microarray. The fluorescence intensity of a successful hybridization event between the labeled target and the immobilized probe is measured by a fluorescent scanner, the data from which can then be analyzed by a variety of methods depending on the individual experiment. Experimental specifics such as probe length and synthesis, number of possible features (density of the microarray), and the solid surface used vary depending on the type of microarray employed and are discussed below.

Printed Microarrays

Printed arrays were the first type of microarray used in research settings and are so called because of the spotting, or "printing," of the probes onto the microarray surface, typically a glass microscope slide. There are a multitude of advantages to using glass slides, including that they are inexpensive, durable throughout high temperatures and stringent washes, and nonporous, allowing for effective kinetics of hybridization, and they have low background fluorescence (19). Printing occurs via either a contact or a noncontact printer. In contact printing, each print pin directly applies a solution of the probe to the slide, resulting in the application of a few nanoliters of probe solution to create a feature of ~100 to 150 μm in diameter. Noncontact printing uses the same technology as computer printers (i.e., bubble jet or ink jet) to expel small droplets of probe solution on the surface. Regardless of the method of printing, contamination control and printing consistency are crucial to preserving the quality of the printed microarray and subsequent hybridization data. Printed microarrays allow for ~10,000 to 30,000 features to be queried, which is a considerably lower density than synthesized oligonucleotide microarrays but a higher density than suspension bead arrays, discussed below. Printed arrays can be further characterized as double-stranded DNA (dsDNA) or oligonucleotide microarrays based on the nature of the probes. Figure 3 depicts a general workflow for the processing of printed microarrays.

In dsDNA microarrays, PCR amplicons are used as the probes. Probes can be amplified using primers designed from known genomic sequences, from shotgun library clones, or from cDNA (20–22). Ideally, each dsDNA probe (amplicon) is 200 to 800 bp and represents a different gene. Amplicon probes generally have a high sensitivity but may suffer in specificity. Hager et al. reported that 21 to 34% of probes either did not match the intended target and/or were contaminated (23). The decreased specificity of dsDNA probes may be beneficial if the user is interrogating regions rich in natural polymorphisms but detrimental if the user requires discrimination of highly similar target sequences (24). Redundancy in the inclusion of multiple gene segments increases the specificity of downstream hybridization experiments. While the production of a single PCR amplicon is straightforward, when this is scaled up to the thousands of amplicons needed for a pan-microbial array or bacterial genome, quality control and information management, as well as efficiency and accuracy, are challenging. PCR amplicons for microarrays must have maximum specificity, maximum yield, and no contamination (due to either nonspecific amplification or contaminants that affect attachment to the microarray surface or that autofluoresce) (25). The purity and quantity of the amplified product should be assessed by agarose gel electrophoresis, followed by sequencing if financially feasible. Attachment of amplicons to the glass slide surface typically occurs by the electrostatic interaction of the negative charge of the phosphate backbone of the dsDNA with a positively charged coating of the slide surface (26). In addition, UV cross-linking can be used to form covalent bonds between the thymidine bases in the DNA and amine groups on treated slides (19).

Oligonucleotide microarrays use short chemically synthesized sequences as the spotted probes. The length of probes typically used in printed microarrays varies from 25 to 80 bp, but Chou et al. report that 150-mer probes are optimal for gene expression microarrays (27). The shorter probe length of oligonucleotide microarrays may adversely affect sensitivity and specificity as compared to dsDNA probes, but they are also less prone to errors during production. Generally, sensitivity and specificity increase with the length of the probe, as does the strength of the hybridization signal. If shorter probes are needed experimentally, the hybridization signal strength can be improved by using spacers or a higher concentration of probe during printing (27). Very long probes may adversely affect specificity due to random matching to nontarget sequences. Thus, it is critical to carefully determine optimal probe length for each microarray design. The probe length also determines how many replicates of the probe or other gene target sequence are needed on the microarray to allow for optimal specificity; i.e., longer probes need fewer probes per gene. Oligonucleotide probes, though easier to manufacture, must be designed such that all probes have similar melting temperatures (within 5°C) and are void of palindromic sequences. Ideally, each probe should be tested experimentally to ensure nonbiased hybridization data (27). Oligonucleotide probes are attached to glass slides by covalent coupling of their modified 5′ or 3′ ends (usually a 5′ amino group) to coated slides that provide aldehyde or epoxy functional groups. Covalent linkage is necessary because, in contrast to dsDNA probes, a significant portion of oligonucleotide probes would be lost during subsequent

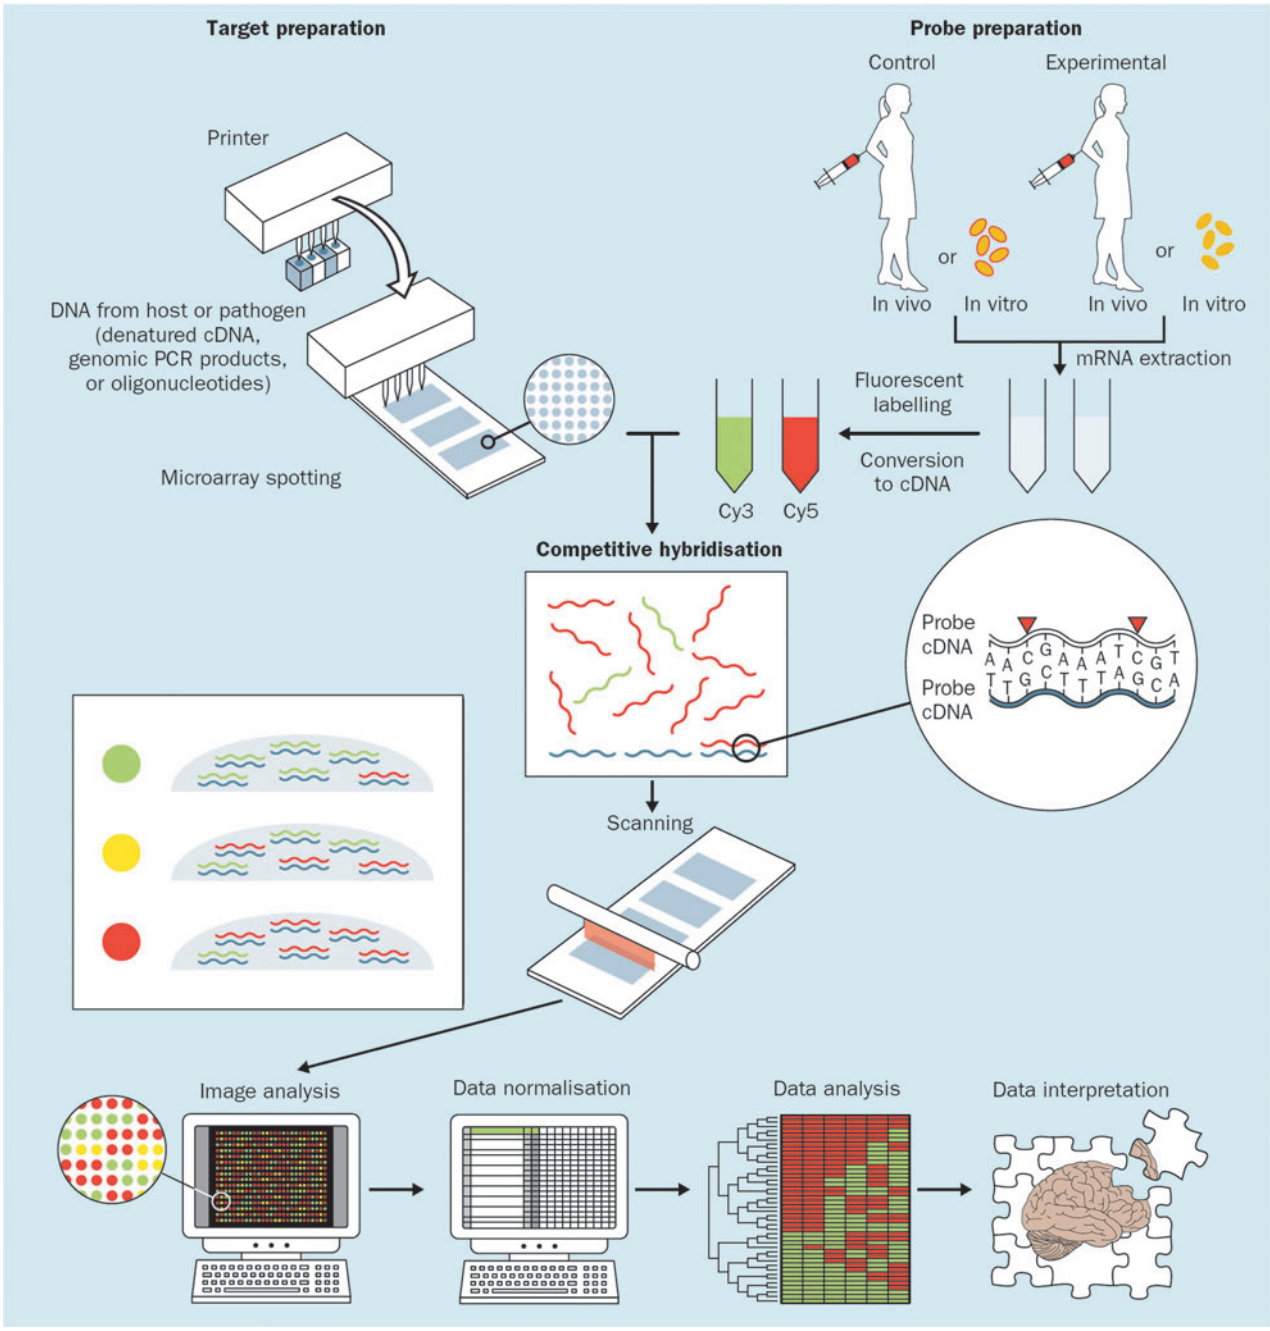

FIGURE 3 General workflow of printed microarrays. Probe preparation begins with the production of either denatured cDNA, genomic PCR products, or oligonucleotides that are subsequently spotted in an array format on a glass slide. In this example, two samples (one control and one experimental) are being compared by extracting mRNA and converting the RNA sets into differentially labeled cDNA sets for hybridization. The inclusion of multiple fluorescent labels allows for color differentiation based upon the quantity of target cDNA from each set that hybridizes to the microarray probes. The fluorescence signal is then scanned and analyzed. Reprinted from reference 55 with permission from Elsevier.

wash steps due to their small size. However, an advantage of the shorter probes is the ability to interrogate smaller genomic regions, such as polymorphisms.

Printed microarrays have the advantages of simplicity and relatively low cost compared to synthesized microarrays, discussed below. Nonetheless, the initial setup of microarray facilities is relatively expensive and requires a dedicated environmentally controlled space, with dust, humidity, and temperature well regulated. Many universities have dedicated microarray core facilities to overcome these challenges. However, these laboratories are generally not Clinical Laboratory Improvement Amendments certified, thereby limiting their diagnostic capability. Printed microarrays are most conducive to user-defined testing, which has largely been limited to microbiology researchers. However, the ability to quickly adjust spotted probes based on

updated annotations or the discovery of new, emerging pathogens makes this approach attractive for potential diagnostic applications. Drawbacks include the laborious production of PCR products or design of oligonucleotide probes and the errors introduced from probe synthesis. Though there are commercially available whole-genome microarrays for select organisms that are useful for research endeavors, there are no commercially available printed microarrays applicable for use in diagnostic microbiology.

In Situ Synthesized Microarrays

Synthesized arrays are high-density microarrays in which the synthesis of the oligonucleotide probes occurs directly on the surface of the array, i.e., *in situ* synthesis. The most widely known *in situ* synthesized microarrays are the GeneChips (Affymetrix, Santa Clara, CA). In contrast to printed oligonucleotide microarrays, *in situ* synthesized arrays are typically made of very short probes (20 to 25 bp), and 11 to 15 probes per target are included to improve analytical performance and statistical accuracy. Probes are manufactured in terms of probe sets: one perfect match probe and one mismatch probe that contains a 1-bp difference in the middle position of the probe (typically position 13 of a 25-bp probe). The use of probe sets increases the specificity of using a very short probe because the mismatch probe acts as a negative control to identify possible nonspecific cross-hybridization events. Generally 11 probe sets are used per 600 bases being interrogated (28). Each probe within a probe set is located in a separate feature.

Manufacturing of GeneChips occurs on a quartz wafer using semiconductor-based photochemical synthesis, which allows for $>10^6$ features on a typical 1.28-cm^2 array, depending on the interfeature space (28, 29). The quartz wafer is modified such that the surface offers hydroxyalkyl groups which can be covalently linked to photo-labile protecting groups. This creates a surface that prevents the addition of reactive nucleotides unless the surface is spatially activated by light. Photolithographic masks are used that have windows acting as filters to either transmit or block UV light from the chemically protected microarray surface. The pattern of windows in each mask represents the desired sequence content for each probe to be included on the microarray by instructing the order of nucleotide addition. UV light deprotects the exposed surface of the microarray, which allows for nucleotide coupling. Areas of the microarray surface in which UV light has been blocked remain protected from the addition of nucleotides. Each added nucleotide is modified with a light-sensitive protecting group such that the synthesis of the oligonucleotide probes occurs by cycling through masking, light exposure, and the addition of either A, C, T, or G bases to the growing oligonucleotide (Fig. 4) (26, 28).

Though GeneChips have been the most utilized to date in the literature, Agilent (Palo Alto, CA) also manufactures high-density oligonucleotide microarrays based on 60-mer probes and inkjet technology. The use of longer oligonucleotides reportedly increases sensitivity by 8-fold relative to GeneChips (30). Agilent microarrays synthesize 60-mer oligonucleotides on glass slides using five-ink (four bases plus catalyst) inkjet printing of nucleotide precursors combined with phosphoramidite chemistry (31, 32). Thus, lithographic masks are not needed.

Synthesized microarrays are not conducive to self-manufacturing, but rather rely on commercial manufacturing. There are limited numbers of different microorganism genome arrays currently available, and commercial customized microarrays are not easily updated and are very expensive. The advantages of these systems are the reproducibility of the manufacturing process and the standardization of reagents, instrumentation (fluidics system, hybridization oven, scanner) and data analysis (28). Additional advantages include controls such as reference probes for intensity normalization, internal standards of known concentrations, and probes arranged in a checkerboard pattern that are homologous to an internal control included in the hybridization mix. It should be noted that experiments performed with GeneChips are limited to one label, whereas Agilent allows for two-color hybridizations. Oligonucleotide microarrays (printed and synthesized) overall allow for much cleaner downstream data than amplicon-based microarrays. This is due to the ability to standardize probe concentrations and hybridization temperatures while avoiding significant nonspecific hybridization (24). Though synthesized oligonucleotide arrays are very robust systems, none are currently commercially available with direct diagnostic microbiology applications.

Suspension Bead Arrays

Expanding on the two-dimensional arrays discussed above, suspension bead arrays are essentially three-dimensional arrays based on the use of microscopic polystyrene spheres (microspheres) as the solid support. Suspension bead arrays build on the well-established technique of flow cytometry to provide multiplexing capability. Initial bead-based assays focused on the detection of antigens and antibodies and were first described in 1977 (33). Early multiplexing approaches used different-sized microsphere sets for the simultaneous detection of two to four antibodies (34, 35). To extend the multiplexing capability of microsphere-based assays, two different fluorochromes (red and infrared, 658-nm and 712-nm emission) are used at varying concentrations to fill 5.6-μm microspheres. Each microsphere then has a specific spectral address based on the red/infrared ratio within the microsphere such that the identity of each of 100 beads is distinct. Microspheres with specific spectral addresses can be coupled to a specific oligonucleotide (probe) that is unique for the target nucleic acids of interest. Once the individual microspheres have been coupled, a mixture of microspheres can be used to probe the sample type of choice. Thus, one can theoretically detect 100 features simultaneously using modern liquid bead array technology. Similar to planar arrays, the target is detected using a third fluorescent reporter.

After target hybridization, the microsphere suspension is analyzed using flow cytometry instrumentation. Luminex Corporation (Austin, TX) developed compact cytometers that specifically detect and process their proprietary microspheres with a high signal-to-noise ratio. The cytometers have two different lasers that the single-file microsphere suspension flows past. A 635-nm laser excites the fluorochromes contained within the microspheres, which allows for the identification of the bead and therefore the probe being analyzed. A 532-nm laser excites the reporter fluorochrome (most commonly, *R*-phycoerythrin or Alexa 532) to quantify the probe-target reaction on the microsphere surface (Fig. 5). The X-Y platform of these compact systems facilitates the reading of 96-well microtiter plates and therefore increases throughput.

Using the principles of the above technology, several chemistries have been developed for nucleic acid detection

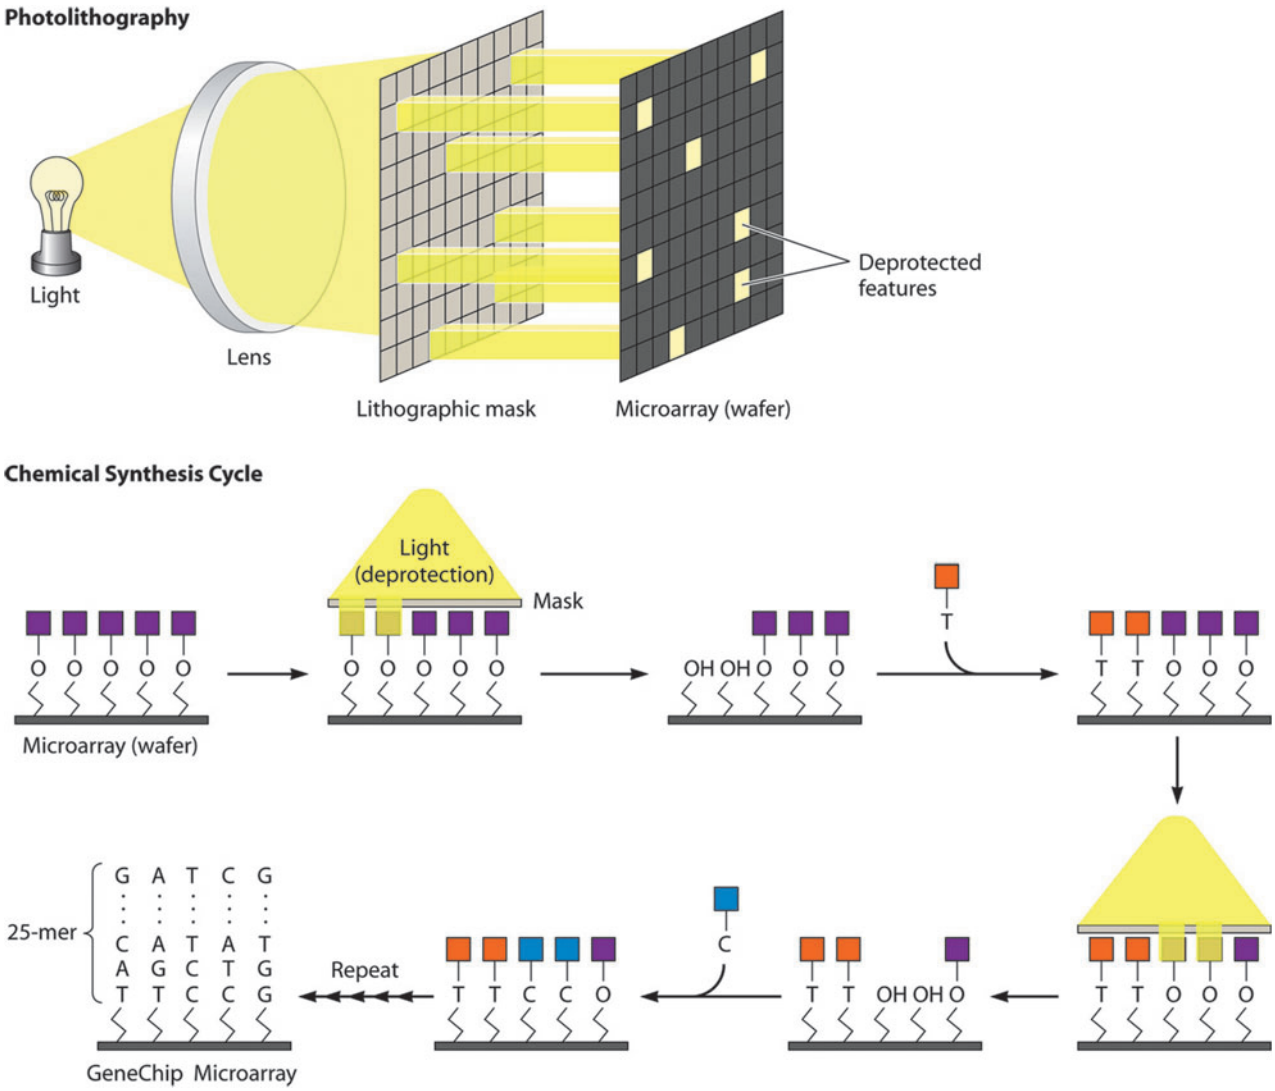

FIGURE 4 GeneChip oligonucleotide microarray. Photolithography: UV light is passed through a lithographic mask that acts as a filter to either transmit or block the light from the chemically protected quartz wafer. Multiple lithographic masks are applied sequentially to determine the sequence synthesis on the microarray surface. Chemical synthesis cycle: As the mask-filtered UV light removes the protecting groups (squares), a single nucleotide washed over the microarray surface is able to couple to the deprotected oligonucleotide chains. Sequential rounds of nucleotide addition combined with changes in the masks form a quartz wafer with 25-mers of predetermined sequence. such as direct DNA hybridization, competitive DNA hybridization, and solution-based chemistries with microsphere capture (36). The earliest assays using liquid bead arrays used the direct hybridization format (37, 38). Direct DNA hybridization uses fluorescently labeled PCR amplicons hybridizing directly to probe capture sequences immobilized on the microspheres. Typically, one of the primers is biotinylated, and a positive hybridization event at the bead surface is measured using streptavidin-*R*-phycoerythrin (Fig. 5, upper inset). In competitive DNA hybridization, unlabeled PCR amplicons compete with labeled oligonucleotides for hybridization to the microsphere-bound capture probes. In this instance, the competitor DNA is biotinylated. The absence of target DNA in the sample results in a positive hybridization event between the labeled competitor DNA and the capture probe on the microsphere and therefore increased fluorescent intensity. The presence of target DNA in the sample binds the labeled competitor DNA and results in low fluorescent intensity.

Solution-based chemistries, including allele-specific primer extension (ASPE), oligonucleotide ligation assay, and single base chain extension, take advantage of the inherent properties of DNA polymerases and ligases and employ unlabeled primers (Fig. 5, lower inset) (36). These chemistries incorporate a capture sequence during the solution-based extension or ligation reaction. During ASPE, the capture primer is only extended if the 3′ nucleotide is homologous to target DNA. In ASPE, one of the deoxynucleoside triphosphates (dNTPs) is biotinylated. Like ASPE, oligonucleotide ligation assay uses a capture primer but is ligase-dependent as opposed to polymerase-dependent. In oligonucleotide ligation assay, a reporter probe homologous to target DNA is biotinylated; ligation only occurs if the complementary target DNA is present in the sample. Single

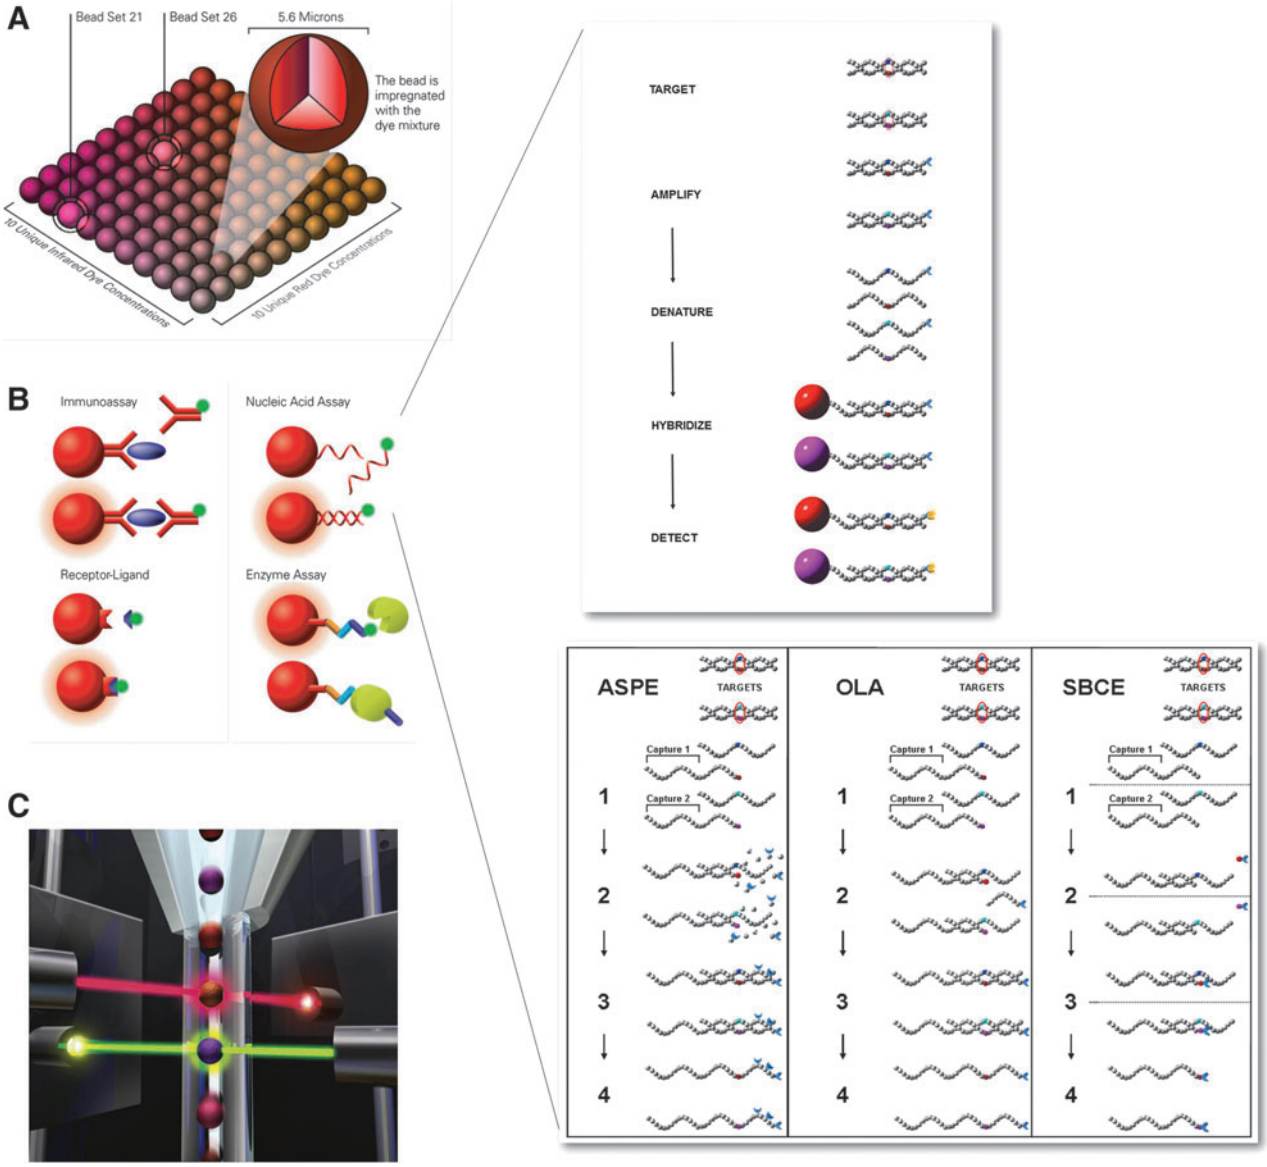

FIGURE 5 Suspension bead microarray. (A) Microspheres 5.6 μm in diameter are filled with varying concentrations of an infrared dye and a red dye to create 100 spectrally distinct beads. (B) Microspheres can then be used in a variety of assays depending on the ligand bound to the bead surface. (Upper inset) Suspension bead direct hybridization. The target is amplified using a biotinylated primer and subsequently denatured and hybridized to microspheres tagged with target-specific sequence probes. A positive hybridization reaction at the microsphere surface is detected using streptavidin-*R*-phycoerythrin. (Lower inset) Solution-based chemistries for microsphere capture. ASPE (allele-specific primer extension): 1, denaturation of target DNA in the presence of specific capture sequence-tagged primers; 2, annealing of target DNA and primers; 3, primer extension and incorporation of biotinylated dNTP; 4, capture sequence-tagged ASPE products. OLA (oligonucleotide ligation assay): 1, denaturation of target DNA in the presence of capture sequence–tagged allele-specific probes; 2, annealing of target DNA and probes in a reaction containing a DNA ligase and biotinylated reporter probe; 3, oligonucleotide ligation; 4, capture sequence–tagged OLA products. SBCE (single base chain extension): 1, denaturation of target DNA in the presence of a capture sequence–tagged primer (in separate reactions for each allele); 2, annealing of target DNA and primers; 3, single base primer extension with incorporation of biotinylated ddNTP; 4, capture sequence-tagged SBCE products that can be multiplexed for detection. (C) After hybridization with the target of interest, the microsphere suspension is analyzed using a flow cytometer. A red laser (635 nm) excites the impregnated dyes of the microspheres to determine the spectral identity of the bead and therefore the probe being analyzed. A green (532 nm) laser excites the reporter fluorochrome to quantify the probe-target reaction on the microsphere surface. Insets reprinted from reference 36 with permission from Elsevier. base chain extension requires separate reactions for each nucleotide query and is used specifically for single nucleotide polymorphism (SNP) detection. A biotin-labeled dideoxynucleoside triphosphate (ddNTP) serves as the chain terminator when the target sequence is homologous to the capture sequence. For every SNP, one oligonucleotide probe with a unique capture sequence is used to assay the two alleles in each of two separate wells with a different labeled ddNTP per well (39). This technique allows for multiplex SNP analysis.

Arguably the most powerful and expansive application of these chemistries is the use of universal capture sequences. The first microsphere-based universal sequences were the ZipCode/cZipCode capture sequences originally used with single base chain extension in SNP genotyping assays (39–42). These 25-bp capture sequences were based on random sequences from the *M. tuberculosis* genome (39). A DNA sequence (ZipCode) is included in the 5′ end of the capture probe, while the complementary sequence (cZipCode) is used to tag specific microspheres. Subsequently, Tm Biosciences (Luminex Molecular Diagnostics, Inc., Toronto, Canada) developed the xTAG (formerly Tag-It and FlexMAP) sequences for use in their assays marketed for clinical use and user-defined assays. The specificity of the xTAG capture sequences resides in their use of only three of the four nucleotides; thus, these sequences are unlikely to hybridize to naturally occurring sequences. In addition, all of the xTAG sequences are matched such that the thermodynamics and hybridization efficiency are not variables in the target hybridization reaction. While the first described use of this technology used competitive hybridization in an HLA assay (43), the applications of the xTAG technology have expanded such that it is used in all commercial assays available through Luminex.

Diagnostic Challenges and Applications of Microarrays

Since its inception in research laboratories in the 1990s, microarray technology has continued to improve due to advances in fabrication, robotics, and bioinformatics as well as the rapid increase in available genomic sequences. Though microarrays have become the preferred method for gene expression analyses, they have yet to routinely replace traditional and other molecular methods (such as real-time PCR) in diagnostic microbiology. For microarray analysis to become a key diagnostic technology in pathogen detection, antimicrobial resistance detection, and genotyping, many obstacles still need to be addressed (see below). It is unlikely that "conventional" planar microarrays will transition into diagnostic laboratories, due to the costs associated with producing and analyzing them, as well as the limited sample throughput they offer. A low-density microarray that offers limited, reliable, and straightforward results without sophisticated equipment and data processing is most appropriate for routine clinical diagnostics and will better comply with regulatory requirements (44). Alternative array platforms, such as suspension bead arrays, have begun to meet these criteria.

With the potential power of microarray analysis come abundant challenges, particularly in relation to the diagnostic laboratory. Clinical implementation of microarrays requires careful consideration of verification and validation methods, quality control monitoring, and reimbursement strategies, to name a few. Additionally, one must account for assay reproducibility in production and analysis, cost of implementation, acquiring the training and skill level needed for execution, as well as information management and intellectual property obstacles. One major drawback to many microarray platforms is the limitation of one patient per chip. Multicolor analysis does allow for the comparison of two samples, but this is not applicable to patient specimens. A major preanalytic challenge not discussed in this chapter is efficient and reproducible sample preparation. Because microarrays can potentially detect nucleic acids from a wide variety of taxa (bacteria, viruses, fungi, protozoa, human), different strategies may be required for sufficient recovery of target nucleic acids. In addition, controlling the coextraction of inhibitors needs to be accounted for in the analytical process. Compared to real-time PCR, microarray analysis requires additional steps such as hybridization and washing, which increases the risk of contamination and the amount of hands-on time needed.

Even with these challenges, microarrays are being used for diagnosing infectious diseases, which can be categorized into two main applications: detection of known pathogens and discovery of novel or uncharacterized microorganisms (45). As mentioned above, low-density microarrays are best suited for detection of known pathogens, in part due to their lower complexity and costs. For targeted detection, fewer features (spots or beads) are needed to detect the most common infectious agents. High-density arrays, including resequencing arrays, are best suited for large surveillance studies and/or pathogen discovery, but their use clinically is limited by their increased complexity and costs. Like other multiplex platforms, microarrays allow for syndromic testing or the detection of numerous pathogens that cause similar clinical presentations.

Diagnostic tests that are both FDA-cleared and CE-marked rely on the suspension bead array technology by Luminex. A respiratory viral panel for the detection of influenza A, influenza B, respiratory syncytial virus, parainfluenza viruses 1 through 3, metapneumovirus, adenovirus, and rhinovirus/enterovirus is commercially available in the United States. The Canadian and European versions of the test also include parainfluenza virus 4 and coronaviruses. More recently, a gastrointestinal pathogen panel has become available which detects *Campylobacter*, toxigenic *Clostridium difficile*, *E. coli* O157, enterotoxigenic *E. coli*, Shiga-like toxin–producing *E. coli*, *Salmonella*, *Shigella*, *Vibrio cholerae*, adenovirus 40/41, norovirus GI/GII, rotavirus A, *Cryptosporidium*, *Entamoeba histolytica*, and *Giardia*. In addition, *Yersinia enterocolitica* is included in markets outside of the United States.

Genomica (Coslada, Spain) offers numerous CE-marked low-density microarrays for *in vitro* diagnostic testing outside of the United States, including detection and typing of human papillomavirus and respiratory viruses; detection of bacterial respiratory pathogens, enteroviruses and herpes viruses, gastrointestinal pathogens, and sexually transmitted infectious agents; and pan-microbial identification from positive blood cultures. The Genomica microarrays use Clinical Array Technology (CLART), which comprises multiplex PCR with subsequent analysis by low-density microarray. The CLART Entherplex microarray (enteroviruses and herpes viruses) has been used to detect infectious causes of encephalitis and meningitis with high accuracy; notably, it detected several previously undetected co-infections (46). The CLART PneumoVir (respiratory viruses) and FluAVir (influenza detection and typing) microarrays have been used to diagnose infections in patients with influenza-like illness and in infants hospitalized with bronchiolitis (47, 48). Depending on the level of service a diagnostic laboratory provides, these microarrays could serve as front-line testing (i.e., national centers, epidemiologic surveillance) or could be implemented as part of a testing algorithm. For example, a more rapid diagnostic test could be used first with only negative specimens or specimens from critically ill patients receiving additional testing by microarray analysis (49).

Low-density arrays, such as the ViroChip developed by DeRisi and colleagues (Howard Hughes Medical Institute

and University of California, San Francisco), have been used to identify emerging viruses such as severe acute respiratory syndrome coronavirus and parainfluenza virus 4 and known viruses causing unusually severe clinical presentations (50–52). High-density microarrays have been developed by Lipkin and colleagues (Columbia University, NY) that detect a large number of known pathogens and also allow for pathogen discovery (53, 54) (see chapter 7). While these microarrays are not used in routine diagnostic laboratories, they have been very beneficial in identifying new and emerging infectious agents for which more targeted assays can later be developed and used diagnostically.

SUMMARY

The evolution of molecular technology to allow for multiplex amplification and detection has provided a number of commercially available diagnostic products that allow for syndromic-based testing. These tests range from rapid identification of organisms from positive blood cultures to detecting common pathogens associated with acute respiratory tract infections and gastrointestinal infections. The ability to multiplex has allowed some of these platforms to detect not only the potential pathogen but also resistance genes. Since many infectious agents clinically present very similarly, it stands to reason that a syndromic-based diagnostic approach has the potential to greatly benefit the patient, the clinical provider, and the laboratory. In addition, many academic medical centers and large health care systems have developed their own user-defined multiplex assays for targeted or syndromic-based testing. This type of testing aims to reduce the number of tests ordered on any single patient, ultimately providing better patient care. Although these tests can be very expensive when compared to more traditional diagnostic tests, the overall financial and clinical impact must be considered. In general, the less expensive options of hybridization and PCR are more widely used in the clinical laboratory than the more expensive, though more robust, options of microarrays, mass spectrometry, and next-generation sequencing. It remains to be seen whether the cost of next-generation sequencing will continue to decrease to allow its use in diagnostic microbiology laboratories and therefore replace some of the technologies discussed here. It is likely that, for the foreseeable future, due to the wide variance in molecular expertise among diagnostic laboratories, next-generation sequencing will not replace multiplex hybridization, signal and target amplification methods, and suspension bead arrays because they provide a cost-effective approach to syndromic-based testing and require only limited to moderate molecular expertise and analysis.

The Skin Microbiome: Insights into Potential Impact on Diagnostic Practice

ELIZABETH A. GRICE

10

THE SKIN HABITAT

No type of culture medium can exactly replicate the complex environment of the skin surface. Slightly cooler than body temperature, exposed to the external environment, and generally arid compared to other body habitats, the skin presents a formidable challenge for the colonization and growth of most microorganisms. To fully appreciate the microbial complexity of the skin, one must first be familiar with the unique features of the skin as a habitat. The outer layer of the skin, the epidermis, is composed of keratinocytes in various stages of differentiation. The most superficial layer of the epidermis, the stratum corneum, forms a semi-impenetrable barrier consisting of several layers of dead, flattened, enucleated, polyhedral, keratin-filled cells, termed corneocytes. Through the process of desquamation, corneocytes are continuously shed from the skin surface through terminal differentiation, providing a continuous supply of nutrients (i.e., keratins) to support the growth of microorganisms. Beneath the epidermis lies the dermis, a connective tissue layer rich in blood and lymphatic vessels. Subcutaneous connective tissue and fat separate the skin from the muscles and organs of the body.

Within the skin, several types of appendages are present, which present unique microenvironments for the skin's inhabitants. Eccrine sweat glands function in temperature regulation and are most densely concentrated on the palms and the soles of the feet. Eccrine secretions consist of primarily water and sodium chloride and, notably, small amounts of antimicrobial peptides. Apocrine sweat glands are present in much fewer numbers than eccrine sweat glands and are most densely concentrated in the axilla and the anogenital area. Apocrine glands have no known useful function but are responsible for the characteristic body odor. Apocrine secretions consist of proteins and lipids that are odorless until acted upon by skin bacteria.

The pilosebaceous unit consists of the hair follicle and the associated sebaceous gland. Sebaceous glands secrete sebum, an oily substance consisting primarily of triglycerides. These glands are most dense on the face and scalp but are found on all of the skin except the palms of the hands and the soles of the feet. Sebum exits from the hair follicle and functions in emolliating and waterproofing the skin. Sebaceous gland size and secretions are under androgenic control and thus become active and attain full size around puberty.

Elizabeth A. Grice, Perelman School of Medicine, Department of Dermatology, University of Pennsylvania, 421 Curie Blvd., 1007 BRB II/III, Philadelphia, PA 19104.

OVERVIEW OF THE SKIN MICROBIOTA

Bacteria

Culture-based isolation of the healthy human skin microbiota most frequently recovers coagulase-negative staphylococci, with *Staphylococcus epidermidis* and *Staphylococcus hominis* being the most abundant isolates (1). These coagulase-negative staphylococci mainly live a commensal lifestyle but can cause nosocomial infection in patients with indwelling or implanted devices (2). Once classified as a *Corynebacterium* species, *Propionibacterium acnes* is also frequently recovered from the skin by cultures. *P. acnes* is a facultatively anaerobic, Gram-positive inhabitant of the hair follicles and sebaceous glands but is also implicated in acne (3). *P. acnes* hydrolyzes triglycerides found in sebum, thus releasing free fatty acids on the skin that then function to acidify and emolliate the skin (4). Particularly favoring the intertriginous regions, the *Corynebacterium* species are somewhat lipophilic, Gram-positive, slow-growing organisms. Species commonly isolated from the skin are *Corynebacterium jeikeium*, *Corynebacterium minutissimum*, *Corynebacterium tenuis*, and *Corynebacterium xerosis*. *Brevibacterium* is also considered a coryneform bacterium, is frequently isolated from the feet, and is implicated in foot odor (1). Gram-negative bacteria are less commonly cultured from the skin, but *Acinetobacter* isolates may sometimes be isolated from intertriginous, moist areas.

Molecular approaches, based on sequencing of the prokaryotic 16S rRNA gene, have revealed an even greater diversity of bacteria present on the human skin. These approaches require broad-range amplification of the 16S rRNA gene, encompassing at least one of the nine hypervariable regions. The hypervariable regions contain sequences that allow taxonomic classification of the bacteria. While Sanger sequencing was initially utilized for bacterial community characterization based on the 16S rRNA gene, high-throughput sequencing technologies that have emerged in recent years such as 454 GS FLX (Roche,

Branford, CT) and MiSeq/HiSeq (Illumina, San Diego, CA) are now most commonly employed for these studies. The studies described below will be primarily those that employ 16S rRNA sequencing-based approaches unless otherwise specified.

Fungi

Culture-independent studies analyzing fungal skin communities have lagged behind bacterial community studies, in part due to slower development of the appropriate databases and tools. Similar to bacterial 16S rRNA studies, fungal diversity may be characterized by sequence analysis of its ribosomal RNA genes, but which gene and/or amplicon to choose is not always clear. The three most commonly used ribosomal amplicon targets are the 18S rRNA gene, the 5.8S rRNA gene, and the internal transcribed spacer region. Generally, the internal transcribed spacer is the most effective locus for providing species-level identification. In fact, this locus is now commonly used as the fungal "species barcode" region because it nearly always contains a sufficient level of variation for species differentiation (5, 6). The 18S and 5.8S loci are more conserved and are therefore most effective for phylogenetically based analyses (7).

By far the most common fungal inhabitants of the skin are the *Malassezia* species (formerly *Pityrosporum* species), as demonstrated by both culture-dependent and -independent techniques (8–10). *Malassezia* is less frequent on the skin of prepubescent individuals (10), indicative of its lipid dependency. Just as the bacterial microbiota of the skin varies topographically, so too does the fungal microbiota. A culture-independent, topographical analysis of the skin of 10 healthy adults at 14 skin sites demonstrated that *Malassezia* dominated core body and arm sites, but sites on the foot were characterized by much greater diversity including *Trichophytum*, *Penicillium*, and *Aspergillus* (8). Further, *Malassezia* species differed in relative abundance by topographical location, with *Malassezia restricta* predominating on the head and face and *Malassezia globosa* predominating on the trunk.

Demodex Mites

A unique feature of the skin microbiota, as compared to other body sites harboring microbial communities, is the presence of the arachnid skin mite, *Demodex*. *Demodex*, particularly *Demodex folliculorum* and *Demodex brevis*, colonizes the pilosebaceous units and increases in prevalence with age (11). *Demodex* produces lipases and utilizes sebum as a food source (12). Other nutritional sources may be cellular debris or bacteria such as *P. acnes* that reside in close proximity within the pilosebaceous unit (9).

While there are currently no reported molecular typing schemes to identify and speciate *Demodex* mites, their discussion is worthwhile because they may both directly and indirectly (through their gut microbiota) contribute to rosacea, a chronic inflammatory disorder affecting the face. Increased density of *Demodex* has been associated with rosacea, particularly the subtypes erythematotelangiectatic rosacea and papulopustular rosacea (13–15). These associations are somewhat controversial, though, because systemic tetracycline treatments improve rosacea without a concurrent decrease in mite populations (16). *Bacillus oleronius*, a Gram-negative bacterium that is a part of the *Demodex*-associated microbiota, has been suggested to play a role in rosacea and triggers inflammatory pathways in a manner reflective of rosacea (17). Serum reactivity to *B. oleronius* proteins was found in 82.6% of rosacea patients, compared to only 26.9% of healthy controls (18). Increased production and aberrant processing of cathelicidin, a cutaneous antimicrobial peptide, are also associated with rosacea (19), which in part may contribute to dysbiotic cutaneous states.

Viruses

Unlike bacteria and fungi, characterization of skin-associated viruses and bacteriophage presents a unique difficulty since they lack a consensus gene that can be amplified and sequenced for widespread taxonomic identification. The phylogeny of closely related groups may be analyzed using specific conserved genes, such as the human papillomavirus (HPV) L1 gene. Comparative genome analysis is further complicated by the high frequency of gene transfer between virus and host genomes and the lack of comprehensive, annotated reference databases and assigned taxonomy. Whole-genome shotgun metagenomics, which does not rely on amplification and sequencing of marker genes, may in part allow a more thorough characterization of skin viral communities. This strategy does not rely on a conserved gene, bypasses PCR, and may provide insight into what microbial communities are doing on the skin surface by analyzing gene content and function. Whole-genome shotgun metagenomics is particularly difficult to perform on skin-derived samples, because high amounts of host DNA and low amounts of microbial DNA present technical limitations for these approaches.

Eukaryotic Viruses

HPV is one of the most extensively studied human skin viruses. PCR amplification and quantification of HPV marker genes have revealed that healthy skin is a habitat for a broad spectrum of HPV strains (20, 21). Sequence analysis of the conserved L1 open reading frame similarly revealed a diverse community of HPV types on healthy skin while identifying novel HPV strains (22). Multiple studies have confirmed the ubiquity and diversity of HPV types throughout human populations (23–25).

Human polyoma viruses (HPyVs) are another major group of commensal human skin viruses. Originally studied in the context of cancer, HPyVs have been found on healthy human skin (26). Molecular techniques have enabled the discovery of multiple types of HPyVs; the most common to human skin are HPyV6, HPyV7, and Merkel cell polyoma virus (26, 27). Whole metagenomic shotgun sequencing of the facial skin virome of five healthy individuals and one individual with Merkel cell carcinoma confirmed a cutaneous viral microbiota dominated by HPVs, HPyVs, and circoviruses (28).

Bacteriophage

Limited knowledge currently exists regarding the bacteriophage of the skin, though these microorganisms likely have complex roles in bacterial community dynamics, at the population level and the genomic level. In particular, bacteriophage may mediate antibiotic-resistance-gene transfer between bacteria, as demonstrated by *Staphylococcus aureus* strains (29, 30), a major cause of skin and soft tissue infections. Culture-dependent techniques paired with genomic analyses as well as prophage analyses have been employed to understand and characterize the

genomic diversity of subsets of skin bacteriophage communities. For example, *P. acnes* bacteriophage seem to be quite limited in their genomic diversity but have a broad host range among clinical isolates (25). This is in contrast to *S. aureus* bacteriophage, which appear to be quite diverse at the genomic level (31–33). Whole metagenomic shotgun sequence analysis of facial skin swabs from five healthy individuals and one individual with a previous Merkel cell carcinoma lesion indicates that two families dominate cutaneous bacteriophage communities, the *Microviridae* and *Siphoviridae* (28).

Acquisition and Early Colonization

At 34 weeks of gestation, the skin has formed a competent barrier able to withstand the terrestrial environment. Immediately following birth, the neonate skin acquires microbiota, and delivery mode may in part contribute to colonization. A study analyzing neonate skin microbiota indicated that babies delivered via vaginal birth ($n = 4$) had skin microbiota similar to their mother's vaginal microbiota (i.e., *Lactobacillus*, *Prevotella*, and *Sneathia* spp.), and babies delivered via Caesarean section ($n = 6$) were colonized with skin microbiota similar to their mother's skin microbiota (i.e., *Staphylococcus*, *Propionibacterium*, and *Corynebacterium* spp.) (34). However, it is still unclear how long this effect lasts and how these potential differences in skin microbiota colonization contribute to health or disease, if at all. Following birth and adjustment to the extrauterine environment, the skin barrier significantly changes, including pH, transepidermal water loss, water content, and sebaceous gland activity (35). Thus, it is expected that the skin microbiota would significantly shift as well, adjusting to the changing habitat that selects for some microbiota and prohibits colonization of others. In analyzing the shifting skin microbiota during the first year of life ($n = 31$), it was found that evenness of the relative abundance of microbiota increased with time (36). In infants, the dominant phylum detected was *Firmicutes*. And though infant skin produces a limited amount of sebum in contrast to adult skin, *Propionibacterium* was detected in the top five abundant genera during 4 to 6 months of age.

Topographical Diversity of Skin Microbiota

Numerous studies employing 16S rRNA gene sequencing have characterized bacterial communities colonizing healthy human adult skin. Generally, the four dominant phyla of bacteria found via 16S rRNA sequencing to reside on adult skin are the *Actinobacteria*, *Proteobacteria*, *Firmicutes*, and *Bacteroidetes* (37). A unique feature of the skin habitat, as highlighted above, is the variability across the surface and the ability to sample that variability in a minimally invasive manner. Differentially dense and numerous hair follicles, eccrine and apocrine sweat glands, and sebaceous glands contribute to the variable cutaneous microenvironments and select for microorganisms that thrive in those specialized environments. Intrapersonal variability is high, similar to other sites of the human body colonized by microbiota (38). However, the dominant types of bacteria recovered from the skin appear to be relatively constant, with the rarer, less abundant types of bacteria accounting for the variability seen within and between individuals. The dominant types of bacteria identified by molecular techniques are the same as those recovered by culture-based techniques, primarily *Staphylococcus*, *Propionibacterium*, and *Corynebacterium* (38–40). Laser capture microdissection followed by 16S rRNA sequencing suggests that bacteria may also be present in subepidermal compartments of the skin (41), though it is unclear if these or any microorganisms identified by sequencing-based approaches are alive. One general limitation of molecular techniques is that they are not able to distinguish between viable and dead microorganisms.

Areas dense in sebaceous glands, such as the face, scalp, and back, are colonized by higher proportions of the lipophilic bacterium *Propionibacterium* (38–40). Heavily sebaceous areas also tend to be low in microbial diversity and are relatively stable temporally, compared to moist and dry sites of the skin (42), likely a reflection of the unique microenvironment afforded by sebaceous secretions. The role of sebum in defining the skin microbiota is apparent in age-associated changes in the composition and diversity of the skin microbiota. Puberty and its associated androgenic-controlled release of sebum from the sebaceous glands coincide with a shift in skin microbiota toward greater relative abundance of *Actinobacteria*, including *Corynebacterium* and *Propionibacterium* (43).

Staphylococcus and *Corynebacterium* dominate moist and/or occluded areas of the skin. For example, in the axilla, abundant amounts of *Corynebacterium* process odorless eccrine, apocrine, and sebaceous gland secretions, thus producing volatile organic fatty acids and thioalcohols that are responsible for the characteristic odor associated with axillary sweat (44–47). 16S rRNA gene sequencing and analysis has confirmed that *Corynebacterium* and *Staphylococcus* are the bacteria present in the highest relative abundance, and interestingly, people using deodorants harbored greater bacterial diversity in their axillae (48).

Dry and exposed areas of the skin harbor more bacterial diversity and less bacterial load than sebaceous, moist, occluded, and haired areas and seem to have less of a selective force, because those bacterial populations are not dominated by individual taxa (40). Instead, drier areas contain greater amounts of *Proteobacteria* and *Bacteroidetes*, in comparison to moist and sebaceous sites (39, 40, 49, 50).

Whole Metagenomic Shotgun Sequencing of Skin Microbiota

Metagenomic techniques to analyze skin microbiota, which employ whole-genome shotgun sequencing to identify and characterize microbiota without relying on amplification of a marker gene such as 16S rRNA, have not yet been widely used. The advantages of such techniques include gaining functional and metabolic insight into the coding potential of the microbiota, strain-level resolution of microbial taxa, and elimination of PCR-associated biases. Such studies have to this point been limited by the low burden of microbes present on the skin (in comparison to other sites, such as the gastrointestinal tract) and high amounts of human genomic contamination derived from skin cells. The Human Microbiome Project Consortium performed a metagenomic analysis of the retroauricular crease skin (the area behind the ear) in 242 individuals. Their findings indicate that the metabolic and functional pathways encoded by the skin microbiota were more constant and diverse than the taxonomic composition, suggesting low metabolic diversity among a taxonomically diverse population (38). An additional finding was that age was associated with differential metagenomically encoded pathways on the skin, including the glyoxylate cycle (38).

DISORDERS CAUSED BY OR ASSOCIATED WITH SKIN MICROBIOTA

Skin Disorders Caused by or Associated with Bacterial Microbiota

A variety of skin disorders are associated with bacterial colonization and/or infection. These disorders may include overt infection, such as folliculitis, carbuncles, furuncles, and other skin and soft tissue manifestations of infection by organisms such as *S. aureus* or *Pseudomonas aeruginosa*. Bacterial colonization and/or infection may also contribute to multifactorial disease, interacting with host and other environmental factors. This is likely the case for disorders such as acne, atopic dermatitis, and dandruff. Finally, commensal bacteria may become pathogenic and cause nosocomial infections, especially on indwelling devices, as exemplified by *S. epidermidis* and *Corynebacterium jeikeium*. Here we will discuss two disorders, acne and atopic dermatitis, in which microbiome science has provided important clues to the pathogenesis of disease. Other common cutaneous bacterial infections and disorders are listed in Table 1 but will not be further discussed.

Acne

Acne vulgaris is the most common disease seen by dermatologists and is generally associated with puberty and androgen exposure and coincides with the time when the sebaceous glands increase in size and commence sebum secretion. It is distinguished by open and closed comedones ("blackheads" and "whiteheads," respectively), pustules, papules, and nodules. The association between *P. acnes* and acne vulgaris has been well established (3), though it is generally regarded as a multifactorial disease in which host factors, environment, and genetics likely play a role in the pathogenesis. Antibiotics are relatively effective in acne treatment, further supporting a microbial role in disease pathogenesis. However, both culture-based and culture-independent 16S rRNA gene sequencing studies have established *P. acnes* as a member of the commensal microbiota in those without acne. Therefore, the question arises of when and how does a commensal become a pathogen? Recent insights into this question suggest that strain-level analysis of *P. acnes* may be required to differentiate commensal from pathogen; a recent study showed that even though the relative abundance of *P. acnes* did not differ between individuals with acne compared to healthy individuals, certain *P. acnes* ribotypes (types of 16S rRNA sequences) were highly associated with acne (51). Whole-genome sequence comparison of the different ribotypes showed that acne-associated strains carry unique genetic elements not present in the strains associated with healthy individuals, which may contribute to virulence and pathogenicity.

Probiotic applications may offer some benefit for treatment of conditions such as acne. Succinic acid, a fatty acid fermentation product of *S. epidermidis*, has been shown to inhibit the growth of *P. acnes* (52). Similarly, *P. acnes* itself may function in some regard as a probiotic and has been shown to suppress growth of USA300 methicillin-resistant *S. aureus* through fermentation of glycerol (53). Bacteriophage therapy has also been suggested as a novel therapeutic for acne. *P. acnes* bacteriophage are limited in genetic diversity, have a broad host range, and are unable to form stable lysogens within their hosts (31), rendering them

TABLE 1 Skin disorders caused by or associated with bacterial colonization and/or infection

Bacteria	Characteristics	Associated disorders
Staphylococcus aureus	Gram-positive, coagulase-positive cocci, often antibiotic resistant	Impetigo
		Folliculitis
		Furuncles
		Carbuncles
		Wound infections
		Atopic dermatitis
		Staphylococcal scalded skin syndrome
Staphylococcus epidermidis	Gram-positive, coagulase-negative cocci	Indwelling catheter infections
		Prosthetic and device infections
Propionibacterium acnes	Gram-positive, lipophilic, aerotolerant anaerobe; resides in hair follicle and sebaceous glands	Acne vulgaris
		Device infection
		Surgical site infection
Corynebacterium minutissimum	Gram-positive aerobic or facultative aerobic coryneform; produces porphyrins that fluoresce coral-red upon Wood's light exam	Erythrasma
Corynebacterium jeikeium	Gram-positive, aerobic, lipophilic coryneform; often antibiotic-resistant; formerly known as group JK coryneform	Indwelling device infections
		Other nosocomial infections
Corynebacterium tenuis	Gram-positive coryneform	*Trichomycosis axillaris*
		Trichomycosis pubis
Pseudomonas aeruginosa	Gram-negative, aerobic, motile	Toe web infections
		Green nail syndrome
		Folliculitis
		Wound infections

ideal candidates for a topical phage therapeutic. Novel probiotic, prebiotic, or bacteriophage-based approaches to treat acne would be desirable, because long-term antibiotic treatment for acne has been associated with acquisition of antibiotic resistance (54, 55). Gram-negative folliculitis (56) and pharyngitis (57) are also associated with antibiotic treatment of acne; these are opportunistic infections that likely result from disturbed microbial community ecology on the skin and in the airways, respectively.

Atopic Dermatitis

Atopic dermatitis (AD) is a chronic relapsing disorder affecting ~15% of children in the United States (58). Features include eczema with papules, vesicles, oozing, and crusting. Typically affected skin sites are the antecubital and popliteal fossae. The pathogenesis is likely multifactorial, with contribution of genetics, environment, and immune response. The incidence of AD has increased significantly over the past 3 decades, highlighting what may be an environmental component of the disease. Commonly associated with AD are colonization and/or infection with *S. aureus*. Profiling of the bacterial microbiota via 16S rRNA gene sequencing confirmed increases in the relative abundance of *S. aureus* during AD flares, with a corresponding decrease in overall bacterial community diversity (59). In the same study, treatments consisting of topical corticosteroids, systemic antibiotics, and/or dilute bleach baths increased skin microbiota diversity and decreased colonization with *S. aureus*, in parallel with improving symptoms of AD. In addition to bacteria, it appears that there may be an overgrowth of the fungi *Malassezia* in AD, with one study finding three times the amount of *Malassezia* in lesional compared to nonlesional skin of AD patients (60). Gastrointestinal probiotics, both during pregnancy and in neonates, may offer some protection against the infant developing AD, though the data thus far appear to be conflicting (61).

Skin Disorders Caused by or Associated with Fungal Microbiota

Fungal infections of the skin commonly present as scaling, erythematous papules, plaques, and patches. Here we will discuss both infections generally accepted as fungal in nature and those with a proposed association with fungal colonization and growth. Infections that we will not discuss in detail, but that are of clinical importance (Table 2), include tinea versicolor (also known as pityriasis versicolor; usually caused by *M. globosa* or *Malassezia sympodialis*), tinea pedis ("athlete's foot"; usually caused by *Trichophyton rubrum*), tinea cruris ("jock itch"; usually caused by *T. rubrum*), intrigo and diaper rash (both usually caused by *Candida albicans*), *Malassezia* folliculitis, and dermatophytoses generally caused by *Trichophyton* or *Microsporum* species.

Dandruff and Seborrheic Dermatitis

Though separate clinical entities, dandruff and seborrheic dermatitis (SD) have many similar features. In both conditions, itching, inflammation, and flaking of the skin are apparent. Dandruff occurs on the scalp, while SD additionally affects facial areas and hairy regions of the body. In both disorders, shampoos that contain antifungal agents (e.g., zinc salts, selenium salts, ketoconazole) are treatment mainstays, suggesting the involvement of fungi in the disease process. Further, a decrease in the amount of *Malassezia* found on the scalp generally correlates with improved scalp condition. Culture-based studies have recognized an overgrowth of *Malassezia* fungi in dandruff and SD (62). Fungal community profiling employing the 26S rRNA gene similarly demonstrated that an increased relative abundance of *Malassezia* was on the dandruff-afflicted-scalp skin (63). The same study reported that dandruff-afflicted skin was colonized with increased relative abundances of *Penicillium* and *Filablasidium floriforme* that correlated with increased severity of dandruff. Nested PCR assays to distinguish *Malassezia* species identified *M. globosa* and *M. restricta* as the major species associated with SD, and the SD strains isolated were significantly different than those from healthy subjects (60). Further studies indicate that oleic acid, a by-product of *Malassezia* metabolism of sebum, administered to human scalps can induce flaking in subjects susceptible to dandruff (64). The picture that is emerging of dandruff and SD is that of multifactorial disease, with a significant role for *Malassezia*, which is also a targetable factor for effective treatment.

Onychomycosis

Onychomycosis is a fungal infection of the nails and is generally thought to be caused by dermatophytes (in particular, *Trichophyton* spp.), which are slow-growing and difficult to culture, resulting in high rates of false-negative

TABLE 2 Skin disorders caused by or associated with fungal agents

Fungal genus	Characteristics	Associated disorders	Associated species
Malassezia	Dimorphic, lipophilic, high lipid content in cell wall; formerly known as *Pityrosporum;* resides in infundibulum of the sebaceous gland	Tinea versicolor	*Malassezia globosa*, *Malassezia sympodialis*
		Dandruff	*M. globosa*, *Malassezia restricta*
		Seborrheic dermatitis	*M. globosa*, *M. restricta*
		Folliculitis	*M. globosa*, *M. restricta*, *M. sympodialis*, *Malassezia furfur*
Candida	Dimorphic, characteristic yeasty odor	Intertrigo	*Candida albicans*
		Diaper rash	*C. albicans*
Trichophyton	Dermatophyte, develops macro- and microconidia	Tinea pedis	*Trichophyton rubrum*
		Tinea cruris	*T. rubrum*
		Onychomycosis	*T. rubrum*, *Trichophyton interdigitale*

culture results. Molecular techniques to detect the pathogenic agent for onychomycosis are becoming more common for its diagnosis. One study of 346 patients with onychomycosis used 18S rRNA PCR and sequencing to detect fungi, in parallel with routine cultures, and found that 18S rRNA sequencing was able to detect about double the positive results as cultures (65). The fungi identified, primarily *T. rubrum* and *Trichophyton mentagrophytes*, were consistent when comparing cultures and sequencing methods. However, a limitation was the inability to resolve taxonomy to the species level in eight of the cases. Other direct DNA detection techniques have been employed, including primers specific to known nail pathogens (66, 67) and PCR followed by restriction fragment length polymorphism (68, 69). Generally, the molecular techniques are more sensitive than cultures for detection of fungi. However, in most studies, a significant portion of cases are found to be both culture- and PCR-negative, suggesting that techniques such as metagenomics that target a broader range of organisms may be of utility for resolving the causative agent in these cases.

Skin Disorders Caused by or Associated with Viruses

Molecular techniques have been particularly useful in identifying known viruses in association with skin disorders. We discuss two viral skin disorders here: Merkel cell carcinoma and cutaneous warts. The identification of the virus associated with Merkel cell carcinoma was possible using a type of metagenomic shotgun sequencing. Greater precision has been attained in identifying HPV strains associated with cutaneous warts using molecular techniques. There are many other cutaneous manifestations of viral infection, and some of these are described in Table 3.

Merkel Cell Carcinoma

Merkel cell carcinoma is a rare but aggressive malignant, neuroendocrine tumor generally presenting as a solitary nodule on the face or neck of elderly or immunosuppressed patients, suggestive of a pathogenic cause. In 2008, Feng et al. employed a method called digital transcriptome subtraction to link a novel virus (Merkel cell polyomavirus [MCPyV]) to 80% of Merkel cell carcinoma cases in their study (70). The development of improved detection methods for MCPyV, specifically an expanded repertoire of quantitative PCR assays and monoclonal antibodies to detect integration and expression of the large T antigen, suggests that most Merkel cell carcinomas are associated with MCPyV (71). Molecular features of the MCPyV, such as genome copy number and mutation analysis, detected in tumors and peripheral blood mononuclear cells may be predictive of disease course (72). As mentioned previously, MCPyVs are commonly found on the skin of healthy individuals, are often asymptomatically carried, and can be shed from the skin as assembled virus particles (73–83). Therefore, there are likely other factors that interact with MCPyV to cause disease, including host immune function.

Cutaneous Warts

Warts are benign flesh-colored papules or nodules, commonly occurring on the hands and fingers, and particularly in children and immune-compromised patient populations. They are caused by HPV, most frequently of the alpha, gamma, and mu genera. Multiplex genotyping PCR assays have been successfully employed to identify HPV types, the most prevalent appearing to be HPV types 1, 2, 27, and 57 (84–86). An assay comprising PCR followed by restriction fragment length polymorphism analysis and Luminex xMAP Technology (Luminex, Austin, TX), revealed that HPV types 2, 3, 27, and 57 were most common in a cohort of Greek children (87). Data obtained from swabs taken from the skin overlying the wart are similar to data obtained from more invasive tissue biopsies (88). Plantar warts, in particular, have been associated with HPV types 1, 2, 27, and 57 (86, 89).

POTENTIAL CLINICAL DIAGNOSTIC APPLICATIONS OF THE SKIN MICROBIOME

While diagnostics based on the skin microbiome are not yet standard practice, the potential is great. It is foreseeable that variants of disease may be identified based on the colonizing microbiota, and as a result, a personalized treatment regimen may be administered. For example, perhaps variants of atopic dermatitis, based on their colonizing microbiota, may respond differently to various treatments (i.e., corticosteroids, antibiotics, dilute bleach baths). Identifying the ideal treatment for the disease variant would eliminate time-consuming troubleshooting and potentially unnecessary use of antibiotics. The microbiome may also be used to predict which cases of disease are at risk for downstream complications. If identified as "at risk," a patient could be more closely monitored, and measures could be taken to prevent the complication from arising. Though not discussed here, this may be a potential approach for

TABLE 3 Skin disorders caused by or associated with viruses

Virus	Characteristics	Associated disorders	Specific strain
Papillomavirus	Double-stranded DNA, circular genome, nonenveloped	Common wart	HPV1, 2, 27, 57 most common
		Plantar wart	HPV1, 2, 27, 57 most common
Polyomavirus	Double-stranded DNA, circular genome, nonenveloped	Merkel cell carcinoma	Merkel cell polyomavirus
Herpesvirus	Double-stranded DNA, linear genome, enveloped	Kaposi's sarcoma	HHV8
		Roseola	HHV6, 7
		Chickenpox, shingles	HHV3
Molluscum contagiosum virus	Double-stranded DNA, linear genome, enveloped, unculturable	Molluscum contagiosum	MCV1 most common

wound care, where the microbiota is thought to influence progression to complication (i.e., osteomyelitis, amputation), but it is unclear which cases are at risk for complication (90, 91). Finally, once a more complete understanding is obtained regarding what is "good" and "bad" microbiota, clinical diagnostic approaches may be used to quickly assess a patient's microbiome.

For any of these potential applications to be feasible, significant advances need to be made to overcome bottlenecks in the pipeline to obtain, analyze, and interpret the large datasets generated by microbiomic and metagenomic approaches. Sequencing technologies are continually evolving and becoming more cost-effective and rapid. However, a major bottleneck is the analysis required to gain meaningful information from the sequence data, which often requires specialized computational and bioinformatics skills that are in short supply. Additionally, standardized approaches are needed, such as sample collection, sequencing approach, and analysis parameters.

CONCLUSIONS

Molecular techniques have been employed for the diagnosis of some skin disorders, but especially those with a straightforward infectious etiology and a known pathogen (i.e., onychomycosis, cutaneous warts). The greater challenge will be applying molecular techniques for the diagnosis of complex, multifactorial diseases, where an alteration in microbial communities may be one of several factors in disease pathology. It is first necessary to gain a more complete understanding of the role of altered microbial communities in disease states. In the future, microbial community analysis may also be used to identify variants of disease, predict best treatment modality, and guide personalized management and care of the patient.

The Gastrointestinal Microbiome

ABRIA MAGEE, JAMES VERSALOVIC, AND RUTH ANN LUNA

11

Through the years, the individual microbes that reside in the human gastrointestinal (GI) tract have been labeled as pathogens, commensals, uncultivable, or unidentifiable. While exploration of particular species in the discovery and diagnosis of disease remains paramount, it is the landscape of the microbial community that continues to offer greater clues to the role of microbes in human health and quality of life. In contrast to other body systems, the human GI microbiome is ecologically diverse and complex and plays an active role in digestion, metabolism, behavior, heart size, and the development of the mucosal immune system, among other associations (1, 2). The composition of the gut microbiota is influenced by diet, age, host genetics, antibiotic treatment, and the environment (e.g., psychological stress, hygiene, climate, and allergies) (3). The microbial communities found in the gut have also been shown to contribute, both negatively and positively, not only to health issues rooted in the GI tract, but also to those of the respiratory and central nervous systems. An imbalance or shift of the gut microbiome has been linked to the development of a variety of disorders including inflammatory bowel disease (4–6), gastric ulcers and cancer (7–10), autism spectrum disorder (11–15), and obesity and diabetes (16–19). Because of the implications related to these changes and the development of "unhealthy" microbiomes, research is ongoing to continue to refine the definition and composition of a "healthy" gut microbiome.

MICROBIOME CHARACTERIZATION

The most rudimentary explorations of the composition of the gut microbiome employed basic microscopy and axenic culture of stool specimens. Today, most gut microbiome studies still rely on stool specimens for characterization. This has allowed for comparison of microbiome data to results obtained from conventional diagnostics. Routine diagnostics for a patient presenting with GI symptoms include Gram stain analysis, stool antigen screens, bacterial culture, and targeted molecular detection of enteric pathogens. The introduction of molecular detection of GI pathogens in clinical laboratories has allowed for the identification of known GI pathogens from stool or stool cultures, thus increasing sensitivity (20). While these testing modalities have improved identification of known pathogens, few techniques provided the ability to identify unknown microbes. However, in the case of a pure cultured isolate unidentifiable via conventional microbiology methods, alternative identification methods were quickly developed, including pyrosequencing of the variable regions of the 16S rRNA gene (21). Bacterial sequencing further expanded the capabilities for the identification of cultured organisms but offered no benefit in the detection and identification of the uncultivable microbes.

Current culture-based diagnostic techniques examine only a small portion of the entire microbial population (e.g., cultivable organisms), neglecting the ecological complexity of the community as a whole. Approximately 80% of the bacterial species in the gut are uncultivable, and many of these fastidious species have complex nutrient and oxygen requirements as well as dependence on one another (22). The microbial community structure of the gut varies among individuals, and its composition is not clearly defined. Greater understanding of the gut microbiome and microbial interactions within the community is essential to the development of future clinical diagnostics and therapies, and the potential utility of community manipulation, via introduction or reduction of a select bacterial population, remains promising.

The introduction of next-generation sequencing technology provided the opportunity to characterize the complete microbial community, exclusive of culture conditions, with massively parallel sequencing of the 16S rRNA gene (23). With a known commensal community, the GI tract was a frequent target for the initial studies to characterize the human microbiome. The employment of 16S ribosomal DNA sequencing methods led to the detection of more than 7,000 phylotypes in the human gut (24). It is the innovation in both high-throughput sequencing technology and bioinformatics applications that enabled the Human Microbiome Project and future 16S rRNA–based microbiome and shotgun sequencing–based metagenomic studies (25, 26).

LONGITUDINAL DEVELOPMENT OF THE GUT MICROBIOME

A healthy gut microbiome has the potential to limit infection and promote general well-being. Native gut populations can directly inhibit the colonization of pathogenic bacteria by blocking binding sites for pathogenic organisms at the mucosa surface, competing for nutrients, and producing bactericidal compounds (27). More than 100

Abria Magee, James Versalovic, and Ruth Ann Luna, Department of Pathology & Immunology, Baylor College of Medicine, Texas Children's Microbiome Center, Department of Pathology, Texas Children's Hospital, Houston, TX 77030.

trillion microorganisms form the mutualistic community of the healthy gut. The gut microbiome is composed mainly of bacteria, which constitute 60% of total fecal mass (28). The total number of bacteria is 10-fold the number of human cells, and the microbial genome contains 100-fold more genes (24). Studies have consistently shown that healthy intestinal microbiomes exhibit more bacterial diversity compared to those associated with disease. The gut microbiota is characterized by approximately 1,100 dominant bacterial species, with approximately 90% of the bacterial population assigned to two phyla (*Firmicutes* and *Bacteroidetes*) (29, 30). *Actinobacteria*, *Cyanobacteria*, and *Proteobacteria* are also minor constituents in the gut microbiota. Looking deeper taxonomically, the genera most closely associated with a healthy gut microbiome include *Bacteroides*, *Bifidobacterium*, *Clostridium*, *Eubacterium*, *Faecalibacterium*, *Lactobacillus*, and *Roseburia*.

The human GI tract is thought to be relatively sterile at birth, undergoing a dynamic and rapid expansion following the initial colonization during the birth process. A variety of factors influence the microbial profile at each stage of life, as depicted in Fig. 1, and these profound changes can be seen at phylum-level characterization (31). Mode of delivery (e.g., vaginal or caesarean) plays a role in the development of community structure and continues throughout infancy. A previous study reported that the pioneer species found in the infant gut were facultative anaerobes and thus species that then altered the gut to a more anaerobic environment (32). Those pioneer species found in the infant gut include but are not limited to *Escherichia coli* and *Streptococcus* spp. While this study identified key differences between the gut microbiomes of infants born vaginally and those of infants born via caesarean section, a more recent study suggested that mode of delivery affected the pace of colonization but ultimately did not affect the sequence (33). With the neonates in this study in the controlled environment of a neonatal intensive care unit, gestational age at birth appeared to affect the colonization pattern most strongly. In a study of the placental microbiome, this finding was upheld, as gestational age at time of delivery was associated with a specific microbial profile but mode of delivery had no such association (34). As infants grow older, the gut microbiota continues to increase in diversity, due to environmental factors as well as diet.

The diet of infants directly influences microbiota composition by supplying substrates important in bacterial function and growth (35). For instance, breast-fed infants have a more stable and fixed bacterial population than formula-fed infants (36). Another study comparing formula-fed infants to breast-fed infants found that the breast-fed infants had a more heterogeneous community than formula-fed infants (37). A major shift is seen in the gut microbial community during the transition from liquids (e.g., milk) to solids. The introduction of solid foods to breast-fed infants results in an increase in enterococci and enterobacteria as well as *Bacteroides*, *Clostridia*, and anaerobic *Streptococcus* spp. (38). After the second year of life, the gut microbiota of both breast-fed and formula-fed individuals begins to more closely resemble the typical microbiome identified in adults.

The infant gut microbiome exhibits greater variability in functional gene content between individuals than is seen in adults (39). These variations can be due to random

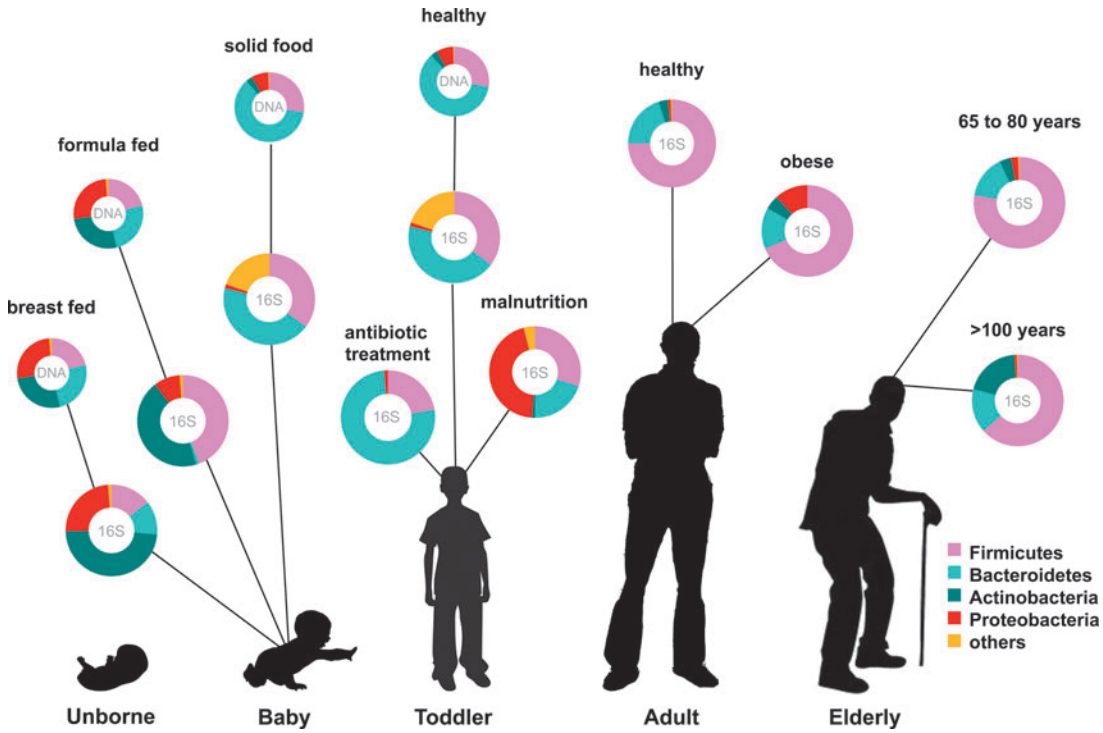

FIGURE 1 The dynamic nature of the gut microbiome over the span of a lifetime. With initial seeding of the microbiome at birth, the bacterial community of the gut continues to evolve through the course of a lifetime. Various factors affect the specific composition of an individual's gut community, and in return, the gut microbiome contributes to health and disease. (Reproduced with permission from reference 31.)

colonization events, differing immune responses, changes in host behavior, and lifestyle factors (40). In a case-study-based exploration of microbiome development, Koenig et al. monitored the gut microbiome of a full-term vaginally delivered infant over a period of 2.5 years (41). This male infant was fed breast milk and formula for the first 134 days of life, with the introduction of solid food to his diet at 4 months of age. Breastfeeding stopped at 9 months of age, and cow's milk was introduced at 1 year. The infant was typically healthy but was treated with antibiotics several times for an ear infection. He was immunized according to the Centers for Disease Control and Prevention-recommended schedule. A gradual increase in bacterial diversity was detected longitudinally, and these changes correlated with changes in diet and antibiotic treatments. Specifically, the introduction of peas and formula was related to a shift in functional genes associated with the adult gut and an increased abundance of specialized microbial groups, such as *Bacteroidetes*, that are known to break down plant polysaccharides. After weaning, a stable bacterial population was observed in regard to function, and this stable state more closely resembled the adult gut microbiome.

Palmer et al. describes the range of microbial profiles in 14 healthy full-term babies born to 13 healthy mothers (40). These authors observed diverse community profiles in the first 6 months of life that progressively became more similar to one another and moved to a more stable adult-like microbiome. This cohort of infants exhibited similar major contributing phyla and overall similar and stable populations over time. In this study, bifidobacteria did not appear to be major constituents of the gut and, if present, appeared after several months of life.

Throughout childhood and adulthood, changes in the relative abundance of bacterial species cause shifts in the overall bacterial composition of the gut. In general, *Verrucomicrobia* and *Actinobacteria* are in greater abundance in the stool of children compared to adults, where there is a predominance of *Bacteroidetes* and *Firmicutes* (42).

Yatsunenko et al. (4) examined how gut microbiomes differ with age and geography. The study included fecal specimens from 531 individuals, with gene content from 110. This study group included healthy children and adults from the Amazonas of Venezuela, rural Malawi, and large cities within the United States. Also included in the study were monozygotic and dizygotic twins. When examining individuals from all three populations, aged 0–17 years, the gut microbiome was shown to evolve toward an adult-like state within 3 years after birth. This group also found that the interpersonal variation was greater among children than adults, and lastly, they observed differences in the phylogenetic composition of fecal microbiota between individuals living in different countries. The latter was particularly distinct between those individuals from the United States and the Malawians and Amerindians, with U.S. individuals more closely related to each other than the non-U.S. individuals. Separation was also seen between the Malawian and Amerindian populations.

Analysis also revealed a dominance of bifidobacteria in the infant microbiome and distinct microbial profiles in the U.S. population and the non-U.S. populations. In the cohort including 110 individuals, Yatsunenko et al. observed an enrichment of genes involved in the *de novo* biosynthesis of folate, while adults in the cohort had a higher representation of genes that metabolize dietary folate. Also overrepresented in the infant population were fermentation pathways found in infant microbiomes. Pathways involved in cobalamin, vitamin B7, and vitamin B1 biosynthesis increased in relative abundance with increasing age of the subjects. Regarding geographical and age-specific differences, non-U.S. breast-fed infants had higher representations of genes related to vitamin B2 biosynthetic pathways and urease (both relevant to human milk) than found in U.S. breast-fed infants. Differences among U.S. adults and non-U.S. adult populations were related to diet, with U.S. adults consuming more rich protein compared to more corn and cassava in the Malawian and Amerindian populations. Genes related to vitamin biosynthesis, biotin and lipoic acid biosynthesis, the metabolism of aromatic compounds, and bile salt metabolism were found more frequently in the U.S. adult population.

Gradual changes in the microbiota occur during early childhood. The adolescent microbiota shifts from an aerobe- and facultative anaerobe–dominated community to one that is dominated by obligate anaerobes (43). From 1 to 2 years of age, the gut microbiome begins to resemble the profile of an adult, with 90% of the population identified as obligate anaerobes (28). The fecal samples of children aged 1 to 7 years are less diverse than those of adults and harbor increased proportions of *Enterobacteria* as well as higher abundances of bifidobacteria and *Clostridia* (44).

Agans et al. (45) employed array technology targeting the microbial community to quantitatively compare the gut microbiome of 22 healthy children of preadolescent/adolescent (11 to 18 years) age with that of 10 healthy adults (22 to 61 years of age). Similar microbiome profiles were observed in the preadolescent/adolescent group compared to the adult group. A 2-fold increase in *Bifidobacterium* was noted in children, but at the class level, there was greater similarity across both groups. The gut microbiomes of healthy adults and children were dominated by *Clostridia*, specifically *Ruminococcus* spp., which are considered the primary carbohydrate degraders in the human gut. *Clostridia* made up over 70% of the total sample abundance in both groups. Major classes such as *Actinobacteria*, *Bacteroidetes*, and *Bacilli* were also present in both groups; however, members of the class *Actinobacteria* appeared to be more abundant among adolescent samples.

The gut microbiome of six relatively healthy children (8 to 14 years of age) living in an urban slum in Bangladesh was compared with that of four healthy children living in an upper-middle-class suburban community of the U.S. over a 5- to 6-month time period (46). As expected, this study revealed distinct differences between the gut microbiota of Bangladeshi children and U.S. children, differences that were attributed to diet and ethnogeography. Overall, a greater microbial diversity in the gut of Bangladeshi children was observed, and a prevalence of *Firmicutes* was seen in the Bangladeshi cohort compared to a prevalence of *Bacteroidetes* in the U.S. children. In the phylum *Bacteroidetes*, *Prevotella* spp. were more abundant in the Bangladeshi population, whereas *Bacteroides* spp. predominated in the U.S. cohort.

The microbiome undergoes changes as individuals get older, and as individuals age, bacterial diversity decreases, a finding consistent with the development of additional health problems with advanced age. The gut microbiome remains relatively stable throughout adulthood but begins to vary more greatly between individuals in advanced age (>65 years), with diversity also differing based on age (47). Claesson et al. described the fecal microbiota of 178 elderly individuals and stratified them based on diet and

residence (e.g., residence location in the community, day-hospital, rehabilitation, long-term residential care), with antibiotic treatment as exclusion criteria (48). Distinct profiles were observed between community-dwelling and long-term residential care subjects. A control group of younger adults was also included and proved more similar to the community-dwelling group. Diversity decreased in the long-term residential care subjects when compared to the community-dwelling subjects as well as the rehabilitation subjects. The long-term residential care cohort had a higher proportion of *Bacteroidetes* compared to the community-dwelling group, which had higher abundances of *Firmicutes* in their gut microbiome. At the genus level, the community-dwelling individuals had higher proportions of *Coprococcus* and *Roseburia*. Metabolomics characterization was consistent with the microbiome findings, with markers of inflammation in higher levels in the long-term residential care individuals and rehabilitation individuals than in the community-dwelling cohort.

Biagi et al. surveyed the gut microbial composition of young adults (20 to 40 years of age), elderly (60 to 80 years of age), and subjects living for over 100 years (i.e., centenarians) in northern Italy (47). The microbiomes of young adults and elderly individuals were found to be similar, but significant differences were identified in the >100 years cohort. The two major phyla, *Bacteroidetes* and *Firmicutes*, dominated the gut microbiome of centenarians, and an increase in facultative anaerobes was observed including *Fusobacterium*, *Bacillus*, *Staphylococcus*, *Corynebacterium*, and certain *Proteobacteria* groups. Select *Proteobacteria* spp. are also considered pathobionts, and under specific circumstances (e.g., inflammation in the elderly), these bacteria can induce disease. As expected, the centenarians had higher levels of biomarkers associated with inflammation. A significant decrease in proportions of *Clostridium* cluster XIVa, which is a major component of the GI mucosal microbiota, was also observed in the centenarian cohort compared to an increase in younger adults and the elderly.

ENTERIC PATHOGENS

Understanding the progression of the gut microbiome from birth to advanced age allows us to identify detrimental perturbations in the healthy gut. The major organisms involved in GI infections and dysbiosis of the gut microbiome are *Vibrio* spp., *Campylobacter* spp., and those species belonging to the family *Enterobacteriaceae* (i.e., *Escherichia*, *Shigella*, *Yersinia*, and *Salmonella*). *Vibrio* spp. are the causal agent of cholera. Symptoms of this disease include watery stools and dehydration. *Campylobacter* is considered one of the leading causes of GI issues in humans (49). Symptoms of a *Campylobacter* infection include diarrhea, abdominal pain, and fever. There are multiple *E. coli* strains that can inhabit the environment as well as the human intestinal tract. This species is easily cultured and has both non-pathogenic and pathogenic strains, with six pathotypes associated with pathogenicity (e.g., enteropathogenic and enterotoxigenic) (50). Enterotoxigenic *E. coli* (ETEC) is the most common cause of diarrhea, which can be mild to life-threatening depending on the host. ETEC strains colonize and adhere to the intestinal tract and are characterized by production of toxins in the host. Enteropathogenic *E. coli* is the causal agent of acute and persistent diarrhea in infants and children in developing regions. Enteropathogenic *E. coli* strains adhere to the gut of the host and cause a decrease in the mucosal surface area as well as produce attaching and effacing lesions in the host. *Shigella* spp. cause invasive inflammatory colitis leading to bloody stool, fever, and severe cramps. These strains invade the host gut cells, replicate, and spread to nearby cells. *Salmonella* spp. cause gastroenteritis by colonization and attachment to the host tissue and release of proteins that are damaging to the host tissue. *Yersinia pseudotuberculosis* and *Yersinia enterocolitica* are the two enteropathogenic species of *Yersinia* and cause fever and gastroenteritis.

Clostridium difficile is a common species in the native gut microbiota but is also capable of causing diarrhea and severe colitis, generally reaching pathogenic population levels following antibiotic therapy. *C. difficile*-associated diarrhea begins with the release of enterotoxins from the pathogen that destroy the intestinal tissue and lead to an extreme inflammatory response. Another important gastric pathogen is *Helicobacter pylori*, a Gram-negative species that colonizes the upper GI tract, is a member of the phylum *Proteobacteria*, and infects 50% of the world's population (51). *H. pylori* uses urease to produce ammonia and bicarbonate, increasing the pH of the gastric fluid and mucosal layer and allowing the pathogen to colonize the mucosa. The colonization triggers an inflammatory response from the host, and *H. pylori* infection has been associated with the development of peptic ulcers, chronic atrophic gastritis, gastric cancers, and gut lymphoma. During infection, *H. pylori* has been reported to drastically alter the normal gut microbiota (7, 52). In addition, antibiotic resistance has also been documented in *H. pylori* (53).

DIET, OBESITY, AND THE GUT MICROBIOME

Considerable changes to the gut community have been attributed to diet alterations, specifically those involving plant dietary fiber (54). Geographic differences generally include dietary differences, and research in this area suggested the classification of the human gut microbiota into three enterotypes: those having predominantly *Prevotella*, *Bacteroides*, or *Ruminococcus* spp. (55, 56). *Prevotella*-dominated gut microbiomes are more closely associated with a rural society, while a *Bacteroides*-dominated gut microbiome is associated with a developed society, and little information is available on the *Ruminococcus*-dominated gut microbiome (56, 57). Microbial diversity in the gut is also greatly increased in individuals with a more plant- and fiber-based diet (e.g., vegetarian).

Diet is also associated with other factors influencing gut colonization such as ethnicity, sanitation, hygiene, and climate (58). Differences in the gut community can be introduced by self-selected diets (e.g., high-fat/high-sugar), and the gut microbiome responds quickly to changes. These diet-induced changes can also contribute to the development of GI disease (e.g., inflammatory bowel disease) (59). Diet has also been shown to affect the gut microbiome and its susceptibility to enteric pathogens. Gupta et al. (60) utilized pyrosequencing in stool specimens to examine the metagenome of the gut of a healthy child and a malnourished child. The family *Campylobacteraceae* was 35-fold higher in the malnourished gut microbiome, and *Helicobacteraceae* was 12-fold higher. The malnourished gut microbiome had a higher abundance of the families *Bacteroidaceae* and *Porphyomonadaceae*, and *Porphyomonadaceae* has been associated with Crohn's disease and inflammatory bowel disease (61).

While the role of diet in the development of obesity is well established, the microbiome also plays a critical role in the interaction between diet and weight. A reduction in microbial diversity, commonly found in disease states, has been observed in obese individuals compared to individuals of a healthy weight (16). Obesity and obesity-associated metabolic disorders have been associated with changes in the gut microbiome, with an increase in *Firmicutes* and a decrease in *Bacteroidetes* in obese individuals (62), but causation has not been definitively established.

In general, obesity is attributed to excess caloric intake compared with expenditures, but mounting evidence suggests that some individuals may be more susceptible to obesity due to their gut microbiome. In mouse model studies, Ley et al. examined the effects of the microbial community on increases in adiposity in mice homozygous for an obesity phenotype and their lean siblings (63). The two major phyla present in mice cecal communities were *Firmicutes* and *Bacteroidetes*, with more than 75% of the *Firmicutes* belonging to the *Clostridium* cluster XIVa (i.e., a mucosal-associated species) and *Eubacterium eligens*, and greater than 88% of the *Bacteroidetes* belonging to *Bacteroidetes* 4b, which is an uncultured group. *Protoebacteria*, *Cyanobacteria*, and *Actinobacteria* made up less than 1% of the mouse cecal microbiota. The cecal microbial communities of the obese mice had a 50% reduction in *Bacteroidetes* when compared to the lean mouse cohort. The obese cohort also had a greater proportion of *Firmicutes* than the lean group.

Via metagenomics and biochemical analyses, changes in *Firmicutes* and *Bacteroidetes* in the gut microbiota of obese mice were shown to affect the metabolic potential of the mouse gut microbiome (64). More environmental gene tags that matched *Archaea* were identified in the obese cecal microbiome than in the lean mouse cohort, and cocolonization of methanogenic *Archaea* spp. found in the gut change the specificity of bacterial polysaccharide fermentation, resulting in an increase in adiposity. The obese mice's gut microbiome was also enriched in genes related to starch and sugar metabolism, galactose metabolism, and butanoate metabolism. These mice also had increased concentrations of butyrate and acetate in their cecum as well as less energy remaining in the feces.

To further investigate the role of the microbiome in the onset of obesity, fecal transplantation using material from four adult twin pairs discordant for obesity was performed in germ-free mice (65). The mice were fed low-fat chow as well as a typical U.S. diet. The mouse transplanted with the obese twin's microbiota had a significant increase in adipose mass and epididymal fat pad weights in comparison to the mouse receiving the lean twin's microbiota. When gene expression was examined, the mice that received the obese twin's microbiota showed a higher expression of microbial genes involved in detoxification and stress responses, as well as in genes involved in the biosynthesis of cobalamin, the metabolism of essential and nonessential amino acids, and the pentose phosphate pathway. There was also an increase in branched-chain amino acids, which have been reported to be linked to obese and insulin-resistant individuals. The mice receiving a fecal transplant from the lean twin exhibited higher expression of genes related to plant-derived polysaccharide digestion, fermentation to butyrate, and fermentation to propionate. Overall, the transplanted mice exhibited distinct taxonomic, metabolic, and transcriptional profiles based on the donor microbiota (e.g., from the lean twin or the obese twin) and body mass index.

THE IMPACT OF ANTIBIOTIC TREATMENT ON GASTROINTESTINAL BACTERIA

Antibiotic treatments, by definition, alter the microbial population of the body. However, the effects of antibiotics on the gut microbiome reach beyond pathogen elimination and persist well beyond the last dose of treatment (see Fig. 2A) (66). Administration of antibiotics immediately reduces microbial diversity (67). Antibiotic treatment in newborns appears to decrease *Bifidobacterium* spp., and the effects can also be passed down, because newborns from antibiotic-treated mothers have shown lower *Bacteroides*

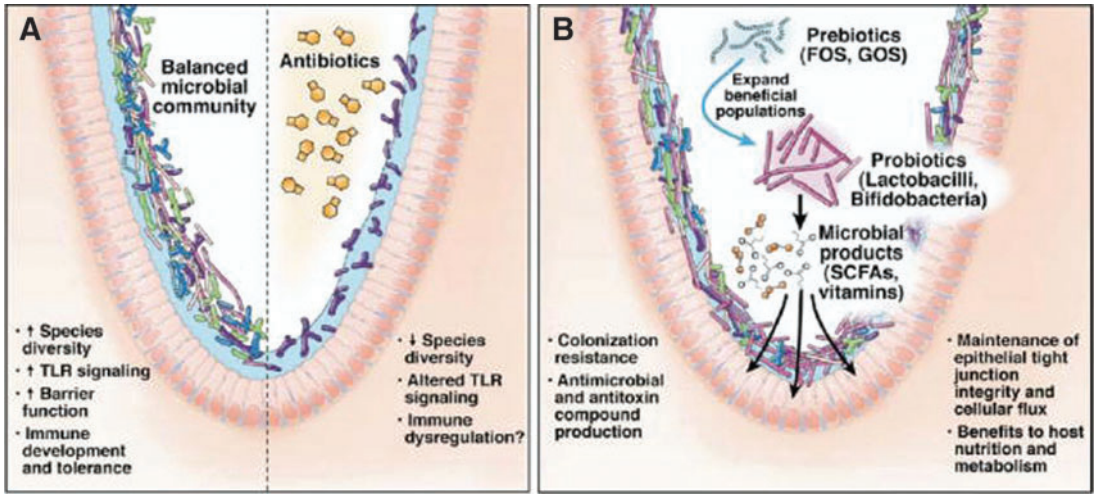

FIGURE 2 Antibiotics, probiotics, and prebiotics in the gut. (A) While antibiotics successfully eliminate pathogenic bacteria, the diversity of the overall bacterial community is diminished and can leave the host susceptible to further disease. (B) Probiotics and prebiotics are effective at manipulating the microbial community and promoting a healthier microbiome profile in the gut. (Reproduced with permission from reference 66.)

populations (68). These newly formed postantibiotic communities can remain in the host for days to several years. Inadvertently, antibiotic treatments can target beneficial populations rather than pathogenic populations. Antibiotic-resistant populations can also increase in the microbiome and cause additional structural shifts in the community.

In a study of three healthy adults before and after treatment with the fluoroquinolone ciprofloxacin, treatment was found to alter the abundance of approximately 33% of the bacterial taxa in the gut (69). The two major phyla present across all specimens were *Bacteroidetes* and *Firmicutes*, with most genera being found within the latter. The three other phyla present but less abundant were *Proteobacteria*, *Actinobacteria*, and *Verrucomicrobia*. Antibiotic treatment also decreased the richness, diversity, and evenness of the community. Four weeks after treatment, the gut community appeared to recover to its pretreatment state.

A gut-based metabolomics study in mice before and after treatment with the fluoroquinolone enrofloxacin showed several differences in profiles. Of note, urea concentrations were increased in the antibiotic-treated mice, and because many bacteria in the gut produce ureases, a decrease in those specific taxa could lead to an accumulation of urea (70). A similar study using vancomycin-treated mice also detected significant differences in the metabolites of the gut following antibiotic treatment (71).

A thorough case study involving a 68-year-old male with no known intestinal disorders and an infected cardiac pacemaker used a multi-omics approach to investigate antibiotic-treatment-related changes in the fecal microbiome (72). Early during treatment, the microbiota was dominated by *Firmicutes*. During the first week of treatment, the families *Lachnospiraceae* and *Ruminococcaceae* were the most abundant taxa. Eleven days after treatment, the total bacterial community decreased. Also, there was a shift in the microbiota to a *Bacteroidetes*-dominated community, along with a significant increase in *Betaproteobacteria*. This group also examined the metabolically active bacteria present in the specimens, and *Firmicutes* was found to be the most active phylum in most samples. At day 14 of treatment, the metabolically active bacteria were *Bacteroidetes*, with *Parabacteroides* as the dominant genus. Also at day 14, there was a decrease in active bacterial taxa and richness. Forty days after the end of treatment, the total and active microbiota began to shift back to its original pretreatment state. However, there remained a decrease in diversity and an absence of *Slackia*, *Bifidobacterium*, *Gemmiger*, *Streptococcus*, *Roseburia*, *Barnesiella*, *Eubacterium*, and *Subdoligranulum*.

GASTROINTESTINAL DISEASE

Extensive research efforts have been dedicated to understanding the etiology and pathogenesis involved with irritable bowel diseases (e.g., Crohn's disease and ulcerative colitis), but these components have not yet been elucidated. These diseases have been linked with both human gene- and microbiome-associated factors (73). Patients with irritable bowel diseases have distinct intestinal microbiomes characterized by decreased bacterial diversity. An overall reduction in *Firmicutes* was observed in the microbiome of Crohn's disease patients (74). Another analysis examining the microbiota of ulcerative colitis patients in relapse and remission reveals the reduced bacterial diversity in ulcerative colitis patients, specifically within the *Firmicutes* (5).

Several microbiome-based studies have focused on irritable bowel syndrome (IBS). Next-generation sequencing technologies and DNA microarrays were utilized to identify specific microbial signatures in the gut microbiome of healthy children and children (7 to 12 years of age) with IBS (42). Two IBS subtypes were analyzed in this study, one described as having hard stool more than 25% of the time and loose stool less than 25% of the time and the other classified as unsubtyped IBS. These two subtypes had distinct microbiome profiles, with at least 70 to 75 different taxa. Analysis also revealed specific taxa to be associated with increased and frequent abdominal pain. Children with IBS had an increased abundance of *Proteobacteria*, specifically *Gammaproteobacteria*, compared to healthy children. At the genus level, these children had greater proportions of *Dorea* and *Haemophilus*. *Veillonella* and *Ruminococcus* spp. were also found to be associated with pediatric IBS, with an unclassified *Ruminococcus* sp. being linked with greater pain severity. Multiple species belonging to the genus *Alistipes* were associated with the children who had recurrent abdominal pain. An increased abundance of *Eubacterium* and *Bacteroides vulgatus* was seen in the gut microbiome of healthy children.

Jalanka-Tuovinen et al. used a phylogenetic microarray technology and a novel computational approach to explore the association between the intestinal microbiota and intestinal symptoms in healthy adults (6). *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, and *Verrucomicrobia* were most abundant in the 15 Finnish subjects included in this study. The microbiota of the individuals who reported the most severe intestinal symptoms remained stable over the course of the study, and statistically significant bacterial taxa associated with symptomology were also identified. Bifidobacteria abundance was decreased in subjects experiencing abdominal pain, a finding consistent with the fact that a known probiotic, *Bifidobacterium infantis*, has been shown to reduce intestinal pain in patients with IBS (75). Taxa from the phylum *Firmicutes* (e.g., *Clostridiaceae*, *Ruminococcaceae*, and *Lachospiraceae*) also appeared to play a role in the manifestation of intestinal symptoms.

A combination approach of quantitative real-time PCR, high-performance liquid chromatography, and conventional culture-dependent techniques was employed to examine the GI microbiota and organic acid profiles of 26 patients with IBS (76). The IBS cohort had higher proportions of *Lactobacillus* and *Veillonella* than the control group (healthy subjects). In the organic acid analysis, the authors revealed that the IBS group had higher concentrations of acetic acid, propionic acid, and total organic acids. The higher acetic and propionic acid concentrations were also associated with GI symptoms, and these effects correlate with an altered IBS microbiome and could be an exacerbating factor in IBS.

Dietary interventions are often suggested as a treatment option for IBS. A low fermentable substrate diet in children with IBS appeared to decrease abdominal pain frequency in a subgroup identifiable by their microbiome profile (77). Diet responders exhibited increased abundance of *Sporobacter* and *Subdoligranulum* spp. and decreased abundance of *Bacteroides* spp. compared to nonresponders. These findings suggest that microbiome characterization may be a useful tool in the selection of treatment for IBS.

THE GUT-BRAIN-MICROBIOME AXIS

Advances in microbiome science have further elucidated the interconnectivity of the gut-brain axis. Specific microbiome profiles have been described in depression, and it is suggested that inflammation caused by the bacterial community in the gut interferes with neurotransmitter signaling. A recent study identified specific bacterial sequences, at the bacterial species/strain level, correlating with depression (78). Increased gut permeability in depressed individuals may also be a contributing factor in the inflammatory process, and increased IgA and IgM responses against commensal bacteria in the gut have been reported (79, 80).

Brain development and behavior are also impacted by the initial bacterial colonization of the gut (81), and the absence of a normal gut microbiome has been shown to alter central nervous system neurotransmission (82, 83). Perturbations in the brain-gut-microbiome axis are also considered as a cause of functional GI disorders (84–86). The correlation between the gut-brain axis, GI symptoms, and the gut microbiome has become highly relevant in the study of autism spectrum disorders (ASD). Gastrointestinal symptoms, ranging from constipation to diarrhea, are frequently reported in individuals with ASD, and several studies have identified altered gut microbiomes (11, 87–90). As in depression, increased intestinal permeability has been reported in patients with ASD, further supporting the "leaky gut" theory (91). Emerging research has also highlighted the potential utility of probiotics in the treatment of symptoms associated with ASD (92), but human clinical trials have yet to be reported.

Several studies have characterized the gut microbiome in children with ASD (11–15). Bacterial sequencing of intestinal biopsies in children with ASD and GI disease as well as neurotypical children with GI disease demonstrated decreased relative abundances of *Bacteroidetes* and increased relative abundances of *Firmicutes* and *Proteobacteria* in ASD compared to the neurotypical group (12). Additional studies have utilized stool specimens and performed comparisons with unaffected siblings and unrelated healthy controls but did not compare to neurotypical children with GI disease. In 2010, Finegold et al. recruited 33 children with ASD, 7 unaffected siblings, and 8 healthy controls (11). Results suggested increased bacterial diversity in ASD, with increased *Bacteroidetes* and decreased *Firmicutes* composition, findings that are contradictory to the study by Williams et al., where a larger sample size of 51 children with ASD was compared with 53 unaffected siblings (12). In further contradiction to previous studies, no significant differences were noted between the groups, but critics have suggested that an unrelated healthy control group is needed to strengthen the study (93). Microbiome comparisons between children with ASD (n = 20) and unrelated healthy controls (n = 20) revealed *Firmicutes* and *Bacteroidetes* as the dominant phyla in the ASD group, with no significant differences noted when compared to healthy controls (14). The most recent pediatric study (ASD [n = 10], pervasive developmental disorder–not otherwise specified [n = 10], and healthy controls [n = 10]) (15) demonstrated separation of groups based on microbiome profiles, but unfortunately the study excluded subjects with GI symptoms.

THE EFFECT OF PROBIOTICS ON THE GUT MICROBIOME

Probiotics have been extensively tested in various animal models, with particular attention given to the impact on inflammation of the GI tract and on the gut microbiome. While there is much anecdotal evidence regarding improved outcomes with probiotic intervention, published human clinical trials related to GI disease remain scarce. The use of probiotics and prebiotics has significant potential in the inhibition of pathogens, restoration of key microbial components, and supplying key nutrients such as short-chain fatty acids as described in Fig. 2B (66).

In a study of 18 healthy adults, administration of probiotics containing either *Bifidobacterium* or *Lactobacillus* strains was not shown to significantly alter the overall microbiome profile of each individual (94). This finding suggests that probiotic intervention will not elicit major changes in a healthy and robust gut community. Another study involving a *Lactobacillus paracasei* intervention found that the efficacy of the probiotic relied heavily on butyrate concentration prior to administration (95). Overall, probiotic treatment was found to increase the *Blautia:Coprococcus* ratio, a finding consistent with better health, and fecal butyrate concentrations represented a potential biomarker for determination of individuals who could benefit from this specific probiotic.

In contrast, a study investigating the effects of a probiotic (*Lactobacillus acidophilus*) and prebiotic (cellobiose) combination on the gut microbiome found that individuals taking the supplement displayed increased abundance of *Lactobacillus*, *Bifidobacterium*, *Collinsella*, and *Eubacterium* spp. partnered with a decrease in *Dialister* spp. (96). The results of these studies suggest that probiotic and prebiotic combinations may be most effective in gut microbiome alteration.

To assess the impact of probiotics on the prevention of infectious disease in the GI tract, a probiotic combination, consisting of *Lactobacillus helveticus*, *Lactobacillus rhamnosus*, *Bifidobacterium longum*, and *Saccharomyces cerevisiae* var. *boulardii*, was given prior to administration of live attenuated ETEC (97). While changes were seen in fecal output and GI complaints in both the probiotic and placebo groups, the probiotic did not increase resistance to orally delivered ETEC. Similarly, oral supplementation with *B. infantis* was assessed in the treatment of IBS, but while *B. infantis* was detected within the GI tract and subtle changes were seen in other taxa, no impact was observed on symptoms in patients with IBS (98).

MANIPULATING THE MICROBIOME VIA FECAL MICROBIOTA TRANSPLANTATION

C. difficile infection (CDI) is most often associated with individuals undergoing antibiotic treatment, causing diarrhea and severe colitis. De La Cochetière et al. examined the association between the most abundant resident fecal microbiota and the later development of CDI (99). The cohort included 260 adult subjects from a former clinical study that were residing in the Paris area. Specimens were collected before antibiotic treatment and 14 days after the beginning of treatment. Comparisons of the gut microbiome showed specific microbial profiles that represented permissive microbial communities and predicted *C. difficile* development. CDI is associated with the release of enterotoxins from the pathogen, which destroys the intestinal tissue and leads to an extreme inflammatory response. CDI is the leading cause of death and hospitalization from gastroenteritis in the United States (100). Occasionally, patients with CDI do not respond well to antibiotic treatments and have recurrent infections with an indefinite number of

relapses (101). A shift in the microbiome is the ultimate cause of CDI infection, and it is for that reason that a purposeful shift in the microbiome, via fecal transplantation, was first suggested as a potential treatment option for the eradication of C. *difficile* in the gut.

Fecal microbiota transplantation (FMT) is currently considered an effective therapy for the treatment of robust and recurrent C. *difficile* infections. FMT employs a bacterial community or bacterial strains from a healthy human gut to alter the composition of an unhealthy gut microbiome. The process as it relates to CDI is depicted in Fig. 3 (102). FMT is becoming a more common clinical practice due to the increased incidence and severity of CDI (103) and has proven to be an effective therapy in curing these patients and reestablishing healthy bacterial populations in the gut. Bacterial diversity in recurrent CDI patients is significantly reduced, with an increase in members of the family *Enterobacteriaceae* and a decrease in *Bacteroidetes* and *Firmicutes* populations.

A dramatic shift in the gut microbial communities of a cohort (n = 3) of patients with CDI was reported following fecal microbiota transfers (104). Prior to transplantation, the fecal specimens of the patients had a high abundance of *Proteobacteria*. Three days following transplantation, the patient gut microbiota began to mimic the donor gut, evidenced by an increase in the abundance of *Firmicutes* and *Bacteroidetes*, an increase in microbial diversity, and an overall shift toward a more healthy gut microbiome profile. After 1 month, a lack of symptoms and negative clinical diagnostic tests for C. *difficile* were noted in all patients. After approximately 4 months, two out of the three patients maintained a microbial profile similar to that of the donor. The third patient's profile began to resemble the pre-FMT composition with an increase in *Proteobacteria*, but this is likely a result of a short-term course of sulfamethoxazole-trimethoprim for the treatment of a urinary tract infection.

Similar findings were reported by Weingarden et al. when a multi-omics approach was employed to examine the effects of FMT on the fecal microbiota composition and bile acid concentrations in 12 patients with recurrent CDI (105). After FMT, the microbiome of each patient closely resembled that of the donor and resulted in an increase

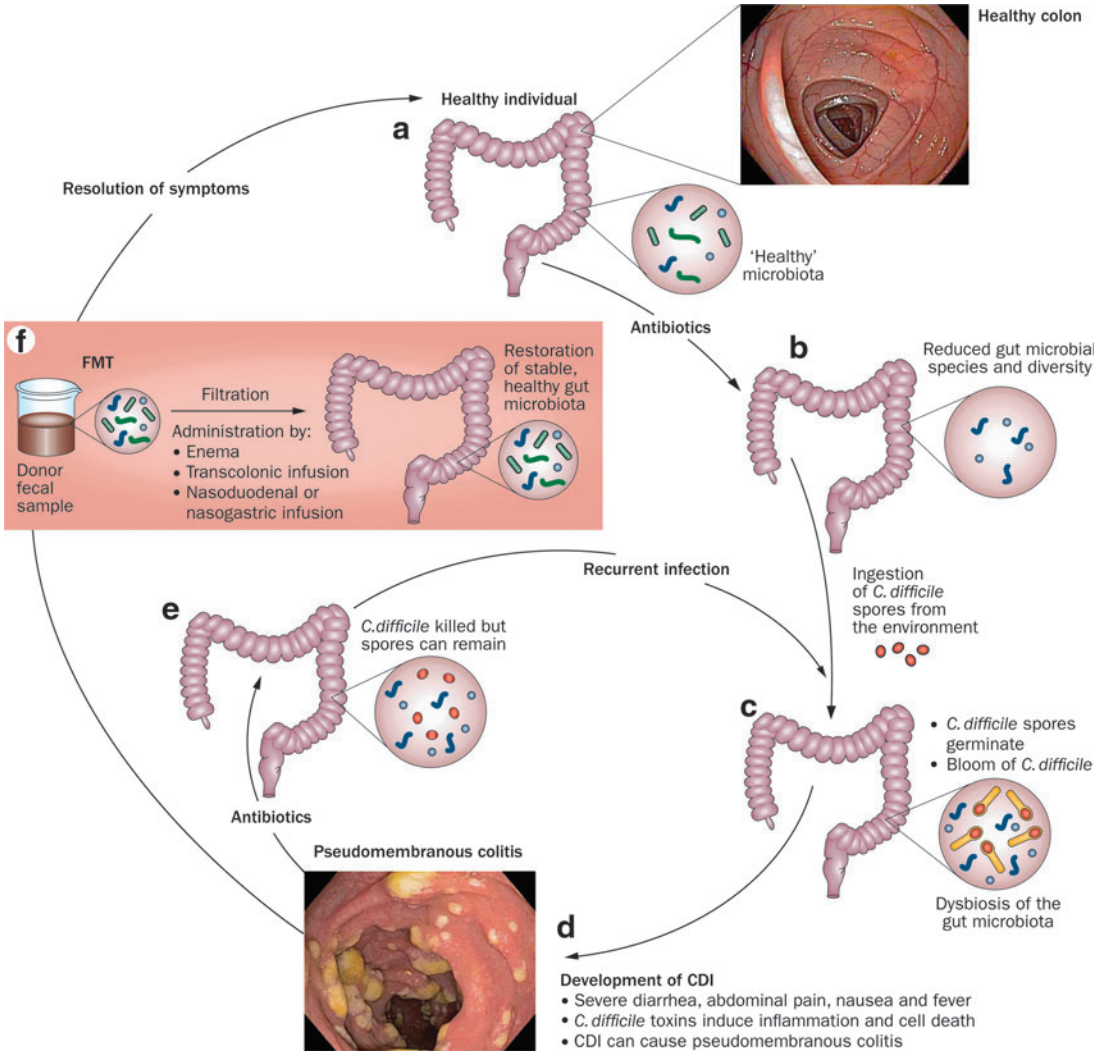

FIGURE 3 Fecal microbiome transplantation for the treatment of *Clostridium difficile* infection. Using material from a healthy donor, fecal transplants have successfully treated C. *difficile* infection and restored a healthy gut microbiome. (Reproduced with permission from reference 102.)

in abundance of *Bacteroidetes* and *Firmicutes* along with a decrease in abundance of *Proteobacteria*. Metabolomics further supported these findings, with the post-FMT metabolite profile resembling the donor profiles, and bile acids and primary bile salts, the predominant metabolites in the post-FMT and donor specimens, were restored to normal.

Beyond treatment of GI pathogens, FMT has also been evaluated in metabolic syndrome. Vrieze et al. transferred the intestinal microbiota from a lean donor to a subject with metabolic syndrome to examine the donor's effects on energy metabolism and energy sensitivity (106). Subjects with metabolic syndrome received small-intestine biopsies and bowel lavages through a duodenal tube. Subjects were assigned to a lean donor or assigned to the control group, which received an autologous gut microbiota infusion. Before and at 6 weeks after the microbiota transfer, insulin sensitivity, large and small intestine gut microbial compositions, and fecal short-chain fatty acids were measured. Improvement in peripheral insulin was seen in metabolic syndrome subjects at 6 weeks following transplant from a lean donor, and short-chain fatty acid concentrations also decreased. The microbiome profiles of obese subjects revealed a less diverse bacterial community characterized by increased abundances of *Bacteroidetes* and *Clostridium* cluster XIVa, which is a mucosal-associated group. Following transplant, microbial diversity increased in the lean donor transplant group, with no change in diversity seen in the control group. Specifically, there was an increase in *Roseburia intestinalis* and *Eubacterium halli* in the lean donor–assigned group.

A current trend in FMT therapy is the use of a more defined microbial population, derived from donor fecal specimens. The composition of these defined communities is known and can be controlled and replicated (107). More research is needed to define the most beneficial microbes from the donor community and determine which combinations would provide the most effective treatment.

THE GASTROINTESTINAL MICROBIOME AS A DIAGNOSTIC BIOMARKER

Significant shifts in the gut microbiome correlate with disease. Specifically, certain taxa appear to be associated with established markers of disease activity. These alterations may prove to be useful as diagnostic biomarkers. In 2010, Willing et al. (108) determined the composition of the gut microbiota in a cohort of 40 twin pairs who were concordant or discordant for Crohn's disease or ulcerative colitis. The authors noticed that several bacterial populations increased or decreased with disease type. Patients with ileal Crohn's disease had a decrease in *Faecalibacterium* and *Roseburia* and increased proportions of *Enterobacteriaceae* and *Ruminococcus*. Similar evidence of microbiome-based biomarker potential was found in a study by Swidsinski et al. (109), in which the mucosal flora in biopsy specimens of patients with inflammatory bowel disease (i.e., Crohn's disease or ulcerative colitis), self-limiting colitis, and IBS were characterized. They found that *Bacteroides fragilis* was responsible for >60% of the biofilm mass in inflammatory bowel disease but for only 30% of the biofilm mass in self-limiting colitis and <15% of the biofilm mass in IBS. Potential biomarkers have previously been proposed in pediatric Crohn's disease, where evaluation of *Campylobacter* spp. other than *Campylobacter jejuni* revealed a significantly greater abundance of *Campylobacter concisus* in children with Crohn's disease (110). Examination of the presence of *Helicobacter* in adults with and without ulcerative colitis revealed significantly higher abundance of the genus *Helicobacter* in patients with ulcerative colitis, as expected (111). These data suggest that robustly observed alterations in the abundance of certain microbes in the intestinal microbiome may prove to be useful biomarkers of disease as well as inflammation.

CONCLUSIONS

The human GI microbiome is dynamic in nature throughout the lifespan of an individual. With changes caused by genetics, diet, and the environment, the microbial community continues to adapt. During the evolution of the gut microbiome, each individual is uniquely predisposed to health and disease. Culture-independent methods could allow us to circumvent possible treatment failures by identifying antibiotic resistance in the metagenome of individual gut microbiomes. Defining the gut microbiome of healthy individuals and those patients affected by gastric diseases and disorders allows for the identification of disease-associated microbes and novel therapeutic targets. Microbiome manipulation via antibiotics, probiotics/prebiotics, and fecal transplantation can successfully alter the bacterial community of the gut and ultimately promote health and quality of life.

The Vaginal Microbiome

DAVID N. FREDRICKS

12

The collection of microbes (microbiota) in the human vagina with their associated genes (microbiome) and gene products helps to shape the physiology of the vagina (1). Different vaginal microbial communities are associated with different metabolic states, immunological responses, and risks of adverse health outcomes including preterm birth and acquisition of sexually transmitted infections. Tools in molecular microbiology have cataloged the diversity of vaginal microbes, leading to a more complete census, and have identified species that may be useful indicators of health or markers of disease risk.

The microbiota of the human vagina is distinct from that found at other human body sites and is characterized by more constrained bacterial species diversity, reflecting the unique properties of the vaginal environment (2). Vaginal microbes are dependent on host-derived nutrients for sustenance, unlike in the mouth or gastrointestinal tract, where nutrients from the diet can be easily co-opted by microbes. Sources of microbial nutrients in the vaginal environment may include glycogen in the vaginal epithelium, vaginal tissue fluid coating the surface of the vagina, mucus from the cervix, menstrual fluid (blood, protein, and endometrial cells) from the uterus, shed vaginal and cervical epithelial cells, and semen with sexual activity. The vaginal environment changes over the lifespan of an individual and also over the course of a menstrual cycle, with the potential for associated changes in the vaginal microbiota (3, 4).

The human vaginal microbiota is important to understand because it may impact the health of women and their sexual partners, the success of pregnancy and conception, and the health of newborns. The data showing a link between the vaginal microbiota and conception are sparse, though the presence of *Lactobacillus crispatus* vaginally and on a transfer catheter tip was associated with an increased rate of successful *in vitro* fertilization (5). Vaginal colonization with group B streptococci is associated with neonatal infection including sepsis and meningitis—hence the mandate for group B streptococci screening of pregnant women, coupled with antibiotic treatment if positive. Newborns delivered vaginally are initially colonized with maternal vaginal bacteria, and this initial exposure may shape the assembly of the indigenous neonatal gut microbiota. For example, there are interesting differences in neonatal microbiota when delivered vaginally versus by cesarean section (6). The vaginal microbiota has been associated with risk of preterm birth in numerous studies (7), with several vaginal bacteria found in amniotic fluid of women suffering from preterm labor (8). Unfortunately, efforts to reduce the rate of preterm birth through antibiotic therapy for bacterial vaginosis (BV) have not met with consistent success, with some studies showing benefit and other studies showing harm (9–11).

The vaginal microbiota (BV) has been linked to risk of sexually transmitted infections including gonorrhea, chlamydia, trichomoniasis, herpes simplex virus, and human papillomavirus infection (12, 13). In addition, BV has been linked to risk of HIV acquisition in women and transmission of HIV to men (14). The vaginal microbiota has also been associated with pelvic inflammatory disease, infertility, and risk of gynecologic infections such as posthysterectomy vaginal cuff cellulitis and postpartum endometritis in numerous studies. Clearly there are many known connections between the vaginal microbiota and states of health and disease, and new connections are coming to light with the development of advanced molecular diagnostic approaches for detecting vaginal microbes. More mechanistic studies are needed to dissect how the vaginal microbiota may mediate these risks, if indeed the microbiota is in the causal pathway to adverse health outcomes.

This chapter provides perspectives on the composition of the healthy vaginal microbiota, the changes in microbiota that ensue with BV, and the links between the vaginal microbiota and disease states. In addition, I will discuss the development of molecular diagnostic tools for detecting vaginal microbes.

THE HEALTHY VAGINAL MICROBIOTA

Before describing the microbiota associated with health, one needs to define "healthy" and distinguish between the terms "asymptomatic," "normal," and "healthy."

I will use the term "healthy vaginal microbiota" to refer to vaginal microbial populations that are common (present in a large fraction of women) and are associated with protection from adverse events such as preterm birth and acquisition of sexually transmitted infections. Women with vaginal microbiotas dominated by lactobacilli are considered healthy per this definition, though not all lactobacilli may impart the same degree of health benefit. Many studies have documented that women without BV have vaginal colonization with a few key *Lactobacillus* species, including *L. crispatus*, *Lactobacillus iners*, *Lactobacillus gasseri*, or *Lactobacillus jensenii*, though other lactobacilli can also be present including *Lactobacillus vaginalis* (15, 16). In

David N. Fredricks, Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Research Center and Division of Allergy and Infectious Diseases, University of Washington, Seattle, WA 98195.

some women a particular *Lactobacillus* species dominates the vaginal community, such as *L. crispatus* or *L. iners*. In other women there is more equal representation of two or more *Lactobacillus* species such that any single species cannot be considered truly dominant. It is common for a few other bacterial species to coexist with lactobacilli in the vagina of healthy women, including *Gardnerella vaginalis*, some *Prevotella* species, and other bacterial taxa that are usually present in low abundance.

Some investigators have proposed that vaginal bacterial communities in humans can be categorized into a handful of community types based on hierarchical clustering of 16S rRNA gene amplicon sequences. For example, Ravel et al. suggested that there are five bacterial community types in the vagina of asymptomatic women, with four of the five clusters notable for abundance of a particular *Lactobacillus* species, and the cluster designated "IV" having diverse microbiotas notable for the presence of species previously linked to BV (15). Indeed, women in cluster IV tended to have BV as documented by Gram stain, but clinical criteria for BV (Amsel criteria) were not assessed in that study. Other investigators have found different vaginal bacterial community profiles, and this may reflect differences in DNA extraction methods, broad-range PCR primers, study populations, and clustering algorithms used to generate community types. For example, Smith et al. found six bacterial community types using cervical swabs, including types dominated by *G. vaginalis* (17). The *G. vaginalis* community type may have been missed in the work by Ravel and colleagues due to use of a broad-range 16S rRNA gene PCR primer (27F) with mismatches to the *G. vaginalis* sequence (18).

Lactobacilli have been considered markers of vaginal health for several reasons. First, multiple studies have associated a lactobacillus-dominated vaginal microbiota with protection from adverse health outcomes, including preterm birth, pelvic inflammatory disease, risk of HIV acquisition and transmission, and risk of other sexually transmitted infections (19–21). It is possible that lactobacilli serve as markers of disease risk but do not have an active role in mediating risk, though this seems unlikely. What direct role could lactobacilli play in promoting health and modulating risks of adverse health events? Glycogen is present in the vaginal epithelium (22). Lactobacilli can convert glucose from vaginal glycogen to lactic acid. The lactic acid helps to decrease the vaginal pH, which may be microbicidal by creating an environment inhospitable for growth of other microbes at this acidic pH of 3.5 to 4.5. In addition, lactic acid has direct antimicrobial properties beyond that mediated by the change in vaginal pH (23). In support of this connection, higher levels of free glycogen in the vagina are associated with lower vaginal pH and higher abundance of lactobacilli (22).

Bacteriocins and other antimicrobial compounds secreted by vaginal lactobacilli may also be toxic for other bacterial species (24). Vaginal lactobacilli thus create an environment that is antagonistic to the growth of many non-*Lactobacillus* species, including some pathogens. In addition, lactobacilli may compete with introduced non-*Lactobacillus* species for existing resources, thereby providing colonization resistance. In summary, vaginal lactobacilli are likely markers of health because they have relatively benign interactions with the human host while tending to inhibit the growth of pathogens, though the relative importance of different inhibitory forces is debated.

THE NORMAL VAGINAL MICROBIOTA

Although having a vaginal bacterial biota dominated by lactobacilli tends to be associated with states of health, are there other vaginal bacterial communities that can be considered normal? The answer to this question depends on your definition of normal. Normal can mean several things, including being within a normal distribution of vaginal bacterial community types, occurring naturally, or found in normal women such as those women without a diagnosed disease. Using these definitions of normal, it is possible to argue that non-*Lactobacillus* vaginal bacterial communities can be normal. For example, vaginal bacterial communities dominated by *G. vaginalis* and some anaerobic bacteria can be found in women who appear to be currently healthy and not symptomatic. To wit, we used quantitative PCR assays targeting common vaginal bacteria in a longitudinal study of women to show that some apparently healthy women have a decrease in lactobacilli and a surge in concentrations of *G. vaginalis* during menses (3). The dynamic nature of the vaginal microbiota during menses was confirmed by other investigators using broad-range 16S rRNA PCR with sequencing, though *G. vaginalis* was likely underrepresented in this analysis due to primer bias, and therefore conclusions about relative abundances of *Gardnerella* during menses cannot be made from this study (25).

Some investigators have insisted that having a vaginal microbiota characterized by diverse anaerobic bacteria that includes BV-associated bacteria should be considered normal (15). It is true that about >50% of women with BV diagnosed by Gram stain of vaginal fluid lack symptoms (26, 27). But are these asymptomatic women with BV-associated vaginal bacteria normal? Since up to 29% of women in the United States have BV (27), which is mostly asymptomatic, one could make the argument that BV is within the normal distribution of vaginal microbiotas. But is a woman with BV as healthy as a woman without BV? Regardless of symptoms, women with BV have elevated risks of preterm birth, HIV acquisition, pelvic inflammatory disease, and other adverse events including postsurgical complications. An appropriate analogy is the middle-age adult who has severe hypertension and hypercholesterolemia; the person may be asymptomatic now, and even have blood pressure and cholesterol values that fall within an elevated but normal distribution. Yet this person has an elevated risk of myocardial infarction and stroke and therefore cannot be considered optimally healthy despite his or her outward appearance and lack of symptoms. Similarly, women with BV may be considered normal (based on some definitions of normal listed above) if asymptomatic, but this categorization ignores the health risks that are consistently associated with BV. Asymptomatic and normal do not equate with healthy.

Fungi can be found in the vagina of asymptomatic women, including *Candida albicans* and *Candida glabrata* (28) and, more rarely, *Saccharomyces cerevisiae* (29), but these organisms are also associated with symptomatic vaginitis. It is not clear why some women colonized with *Candida* species develop inflammation and symptoms while others do not, but differences in host factors are suspected (30).

Detailed surveys assessing for the prevalence of archaea in vaginal samples have not been reported.

Several viruses and numerous bacteriophage have been detected in the vagina of asymptomatic women, including herpes simplex virus, cytomegalovirus, and human papillomavirus. These viruses are also associated with pathology in the reproductive tract of some women, highlighting the

observation that microbes with pathogenic potential can also be found in normal or asymptomatic women. *Lactobacillus* phages have been detected in the human vagina, and some investigators have hypothesized that these viruses may shape the vaginal bacterial biota by depleting lactobacilli (31). However, there are no clear studies showing a temporal relationship between bacteriophage acquisition and loss of lactobacilli or development of BV.

BV

BV is a very common condition in women of reproductive age. The National Health and Nutrition Examination Survey (NHANES) assessed for the prevalence of BV using Gram stain of vaginal fluid in a nationally representative sample of women in the United States, revealing that 29% of women had BV and 84% of women did not report symptoms, although these women were not examined for the presence of vaginal discharge or amine odor (27). BV is the most common cause of vaginal discharge, though ~40% of women with BV by Gram stain of vaginal fluid lack symptoms in most studies (32). It is not known why some women with BV are symptomatic while others are less affected or completely asymptomatic, though differences in microbial populations and their metabolites may help drive differences in symptoms (16). BV is considered by many to be a dysbiotic condition and is characterized by a decrease in abundance of most lactobacilli coupled with an increase in abundance of anaerobic bacteria in complex communities. Although many risk factors for BV are known, the proximate factors that lead to this shift in vaginal microbiota are not clear.

The diagnosis of BV was originally based on assessing for the presence of four clinical criteria, commonly known as Amsel criteria based on the original publication by Amsel et al. (33). A diagnosis of BV requires the presence of three of the following four criteria:

1. A homogeneous, thin, gray-white discharge that smoothly coats the vaginal walls.
2. A vaginal pH of >4.5.
3. A positive "whiff test" for amines, which is the presence of a fishy odor when 10% potassium hydroxide (KOH) is added to a sample of vaginal fluid, usually on a microscope slide.
4. The presence of clue cells on saline wet mount visualized by light microscopy. Clue cells are shed vaginal epithelial cells that are studded with bacteria, usually coccobacilli, and obscure the edges of the epithelial cells. At least 20% of epithelial cells should be clue cells to yield a positive result.

The advantage of using Amsel criteria to diagnose BV is that the approach is relatively cheap and employs little technology except pH paper, KOH, and a light microscope. There is some subjectivity to the Amsel diagnostic approach since it relies on the sense of smell for the whiff test and the recognition and quantification of clue cells, which requires some experience.

A more objective approach for the diagnosis of BV is based on interpretation of vaginal fluid smear Gram stains, where multiple observers can assess and validate the results. The microscopist notes the abundances of several bacterial morphotypes (bacterial shapes and Gram stain characteristics) such as bacterial forms resembling lactobacilli, *Gardnerella/Bacteroides*, and *Mobiluncus* when using Nugent criteria to define BV (34). A low Nugent score of 0 to 3 is characterized by large numbers of lactobacillus morphotypes and normal vaginal microbiota, a score of 7 to 10 indicates decreased lactobacillus morphotypes and increased abundance of coccobacilli, indicative of BV, and a score of 4 to 6 is considered intermediate between these two poles. The scoring system of Ison and Hay is another approach for using Gram stain to diagnose BV (35). The problem with Gram stain as a diagnostic test is that interpretation of the smear results requires an expert microscopist skilled at this specific task, and the resulting turnaround time is long, so it is not a feasible point-of-care test. Gram stain remains the "gold standard" for diagnosis of BV and thus is commonly employed in research studies where turnaround time of results is not paramount.

Numerous reviews have summarized the adverse health outcomes associated with BV, ranging from preterm birth to acquisition of HIV infection. What is missing from most studies is mechanistic insight into how vaginal bacteria associated with BV may mediate these health risks. One persistent scientific conundrum arises from the observation that BV is consistently associated with risk of preterm birth, yet most (though not all) studies of antibiotic treatment for BV in pregnancy have failed to show a benefit in reducing this risk (36–38).

The Microbiology of BV: Cultivation Studies

BV is characterized by a bloom of anaerobic and facultative bacteria in the vagina, with an increase in species richness and diversity. Early cultivation studies identified numerous bacterial species associated with BV, including those in the genera *Prevotella*, *Porphyromonas*, *Mobiluncus*, and *Mycoplasma* (39). However, cultivation has not been a reliable diagnostic test for BV. In the 1950s Gardner and Dukes isolated a bacterium from women with the condition nonspecific vaginitis, now known as BV, and made the argument that this bacterium was the primary cause of BV (40). Originally named *Haemophilus vaginalis*, the isolated organism was renamed *Gardnerella vaginalis* in honor of Gardner. Subsequent studies have revealed that G. *vaginalis* is indeed present in most women with BV but is also present in the majority of women without BV when sensitive detection methods are used (41). The failure to induce BV in most women inoculated with pure cultures of G. *vaginalis* (40) and the presence of G. *vaginalis* in women without BV provide evidence against the fulfillment of Koch's postulates for disease causation. On the other hand, high concentrations of G. *vaginalis* are a more specific indictor of BV, and this may indicate a threshold effect wherein bacterial levels that exceed a particular threshold lead to onset of BV (42). Supporting this concept is work on vaginal biofilms in women with BV showing that G. *vaginalis* is a major constituent of dense mats of bacteria coating the vaginal epithelium in some women with BV (43, 44). Accordingly, it may not be the mere presence or absence of G. *vaginalis* that is important in BV, but rather the density of bacteria, interactions with other bacterial species, and what these bacteria are doing. When highly sensitive PCR detection methods are used, the presence of G. *vaginalis* has very poor specificity for BV (41). In addition, high concentration of G. *vaginalis* can be found in some women without BV during menses (3).

The Microbiology of BV: Broad Molecular Surveys

Our understanding of the microbiology of BV has been greatly expanded through the use of nucleic acid–based

microbial detection and identification methods. The primary method employed in this approach has been broad-range 16S rRNA gene PCR with sequencing of amplicons (15, 16, 45, 46), though other phylogenetically informative genes have also been used as PCR targets, such as *cpn60* (47, 48). A nucleic acid amplification-independent approach relies on high throughput metagenomic sequencing of community DNA to identify microbes and their genes; this approach is tractable but has been little used to study BV. One advantage of these molecular approaches is that fastidious or uncultivated bacteria are revealed, providing a more complete census of microbes. However, biases exist with each approach, and this is also true for broad-range PCR methods where the consensus primers used to bind conserved DNA sequences may not efficiently amplify the DNA from all species in a way that represents the true abundances in the sample (18, 49). It is the intervening variable sequence between primer binding sites that provides the phylogenetic resolution to identify genera and species, but first, amplification must occur in the target gene.

There have been many large studies analyzing the vaginal microbiota of women with BV, and usually comparing the microbiota to women without BV or in some cases to women who were designated asymptomatic. These studies highlight the fact that women without BV tend to have vaginal bacterial communities dominated by lactobacilli, whereas women with BV have vaginal bacterial communities that are more diverse, with many putative anaerobes, and have more evenness based on sequence reads (i.e., less likely to show domination of a single bacterial species, though this can occur in BV) (16). Some investigators have reported that diverse anaerobic bacterial communities can occur in asymptomatic women, but these women usually had BV by Gram stain, and unfortunately, Amsel criteria were not assessed (15). We know that a large fraction of women with BV by Gram stain are asymptomatic (27).

Several new bacterial species have been identified or detected in the human vagina using molecular surveys and associated with BV, including *Atopobium vaginae*, *Sneathia amnii*, *Sneathia sanguinegens*, an *Eggerthella*-like bacterium, two novel *Megasphaera*-like bacteria, several *Prevotella* species, and several bacteria in the *Clostridiales* order that we have designated BV-associated bacterium 1, 2, and 3 (BVAB1, BVAB2, BVAB3) (45, 46, 50).

The microbiology of BV is heterogeneous, and this is demonstrated in a study of 220 women in Seattle who had their vaginal swab subjected to broad-range 16S rRNA gene PCR with pyrosequencing (Fig. 1) (16). Some women with BV had vaginal bacterial communities dominated by *Prevotella* species, some by BVAB1, and some by *Sneathia* species. Other women had vaginal bacterial communities that were more even, without species domination. All women with BV had highly complex communities of bacteria, which contrast to the *Lactobacillus* genus domination in women without BV. It is not clear why these different bacterial consortia form in BV, and nor is the nature of the cross-species interactions, but it is clear that BV is never a mono-microbial process.

Bacterium-specific quantitative PCR (qPCR) has demonstrated that onset of BV is associated with acquisition of BV-associated anaerobes, and antibiotic treatment for BV is associated with depletion of these anaerobes. Interestingly, treatment with antibiotics does not usually lead to

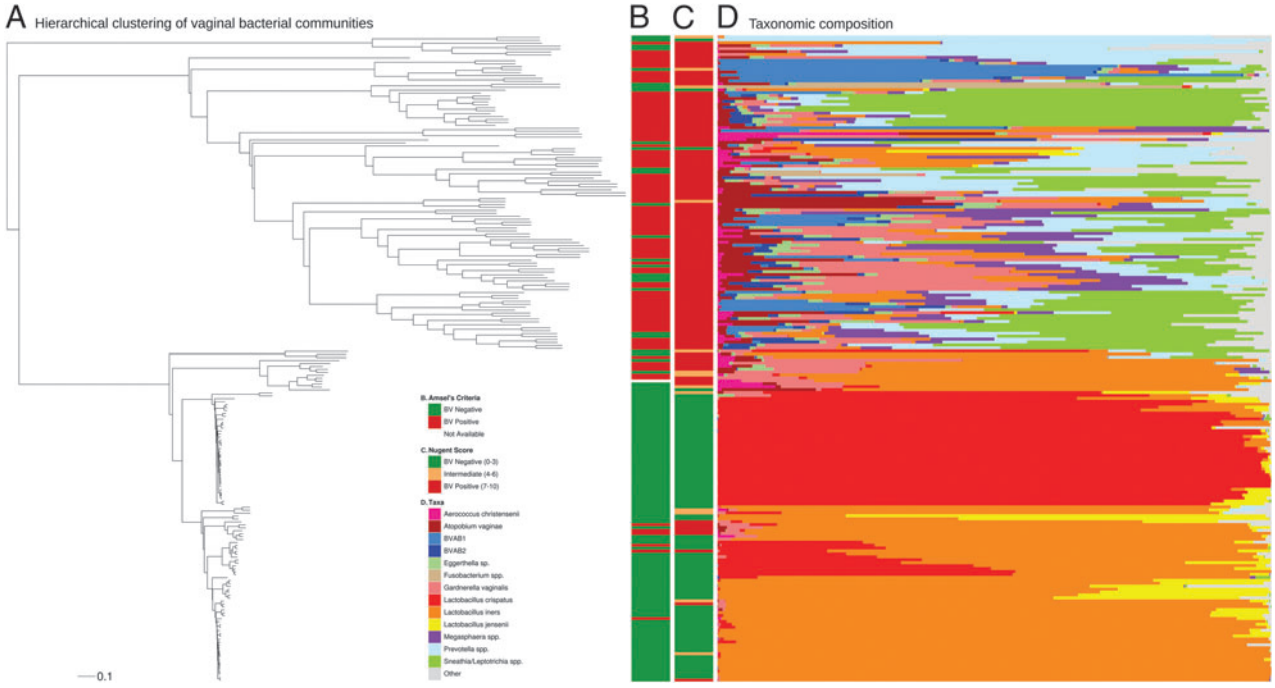

FIGURE 1 Vaginal bacterial communities in all women. (A) A novel variant of hierarchical clustering was used to generate a clustering tree depicting the bacterial diversity in 220 women with and without BV. The scale bar represents KR distance, a generalization of UniFrac. The colored bars represent bacterial taxa that were most abundant in each sample. Less abundant taxa are grouped in the "other" category. BV status by Amsel criteria (B) and Gram stain (C) is provided for all women in the two vertical bars. In the absence of BV, the vaginal microbiota was dominated by *Lactobacillus crispatus* or *Lactobacillus iners*. Women with BV had more diverse bacterial communities (16).

eradication of G. *vaginalis*, though concentrations usually decrease with therapy (51). It is notable that the antibiotics deemed to be most effective in BV are metronidazole and clindamycin, which have excellent coverage against anaerobic bacteria. These antibiotics are effective when given vaginally or orally, though there is a high rate of BV recurrence after antibiotics are stopped. Metronidazole is not a reliable antibiotic for treating G. *vaginalis* infection (39).

Diagnostics for BV

There is a need for rapid, objective, and accurate diagnostic tests for BV given the limitations of (Amsel) clinical criteria and vaginal fluid Gram stain interpretation (e.g., Nugent criteria).

Currently available technologies include the BD Affirm VP III test, which uses a nucleic acid probe to detect a high concentration of G. *vaginalis* in a nonamplified assay (52–54). The assay can be completed in under an hour. The rationale behind this assay is that G. *vaginalis* may be present in women without BV but is not likely to be detected in this platform given the nonamplified format and low assay sensitivity or high detection threshold. In contrast, women with BV tend to have high concentrations of G. *vaginalis*, and thus the assay has reasonable specificity for BV. The flaw in this approach is that some normal women experience very high concentrations of G. *vaginalis* during menses and yet do not have BV, so there may be some false-positive results.

The OSOM BVBLUE assay is a point-of-care diagnostic that operates by producing a chromogenic compound in the presence of sialidase activity. Sialidase is known to be elevated in vaginal fluid from women with BV, and several bacterial species may produce these enzymes. The assay can be completed in 10 minutes. This assay has performed well with some patient populations (55, 56) and less well in others (57).

The Potential for Molecular Diagnostics in BV

Several published studies have tested the utility of species-specific PCR assays for the diagnosis of BV using either conventional PCR assays or qPCR. One of the earliest such studies was published by van Belkum et al. in 1995 and showed that G. *vaginalis* was present in 10 of 11 women with BV but present in 40% of women regardless of BV status, highlighting the poor specificity of G. *vaginalis* PCR for BV (58). Similarly, in 2001 Schwebke and Lawing analyzed the prevalence of *Mobiluncus* in vaginal samples from 74 women and noted a sensitivity of 84.5% for BV. *Mobiluncus* was also detected by PCR in 38% of women without BV, again showing limited specificity for BV, though the species *Mobiluncus curtisii* was more specific (59). In 2002 Obata-Yasuoka described a multiplex PCR assay to detect the three bacterial Gram stain morphotype-genera (*Gardnerella*, *Bacteroides*, and *Mobiluncus*) associated with BV by Gram stain, demonstrating a sensitivity of 78.4% and a specificity of 95.6% compared to Nugent score (60).

The advent of advanced molecular methods for characterizing the vaginal microbiota in women with BV has led to the identification of many additional bacteria that could be used as markers of BV (45, 46, 61). For example, in 2004 Verhelst et al. and Ferris et al. used species-specific PCR assays to show some utility of A. *vaginae* as a marker of BV (45, 62). Bradshaw et al. (50) applied PCR assays for A. *vaginae* and G. *vaginalis* to vaginal samples from 358 women and demonstrated a sensitivity of 96% and specificity of 77% for A. *vaginae* PCR in diagnosis of BV. The PCR assay for G. *vaginalis* was 99% sensitive but only 35% specific, showing once again that the presence of G. *vaginalis* is a poor indicator of BV. Sha et al. used quantitative PCR to show that using a selected threshold for concentration of bacterial DNA could improve the specificity of the PCR assay for G. vaginalis (63). Similarly, Menard et al. linked quantity of bacterial DNA to diagnosis of BV, with a focus on A. *vaginae and* G. *vaginalis* (42, 64). Use of quantitative cutoffs to define positive test results was essential to improve specificity in these studies, with some expected decline in diagnostic sensitivity.

Fredricks et al. used a panel of conventional species-specific PCRs applied to vaginal samples collected in a cross-sectional study of >200 women, with sequence confirmation of the amplicons to assure amplification of the intended bacterial target. PCR detection of either a vaginal *Megasphaera* species or BVAB2 yielded a sensitivity of 99% and a specificity of 89% for diagnosis of BV compared to Amsel clinical criteria, and a sensitivity of 95.9% and a specificity of 93.7% compared to Nugent criteria for diagnosis of BV (41). Of note, the subjects in this study were drawn from two clinics in Seattle, Washington, and the performance characteristics may differ in other populations of women. Zozaya-Hinchliffe et al. also found an association between detection of *Megasphaera* species by qPCR and presence of BV, but in a cohort of women with mucopurulent cervicitis (65). The results of a more extensive panel of qPCR assays targeting vaginal bacteria and applied to vaginal samples from 37 women were described by the same group in 2010, again showing the utility of *Megasphaera* species and many other bacteria as markers of BV, though the study population was of limited size (66).

How do bacterium-specific PCR assays for BV perform in populations of women outside the United States and Europe? Almost every study published to date shows that the prevalence of vaginal bacteria is different in different studies, and this likely reflects differences in study populations and risks for BV, the DNA extraction methods employed, and different PCR assays performed with different DNA detection thresholds and different specificities for the bacterium being targeted. Nevertheless, studies from China (67), Africa (68, 69), and Greenland (70) suggest that the vaginal bacterial species present in these women are generally similar to what is found in the United States and Europe. It does not appear that that there are vaginal bacterial species that are unique to a given population of women. More recent studies have confirmed the value of key bacterial species as indicators of BV, have highlighted the value of quantification of bacterial DNA by PCR to identify DNA thresholds indicative of BV rather than low-level colonization, and have illuminated the value of using multiple species rather than a single target to inform the diagnostic algorithm (71–74).

Is PCR-based diagnosis of BV ready for deployment? There are "reference" labs that are currently offering many of these species-specific PCR assays to clinicians. Determining the true value of these assays requires having well-defined protocols (such as DNA extraction and quality control) and assays with validated lack of cross-reactivity with other species. Furthermore, we need a much better understanding of how the performance of these PCR assays for diagnosis of BV differs in different populations of women. For instance, does one need to use different assay targets or different DNA thresholds to indicate a positive result when used in a population of commercial sex

workers with high risk for BV seen at an STD clinic compared to college women seen at a student clinic? There have been few large studies investigating these questions, and no studies have compared large numbers of women in different settings.

The ability to diagnose BV using PCR is very exciting because it offers the potential to combine these BV PCR assays (41) with other nucleic acid–based assays in a single platform for detecting multiple genital tract infections simultaneously, such as infection with *Trichomonas vaginalis*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex virus, or C. *albicans*. Metagenomic methods that rely on sequencing whole-community DNA offer another avenue for characterizing vaginal microbial populations, but there are few studies using this as a diagnostic approach, and it is not currently practical outside a research setting.

Microbial Communities of the Male Urethra

BARBARA VAN DER POL AND DAVID E. NELSON

13

HISTORICAL UNDERSTANDING OF THE MICROBIAL COMMUNITIES OF THE MALE URETHRA

Traditionally, the male urethra in healthy men was believed to be sterile or only transiently colonized by microorganisms. This view reflected technical limitations in studying this site that were not easily surmounted until methods for cultivation-independent bacterial identification became available. First, while the obvious analogous compartment to the male urethra may be the female urinary tract, given the function of the penis, the male urethral compartment is most often compared to the vaginal microenvironment. A simple Gram stain of these two body sites demonstrates substantial differences. Vaginal samples from healthy women typically contain significant numbers of epithelial cells and a large number of microorganisms including *Lactobacillus* and *Candida* species among others (see chapter 12). In contrast, it is unusual to identify similar numbers of microorganisms by simple Gram stain of urethral smears obtained from healthy men. An unintended consequence has been that far less effort has gone into characterizing the relatively sparse microorganisms that are routinely observed, and ignored, in urethral specimens from healthy men. As described later in this chapter, recent cultivation-independent surveys of male urethral swab, urine, and semen specimens have confirmed that the male urethra harbors smaller absolute numbers of microorganisms than the vagina but have also identified a surprisingly diverse array of bacterial taxa, many of which correspond to pathogens and commensal organisms found in the vagina. This has led to the reemerging idea that the microbiology of the male urethra may be more complex than is appreciated and that the composition of urethral microbial communities, collectively the urethral microbiome, might play a role in male urethral health and disease analogous to the role of the vaginal microbiome.

There are multiple challenges associated with culture-based methods for detecting microorganisms in the male urethra. Some of these are related to the form and function of this body compartment. While the vagina is exposed, via sexual activities or hygiene practices, to outside influences, it also remains a partially protected environment with little efflux. In contrast, the male urethra is repeatedly flushed by urination and ejaculation. This results in lower organism loads and enrichment for organisms that can adhere to and/or invade the urethral epithelium. Since little is known about the composition of the normal microbiome of the male urethra, optimal media and conditions for the cultivation of urethral microorganisms are often unknown. Illustrating this, five of the most common sexually transmitted bacterial pathogens of the male urethra (*Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, *Mycoplasma genitalium*, and *Ureaplasma urealyticum*) can only be cultivated using highly specialized cultivation methods. Additionally, the necessary culture conditions for these five pathogens are highly divergent, ranging from culture on agar media, culture in broth, and tissue culture often requiring days to weeks to cultivate organisms.

The physiological form of the penis presents challenges, compared to the vagina, regarding collection of adequate specimens for cultivation of organisms. Sampling of the male urethra, which provides the best specimens for microbial culture, is painful and provides very limited specimen volume. In clinical practice, urethral sampling is never performed in healthy men and is typically only performed when men present with urethritis or other urinary tract complaints. Coupled with the development of rapid and specific nucleic acid amplification tests (NAATs) for diagnosis of many sexually transmitted infections (STI) that function well with urine (1), this clinical limitation led to a dramatic decline in the collection of male urethral specimens from which residual portions might be used for research into the microbiome of this compartment. Although residual urine specimens are still routinely collected and retained by many STI research groups, the acidity of urine makes this specimen inferior to urethral swabs for culture of many fastidious urethral microorganisms. Further, fastidious organisms usually do not survive in stored urine specimens.

Despite the challenges associated with urine and urethral specimens, attempts to culture male urethral bacteria began in the 1950s and expanded widely by the 1970s. This was driven by three factors. First, it began to be appreciated that a significant proportion of men who presented with urethritis failed to respond to penicillin treatment and were negative for *N. gonorrhoeae*. This resulted in development of the name of the syndrome nongonococcal urethritis (NGU) when no other etiologic agent of urethritis was identified (2–4). Second, a broader range of media and methods for culture of anaerobes became widely available (5–7). Finally, this was the era when many microorganisms, now recognized as causal, were first

Barbara Van Der Pol, Division of Infectious Diseases, University of Alabama at Birmingham School of Medicine, Birmingham, AL 35294. **David E. Nelson,** Department of Microbiology and Immunology, Indiana University School of Medicine, Indianapolis, IN 46202.

associated with NGU including C. *trachomatis* (8, 9), M. *genitalium* (10), U. *urealyticum* (11–14), herpes simplex virus (15), and T. *vaginalis* (16). Success triggered the search for additional NGU-associated pathogens that continues today. However, since most of the early studies of urethral bacteria focused on identifying agents of NGU when incidence of this syndrome was rapidly increasing, the studies often suffered design weaknesses including imprecise clinical definitions, lack of case-control and treatment studies, and investigation of one or a few targeted microorganisms (17–23). Nonetheless, by the mid-1970s it was generally appreciated that aerobic bacteria including *Staphylococcus*, *Streptococcus*, *Lactobacillus*, *Haemophilus* (subsequently determined to be *Gardnerella vaginalis*), and a handful of poorly differentiated anaerobes at least periodically colonized the healthy male urethra.

A case-control study of men with and without NGU by Bowie et al. in 1977 provided the foundation upon which many more contemporary studies of the male urethral microbiome have been built (13). Goals of the study were to identify proportions of NGU cases that could be attributed to C. *trachomatis* and U. *urealyticum* and to identify other urethral pathogens possibly associated with this syndrome. Corresponding urine, urethral swab, and postprostatic massage specimens from 69 men with well-defined urethritis and 39 controls without urethritis were subjected to broad-range anaerobic and aerobic culture. The results confirmed that C. *trachomatis* infection was strongly associated with NGU (8, 24, 25) and provided early evidence that U. *urealyticum* was more frequent in men with nongonococcal nonchlamydial urethritis (NGNCU) than in similar men without urethritis (14). No significant association between NGU or NGNCU and other bacteria was found, but the results provided one of the first pictures of the urethral microbiome in sexually active adult men. Aerobes were almost ubiquitous, and *Staphylococcus epidermidis*, various *Corynebacteria* spp., lactobacilli, and G. *vaginalis* were each detected in specimens from at least half the men in one or more of the NGU, NGNCU, and control subgroups. Aerobic lactobacilli, G. *vaginalis*, and α-hemolytic streptococci were enriched in the controls compared to the combined NGU group (NGU and NGNCU). Anaerobes were also cultured from 91% of the control group. These included multiple *Bacteroides* spp. and undifferentiated lactobacilli, *Propionibacterium* and *Eubacterium*, and Gram-positive cocci. Gram-negative bacteria were more frequent in the control group than in the combined NGU group, and complete absence of anaerobes was significantly less frequent in the control group (9%) than in the NGNCU group (34%). The authors were unable to draw firm conclusions concerning the significance of these differences but proposed that altered microbiomes in men with NGU might predispose them to infection with urethral pathogens. This important hypothesis continues to guide studies of the urethral microbiome today.

Culture-based investigations of the male urethral flora declined in the 1980s, likely because attention was focused on NGU pathogens that were becoming more firmly established such as C. *trachomatis*. Enthusiasm may also have been diminished by preliminary associations of NGU with various urethral microorganisms including *Bacteroides ureolyticus* (26–28), G. *vaginalis* (29–32), and *Clostridium difficile* (33) among other organisms, which were subsequently determined to be more likely to be commensals in later case-control and treatment studies (13, 14, 32–41). Nonetheless, these studies employed improved cultivation approaches that expanded the list of bacteria known to colonize the urethra.

A key question that remained unanswered until the 1980s was, What was the origin of nonpathogenic microorganisms in the adult male urethra? Although indirect evidence for sexual transfer of a variety of bacterial vaginosis (BV)–associated taxa from men to women, and of G. *vaginalis* specifically, existed (42–44), the respective roles of sexual exposure, maternal transfer, auto-inoculation and/or environmental reservoirs in establishment of the urethral microbiota were unclear. A cross-sectional, cultivation-based study of 16 adolescent men who denied previous sexual activity (group 1), 42 young men who reported sexual activity and who did not have pyuria (elevated white blood cell counts in urine) (group 2), and 32 young men who reported sexual activity and had pyuria (group 3) provided some of the first answers (45). Urine and urethral swab specimens from the young men were cultured for both anaerobic and aerobic bacteria and for specific STIs including C. *trachomatis*, N. *gonorrhoeae*, U. *urealyticum*, and *Mycoplasma* spp.

Aerobic bacteria were isolated from every subject, and similar numbers of species were isolated from individuals in the three groups. Diptheroids, coagulase-negative staphylococci, lactobacilli, and streptococci were abundant in all three of the groups. Since these taxa are common on the penile skin and glans, the authors speculated that these represented normal flora of the distal urethra. Interestingly, α-hemolytic streptococci were more abundant in group 1, suggesting that these might be commensal and displaced by bacteria subsequently introduced through partnered sexual activity. Anaerobes were isolated from approximately 80% of the specimens in each of the groups, but greater numbers of anaerobic taxa were isolated per specimen in sexually active groups 2 and 3. *Peptostreptococcus* and *Bacteriodes* spp. were almost exclusively isolated from groups 2 and 3; many of these resembled vaginal bacterial associated with BV. G. *vaginalis* was frequent in specimens from groups 2 and 3 but was only identified in a single group 1 specimen. *U. urealyticum* and *Mycoplasma* spp. were observed frequently and were exclusively identified in specimens from the sexually active young men, supporting the hypothesis that these organisms may be sexually transmitted. No anaerobes were statistically associated with NGNCU, consistent with previous studies (13, 27, 46). In summary, this landmark study established that the adolescent male urethral microbiota is established prior to initiation of partnered sexual activity and is additionally shaped by subsequent sexual exposures.

A few detailed cultivation-based studies of male urethral specimens have been periodically reported since the late 1980s. A study by Mazuecos and colleagues (92) identified bacteria in urethral specimens from 110 adult men; 35 did not have urethritis, 17 had gonococcal urethritis, and 58 had NGU. Streptococci were more frequent in healthy men than men with NGNCU, diversity in the gonococcal urethritis group was substantially lower than other subgroups, and Gram-negative anaerobes were more frequent in men with urethritis than controls. Bacteria found previously in vaginal specimens were identified including *Veillonella*, *Porphyromonas*, *Bacteroides*, *Clostridium*, and *Prevotella* spp. A study by Willen and colleagues of specimens from the vas deferens, prostatic secretions, semen, urethra, and coronal sulcus from 97 healthy men showed that the upper male genital tract (prostate gland and vas deferens) is usually sterile, as is semen, until it passes through the urethra

(47). Over 80% of the semen samples collected from these men yielded positive bacterial cultures, and the same species of bacteria were often isolated from corresponding prostatic secretion, semen, and urethral specimens. Over 70% of isolates identified in coronal sulcus swabs were detected in urethral specimens, indicating that there is substantial cross-talk between these habitats. However, only 1 of 61 surgically collected vas deferens samples yielded viable bacteria.

Krieger reported similar results from localization studies of bacteria in serial urine and postprostatic massage specimens collected from men with prostatitis (48). Gram-negative and Gram-positive bacteria were detected relatively frequently, but these only rarely localized specifically to the prostate fluid specimens, indicating that the organisms originated in the lower genital tract, usually in the urethra (48). The same group detected bacterial 16S rDNA in approximately 77% of surgically collected prostate specimens in another study, but these specimens rarely yielded bacteria in culture (49). A more recent study of 18 healthy men and 24 men with persistent nonspecific urethritis differentiated closely related *Corynebacterium* spp. and *Staphylococcus* spp. in urethral specimens (50). Bowie's original observation that lactobacilli were more frequent in urethral specimens from healthy men compared to men with urethritis was also confirmed, because 100% of the healthy men and none of the men with persistent, nonspecific urethritis were colonized with lactobacilli (14). Correlations between the loss of urethral microbial diversity and persistent nonspecific urethritis, and positive association of persistent nonspecific urethritis with opportunistic bacteria including micrococci, enterococci, and *Staphylococcus aureus* were also reported (50). Provocatively, staphylococci isolated from the men with persistent nonspecific urethritis had higher decomplementary activity, which was defined as the decrease in complement activity under the influence of culture supernatants, than did isolates from the no-urethritis control men. This illustrates that finer differentiation of urethral microorganisms can differentiate pathogenic and nonpathogenic microorganisms from broader higher taxonomic divisions that show weak or no disease association. This could be particularly pertinent to identification of new agents of NGU considering that differentiation of species of commensal and pathogenic *Mycoplasma* spp. (*Mycoplasma hominis* vs. *M. genitalium*) and *Ureaplasma* spp. (*U. urealyticum* vs. *Ureaplasma parvum*) resolved conflicting data concerning roles of specific members of these genera in this syndrome (51–56). Collectively, the cultivation-based studies described above reinforced the idea that the upper genital tract of healthy men is usually sterile but that the distal urethra contains a diverse and dynamic microbiota.

CULTIVATION-INDEPENDENT CHARACTERIZATION OF THE MALE URETHRAL MICROBIOME

Cultivation-independent characterization of the urethral microbiome could not be accomplished without two key technological advances. First, PCR made specific amplification of rare bacterial nucleic acids in complex milieus of clinical specimens feasible for the first time (57). Second, Pace and colleagues showed that knowledge of a bacterium's 16S small subunit rRNA sequence (16S sequencing) was often sufficient to identify the organism, even if the bacterium could not be cultivated (58). The coupling of degenerate 16S PCR with high-throughput DNA sequencing has driven the subsequent rapid evolution of cultivation-independent approaches for characterization of bacterial communities in general. Excellent reviews of this topic for the reader interested in more detail have been written by Clarridge (59) and Köser (60).

Riemersma and colleagues were the first to characterize urethral microbial communities using a cultivation-independent 16S-based approach. Despite the small size of their study, it was significant for its novelty and findings (61). Urine was collected 2 weeks apart from five healthy men and five men with NGNGU. Men in the latter group were treated with azithromycin, which is effective against *Chlamydia* and potentially *Mycoplasma*, at enrollment. Bacteria in urine were identified using a degenerate 16S PCR and restriction fragment length polymorphism (RFLP) approach where representative restriction fragments were sequenced. Reagents were analyzed to differentiate potential contaminants which included *Pseudomonas* spp. in the local water source. In the control group 71 RFLP types were identified, and 84 were identified in the urethritis group. This study detected much greater microbial diversity than had been found using cultivation-dependent methods in previous studies. RFLP types were frequently identified in only one of the two corresponding urine samples, indicating that many bacteria were not stable residents of the microbial communities. Sequences from *M. genitalium* and *Haemophilus parainfluenzae*, known urethral pathogens, were each detected in one urine specimen from a participant with NGNCU. Interestingly, one RFLP type was detected in all five healthy men but in none of the men with urethritis; however, this bacterium was not identified. Many RFLP types corresponded to taxa that had been cultured from urethral and urine specimens in previous studies, including streptococci, *Corynebacterium*, *Veillonella*, and *Gemella*.

The potential of broad-range 16S sequencing for investigation of the urethral microbiome was suggested by early studies of vaginal bacteria in women with and without BV (62–66) (see also chapter 12). Although it had long been appreciated that BV was associated with replacement of vaginal lactobacilli with a population of mixed anaerobes, these studies revealed that remarkable microbiological diversity was associated with this syndrome (67, 68). Although many taxa associated with BV corresponded to anaerobic taxa that Bowie and others had previously identified in specimens from men with NGNCU, another 5 years passed before male specimens were similarly analyzed. One reason for this delay may have been the belief that bacterial loads were too low in male specimens or the difficulty associated with collection of male urethral samples. Some researchers investigated previously described members of the urethral microbiome in men with NGU using panels of sensitive PCR probes for known urethritis- and BV-associated organisms. In a study by Masue and colleagues urine specimens from 161 men with urethritis were analyzed using multiplex PCR for 16 known and suspected urethral pathogens (69); 43.6% of the specimens from these symptomatic men tested negative for all organisms. This once again highlights the need for further research in this area to examine the entire microbiome rather than a subset of known organisms to identify the causative agent or mechanisms involved in this large proportion of cases of NGU.

To study the urethral microbiome among a broad cross-section of men, Dong and colleagues assessed the relationship between organisms detected in corresponding urethral

swabs and urine samples (70). This study was conducted among attendees of a sexually transmitted diseases clinic in the midwestern United States. Urethral swabs were collected first, followed by collection of a urine specimen (≤60 ml) from 32 men. Of these 32, 10 were diagnosed with one or more STIs (*C. trachomatis*, *N. gonorrhoeae*, and/or *T. vaginalis*), while the remaining 22 were not, so the analyses were stratified based on STI diagnosis and urethritis. Microbiome analysis was based on 16S rRNA pyrosequencing of the V1 to V3 regions, and bacterial taxa were assigned using Ribosomal Database Project classifier v2.2 (71). In the STI and no-STI groups, as well as the urethritis and no-urethritis groups, the relative abundance of the most common genera was similar in corresponding urethral swab samples and urine specimens. Analysis of intra-individual variation also demonstrated that corresponding urine and swab specimens from any individual in the study were usually more similar to one another than to any other study specimen. These data suggest that for larger studies, urine is a useful sample type that provides data, particularly on the population level, that is representative of male urethral microbial communities.

In addition to validating the use of urine as an appropriate specimen for microbiome analysis, the study by Dong et al. demonstrated that in men without urethritis and/or STI the male urogenital tract supports diverse bacterial taxa. These included known STIs (e.g., *N. gonorrhoeae* and *Mycoplasma* spp.) as well as a number of genera associated with BV in women (e.g., *Prevotella*, *Atopobium*, *Sneathia*, *Streptococci*, *Veillonella*, *Aerococcis*, *Anaerococcus*) (72, 73). Based on these findings, additional research was conducted with samples obtained from sexually transmitted disease clinic attendees who did not have urethral symptoms during their clinic visit. In this study, urine samples were used to assess the microbial communities of 19 men who had fewer than five polymorphonuclear cells on Gram's stain smears, 8 of whom had an asymptomatic STI (74). Similar to the findings from men with urethritis, in this population of men without urethral complaints the microbial communities comprised a high diversity of organisms, with more than 70 genera identified across all specimens. *Lactobacillus*, *Streptococcus*, and *Staphylococcus* spp. were more common in men without a concomitant STI, while in men with an STI *Prevotella*, *Gemella*, *Sneathia*, and *Leptotrichia* spp. were more common.

These feasibility and proof-of-concept studies led to a longitudinal assessment of the urogenital microbiome in young men recruited from community settings. Adolescents between the ages of 14 and 17 were targeted for participation since this is an important developmental phase during which, among other things, the sexual repertoire is expanding, and thus organisms may be introduced into the urethral niche. Behavioral data were collected on a daily basis, and urine samples were obtained monthly for up to 2 years. Microbiome data were obtained using full-length 16S rRNA gene PCR and Sanger sequencing and three independent 16S rRNA gene subregion pyrosequencing approaches. The recurring collection of urine specimens allowed the first assessment of stability of the microbial community composition in healthy individuals. In the preliminary analysis of data from 18 young men, variations in organisms identified, and their relative abundance, were observed over the first 3 months of follow-up (75). Despite this variation, samples from any given individual were more similar to each other than to samples from other participants.

In addition to analysis of variation over time, samples from this cohort also revealed interesting features of urethral microbial communities among healthy young men. Perhaps not surprisingly, the urethral microbiome is similar to that of other mucosal surfaces: *Lactobacillus*, *Prevotella*, *Streptococcus*, and *Staphylococcus* were found in the majority of urine specimens. Sexual activity appears to influence the communities since, in this small population, *Mycoplasma*, *Ureaplasma*, and *Sneathia* were identified only among men who had engaged in partnered sexual activity. Additionally, some young men who reported no (lifetime) partnered sexual experiences were colonized with organisms routinely associated with BV in women (e.g., *Gardnerella*, *Atopobium*, etc.). Further research is needed to elucidate the role these organisms in the male urethra may play on downstream risk of BV in women.

Circumcision status was captured during this study, and this factor appears to influence the communities of both the coronal sulcus (see reference 75 for additional information about the microbiome of this habitat) and the urogenital microbial communities. For example, urine specimens from circumcised participants were enriched in aerobes and putative cutaneous taxa including *Corynebacterium* and *Staphylococcus*, whereas only specimens from uncircumcised participants contained *Prevotella*. For many years there has been strong epidemiologic data regarding the reduction in risk of HIV acquisition as a result of circumcision, but the mechanism of this protection is still not understood. Emerging epidemiological links between circumcision and STI susceptibility in men (76) suggest that the composition and dynamics of male urogenital tract microbiomes could have ramifications for health and susceptibility to infectious diseases in both men and women. The finding that circumcision influences the colonization of the urogenital compartment of healthy young men may lead to improved understanding of organisms that provide a beneficial or protective effect or those that result in increased susceptibility to infection.

POTENTIAL FOR DIAGNOSTICS AND EPIDEMIOLOGIC APPLICATIONS

As a result of the incredible pace of growth in the field of next-generation sequencing (NGS) and microbiome analysis, the length and accuracy of reads are increasing and the costs of sequencing are decreasing. This has led to development of both research tools and clinically accessible, often highly automated, assays for a variety of health-related conditions. The landscape of clinical diagnosis has been radically altered by the application of NGS and other molecular tools in ways that make the future of clinical laboratory science dynamic and exciting (77, 78). The influence of NGS will not require that every clinical laboratory begin to perform sequencing, and all of the necessary analysis to interpret the data generated, for every analyte or condition of interest. While in some cases sequencing may be of great benefit clinically, the majority of advances are going to result from an improved understanding of the urethral microbiome.

The "-omics" revolution, which includes genomics, transcriptomics, proteomics, and metabolomics, will provide information that can be used to impact the future of molecular medicine (Table 1). An important caveat of genomic approaches is that they do not differentiate bacterial nucleic acids from viable and nonviable bacteria. Also, the sensitivity of PCR-based diagnostics and 16S sequencing

TABLE 1 Potential diagnostic and clinical utility

Output: bioinformatics			

approaches can be a limitation in specimens that contain low bacterial loads, as is the case with most urethral specimens. Contaminating bacterial nucleic acids in PCR reagents and specimen collection tubes and from laboratory workers are real risks with these approaches. Transcriptomics and proteomics are critical to understanding the gene expression and protein profiles that are involved in the phenotype (rather than the genotype) characterization of organisms and may help overcome some of these limitations. For example, a drug-resistance gene may be present in the genome, but it may not be expressed, and thus the organism may remain sensitive to the compound in question despite the presence of the gene. Information regarding phenotypes may be highly relevant to decisions related to targeted treatment regimens. These studies may be particularly relevant to vaccine development in the STI field (79). Metabolomics, the newest in the field of -omics, is highly relevant to understanding organism-host interactions and whether those interactions are more likely to be protective or associated with disease. The need for applied data from these newer -omics is clear, but as yet little has been done as it relates to the male urethral habitat.

Genomics is the oldest, and thus often the most advanced, of these fields of study. Genomics can (i) improve our understanding of a healthy microbial environment, (ii) identify new pathogens associated with disease, (iii) provide improved diagnostic targets for known pathogens, (iv) identify biomarkers for risk of future infection, (v) identify drug resistance genes in known pathogens, and (vi) identify targets for novel drug development. Examples of the potential for prevention, diagnostic, and treatment applications of these types of data related to the male urogenital tract are described below.

An illustration of the impact of sequencing on our understanding of the male urethral microbiome is the evolution of our understanding of the role of *Ureaplasma* in NGU. For many decades investigators have attempted to understand the role of these organisms in the development and persistence of NGU as mentioned above (80). With additional sequence information, Robertson and colleagues proposed that the species formerly known as *U. urealyticum* in fact comprised two species (*U. parvum* and *U. urealyticum*) (81). New epidemiologic data are shedding light on the fact that *U. parvum* may be very common in healthy men, while *U. ureaplasma* is associated with NGU (82). The disease-specific focus of many of the recent studies does not allow us to draw conclusions regarding the role, if any, of *U. parvum* in maintaining a healthy urethral environment.

The potential application of information generated by microbiome analyses is already being realized in research settings. Manhart and colleagues have used PCR assays developed for identification of BV-associated organisms in an effort to identify organisms related to NSU in men (39). Urine from 157 men with NSU and 102 controls was tested using these assays. In this study, *Leptotrichia* and/or *Sneathia* spp. were significantly associated with urethritis and accounted for 15% of NSU cases. Interestingly, other organisms associated with BV (BVAB-2, BVAB-3, and *Megasphaera*) were found only in men with *Leptotrichia* and/or *Sneathia* spp. Future research will determine whether *Leptotrichia* and/or *Sneathia* spp. are causative agents of urethritis and would be appropriate targets for a diagnostic assay or whether these organisms may be useful as a diagnostic biomarker of a group of other organisms that cause disease in men. This information may have clinical utility in the near future or may influence the direction of researchers interested in this area of study. However, the limitation of this type of approach is that it focuses on (i) previously identified pathogens and (ii) only men with disease.

The ability to identify the most common and most abundant organisms in healthy men using microbiome analyses provides an opportunity to define the constituents of a healthy urethral environment. Our understanding of the vaginal microenvironment has taught us that the presence of certain microbes (i.e., lactobacilli) is essential to maintaining vaginal health, and we may find an analogous situation in the male urethra. Currently few studies have attempted to determine the microbial community structures in healthy men other than as a comparison, or control group, in studies of men with urethritis. In the study of adolescent men described in the preceding section, we have begun to develop an emerging picture of the composition and stability of the urethral microbiome in healthy young men (75).

An interesting secondary analysis of data from this project was made possible by the high rate of chlamydial infection observed during the longitudinal follow-up of these young men who were routinely asymptomatic. Eleven incident chlamydial infections were identified among the first 54 participants, 78% of whom had not reported any lifetime sexual exposure at enrollment. The Sorensen's Index of similarity was increased in the samples collected at the visit during which infection was identified compared to the sample collected 1 month prior to infection. Similarly, the total numbers of sequences from samples at enrollment and 1 month postinfection were higher than the numbers obtained from the infection and 1 month preinfection visits (Fig. 1). Further analysis demonstrated the appearance and disappearance of certain taxa in relation to the identified onset of chlamydial infection. Of particular

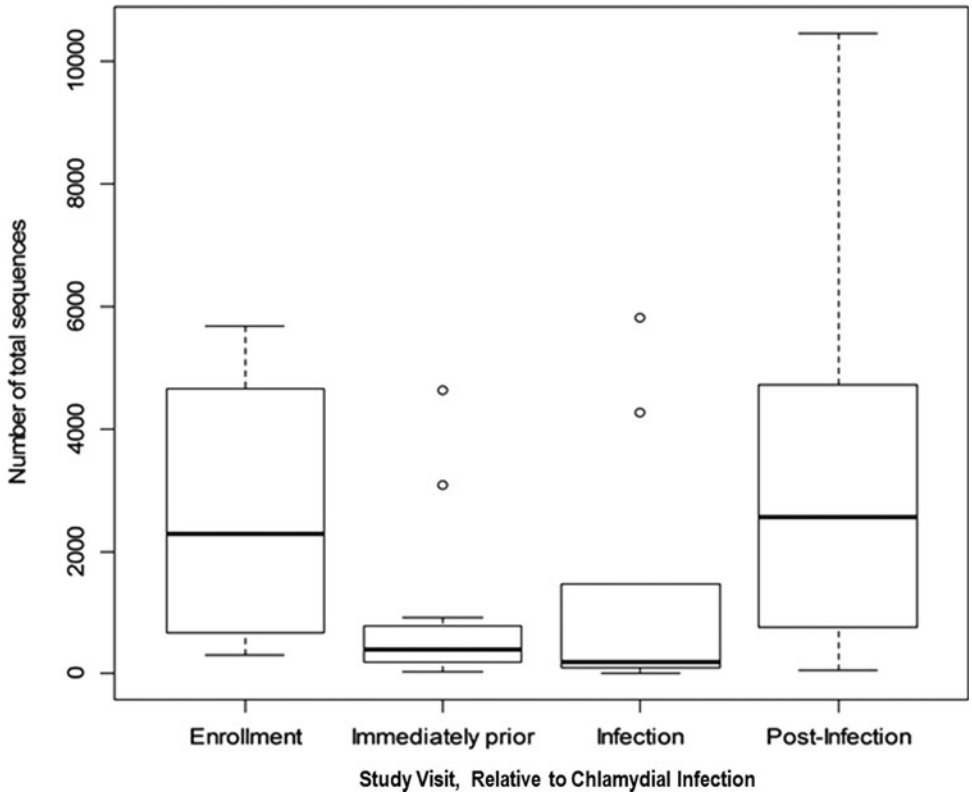

FIGURE 1 Sequence diversity before, during, and after an STI. Total number of sequences obtained from samples collected at baseline, 1 month prior to infection with *Chlamydia trachomatis*, at the time infection was detected, and 1 month posttreatment.

interest in this study was the fact that some taxa (i.e., *Veillonella*) appeared for the first time concurrently with chlamydia and remained following antibiotic treatment (Fig. 2).

A well-described epidemiologic feature of chlamydial infection is that one of the most relevant predictors of current infection is a history of previous infection. As a result, the Centers for Disease Control and Prevention recommend follow-up screening within 3 to 6 months of treatment for a diagnosed infection (83). Although the sample size is extremely small ($n = 11$) for this evaluation, it is possible that the altered microbial composition has either lost a protective member of the community or gained organisms that result in an environment that is more receptive to infection. The data suggest that further longitudinal studies using microbiome analyses may help to identify mechanisms through which chlamydial infection alters the susceptibility of the host to future infections. It is important to recognize that such studies will have to take host immune factors into account as well as the microbial community profiles since it is likely that susceptibility to STIs in general, and chlamydia specifically, is affected by multifactorial influences. With this caveat in mind, this study illustrates the potential for application of microbiome analysis to our understanding of the complex relationship between commensal and pathogenic organisms. In much the same way that the absence of lactobacilli in vaginal samples is considered to be a biomarker of vaginal disease, future

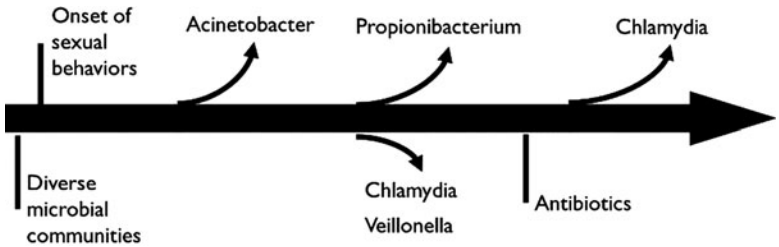

FIGURE 2 Exemplar timeline of community composition changes associated with STI. Example of microbial community changes associated with a common STI (*C. trachomatis*). The male urethral microbiome is diverse and complex prior to onset of partnered sexual behaviors. In a longitudinal study, for some men genera routinely found in the urogenital compartment are notably missing prior to and during infection with chlamydia (e.g., *Acinetobacter* and *Propionibacterium*, P values ≤ 0.05), while others (e.g., *Veillonella*) are first detected during chlamydial infection but remain following antibiotic treatment.

research may identify biomarkers that predict risk of future chlamydial infections or other STIs.

C. trachomatis also provides an example of the utility of NGS as it applies to improving diagnostic assays. First-generation NAATs were widely introduced in the late 1990s throughout the United States and Western Europe. An interesting evolutionary phenomenon that occurred in Sweden was detected in 2006 (84). The Swedish chlamydial screening program used two NAAT platforms at this time. These platforms utilized different amplification targets, both of which were located on the cryptic plasmid. Positivity rates began to decline in counties using one of the NAATs, while rates remained steady in counties using the other assay. Subsequent testing revealed a high number of false-negative results in the counties with apparent decreases in the positivity rates. Sequencing revealed a 377-bp deletion in the new variant that encompassed the primer target region for the assay that had begun to have a high false-negative rate (85, 86). This is the first description of an evolutionary response to diagnostic, rather than antimicrobial, pressure. NGS is a tool that can rapidly identify such changes, and in this case, the second generation of most chlamydia NAATs contains two target regions to avoid this problem in the future for this organism.

Unlike *C. trachomatis*, which is considered to have limited genetic exchange with other organisms due to its intracellular lifestyle, *N. gonorrhoeae* is recognized as having a high degree of genetic flexibility (87, 88). This often complicates diagnosis since target regions are subject to mutations (89). Further, the issue of drug susceptibility is a key factor in the control of *N. gonorrhoeae*. Since the first widespread use of antibiotics against this pathogen, the gonococcus has developed or acquired resistance mechanisms to all classes of compounds except cephalosporins, and only one injectable form of this compound is currently recommended for treatment of uncomplicated gonococcal infections (83). No commercially available molecular diagnostics exist at this time that can identify the presence of genes related to resistance or the transcription of those genes. As global STI control efforts become more reliant on molecular diagnostics, standardized tools that can provide information related to antimicrobial susceptibility are desperately needed. At this point, culture capacity must be maintained to fully evaluate the phenotype of organisms (i.e., drug susceptibility and resistance patterns). However, the future holds vast potential for moving toward molecular assessments based on both genomics and proteomics (90). Organisms that both contain known resistance genes and express appropriate proteins, suggesting that the mechanism is active, may be managed clinically in ways that differ from the management of infection with fully susceptible organisms. While this may never be a cost-effective public health measure, molecular tools will certainly be applied to monitoring the spread of drug resistance and improving our understanding of the epidemiology of diseases of the male urethra.

Beyond diagnostics and disease management, genomics and proteomics have and will continue to have a role in the identification of virulence factors and the development of vaccines for currently known STIs and those that may be discovered in the future. Understanding the virulence factors of pathogens is a critical step in the process of identifying new or improved targets for the treatment of vaccines. Identifying genes and proteins that are appropriate antigens for vaccines is a commonly used tool that will continue to be relied upon as we learn more about the organisms for which vaccines would be desirable. Identification of virulence factors may be used to genetically modify pathogens into attenuated organisms that may have utility as live organism vaccines. This is an area in which efforts will be substantially intensified in the years to come.

CONSIDERATIONS

While genomics and other -omics are exciting new tools in our research repertoire, it is important to remember that microbiome studies should be focused on answering specific questions and testing hypotheses as we move forward. The field has been in the exploratory stage for the last decade, with a very real need to develop an overarching understanding of microbial communities in states of health and disease. However, future studies should be hypothesis-driven, data-generating studies with translational outcomes in mind from the outset.

There are important considerations concerning the application of microbiome studies to routine epidemiology or clinical utilization for diagnostics or treatment assessment. The possibilities for application of data obtained from -omics research is often limited by our ability to process the data generated by the studies. Bioinformatics analyses of this type of research is a field that is evolving as rapidly as sequencing technologies. As more whole-genome sequences are available, and as technologies that provide deeper sequencing coverage continue to improve, the assembly of the data becomes somewhat more precise, but the data overload continues to require methods of analysis that can control for the expected false discovery rate that comes with gigabytes of data. As a result, analyses of a data set may provide very different interpretations today than we would have had 1 year ago. This results in a continual "moving target" of analyses and comparisons. Further, given the cost and technical expertise required to obtain and analyze samples for microbiome analysis, we will always have limited sample sizes. Thus, we need to exercise caution in making global statements and microbiome composition in the male urethra. Finally, microbiome analyses are confounded by the natural intra-individual variation in community composition that may occur as a result of (i) time since urination, (ii) partnered sexual behaviors, (iii) diet, (iv) consumption of vitamins or other nonantimicrobial compounds, (v) drug use, (vi) other systemic infections, (vii) hygiene habits, or (viii) any of a multitude of other possible behaviors and environmental stressors. Thus, we may never fully understand the "core" microbial community profiles that are associated with a healthy urethral environment. Hopefully we will be able to identify key microbial players (both commensal and pathogenic organisms) and begin to understand the complex interactions that result in a variety of health states.

Diagnostics that are based on NGS will have to take all of these complexities into account, and manufacturers will have to develop complex interpretative software to provide useful feedback to clinicians. While this may be an area of potential application in the near future for critical illnesses such as cancer and cardiovascular disease, it is unlikely that urethral diseases will warrant the capital investment that would be required to use NGS for detection of urethral pathogens or susceptibility profiles such as one might envision as part of a personalized medicine profile. Thus, it is likely that the most obvious clinical application of the data obtained from -omics research will be for developing new, or improving existing, diagnostic targets and perhaps monitoring the spread of antimicrobial resistance.

SUMMARY

Targeted treatment and/or more personalized health management in the future may include evaluation of an individual's microbial community profile, types, numbers, and relative abundance of bacteria, with resulting suggestions for risk management and health maintenance. It has been hypothesized that some cases of NGU may actually be the result of dysbiosis within the microbial community and the resulting inflammatory response rather than the result of a specific etiologic agent (91). Better understanding of the microbiome of the male urethra will be essential to disentangling the role of pathogens and host immune response in men. Powerful -omics tools should assist us with finally understanding the organisms that are epidemiologically associated with urethritis and with a healthy microenvironment. This may lead to new diagnostics, new treatment strategies (which may even include probiotics), and the identification of biomarkers related to onset of unhealthy immune responses. Although research regarding the male urethral habitat is a much more recent interest than research related to the vaginal microenvironment, the application of new technologies should help to improve our understanding of this body site in the near future. This will allow sexual health researchers to begin to build a more comprehensive picture of the dynamic interpersonal interchanges that lead to disruption of sexual health among both men and women.

The Human Virome in Health and Disease

KRISTINE M. WYLIE AND GREGORY A. STORCH

14

Early studies of the human microbiome were directed at bacteria. However, just as the bacterial microbiota affects human health and disease, viruses have analogous interactions. Thus, the human microbiome should be thought of as having a viral component, which is designated the human virome (Fig. 1 and Table 1). The definition of the human virome is complicated by the complexity of viruses and their life cycles. Viruses may be associated with acute infections that may or may not produce manifestations of disease and in which the presence of the viral etiologic agent is transient. In other cases, viral infections are persistent with prolonged presence of the implicated virus and ongoing replication. Persistent infections may or may not be associated with disease. In addition, some viruses become latent following acute infection. During latency, the viral genome persists, but viral replication does not occur, although transcription of some viral genes may take place. Another component of the virome consists of sequences within the human genome that appear to have resulted from remote incorporation of viral elements into the human genome. Designated as endogenous human retroviruses, these sequences cannot generate infectious viral particles. They occupy approximately 4.8% of the human genome (1). Finally, bacteriophages are viruses that infect the bacteria that make up the human endogenous microbiota. While all of the forms of viral infection described above may legitimately be considered part of the human virome, this chapter will focus on the first three groups: namely, viruses that infect eukaryotic cells and are capable of independent replication. The reason for that focus is that these are the viruses that have been associated to date with human disease and are the targets of diagnostic testing.

As is also true of the nonviral human microbiome, the concept of the human virome is inseparable from the development of powerful culture-independent methods to detect viruses that have revealed much greater diversity than was previously appreciated. Unlike bacteria, for which a specific DNA molecule, namely the gene encoding 16S rRNA, can be used to achieve a census of resident bacteria, no single DNA or RNA segment or molecule can be used to detect and classify all viruses. Also, the fact that viruses typically have genomes that consist of either DNA or RNA means that comprehensive methods to detect viruses must address both genomic categories. Because of these considerations, studies of the virome require metagenomic sequencing (also referred to as "shotgun" sequencing), in which sequencing is performed on all of the nucleic acid present in a sample without prior isolation or culture of each species. Metagenomic sequencing has been greatly facilitated by the development of high-throughput sequencing methods (also known as "next-generation" or "massively parallel" sequencing) (see chapter 6).

Among the reasons for being interested in the use of high-throughput sequencing to characterize the human virome is its potential use as a viral or microbial diagnostic tool. This possibility is intriguing because of the possibility of culture-independent detection of an unlimited number of viruses and other microbes within the same diagnostic test. Also, high-throughput sequencing-based diagnosis offers the possibility of generating information in addition to the presence or absence of microbes that goes far beyond traditional culture-based or PCR-based diagnosis, including detailed identification and characterization to the level of serotype, genotype, or individual strain; detection of antimicrobial drug resistance genes; and detection of genes associated with virulence or other properties of interest. One of the prerequisites for using high-throughput sequencing as a diagnostic tool is to have information about the background pattern of microbes that will be detected in healthy individuals. This information can be supplied by studies that survey the microbiome at various body sites of interest.

After reviewing methodological aspects of virome studies, this chapter will provide a comprehensive view of studies of the human virome that have been carried out to date.

METHODS FOR VIROME STUDIES

Metagenomic sequencing is now the method of choice for defining the human virome. This method generates nucleotide sequence data from nucleic acids extracted from a sample containing mixed organisms as well as material of host origin. Thus, a metagenome is the composite of all of the genomes from a sample of mixed organisms. The steps involved in carrying out metagenomic sequencing for viruses are shown in Fig. 2 and include (i) initial sample processing (e.g., concentration, filtration, or neither) and nucleic acid extraction, (ii) library construction with possible enrichment for viral sequences (e.g., by target amplification or capture), (iii) nucleotide sequencing, typically using a high-throughput sequencing platform, (iv) primary sequence analysis, including initial processing and cleanup of raw data generated by the sequencing instrument

Kristine M. Wylie and Gregory A. Storch, Department of Pediatrics, Washington University, St. Louis, MO 63110.

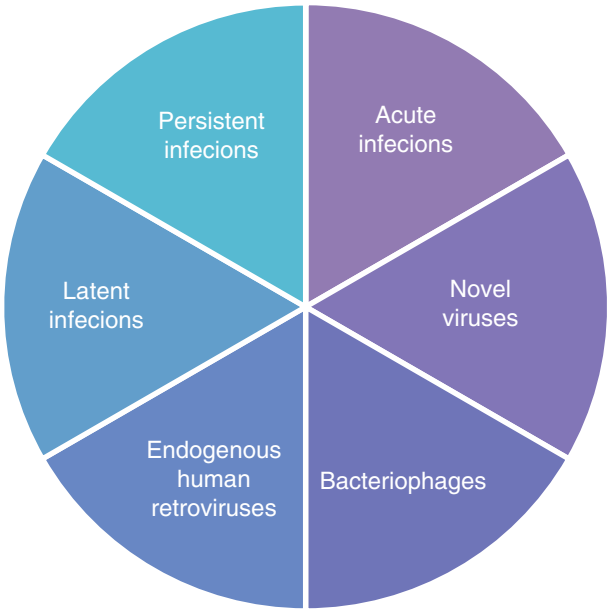

FIGURE 1 Components of the human virome.

followed by comparison of cleaned sequences with standard databases, and (v) interpretation and additional analysis.

Within this general framework, several approaches that have been used for the detection of viral sequences are also shown in Fig. 2. The first and most basic is to sequence DNA and RNA extracted directly from a clinical sample without prior processing. This method requires either a nucleic acid extraction protocol that recovers both DNA and RNA or, alternatively, separate DNA and RNA extractions. This method has been used in several studies (2–4). In some studies, DNase treatment of the sample before and/or after nucleic acid extraction has been used to increase the percentage of sequencing reads that were viral (5–8). The advantages of sequencing without efforts to enrich for viruses are that selective biases are not introduced by the enrichment procedures and that nonviral microbes can be assessed using the same sequence data. An additional advantage is that no processing steps are included that might decrease the ability to detect novel viruses that might be present in the sample. The disadvantage is that most of the sequences determined are of human or nonviral microbial origin because human and nonviral microbial nucleic acids are usually present in the sample in much greater abundance than viral nucleic acids.

Many methods have been described for virus enrichment, including ultracentrifugation, filtration, and polyethylene glycol precipitation (5–7). While detection of some viruses can be improved by prior enrichment, these methods may also introduce biases against other viruses (8). Methods that incorporate purification of virus-like particles have the advantage that all sequence reads are presumably of viral origin, theoretically allowing detection of novel viruses whose nucleic acid sequence is divergent from all previously sequenced viruses. In contrast, highly divergent viruses might be missed by methods that rely on identifying sequences as viral by matching them against databases of known viral sequences.

An alternative approach to physical enrichment of virus-like particles is to perform selective amplification of viral genomes or relevant segments prior to high-throughput sequencing. For example, to facilitate sequencing of influenza genomes, Hoper et al. (9) designed two PCR reactions for each of the eight influenza gene segments. The amplified segments include redundancy for the most variable regions. High-throughput sequencing of the PCR amplicons provides complete genome coverage. Other amplification methods that have been used include rolling circle amplification, which amplifies small circular genomes such as those of polyomaviruses or anelloviruses (10–12), and the multiple strand displacement assay (13).

An important issue with regard to metagenomic sequencing is the introduction of methodological biases that distort the distribution of sequences that are detected. This can result in failure to detect some pathogens or in distorted representation of mixed communities. Because the number of target virus sequences in clinical samples may be low, most metagenomic protocols include nonspecific amplification of target nucleic acid using random primers. The nonspecific amplification can be an important source of bias. For example, regions of high GC or AT content

TABLE 1 Components of the human virome with clinical significance

Categories	Examples	Advantages/anticipated benefits of applying high-throughput sequencing
Acute viral infections	Influenza, rotavirus, respiratory syncytial virus	Subtyping; identification of drug resistance genotypes; detection of viral variants that are missed by standard molecular tests; detection of mutations associated with increased virulence and/or transmissibility; use of human gene response to distinguish symptomatic infections from asymptomatic infections
Persistent viral infections with clinical significance	HIV, hepatitis C virus, congenital cytomegalovirus	Subtyping; identification of drug resistance genotypes; detection of viral variants that are missed by standard molecular tests; viral population analysis; ability to observe viral evolution over time; use of human gene response to distinguish symptomatic infections from asymptomatic infections
Persistent viral infections with unknown significance	Torque Teno virus and other anelloviruses; low-risk papillomaviruses	Appreciation of the presence of asymptomatic viruses and/or immune response to the viruses
Novel viruses	WU and KI polyomaviruses, VA and MLB astroviruses, Dandelong virus	Important approach for discovering viruses that are not detected by existing tests

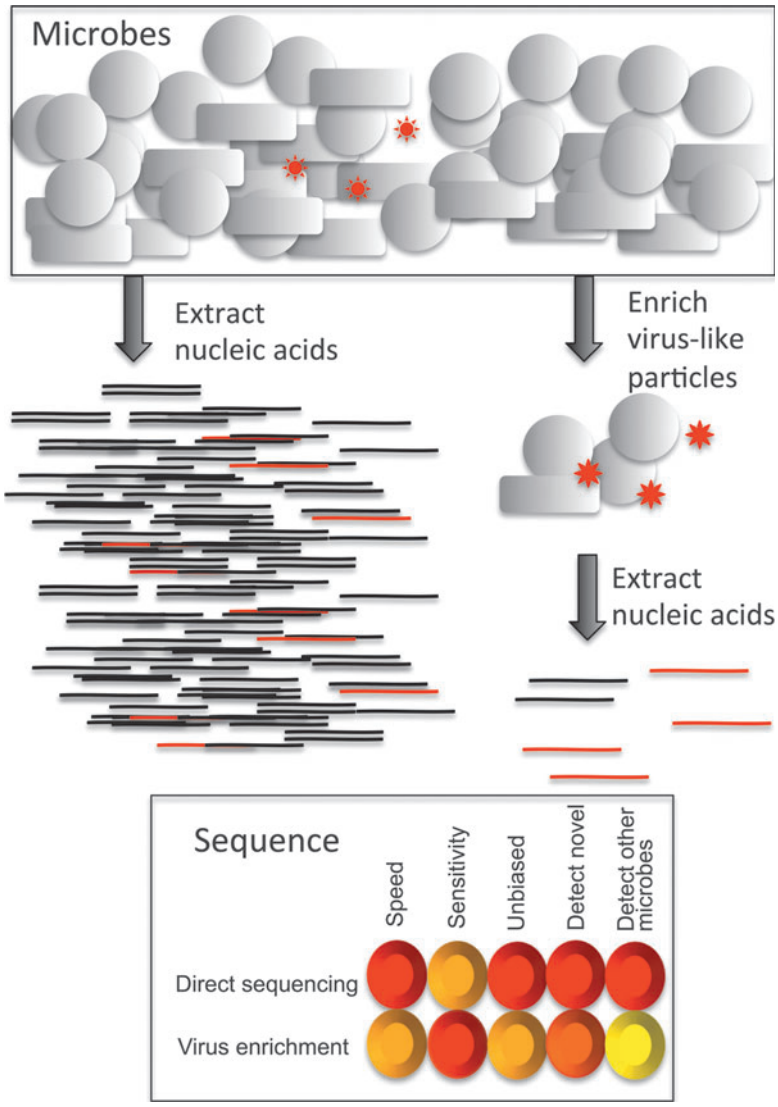

FIGURE 2 Approaches for detecting viral sequences using metagenomic shotgun sequencing. Nucleic acid can be extracted directly from a population of microbes, after which viral sequences, represented by red lines, may be a minor component of the total nucleic acid, as depicted on the left side of the figure. Sequencing libraries can be constructed directly from DNA or reverse-transcribed RNA, and rare viral sequences can be detected by ultra-deep sequencing. Alternatively, viral particles can be enriched prior to nucleic acid extraction and sequencing by filtration, DNase treatment, or ultracentrifugation. Post-enrichment, the majority of nucleic acid is from viruses, as is depicted on the right side of the figure. Relative strengths and weaknesses of sequencing by these approaches are represented by the circles in the bottom panel, with red representing relative strength, yellow representing a relative weakness, and shades of orange falling in between.

can be inefficiently amplified and thus underrepresented in sequencing libraries (14). Additives such as betaine (15) for high-GC regions and tetramethylammonium chloride (16) for high-AT regions may improve the evenness of amplification. Choices of enzyme and thermocycler characteristics have also been shown to be important sources of bias (17). These factors interacted with GC content so that different conditions were optimal for targets with different GC contents. Rosseel et al. (18) implicated annealing bias of the amplification primer as the main source of sequencing bias. Genome regions with homology to bases in the amplification primer located immediately 5′ to the random bases at the 3′ end were preferentially amplified and sequenced. In addition, increasing the number of random bases at the 3′ end of the amplification primer from 6 to 12 improved the evenness of coverage. RNA structure and GC content of the target were not important determinants of bias in that study. Amplification reactions other than PCR, including recombinase polymerase amplification, linear amplification for deep sequencing (19), and multiple displacement amplification (20) have been found to be advantageous under some conditions (14), although multiple displacement amplification has also been shown to distort quantitative analysis of metagenomes (21).

TABLE 2 Common high-throughput sequencing platforms

Platform	No. of sequence reads per run	Max sequence length	Time required for sequence run	Comment
Roche 454 GS FLX+	1 million	700–1,000 bases	23 hours	Only supported until 2016
Illumina GA IIX	640 million paired-end reads	150 bases	~13 days	Early Illumina implementation; has been replaced with the HiSeq series
Illumina MiSeq	44–50 million paired-end reads	300 bases	~55 hours	Shorter reads can be generated in less time; longer reads can help identification of more divergent viral sequences
Illumina HiSeq 2500	6 billion paired-end reads or 1.2 billion paired-end reads in rapid mode	100 or 150 bases	~11 days or ~27 hours in rapid mode	Greater depth of sequencing can be useful for detecting rare viruses; overlapping sequences can be assembled to improve detection of divergent viral sequences; comments apply to other HiSeq platforms (HiSeq 2000, 1500, 1000)
Illumina HiSeq 2000	6 billion paired-end reads	100 bases	~11 days	
Illumina HiSeq 1500	3 billion paired-end reads or 600 million in rapid mode	100 or 150 bases	~8.5 days or ~27 hours in rapid mode	
Illumina HiSeq 1000	1.5 billion	100 bases	~8.5 days	

The platform used for high-throughput sequencing can also be a source of bias. Each of the currently available high-throughput sequencing platforms has specific advantages and disadvantages (Table 2). In the early days of massively parallel sequencing, the 454 GS FLX platform from Roche 454 Life Sciences (Branford, CT) was used for virome characterization and virus discovery. This platform generates approximately 1 million sequences per run, with a sequence read length of up to 700 to 1,000 bases. The relatively long length of these sequences is advantageous for the discovery of viruses whose genomes are divergent from reference genomes. In such cases, the longer read length can help detect sequence similarities between the newly generated sequence and reference databases, which might not have been detected with a shorter read length. However, high-quality nucleic acid is required to obtain long reads, and this can be a limiting factor because samples are often not stored optimally or may be frozen and thawed multiple times prior to sequencing. The Illumina (San Diego, CA) MiSeq platform generates 50 million 300-base, paired-end sequences, meaning that 300 bases of sequence is generated from each end of each DNA fragment in the sequencing library. Therefore, if the sequencing library is constructed with fragment sizes of <600 bases, the entire contiguous sequence of the fragment can be reconstructed.

A MiSeq sequencing run generating the maximum read length requires ~55 hours. The Illumina HiSeq 2500 platform generates up to 6 billion paired-end reads, with read length of up to 100 bases in regular mode or 1.2 billion paired-end sequences of up to 150 bases in rapid mode. HiSeq runs require ~11 days in regular mode or approximately 40 hours for the maximum read length in rapid mode. A further advantage of the large number of reads generated by the Illumina platforms such as the GA IIx and the HiSeq is the higher likelihood of detecting sequences that are rare within the sequencing library. Sequencing using the Illumina GA IIx sequencer has been shown to be more sensitive for detecting viruses compared to Roche 454 using GS FLX Titanium reagents (2, 13).

A crucial step in detecting viruses in metagenomic sequence data sets is the recognition and classification of sequences, which is achieved by comparing sequence reads derived from the sequencer to reference databases. The series of informatics procedures involved in carrying out this task is referred to as the virus analysis pipeline. The most common approach is to classify sequences based on similarity to reference genomes (3). Most virus analysis pipelines incorporate a nucleotide sequence alignment step that allows high-confidence identification of viral sequences that are very similar to a reference sequence, followed by a translated alignment that allows detection of more divergent sequences with conserved protein sequences. Rapid sequence alignment tools have been developed that allow identification of viruses using this process to take place within minutes to hours. Profile hidden Markov models (22) are used to detect even more dissimilar sequences, by modeling conserved amino acid positions within a protein family. While the linear sequence of a protein may not be conserved, certain amino acid characteristics may be conserved to maintain protein fold and function. Hidden Markov models can be used to identify novel viruses by evaluating amino acid positions that are highly conserved among viral protein families (22). A limitation of using sequence similarity to identify viruses in metagenomic data sets is that currently available reference genome sets are not complete, because the sequence diversity of viruses is not fully represented. However, the number of viral genomes submitted to public databases increased nearly 9-fold from the year 2000 to 2014 (23), and improvements in technology and sequencing costs make it certain that this trend will continue. The addition of viral reference sequences will improve sequence classification, but the rapidly changing databases require adaptability, because reference genome sets used in analysis must be continuously updated. In addition, larger reference databases will require ongoing increases in computational capacity.

The richness of viral information derived from metagenomic sequence data sets varies depending on the number

of virus sequences detected and the extent and depth of virus genome coverage. In some cases, complete or nearly complete viral genome sequences can be identified, allowing for detailed genome characterization, including relevant typing or subtyping, and for analysis of specific genes that may confer virulence or drug resistance and of genes corresponding to known or predicted epitopes. In other cases, few sequence reads are identified, allowing only detection of the virus without additional characterization.

Bibby et al. (24) carried out *in silico* experiments to evaluate different processes for aligning sequence reads against relevant databases and found that sequencing read lengths of 200 nucleotides or more resulted in more accurate virus pathogen identification than read lengths of 100 nucleotides. They also found that nucleotide alignment provided more accurate identification than translated amino acid alignments and that use of focused viral-only databases resulted in better classification than use of larger databases containing diverse organisms. These findings are derived from experiments in which the virus identified is present in the reference database. For detection of viruses with differences from reference genomes, translated alignments and/or larger, more comprehensive databases may be required. In addition, use of a focused viral-only database can result in misclassification of sequences with similarity to both viral and other (e.g., human) references. This happens when, for instance, a nonviral sequence has a weak, translated alignment to the viral reference database but has a strong nucleotide alignment to its own reference genome.

THE HUMAN VIROME: GENERAL DESCRIPTION

Previous studies to define the viruses that infect humans have been based on viral culture, visualization by electron microscopy, antigen detection, nucleic acid detection, and detection of an immunologic response. Here we review studies that are based on application of high-throughput sequencing.

A recent study characterized the human DNA virome in 102 normal subjects enrolled in the Human Microbiome Project (3), providing the first view of the human virome in a large cohort of carefully screened healthy adults. Because of the methods used by the Human Microbiome Project for nucleic acid extraction and sequence library construction, the analysis was limited to double-stranded DNA viruses and single-stranded DNA viruses with double-stranded DNA replicative intermediates. Using carefully predefined procedures, subjects were sampled at up to five standard body sites (nose, skin, mouth, vagina, and stool). Sequences of multiple DNA viruses were detected in most subjects, with an average of 5.5 genera per subject. The main viral groups detected in these asymptomatic individuals were papillomaviruses, polyomaviruses, herpesviruses, adenoviruses, and anelloviruses (Fig. 3). In some cases, multiple species from a genus were found in the sample, including mixtures of papillomaviruses considered either high risk or low risk for malignancy. Viral nucleic acid was detected less frequently in stool than in the other sites. Individuals had distinct viral profiles, and follow-up studies of the same individual showed that a number of the components of the virome of an individual were stable over weeks to months. This was especially true for the roseoloviruses, which were stable in >90% of subjects, and papillomaviruses, which were stable in up to 50% of subjects. Because the study subjects were all asymptomatic healthy adults, the viruses detected can be considered to be commensal, making up the DNA component of the normal viral microbiota. The long-term effects of the presence of apparently commensal viruses on human health remain to be determined.

GASTROINTESTINAL TRACT VIROME

The gastrointestinal (GI) tract has been the subject of more virome studies than other body sites. Early studies showed that the predominant DNA viruses in the GI tract were bacteriophages, and the predominant RNA viruses were plant viruses thought to be introduced with diet, nonreplicating within the gastrointestinal tract. An early study (25) studied the stool virome in a single infant and found numerous sequences corresponding to bacteriophages but only a single sequence corresponding to a eukaryotic virus. Minot et al. (26) studied sequences from virus-like particles purified from the stool of healthy adult volunteers and found no eukaryotic viruses. In data from the Human Microbiome Project, eukaryotic viruses were rarely found in stool from healthy adults. However, roseoloviruses, papillomaviruses, polyomaviruses, adenoviruses, and circoviruses were occasionally detected (3).

Studies of individuals with diarrhea, mostly children, have shown abundant eukaryotic viral sequences. Two early studies used Sanger sequencing to carry out metagenomic analyses of stool samples from children with diarrhea. Finkbeiner et al. (27) studied samples from 12 children under 5 years of age, analyzing 384 cloned segments per sample. The analysis was directed at the detection of RNA viruses, although some DNA viruses were also detected. Of the 12 children, 10 had sequences from at least one eukaryotic virus genus, and 5 had 2 or more genera. In all, sequences from 7 families plus 3 unclassified genera were detected. In addition to recognized pathogenic viruses including rotavirus, calicivirus, adenovirus, astrovirus, and picornavirus, viruses of uncertain pathogenicity were also detected, including adeno-associated viruses, picobirnaviruses, anelloviruses, nodavirus, and mimivirus. A novel human astrovirus designated MLB1 was also discovered.

Victoria et al. (28) performed metagenomic analysis of stool samples from 35 children in Pakistan with nonpolio acute flaccid paralysis, plus 6 healthy children who were family contacts of individuals with diarrhea. Analysis was based on Sanger sequencing of 35 to 240 subcloned fragments per stool sample. In addition, high-throughput sequencing using the GS FLX 454 system was also performed on a subset of 10 samples, yielding 3,715 to 25,516 high-quality sequences per sample. Analysis of the Sanger sequencing results showed sequences corresponding to eukaryotic viruses in 29 (83%) of the 35 children with acute flaccid paralysis, with an average of 1.4 eukaryotic viruses per sample, which increased to 2.6 with high-throughput sequencing. The viruses detected were from seven virus families plus four novel virus groups. The most common viruses were single-stranded RNA viruses from the order *Picornavirales* (human enteroviruses A-C, parechovirus, rhinovirus, cardiovirus, aichivirus, cosavirus) and dicistrovirus-like virus. Also detected were double-stranded RNA viruses (rotavirus and picobirnavirus) and DNA viruses (including *Adenoviridae*, bocavirus, and anelloviruses). All six of the stool samples from healthy children also contained eukaryotic viral sequences with a predominance of viruses in the order *Picornavirales*, plus anellovirus and

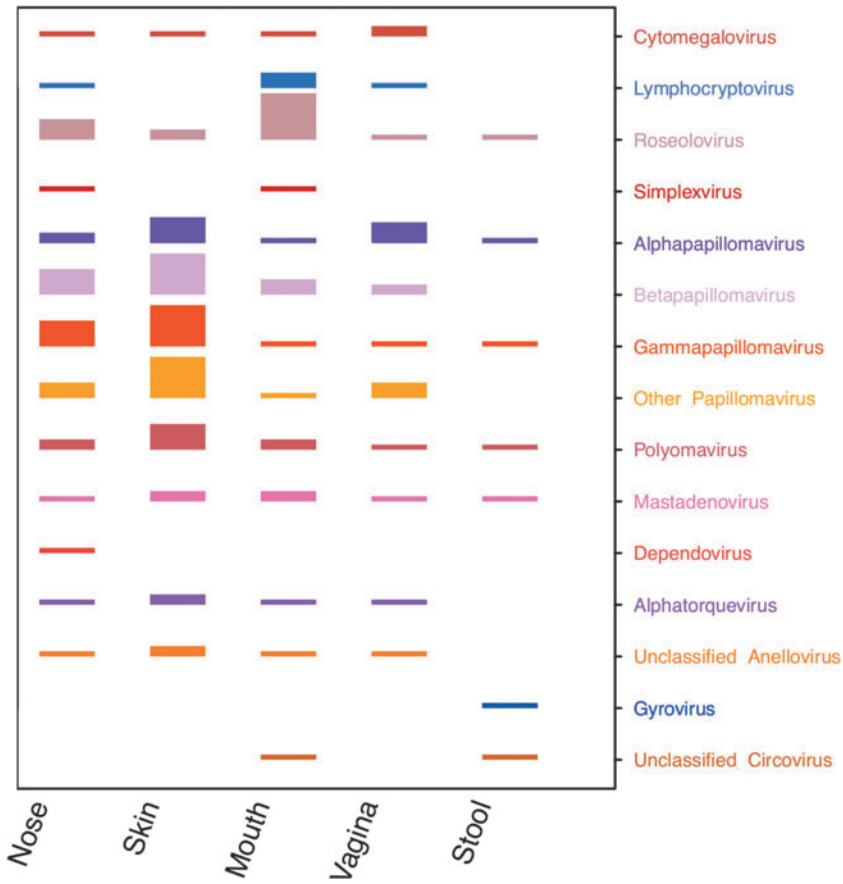

FIGURE 3 The human virome in five human body habitats. All of the viruses detected in the five body habitats are shown. Each virus is represented by a colored bar and labeled on the *y*-axis on the right side. The relative height of the bar reflects the percentage of subjects sampled at each body site in whom the virus was detected. The bar representing roseoloviruses in the oral samples reflects the maximum bar height because 98% of the individuals who were sampled in the mouth harbored roseoloviruses. Reprinted without modification from reference 3 under Creative Commons License 4.0 (http://creativecommons.org/licenses).

circovirus-like virus. Surprisingly, the percentage of all sequences that were viral was higher in the healthy children than the children with acute flaccid paralysis (49% vs. 23%).

Smits et al. (29) performed high-throughput metagenomic sequencing on stool samples from 27 patients in the Netherlands who represented either sporadic cases of diarrhea or were part of outbreaks. Most of the patients were adults, and the cause of their diarrhea was unknown after extensive diagnostic testing. Metagenomic analysis was performed on separate RNA and DNA extracts prepared from stool homogenates, followed by random PCR amplification, library preparation, and sequencing using 454 pyrosequencing. Sequences of mammalian viruses were found in stool samples from 13 patients and included picobirnaviruses in 9, anelloviruses in 2, circoviruses in 2, Epstein-Barr virus (EBV) in 1, aichi virus in 1, and bufavirus in 1.

In the largest study published to date, Holtz et al. (30) studied the stool virome of 87 young children from Melbourne and the Northern Territory of Australia. Methods involved total nucleic acid extraction from diluted stool samples followed by random PCR amplification, library preparation, and sequencing using the 454 GS FLX Titanium platform. Sequences from one or more viruses were detected in 66% of the samples, and 40% of the samples had sequences from two or more viruses. Sequences from eight virus families were detected in one sample. In all, sequences were detected from 22 virus families, of which the most common were *Anelloviridae*, *Picornaviridae*, and *Adenoviridae*. In addition to viruses anticipated to be present in the GI tract, the viruses detected also included respiratory viruses such as human parainfluenza type 3 and a number of plant viruses. PCR assays for a number of viruses were performed, and results were generally concordant with sequencing results. In addition, several novel viruses were detected but not fully characterized.

To summarize the studies of the GI tract, sequences from diverse eukaryotic virus families have been detected in stool samples from individuals with diarrhea. These viruses include those currently known to be causes of gastroenteritis in humans and some that are not currently recognized as GI tract pathogens. Viruses from outside the GI tract have also been detected. Studies done to date of individuals with diarrhea have included mainly children as subjects, and those of individuals without diarrhea have included mainly adult subjects. Thus, more studies on

children without diarrhea and adults with diarrhea are needed to complete the picture of the human GI tract virome. In addition, studies of immunocompromised subjects and subjects with chronic gastrointestinal diseases are needed.

RESPIRATORY TRACT VIROME

The occurrence of pathogenic and nonpathogenic viruses in the respiratory tract has been extensively described based on traditional methods of viral culture, antigen detection, and PCR. However, metagenomic studies are still relatively limited. The earliest application of metagenomics to the respiratory tract virome was a study comparing the DNA virome of individuals with cystic fibrosis (CF) to that of normal individuals (31). The analysis was carried out on expectorated sputum samples that were processed by filtration and ultracentrifugation to isolate virus-like particles, followed by DNase treatment to remove free DNA. Purified DNA was amplified using the multiple strand displacement assay, and high-throughput sequencing was performed using the 454 GS FLX pyrosequencing platform. Sequences from bacteriophages were prominent. Sequences from eukaryotic viruses were more common in the individuals with CF than in the normal individuals. A total of 15 eukaryotic virus families were detected in the CF samples, compared to 12 in the samples from non-CF individuals. Prominent taxa in both groups included *Herpesviridae*, *Adenoviridae*, *Papillomaviridae*, and *Poxviridae*.

One of the most extensive analyses of the respiratory tract virome was part of a study of febrile illness in children 2 to 36 months of age evaluated in a hospital emergency department for fever without a source (32). Samples from a comparison group of afebrile children without an acute illness were also analyzed. Nasopharyngeal secretions from both groups were analyzed by a multiplex PCR panel supplemented by PCR assays for several other viruses found in the respiratory tract. Thirty-one percent of the afebrile children were positive for a respiratory virus. Rhinovirus was the most common virus, detected in 16%. Other viruses detected included adenovirus, enteroviruses, human metapneumovirus, bocavirus, coronavirus HKU1, and the KI and WU polyomaviruses (KIPyV and WUPyV). A subset of 131 nasopharyngeal samples from both groups was also analyzed by high-throughput sequencing (2). Sample preparation included total nucleic acid extraction followed by random PCR amplification without any enrichment by filtration or centrifugation. Sequencing was performed using the Illumina GA IIx platform. Analysis of samples from 50 children with fever and 81 nonacutely ill, afebrile children revealed viral sequences from 17 genera, 15 of which were present in samples from febrile children compared to 9 for samples from nonacutely ill children (Table 3). Viruses from the genus *Enterovirus*, which includes the rhinoviruses, were the most common in both groups of children. Anelloviruses were detected frequently in both groups but occurred more frequently in the febrile children (33).

In another study of respiratory viruses in children, Lysholm et al. carried out a metagenomic analysis of 210 nasopharyngeal aspirates from children with acute respiratory infection, of whom approximately 70% were less than 7 years of age (5). Analytic procedures included separate DNA and RNA extractions, ultracentrifugation to isolate virus-like particles, treatment with DNase, and amplification by random PCR followed by high-throughput sequencing carried out using the 454 GS FLX pyrosequencing system. Viruses accounted for almost 40% of the total sequence reads. More than 90% of the virus sequences detected were from the families *Paramyxoviridae*, *Orthomyxoviridae*, and *Picornaviridae*. Respiratory syncytial virus and human metapneumovirus were the main paramyxoviruses detected, but wild type measles virus was also present. Rhinovirus A viruses were the predominant *Picornaviridae*, but two novel rhinovirus C viruses were also detected. In addition to the three predominant families, viruses from at least five other families were detected, including human bocaviruses, KIPyV, coronavirus OC43, anelloviruses, and human picobirnavirus. No healthy subjects were included in this study, precluding an assessment of the relative frequency of detected viruses in ill compared to healthy individuals.

TABLE 3 Viruses detected by sequencing in nasopharyngeal secretions from febrile and afebrile children 2 to 36 months of age

Virus	No. positive (% of total)	
	Afebrile (n = 81)	Febrile (n = 50)
Anellovirus	25 (31)	26 (52)
Enterovirus	17 (21)	13 (26)
Mastadenovirus	3 (4)	9 (18)
Parechovirus	0 (0)	3 (6)
Respirovirus	1 (1)	3 (6)
Metapneumovirus	0 (0)	2 (4)
Pneumovirus	1 (1)	2 (4)
Polyomavirus	0 (0)	2 (4)
Astrovirus	0 (0)	1 (2)
Bocavirus	1 (1)	1 (2)
Cytomegalovirus	0 (0)	1 (2)
Dependovirus	0 (0)	1 (2)
Influenzavirus A	0 (0)	1 (2)
Morbillivirus	0 (0)	1 (2)
Roseolovirus	3 (4)	1 (2)
Coronavirus	1 (1)	0 (0)
Pestivirus	1 (1)	0 (0)

Young et al. (34) studied the DNA virome in six lung transplant recipients undergoing posttransplant bronchoscopy, plus three HIV-positive individuals. The analytic procedures included purification of virus-like particles followed by concentration and treatment with nucleases to eliminate nonencapsidated nucleic acids. High-throughput sequencing was carried out using the Illumina MiSeq platform. The predominant virus sequences detected were from anelloviruses, which were detected in all bronchoalveolar lavage samples. Sequences corresponding to as many as 17 anelloviruses were detected in individual lung transplant recipients. Richness of anelloviruses and quantitative levels were higher in bronchoalveolar lavage samples from lung transplant recipients than those from HIV-positive individuals. The only other eukaryotic viruses detected were EBV, HHV-7, and human papillomavirus, with very low numbers of sequence reads. The low yield of large DNA viruses may have resulted in part from the filtration procedure used, which was shown to decrease the yield of these viruses. Antiviral prophylactic therapy received by the lung transplant recipients may have also

contributed to the limited detection of large DNA viruses. Detailed studies of anelloviruses in a larger number of subjects revealed that the levels of anelloviruses were much higher in lung transplant recipients than in HIV-positive individuals or in healthy control subjects. Anellovirus levels in lung transplant recipients were not correlated with clinical variables but were correlated with the deviation of the bacterial microbiome in bronchoalveolar lavage fluid from that of healthy subjects.

The studies described above begin to define the respiratory tract virome. Available methods can detect sequences from numerous eukaryotic viruses in both symptomatic and asymptomatic individuals. Viruses detected include those that are well recognized as respiratory tract pathogens, plus others of uncertain pathogenicity, especially anelloviruses. Immunosuppression may increase the level of some viruses including herpesviruses and anelloviruses. More studies are required under different clinical circumstances to achieve a clearer picture of the virome associated with health and disease in a variety of patient populations.

PLASMA VIROME

Early sequencing-based studies of viruses in plasma used DNase treatment (35) or a combination of ultracentrifugation and DNase treatment (8) to enrich for viruses prior to sequencing. These studies found anelloviruses, hepatitis G virus (GB virus-C), and the newly described parvovirus PAR4 in plasma samples from adults with symptoms of acute viral infection (35) and detected anelloviruses in plasma from healthy blood donors (8). Other studies have used high-throughput sequencing to analyze nucleic acid extracted from plasma without prior procedures to enrich for viruses. The study of the virome in young children with the syndrome of fever without a source described in the respiratory virus section (2, 32) also included plasma samples from febrile children 2 to 36 months of age and from nonacutely ill afebrile children from the same age group. Using a panel of PCR assays, this study found multiple viruses in the plasma of febrile children. Adenoviruses, HHV-6, enteroviruses, parechoviruses, and human bocavirus were the viruses detected most frequently. The PCR panel detected very few viruses in plasma samples from afebrile children. High-throughput sequencing, performed as described for the respiratory samples, was carried out on samples from 23 febrile and 22 afebrile children. Sequences from numerous viruses were detected in the samples from febrile children including adenovirus, roseolovirus, enterovirus, astrovirus, dependovirus, erythrovirus, flavivirus (GB virus C), orthohepadnavirus, and polyomavirus. Only anellovirus was detected in the samples from afebrile children. Anellovirus sequences were common in both groups but were more common in children with fever (33).

The plasma DNA virome of immunocompromised patients was analyzed by De Vlaminck et al., who studied 96 heart and lung transplant recipients with serial samples following transplantation (36). Viruses detected included members of seven orders and families, of which the predominant one was *Anelloviridae*, followed by *Herpesvirales*, *Polyomaviridae*, *Adenoviridae*, *Caudovirales*, *Poxviridae* and *Retroviridae*. The composition of the virome was influenced by antiviral therapy, immunosuppression, and time after transplantation. Not surprisingly, the proportion represented by *Herpesvirales* decreased with the use of the antiviral drug valganciclovir. The proportion represented by *Anelloviridae* generally increased with increasing levels of immunosuppression. The total viral load increased after transplantation, and this was associated with a decrease in viral loads of *Herpesvirales* and *Adenoviridae* and an increase in the *Anelloviridae* for patients who were treated with both antivirals and immunosuppressants. Notably, the presence of organ rejection correlated with a lower burden of *Anelloviridae*, suggesting that the anellovirus load in the plasma reflected the immune state of the patient, with increasing *Anelloviridae* correlating with decreased immune competence.

The plasma DNA virome was also studied using high-throughput sequencing in 10 adults with HIV/AIDS and 10 normal adults (37). The main virus sequences detected in the plasma of the individuals with HIV/AIDS corresponded to bacteriophages. In contrast, bacteriophage sequences were not detected in the plasma of normal individuals, in whom sequences corresponding to torque teno virus and other anelloviruses were predominant. Another study that compared the plasma virome in HIV-positive individuals from the United States and Uganda with low and high CD4 counts found sequences of multiple viruses in addition to HIV, including hepatitis B, C, and G; anelloviruses; and human endogenous retroviruses (37). Anellovirus sequence read counts were higher in individuals with lower CD4 counts, suggesting a loss of immunologic control.

Although the number of studies is limited, several points are emerging concerning the plasma virome. First, anelloviruses are common in both well and ill individuals. Evidence is accumulating that the level of anelloviremia may be an indicator of the immune state of the individual. Second, sequences corresponding to pathogenic viruses may be detected in the plasma of immunocompromised individuals, whether or not they are acutely ill. In contrast, in nonimmunocompromised individuals, pathogenic viruses are rarely detected in plasma of those who are well but may be detected in those with acute febrile illness. This may be more common in children than adults. Further studies are needed to achieve better definition of the plasma virome. Studies to date suggest that analysis of plasma may have diagnostic utility and could be carried out using a variety of test formats.

SKIN VIROME

As described in the section on general considerations related to the human virome, papillomaviruses and polyomaviruses are the main components of the skin virome. In a PCR-based study, Antonsson et al. (38) showed that a wide variety of papillomaviruses were detected in skin samples from healthy individuals. The distribution of types varied in individuals from different countries. PCR-based studies of infants showed that beta- and gamma-papillomaviruses were detected early in life (39). A landmark study was the discovery of Merkel cell polyomavirus (MCPyV) by Feng et al. (40) using high-throughput sequencing with digital transcriptome subtraction. This study linked the virus to Merkel cell carcinoma, a rare skin tumor that occurs primarily in individuals who are immunocompromised. Clonal integration of the viral genome in the DNA of Merkel cell carcinoma has been demonstrated, suggesting a causal role for the MCPyV in the generation of the cancer. Subsequent studies have shown that normal individuals may shed MCPyV (11) and have led to the discovery of 10 additional human polyomaviruses (11, 41, 42) usually found in cutaneous

samples. A study of the skin DNA virome of an individual with a history of previous Merkel cell carcinoma plus five healthy individuals found that sequences from three viral families (the *Polyomaviridae*, the *Papillomaviridae*, and the *Circoviridae*) were commonly detected and accounted for most of the viral sequences detected (43). The methodology employed included high-throughput sequencing using the HiSeq 2000 platform following multiple displacement amplification (20), which favors the amplification of circular genomes and may have affected the relative proportions of viruses detected in this study. Extensive diversity was detected within the three predominant virus families. Sequences from MCPyV were detected in all six subjects, and sequences from HPyV 6 and 7 were also commonly detected. Sequences of papillomaviruses were also detected in all subjects, with an average of 12 strains per subject.

Oh et al. (44) examined the skin microbiome including the DNA virome in 15 healthy adults sampled at 18 distinct skin sites. Because of low sample input, library preparation was done using the Nextera system followed by sequencing on the Illumina HiSeq platform. The subjects had viruses that included papillomaviruses, polyomaviruses (MCPyV), and poxvirus (molluscum contagiosum virus). Of the 18 sites sampled, the nares and the adjacent alar crease sites had the most virus sequences detected. These data and the study from the Human Microbiome Project described above (3) establish the *Papillomaviridae* and *Polyomaviridae* as common components of the human virome, with sequence divergence that has not yet been fully characterized. These are viruses that can be present in normal individuals but have the potential to cause disease, including warts and cutaneous malignancies.

METAGENOMIC STUDIES OF SEWAGE (THE SEWAGE VIROME)

An alternative approach to evaluating the human gastrointestinal microbiome or virome is to carry out studies on human sewage, because this allows sampling of human gastrointestinal contents on a population basis. However, a human origin for viruses and other microbes detected in sewage cannot be assumed since sewage transmission lines may be entered by insects and animals that may contribute their own microbes. Studies using traditional methods have shown the presence of numerous enteric viruses in sewage including adenovirus, norovirus, reovirus, rotavirus, and members of the *Picornaviridae* family (reviewed in reference 45). Other newly discovered viruses including picobirnavirus (46), cardioviruses, cosavirus, circoviruses, and human bocavirus have also been detected using directed PCR assays (45). The first metagenomic study of sewage was carried out by Bibby et al. (24), who performed studies on sewage sludge residuals resulting from municipal wastewater treatment, termed "biosolids." Using 454 pyrosequencing, they detected 10 human pathogenic viruses. Corrected for genome size, the most abundant human viruses were parechovirus, coronavirus, torque teno virus, herpes virus, and aichi virus. Other human pathogenic viruses detected were adenovirus, tanapox virus, orf virus, and hepatitis C virus.

Cantalupo et al. (47) used 454 pyrosequencing to analyze sewage samples from Pittsburgh, Barcelona, and Addis Ababa. In all, 234 viruses from 26 virus families were detected, with bacteriophage being predominant. More than 90% of the eukaryotic viruses detected were plant viruses. Seventeen viruses known to infect humans were detected, including adenovirus type 41, astroviruses, Norwalk and Sapporo virus, human papillomavirus 112, human bocaviruses, human picobirnavirus, aichi virus, klassevirus, parechoviruses, and HPyV6. Selective PCR testing revealed the presence of additional human viruses including JC polyomaviruses. In addition, there was evidence for multiple novel viruses, suggesting extensive diversity. In another study, Aw et al. (7) used the Illumina platform to sequence sewage samples from East Lansing, Michigan. As in other studies, bacteriophages were the predominant viruses detected. Animal and plant viruses were also detected. Human viruses represented 3% of viruses detected and included viruses from the families *Adenoviridae*, *Polyomaviridae*, *Picornaviridae*, and *Papillomaviridae*. The large majority of viral sequences could not be characterized, suggesting the presence of extensive diversity.

THE CANCER VIROME

Large sequence-based studies of cancer have begun to characterize the cancer virome. Tang et al. studied RNA sequencing data generated by The Cancer Genome Atlas Research Network from 4,443 tumors from 19 cancer types (48). They found that tumorigenic viruses were common in several tumor types (cervical, head and neck, liver), but were not associated with other tumors (breast, brain). Cervical cancer was the most highly virus-associated, with nearly all cases associated with high-risk papillomaviruses (96% positive for papillomaviruses in this study). Head and neck cancers were also associated with papillomaviruses in 14.1% of the cases. Hepatitis B virus was found in 11 of 34 hepatocellular carcinomas (32%). Although hepatitis C virus is also associated with hepatocellular carcinomas, it was only detected in one sample, likely due to the methods used for sample preparation. In addition, recurrent integrations were observed in or near six cancer genes: *ERBB2*, *PVT1* and *LOC727677* long noncoding RNAs downstream of the oncogene *MYC*, *RAD51B*, *MLL4*, and *FN1* in cervical, head and neck, and liver cancers.

A comprehensive characterization of bladder carcinomas by The Cancer Genome Atlas Research Network found viral DNA in 7 of 122 tumors (6%) (49). In one case, human papillomavirus 16 was integrated into *BCL2L1* (an apoptosis regulator). In another case, the BK polyomavirus (BKPyV) was integrated into *GRB14* (a signaling adaptor protein for receptor tyrosine kinases). These findings suggest that viruses may have a role in the development of a small proportion of bladder cancers.

Gastric cancers have been found to be highly associated with infectious agents, including EBV. In fact, the EBV-positive tumors were classified as one of four subtypes of gastric tumor (50). The EBV-positive tumors were associated with hypermethylation of gene promoters. EBV-positive tumors were also highly associated with mutations in *PIK3CA* (80% of tumors compared to 3 to 42% of tumors in other tumor subtypes), the gene for the catalytic subunit of the PI3 kinase, which has many roles in the cell including regulating cell growth and division. EBV correlated inversely with mutations in the tumor suppressor *TP53*. The viruses described in this section up to this point are all well-known human viruses, but as discussed above in the section on the skin virome, a novel virus was found to be associated with cancer in 2008 (40). Merkel cell polyomavirus was found in 80% of tumors evaluated, and the virus was clonally integrated in 75% of those

cases. This raises the possibility that additional unknown viruses may be discovered to be etiologic agents of cancer. Viral causes of cancer are of great interest, particularly in light of the fact that the viruses that have been shown to be associated with tumors (papillomaviruses, polyomaviruses, EBV) are viruses that are common in healthy individuals (3). An important question is why these viruses cause cancer in some people but not others.

CONCLUSIONS

The development of high-throughput nucleotide sequencing has made it possible to undertake comprehensive studies of the human microbiome. Studies of the human virome, the virus component of the microbiome, are much less advanced than studies of the bacterial component. Virome studies are complicated by the varied life cycle of viruses that includes persistent and latent states of infection for some viruses. Nevertheless, the metagenomic methods required for studies of the virome are now advancing rapidly, and pictures of the virome at various body sites are emerging. These studies define the "virus space" of humans and are the foundation for further studies of the role of viruses in human health and disease. They also provide baseline information that is required for the application of molecular detection methods including high-throughput sequencing to the process of diagnostic virology. Further studies are required to define the effects of age, geography and other environmental exposures, and the immune state of the human host. An anticipated spinoff of studies of the human virome is the discovery of novel viruses, some of which may be linked to human disease.

Molecular Detection of *Staphylococcus aureus* Colonization and Infection

KATHY A. MANGOLD AND LANCE R. PETERSON

15

HISTORY OF SCREENING FOR *S. AUREUS* AND MRSA

Prevention and control of infection with *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), have been a major health care focus since at least the middle of the 20th century (1). By 2005, mortality from MRSA in the United States exceeded that due to infections from salmonella, tuberculosis, influenza, and HIV combined (2, 3). Since that time, global efforts to reduce MRSA infection rates appear to have had some impact in both Europe and the United States (4–6). However, the improvement has not been uniform, with selected academic medical centers not realizing a reduction in disease (7), and at least one large state (Illinois) reporting an increase in overall MRSA infection reflected in their most recent data, with 11.7 MRSA infections/1,000 hospital discharges in 2009, 11.6 in 2010, 10.7 in 2011, and then up to 14.2 in 2012 (8).

Performing a PubMed search on the keywords "MRSA and infection control" in early 2016 detected more than 5,300 articles published since 1980. The conclusion of the first article in this list stated that "during a five-year period . . . Standard barrier nursing methods were unsuccessful. In the subsequent 6 years all patients were nursed in an isolation unit; the number of patients infected with methicillin-resistant *Staph. aureus* had fallen from 130 to 14" (9). While much discussion continues over the role of active surveillance testing (AST) for prevention of both MRSA and *S. aureus* infection (10), it is clear that this approach is widely used and has been very successful (11). One of the reasons that AST for MRSA should be expected to work is that the greatest risk factor for developing clinical disease is first to become colonized in the nares with MRSA (12). People who are either colonized or infected with MRSA are equally likely to have their skin and surrounding environment contaminated with this organism, so it can be readily contracted by others coming close to or touching them (13). Therefore, strategies to limit transmission that consider both colonized and infected persons are most likely to be successful (14).

Kathy A. Mangold, Department of Pathology and Laboratory Medicine, NorthShore University HealthSystem, Evanston, IL 60201, and the Pritzker School of Medicine, University of Chicago, Chicago, IL 60637. **Lance R. Peterson,** Department of Pathology and Laboratory Medicine and Department of Internal Medicine, NorthShore University HealthSystem, Evanston, IL 60201, and the Pritzker School of Medicine, University of Chicago, Chicago, IL 60637.

MEDICAL UTILITY

The medical impact of *S. aureus* infection on society is important for three critical reasons. First, *S. aureus*, both methicillin-susceptible strains (MSSA) and MRSA, is a major cause of health care-associated infection, which was outnumbered only by *Clostridium difficile* infection as the most commonly reported cause of U.S. health care-associated infection in 2010 (15); it is the most frequent cause of pneumonia and surgical site infection (SSI) and the third most common etiology for nosocomial bloodstream infection (BSI), only after *Candida* species and coagulase-negative staphylococci. Second, this infection results in substantial morbidity and mortality, with MRSA bacteremia resulting in death nearly twice as often as BSI from MSSA (16, 17), leading to a prolonged length of hospital stay (18); SSI from MRSA has more than 3-fold the mortality compared to MSSA disease (19). Finally, infections from these pathogens result in considerable excess cost to the U.S. health care system, usually estimated in the tens of thousands of dollars per patient (19–21), again with MRSA being more costly than MSSA infection (19).

Nasal Screen for MRSA Control

Performing AST for MRSA has generally involved the swabbing of either the nares alone or a combination of nares/throat/axilla/inguinal/rectal/perirectal areas and then testing those collected swabs as a single sample (22, 23). In the past these were processed using either nonselective agar (sheep's blood agar or chocolate agar) or selective medium (mannitol salt agar). More recently, chromogenic media and rapid molecular testing (PCR) have become available (22, 23).

The general rationale for performing AST is to appropriately place MRSA-colonized patients into contact precautions to effectively provide a barrier between the affected patient and health care workers and diminish acquisition of MRSA directly from the patients and their surrounding environment. By preventing the health care worker from even transiently acquiring MRSA, there is less likelihood of transmission to other patients who may develop MRSA clinical infection after they become colonized. There are three main issues to resolve when planning an MRSA AST program: (i) what body site(s) to test, (ii) what test to use, and (iii) whom to test. When testing a single body site, the nares is generally chosen because the anterior nares is the usual colonized site for

S. aureus, including MRSA, in humans. However, while it is the most common colonization site, it can miss up to 35% of MRSA-colonized individuals. Kunori and colleagues suggested that culturing the nares and any wound (e.g., clinically infected site) could approach 100% sensitivity (24), which seems a prudent approach for most AST programs. Two large studies from the United States have clearly demonstrated that broadly applied, active surveillance with rapid testing of nasal swabs can be associated with a dramatic reduction in clinical MRSA infection (25–28).

When deciding what test to use, the laboratory routinely assesses test cost and processing workflow in the final decision. One of the biggest challenges for the acute care hospital is deciding how sensitive a rapid test needs to be to provide a reliable result soon enough to impact MRSA control by implementing contact precautions for sufficient hospitalization time and to affect MRSA spread. Most laboratories now choose between commercial chromogenic agar and a real-time PCR as their test of choice. Both approaches can offer a result within 24 h of sample receipt by the laboratory; however, the sensitivity of a 24-h test is approximately 80% with agar medium (29), whereas it exceeds 95% for most commercial real-time PCR assays (30). Robicsek and colleagues suggested that the overall mean percentage of days patients colonized or infected with MRSA were cared for under contact precautions was a key element in determining the success or failure of an MRSA AST program (25), and Peterson subsequently argued that this needed to meet or exceed 80% in most settings (10). Since the average length of stay for U.S. acute care hospitals is 4.8 days (31), this implies that testing needs a sensitivity approaching 100% if the turnaround time from sample receipt to reported result approaches 1 day. In support of rapid testing, a systematic review and meta-analysis found a significant reduction in risk for MRSA bloodstream infections (0.54, 95% CI 0.41 to 0.71) when comparing nursing units using rapid screening tests and those not undertaking screening (32) but concluded overall that applying screening was more important than the actual test used.

The final decision is that of whom to test. Debate over whether universal surveillance is required, as opposed to a more targeted approach, continues, with a comprehensive Agency for Health Care Research and Quality (AHRQ) review suggesting the issue is not yet resolved (33). Subsequently, Kavanagh and colleagues pointed out that 41 of 43 studies included in this review demonstrated reduction of clinical disease associated with AST and argued that the evidence was compelling that using surveillance as an approach for MRSA control was effective (11). One reason for considering universal AST, at least at the beginning of the program, is that it is now difficult to predict which patients are at high risk for MRSA colonization simply by where they are cared for in the hospital. McKinnell and colleagues found that several conditions—including health care contact, previous health care-associated pathogens, and select comorbid conditions (open wounds, congestive heart failure, diabetes, chronic obstructive pulmonary disease, renal impairment, and immunosuppression)—and intensive care unit (ICU) admission were not a risk factor for MRSA colonization (34). Importantly, if one does choose to perform universal admission AST, it does not need to continue indefinitely. Robicsek and colleagues demonstrated the development of electronic prediction rules for the NorthShore University HealthSystem's universal AST program, whereby they could achieve 90% detection of MRSA-colonized individuals by testing only 50% of admissions (35)—a change in approach that was implemented on January 10, 2012, to reduce testing costs while maintaining control of MRSA nosocomial clinical infection.

Presurgical *S. aureus* Screening and Decolonization

Currently, the other major application for *S. aureus* surveillance, both MSSA and MRSA, is in the preoperative patient, where *S. aureus* clinical disease is a significant risk for postoperative SSI. The usual practice is to perform nasal swabbing for *S. aureus* in the period before surgery (no more than 30 days) and then decolonize those patients positive for *S. aureus* using a typical regimen of intranasal mupirocin twice daily for 5 days accompanied by chlorhexidine bathing. In this setting either culture or molecular testing can be used, with the caveat being that a less sensitive test will detect fewer patients. Since up to 1/3 of adults are carriers of *S. aureus* in the anterior nares (24), sensitivity can be important in maximizing the number of patients detected when preoperative testing is undertaken. The benefit of this practice is significant, particularly for operations involving prosthetic implants and cardiovascular surgery.

Colonization with *S. aureus* raises the risk of SSI several fold (36), so it is not surprising that decolonization can have a clinically meaningful impact. In a before-after trial of 1,495 prosthetic joint recipients reported by Hacek and colleagues, nasal screening followed by decolonization of those nasally colonized with *S. aureus* reduced the overall SSI rate from 1.7% to 0.77% (55%) and was cost-effective (37). In a subsequent randomized, double-blind, placebo-controlled, multicenter trial of 6,771 surgery patients that were screened and then decolonized using mupirocin and chlorhexidine in the intervention arm, a similar outcome was found (38). The effect of mupirocin-chlorhexidine treatment for deep SSIs was highly significant (relative risk, 0.21; 95% CI, 0.07 to 0.62). Interestingly, the time to the onset of infection also was shorter in the placebo group than in the intervention group ($P = 0.005$). Both of these studies used PCR as the assay for detecting *S. aureus* colonization via nasal swabbing. The hypothesis about the effect of this practice is that mupirocin decolonization effectively removes *S. aureus* from the nares for at least 30 days after treatment (39) and therefore eliminates the potential for patients to contaminate their surgical incision by rubbing their nose and then the operative site for the important time period following surgery when the incision may not be fully closed.

A third investigation focused only on MRSA and involved a prospective, controlled, interventional cohort study using 33 surgical wards in 10 hospitals from nine countries in Europe and Israel (40). They found that in cardiothoracic, neuro, orthopedic, plastic, and vascular surgery wards their strategy 2 (MRSA screening, contact precautions, and decolonization) was associated with decreased MRSA clinical cultures (15% monthly decrease, adjusted incidence rate ratio [aiRR] 0.85, 95% CI 0.74 to 0.97) and MRSA clinical infections (17% monthly decrease, aIRR 0.83, 95% CI 0.69 to 0.99). This investigation used culture of pooled nasal and perineal swabs that was plated onto chromogenic medium as well as incubation overnight in an enrichment medium followed by a

second plating to increase test sensitivity. Economically, the practice of preventing SSI by treating *S. aureus* colonization has been demonstrated as cost-effective (41) due to the high cost of caring for patients with *S. aureus* SSI.

LABORATORY DETECTION OF *S. AUREUS*

Premolecular Methods for Detecting *S. aureus*

This testing relied on culture, either using direct plating or combining broth enrichment with solid agar detection. Historically, most media contain an indicator to distinguish *S. aureus*, inhibitory substances to suppress other organisms, and antistaphylococcal antibiotics to select for methicillin resistance (42). Indicators used in screening media systems have included a carbohydrate, most commonly mannitol, and a pH indicator, traditionally phenol red, to highlight potential MRSA colonies. Recently, chromogenic indicators have replaced the other compounds (42, 43). Inhibitory substances included NaCl, ciprofloxacin, polymyxin B, aztreonam, tellurite, and desferrioxamine. Time and temperature of incubation can vary among the studies (42). Since 2010 the use of molecular techniques for direct detection of MRSA has become more commonplace (43), with many commercial assays available (to be subsequently reviewed in this chapter). Currently, real-time PCR assays are available that detect MRSA directly from swabs and selected clinical samples, as well as those assays that target both MRSA and MSSA (43).

Development of Molecular Targets from the *S. aureus* Genome

Early in the 21st century whole-genome sequencing was applied to *S. aureus*, and insights into virulence, toxigenicity, and antibiotic resistance rapidly emerged (44). A clear picture emerged of what happens to MSSA when it changes to MRSA upon the acquisition of staphylococcal cassette chromosome *mec* (SCC*mec*), which is a genomic island encoding methicillin resistance. All SCC*mec* elements reported to date carry the *mec* gene complex (*mec*) and are inserted at the integration site sequence for SCC, which is located at the extremity of the SCC element (45). This understanding led to the development of real-time multiplex PCR assays that could detect MRSA directly from clinical specimens, initially nasal swabs, in less than 1 h (46). The general design of these includes multiple primers specific to the different SCC*mec* right extremity sequences in combination with primers and probes specific to the *S. aureus* chromosomal orfX gene sequences located to the right of the SCC*mec* integration site (46). This discovery and assay development remain the basis of most rapid molecular tests for MRSA and MSSA today (47).

Early Molecular Assays

The first molecular test for *S. aureus* that was available for clinical testing was the Gen-Probe Accuprobe *Staphylococcus aureus* Culture Identification Test for testing positive blood cultures in the early 1990s (48). This test hybridizes a chemilluminescent labeled, single-stranded DNA probe for the 16S rRNA to form a DNA:RNA hybrid that specifically detects *S. aureus*. It provided species identification in a relatively short time (<1 h versus 12 to 16 h for culture) but still required additional susceptibility testing for methicillin resistance.

The initial PCR tests were in-house laboratory-developed assays that targeted a unique portion of the *S. aureus* genome, such as the *femA* gene (49). Other targets such as the *nuc* or *spa* genes have also been used (50). The limitation of this approach was that while it was satisfactory for detecting *S. aureus*, there was no ability to separate MRSA from MSSA, so culture of the specimen was required to determine if the detected isolate was methicillin resistant. Some have tried to multiplex these *S. aureus*-specific targets with *mecA* to detect the presence of MRSA, but this approach has generally been unsatisfactory when the specimen being tested has a high likelihood of containing methicillin-resistant coagulase-negative staphylococci (MR-CoNS), which harbor the same *mecA* gene and are typically present in nasal swabs (46). The exception to this problem of interference from MR-CoNS is detection of MRSA and MSSA in signal-positive blood culture bottles. Paule and colleagues found that the problem could be resolved by first determining if the amplification efficiency of the *femA* and *mecA* PCR reactions had similar amplification efficiencies (51). When that was the case, then dividing the *femA* cycle threshold (C_T) value by the *mecA* C_T value would give a C_T ratio that could differentiate an MRSA result from a mixture of MSSA and MR-CoNS. They used this strategy to call a *femA*-detected sample positive for MRSA only if the *femA*/*mecA* C_T ratio was between 0.9 and 1.1 (51), which provided an assay with 100% sensitivity and specificity for accurately detecting MRSA and MSSA. Another interesting early approach was to use magnetic beads in an immunomagnetic enrichment assay with biotinylated antispa antibody and streptavidin-coated paramagnetic beads to remove *S. aureus* from MR-CoNS followed by amplification of the optimized sample using primers for *femA* and *mecA* (52). While the sensitivity of this test was 100%, the specificity of the assay was only 64% (52), suggesting the difficulty of completely removing MR-CoNS from clinical samples.

Initial Commercial PCR

The first of the modern era molecular diagnostic tests for MRSA surveillance was that of Infectio Diagnostic Inc., with its IDI-MRSA Test, which was FDA cleared in March 2004. While this test was labor-intensive compared to newer versions of this assay, it was able to detect MRSA in the presence of other bacteria directly from nasal swabs (46). Since NorthShore was about to launch the first multihospital, universal surveillance program for MRSA control in North America, this test was chosen over the in-house-developed test that required culture of positive *femA*-positive specimens to determine which were MRSA. Testing began in August 2005, and the large-scale evaluation of the initial test found that it was very reliable, with a sensitivity of 98% and a specificity of 95% during high-volume testing (53). With this initial assay, one medical technologist could comfortably perform approximately 100 tests per day using a modified achromopeptidase lysis method—a very high volume for most microbiology testing at the time.

Peptide Nucleic Acid Fluorescence *In Situ* Hybridization

Peptide nucleic acid fluorescence *in situ* hybridization (PNA-FISH) is another application of molecular diagnostics that has been applied to *S. aureus* diagnostics (54), primarily on signal-positive blood culture bottles (55). The

PNA-FISH assay detects *S. aureus* and CoNS in 3 h and has performed well in a large comparative trial (921 blood cultures positive for bacteria) with culture-based matrix-assisted laser desorption ionization-time of flight mass spectrometry as the reference identification method (56). Importantly, in the near future this method will be able to be used directly on signal-positive blood culture bottles (57), and at that time will be the faster and less expensive of these two approaches. Currently, the PNA-FISH assay begins with a 90-min staining procedure that consists of smear preparation and fixation, hybridization with PNA probe, washing off of unbound probe, and interpretation of the slides (58). Subcultures of the original specimen onto solid media are required for confirmation of colony morphology, to detect mixed cultures, and to perform susceptibility testing (56); thus, PNA-FISH cannot distinguish between MSSA and MRSA. The main limitations of the PNA-FISH method have been relatively long turnaround time, the lack of an automated reader, and the inability to provide susceptibility test results, which has led to relatively low penetration of these methods into clinical microbiology laboratories. A recent update is the *Staphylococcus* QuickFish BC that, according to the manufacturer, is capable of identifying *S. aureus* within 20 min; similar FISH hybridization assays using beacon-based technology are also commercially available (59, 60), but all still do not have the capability to distinguish between MSSA and MRSA.

Current Commercial Assays

The list of commercial assays for the molecular detection of MSSA and/or MRSA is continually expanding, as shown in Table 1. Some are modified versions of earlier releases, occasionally under new branding, but all seek to decrease the frequency of false negatives and false positives or decrease the hands-on effort necessary to perform the testing.

All nucleic acid tests rely on sequence recognition for specificity, including capture oligonucleotides, primers for targeted PCR, and/or fluorescently labeled hybridization probes. Sequence variants between strains that occur within a targeted sequence recognition site will disrupt the assay and may yield a false-negative result. For example, the original IDI-MRSA Test, now known as BD GeneOhm MRSA achromopeptidase (ACP) assay, was designed to target six distinct *mec* right-end joining-region (MREJ) genotypes in the SCC*mec* cassette, whereas over 20 MREJ genotypes have now been reported in the literature (45, 61). Therefore, many nucleic acid amplification (NAAT) assays use multiple primer sets (one test uses 18 primer pairs) to ensure that most genotypes are targeted, reducing the number of false negatives reported. As additional sequence variations are identified, it would be advantageous to add appropriate oligonucleotides, if necessary, to avoid missing these rare variants; however, modifications like this are not permitted in FDA-cleared kits and would require additional validation experiments.

Another source of false-negative results is the recently discovered *mecA* variant labeled first as $mecA_{LGA251}$ and now known as *mec*C (62). Identified as part of the novel SSC*mec* type XI, the methicillin-resistant transpeptidase produced by *mec*C has ~63% amino acid identity to the penicillin-binding protein 2a (PBP2a) encoded by *mecA* (63). With only ~69% similarity between the two DNA sequences, the *mec*C gene sequence is not detected by molecular tests targeting the *mecA* gene. Since these are primarily livestock-associated strains (64), only a few commercial assays currently include the *mec*C gene as a target in their multiplex assays. However, in Denmark, where *mec*C frequency in human MRSA infections has been retrospectively determined, an increase in frequency was seen, from 1.5% prior to 2010 to 1.9% and 2.8% in 2010 and 2011, respectively (65), and therefore *mec*C may become an important target in the near future.

As previously mentioned, an early goal of testing was to detect MRSA without also falsely reporting as positive those specimens containing both MSSA and MR-CoNS. The IDI-MRSA test accomplished this goal by having one PCR primer targeting MREJ in the SCC*mec* cassette and the other primer targeting the *orfX* sequence specific for *S. aureus* (66). Any successful amplification would indicate both sequences on the same chromosome. No amplification would occur if the two targets were on separate chromosomes, as would be the case for a specimen containing MSSA and MRCoNS. However, using this stratagem produced different false-positive results when the specimen harbored an "empty SCC*mec* cassette"—the SCC*mec* remnant without the *mecA* gene itself (67). To significantly reduce the empty SCC*mec* cassette problem, many of the current commercial assays detect both the MREJ-orfX target and the *mecA* gene in a multiplex reaction.

With the realization that screening for MSSA colonization in preoperative patients is as clinically important as MRSA screening, contemporary molecular assays have been designed to detect and identify both targets. Finally, several modern technologies can efficiently identify dozens, even hundreds, of targets, leading to the commercial availability of pathogen panels, particularly for the detection of microbes responsible for sepsis.

Today, commercial assays for MSSA, MRSA, and several other clinically relevant pathogens are as varied as their numbers. Brief descriptions of some important elements of the FDA-cleared assays are listed below, and the sensitivity, specificity, and limit of detection for both FDA-cleared and Conformité Européenne-In Vitro Device (CE-IVD) marked assays are listed in Table 2 (56, 59, 60, 68–101). As with all *in vitro* diagnostic tests, positive and negative predictive values are highly dependent on the prevalence of the disease in the population, making accurate comparisons difficult and therefore predictive values are not included in this review.

BD GeneOhm and BD MAX

The first commercial PCR assay for MRSA has been modified to improve the test's accuracy and to reduce the labor-intensive preparation of the original test. The BD GeneOhm MRSA ACP assay employs molecular beacon chemistry, initially performed in the real-time PCR SmartCycler (Cepheid, Sunnyvale, CA) instrument to screen nasal swab specimens within 3 h. Each SmartCycler can perform 16 individual analyses after a brief achromopeptidase lysis step; it requires minimal benchtop space, and the SmartCycler instruments can be daisy-chained for screening programs requiring more capacity. This platform is also used for the expanded BD GeneOhm StaphSR, which detects both MRSA and MSSA (using *nuc* as an *S. aureus*-specific target) in positive blood cultures. Although not FDA-cleared for detection use with nasal swabs, the success of the same chemistry in the BD GeneOhm MRSA ACP assay indicates that the StaphSR could be successful in screening nasal swabs for both MRSA and MSSA after proper laboratory validation. However, at least two studies

[b]PI, manufacturer's package insert.

revealed the failure of the BD GeneOhm StaphSR to detect either MRSA or MSSA in blood cultures when the strains contained MREJ types different from the six recognized in the BD GeneOhm assays (102, 103). With the newer platform from BD Diagnostics (Franklin Lakes, NJ), the BD MAX MRSA uses a slightly different probe chemistry (5′ exonuclease probes commonly referred to as TaqMan probes) but targets the same six MREJ types as the BD GeneOhm assays.

Newer assays for this platform, namely the BD MAX MRSA XT and the BD MAX StaphSR, currently target 11 MREJ types to avoid missing many known MRSA strains. Both assays also target both the *mecA* and *mecC* genes to avoid detecting empty cassettes; these improvements were designed to aid in the detection of MRSA strains. Like BD GeneOhm StaphSR, the BD MAX StaphSR assay targets *nuc* as the *S. aureus*-specific target to detect MSSA in the specimens. The BD MAX instrument has a much larger benchtop footprint than the SmartCycler but can perform 24 individual analyses from cell lysis through detection, including different assays in the same run. There is less hands-on time for the BD MAX than the GeneOhm, and results are available within 2.5 h. All three BD MAX assays are FDA cleared for nasal specimens only, and no validation studies analyzing other specimen types have been published.

Biofire FilmArray Blood Culture Identification Panel (BCID)

This is one of several newer assays that detect not only MRSA and MSSA in signal-positive blood culture bottles but detect multiple pathogens that can cause sepsis. The BCID panel detects 19 bacteria (both Gram-positive and Gram-negative species), 5 yeasts, and 3 antibiotic-resistance genes (*mecA*, *vanA/B*, and bla_{KPC}). It is a nested multiplex real-time PCR assay performed on the FilmArray instrument, a small benchtop closed system with only 2 min of hands-on time that processes a single sample from start to finish within 1 h (104). Details on the precise targets and probe chemistry for MRSA or MSSA in the BCID assay are not publicly available. The FilmArray BCID assay is FDA cleared for positive blood culture bottles only; no validation studies analyzing other specimen types have been published.

Cepheid GeneXpert

The GeneXpert systems are random-access, single-sample instruments handling everything from sample to result, which facilitates placement in both low- and high-capacity moderately complex, real-time environments with various configurations containing 1 to 80 modules. The smaller systems are small benchtop models, whereas the Infinity-48s and the Infinity 80 are large floor models. There are four Xpert assays that are FDA cleared for the detection of *S. aureus*—both MRSA and MRSA/SA Nasal Complete for nasal specimens, MRSA/SA Blood Culture for positive blood culture bottles, and MRSA/SA SSTI for skin and soft tissue swabs. Additional applications have been evaluated and are listed in the tables. The assays require very little hands-on time, and results are available in approximately 1 h. All four use TaqMan probe real-time PCR targeting six types of SCC*mec* cassettes to detect MRSA, with three tests that also detect MSSA targeting the *spa* gene. As with early versions of MRSA assays from other manufacturers, the Xpert MRSA assay was prone to falsely identifying empty cassette strains as MRSA-positive (105–108), but the other Xpert assays now also target the *mecA* gene itself. However, the number of SCC*mec* types recognized by all Xpert assays has not been increased, which could lead to some strains being falsely identified as MSSA (73, 106, 109).

Epoch Biosciences MRSA/SA ELITe MGB

This assay is a two-step procedure best used in high-throughput environments employing batch processing. The first step requires a cell suspension of bacteria from nasal swabs, followed by DNA extraction in the automated bioMérieux NucliSENS easyMAG instrument. The second step is real-time PCR in the Applied Biosystems 7500 Fast Dx. Both instruments are placed on the benchtop and therefore have a relatively large footprint. Batches of 24 specimens are processed and resulted within 3.5 h. The detection chemistry used is the triplex-forming minor-groove-binding (MGB) hybridization probes targeting conserved sequences in *ldh1* to identify *S. aureus* and in *mecA* to identify methicillin resistance. The fluorescence of the unbound probe remains quenched while in solution, and fluorescent signal is emitted when the probe is hybridized to the correct complementary sequence. The C_T value for both targets is measured, and similar values are indicative of MRSA but can also indicate the presence of both MR-CoNS and MSSA if they are present at the same density. Different relative values or a signal only for *ldh1* is indicative of MSSA. In one study, the MRSA/SA ELITe MGB detected MRSA isolates containing *mecA* variants including *mecC* not identified by Xpert MRSA/SA (73). The MRSA/SA ELITe MGB is FDA cleared for nasal specimens only, and no validation studies analyzing other specimen types have been published.

Nanosphere Verigene

Another of the newer assays that detects multiple pathogens in addition to MRSA and MSSA is the Verigene Gram Positive Blood Culture (BC-GP). Performed on the single-sample Verigene small benchtop instrument that uses gold nanoparticle probes as part of the multiplexed microarray detection system, the BC-GP detects 12 Gram-positive bacteria and 2 antibiotic-resistance genes (*mecA* and *vanA/B*). The instrument performs cell lysis, DNA extraction, multiplex PCR, and microarray hybridization within 2.5 h. The Verigene BC-GP assay is FDA cleared for signal-positive blood culture bottles only, and both the Verigene BC-GP and the FilmArray BCID performed equally well in one comparison (87). A 30- to 41-h improvement in turnaround time compared to standard microbiology testing has been documented (110, 111). No validation studies analyzing specimen types other than positive blood cultures have been published.

Roche LightCycler and cobas

The only FDA-cleared assay for MRSA detection provided by Roche Molecular Diagnostics (Pleasanton, CA) is the LightCycler MRSA Advanced Test. The bacteria from nasal swab specimens are first lysed using heat and mechanical beating to release the DNA in a MagNA Lyser instrument, followed by real-time PCR performed in the LightCycler 2.0 instrument using fluorescence resonance energy transfer probes targeting the SCC*mec*/*orfx* region.

Both instruments are benchtop models capable of processing up to 30 specimens, with results available within 2 h and 41 min of hands-on time, compared to 2.5 h with 75 min of hands-on time for BD GeneOhm MRSA (112). Both are significantly quicker than culture, which requires 24 to 48 h for results (112).

Roche also produces three CE-IVD marked assays, not yet available in the United States, that detect MRSA: the cobas MRSA/SA for the analysis of nasal swabs (currently pending FDA clearance) and the LightCycler SeptiFast *mec*A MGRADE and LightCycler SeptiFast MGRADE assays for direct testing of whole-blood specimens, the last targeting a total of 25 blood pathogens. The cobas MRSA/SA assay is designed to detect eight MREJ types of MRSA and the *S. aureus*-specific capsular polysaccharide enzyme gene to recognize MSSA on the high-throughput cobas 4800 instrument (a floor model) with results for 6 to 94 nasal swab specimens available in 1.5 to 4 h. Roche obtained FDA 510(k) approval for the cobas MRSA/SA Test in January 2015, but availability in the U.S. is uncertain. Like the LightCycler MRSA Advanced Test, the LightCycler SeptiFast assays are performed on the LightCycler 2.0 instrument, but the latter are designed to analyze 1.5 ml of whole blood without culture or a lysis step. The assay targets a region of the internal transcribed spacer between the 16S and 23S genes of bacteria or between the 18S and 5.8S rDNA sequences of fungi that differentiate 19 bacteria and 6 fungi, with a subsequent test for the presence of a *mec*A gene. Although validated for whole blood to detect sepsis, the LightCycler SeptiFast has been used to detect pathogens in patients with infectious endocarditis (113), urinary tract infections (114), and purulent body fluids (115).

IMPLICATION OF MOLECULAR TEST CHOICE

There are three main components for decision making when approaching what to use for controlling MRSA and reducing *S. aureus* SSI, once the choice has been made to use screening as a tool for reducing infections resulting from these pathogens. A critical aspect is how testing will impact laboratory staffing (e.g., workflow) and reagent cost. Selecting a method that requires minimal hands-on time or one that is potentially automatable with a "sample in–answer out" format can help lessen the pressure on increasingly limited expert staff availability as well as fit into future lab design that likely will involve advanced robotics (116). Table 3 lists the parameters that are important to laboratory workflow and that are known for the commercial assays reported in this review. With laboratory budgets under pressure for reducing expenses, the test cost can become an important aspect of assay choice. The current manufacturer's suggested retail price for molecular diagnostics ranges from $26 to $42 per test (30), and while discounts are available, these costs can be significant to an organization when thousands of assays are performed annually.

A second issue is the cost to the hospital that is not directly related to laboratory expense but results from other charges accrued related to test performance. For example, an MRSA surveillance test with lower specificity can generate significant expense due to unnecessary patient isolation compared to a test with better specificity performance (30). Contact isolation (precautions) can range from $60.40 to $118.84 per day (117–119). This implies that for each 1% lower specificity at a hospital where the mean length of stay is 5 days, the additional isolation cost generated when performing 10,000 samples will range from $30,000 to $60,000 (30), a significant additional expense for even a few percent difference in specificity.

Evidence of patient benefit should be a major driver of the final choice, and it can differ between surgical *S. aureus* infection prevention and MRSA control programs. For surgical infection prevention, sensitivity is key since if colonization with *S. aureus* (MSSA and MRSA) is not detected, then decolonization will not be performed and the risk of a postoperative SSI increases (37, 38). In this setting NAAT is preferred due to the relative insensitivity of culture (29), even though testing can be done several days in advance of surgery for nonurgent or emergent cases.

Improved prevention of MRSA infection has driven much discussion during the past decade, ranging from advocacy of universal admission testing for detecting all those colonized (10, 11, 25–28) to doing no testing and simply decolonizing everyone with mupirocin and chlorhexidine (120). Perhaps the two best studies to compare for this decision are the large multicenter U.S. trials by Jain and colleagues from the Department of Veterans Affairs (26) and that by Huang et al. in the Hospital Corporation of America (HCA) hospitals (120). At the end of their programs, the overall Veterans Affairs ICU MRSA infection and BSI rates compared to those of Huang et al. were 0.62 versus 2.1 infections/1,000 patient days and 0.09 versus 0.47 BSI/1,000 patient days, respectively; in these two measures the VA demonstrated 3- to 5-fold lower infection rates when using universal MRSA surveillance and contact precautions for patients found to be colonized with MRSA. Also, a pair-wise group comparison of risk ratios found no statistical difference between decolonization versus screening and isolation (risk ratio of 0.9234; 95% CI 0.7311 to 1.1662; $p = 0.5034$) when coagulase-negative (skin) staphylococci were removed from the analysis in the HCA study (120), suggesting no benefit from universal decolonization compared to surveillance and targeted intervention. Table 4 includes a recent analysis of our NorthShore University HealthSystem data compared to the HCA study, which further supports the utility of a targeted approach for MRSA using NAAT methodology.

CONCLUSIONS AND FUTURE DIRECTIONS

At this time it is clear that surveillance for *S. aureus* (both MSSA and MRSA) can be very useful in improving patient outcome and that molecular diagnostic tests have a significant role to play. Real-time PCR test platforms are likely to become more numerous and easy to use, resulting in lower costs and facilitating further penetration into medical care practice. Within the next decade novel technologies are likely to emerge that will further enhance detection of these organisms and lower costs. In the summer of 2014 the U.S. Department of Health and Human Services released a 5-year funding opportunity announcement titled "Partnerships for Diagnostics to Address Antimicrobial Resistance of Select Bacterial Pathogens (R01; RFA-AI-14-019)" with the goal of funding 10 to 15 sites for developing "diagnostics that will enable rapid, sensitive, specific, culture-independent detection of high-priority antimicrobial-resistant Gram-negative bacterial pathogens." Additional goals of this funding opportunity are to attain a diagnostic test time of <3 h for reporting species and resistance profile information that is easy to use (i.e., closed sample-to-answer system with minimal operator training and expertise required), random access, and

TABLE 3 Laboratory workflow for commercial assays for MRSA/MSSA molecular testing (*Continued*)

Name	Instrument	Footprint[a]	Single/random access/batch[b]	Maximum samples in 8 h per instrument	Result requires interpretation	Time to result (h)	Hands-on time (min)
BD GeneOhm StaphSR	SmartCycler	Medium countertop	Random access	32	No	3	NA
Xpert MRSA	Xpert	Small to large countertop versions	Random access	6–480	No	1.25	3
Xpert MRSA/SA Blood Culture	Xpert	Small to large countertop versions	Random access	8–640	No	1	3
Xpert MRSA/SA Nasal Complete	Xpert	Small to large countertop versions	Random access	8–640	No	1	3
Xpert MRSA/SA SSTI	Xpert	Small to large countertop versions	Random access	8–640	No	1	3
FluoroType MRSA	BioShake iQ and FluoroCycler	Small countertop	Single or batch	48	No	2.5	NA
hyplex MRSA	Thermal cycler and microplate reader or ELISA processor	Large countertop	Single or batch	288	Yes	2.5	5 or 30 for 96 samples
hyplex MRSA plus	Thermal cycler and microplate reader or ELISA processor	Large countertop	Single or batch	288	Yes	3.5	5 or 30 for 96 samples
FilmArray Blood Culture Identification	FilmArray	Small countertop	Single	7	No	1.2	3
hemoFISH Gram (+) Panel	Fluorescent microscope	Large countertop	Single	80	Yes	0.5	10
hemoFISH Masterpanel	Fluorescent microscope	Large countertop	Single	80	Yes	0.5	10
hemoFISH *S. aureus*/CNS Screen	Fluorescent microscope	Large countertop	Single	80	Yes	0.5	10
S. aureus and/or other *Staphylococcus* species PNA FISH culture	Fluorescent microscope	Large countertop	Single	NA	Yes	1.5	NA
S. aureus PNA FISH	Fluorescent microscope	Large countertop	Single	NA	Yes	2.5	NA
Staphylococcus QuickFISH BC	Fluorescent microscope	Large countertop	Single	NA	Yes	0.35	NA
AccuProbe *Staphylococcus aureus* Culture Identification	GEN-PROBE LEADER Luminometer	Large countertop	Single	Thermal Cycler/ sequencer dependent	Yes	<1	NA
MALDI Biotyper	MALDI Biotyper CA	Medium countertop	Single	1,568	No	1	<5
VYOO Sepsis	Multiple real-time PCR platforms	Medium to large countertop	Single	NA	NA	8	NA
PLEX-ID BAC Spectrum BC	PLEX-ID	NA	Single	NA	NA	12–16	NA
Verigene Gram Positive Blood Culture (BC-GP) Test	Verigene Reader and Processor SP	Small countertop	Single	3	No	2.5	5
VITEK MS	VITEK MS	Floor	Single	384	No	0.2*	<5

[a]Small countertop (<30 in. wide), medium countertop (30–60 in. wide), large tabletop (>60 in. wide), or floor.
[b]Although all assays can be used for a single specimen, "batch" is used if that is the most efficient practice. Similarly, random access is reserved for instruments that are capable of performing more than one assay in a single run and not for instruments capable of performing only one test at a time.
[c]NA, not available.

TABLE 4 Comparison of health care-associated infection outcome of universal decolonization (120) with concurrent data from NorthShore University HealthSystem (authors' unpublished data)

Data on:	Universal decolonization results (120)	NorthShore targeted isolation results	Comments
Scope/population	18 months/29 ICUs, 101,600 patient days	38 months/4 ICUs, 55,350 patient days	Similar hospital types
Outcome	No screening and decolonize all	Screen all and only isolate positives	
Rate of MRSA clinical isolates	2.1 per 1,000 patient days	0.3 per 1,000 patient days	NorthShore data based on 342,000 hospital-wide patients
Rate of all cause ICU bacteremia	3.6 per 1,000 patient days	1.0 per 1,000 patient days	NorthShore rate 3.6-fold lower
Rate of MRSA bacteremia	0.47 per 1,000 patient days	0.018 per 1,000 patient days	NorthShore rate 26.1-fold lower
Cost	$40 per patient[a]	$27–$37 per patient (includes all MDROs)	NS cost range based on test price for all assays used

[a]Range of prices for 5 days of Bactroban Nasal from 11 online pharmacies is $135.48 to $145.44 (http://www.goodrx.com/bactroban-nasal), as of October 24, 2014.

non-NAAT-based. With such a stimulus we should expect novel assay development that will enhance our current capacity.

An example of an anticipated new innovation is GeneWeave Biosciences' sample in–answer out diagnostic system called the vivoDx, which includes a universal reagents-on-board test kit for MRSA surveillance. The assay is developed around Smarticles, which are highly engineered phages developed to target a desired bacterial species, group, or family, and a substrate reagent that induces light production at the end of the assay read by a photomultiplier tube within the vivoDx instrument, all in under 4 h (121). Interestingly, the test results are inoculum independent, so this assay is expected to work for various bacterial infections and provide identification and susceptibility directly from clinical samples. FDA clearance trials for this new technology began in late 2015, with the MRSA test expected to be commercially available in 2016.

S. aureus was first described in modern medicine 135 years ago by the Scottish surgeon Alexander Ogston, who recognized it as the prominent cause of pus in postoperative infection (http://www.antimicrobe.org/h04c.files/history/S-aureus.pdf). Over the decades it has caused countless infections and eventually adapted to the development of antibiotics by becoming resistant to most of them. With progress in diagnostic microbiology, first using culture and more recently with the availability of rapid molecular diagnostics, we better understand how to detect and prevent infections from this pathogen. We now have a wide array of NAAT that assist in the management of these infections, and the future holds promise for even newer technology to deploy in the fight against this organism.

Disclosure: *The authors are solely responsible for this report. During the past 5 years L.R.P. has received research grants from BD-GeneOhm, Cepheid, MicroPhage, Nanosphere, NIAID, NIH, Roche, 3M, AHRQ, GeneWeave, IMDx, CareFusion, and the Washington Square Health Foundation for work in molecular diagnostics. L.R.P. has performed consultation for BD-GeneOhm, Cepheid, MicroPhage, Nanosphere, and Roche in this area of research. K.A.M. has no conflicts to report.*

Molecular Diagnostics for *Clostridium difficile*

FRÉDÉRIC BARBUT AND CURTIS J. DONSKEY

16

Clostridium difficile is the most important cause of health care-associated diarrhea in developed countries (1–3). During the past decade, the emergence of an epidemic C. *difficile* strain, termed PCR-ribotype 027 or North American pulsed-field gel electrophoresis type 1 (NAP1), has been associated with dramatic increases in the incidence and severity of C. *difficile* infection (CDI) in North America and Europe (1, 4). In the United States, C. *difficile* now causes more hospital-onset infections than any other pathogen (~80,000 infections annually), resulting in an estimated 14,000 deaths each year (2, 3). Moreover, these numbers greatly underestimate the true burden of CDI because up to 75% of cases in the United States now have their onset in long-term care facilities or the community (2).

In the context of these changes in the epidemiology of C. *difficile*, efficient and accurate strategies to diagnose CDI are crucial to guide management and prevent transmission. Efficient testing for CDI may reduce delays in initiation of isolation and treatment for confirmed CDI cases, while also allowing rapid discontinuation of empirical therapy and isolation when testing is negative. Accurate testing strategies can prevent unnecessary isolation and treatment due to false-positive results and lack of isolation and treatment due to false-negative results. In this chapter, we review the diagnostic methods available for CDI testing, focusing primarily on molecular methods. We also highlight clinical factors that are essential to consider in efforts to optimize the efficiency and accuracy of CDI testing.

GENERAL CONCEPTS

The diagnosis of CDI is usually based on a combination of clinical symptoms consistent with the diagnosis and laboratory tests confirming the presence of a toxigenic strain or toxin in stool. In the absence of a positive laboratory test, histopathologic or endoscopic findings may be used to support the diagnosis (5, 6). According to the European Society of Clinical Microbiology and Infectious Diseases guidelines, an episode of CDI is defined as "(i) a clinical picture compatible with CDI and microbiological evidence of toxin producing C. *difficile* in stool without evidence of another cause of diarrhea or (ii) pseudomembranous colitis" (5). A similar definition is given by the Society for Health Care Epidemiology of America and the Infectious Diseases Society of America: "A case of CDI is defined by the presence of symptoms (usually diarrhea) and either a stool test positive for C. *difficile* toxins or toxigenic C. *difficile*, or colonoscopic or histopathologic findings revealing pseudomembranous colitis" (6).

Clinical symptoms are required for the diagnosis of CDI because asymptomatic carriage of C. *difficile* is common, particularly in health care facilities, and treatment is not recommended for carriers (7–12). For example, in a multicenter study in France, the prevalence of carriage among asymptomatic hospitalized patients was 5% (12). In a more recent multicenter study in Canada, the incidence of asymptomatic carriage among hospitalized patients was 7% (10). Rates of asymptomatic carriage are typically even higher in long-term care facilities, with as many as 51% of asymptomatic residents carrying toxigenic C. *difficile* strains in outbreak settings (13). Education of clinicians and nursing staff on appropriate selection of patients for testing is essential because currently available tests do not accurately distinguish CDI from asymptomatic carriage of toxigenic C. *difficile*. It is also recommended that laboratories only accept unformed stools (defined as stools taking the shape of the container) for testing unless ileus due to C. *difficile* is suspected (14). In addition to the detection of asymptomatic carriers, inappropriate testing can also result in false-positive test results in the absence of carriage of C. *difficile* when enzyme immunoassays for toxin are used due to suboptimal specificity of these tests (15, 16).

Performance of a test of cure after CDI treatment is not recommended (5, 6, 14). It has been demonstrated that PCR and glutamate dehydrogenase (GDH) tests often remain positive after resolution of symptoms, and ~20% of patients may have positive tests at the end of treatment (17). Moreover, after discontinuation of metronidazole or vancomycin treatment, as many as 56% of patients who remain asymptomatic have positive cultures 1 to 4 weeks after treatment cessation (18). Resolution of diarrhea is the appropriate criteria for assessing the efficacy of treatment.

Repeat testing during the same episode of diarrhea is a common practice that should also be discouraged. Repeat testing increases the possibility of false-positive results and does not substantially increase the yield of true positives (19, 20). For example, Aichinger et al. (20) found that the gain (defined as the rate of negative results that converted to positive) of repeat testing was only 1.9% and 1.7% for enzyme immunoassay (EIA) for toxins A and B and PCR, respectively. In practice, some laboratories prohibit repeat

Frédéric Barbut, National Reference Laboratory for C. *difficile*, Hôpital Saint-Antoine, Assistance Publique-Hôpitaux de Paris, Paris, France and UPMC Univ. Paris 06, GRC no. 2, Epidiff, Paris, France. **Curtis J. Donskey,** Infectious Diseases Section, Cleveland VA Medical Center, and Case Western Reserve University School of Medicine, Cleveland, OH 44106.

testing for 5 or 7 days after an initial negative test to avoid inappropriate repeat testing.

LABORATORY METHODS FOR *C. DIFFICILE* TESTING

The methods used for the diagnosis of CDI have rapidly evolved over the last 10 years. The available laboratory tests fall into three groups depending on their target: methods that detect free toxins A and B in stools, methods that detect the presence of a toxigenic strain, and methods that detect the presence of C. *difficile* in stools (Fig. 1) (21). Two methods are regarded as reference methods: the stool cytotoxicity assay (CTA), which detects free toxins in the feces, and toxigenic culture, which detects toxigenic C. *difficile* strains (21).

Stool Cytotoxicity Assay

The CTA is the historical "gold standard" approved by the U.S. FDA. This test was first described by Chang et al. and is still considered a reference method for the diagnosis of CDI (22, 23). A stool filtrate is inoculated on cell culture, and a specific cytopathic effect (rounding of the cells) is observed after 24 to 48 h of incubation. The cytopathic effect is mainly due to the toxin B-associated cytotoxic activity, which is 10^3 to 10^4 times more potent than that of toxin A (24). This method is sensitive (limit of detection of toxin B is around the picogram of toxin) and inexpensive (25).

Although CTA has some advantages, there are several drawbacks. CTA requires cell culture facilities, and it is technically difficult to perform. CTA also takes much longer than many current rapid tests (25). CTA results are not available before 24 to 48 h, and in the case of a positive result, a confirmatory test must be performed with neutralizing antibodies to ensure the specificity of the cytopathic effect. In addition, CTA is not standardized, and the technique varies according to the type of cells used, the dilution of the stool, and the incubation period.

It is possible that more rapid CTA-type assays will be available in the future. For example, a real-time cell analysis assay (ACEA Biosciences) based on electronic impedance technology was described in 2010 for quantitative detection of toxin B in stool samples (26). The system provides automated data acquisition in real time and is amenable to a high-throughput, on-demand platform.

Toxigenic Culture

Toxigenic culture is also considered a gold standard for CDI diagnosis. This is a two-step method, with the initial step being isolation of C. *difficile* in culture (27). In the second step, the capacity of the strain to produce toxins *in vitro* is determined by cytotoxicity assay (by inoculating colonies in broth and testing the supernatant on cell culture). An enzyme-immunoassay for toxins A and B can be used as an alternative method to confirm toxin production, although this application is not systematically validated by the manufacturers. Finally, PCR targeting *tcdA* and/or *tcdB* after DNA extraction from colonies could also be used to detect the presence of the genes encoding for toxins.

Different selective media, either homemade or commercially available, can be used and are usually derived from the cycloserine cefoxitin fructose agar medium (28). The media generally contain antibiotics (cycloserin and cefoxitin) to ensure selectivity and sometimes taurocholate or lysozyme to promote germination of spores and enhance sensitivity of the media (29, 30). Chromogenic media are

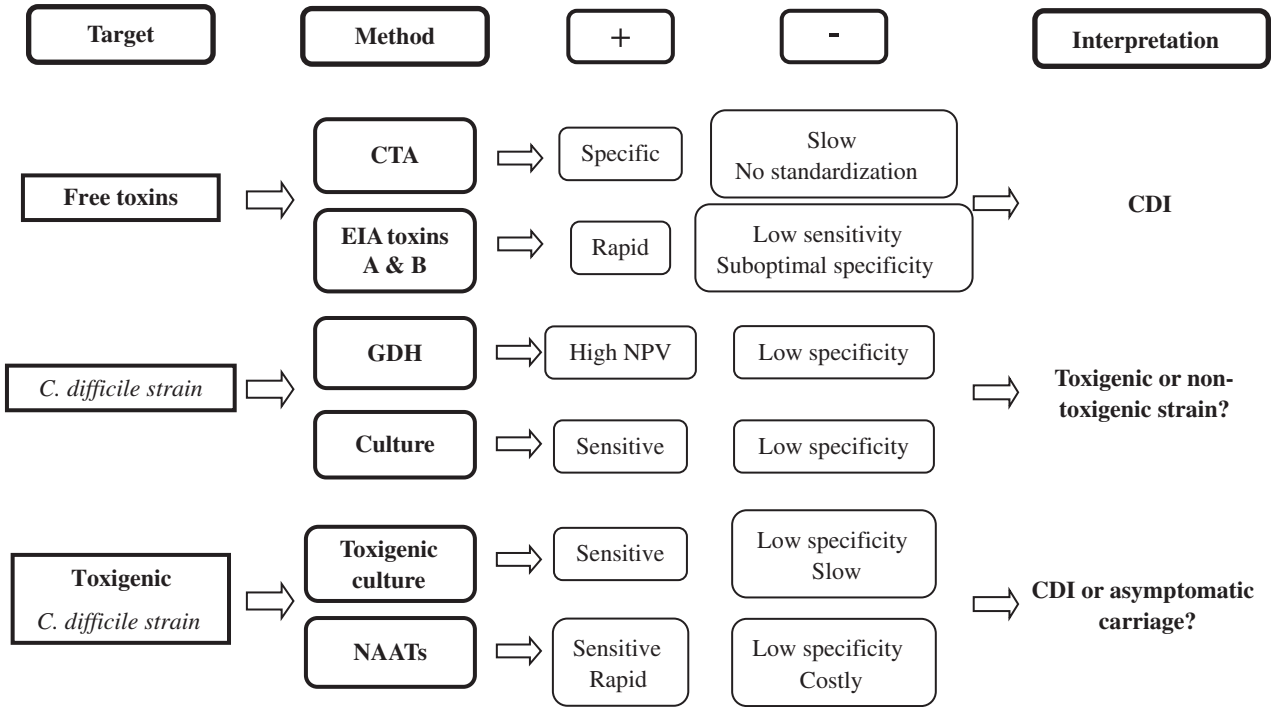

FIGURE 1 Different diagnostic methods and their targets. +, advantages; –, disadvantages; NPV, negative predictive value. Adapted from reference 25.

now available and allow an easy and more rapid identification of *C. difficile* due to the black color of the colonies (31). Ethanol or heat shock can be performed before plating to reduce the endogenous flora and to optimize the recovery of *C. difficile* strains (32). Sensitivity is about 2,000 bacteria per gram of stool. After 48 h in an anaerobic atmosphere, colonies are easily identified by their odor due to the production of *para*-cresol and their typical aspect (large gray colonies). They exhibit a green "chartreuse" fluorescence under UV light. Biochemical methods (e.g., RapID ANA II System, Thermo Fisher Scientific, Waltham, MA), gas liquid chromatography, latex agglutination, or matrix-assisted laser desorption ionization-time of flight mass spectrometry can be performed to confirm presumptive identification.

Although toxigenic culture is a very sensitive method, the time required (2 to 5 days) for testing is too long for routine clinical use. Toxigenic culture remains invaluable for epidemiological purposes and for antimicrobial susceptibility testing. In addition, toxigenic culture is commonly used as a gold standard for comparison with new testing methods.

Glutamate Dehydrogenase

GDH is a metabolic enzyme produced in relatively large amounts by *C. difficile* strains. Its detection is simple and rapid using EIA tests (mostly well-type EIA or membrane-type EIA), and numerous tests are available to detect this enzyme in stools. EIAs for GDH are sensitive (about 88 to 89% compared to the culture) (21). The advantage of these tests is their high negative predictive value, which allows the diagnosis of CDI to be ruled out by a negative result. In the meta-analysis conducted by Shetty et al., the negative predictive value varied between 94.6 and 100% (33). However, tests that detect GDH in stools lack specificity. A positive result indicates the presence of *C. difficile* but cannot predict the toxigenicity of the strain. In addition, GDH can be produced by some organisms other than *C. difficile* (34). A second test must be used to confirm the toxigenicity of the *C. difficile* isolate. GDH is therefore a good screening test and can be used as the first step of a diagnostic algorithm.

It was recently reported that sensitivity of GDH detection may vary depending on strain genotype. In particular, compared to Xpert *C. difficile*, a PCR-based method, sensitivity of GDH algorithms would be significantly lower for PCR-ribotypes other than 027 (35). However, these results were not confirmed in a subsequent study that found no difference in detection ability between the PCR-ribotypes and showed that PCR was globally more sensitive (36). A third study compared the sequence of the *gluD* gene encoding for GDH and showed that sequences of 24 out of 25 PCR-ribotypes tested were identical and that the change in the remaining one did not affect immunoreactivity (37).

EIAs for Toxins A and B

EIAs targeting toxins A and B ("free toxins") in stools became widely used by laboratories because they provide rapid results and are easy to use (21). These assays usually target both toxins A and B to detect toxin A^- toxin B^+ (A^-B^+) strains. It is now widely accepted that these tests cannot be used as stand-alone tests for the diagnosis of CDI, primarily because they lack sensitivity. René et al. (38) demonstrated that sensitivity of different EIA tests for toxins A and B compared to cytotoxicity assay varied between 41 and 67% depending on the test used. The performance of EIA was even worse compared to toxigenic culture, varying between 33 and 57% (38). Similarly, Crobach et al. (23) reported that the mean sensitivities of membrane-type and well-type EIA for toxins A and B were 72% and 82%, respectively, compared to CTA, and 52% and 66%, respectively, compared to toxigenic culture.

As noted previously, the use of EIA for toxins A and B as a stand-alone test is also problematic due to the suboptimal specificity of these assays (15, 16). Suboptimal specificity is particularly an issue in settings where the prevalence of CDI is low or if a patient being tested has a low pretest probability of CDI. For example, if the specificity of an EIA for toxins A and B is 97% and the pretest probability of CDI is 3%, the positive predictive value of a positive test would be 50% (i.e., 50% of positive tests would be false positives). One example of a setting where stand-alone EIAs for toxins A and B may result in false-positive tests is in a pediatric hospital population where the prevalence of CDI is low (16). In this setting, only 72 of 112 (64%) EIA-positive stool samples had detectable *C. difficile* by culture, suggesting that about one-third of all positive tests were false positives (16).

To date, only one commercially available EIA assay combines simultaneous detection of GDH and toxins A and B (C. diff Quik Chek Complete, Techlab; Encart *Clostridium difficile* GDH et toxins A & B, Theradiag). Concordant results (GDH+toxin+ or GDH–toxin–) readily allow for diagnosis or exclusion of CDI. A second test is required in the case of discordant results. This assay was successfully used in a two-step protocol for primary screening for CDI in a study in which discordant results (GDH +toxin–) were confirmed by PCR (39). Results for 87% of the samples could be reported rapidly after the C. diff Quik Chek Complete assay. A confirmation test was required for only 13% of the samples. This finding resulted in an improved turnaround time for the detection of toxigenic *C. difficile* compared to an algorithm based on GDH screening followed by CTA. Conversely, Goldenberg et al. (40) did not find any benefit in terms of sensitivity, specificity, and costs from coupling GDH with EIA for toxin as the first part of a testing algorithm when compared with an algorithm based on GDH detection alone.

Nucleic Acid Amplification Tests

NAATs are the most recent tests developed for the diagnosis of CDI. Most of these methods target a conserved region of the gene coding toxin B (*tcdB*) (Simplexa *C. difficile* Universal Direct [FOCUS Diagnostics], BD GeneOhm Cdiff Assay [BD Diagnostics], BD MAX Cdiff [BD Diagnostics], Portrait Toxigenic *C. difficile* Assay [Portrait, Great Basin], ProdesseProGastro Cd assay [Gen-Probe]), whereas others target the toxin A gene (*tcdA*) (Illumigene [Meridian Bioscience] and AmpliVue [QUIDELMolecular]) (Table 1) (21, 41, 42). Some molecular methods are multiplex PCR and detect several genes (RIDAGENE *Clostridium difficile* & Toxin A/B [R-biopharm; *tcdA*, *tcdB*, and genes specific for *C. difficile*], Xpert *C. difficile*/Epi [Cepheid; *tcdB*, binary toxin gene and deletion in position 117 in the *tcdC* gene], GenoTypeCDiff [HAIN LIFESCIENCE; *tcdA*, *tcdB*, binary toxin genes, genes responsible for fluoroquinolone resistance, deletion in *tcdC* including deletion in 117, specific gene for *C. difficile*], or Verigene CDF test [Nanosphere Inc., Northbrook, IL; *tcdA*, *tcdB*, binary toxin

TABLE 1 Comparison of current diagnostic methods

Diagnostic method	Target	Principle	Turnaround time
Stool cytotoxicity assay	Free toxins B (and A)	Cytotoxicity on cell culture	24–48 h
Toxigenic culture	Toxigenic *C. difficile*	Culture and *in vitro* determination of toxigenicity	2–5 days
EIA for GDH	*C. difficile*	EIA	15 min–2 h
EIA for toxins A and B	Free toxins A and B	EIA	15 min–2 h

gene, *tcdC* deletion) (21, 43). Finally, *C. difficile* is also included in tests that simultaneously detect a panel of other viruses and bacteria responsible for infectious diarrhea (Seeplex Diarrhea ACE Detection; Seegene), Xtag Gastrointestinal panel; Theradiag). This list is not exhaustive, and new tests are marketed regularly.

The NAATs vary according to the target and differ in the amplification method (Table 1). Use of real-time PCR predominates, whereas other methods are based on loop-mediated isothermal amplification (e.g., Illumigene) or helicase-dependent amplification (AmpliVue and Portrait assays).

Laboratory turnaround time can range from less than 1 h (Xpert *C. difficile*/Epi) to up to 4 to 5 h (GenoTypeCdiff and Seeplex Diarrhea ACE Detection) (Table 1). NAATs can be performed in batches (e.g., RIDAGENE *Clostridium difficile* & Toxin A/B) or on demand (AmpliVue) depending on the system used. Results are often interpreted using a software system, but amplified products can sometimes be visualized on strips (e.g., AmpliVue, GenoTypeCdiff). Other characteristics such as the DNA extraction method, use of internal controls, manual assays, or fully automated systems must be taken into consideration when choosing a molecular method.

A recent meta-analysis including different molecular methods showed that the pooled sensitivity was 92% compared to toxigenic culture and 87% compared to cytotoxicity assay (44). In another study evaluating the diagnostic accuracy of real-time PCR, similar results were found with an overall mean sensitivity of 90% (45). Thus, studies that compared different NAATs to a reference method were not able to show any significant difference between the different NAATs. However, these studies were not designed and powered for such conclusions. To show differences in terms of sensitivity between different methods, testing thousands of stools would be required with comparison to a reference method such as toxigenic culture.

One concern regarding NAATs is potential genetic modification of the regions targeted by the primers (21). A mutation in this region may lead to a false-negative result with such methods. Another potential limitation of the NAATs is the possible emergence of atypical strains (e.g., strains that do not produce toxin B and thus lead to a false-negative result if a molecular method detecting *tcdB* is being used).

The financial cost of molecular methods is another major consideration because the cost of these tests is high in comparison to EIA for toxin or GDH. One approach to reduce costs of testing is to use a less expensive screening test, with NAATs reserved for confirmatory testing. For example, a two-step algorithm based on an initial GDH screen with a NAAT only in the case of a positive GDH result can decrease laboratory costs relative to NAAT as a stand-alone test. Vasoo et al. (46) found that the implementation of a two-step algorithm with initial testing with a combined GDH and toxin assay followed by PCR for indeterminate results led to a significant cost saving per test compared to the use of PCR alone. The calculated cost per 1,000 tests was $13,663 using the two-step algorithm (C. diff QuikChek Complete reflexed to BD GeneOhm Cdiff Assay for discordant results) versus $26,950 and $25,000 for BD GeneOhm Cdiff Assay alone and ProdesseProGastro Cd assay alone, respectively. Culbreath et al. also found that laboratory costs were reduced when using a two-step strategy based on GDH and PCR (i.e., C. diff QuikChek Complete and Xpert *C. difficile*, cost was $70,633) compared to PCR alone (i.e., Xpert *C. difficile*, cost was $159,877) (38). In contrast, in a cost-benefit analysis that included both laboratory costs and estimated hospital costs of isolation and treatment, Schroeder et al.

(47) found that stand-alone on-demand PCR was favored in most settings, whereas on-demand PCR preceded by lateral-flow GDH testing was favored if a missed CDI case resulted in less than $5,000 of extended hospital stay costs and <2 transmissions, if lateral-flow GDH diagnostic sensitivity was >93%, or if the symptomatic carrier proportion among the toxigenic culture-positive cases was >80%.

STRATEGIES TO OPTIMIZE LABORATORY TESTING FOR CDI

Although there is general agreement that EIA for toxins should not be used as a stand-alone test, there is still considerable debate regarding strategies to optimize laboratory testing (21, 48–51). The main area of debate relates to whether it is sufficient to detect the presence of a toxigenic *C. difficile* strain or whether detection of both the organism and toxin is required for optimal testing (21, 48). In the United States, many laboratories have switched from toxin EIA to NAATs as a stand-alone test for CDI (i.e., detection of toxigenic strains but not toxin) (14). The major concern about this approach is that NAATs have suboptimal specificity because they can detect asymptomatic carriers (21, 48–51). As noted previously, rejection of formed stools by the laboratory can reduce the potential for detection of asymptomatic carriers (14). However, testing of asymptomatic carriers who develop diarrhea due to laxatives or viral infections can result in false-positive tests and unnecessary CDI treatment (15, 52). As will be discussed, although there is a potential for adverse consequences due to unnecessary treatment of asymptomatic carriers identified through inappropriate testing, it is also possible that identification and isolation of carriers may be beneficial if the risk for transmission is reduced.

In the United Kingdom, guidance published on behalf of Department of Health/Advisory Committee on Antimicrobial Resistance and Health Care Associated Infection in 2012 concluded that NAAT testing alone was insufficient and testing should include detection of toxin (53). Specifically, a two-test algorithm was recommended in which an EIA for GDH or NAAT for toxin genes is used as an initial sensitive screen, followed by a relatively sensitive EIA for toxins A and B for cases in which the screening test is positive (Fig. 2) (46, 53). This recommendation was based on a large observational study of more than 6,000 patients with diarrhea that sought to derive an optimum laboratory diagnostic algorithm for CDI (54). In comparison to patients with diarrhea but negative for *C. difficile*, patients with diarrhea and CTA positivity had increased mortality, whereas those with detection of toxigenic *C. difficile* but not toxin (toxigenic culture positive, CTA negative) did not. The authors classified patients

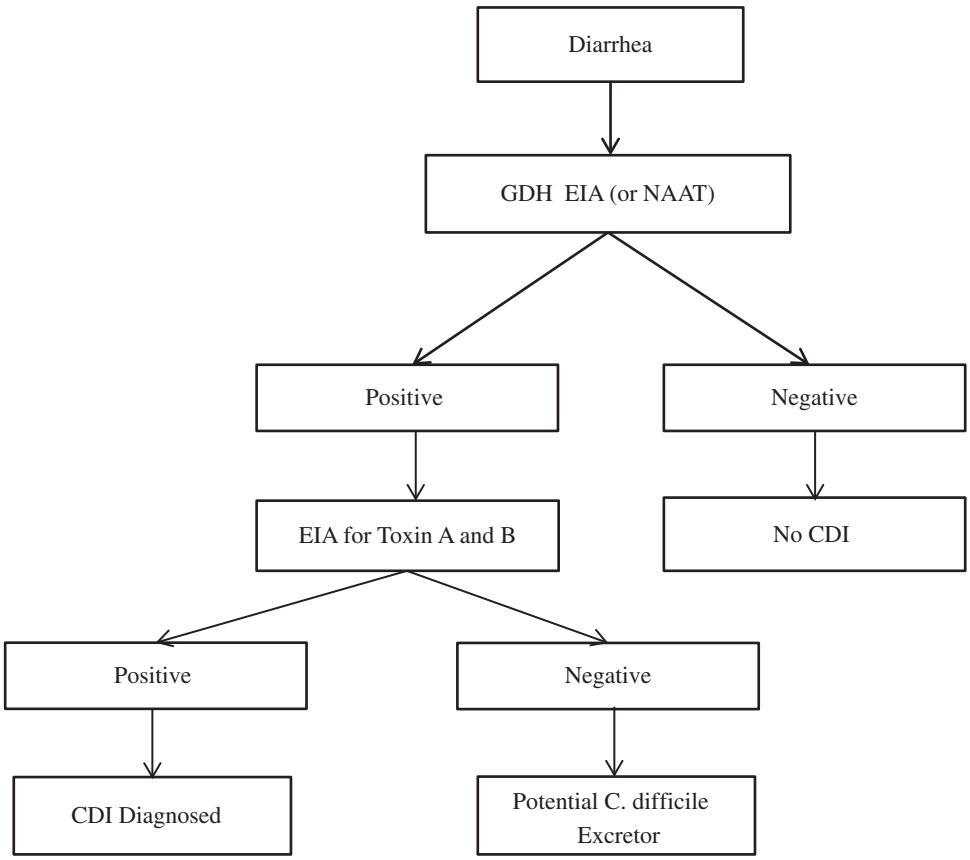

FIGURE 2 Two-step diagnostic testing algorithm for CDI from the United Kingdom Department of Health/Advisory Committee on Antimicrobial Resistance and Health Care Associated Infection (51). A relatively sensitive EIA for toxin A and B is recommended. Patients with positive GDH or NAAT but negative EIA are classified as potential *C. difficile* excretors (i.e., asymptomatic carriers with diarrhea not due to CDI). Fecal excretors may be isolated to prevent cross-transmission, but not routinely treated unless indicated based on clinical interpretation.

with positive toxigenic culture but negative CTA as potential C. *difficile* excretors (i.e., asymptomatic carriers with diarrhea not due to CDI) (54); it was recommended that such patients be isolated to prevent cross-transmission but not be routinely treated. One notable aspect of this study is that all unformed stools submitted to the laboratory from hospital patients >2 years old and from individuals in the community >65 years old were tested for CDI irrespective of whether CDI testing was requested. Thus, it is likely that many samples from patients with obvious alternative explanations for unformed stool or not meeting criteria for diarrhea (defined as three or more unformed stools in 24 hours) were tested; such testing would not be recommended in settings where NAATs are used as stand-alone tests (6, 14, 15).

Smaller studies have reached differing conclusions regarding whether patients with positive tests for toxigenic C. *difficile* but negative toxin assays are at a low risk for complications due to CDI. Longtin et al. (55) found that cases detected by PCR, but not by a three-step algorithm (GDH, EIA for toxin A and B, and CTA), were significantly less likely to develop complications (30-day all-cause mortality, colectomy, admission to ICU, and hospital readmission for CDI) compared to cases detected by PCR and the three-step algorithm (3% versus 39%, respectively). In contrast, in a prospective study of 132 patients, Guerrero et al. found that EIA-negative patients with CDI did not differ in clinical presentation from EIA-positive patients; notably, 21% of EIA-negative patients had severe CDI, including one patient who died of fulminant CDI (56). Similarly, in a study of 143 CDI patients, there was no correlation between the presence of the free toxin in stool and the severity of the disease; 42% of patients classified as having severe CDI had negative EIA for toxin despite the use of a relatively sensitive EIA (57). Finally, it has been shown that some patients harboring toxigenic strains of C. *difficile* but without free toxin in stools have pseudomembranes during endoscopic examination, suggesting that some CDI cases may be missed by reliance on toxin tests only (58, 59).

It should also be noted that asymptomatic carriers may have toxin in stool. For example, Kyne et al. (60) detected cytoxin activity by CTA in stools of 15 of 19 (79%) asymptomatic carriers, and 3 of the 4 negative specimens were from patients carrying nontoxigenic strains. Koo et al. (61) detected toxin by EIA in 3 of 11 (27%) asymptomatic carriers of toxigenic C. *difficile*. It has also been demonstrated that many patients continue to shed toxin in stool after CDI treatment (62, 63). For example, Louie et al. (63; unpublished data) found that toxin was suppressed to undetectable levels during treatment with vancomycin or fidaxomicin, but reappearance of toxin was observed in the 22 days after treatment in about 25% of stool specimens tested from patients who did not develop recurrent symptoms. Reappearance of toxin correlated with recurrent shedding of C. *difficile* in stool. Thus, if diarrhea develops in patients with recent CDI, it is important to consider that a positive toxin assay, in addition to a positive GDH or NAAT test, may be present if diarrhea occurs due to reasons other than recurrence of CDI (e.g., laxatives, viral gastroenteritis).

Taken together, the findings of these studies highlight the continued need for clinical judgment in the diagnosis of CDI. For facilities using NAATs as stand-alone tests, ongoing education of providers and nursing staff regarding appropriate indications for CDI testing is needed to reduce the risk that asymptomatic carriers will be diagnosed with CDI and treated unnecessarily (64, 65). In settings where sensitive screening tests are followed by a relatively sensitive EIA for toxins A and B, it must be appreciated that even relatively sensitive toxin tests miss some patients with CDI (38). Planche et al. (54) cautioned that the need for CDI treatment in toxin-negative patients is a clinical decision. Furthermore, Bignardi et al. (50) found that 9 of 102 (9%) GDH-positive but EIA-negative patients who had persistent or recurrent diarrhea subsequently were diagnosed with CDI based on clinical presentation and a positive GDH and EIA.

CLINICAL AND INFECTION CONTROL CONSIDERATIONS

Reducing Delays in Diagnosis

Efforts to expedite the diagnosis of CDI may be beneficial for several reasons. First, delays in diagnosis may increase the risk of transmission. Sunkesula et al. (66) found that patients with CDI presented a high risk for skin and environmental shedding at the time the order for testing was placed, suggesting that preemptive isolation of patients with suspected CDI might be beneficial. Second, if patients with suspected CDI are preemptively isolated, rapid diagnostic testing will allow timely discontinuation of isolation for those patients who subsequently test negative for CDI. Third, rapid diagnosis of CDI will reduce the time to initiation of treatment for patients with CDI and the time to discontinuation of empirical therapy in patients who test negative. Finally, efforts to expedite diagnostic testing for CDI may reduce inappropriate empirical therapy if clinicians are assured that results will be available in a timely manner (67).

Table 2 provides a summary of three recent studies that have examined the impact of interventions to expedite CDI testing (64, 68, 69). While some studies have focused on reducing delays in laboratory testing, often by switching to molecular or other rapid tests, others have included efforts to reduce delays in specimen collection and delivery to the laboratory. For example, Kundrapu et al. (64) identified a number of modifiable factors that contributed to delays (e.g., delays in communication of the test order to nursing, not providing stool collection supplies to patients in a timely fashion, rejection of specimens due to leaking of containers or incorrect labeling, and laboratory delays due to batch processing of specimens for once-daily GDH testing); an intervention to address several of these factors resulted in a significant decrease in the time required to complete CDI testing. Barbut et al. (69) found that a change from toxigenic culture and CTA to a NAAT or a two-step algorithm including GDH and NAAT resulted in a significant reduction in the time to reporting of test results and earlier initiation of treatment, reduced empiric therapy in patients without CDI, and a decrease in processing of multiple samples. The authors concluded that reducing delays in testing may improve the quality of patient management.

Reducing Inappropriate Testing and Treatment

As noted previously, a major concern regarding the use of NAATs is suboptimal specificity due to detection of asymptomatic carriers with unformed stool due to other causes (48). A number of studies have demonstrated that changing from EIA testing to NAATs may result in significant increases in the incidence of CDI (55, 70–74). For exam-

TABLE 2 Summary of three recent studies that have examined the impact of interventions to expedite CDI testing

Reference	Change in laboratory testing		Other interventions
	Preintervention	Intervention	
66	Toxigenic culture and external toxin assay	EIA for toxin A	Education of physicians
62	GDH screen with PCR confirmatory test	PCR CDI testing made priority (processing ≤2 h)	Education of nurses, physicians Change to a no-leak stool container CDI test specimens made a priority for transport to the laboratory
67	Toxigenic culture and CTA	Phase 2: PCR Phase 3: GDH followed by PCR	N/A

ple, Fong et al. (70) observed an increase in CDI incidence rates from 4.9 to 10.3 when switching from EIA to PCR. Although such increases may be due in part to detection of CDI cases that were missed by insensitive EIA tests, there is also concern that a significant proportion of the increase may be due to detection of asymptomatic carriers by sensitive NAATs. Dubberke et al. (15) found that 36% of patients tested for CDI did not meet criteria for testing because they did not have clinically significant diarrhea, including many patients who had received laxatives. Similarly, Kundrapu et al. (75) reported that in a VA hospital 22% of patients with CDI based on PCR testing either did not have clinically significant diarrhea or had a clear alternative explanation for diarrhea (e.g., laxatives).

Although there is concern that inappropriate testing may lead to treatment of asymptomatic carriers, there is limited data on effective strategies to address this issue in facilities that use NAATs as stand-alone diagnostic tests. It is likely that ongoing education of physicians and nurses along with monitoring and feedback will be necessary to reduce inappropriate testing (19, 65). Such stewardship approaches have been effective in improving adherence to CDI practice guidelines, including reducing inappropriate testing (65; authors' unpublished data).

Another potential strategy to address inappropriate testing might be to use supplementary tests that measure colonic inflammation. For example, fecal lactoferrin and fecal calprotectin are biomarkers of intestinal inflammation that has been evaluated in infectious diarrhea and inflammatory bowel disease (76, 77). In one study, fecal lactoferrin levels were higher in toxin-positive than in toxin-negative patients with positive GDH and PCR (76). Elevated lactoferrin has also been associated with moderate to severe CDI (77). In another study, fecal calprotectin levels were higher in EIA toxin-positive samples than in EIA toxin-negative but PCR toxin gene-positive patients, and both were higher than C. *difficile*-negative control patients (78). Further studies are needed to determine if measurement of fecal lactoferrin or other inflammatory markers are useful to distinguish asymptomatic carriers who do not benefit from treatment and patients with CDI who would benefit from treatment. Such studies should compare these inflammatory markers with toxin, which has been proven to be useful as a predictor of adverse outcomes (54).

False-Negative Tests Due to Empirical CDI Therapy

One of the guiding principles of infectious disease management is that diagnostic specimens should be collected prior to initiation of antimicrobial therapy whenever feasible. The rationale for this recommendation is that prior antimicrobial therapy may result in false-negative diagnostic test results, particularly cultures (79–81). Clinicians caring for patients with suspected CDI often prescribe empirical CDI therapy prior to collection of stool specimens for diagnostic testing (67). In a recent study, Sunkesula et al. (17) demonstrated that such empirical therapy may result in rapid conversion of CDI test results, including PCR, GDH, and toxigenic culture, to negative (Fig. 3). For PCR, 14%, 35%, and 45% of positive tests converted to negative after 1, 2, and 3 days of treatment, respectively. Increased age and infection with NAP1/027 strains were associated with persistent positive PCR results. For 9 CDI patients who received empirical therapy, 4 (44%) converted to negative PCR results compared to 0 of 23 CDI patients who did not receive empirical CDI treatment.

Based on these data, clinicians managing patients with suspected CDI should be aware that empirical therapy may result in false-negative CDI test results. For patients who are prescribed empirical therapy for suspected CDI with mild to moderate symptoms, it might be reasonable to stipulate that empirical therapy should only begin after a stool specimen for testing has been collected (17). If immediate empirical therapy is indicated for suspected severe CDI, efforts should be made to expedite collection of stool specimens for diagnostic testing.

Diagnostic Testing in Patients with Suspected CDI and Ileus

A small proportion of CDI cases present with no diarrhea due to ileus (6). Diagnostic testing in patients with suspected CDI with ileus is challenging because stool specimens are not available for testing. In these cases, computed tomography scans may be useful if they show findings consistent with CDI and if other intra-abdominal conditions that present similarly are ruled out. In severe CDI cases, computed tomography findings may include colonic mural thickening diffusely throughout the colon or localized, pericolonic fat changes, trapping of contrast material between thickened folds (accordion sign), and ascites (82). Sigmoidoscopy or colonoscopy may also be useful in these cases to evaluate for the presence of pseudomembranous colitis (6). Finally, perirectal swab specimens could potentially be useful as a diagnostic approach in patients with suspected CDI and ileus. In a study of 139 patients tested for CDI by PCR (Xpert C. *difficile*), the sensitivity, specificity, positive predictive value, and

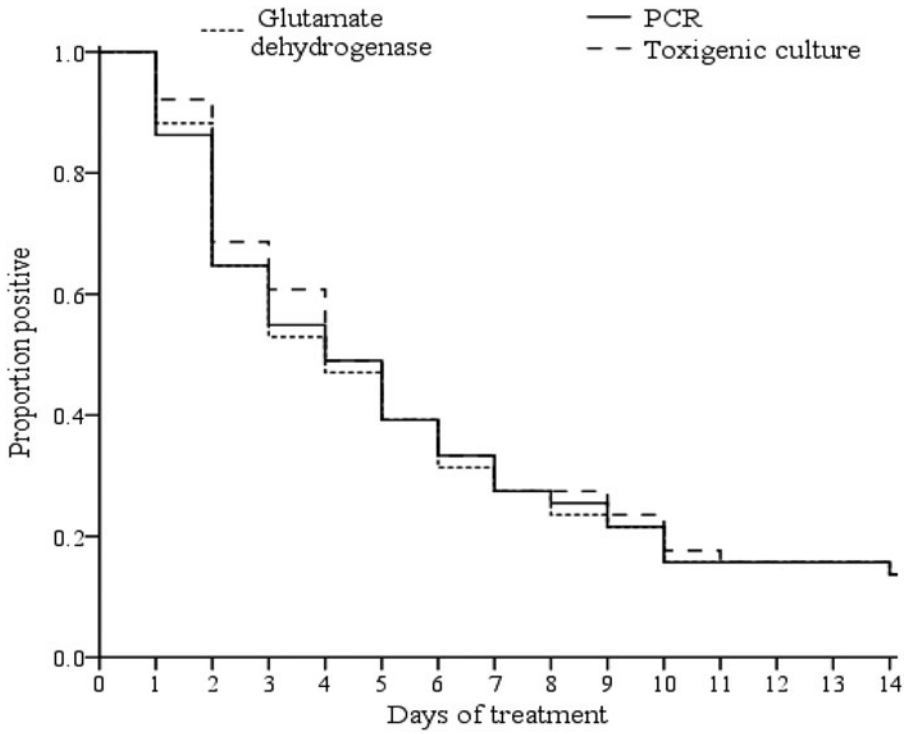

FIGURE 3 Kaplan-Meier curves showing time to conversion of CDI test results from positive to negative during CDI therapy, by test type (toxigenic culture, PCR for toxin B genes, and GDH). Reprinted from reference 17.

negative predictive value of testing perirectal swabs versus stool specimens were 96%, 100%, 100%, and 99%, respectively (83). However, because the study did not include patients with ileus, further studies are needed to confirm that perirectal swab PCR tests are useful in this setting.

Screening for Asymptomatic Carriage of *C. difficile*

Although it is known that asymptomatic carriage of toxigenic C. *difficile* is common in health care facilities, current infection control measures focus on preventing transmis-

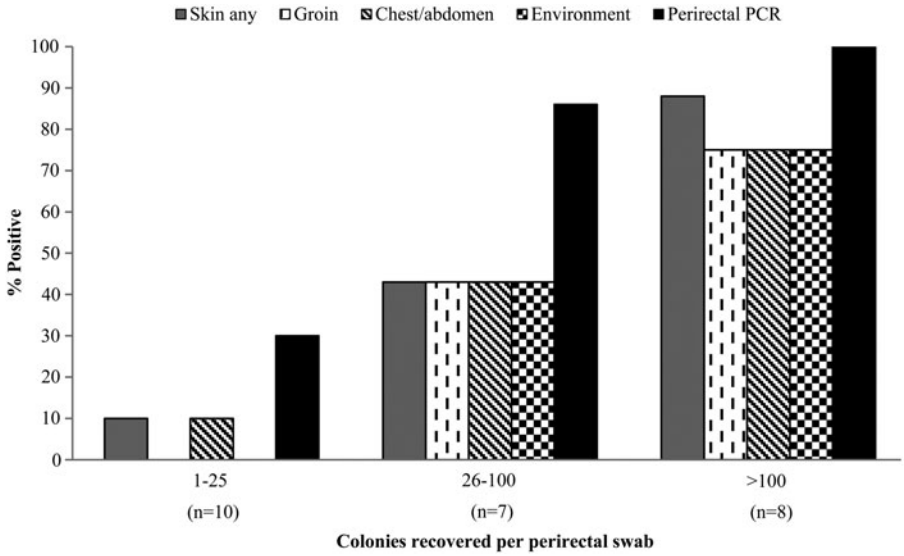

FIGURE 4 Percentage of positive perirectal PCR results and skin and environment cultures for long-term care facility residents with asymptomatic carriage of C. *difficile* based on positive perirectal cultures, stratified by the number of C. *difficile* colonies recovered per swab. Skin sites cultured included the groin and combined chest and abdomen. Environmental sites cultured included the bed rail and bedside table. Twenty-five sets of specimens were collected from 21 asymptomatic carriers. Reprinted from reference 88.

sion from CDI cases (5, 6). It is not recommended that screening cultures be used to identify asymptomatic carriers, and treatment of carriers is not recommended (5, 6). However, there is evidence that asymptomatic carriers could be an underappreciated source of transmission. For example, Clabots et al. (84) found that 84% of nosocomial acquisitions of *C. difficile* on a medical ward were linked to newly admitted asymptomatic carriers based upon restriction enzyme analysis typing. More recently, Curry et al. (85) demonstrated by using multilocus variable number of tandem repeats analysis genotyping that incident CDI cases in a tertiary care hospital were as frequently linked to asymptomatic carriers as to CDI cases (29% versus 30%, respectively). In contrast, in a small study from Oxfordshire, England, none of 13 asymptomatic carriers of toxigenic *C. difficile* were linked to subsequent transmissions to CDI cases diagnosed within 3 months, suggesting that transmission events from individual carriers may be relatively infrequent (86). Although no studies to date have demonstrated that screening for and isolating carriers reduce transmission, a recent mathematical modeling study suggested that screening for asymptomatic carriage on admission could reduce new colonization and hospital-onset CDI cases (87).

If screening for asymptomatic carriers is to be considered as a control measure in the future, there will be a need for simple and effective methods to rapidly identify carriers. Because culture for *C. difficile* is not routinely available and may require days for processing, molecular methods may be preferred. In a recent study, a commercial PCR assay (Xpert *C. difficile*) of perirectal swab specimens detected 17 of 25 (68%) asymptomatic carries of toxigenic *C. difficile*, including 93% with skin and/or environmental contamination (88). Notably, the number of colonies recovered from perirectal swabs varied widely, and a low burden of colonization was associated with a low risk of skin or environmental shedding and a low likelihood of having a positive perirectal PCR result (Fig. 4). These findings suggest that a commercial PCR assay of perirectal swab specimens could provide a sensitive and rapid means to identify asymptomatic carriers of *C. difficile* at high risk for shedding of spores. The study was conducted in a long-term care setting, and therefore additional studies are needed in hospitals.

CONCLUSION

Efficient and accurate diagnostic testing strategies for CDI are essential to guide management and prevent transmission. EIAs for toxins A and B are no longer recommended as stand-alone tests for CDI due to their suboptimal sensitivity and specificity. NAATs have been an important advance due to their sensitivity and efficiency. However, these tests lack specificity in settings where inappropriate testing results in detection of asymptomatic carriers. Use of two-test algorithms, in which a NAAT or GDH test is used as an initial sensitive screen, followed by a relatively sensitive EIA for toxins A and B for cases in which the screening test is positive, has been proposed as a strategy to improve specificity. However, some asymptomatic carriers of *C. difficile*, including those recently treated for CDI, often have positive stool assays for toxin, suggesting that toxin assays may also have suboptimal specificity. Thus, it remains important for clinicians to be aware of the performance characteristics of CDI tests used in their facility and of the need to consider clinical presentation in the diagnosis of CDI.

Efforts to improve CDI testing must address clinical factors that contribute to suboptimal testing. Delays in diagnosis are often due to delays in collection or transport of specimens to the laboratory. Inappropriate testing often occurs due to lack of knowledge on the part of clinical staff. Recent studies have demonstrated that multifaceted interventions focusing on nurses and physicians in addition to the laboratory may result in significant improvements in the timeliness and appropriateness of testing and increased adherence to management guidelines.

Overview of Molecular Diagnostics in Multiple-Drug-Resistant Organism Prevention: Focus on Multiple-Drug-Resistant Gram-Negative Bacterial Organisms

KAEDE V. SULLIVAN AND DANIEL J. DIEKEMA

17

The combination of increasing rates of antibiotic resistance and the decreasing pace of new antibiotic development has become an urgent public health crisis (1). Multiple-drug-resistant bacterial organisms (MDROs) have now become common causes of health care-associated infection (HAI), the most prevalent being methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and a variety of multiple-drug-resistant Gram-negative rods (MDR-GNRs; organisms that are resistant to most, if not all, available antibiotic classes through myriad mechanisms, including production of β-lactamases with increasingly broad activity) (2–4).

Given the limited treatment options, prevention of MDRO infections is paramount. MDRO prevention approaches can be broadly categorized into (i) measures to improve antimicrobial use, (ii) measures to prevent transmission of MDROs, and (iii) measures to prevent infection among patients who are asymptomatic carriers of an MDRO. For example, all hospitals should have antimicrobial stewardship programs that are designed to control the emergence of multiple-drug resistance (5). Once an individual is colonized or infected with an MDRO, the Centers for Disease Control and Prevention (CDC) recommends the use of contact precautions to prevent spread in the health care setting (6). Some hospitals also practice focused decolonization of MDRO carriers in an effort to prevent subsequent infection (7). Given that routine clinical cultures identify only a minority of those who carry an MDRO (8, 9), the use of active screening for MDRO carriage is also common. Current CDC guidance recognizes active MDRO surveillance as an important "tier 2" measure, to be applied during outbreaks or when rates of a targeted MDRO are not decreasing (6).

Some of the major obstacles to both antimicrobial stewardship and active MDRO surveillance have been (i) long turnaround time (TAT), (ii) poor sensitivity of culture-based diagnostics, and (iii) poor specificity of phenotypic confirmatory testing. For example, culture-based assays for MDRO detection can take between 24 and 72 h to complete, during which infection prevention interventions such as initiation of isolation precautions will be delayed unless they are applied to all screened patients while awaiting results. Thus, rapid molecular detection of MDRO carriage has long been considered an "unmet clinical need" (10). This chapter will review advancements in the area of molecular testing for MDRO prevention with a focus on molecular approaches to MDRO surveillance. We will cover MDR-GNRs in the most detail, given that other chapters in this volume provide detailed information about MRSA (chapter 15, this volume) and VRE (chapter 18). Rapid molecular diagnostics that support expedited antimicrobial management of infected patients are discussed in other chapters (chapter 26). Limitations will also be discussed.

MDRO SURVEILLANCE AND PREVENTION: A COLLABORATIVE EFFORT

The incorporation of microbiological surveillance into MDRO prevention efforts is a complex endeavor and requires laboratories to collaborate closely with hospital infection prevention programs and patient care unit personnel (i.e., nurses, physicians, allied health, housekeeping, etc.) to ensure that interventions linked to MDRO surveillance results are implemented safely and efficiently. The steps required to improve the likelihood of success of active MDRO surveillance programs are beyond the scope of this chapter, but key elements include optimizing the TAT from specimen receipt in the laboratory to notification of results; monitoring and optimizing the initiation of infection prevention interventions (i.e., implementation of isolation precautions, decolonization); monitoring and preventing unintended adverse consequences of the interventions (e.g., reduction of clinician bedside visits or increased incidence of adverse events in patients on isolation precautions); and measurement of meaningful outcomes to evaluate the effectiveness of the MDRO surveillance program (11).

One important concept when assessing the impact of molecular diagnostics on MDRO transmission is the gap between analytic versus actual TAT. A major advantage of molecular MDRO detection is, of course, speed. However, too often we focus only on the analytic TAT of a test from

Kaede V. Sullivan, University of Pennsylvania School of Medicine, Philadelphia, PA 19104. **Daniel J. Diekema,** University of Iowa Carver College of Medicine, Iowa City, IA 52242.

the laboratory perspective. The meaningful TAT measure is the time from when a test is ordered to when the result is translated into action (e.g., institution or removal of contact precautions, decolonization). For an MDRO detection test to be truly considered rapid, it should provide at least same-day TAT. A rapid test with an analytic TAT of 2 h that is batched and performed once daily represents little improvement in TAT over culture-based methods. Similarly, some molecular tests require an isolated bacterial colony to perform and thus are not truly rapid, given that 24 h or more may be required to grow the organism. Thus, the most useful rapid molecular tests are those that can be performed directly on patient samples (or on enrichment broth cultures after an abbreviated period of incubation). Ultimately, if the improved analytic TAT of molecular MDRO detection tests is to provide any benefit, there must be a robust postanalytic system in place to ensure that results are translated into action. In other words, unless the performance characteristics of a given test are significantly superior, there is no reason to convert to a test with shorter analytic TAT if the actual TAT of the test will not be meaningfully reduced.

MRSA

MRSA is the most prevalent MDRO in hospitals in most countries and is currently the most common cause of HAI involving an MRDO in U.S. hospitals, accounting for 8.5% of device-associated HAIs reported to the National Healthcare Safety Network (NHSN) (12). First recognized in 1961, shortly after the introduction of methicillin for clinical use (13), MRSA has spread rapidly in hospitals and community settings worldwide in the decades since, with a few successful clones accounting for much of the spread (14). Because it is so common, MRSA is the MDRO with which we have the most experience with respect to detection of asymptomatic carriage ("active surveillance").

Methicillin resistance in *S. aureus* is mediated by an altered penicillin-binding protein (PBP2a), one that has poor affinity for β-lactam antibiotics. The PBP2a protein is encoded by the *mecA* gene, which is carried on the staphylococcal cassette chromosome *mec* (SCC*mec*) element, which integrates into the *S. aureus orfX* gene. A homologue, designated *mecC*, was first reported in livestock in 2011 but has now been recovered from humans and is only 69% identical to *mecA* at the DNA level (15).

Chapter 15 in this volume reviews a variety of MRSA detection strategies, but the most common phenotypic approach involves recovery of MRSA from a screening swab on a commercially available chromogenic agar medium (16). While these media perform well for detection of MRSA carriage, optimal sensitivity requires incubation in enrichment broth, which increases TAT time by up to 18 h (17). In addition, sampling of multiple body sites beyond the nares (e.g., throat, rectum, and others) is required to achieve optimal sensitivity (17–19). These factors should be considered when evaluating studies that compare the performance of culture-based screening methods against molecular MRSA detection assays.

As detailed in chapter 15, there has been widespread adoption of FDA-approved molecular platforms for the detection of MRSA directly from patient samples. These include the Xpert MRSA (Cepheid, Sunnyvale, CA), the BD GeneOhm MRSA ACP (BD Diagnostics, La Jolla, CA), and the LightCycler MRSA Advanced (Roche Molecular Diagnostics, Pleasanton, CA). Interestingly, despite the fact that a single gene (*mecA*) confers methicillin resistance in *S. aureus*, the development of molecular assays that detect MRSA directly from patient specimens has been challenging. First, the *mecA* gene found in *S. aureus* is highly homologous to that carried by coagulase-negative staphylococci (CoNS), and most CoNS are methicillin resistant (14, 20). Thus, the major obstacle encountered in early assays utilizing *mecA* primers was the false-positive test resulting from detection of methicillin-resistant coagulase-negative staphylococcus (MR-CoNS) in mixed samples. To overcome this limitation, widely used commercial assays amplify and detect a region at the SCC*mec-orfX* junction that does not actually contain the *mecA* gene (21). These assays demonstrated satisfactory performance characteristics (sensitivity, specificity, and agreement with culture of >90%), although some strains of methicillin-susceptible *S. aureus* (MSSA) were observed to contain this target while having "lost" the *mecA* gene through excision or mutation (the so-called *mecA* dropouts or empty cassette variants) (22). Although initially believed to be rare, these strains were soon recognized to be common causes of false-positive tests. Inclusion of *mecA* primers in these assays has largely addressed the problem, although false positives that result from simultaneous detection of an empty cassette variant of MSSA and MR-CoNS are still possible (23). Data from the MOSAR WP2 Study Team also suggest that certain MR-CoNS alone may test false positive due to homogeneity of the SCC*mec-orfX* region (24). These false-positivity issues can result in low positive predictive values (PPV) in low-prevalence populations (25, 26). For example, in a cohort of 1,891 patients (3% of whom had MRSA in culture) who were screened using the Xpert MRSA assay and broth-enriched culture, Roisin and colleagues reported a PPV of only 38% for the Xpert MRSA assay. Fifteen patients grew MSSA in culture that tested positive by the Xpert assay on isolated colonies. In addition to empty cassette variants, some had sequence homology with the SCC*mec-orfX* junction sequences targeted by the assay (27). False-positive MRSA surveillance tests may result in unnecessary initiation of isolation precautions and/or decolonization procedures, which are not without risk.

Falsely positive tests are not the only issue for current molecular MRSA assays. As widely reported, strains of MRSA with novel SCC*mec* elements and *mecA* genes can result in falsely negative tests (28, 29). The International Working Group on the Classification of Staphylococcal Cassette Chromosomal Elements recently published a guideline for reporting novel *mecA* gene homologues (30). The prevalence and range of such strains are not well understood, but ongoing surveillance and cataloguing of different *mecA* types will be necessary for molecular detection assays to keep pace with the genetic evolution of MRSA. In addition, while *mecC*-expressing strains of MRSA remain uncommon in humans, their emergence has necessitated the re-evaluation of existing assays that rely on detection of *mecA* and the development of *mecC*-specific primers to ensure that *mecA* variants are detected (31, 32).

These issues highlight the importance of retaining culture-based screening methods in parallel with molecular platforms, to monitor for emerging strains that may present problems for existing assays. In addition, bacterial isolates derived from culture-based screening can be used for molecular typing and antimicrobial susceptibility testing (which may include testing against agents used for topical decolonization, such as mupirocin and chlorhexidine [33]).

Finally, specimens from body sites that fall outside of FDA-approved indications can be tested using culture, which is important for optimizing sensitivity of MRSA screening (17–19). Thus, depending on work flow, the molecular test may be used to reduce TAT but cannot replace culture altogether.

VRE

The rapid spread of MRSA in many hospitals in the 1980s led to a significant increase in the use of vancomycin, which no doubt favored the eventual acquisition and spread of vancomycin resistance among the enterococci. VRE is second only to MRSA as a multiple-drug-resistant cause of HAI and is responsible for 3% of HAIs reported to NHSN during 2009–2010 (12). Not surprisingly, it is also the next most common target of tests developed for detection of MDRO carriage. Vancomycin resistance in enterococci is mediated by several genes designated *vanA*, *vanB*, *vanC*, *vanD*, etc., which act by modifying or removing the vancomycin-binding target D-Ala-D-Ala in the cell wall peptiglycan (34). Among these, *vanA* and *vanB* predominate among clinically significant enterococci (*Enterococcus faecium* and *Enterococcus faecalis*) and are the only two that have major epidemiological significance due to the transmissibility of the resistance genes and outbreak potential (34).

Culture-based assays for detection of VRE carriage have traditionally taken 48 to 72 h or longer, but more recently there are chromogenic agar media that perform well (sensitivity and specificity >95%) for the detection of VRE in perirectal swabs or stool with TATs of approximately 24 h (35). Commercial detection assays that utilize real-time PCR to target the important targets (*vanA* and *vanB*) have been developed and can reduce the TAT to 2 to 4 h or less.

One of the challenges related to molecular detection of VRE carriage arises from the fact that the reservoir for VRE is within the rich microbiota of the intestine, a microbial community that is profoundly impacted during hospitalization and by receipt of antimicrobial therapy (36). All *vanA* and/or *vanB* detection assays have lower limits of detection ranging from 10 to 100 CFU/ml (10, 37, 38), so it is possible that VRE may be present at levels below detection upon hospital admission and become detectable after antimicrobial receipt causes expansion of the VRE population (36). This sequence of events could be misinterpreted as VRE acquisition (which could in turn focus infection prevention efforts solely on transmission prevention activities rather than on antimicrobial stewardship). An additional problem with direct detection of VRE from fecal flora is that intestinal anaerobes may also carry the *vanB* resistance determinant (37). Because *vanB* is also less prevalent among VRE than is *vanA*, published evaluations of the performance of rapid *vanB* detection assays reveal positive predictive values as low as 1 to 10% (38–40). Rapid molecular VRE screening tests are therefore useful mainly for detection of *vanA*-bearing enterococci. Indeed, the only FDA-approved commercial assay available in the United States at present, the Xpert *vanA* (Cepheid, Sunnyvale, CA), targets *vanA*.

In contrast to active surveillance for MRSA carriage (which is now mandated in some states), little enthusiasm has developed for routine screening for the VRE carrier state. There are two main reasons for this. First, VRE are much less common as invasive pathogens than MRSA and tend to impact a smaller subset of (usually highly immunocompromised) patients (3). Second, there are no effective decolonization options for VRE carriers, as there are for MRSA carriers.

MDR-GNRS

Compared to MRSA and VRE, for which a single gene (*mecA*, *vanA*) provides a "gold standard" for MDRO detection, MDR-GNRs present a much greater challenge. A variety of resistance mechanisms can contribute to antimicrobial resistance. These include drug destruction through hydrolysis, efflux of drugs from the periplasmic space, reduction in penetration of drugs through the bacterial cell membrane, and alteration of the drug target resulting in reduced drug binding. However, the MDR-GNRs that have the greatest potential for spread are those that harbor plasmid-mediated β-lactamases. Those that are capable of hydrolyzing extended-spectrum cephalosporins and carbapenems are of highest concern.

The first report of a plasmid-mediated β-lactamase in *Enterobacteriaceae* was published in 1965. Datta et al. described the isolation of an enzyme that hydrolyzed penicillin from an isolate of *Escherichia coli* from Greece that was named TEM-1 (41). Subsequently, in 1972, Pitton described a "sulfhydral variant" β-lactamase (SHV-1) in *Klebsiella pneumoniae* and *E. coli* (42). Organisms that produce TEM-1, TEM-2 (a single amino acid variant of TEM-1), and SHV-1 hydrolyze ampicillin, carbenicillin, ticarcillin, and cephalothin but remain susceptible to oxyimino-β-lactams (including cefotaxime, ceftazidime, ceftriaxone) and monobactams (e.g., aztreonam). In 1983, Kliebe et al. reported an SHV-1-derived β-lactamase (SHV-2) in a German isolate of *Klebsiella ozonae* with transferable resistance to the oxyimino-β-lactams (43). This was followed by a TEM-2-derived extended-spectrum β-lactamase (ESBL) (TEM-3) in 1988 (44). Since that time, plasmid-mediated ESBLs deriving from SHV-1, TEM-1, and TEM-2 ESBLs have been reported around the world. In each case, 1 to 4 amino acid substitutions in the active site of the original β-lactamase led to improved hydrolysis of oxyimino-β-lactams. Subsequently, in the late 1980s, non-TEM, non-SHV ESBLs were reported in Japan and Germany. The Japanese strain was originally published with the name FEC-1, although DNA sequencing later showed that it was very closely related to CTX-M-3. The German strain was called CTX-M to denote its ability to hydrolyze cefotaxime more efficiently than ceftazidime (45, 46). CTX-M enzymes are currently the predominating ESBL worldwide (47).

There are now over 150 CTX-M enzymes that are classified into groups by amino acid sequence. They include the CTX-M-1, CTX-M-2, CTX-M-8, CTX-M-9, and CTX-M-25 groups (48; http://www.lahey.org/Studies/). CTX-M, TEM-, and SHV-derived ESBLs are classified as Ambler class A β-lactamases and are members of group 2be in the Bush-Jacoby classification system (49–51). They are inhibited by clavulanate, tazobactam, and sulbactam and do not hydrolyze cephamycins efficiently. Other class A ESBLs include BEL, BES, SFO, TLA, GES, PER, and VEB, but they are thought to be less common and tend to be distributed in a regionalized manner (50, 51). Finally, β-lactamases that hydrolyze oxacillin or cloxacillin at rates >50% of benzylpenicillin distinguish the OXA family of β-lactamases. OXA β-lactamases have their own Ambler class (class D) and Bush-Jacoby groups (2d, 2de, and 2df) (49, 50). OXA-derived ESBLs are mostly derived from

OXA-10 and are weakly inhibited by Ambler class A β-lactamase inhibitors.

AmpC β-lactamases are capable of hydrolyzing penicillins, cephalosporins (including oxyimino-β-lactams), and monobactams. Notably, most AmpC β-lactamases hydrolyze cephamycins and are generally not inhibited by clavulanic acid. AmpC β-lactamases are typically inhibited by cloxacillin, oxacillin, aztreonam, and boronic acid (52). While chromosomally mediated AmpC is typically absent in many *Enterobacteriaceae* including *K. pneumoniae*, *Klebsiella oxytoca*, *Proteus mirabilis*, and *Salmonella* spp., plasmid-mediated AmpC β-lactamase production has been documented in all of these organisms (53, 54). The reverse is also true: *Enterobacter cloacae* and *Enterobacter aerogenes* and other *Enterobacteriaceae* that harbor AmpC in their genome have been reported to carry ESBL determinants (55, 56).

Until recently, carbapenems were active against most clinically encountered MDR-GNRs. In 2001, Yigit et al. reported a strain of *K. pneumoniae* from North Carolina with MICs of 16 μg/ml for imipenem and meropenem. It carried three plasmid-encoded β-lactamases: SHV-29, TEM-1, and a novel β-lactamase that was named *K. pneumoniae* carbapenemase (KPC-1) (57). Today, 21 KPC variants have been reported, but in 2008, the nucleotide sequence of KPC-1 was determined to be identical to that of KPC-2, and the former was removed from the KPC nomenclature (http://www.lahey.org/Studies/; 58). Outbreaks involving KPC-producing organisms have been reported in the United States, South America, Western Europe, Israel, and China, and these organisms have become endemic in all of these regions (59). KPC-producing organisms typically show high levels of penicillin and cephalosporin resistance and variable carbapenem resistance. Unlike other Ambler class A β-lactamase producers, KPC (like AmpC) is inhibited by boronic acid but is only weakly inhibited by clavulanate, tazobactam, and sulbactam (60). IMI-2 and GES carbapenemases are also class A carbapenemases but are encountered less frequently (59).

Ambler class B carbapenemases (metallo-β-lactamases or MBLs) can be distinguished from class A members by their ability to hydrolyze virtually all therapeutically useful β-lactams, β-lactam inhibitors, and carbapenems. MBLs do not hydrolyze monobactams, but plasmids carrying MBL determinants frequently encode ESBL determinants that lead to their hydrolysis. MBLs are inhibited by EDTA, which is a chelator of zinc, a key player in β-lactam hydrolysis in MBL. In 2009, Yong et al. reported novel MBL-producing *K. pneumoniae* and *E. coli* isolates from a patient who was hospitalized in New Delhi, India (61). This strain was named the New Delhi MBL (NDM), and it is the most recently identified MBL. Plasmids carrying the bla_{NDM} gene often bear multiple resistance determinants, creating significant therapeutic challenges. The majority of early NDM cases had epidemiological links to the Indian subcontinent, but intra-hospital outbreaks have now been reported in the United States and other countries (62, 63). The VIM (Verona integron-encoded MBL) family of MBL was first documented in *Pseudomonas aeruginosa* in Verona, Italy, in 1997, but acquired cases have been documented in various *Enterobacteriaceae* and non-glucose-fermenting organisms (64, 65). Plasmid-borne IMP-1 was also first reported in *P. aeruginosa* in Japan in 1988 (66) and later in *Enterobacteriaceae* (67). IMP carbapenemases are now particularly endemic in Taiwan and Japan, and VIM is highly prevalent in the Mediterranean countries, but strains harboring bla_{IMP} and bla_{VIM} have now been reported throughout the world (59).

OXA-48 and its relatives, by one- to five-point mutations (OXA-162, OXA-163, OXA-181, OXA-204, OXA-232), weakly hydrolyze carbapanems and third-generation cephalosporins. There are no known inhibitors for class D carbapenemases. OXA-48 originated in Turkey and was first reported in 2003 (68) but has now spread to Mediterranean Europe and Africa (69).

CULTURE-BASED SCREENING FOR ESBL- AND CARBAPENEMASE-PRODUCING ORGANISMS

Rectal swab culture using selective agar is the most practical approach for screening patients for asymptomatic carriage of MDROs. Stool, urine, wound, and sputum and other upper respiratory tract specimens have also been included in various evaluations (70). For ESBL screening with rectal swabs, there are data supporting the practice of incubating swabs in enrichment broth prior to inoculation of media (71). Recent advances in ESBL-screening media formulations have led to enhanced sensitivity for the detection of ESBL producers. The ChromID ESBL (bioMérieux, Marcy l'Etoile, France) and Brilliance Oxoid (Oxoid Ltd, Basingstoke, United Kingdom) contain cefpodoxime to select for both CTX-M and other class A ESBLs. The antibiotics present in the CHROMagar ESBL (CHROMagar, Paris, France) are not disclosed. These products also contain chromogenic substances that identify organisms, some to the species level. Grohs et al. published a side-by-side evaluation of ChromID ESBL, Brilliance Oxoid, CHROMagar ESBL, BD Drigalski agar (similar to MacConkey but containing ceftazidime), and an in-house medium containing Drigalski agar and cefotaxime to detect CTX-M-producing organisms. A total of 2,337 rectal e-Swabs (Copan Diagnostics Inc., Murrietta, CA) were collected from 267 patients, inoculated directly to agar plates using the Copan Wasp system, and incubated for 18 h (72). ESBL detection on any of the media was considered the gold standard definition of "ESBL-positive." All five types of media had comparable sensitivity of >95%. Specificity was 72.3%, 72.9%, 57.9%, 63.9%, and 59.2% for the five types of media, respectively. False positives were mainly related to the recovery of organisms producing AmpC β-lactamase and underscored the need to confirm ESBL production status in the organisms recovered from these media.

For carbapenemase detection, the CDC has published a procedure that involves overnight incubation of rectal swabs in 5 ml of trypticase soy broth with the addition of a 10-μg disk of meropenem or ertapenem. Broth is then subcultured to MacConkey agar, and any resulting lactose-fermenting colonies are selected for confirmatory testing (73). Commercially available screening media include the CHROMagar KPC (CHROMagar), ChromID Carba (bioMérieux), Brilliance CRE (Oxoid), and the Remel Spectra CRE (Remel, Lenexa, KS). The Colorex KPC (CHROMagar) is a ready-to-use version of the CHROMagar KPC. Unfortunately, culture-based screening for carbapenemase-producing organisms can be challenging due to variations in carbapenem hydrolysis. Carbapenemase-producing isolates with imipenem and/or meropenem MICs of ≤1 μg/ml are well documented and may fail to be recovered on screening media (74).

Wilkinson et al. used 130 previously characterized carbapenemase-producing isolates and examined the analytical sensitivity and specificity of Colorex KPC (CHROMagar), ChromID Carba (bioMérieux), ChromID ESBL (bioMérieux), Brilliance CRE (Oxoid), and the CDC screening protocol. The Colorex KPC, Brilliance CRE agars, and CDC protocol repeatedly failed to detect KPC, NDM, VIM, IMP, and OXA-48 carbapenemase producers at 18 h of incubation at low inocula (100 CFU/spot) (75). Detecting 125/130 of the carbapenemase producers tested, ChromID ESBL had the highest sensitivity at 96% at low inocula, but predictably, it had a specificity of only 6% due to the recovery of non-carbapenemase producers. ChromID Carba followed with sensitivity and specificity of 91% and 89%, respectively. As a group, the screening media recovered organisms in only 9%, 46%, and 78% of plates inoculated with low inocula of OXA-48, IMP, and NDM-1, respectively. This study suggested that ESBL media may be useful for screening patients with carbapenemase-producing organisms but would come at the cost of low specificity. Also, media designed to detect carbapenemase producers may have difficulty detecting isolates with low carbapenem MICs. False positives involving the growth of AmpC producers and *P. aeruginosa* were observed in both types of media. Because OXA-48 is particularly difficult to recover reliably from selective media due to weak hydrolysis of both cephalosporins and carbapenems, Nordmann et al. proposed a novel agar called SUPERCARBA with a Drigalski agar medium base, ertapenem (0.25 g/ml), zinc (to enhance expression of MBLs), and cloxacillin to inhibit ampC cephalosporinase. This medium was reported to detect OXA-48 consistently with inocula in the 10^1 to 10^2 range (76).

PHENOTYPIC CONFIRMATION OF ESBL AND CARBAPENEMASE PRODUCTION

Previously, CLSI and EUCAST recommended a two-step procedure for identification of ESBLs. It involved, first, selection of isolates that are likely to be ESBL producers based on oxyimino-β-lactam MICs, followed by inhibitor-based phenotypic confirmation. Selection of isolates required assessments of disk diffusion or MICs using broth microdilution (or agar dilution for EUCAST) with indicator oxyimino-β-lactams (typically cefotaxime and ceftazidime). Recommended phenotypic ESBL confirmatory methods harnessed the ability of clavulanic acid to bind irreversibly to the serine residue in the active site of an ESBL, disabling the enzyme's ability to bind and hydrolyze β-lactam substrates. Antibiotic susceptibility testing of an ESBL isolate with an oxyimino-β-lactam (typically cefotaxime and ceftazidime) alone and in the presence of clavulanic acid should therefore produce a decrease in the MIC or an increase in the diameter of the zone of inhibition in an ESBL-producing organism. If pursuing phenotypic confirmation of ESBL production, both CLSI and EUCAST recommend the use of broth microdilution and disk diffusion techniques. EUCAST also supports gradient testing (i.e., E-test) and the "double disk synergy" procedure (77, 78).

Unfortunately, the "screen and confirm" approach to ESBL identification and confirmation had some challenges. First, *Enterobacteriaceae* that harbor both ESBL and AmpC determinants have a propensity toward lower MICs for the oxyimino-β-lactams that may not meet ESBL "screening" criteria (79). Second, because AmpC is not inhibited by clavulanic acid, these isolates may lead to false-negative confirmatory ESBL test results. The addition of cefepime (which is stable against AmpC hydrolysis) to cefotaxime and ceftazidime in confirmatory testing can help to overcome this problem because it is stable in the presence of AmpC. Alternatively, agar plates used for disk diffusion and double disk synergy testing can be supplemented with cloxacillin to suppress AmpC β-lactamase activity. Finally, commercially available disks or tabs with ceftazidime and cefotaxime with both clavulanic acid and cloxacillin, such as those included in the Total ESBL + AmpC Confirm Kit (Rosco Diagnostica, Taastrup, Denmark), can be useful (77, 78). The AmpC + ESBL Detection Set (MAST Group, Merseyside, United Kingdom) uses a similar format, but the ESBL and AmpC inhibitors are not disclosed. Finally, false-positive ESBL confirmatory tests are well documented. KPC can be inhibited variably by clavulanic acid and may result in a false-positive result. *K. oxytoca* that harbors chromosomally mediated K1 β-lactamase may also lead to positive results, although this phenomenon can be easily recognized by the enhanced hydrolysis of cefotaxime over ceftazidime.

In 2010, CLSI therefore lowered cefotaxime, ceftriaxone, and ceftazidime MIC interpretive breakpoints, recommended that cephalosporin MIC interpretations be reported "as found," and ceased to recommend routine ESBL screening and confirmatory procedures if the revised breakpoints were implemented (80). EUCAST made similar adjustments in 2011 (81). The rationale presented included emergence of ESBLs with MICs in the susceptible range (79), PK/PD data suggesting that the optimal time above MIC of 40 to 50% of the dosage interval can be more reliably achieved with lowered interpretive breakpoints (82), animal model data suggesting superior correlation between MIC and outcome compared to resistance mechanisms (83), reduction of reporting delay while awaiting ESBL confirmatory testing results, and simplification of laboratory testing (80).

Automated antimicrobial susceptibility testing systems have also been evaluated for their ability to identify ESBLs. Studies using molecular testing to determine reference standard ESBL status with $bla_{\text{CTX-M}}$, bla_{TEM}, and bla_{SHV} PCR assays have provided mixed results. The BD Phoenix ESBL test (BD Diagnostics, Sparks, MD) appears to perform with sensitivity and specificity >95%, but in a study involving the testing of 1,129 *Enterobacteriaceae* isolates, Spanu et al. reported false negatives in six SHV-2- or SHV-5-producing isolates. Two false positives were also noted in isolates with *K. pneumoniae* and *E. coli* hyperproducing SHV-1 (84). Similarly, false-negative results have been reported in both the Vitek 2 and MicroScan Walkaway systems, with TEM-, SHV-, and CTX-M ESBL producing isolates, while AmpC β-lactamase production has been associated with false positives (84–86).

Identification and phenotypic confirmation of carbapenemase production are also challenged by highly variable inhibition by β-lactamase inhibitors and widely ranging carbapenem MICs. The latter is a problem particularly in NDM, VIM, and OXA-48 isolates (74). Like ESBL reporting, both CLSI and EUCAST recommend reporting carbapenem MIC interpretations as found using interpretive breakpoints that have been successively lowered since 2010 (80, 81).

EUCAST supports the use of inhibitor-based disk diffusion methodology to detect carbapenemase production: a meropenem disk (10 μg) with and without an EDTA or

dipicolinic acid disk, phenylboronic acid or aminophenylboronic acid disk (which inhibits KPC), a disk with both dipicolinic acid and aminophenylboronic acid (to inhibit both MBL and KPC when they are both expressed), and cloxacillin (to inhibit AmpC β-lactamases, which are also inhibited by boronic acid derivatives) (78). There are no known inhibitors for OXA-48. The KPC+MBL Confirm Kit (Rosco Diagnostica) is a commercially available kit that provides all of the above components. The Carbapenemase Detection Set (D70C; MAST Group) is also available in a similar format, but as with other MAST Group products, the identity of the KPC, MBL, and AmpC inhibitors is not disclosed. In two evaluations, the inhibitor approach confirmed KPC and NDM production nearly 100% of the time in previously characterized isolates (87, 88) but did not detect OXA-48 well. In one study, both the Rosco and MAST Group kits had difficulty detecting VIM and IMP production also (88).

The Carba NP is an alternative phenotypic method of demonstrating carbapenemase production that was originally described using a microwell format. Bacterial lysate is added to a solution containing phenol red, zinc, and imipenem monohydrate. Hydrolysis of imipenem leads to an acidic pH change, which produces a color change from red to yellow. This assay was originally reported to perform sensitivity and specificity of 100% (89–91). Tijet et al. performed the CarbaNP on 74 previously characterized carbapenemase producers and reported 29 false negatives. With a heavier inoculum than the originally recommended 10-μl loopful, 15 additional OXA-48 isolates that initially tested negative tested positive. In their analysis, the authors therefore recommended use of a heavier bacterial inoculum (92). Finally, the modified cloverleaf (Hodge) test, which was previously recommended by CLSI, has satisfactory sensitivity for the detection of KPC production but may test false negative in MBLs and OXA-48 isolates (87, 88). Also, false-positive tests are common in isolates producing AmpC β-lactamase with concurrent impermeability related to porin mutations (87). CLSI no longer recommends it for routine testing.

MOLECULAR DETECTION METHODS FOR MDR-GNR SURVEILLANCE

Laboratory-Developed Tests

PCR-based detection of TEM- and SHV-based ESBLs can be challenging because they resulted from single-point mutations of TEM-1, TEM-2, or SHV-1 β-lactamases. A practical approach for distinguishing ESBL and non-ESBL TEM- and SHV-β-lactamases is to perform DNA PCR using universal bla_{TEM} and bla_{SHV} oligonucleotide primers followed by Sanger sequencing of the amplicons. Various primer sets have been published for universal bla_{TEM} and bla_{SHV} detection using simplex or multiplex, conventional or real-time PCR approaches (93–95). The CTX-M family of ESBLs can be accurately detected using a single universal bla_{CTX-M} PCR reaction (96–101). Differentiation between the CTX-M groups (1, 2, 8, 9, and 25) has been described using conventional (99) and real-time PCR (101) approaches.

The emergence of KPC-producing and NDM-producing organisms has provided a powerful impetus for the development of molecular assays that detect bla_{KPC}, bla_{NDM}, bla_{VIM} bla_{IMP}, bla_{OXA-48}, and other carbapenemase determinants. Real-time PCR assays that detect bla_{KPC} have been described as stand-alone tests, but determination of KPC gene variants (KPC 2 to 11) has been achieved using restriction enzyme digestion of a bla_{KPC} PCR reaction product or multiplex PCR (102, 103). Similarly, real-time simplex PCR assays have been described for detection of bla_{NDM} (104, 105). Various duplex PCR assays that detect bla_{KPC} bla_{NDM} have also been described, but worldwide dissemination of various carbapenemase determinants has precipitated the development of more extensive multiplex PCR assays in both conventional and real-time formats (106–111). Finally, direct detection of carbapenemase determinants from seeded stool samples (112, 113); perianal, perirectal, and rectal swabs (114–116); and nasal swabs (117) has been described. Vasoo et al. used a duplex PCR to detect bla_{KPC} and bla_{NDM} on surveillance perianal/perirectal swabs and compared detection when used directly from the swab or following incubation in enrichment broth. They reported no difference in detection (116).

Commercial Molecular Assays for ESBL and Carbapenemase Determinants

Hyplex ID Systems

The Hyplex ESBL ID and SuperBug ID products (Amplex Biosystems GmbH, Gars, Germany) use multiplex real-time PCR followed by amplicon detection through hybridization with reverse probes that are immobilized on ELISA-microwell plates. Hybridization complexes are then detected visually using peroxidase-conjugated antibodies. Testing requires 4.5 to 6 h. The Hyplex ESBL ID detects bla_{TEM}, bla_{SHV}, bla_{CTX-M}, and bla_{OXA}; SuperBug ID detects bla_{KPC}, bla_{NDM}, bla_{VIM}, bla_{IMP}, and bla_{OXA-48}. Ambretti et al. tested 130 previously characterized clinical isolates. SuperBug detected 70/70 isolates with bla_{KPC}, bla_{NDM}, and bla_{VIM} (no isolates with bla_{IMP} or bla_{OXA-48} were tested). Two isolates harboring ESBLs tested false positive for bla_{KPC} but had "borderline" optical density values that were close to the 0.4 cutoff (118). Kaase et al. also reported an *E. coli* isolate with bla_{GES} that tested borderline for bla_{OXA-48}. Also, 3/3 isolates with bla_{IMP} tested falsely negative by SuperBug ID (119). Finally, in a study based in Greece, Avlami et al. used the Hyperplex MBL ID (which was later expanded and replaced by the SuperBug assay) to perform direct testing on blood ($n = 90$), urine ($n = 60$), respiratory specimens ($n = 85$), and wound swabs/pus ($n = 91$). Hyperplex MBL ID detected bla_{VIM} in 72/73 cultures that grew bla_{VIM} but detected an additional 5 that did not grow in culture (120). The authors felt that isolate selection for inclusion in the study could have accounted for these results.

Cepheid Xpert MDRO

The Xpert MDRO assay (Cepheid) is performed on the GeneXpert instrument, an automated system that performs DNA extraction, real-time PCR, and detection. The Xpert MDRO assay detects bla_{KPC}, bla_{NDM}, and bla_{VIM} and requires 47 minutes to complete after buffered specimen is added to the cartridge. Tenover et al. tested 328 rectal swabs from Spain and New York (121). Ten tested positive for bla_{VIM}, and nine of these grew bla_{VIM} isolates in culture. The tenth was deemed a false-positive result. Forty-three specimens tested positive for bla_{KPC}; 40 grew in culture and 2 tested positive for bla_{KPC} by sequencing of enrichment broth that was inoculated in parallel to standard culture and Xpert testing. The final isolate was negative either on standard culture or from enrichment broth.

Sensitivities of Xpert MDRO for bla_{VIM} and for bla_{KPC} were 100% (95% confidence interval: 72 to 100%) and 100% (93 to 100%), respectively, and specificities were 99% (98 to 100%) and 99% (97 to 100%). Sixty-six simulated rectal swabs were prepared using stool matrix spiked with *K. pneumoniae* harboring bla_{NDM} at concentrations ranging from 150 to 1,800 CFU/ml. Sixty-five of the 66 tested positive for bla_{NDM} by Xpert MDRO. Data is emerging for the Xpert Carba-R assay, which is marketed as a CE IVD product and detects bla_{KPC}, bla_{NDM}, bla_{VIM}, bla_{IMP-1}, and bla_{OXA-48}.

NucliSENS EasyQ KPC

The EasyQ KPC assay (bioMérieux) is performed on the NucliSENS EasyQ instrument, an automated system that performs real-time nucleic acid sequence-based amplification and target detection using molecular beacons. Because DNA extraction is required prior to amplification by the instrument, total testing can require up to 5 h. McEwan et al. used the NucliSENS easyMAG instrument to extract nucleic acid from 806 specimens (619 rectal swabs and 187 stools) followed by nucleic acid sequence-based amplification on the NucliSENS Easy Q instrument (122). Twenty-eight specimens tested positive by both EasyQ KPC and direct culture on ChromID ESBL agar. EasyQ KPC tested negative in two specimens that grew on culture and tested positive for bla_{KPC} using an alternative bla_{KPC} PCR assay, but one tested positive upon repeat. Nine specimens tested positive by EasyQ KPC but negative by culture. These were not resolved using alternative molecular methods. Spanu et al. tested 300 previously characterized isolates, 111 of which were KPC (123). EasyQ KPC detected 100% of KPC-producing isolates and did not test falsely positive in the 222 non-KPC-producing isolates.

Check Direct CPE and Check-MDR Real-Time Assays

Check-MDR ESBL and Check-MDR Carba Real-Time PCR (Check Points BV, Wageningen, The Netherlands) can be performed on a variety of real-time platforms including ABI 7500 (Life Technologies, Grand Island, NY), CFX96 (Bio-rad, Hercules, CA), Lightcycler 480 (Roche Diagnostics, Indianapolis, IN), m200rt (Abbott, Abbott Park, IL), and the SmartCycler II (Cepheid). For DNA target detection, these assays rely on two specific oligonucleotide ligation probes that are joined by a DNA ligase only when they match exactly with the target DNA. This approach is used to enhance specificity. The DNA probes also contain two universal primer binding sites as well as a binding site for the molecular beacon required for target detection. The Check-MDR ESBL detects ESBL CTX-M-1, CTX-M-2, and CTX-M-9 groups and the most common ESBL mutations (TEM-E104K, TEM-R164S, and SHV-G238S). Check-MDR Carba detects bla_{KPC}, bla_{NDM}, bla_{IMP}, bla_{VIM}, and bla_{OXA-48}. Both assays require 4.5 h to complete testing in addition to the time required for DNA extraction. They are appropriate for bacterial colony testing only. Cuzon et al. tested 90 previously characterized carbapenemase-producing organisms with bla_{KPC} ($n = 14$), bla_{NDM} ($n = 22$), bla_{IMP} ($n = 11$), bla_{VIM} ($n = 21$), and bla_{OXA} ($n = 21$) and 93 isolates without carbapenemase determinants and reported sensitivity and specificity of 100% for each target (124). Willemsen et al. tested 489 previously characterized isolates, 355 of which were ESBL producing and 134 of which were not (125). Discordant results were reported in 30 isolates. The Check Points CT 103 microarray was used to adjudicate discrepant results. PCR and Check Points CT 103 results were concordant in 26/30 of these cases. In the remaining four isolates, CTX-M1 and unusual variants of TEM and SHV mutations were associated with false-negative results.

In contrast to the Check-MDR ESBL and Carba assays, the Check Direct ESBL and CPE products were designed for direct testing of perianal and rectal swab specimens. The product is compatible with ABI 7500, CFX96, the LightCycler 480 system (Roche), and the Rotor-Gene Q (Qiagen, Valencia, CA) instruments as well as the BD MAX platform. Swabs are collected and transported in appropriate molecular transport medium. Each well of a NucliSENS easyMAG automated DNA extraction cartridge receives 200 µl of fluid with 5 µl of internal control, and this is followed by DNA extraction. In the Check Direct ESBL product, primers and probes required for real-time PCR reactions are provided to detect CTX-M-1, CTX-M-2, and CTX-M-9 groups and ESBL mutations SHV-G238S and SHV-G238S + E240K. bla_{KPC}, bla_{NDM}, bla_{VIM}, and bla_{OXA-48} are detected by Check Direct CPE. Testing requires 2 h. Nijhuis et al. spiked stool matrix with 62 previously characterized carbapenemase-producing isolates that represented the assay targets and 21 non-carbapenemase-producers (126). Analytical specificity was 100%. The limit of detection was reported as ranging from 2×10^2 to 2×10^4–2×10^5 CFU/ml.

Check-MDR CT Assays

Check Points BV also produces the Check-MDR CT 101, 102, and 103 assays, which use a microarray format. Check-MDR CT 101 is designed to detect bla_{TEM}, bla_{SHV}, bla_{CTX-M}, and plasmid-mediated AmpC determinants including $bla_{CMY-1/MOX}$, bla_{ACC}, bla_{DHA}, $bla_{ACT/MIR}$, and $bla_{CMY,\ II/FOX}$. CT 102 detects bla_{KPC}, bla_{NDM}, bla_{VIM}, bla_{IMP}, and bla_{OXA-48}, in addition to the ESBL determinants from Check-MDR CT 101. CT 103 detects all of the ESBL, AmpC, and carbapenemase targets from the CT 101 and CT 102 microarrays. The Check KPC/ESBL detected bla_{TEM}, bla_{SHV}, bla_{CTX-M}, and bla_{KPC} but was expanded and replaced by CT 102. The Check-MDR CT assays also rely on ligation-mediated amplification. Ligated probes have universal primer sites and binding sites that allow hybridization to specific positions on a microarray located on CP array tubes. The tubes are inserted in a Check Points Tube Reader. Array images are generated and are analyzed using dedicated software.

The performance of the Check-MDR CT 102 has been described in studies using previously characterized bacterial isolates (127, 128). Occasional false-negative results for isolates harboring bla_{KPC} and bla_{OXA-48} have been reported. An AmpC β-lactamase-producing organism with no carbapenemase production tested false positive for bla_{VIM}. Similar studies describe the performance of Check-MDR CT 103 (129, 130). Similar to the Check-MDR-CT 102, a false-negative result was reported in an isolate of *K. pneumoniae* with bla_{OXA-48} (130). Also, while sensitivity and specificity for ESBL determinants bla_{TEM}, bla_{SHV}, and bla_{CTX-M} have been reported to be satisfactory, discordance between gold standard PCR and Check-MDR CT 103 has been noted for CTX-M subgroup $bla_{CTX-M-15}$ (131).

MDR-GNRs are highly concerning due to the limited treatment options available to patients with infections requiring treatment. Both sensitivity and specificity can be problematic in culture-based screening for MDR-GNR.

TABLE 1 Advantages and disadvantages of culture-based versus molecular-based surveillance methods

Organism	Culture-based screening		Phenotypic confirmation		Molecular-based screening and confirmation	
	Advantages	Disadvantages	Advantages	Disadvantages	Advantages	Disadvantages
All	Specialized skills are not required Bacterial isolates available for molecular typing and susceptibility testing Detection of emerging mutants of existing resistance determinants or novel families	TAT of >24 h common	Specialized skills are not required Provides some epidemiologic data for infection control purposes	Lengthens TAT unless integrated into routine susceptibility testing	May reduce TAT May increase sensitivity	May be costly Laboratory-developed tests (LDTs): require specialized skills Commercial assays: targets are proprietary, and commercial response to emerging mutants may be delayed
MRSA		Broth enrichment step required to achieve acceptable sensitivity	PBP2a detection is generally rapid, sensitive, and specific	Monoclonal antibody tests for PBP2a may have poor sensitivity in small colony variants and isolates with weak PBP2a expression	Highly automated commercial assays are available	False positives due to "*mec*A dropouts" False negatives in SCC*mec* and *mec*A mutants
VRE		Lower limit of detection makes it difficult to distinguish new acquisition from "unmasking" of carriage after antibiotic exposure	Not applicable	Not applicable	Highly automated commercial assays are available	PPV for *van*B-bearing *Enterococcus* spp. is poor due to *van*B carried by intestinal anaerobes
ESBL		Breakthough of AmpC and K1 β-lactamase producers reduces specificity of selective media More labor required for confirmatory testing Broth enrichment step required to achieve acceptable sensitivity	May perform well if AmpC suppression or detection is incorporated into testing	False negatives in isolates with both AmpC and ESBL False positives with KPC and K1 β-lactamase producers Automated expert systems can be inaccurate	Improved specificity compared to phenotypic confirmatory methods Microarrays allow efficient confirmation of TEM- and SHV-derived ESBLs with microarrays	Few assays are designed to detect targets directly from specimens PCR detection of TEM- and SHV-derived ESBL requires sequencing Microarray assays are costly
Carbapenemase producers		Reduced sensitivity of some carbapenemase-selective agar media for weak carbapenemase producers (e.g., OXA-48) Isolates with other carbapenem resistance mechanisms may grow through (e.g., AmpC or ESBL plus porin mutation)	Performance of CarbaNP assay is promising	Reduced sensitivity of inhibitor-based methods and possibly the CARBA NP with weak carbapenemase producers OXA-45 has no known inhibitors CarbaNP data performance is mostly based on LDT data. Data supporting commercial products are sparse	Improved specificity compared to phenotypic confirmatory methods Swifter detection of multiple carbapenemase determinants simultaneously Provides epidemiologic data for infection control purposes	Data are still sparse for commercial assays designed to detect targets directly from specimens Microarray assays are costly

Carbapenemases with weak hydrolytic activity against the carbapenems (e.g., OXA-48 and some strains of NDM, VIM, and IMP) can be difficult to recover from commercially available media. The burden of confirmatory testing can be particularly significant if using selective media with suboptimal specificity. Phenotypic ESBL and carbapenemase confirmatory testing methods are associated with various performance-related challenges. With an optimized work flow, molecular diagnostics performed directly on patient specimens may provide an alternative screening method with shorter TAT, improved sensitivity and specificity, and valuable epidemiological data needed to understand health care-based transmission patterns. Until recently, molecular detection of MDR-GNR determinants was largely limited to reference laboratories, but commercially available molecular diagnostic platforms are beginning to emerge, making such testing more widely accessible.

WILL ADOPTING MOLECULAR MDRO DETECTION ASSAYS REDUCE MDRO INFECTION RATES?

As the technology for molecular detection of MDRO carriers advances, the most important question is whether such technology will be helpful in reducing MDRO transmission and infection rates. From a technical, performance-based perspective, molecular detection methods have made considerable progress, particularly in the realm of MDR-GNRs. However, as we have discussed, they are presently not without weaknesses, as summarized in Table 1.

From the broader, hospital system-based perspective, the clinical impact of active MDRO surveillance rests upon the assumption that detecting asymptomatic MDRO carriers guides interventions that will either prevent MDRO transmission (e.g., contact precautions, cohorting of colonized and infected patients) or prevent infection among carriers (e.g., decolonization). When evaluating literature regarding the utility of active MDRO surveillance, one must distinguish between outbreak and endemic settings. There are many reports of active surveillance being used to help control MDRO outbreaks and/or reduce MDRO infection rates when such surveillance is introduced in response to elevated infection rates (6, 8). In these situations, active surveillance is generally instituted as just one of several interventions, and thus the incremental contribution of the detection of MDRO carriers is not quantifiable. However, it makes sense in outbreak settings to quickly define the potential reservoir of carriage and infection with the outbreak pathogen and to use active surveillance to guide other interventions such as patient isolation and cohorting. Thus, the CDC recommends active MDRO surveillance as one of the tier 2 measures to be implemented during outbreaks or when rates of MDRO infection are not declining in response to other infection prevention measures (6).

In contrast, published data to support the use of active MDRO surveillance in the endemic setting are weak and conflicting, with several recent well-designed trials demonstrating no impact of active MDRO surveillance (132–135). A pragmatic cluster-randomized trial (REDUCE MRSA) demonstrated little impact of active MRSA screening and isolation when compared to universal decolonization approaches in intensive care unit patients (135). Additionally, the MOSAR group recently reported results from a three-phase time-series and multicenter cluster randomized intensive care unit trial, finding that in the setting of sustained high levels of hand hygiene and chlorhexidine bathing, active surveillance (for MRSA, VRE, and MDR-GNR) and isolation did not reduce MDRO acquisition rates, regardless of whether rapid molecular or conventional testing was performed (134).

Notably, proponents of active MDRO surveillance have pointed to the slow TAT of MDRO detection test results for the failure of some studies to demonstrate effectiveness (136, 138). Indeed, more studies are needed to determine the impact of faster TATs for MDRO detection. We need studies that compare rapid (<24 h TAT) MDRO testing to slower (culture-based) testing, using concurrent control groups and measuring meaningful outcomes (MDRO transmission/acquisition and infection events). Such studies have been performed almost exclusively for MRSA testing

TABLE 2 Summary of studies assessing impact of rapid versus culture-based detection of MRSA carriage[a]

Study	Design	TAT difference	MRSA outcome	Major limitations
Aldeyab (140)	Nonrandomized cluster crossover trial	PCR: 19 h Culture: 52 h	No difference in event rates (acquisition + infection)	Long PCR TAT Not randomized
Hardy (141)	Nonrandomized cluster crossover trial	PCR: 22 h Culture: 79 h	Reduced acquisition rate in PCR group (0.29 vs. 0.41 per 100 bed days)	Long PCR TAT Not randomized 2-fold more unscreened in culture arm 71% decolonized in PCR arm vs. 41% in culture arm Only 17% of carriers placed in isolation rooms
Jeyaratnam (143)	Cluster-randomized crossover trial	PCR: 22 h Culture: 46 h	No difference in acquisition or infection rates	Long PCR TAT
Roisin (143)	Cluster-randomized crossover trial	PCR: 25 h Culture: 96 h	No difference in acquisition rate	Long PCR TAT Long delay between analytic TAT and actual TAT for PCR (11 vs. 25 h)

[a]Limited to those using concurrent control groups and reporting MRSA infection or colonization outcomes.

and are summarized in two recent systematic reviews (138, 139). Both reviews found the existing literature to be scant and the individual studies to have important limitations. As a result, rapid MRSA detection tests have not been convincingly demonstrated to reduce MRSA transmission or infection rates when compared with culture-based screening. As summarized in Table 2, however, some of the best-designed studies were only able to reduce the overall TAT of the rapid (PCR) tests to 19 to 25 h (140–143). This reiterates the challenge described earlier, of setting up a system to expedite all aspects of testing, including the extremely important postanalytic arm of notification and intervention.

In addition to comparative clinical studies, several groups have performed modeling studies to determine the likely impact of rapid MRSA testing on outcomes (144–146) and found that the improvement in TAT compared with culture methods provided little benefit at substantially increased cost, particularly if applied universally (i.e., to all admitted patients).

Thus, at the time of this writing there is not sufficient evidence to conclude that investments in routine rapid MDRO testing, in the endemic setting, will reduce MDRO transmission or infection rates. However, there is reason to believe that moving to rapid testing can reduce the number of contact precaution (isolation) days, particularly under policies that involve preemptive isolation either of all admitted patients or of those with a history of MDRO carriage (147). Given the negative consequences that contact precautions can have on patient satisfaction, patient safety, and cost of care (148), this impact of rapid MDRO detection should be considered in hospitals that employ preemptive contact precautions while awaiting MDRO surveillance culture results. In a randomized controlled trial, Shenoy et al. assigned patients with a history of MRSA infection or colonization to the local standard of care for discontinuation of contact precautions (three negative surveillance MRSA nasal cultures) or real-time PCR on the Cepheid GeneXpert platform. Contact precautions were discontinued more often, and a there was a significant reduction in contact precaution days in the PCR group (149).

Since MRSA is endemic in health care settings worldwide, the MRSA testing literature reviewed above does not address the potential impact of early detection of an MDRO that has not yet been detected in a given locale. The challenges of detecting epidemiologically important MDR-GNRs with available culture-based phenotypic methods make it likely that a newly emerging MDR-GNR could spread within a facility before it is discovered. Since certain MDR-GNRs, such as KPC-producing *K. pneumoniae*, can cause explosive, deadly, and difficult-to-control outbreaks, any test that could more rapidly detect carriers would be important to provide an early warning, in addition to the value of a subsequent outbreak response. Thus, a widely available molecular method that rapidly and accurately detects epidemiologically important MDR-GNRs will be an important step forward for clinical laboratories and infection prevention programs.

FUTURE DIRECTIONS

Due to many of the challenges we have discussed, rapid molecular detection of MDRO carriage remains in its infancy, with assays only widely adopted for MRSA. Future work will bring improved rapid testing options for other emerging MDROs, including new MDR-GNRs that are increasingly important public health threats. Those tests that have good performance characteristics will be useful adjuncts during management of MDRO outbreaks or when rates of a specific MDRO are elevated and not responding to standard MDRO prevention approaches (6).

Most importantly, well-designed clinical trials should be performed to help determine how these tests should be incorporated into MDRO prevention efforts, especially in endemic or nonoutbreak settings. Because endemic MDRO infection and colonization rates are associated with so many factors, detecting any incremental benefit of rapid detection of MDRO carriers requires large multicenter cluster-randomized trials. These trials are difficult to perform and resource-intensive. However, funding such studies is an essential step in determining how best to approach MDRO prevention well into the future.

Finally, we hope that the eventual increased availability of whole-genome sequencing (see chapter 3) will facilitate future MDRO surveillance and prevention efforts, in particular through earlier recognition of emerging MDROs that may be missed by commercial assays.

Detection of Vancomycin-Resistant Enterococci

ALLISON J. McGEER AND BARBARA M. WILLEY

18

BACKGROUND AND OVERVIEW

Vancomycin is a glycopeptide derived from soil bacteria that was authorized for use in 1958 for infections due to Gram-positive bacteria resistant to penicillin, erythromycin, and tetracycline. Toxicity led to its rapid replacement by methicillin in 1960; however, vancomycin use was again required by the 1970s for infections due to methicillin-resistant *Staphylococcus aureus* (MRSA) and toxigenic *Clostridium difficile*. In 1986, the first outbreak of enterococci with high-level resistance to vancomycin and teicoplanin was reported in the United Kingdom (1). A year later, infections due to vancomycin-resistant *Enterococcus faecalis* infections were identified in the United States (2, 3).

The rapid emergence of vancomycin-resistant enterococci (VRE) in the United States was fueled by the endemnicity of ampicillin-resistant *Enterococcus faecium* clonal complex 17 (CC17) in many American hospitals (4), a lack of awareness of the importance of patient colonization in propagating outbreaks, the absence of sensitive screening methods for detecting colonized patients (5), and an incomplete knowledge of the mode of transmission (6). In the late 1990s, enterococci of CC17 arrived in Europe (7–11), and hospital VRE outbreaks followed, until to date they are globally prevalent (12–16). VRE are adept at acquiring operons and readily share these *in vivo* with receptive bacterial strains encountered in the intestine or hospital environment, such that outbreaks are often polyclonal. The *vanA* and *vanB* operons are the most successful VRE genotypes, but new genotypes continue to emerge. Fortunately, transfer of *van* operons to *C. difficile* and to MRSA has remained rare, and even fully functional *vanG* vancomycin resistance genes in *C. difficile* appear to be insufficient to mediate high-level resistance (17, 18).

VRE are formidable masters of environmental survival (19), a feature that contributes enormously to their ability to cause and sustain outbreaks. Patient-to-patient transmission occurs via both health care workers' hands and fomite contamination, and transmission between patients is remarkably efficient (6, 20). Ensuring that medical equipment and surfaces are VRE free is paramount, as is prompt implementation of additional precautions for VRE-colonized patients, screening of contacts, hand hygiene, and antimicrobial stewardship (6, 20). Clinical microbiology laboratory support is critical in promptly identifying patients newly colonized or infected with VRE.

Allison J. Mcgeer and Barbara M. Willey, Mount Sinai Hospital, Toronto, Ontario M5G 1X5, Canada.

In this context, it is useful to understand that VRE success has also been partly due to inadequacies of detection methodology (5, 21–24) and/or failures in laboratory support. Microbiology laboratories need to continuously evaluate the performance characteristics of new screening tests against the need for speed, sensitivity, and specificity. They also need to be aware of the impact of the ongoing evolution of VRE and the appearance of new resistance determinants (25), some of which mediate only borderline resistance, which may make laboratory recognition of VRE more difficult (22). Continued glycopeptide use for a variety of infections sustains the selective pressure for VRE to emerge and spread. Laboratory failures have been attributed to mutations that affect PCR gene targets (21), heterogeneous expression (26, 27), inducible or delayed phenotypes (23), and low-density (5, 24) and/or low-level expression of resistance (23) such that strains appear susceptible or fail to be isolated on selective media (24, 28–30).

This chapter elucidates the basis for intrinsic and acquired glycopeptide resistance mechanisms as well as characteristics of the various genotypes and phenotypes found in enterococci. It discusses the relationships and shared genotypic origins as these pertain to VRE epidemiology. Against this backdrop, phenotypic and genotypic VRE detection methods applicable to clinical diagnostic microbiology laboratories will be reviewed, recognizing that the general trend for unusual variant strains is to be referred for detailed characterization to reference laboratories where expertise and advanced tools are available.

CELL WALL PEPTIDOGLYCAN SYNTHESIS AND VANCOMYCIN RESISTANCE

D-Alanyl:D-Alanine Precursors

Vancomycin is bactericidal only against Gram-positive genera that produce D-alanyl:D-alanine (D-Ala:D-Ala) ligases (*ddl*) (31). Chromosomally encoded *ddl* determinants yield species-specific enzymes active in the cytoplasm that add D-alanine to the C-terminal ends of UDP-MurNAc-tetrapeptides to synthesize pentapeptides, the essential building blocks of peptidoglycan cell walls. Pentapeptides ending in D-Ala:D-Ala are transported from the cytoplasm through the cell membrane and cross-linked by transglycosolation and transpeptidation reactions to form cell wall peptidoglycan. Vancomycin forms high-affinity hydrogen bond attachments to D-Ala:D-Ala and actively blocks transglycosolation, leading to loss of peptidoglycan integrity and cell death.

D-Alanyl:D-Serine Precursors

Enterococcus gallinarum and *Enterococcus casseliflavus* are common gut inhabitants that are much less pathogenic than *E. faecalis* and *E. faecium* (32). They differ from other enterococci in that they are capable of producing peptidoglycan precursors terminating in D-alanyl:D-serine (D-Ala:D-Ser) as well as those terminating in D-Ala:D-Ala (33). Production is mediated by intrinsic VanC-type operons (32). In the *vanC1*, *vanC2*, and *vanC3* operons that are associated with *E. gallinarum*, *E. casseliflavus*, and *Enterococcus flavescens*, respectively (34), the N-terminal loop of the membrane-bound sensor protein, $VanS_C$, protrudes through the cell membrane. When this sensor protein detects vancomycin, the histidine kinase cytosolic domain autophosphorylates, leading to phosphorylation of VanR and activation of the promoter (P_H) to transcribe *vanC-vanXY-vanT* (35) and produce peptidoglycan precursors terminating D-Ala:D-Ser (33), which have low affinity for vancomycin. This inducible ability to switch precursor types enables these enterococci to grow normally in the presence of vancomycin at concentrations up to16 mg/l without incurring a fitness cost (36). However, these species are not resistant to teicoplanin, they are rarely transmitted person to person, and their intrinsic VanC-type operons are nontransmissible, and for epidemiological purposes, species with these operons are not considered to be true VRE (32).

D-Alanyl:D-Lactate Precursors

Numerous environmental organisms have vancomycin resistance mechanisms that are similar to VRE. These organisms contain VanR/VanS regulatory systems and complex *van* operons that replace D-Ala:D-Ala with D-Ala:D-Lac pentapeptides. Since vancomycin cannot bind to D-Ala:D-Lac, cell wall integrity in such organisms is retained at vancomycin concentrations in excess of 800 mg/l. These organisms include *Streptomyces coelicolor*, *Paenibacillus thiaminolyticus* (whose *vanH-vanA-vanX* exhibit >90% homology with contemporary VRE), *Paenibacillus popilliae* (37, 38), *Paenibacillus apiarius*, and *Rhodococcus* species (39) with only slightly lower homology to *vanA* operons in VRE.

EPIDEMIOLOGY AND ORIGINS OF *VAN* OPERONS IN *E. FAECALIS* AND *E. FAECIUM*

Early evidence suggested that VRE emerged in response to years of use of a vancomycin analogue, avoparcin, as a growth promoter in the European food industry. The use of copper sulfate may also have contributed, because the copper resistance *tcrB* gene has been associated with *vanA* operons in porcine *E. faecium*. During the late 1980s, *E. faecium* containing *vanA* operons was found in food and food animals in many European countries (40–42), as well as in the feces of healthy people. It was postulated that, to survive avoparcin (43), animal enterococci had acquired protective gene clusters from inherently vancomycin-resistant enteric or environmental organisms. But because VRE were also identified from animal sources in the United States, where avoparcin had not been used, alternative mechanisms had to be considered. Inadvertent introduction of VRE from Europe in animals or humans is one potential explanation. Another is that vancomycin-resistant operons were acquired in enterococci in the United States from *P. popilliae*, which was intentionally seeded into soil in the eastern United States as a biopesticide to deter Japanese beetles (37). Sequence homology and similarity in gene organization between the *P. popilliae vanF* operon (38) and the acquired *vanA* and *vanB* VRE operons make this an attractive hypothesis.

Numerous groups have identified that as many as 50% of some human populations have anaerobic fecal bacteria which contain *vanA*, *vanB*, *vanD*, and *vanG* operons, raising another possibility—that the gut microbiome may form a reservoir for exchange of *van* operons (44, 45). While VRE strain differences in antibiograms (42), *purK* alleles (46), and Tn*1546* sequences (47) provide supportive evidence that there have been multiple introductions of *van* operons into VRE, these differences do not help in identifying specific sources. Although there may have been multiple introductions, all acquired operons were originally derived from only two operon groups (48), which can be distinguished on the basis of structure, orientation, and function of resistance genes. These conform to either *vanH-ligase-vanX*-type (as in *P. popilliae*) or to *ligase-vanXY-vanT*-type operons(35), the latter most resembling *vanC* type from *E. gallinarum* and related species (Fig. 1 and Fig. 2). This relatedness of *van* operons in *E. faecalis* and *E. faecium* to those in diverse genera explains why all PCR tests lack specificity for VRE when testing is performed on samples containing broad bacterial communities such as fecal flora (49).

VAN OPERONS ACQUIRED BY ENTEROCOCCI

Over the last 20 years, clinically relevant enterococcal species have acquired a myriad of different *van* operons (25, 48). These include the pentadepsipeptide-producers *vanA* (50), *vanB* (26, 51–55), *vanD* (56), and *vanM* and the D-serine-producers *vanE* (57), *vanG* (58), *vanL* (59), and *vanN* (60). Many variants have also been identified. To date, only *vanA* and *vanB* (61) and, more recently, *vanM* (62) have been disseminated widely in clinically relevant enterococci.

Figure 2 shows relationships between acquired and intrinsic operons from plausible representative progenitors. While each genotype is associated with a phenotype, mutations or insertional inactivation in regulatory genes commonly alter these profiles. Thus, *vanS* alterations in *vanA* operons can result in isolates with *vanB* phenotypes that are teicoplanin-susceptible (30), with *vanD* phenotypes that are teicoplanin-intermediate or low-level resistant (63, 64), or with apparently glycopeptide-susceptible phenotypes (29). Although rare, vancomycin dependency during therapy in enterococci (65) and staphylococci (66) has also been described. In *E. faecalis*, *E. faecium*, or *Enterococcus avium*, or in the vancomycin-resistant *Staphylococcus aureus* VRSA-9, where mechanisms were investigated, dependency was found to be due to impairment of chromosomal *ddl* after acquisition of *vanA* or *vanB* operons resulted in the cessation of intrinsic pentapeptide production. Withdrawal of vancomycin terminates induction of all pentadepsipeptide transcription, which terminates production of cell wall precursors and results in strain death.

ACQUIRED D-ALA:D-LAC OPERONS

vanA

vanA was the first acquired D-Ala:D-Ala operon to be characterized from an *Enterococcus* species, and its dissemination

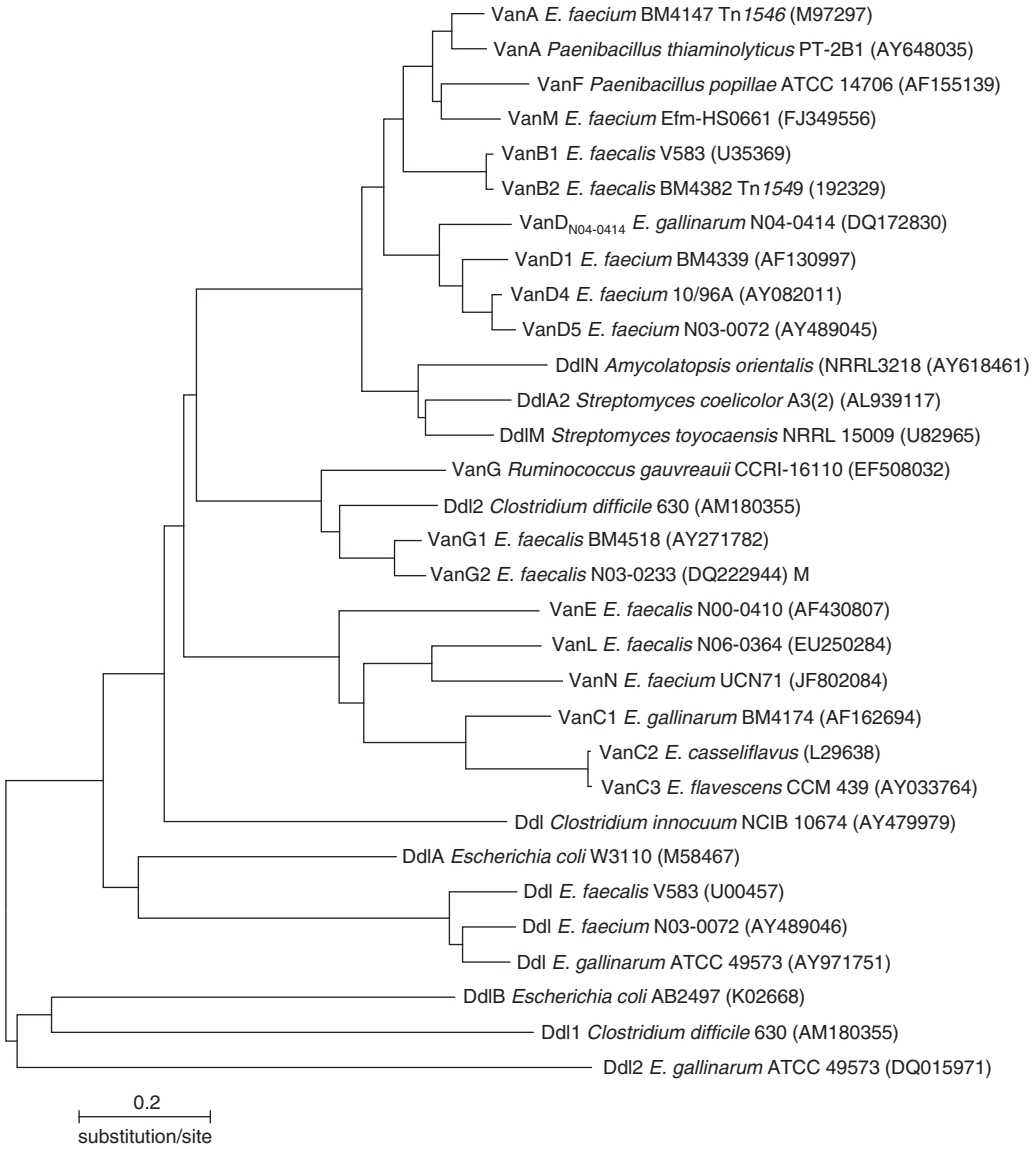

FIGURE 1 Phylogenetic tree constructed using MEGA6 (202) showing the relationships of D-Ala-D-Lac ligases, D-Ala-D-Ser ligases, and D-Ala-D-Ala ligases (Ddl). The proteins were aligned using ClustalW (203), and the tree was constructed with the neighbor-joining method (204) using 247 amino acids. The evolutionary distances were computed using the JTT matrix-based method (205), and the units are number of amino acid substitutions per site. Robustness of the data was tested by bootstrap analysis (206) using 1,000 replicates. GenBank accession numbers are shown in brackets. (Figure courtesy of David A. Boyd, National Microbiology Laboratory, Winnipeg, Canada.)

was found to be plasmid mediated (1, 50, 67). Isolates were highly resistant; MIC typically ranged from 64 mg/l to 1,000 mg/l for vancomycin and >32 mg/l for teicoplanin (68, 69). *E. faecium* dominates in *vanA* outbreaks (50), but the occasional *E. faecalis* (50, 70, 71) or other species may acquire the operon via horizontal plasmid transfer *in vivo* in the intestine (51). The *vanA* operon is an eight-gene cluster spanning ~11 kb within Tn*1546* (72). Tn*1546* is typically located in one of a variety of large conjugative multidrug-resistance plasmids, such as Inc18-related plasmids (73, 74) in *E. faecium* and pheromone-response plasmids in *E. faecalis*. *vanA* is controlled by a two-component OmpR-PhoB subclass system comprising a transcription response regulator, *vanR*, and a histidine kinase sensor, *vanS* (67, 75, 76). The N-terminal loop of VanS protrudes from the cytoplasm through the cell membrane (76). On vancomycin exposure (31, 67), the VanS histidine residue is induced to become autophosphorylated, which in turn phosphorylates VanR (77), leading to increased DNA binding of P_R and P_H promoters and initiation of *vanH-vanA-vanX* gene transcription; this in turn results in the production of pentadepsipeptides with D-Ala:D-Lac C-termini (76). *vanH* encodes dehydrogenation of pyruvate to produce the needed D-lactate substrate (78), and *vanX* encodes D,D-dipeptidases to destroy any D-Ala:D-Ala pentapeptides that continue to be produced. *vanA* also carries two accessory genes, *vanY*

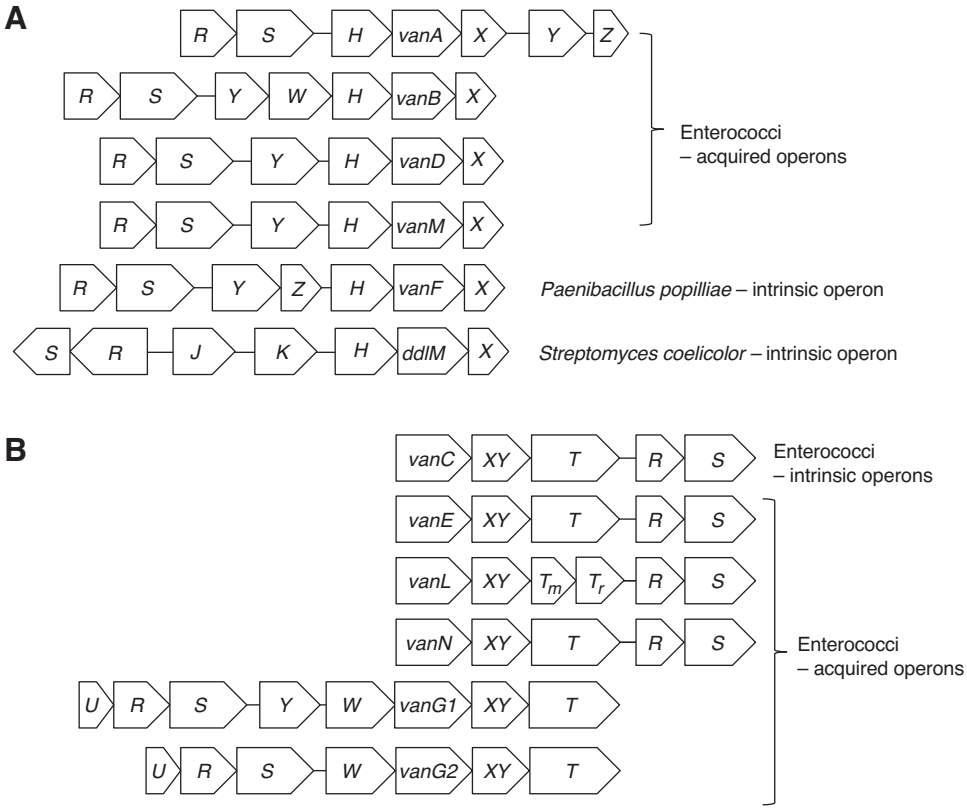

FIGURE 2 Schematic diagram of (A) the D-Ala-D-Lac operons found in enterococci and *Paenibacillus popilliae* and *Streptomyces coelicolor* and (B) the D-Ala-D-Ser operons found in enterococci. The operons are aligned at the D-Ala-D-Xxx ligase genes. Other genes are *vanU* (*U*), transcriptional activator; *vanR* (*R*), response regulator; *vanS* (*S*), sensor histidine kinase; *vanW* (*W*), unknown function; *vanH* (*H*), dehydrogenase; *vanT* (*T*), serine racemase; $vanT_m$ (T_m), serine racemase membrane domain; $vanT_r$ (T_r), serine racemase racemase domain; *vanY* (*Y*), carboxypeptidase; *vanX* (*X*), dipeptidase; *vanXY* (*XY*), dipeptidease/carboxypeptidase; *vanZ* (*Z*), unknown function but known to be involved in teicoplanin resistance; *vanK*, aminoacyl transferase; *vanJ*, teicoplanin resistance membrane protein. (Figure courtesy David A. Boyd, National Microbiology Laboratory, Winnipeg, Canada.)

and *vanZ* (79, 80). The D,D-carboxypeptidase mediated by *vanY* clears any late-stage D-Ala:D-Ala pentapeptide precursors that are missed by VanX D,D-dipeptidases (79, 81), while *vanZ* confers low-level teicoplanin resistance (76, 80). Because Tn*1546* forms stable associations with epidemic lineages, the most notable being *E. faecium* isolates belonging to multilocus sequence type CC17 with modified PBP5 mediating ampicillin resistance (82), transmission of the *vanA* operon is facilitated (4).

Recently, dissemination of *E. faecium* not recognized as *vanA*-containing VRE because of insertional inactivation of the *vanS* sensor gene has presented a new challenge (28). These strains may appear glycopeptide susceptible. However, *in vitro* studies have shown that these strains also readily switch from vancomycin-susceptible to vancomycin-resistant after exposure to subinhibitory doses of vancomycin (83), presumably mediated by an as yet unrecognized promoter. These variably expressing *vanA E. faecium* strains are particularly troubling because they are only detectable by PCR for *vanA*, which may enable them to spread unnoticed (28–30). Interestingly, while these strains are inhibited on most chromogenic agars, ~60% grow on Brilliance VRE agar (Oxoid, Nepean, Canada). However, their presence may be discounted as breakthrough because phenotypic methods will fail to confirm them as VRE (29). Other atypical phenotypes have also been described. In an outbreak in France, VRE with low-level resistance to both vancomycin and teicoplanin were found to contain a *vanA* operon in which the *vanY* accessory gene had been inactivated by the IS*16* element (63). Because the operon's DD-carboxypeptidase was not produced, the failure to eliminate late-stage D-Ala:D-Ala pentapeptides led to the unusual *vanD*-like phenotype (64). This potential for phenotype/genotype "mismatches" underscores the importance of the combined use of phenotypic and genotypic methods during investigations of VRE outbreaks (84).

In 2002, a swab from a foot ulcer of a Michigan patient yielded an MRSA isolate containing Tn*1546* complete with a *vanA* cluster (85, 86). It appeared to have transferred *in vivo* from *E. faecalis* to coisolated MRSA, creating the first clinical VRSA isolate. By 2007, eight similar events yielding VRSA had been identified in the United States (six of which were in Michigan), and such events have been identified in South Asia, Iran, and Brazil. This highlights the need for screening *S. aureus* for vancomycin resistance in patients or populations at risk of colonization with VRE.

The rarity of VRSA isolates appears to be due to plasmid incompatibilities and host barriers that inhibit gene transfer between unrelated species (87). In the first reported case of VRSA, acquisition of the *vanA* cluster by MRSA events required cooperation between different conjugative plasmids (73). A donor Inc18-like enterococcal plasmid acted as a suicide vector, releasing the transposon in the MRSA cytoplasm without itself surviving. The released transposon inserted into a recipient pSK41-like staphylococcal plasmid via "illegitimate recombination" (74). Although Inc18-like plasmids are commonly associated with Tn*1546* in *E. faecium*, *E. faecium* and *S. aureus* seldom share plasmids. VRE donor strains have been identified in only four VRSA cases and comprise three *E. faecalis* strains and one *E. avium* strain. Transposition seems to occur only during rare coincidental encounters between species of enterococci less commonly linked to VanA-Tn*1546* carriage, and only when MRSA carries compatible recipient plasmids.

Although all strains of VRSA expressed high-level vancomycin resistance, they became susceptible to cloxacillin when simultaneously exposed to oxacillin and vancomycin. When *vanA* pentadepsipeptides are cross-linked into the cell wall, the low-affinity PBP2a proteins are not used, and cloxacillin resistance is lost. Regardless, it is crucial for *vanA*-VRSA to be detected; it may only be a matter of time before these organisms acquire an escape from this paradoxical dead end.

vanB

First identified in *E. faecium* and *E. faecalis* in 1989, *vanB* was easily distinguished from *vanA* by lower levels of resistance to vancomycin (MIC: 16 to 64 mg/l) and susceptibility to teicoplanin (MIC: 0.064 to 1 mg/l) (53, 68, 69). Teicoplanin susceptibility is due to the lack of interaction between the drug and the $VanS_B$ sensor protein. However, development of teicoplanin resistance has been reported from rare cases where infections due to *vanB*-containing VRE were treated with teicoplanin (53). *vanB* genes share low sequence homologies with comparable *vanA* genes (31% ligase identity). They are similar in that they have operon regulation via a two-gene $vanR_B$-$vanS_B$ system (53), reduction of pyruvate to D-lactate by the $vanH_B$-dehydrogenase, ligation of D-lactate to C-termini of UDP-MurNAc-tetrapeptides by the *vanB* ligase, resulting in vancomycin-resistant pentadepsipeptide precursors, and concurrent hydrolysis of intrinsic D-Ala:D-Ala pentapeptides by $vanX_B$-encoded D,D-dipeptidases (52–54). However, the location and function of *vanB* accessory genes are distinct: $vanY_B$ and a gene of unknown function, *vanW*, are upstream of $vanH_B$-*vanB*-$vanX_B$ genes (52). In contrast to *vanA*, the $VanY_B$ D,D-carboxypeptidase in *vanB* is unable to eliminate late stage D-Ala:D-Ala pentapeptides and thus is susceptible to teicoplanin. These differences between *vanA* and *vanB* suggest distinct progenitors and separate evolution.

When the European *vanB* prototype strain (V583) (53) was compared to similar U.S. isolates circulating in 1993, a 3.6% sequence divergence between ligase genes was identified, and variants were designated *vanB2* (55). Another ligase variant exhibited 5% and 3.6% sequence divergences from the prototype *vanB* and *vanB2* ligases, respectively, and was designated *vanB3* (88). *vanB1* typically locates within the composite transposon Tn*1547* (52, 54, 89) or within a large chromosomally located serine recombinase-type conjugative element. By contrast, *vanB2* operons are mobilized by Tn*1549*/Tn*538* (26, 89, 90) tyrosine recombinase-type integrative conjugative elements (89), which usually integrate directly into the chromosome in the absence of plasmids. *vanB* strains of VRE have striking phenotypic variability in vancomycin resistance (vancomycin MIC: 6 to 256 mg/l), which is mediated by sequence variability in $vanS_B$ (75, 91, 92).

vanB outbreaks were first observed in Baltimore in the United States (68), but their current low prevalence in Canada (93, 94) and elsewhere in North America contrasts to their escalating "comeback" noted throughout Europe (8) from Spain (95, 96) though France (7) and Germany (92, 97) to Scandinavia (26, 90) and their predominance in VRE in Australia (44, 98, 99). However, it is important to note that there is no active surveillance system for VRE in the United States; thus, *vanB*-containing strains, which are less likely to grow on selective agar media, may go undetected in many hospitals if they are not causing overt infections. The European resurgence appears to be partly due to the acquisition by *E. faecium* CC17 of Tn*1549*/Tn*5382* harboring the *vanB2* operon (4, 9, 10, 61, 90, 96) and partly due to its mobilization in pRUM-like *repA*-containing conjugative megaplasmids equipped with *axe-txe* addiction systems (89, 97, 100). Addiction systems guarantee plasmid retention as the plasmid inserts genes into the chromosome that encode toxins lethal to the host if the plasmid-mediated antitoxin mechanism is lost. These strains often also encode virulence determinants (i.e., *hyl*, *esp*, pilus-encoding genes) to promote adherence and intestinal colonization (9, 101, 102).

As noted above, the rarity of *vanB*-containing VRE in North America may also be due in part to failure of detection. Vancomycin MICs in some *vanB* lineages commonly fall just below their established categorical threshold for resistance (91, 103). Detection also fails due to the continued use of formulations of VRE-selective agars that are insensitive (Table 1). In addition, some molecular assays (Table 2) detect *vanA* and *vanB* genes, but in some countries there is no reporting of *vanB*-positive results from those kits (i.e., BD GeneOhm VanR and Cepheid Xpert assays in the United States); this leads to the perception of a zero prevalence of *vanB* in enterococci in those regions. To further complicate VRE management and control, many *vanB2* operons have been found in fecal flora other than enterococci (e.g., *Clostridium* species) (45, 104–106); thus, it is not always possible to recover VRE from culture in PCR-positive specimens (49, 107, 108)—hence the reluctance to report their presence. However, recovery failures have since been additionally attributed to low densities in fecal flora (24), poor sensitivity of automated susceptibility testing (22), use of overly selective chromogenic agar formulations (109–115), and medium variations (116) in commercially prepared CLSI vancomycin screen agars used in the screening of clinically significant *E. faecium* and *E. faecalis* isolates (117).

vanB-containing VRE can be ruled out in PCR-positive specimens by culturing the specimens in nonselective brain heart infusion broth enrichment prior to extended incubation (36 to 48 h) on selective agars proven to support VRE with low vancomycin MIC (112, 113). The significance of PCR-detected non-VRE *vanB* in human gut microbiota remains unclear: while it has been difficult to identify their source by selective culture, functional operons have been identified in many different gut anaerobes (39, 44, 98, 104, 107, 108, 118). Both *vanB* VRE and *vanB* non-VRE prevalence appear to vary greatly in

different geographic locations (49, 119). It is possible that in some geographic areas there are bidirectional reservoirs in the human gastrointestinal tract which may enable the further spread of the *vanB* operon.

The ongoing risk of *vanB* emergence means that, even in areas of current low prevalence such as the United States, phenotypic detection methods should be designed to identify low-level *vanB2*-type vancomycin-resistant isolates and verification collections should comply with *Cumitech 31A* verification guidelines (120) to include adequate numbers of *vanB* and other genotypes with low-level vancomycin MICs to ensure that methods used in clinical microbiology laboratories are capable of detecting these strains. Current automated susceptibility testing systems and commercially prepared screen agars have all been documented to fail in the detection of some *vanB1* and *vanB2* strains, especially when the vancomycin MIC falls within the 6 to 16 mg/l range (22, 116).

vanD

The first *vanD*-containing isolate was an *E. faecium* strain recovered from a patient hospitalized in New York in 1991. Subsequently, *vanD E. faecium*—and one *vanD E. avium* isolate (121)—have been identified from Boston (56), Canada (122), Brazil (123), France (121, 124–126), and Australia (127, 128), either as single isolates or in small outbreaks (56). *vanD*-encoding isolates have moderate-level vancomycin resistance and reduced susceptibility or low-level resistance to teicoplanin. The ligase of the first isolate demonstrated 69% homologies to *vanA* and *vanB* and 43% to *vanC*, and orientation of the $vanH_D$ dehydrogenase, the *vanD* ligase, and the $vanX_D$ D,D-dipeptidase genes is similar to that for *vanA* and *vanB*. Isolates have a two-component regulatory system, $vanR_D$ and $vanS_D$, but the resistance is nonetheless usually constitutive. Some isolates have chromosomal *ddl* impairment due to insertional inactivation. The small number of identified isolates have an intriguing array of mutational modifications or insertions in $vanR_D$ or $vanS_D$ genes with or without an impaired host *ddl* but have had similar phenotypes. An exploratory study to look for *van*-gene reservoirs in fecal flora of hospitalized patients found unexpectedly high *vanD* carriage rates of 43.8% in Montreal, Canada, and 26.7% in Boston, Massachusetts, and these investigators found a complete *vanD* operon in *Ruminococcus gauvreauii* (45, 118, 129). Thus, gut anaerobes may be a source for these clusters in VRE. However, how they are mobilized and acquired is unclear. Fortunately, isolates remain uncommon, and few have been associated with person-to-person transmission in hospitals.

vanM

vanM was the first mobile inducible operon to be identified after *vanA* that produced precursors terminating in D-Ala:D-Lac and that conferred high-level resistance to both vancomycin (MIC: >256 mg/l) and teicoplanin (MIC: 96 mg/l) (62). These operons were detected in multiple strains of *E. faecium* isolated from clinical infections in China in 2010. While sequencing of the *vanM* ligase demonstrated homology to *vanA* (79.9%), *vanF* (78.8%), *vanB*

(70.8%), and *vanD* (66.3%) genes, the overall gene organization most resembled the *vanD* operon. But in common with *vanA*, the *vanM* operon was readily transmitted by conjugative transfer in a 150-kb plasmid, which was made clear by its mobilization into *E. faecium* of diverse lineages as demonstrated by pulsed-field typing. This operon probably emerged some years earlier, as a 2008 Toronto isolate from a patient from the local Chinese community was found to share 100% homology across the operon. All *vanM* reported from China have been ampicillin-resistant *E. faecium* with high-level vancomycin resistance (MIC: >256 mg/l); however, only 35 (70%) exhibited high-level teicoplanin resistance (MIC: 32 to 128 mg/l). Most isolates were of the CC17 lineage.

ACQUIRED D-ALA:D-SER OPERONS

vanE

The chromosomally encoded five-gene *vanE* operon was first described in 1999 (57); the initial and all subsequent isolates have been found in *E. faecalis* in geographically distinct locales (i.e., Australia and Canada) with no significant evidence of clonal spread (130–133). The operon has organizational similarity and moderate sequence homologies (43 to 60%) to equivalent genes of *van*C-type clusters. Vancomycin resistance is constitutive in some isolates and inducible in others. In common with *van*C-type operons, all *vanE* operons produce peptidoglycan precursors terminating in D-serine, and these resulted in low-level vancomycin resistances (MIC: 6 to 16 mg/l) and teicoplanin susceptibility. *vanE*-mediated vancomycin resistance in clinical *E. faecalis* isolates tested by automated susceptibility systems may go undetected, and most VRE-selective agars do not reliably support the growth of this phenotype; thus, its prevalence may be underestimated. While attempts to mobilize the *vanE* operon have to date been unsuccessful so that the precise conditions and mechanism of acquisition and transfer remain unclear, Boyd et al. have demonstrated the *vanE* operon in *E. faecalis* N00-004 to be associated with the integrative conjugative element Tn*6202* (122).

vanG

In 1996, a cluster of *E. faecalis in* Australia with low-level vancomycin resistance (MIC: 12 to 16 mg/l) and susceptibility to teicoplanin (MIC: 0.5 mg/l) was found to have novel transferable chromosomally located seven-gene clusters (58). These encoded D-Ala:D-Ser peptidoglycan precursors similar to those synthesized by *van*C and were regulated from the 5′ end by a constitutive system encoded by three genes ($vanU_G$, $vanR_G$, and $vanS_G$), all transcribed from the P_{UG} promoter. Induction of the downstream five-gene cluster ($vanY_G$, $vanW_G$ [a gene with unknown function], *van*G, $vanXY_G$, and $vanT_G$) was initiated at the P_{YG} promoter (134, 135). Two additional *van*G *E. faecalis* isolates have been identified in Canada (136), one with only minor sequence divergence (>99% homology) and a second with 87% homology to the Australian *van*G. Investigations by Domingo et al. found a high prevalence of *vanG* in nonenterococcal species in human gut flora from patients in Quebec. After protracted incubation of an anaerobic culture, a vancomycin-resistant *R. gauvreauii* isolate with a partial *van*G-like cluster in its chromosome was found (45, 118, 129). An operon with gene organization and homology similar to *van*G was also found in about 85% of C. *difficile* clinical isolates. Although the operon was fully functional and produced precursors terminating in D-serine, the isolates remained vancomycin susceptible.

vanL

The *vanL* determinant was first identified in an *E. faecalis* isolate (vancomycin MIC: 8 mg/l) from a single rectal swab from a Canadian patient in 2006 (59). This cluster had a gene organization comparable to *van*C, with the exception that the *vanT* serine racemase was encoded by two separate genes. The *vanL* ligase gene demonstrated 57% homology with the *vanC1* ligase from *E. gallinarum*. No plasmids were demonstrated, and several attempts to transfer the operon were unsuccessful.

vanN

vanN was identified in an *E. faecium* isolate causing bacteremia in France in 2008 (60). The isolate produced low-level vancomycin resistance (MIC: 16 mg/l) as a result of D-Ala:D-Ser precursor production and was susceptible to teicoplanin (MIC: 1 mg/l). Sequencing identified that its closest relative was *vanL* (homologies 50 to 74%). It was constitutively expressed due to an amino acid substitution in the H domain of $vanS_N$ and was transferable by conjugation at low frequency by a 150-kb plasmid. *vanN* is unusual in that it was the first acquired operon producing D-Ala:D-Ser precursors to be found in *E. faecium* and in which the mechanism of transfer was plasmid-mediated. However, additional isolates have not been identified.

LABORATORY DETECTION OF ACQUIRED VANCOMYCIN RESISTANCE

Clinical microbiology laboratories must be able to detect vancomycin resistance in *E. faecium* and *E. faecalis* rapidly and accurately, as vancomycin is often the therapy of choice for susceptible isolates of these organisms and therapy will fail if resistance goes undetected. The detection of resistance by culture to selective screen agars from rectal swabs is also obviously critical for those hospitals/regions with transmission control programs for VRE (Table 1).

Enterococci with *vanA*, *vanB*, and *vanM* operons all have been shown to spread rapidly after introduction into new hospital settings, and rapid laboratory detection by molecular methods from rectal swab screens of high-risk patients when they are admitted can prevent further transmission (Table 2). Increasing medical tourism and global travel mean that introductions of novel VRE strains are an ongoing threat in all jurisdictions. All laboratories must have the capacity to detect newly introduced strains, as most strains appear to be able to cause both clinical infections and difficult-to-control outbreaks. This might seem daunting; however, if protocols sensitive to low-level vancomycin resistance phenotypes are implemented, then detection of other VRE regardless of genotype will be feasible.

Knowledge of VRE epidemiology in surrounding regions is important, as laboratories must be ready for the unexpected. The approach most likely to reduce major errors is to implement a combination of well-evaluated methods with overlapping detection capabilities that pay special attention to difficult-to-detect regional phenotypes and use molecular tests strategically. Clinical laboratories with the capacity to use both genotypic and phenotypic methods are more likely to detect new variants, an approach that will protect infected patients from inappropriate therapy

and hospitalized patients from avoidable exposure to VRE. The additional laboratory costs associated with this approach are likely to be more than balanced by reduced expenditures in infection control, housekeeping, and the costs of management of hospital-acquired infections (137–139).

To identify VRE accurately, laboratories must ensure (i) that their species-level identification of enterococci is accurate so as not to confuse intrinsic with acquired vancomycin resistance mechanisms, (ii) that routine susceptibility determination from clinical specimens is performed and is sufficiently sensitive to detect low-level glycopeptide resistance, and (iii) that agars for selective culture of stool, rectal, or environmental swabs are adequate to identify isolates with borderline resistance or those that are present in low densities. In some cases, a relevant genotype may fail to be expressed in culture but may emerge as resistant during therapy, such that direct genotypic testing may be a prerequisite to its detection and control. Each method's limitation should be understood to ensure that, when used together, the chosen methods will be sufficiently sensitive to cover all possibilities.

As already discussed, VRE are constantly evolving and notoriously prone to change, and the varied expression that is a result of gene mutation means that no single method will detect every isolate. Unusual phenotypes should be referred to reference centers for characterization, as they may represent novel strains or operons that may spread within hospitals. The characteristics of the novel genes will need to be incorporated into decisions about VRE identification and susceptibility testing in the future and in the evaluation of new test methodologies.

Antimicrobial Susceptibility Testing

While commercial susceptibility testing methods detect high or moderate levels of constitutive vancomycin resistance in enterococci with ease, all incur varying degrees of major errors due to low-level, heterogeneous, delayed or inducible phenotypes. Disk diffusion (140), agar gradient susceptibility (141), and commercial broth microdilution susceptibility panels for vancomycin resistance in enterococci should always be accompanied by parallel spot inoculation of enterococcal suspensions onto CLSI-recommended screening agar to reduce detection failures (69, 117, 142, 143).

Broth Microdilution

The reference method for glycopeptide susceptibility testing of enterococci is broth microdilution as per CLSI (103, 117) and EUCAST (144) guidelines. The standardized procedure uses cation-adjusted Mueller-Hinton broth and antibiotics prepared as per CLSI (117) and/or manufacturers' instructions, with inoculation with freshly prepared bacterial suspensions to obtain a final suspension of 10^4 CFU per well. For vancomycin, test wells are examined for any visible growth after 24 h at 35°C, and categorical interpretation is per CLSI M100-series (103) or EUCAST (144) breakpoints. However, use of these set breakpoints does not always correctly categorize isolates, since mutations producing small-colony variants (145), heterogeneity, inducibility, low-level expression, or vancomycin sensor inactivation (as previously discussed) may all affect growth in vancomycin, and molecular detection of resistance genes may be required to rule out or detect VRE (91). But broth microdilution testing requires significant technical expertise, and acquisition of all the necessary antibiotic powders may be costly; thus, testing in clinical laboratories is usually performed using commercially prepared panels. TREK Sensititre (Thermo-Fisher Scientific), MicroScan (Beckman Coulter) (146, 147), and Phoenix (BD) (148, 149) most closely resemble reference broth microdilution, but all deviate to some extent from the standard method by use of proprietary broth formulations or fluorescent chemicals to aid endpoint determinations. Because commercial panel constituents and software are regularly modified, only recent studies may accurately reflect current performance, especially for difficult-to-detect phenotypes.

The VITEK 2 (bioMérieux) system is another commonly used commercial system with bacterial suspension preparation as the only nonautomated step. In this system, broth microdilution susceptibility testing is conducted within miniaturized wells set in a plastic card format. The wells are electronically monitored for changes in turbidity over time (i.e., due to growth in broth with antibiotic versus without antibiotic). Because MIC endpoints are predicted algorithmically against a species-specific database in order to achieve earlier results, it is imperative that accompanying organism identification is accurate; otherwise, significant susceptibility errors will occur (23, 69, 150). More recently, VITEK 2 susceptibility testing problems related to suboptimal organism identification appear to have been solved by the transition in many clinical laboratories from the less accurate VITEK 2 to the VITEK MS Plus or similar matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) systems which, in contrast, perform highly accurate species-level identifications of enterococci (151, 152). Nonetheless, suboptimal sensitivity of VITEK 2 for *vanB*-containing isolates persists (116, 153–157). During an outbreak in a Rome hospital in 2007 (149), two VITEK 2 cards were compared with reference broth microdilution, Etest, disk diffusion, and conventional *vanA*/*vanB* PCR. Of 25 *vanA* isolates, all resistant to vancomycin by broth microdilution, the AST-P534 card reported 17 as vancomycin resistant and two as teicoplanin resistant, while the AST-P535 card reported 24 as vancomycin resistant and 4 as teicoplanin resistant. A 2014 multicenter Scandinavian study circulated a panel of 30 enterococci of *vanB1*, *vanB2*, *vanE*, and *vanG* genotypes, together with susceptible isolates to five laboratories; the overall VITEK 2 sensitivity was 87% (95% CI: 79 to 92%) with a major error rate of 7% (the maximum acceptable rate is 3%) (116, 120). Thus, laboratories using commercial broth microdilution systems should continue to use CLSI agar screening plates to detect VRE (103). Any vancomycin-susceptible/CLSI screen-positive should be tested by PCR for *vanA* and *vanB* genes, and if negative should be referred for testing to rule out unusual *van* genotypes.

Agar Gradient MIC Testing

The AB-Biodisk Etest (141) (now bioMérieux) is also widely used around the world; however, because of this method's single-vendor status, it was not standardized by CLSI or EUCAST. It is to be hoped that the availability of the M.I.C. Evaluator (Thermo-Fisher) and Liofilchem (Alere) strips will result in procedure standardization. When used in accordance with original AB Biodisk Macro-Etest VRE or GISA protocols (141), Etest gradient strips are highly sensitive for detecting glycopeptide resistance (111). The unconventional approach deviates substantially from CLSI methods, but modification of AB Biodisk

methods in an attempt to follow CLSI guidelines results in poor sensitivity for strains demonstrating heterogeneous or low-level resistance. The critical elements of the AB-Biodisk recommendations are the following: (i) use a heavy enterococcal suspension equivalent to a 2 MacFarland standard; (ii) use brain heart infusion agar containing 60 g/l casein; (iii) let the suspension dry for 15 min before vancomycin and teicoplanin Etest strips are placed on the agar surface; (iv) extend the incubation period to a full 48 h; (v) examine the two elliptical inhibition zones at both 24 h and 48 h; and (vi) read the endpoints at 100% inhibition to include all subpopulations present. It is important not to miss haze or pinpoint colonies within the elliptical zone; these colonies are often not visible on Mueller-Hinton or brain heart infusion agar without casein at 48 h. For detecting resistant subpopulations, it is advantageous to use PCR for genotype confirmation. If the AB-Biodisk methods are followed, the Etest agar gradient strip becomes one of the more reliable methods available for difficult-to-detect VRE phenotypes.

Disk Diffusion

Disk diffusion was removed as a testing option from the CLSI M100 guideline in 2014 (103), because it was considered too insensitive and subjective for detecting vancomycin resistance, especially for *vanB* strains with low-level MICs. However, EUCAST (144) continues to provide disk diffusion method guidelines for detecting VRE even though a 2014 VRE detection method comparison found a 7% major error rate for vancomycin susceptibility with disk diffusion testing. These authors stressed that if inhibition zones were interpreted by experienced readers, disk diffusion had a sensitivity equivalent to the CLSI agar screen method and was superior to the results of VITEK 2 testing (116). Furthermore, they concluded that the method would perform better if laboratories that use disk diffusion as their primary susceptibility testing method were trained in the differences between fuzzy-edged zones (typical of VRE) and sharp-edged zones (associated with vancomycin susceptibility) (116). Endpoint subjectivity of disk diffusion and agar gradient strip MIC methods might also be reduced by electronic imaging, which will allow for magnification that should make differences between fuzzy and sharp edges more evident.

CLSI Agar Screen

When VRE emerged, it was clear that not all strains were reliably detected by susceptibility testing methods available to most clinical laboratories. Thus, the vancomycin agar screen method was developed to provide an inexpensive and reliable means to prevent detection failures (142, 146). Standardization studies found that brain heart infusion agar with 6 mg/l vancomycin was the most sensitive and specific formulation, and the CLSI agar screen became recommended for parallel spot-testing of all enterococcal suspensions prepared for routine susceptibility testing (103, 143). For the most part, this method has retained its sensitivity and specificity, but as with any method using non-chemically defined media, quality may vary by manufacturer and should periodically be reassessed. A 2014 multicenter study designed to determine how well Scandinavian laboratories were able to detect enterococci with low-level vancomycin resistance found that the sensitivity of the CLSI agar screen varied between centers. In centers where unacceptably low detection sensitivities were identified, the poor performance was found to correlate with particular manufacturers of commercially prepared screen agars (e.g., Oxoid agar: 89%; 95% CI: 82 to 93%) (116) and the authors concluded that the overall sensitivity of 93% (95% CI: 92 to 95%) for the agar screen was acceptable because it was better than the overall performance of other methods tested in parallel (116). These data suggest that it would be prudent for this method to be periodically reassessed using contemporary hard-to-detect strains; alternatively, more stringent control of the agar should be implemented on a routine basis using a more appropriate quality standard.

CLSI recommends the *vanB E. faecalis* strain ATCC 51299 as a positive control (103), but the vancomycin MIC range of this strain is typically anywhere between 16 and 64 mg/l. Thus, it will not detect overly inhibitory agar preparations that suppress growth of isolates with vancomycin MIC in the 6 to 16 mg/l range. An additional problem introduced with the use of this VRE as a control strain was its repeated link to laboratory contamination events that resulted in false-positive clinical specimen reports (158, 159). In 1999, the Ontario Quality Management Program–Laboratory Services (160) recommended *E. gallinarum* ATCC 49573 to be used in lieu of the VRE *E. faecalis* ATCC 51299 because it has a stable vancomycin endpoint of 8 mg/l, which is more appropriately able to control the required vancomycin content of 6 mg/l. Furthermore, use of this benign alternative increased the confidence with which *vanB E. faecalis* results from this plate were received, ensuring that growth was the patient isolate and was not due to accidental splashing causing cross-contamination; this enabled VRE confirmation to be expedited by performing PCR directly from the growth spot on the agar (158, 160).

Primary Surveillance Screening

Soon after VRE was recognized, it was realized that, in most patient populations, the ratio of colonized to infected patients was as high as 20:1. Colonized patients form an important reservoir for VRE in hospitals, and detecting VRE-colonized patients is required to prevent and control hospital outbreaks (161). Thus, agar formulations developed for isolating enterococci in environmental laboratories were adapted by reference clinical laboratories to enhance their selection capabilities for VRE (Table 1) (114). The agar bases most commonly used were m*Enterococcus* (Difco) and Bile Esculin Azide (also known as Enterococcosel Agar); once supplemented with vancomycin, the former was sensitive but required incubation to be extended to 72 h, while the latter was specific but relatively insensitive, and both had difficulty with detection of low-level resistance (Table 1). Further, these agar media generally failed to inhibit enteric bacterial species with intrinsic resistance to vancomycin, such as the lactobacilli, pediococci, and leuconostocs, and these had a tendency to mask the growth of VRE or cause false-positive results due to mixes. While the development of chromogenic agars has significantly improved performance (Table 1), they are based on distinct formulations, most proprietary, and some incorporate substances inhibitory to species of *Enterococcus* not generally associated with VRE (85, 110, 162–164). In some cases, this resulted in a lack of sensitivity for isolates containing *vanC* or *vanB* operons with low-level vancomycin resistance (111, 165). Time to detection is significantly improved, although chromogenic agars are still unable to identify all VRE within a 24-h period, and breakthrough growth of

MacroEtest on BHIA (MET, bioMérieux, medium)	111	BMD, PCR	144	Only B: 129/129	94.6/–	48 h

[a]Guidelines/institutes: CLSI, Clinical and Laboratory Standards Institute (103, 117); EUCAST, European Union Committee on Antimicrobial Susceptibility Testing (144).
[b]See Table 1 for acronyms for selective differential agars and methods used as comparisons and for other abbreviations.

E. faecalis or coagulase-negative staphylococci may still present minor problems (112, 113, 115, 162, 163, 165).

MOLECULAR DETECTION OF VRE

Usually, clinical microbiology laboratories undertake routine diagnostic testing including the isolation of VRE from surveillance and clinical cultures, with only a small proportion performing additional molecular detection of VRE (Table 3). While some laboratories with PCR capacity still perform one of the many possible in-house conventional PCR assays for VRE detection and/or confirmation (11, 21, 34, 88, 107, 166–172), for ease of use, many others now rely on commercially available kit-based assays (49, 119, 173–192). Referral laboratories are required to perform genotypic confirmation on isolates for diagnostic laboratories without PCR capacity and to characterize isolates that may represent novel genotypes or variant operons. As seen in Table 3, most commercial molecular assays only target the two common VRE genotypes, *vanA* and *vanB*, because these together account for >99% of clinically relevant isolates today.

In most parts of the world this is currently adequate, but as new epidemic genotypes emerge (i.e., *vanM* in China) (62), manufacturers will need to modify the assays to include new targets. Commercial PCR assays yield information regarding VRE genes more rapidly than culture and may be more sensitive than unenriched surveillance cultures, particularly for isolates exhibiting borderline vancomycin MIC values that are associated with some *vanB* genotypes. They remain, however, substantially more expensive than culture-based testing and thus are less commonly the primary method for VRE detection. However, there are circumstances in which molecular assays are a valuable addition to culture-based testing or may replace culture-based testing (171, 185). For instance, the substantially shortened time to results may make molecular testing a cost-effective choice for screening of high-risk patients or in the management of outbreaks. Similarly, molecular testing may be necessary in the management of outbreaks of "vancomycin variable" VRE (28–30). Other laboratories have used molecular testing to obtain rapid genotypic confirmation of suspected VRE isolated in culture (193); molecular testing can also be employed directly on blood cultures to shorten time to identification of VRE (175, 190).

Test accuracy related to primer design (21) and cost are critical in assessing the suitability of a commercial molecular test for clinical laboratory use. However, other important considerations are test complexity, whether controls are internally integrated or must be run separately in parallel, and whether the assay was designed for batch or random access testing. Technically complex assays are associated with the need for expertise, increasing personnel costs and introducing erratic personnel demands on the clinical laboratory during outbreaks. Requirements for batch testing delays reporting and may result in increased costs beyond the laboratory. On-demand commercial molecular testing options are available that obviate the need for batch testing.

One important limitation of all molecular assays is the fact that *vanB* operons are present in a variety of stool anaerobes, such that a positive test from stool or rectal swab specimens does not necessarily mean that a patient is colonized with VRE. As a result of this nonspecificity, commonly used commercial assays in the United States, such as BD GeneOhm VanR or the Cepheid Xpert *vanA*, were FDA cleared only for *vanA*. In Australia, Canada, and Europe these assays have been used to detect both *vanA* and *vanB* genotypes. Like other commercial assays, the Roche LightCycler VRE Detection kit detects *vanA* and *vanB*, but uniquely, it further distinguishes *vanB* as *vanB1* or *vanB2/3* using fluorescent resonance electron transfer probes combined with melting curve analyses. The newer Nanosphere Verigene assay detects *vanA* and *vanB* directly from positive blood cultures (175, 183, 184, 190, 194), as does the Seegene Seeplex assay (181), but these assays have undergone only limited verifications to date and thus have not yet been widely adopted.

Roche LightCycler VRE Detection Kit

The first commercial multiplex PCR assay, originally developed at the Mayo Clinic for detecting *van* genes, was the Roche LightCycler VRE Detection kit, a qualitative "research use only" assay run on the LightCycler instrument (Roche Diagnostics GmbH, Germany) (186). The assay amplifies *vanA*, *vanB1*, and *vanB2/3* genes, which are distinguished by the different temperatures at which the specific fluorescent resonance electron transfer hybridization probes "melt" from each amplicon during the final heating step. Early evaluations of this assay reported high inhibition rates; however, with appropriate extraction methods, this can be avoided. Thus, magnetic extraction using the Roche Total Nucleic Acid Isolation kit and the automated MagNA Pure instrument (Roche Applied Sciences)—which processes 32 samples in ~100 min—results in inhibitor-free reactions, while rapid DNA extraction by disruption in glass beads and saline followed by centrifugation risks failure due to inhibitors (188, 195). Both the extraction and PCR assays require technical expertise. Kits require—20°C for reagent storage, dedicated pipettes, and a PCR clean room for reagent preparation, and positive and reagent controls are run in separate tubes. The assay runs for 1 to 1.5 h depending on the number of samples, and performing the assay is intuitive but does require training. It has an advantage over other commercial assays in that it distinguishes *vanB1* from *vanB2/3*, which can be useful for patient management as *vanB2* operons are more commonly associated with anaerobes, while *vanB1* operons are more often in VRE (119, 180, 188, 191, 195). Both extraction approaches enable the swab to be cultured after it has been used for PCR. It is critically important to ensure that specimens positive for *vanB1* and *vanB2/3* genes are cultured on selective agars known to support the growth of enterococci with low-level vancomycin MICs (4 to 6 mg/l) or with inducible or heterogeneous expression of resistance. On the whole, this is a high-performance test, as long as it is understood that *vanB* may be present in anaerobic bacteria and *vanB2* genes may be present in anaerobes and in *Enterococcus* species (49, 119, 180).

BD GeneOhm (IDI) VanR Assay

The GeneOhm (IDI) VanR assay (BD Diagnostics) was developed in Quebec, Canada, to detect *vanA* and *vanB* genes from fecal surveillance specimens (187). It was the first VRE-related molecular test to gain FDA clearance for amplification of the *vanA* gene directly from rectal swabs. The GeneOhm VanR assay is a medium-complexity assay that performs DNA extraction and PCR amplification in the random-access modular Cepheid SmartCycler instrument. Although the assay comes in kit form, it requires a moderate degree of expertise because there are several precision pipetting and centrifugation steps in the protocol. The kit buffer enables the swab to be cultured after use for PCR. Each test (up to a maximum of six tests in an eight-module instrument) and a set of positive and negative controls are run in separate plastic PCR tubes that are placed into separate modules in the SmartCycler instrument for simultaneous amplification during the PCR run. To increase capacity when larger specimen batches require testing, multiple instruments may be linked together, in which case they are able to act as random access devices as long as every time the PCR run is initiated, it is done with an accompanying set of controls. If either the positive or negative control fails, all other tests will automatically fail regardless of their individual results.

The extraction comprises a basic spin column and is thus prone to inhibition, which may result in amplification failure. If inhibition occurs, the specimen is diluted and the test and controls are repeated. The VanR assay detects *vanA* and *vanB* genes, but does not distinguish between the *vanB1* and *VanB2* variants. The assay run takes ~1 h, and reporting of results is simple and direct. Overall the assay is less challenging than the Roche LightCycler assay, but with only marginally less hands-on time needed to set it up. The system is limited to six specimens in a batch unless multiple instruments are available, and time to result may be delayed by the wait for free modules in the instruments.

Cepheid Xpert *vanA/vanB* Assay

The Xpert *vanA/vanB* PCR assay is run on the GeneXpert instrument (Cepheid) (40, 173, 179, 182, 192). It was designed for direct testing of stool or rectal swab specimens, but it has since been validated for use on isolates. A clear advantage of this system compared to other commercial VRE assays is the simplicity of design, minimal hands-on time, and low degree of expertise required to run the assay. Other than the buffer, all extraction and amplification reagents, including the PCR tube itself, are built into the test cartridge. The cartridge contains an internal control of *Bacillus* spores to ensure that DNA extraction and PCR amplification are successful prior to reporting a negative result. Inhibition is generally preventable by avoiding overinoculation of fecal material. In the United States, the assay is FDA cleared only for *vanA* (*vanB* results are suppressed), but it is used widely for *vanA* and *vanB* in Australia, Europe (CE marked), and Canada (Health Canada approved) (189, 193). GeneXpert instruments are designed for random access testing, with modules that can hold 4, 8, 16, 48, or 80 cartridges, each of which can be a different assay.

A single Xpert *vanA/vanB* cartridge takes ~1 min to set up, and run time is less than 1 h. Results automatically print with crossing thresholds and clear interpretations for each detectable target. These may be reported directly via an interface to the laboratory information system, with hands-off finalized reporting of negatives if so desired. Kit storage is at room temperature, and setup does not require a clean room. However, single-package sterile plastic pipettes for buffer transfer are recommended, as are dedicated clean pipettes with filter tips for when direct testing

from liquid specimens is performed, because cross-contamination during handling can occur. Compared to other molecular VRE assays, the test cost is high, but this is offset by its low complexity, random access testing, and integrated positive and negative controls. Another advantage is that PCR may be performed directly from colonies selected from chromogenic agars or primary cultures without disrupting bench workflow and without incurring delays (189, 193). The assay does not distinguish *vanB1* from *vanB2* or detect other targets (*vanE* and *vanM*), which may be useful for patient management in some regions.

Other Molecular Tests

A number of other molecular tests are under development. These include the Seeplex VRE kit (Seegene, South Korea) (181, 185), the iNtRON kit (LG Life Sciences, South Korea) (196, 197), and the NanoCHIP Infection Control Panel (ICP) assay (Savyon Diagnostics, Israel) (198). At least one group has demonstrated loop-mediated isothermal amplification tests that may also be useful (167), and the Verigene (Nanosphere) is one of the first of several products likely to be available in the future that will permit the rapid detection of both species and *vanA*/*vanB* genes conferring resistance in blood cultures positive for Gram-positive cocci (175, 190). None of these tests has yet been validated by a sufficiently large and varied sample of VRE to adequately assess its performance characteristics. Many laboratories also continue to use a variety of different noncommercial PCR tests for the detection of vancomycin resistance genes (152, 176, 199, 200), a logical alternative as long as care is taken to ensure that regional variants of VRE are identified and that the culture methods used are able to grow the newly imported variants.

CONCLUDING REMARKS AND FUTURE PERSPECTIVES

Adequate hospital-based transmission control programs for VRE strongly depend on the quality and efficiency of laboratory testing. Microbiology laboratories need to consider all factors including sensitivity of methods for detection of existing VRE, including their ability to detect newly introduced clones/genes, time to detection/reporting, and cost. Currently, in most laboratories, a mix of culture and molecular testing is likely to be most efficient, with careful attention paid to strategic use of molecular testing when rapid turnaround time is most needed, and to the extent to which detection of isolates with borderline resistance to vancomycin is needed. All laboratories need to be aware that low MICs and low fecal density of enterococci will continue to be a challenge for control programs (24).

A better understanding of the differences between genes associated with vancomycin resistance in enterococci as compared to those in other nonpathogenic organisms may assist the designers of molecular tests in developing more specific tests. However, the variability of gene sequences within enterococci, the close relationship between *van* genes in enterococci and other genera, and the plasticity and rapid evolution of enterococci means that the dual problem of lack of specificity of *van* gene detection for VRE and lack of sensitivity due to gene variants being missed is likely to persist. This should not be interpreted to mean that molecular tests are not useful; rather, it means that enterococci will continue to be challenging organisms, in which careful test interpretation is always needed, and tests must continue to coevolve with the microbes.

Not all newly proposed rapid tests for the detection of VRE are molecular; one recent attempt proposes an immune-chromatographic assay to detect *vanA* ligase-producing enterococci (201). However, the plasticity of enterococci makes maintaining sensitivity in new enterococcal variants an ongoing challenge. In this light, our best hope for better diagnostics may lie in developing methods that include sequencing and permit the identification of variability in the genome.

The Impact of Molecular Diagnostics on Surveillance of Foodborne Infections

JOHN BESSER, HEATHER CARLETON, RICHARD GOERING, AND PETER GERNER-SMIDT

19

The Centers for Disease Control and Prevention (CDC) estimates that foodborne diseases cause illness in one in six Americans (or 48 million people) each year, leading to 128,000 hospitalizations and 3,000 deaths (1, 2). Among the known foodborne pathogens, bacteria proportionally cause the most severe illness, being associated with 64% of hospitalizations and 64% of the deaths. The foodborne bacteria associated with most hospitalizations and deaths are *Salmonella*, *Campylobacter*, Shiga toxin-producing *Escherichia coli* (STEC), and *Listeria monocytogenes*. These bacteria are all zoonotic; i.e., they may be found in the normal intestinal biota of animals without causing disease and may spread to the environment and contaminate the food we eat.

Public health surveillance is the continuous, systematic collection, analysis, and interpretation of health-related data (http://www.who.int/topics/public_health_surveillance/en/). In the area of foodborne disease, surveillance is used to detect outbreaks, count illnesses, determine foods and settings causing illness (attribution), track trends to monitor the efficacy of control efforts, and provide physicians with information for patient care. This chapter will primarily focus on outbreak detection and investigation.

Outbreaks of foodborne infections are common, with more than 800 reported in the United States in 2011 and 2012 (3). Outbreaks are investigated and controlled using a multipronged approach involving microbiologists and epidemiologists from the food producers, public health, and food and veterinary authorities. The role of the microbiology laboratory in outbreak investigation and the potential for enhancement by molecular-based subtyping depends both on how the outbreak is detected and the stage of the investigation. Foodborne disease outbreaks are detected by one or more of three basic mechanisms including (i) syndromic surveillance, (ii) notification (reporting of outbreaks recognized by the public or medical community), and (iii) pathogen-specific (laboratory-based) surveillance (4). Each of these mechanisms has strengths and limitations and functions to a greater or lesser extent in different jurisdictions. Although they are described here separately, more than one method may be used in individual investigations.

John Besser, Heather Carleton, and Peter Gerner-Smidt, Enteric Disease Laboratory Branch, Centers for Disease Control and Prevention, Atlanta, GA 30333. **Richard Goering,** Department of Medical Microbiology and Immunology, Creighton University School of Medicine, Omaha, NE 68178.

Syndromic surveillance refers to the collection and analysis of preclinical and prediagnostic health information as an early warning system to detect trends of public health importance. Preclinical data are obtained from sources such as school absenteeism or sales of diarrhea medications. Examples of clinical prediagnostic data sources are emergency room admission complaints and diagnostic test orders (5). These data may be obtained before laboratory testing and therefore potentially trigger an investigation faster than laboratory-based surveillance. However, the lack of specific laboratory information creates substantial signal-to-noise problems, which requires standard investigations to establish that the outbreak is real and to identify populations at risk. The usefulness of syndromic surveillance for foodborne disease has not been established (4) and will not be discussed further in this chapter. An exception is the surveillance of rare and highly specific diagnosed syndromes such as postdiarrheal hemolytic uremic syndrome or botulism, which functions in much the same manner as pathogen-specific surveillance.

Notification is a method of outbreak detection by which illness clusters are directly reported to public health agencies. The connection between cases is made by the public or health care providers who notice a greater than normal occurrence of patients with symptoms typical of foodborne infections or intoxications. This is sometimes referred to as "event-based surveillance," with the typical scenario being a church, school, or restaurant event where participants notice that others are ill. Since laboratory identification of a specific pathogen is not necessary for initial detection of the outbreak, notification is one of the most effective tools available for identifying new disease-causing agents. The STEC strain O157:H7 was initially identified as a public health problem through investigation of a reported disease cluster at a fast-food restaurant (6). Event-associated outbreaks are usually, but not always, caused by errors in terminal food preparation, such as improper cooking, handling, or storage.

In pathogen-specific surveillance, laboratory-based diagnostics and subtyping are used to detect clusters of disease that may represent outbreaks. Cases are often linked through shared disease etiology, such as illnesses due to *Salmonella* spp. or *L. monocytogenes*, that are reported to public health agencies by physicians and clinical laboratories. This type of surveillance is greatly enhanced by increasing the specificity of the case definition through

molecular subtyping. With this approach, it is not necessary for cases to be in the same location for clusters to be recognized (as is needed for notification and usually when old, less discriminatory subtyping methods are used); pathogen-specific subtyping-based surveillance is our most effective tool for identifying widespread low-level outbreaks caused by problems in food production, processing, and distribution. While not as common as local "church supper" type outbreaks, typically identified through notification, the problems identified in this way are generally amenable to control since they involve systems that are often centralized and regulated. Investigation of these outbreaks is one of our best tools for discovering previously unrecognized unsafe food production practices and new vehicles of contamination.

Laboratory testing is required for initial recognition of outbreaks detected through the pathogen-specific surveillance process, but not necessarily for outbreaks detected by notification. The raw material for pathogen-specific surveillance is isolates, specimens, and disease data from patients diagnosed in hospitals and clinics. For rare conditions such as listeriosis, large outbreaks may be detected solely by species-level information. For example, a 2011 multistate outbreak of *L. monocytogenes* associated with contaminated cantaloupe was initially detected by an unusual number of cases in Colorado during a short time period (7). For detecting outbreaks when they are smaller, or detecting outbreaks due to more common pathogens such as *Salmonella*, more discriminating subtyping methods are necessary to distinguish trends from background noise. It is in the area of pathogen-specific surveillance that molecular epidemiological techniques have had their greatest impact to date. In the past, traditional methods such as biotyping, antibiograms, serotyping, and phage typing were the only subtyping methods available, but since the 1980s these methods have gradually been replaced by molecular subtyping methods for outbreak investigations because they provide superior discriminatory power and thereby provide better sensitivity and specificity for outbreak investigations. This increased discrimination adds specificity to the cluster definition: cases that are more likely to share an epidemiological association are grouped together and cases less likely to be associated are excluded, thereby increasing the chance that smaller trends will be identified and outbreaks will be solved. Although foodborne outbreaks may be caused by multiple different strains (polyclonal or polymicrobial outbreaks), focusing on a specific strain is useful in the initial phase to identify the outbreak (8). Cases that may have been overlooked in the preliminary case findings may be added during subsequent phases of the investigation. In general, as the laboratory tests and case definition become more specific, outbreaks become easier to detect and solve. The current "gold standard" for laboratory surveillance of outbreaks is pulsed-field gel electrophoresis (PFGE). This is a universal subtyping method, since it may be used to subtype almost any pathogen with just a few modifications. It will be described in more detail later.

PFGE is the preferred method used by PulseNet, the national molecular subtyping network for foodborne disease surveillance (9), and by its global counterpart, PulseNet International (10). Since 1996, PulseNet has revolutionized the response to foodborne outbreaks in the United States. In this network of more than 80 public health and food regulatory agency laboratories, the foodborne pathogens are subtyped as they are received in the laboratory, and the data are uploaded to the national databases at CDC. The PFGE profiles are analyzed in real time both locally and centrally at CDC, and every time clusters of cases with indistinguishable patterns are identified, this information is passed on to the epidemiologists for follow-up. This surveillance has proven extremely efficient for outbreak investigation, and at any one time on average 25 clusters are being investigated. The network has been critical for the successful investigation of almost all high-profile outbreaks that have occurred in the United States since its inception. These investigations have led to the identification of many new vehicles that likely would not have been identified without the molecular subtyping information provided by PulseNet. However, the issue of cluster definition is becoming more complicated with the implementation of whole-genome sequencing (WGS) because even highly epidemiologically related isolates vary at the genomic level.

Once outbreaks are detected, the role of laboratory testing and molecular diagnostics varies with the phase of investigation. The main components of outbreak investigations were described by Reingold (11). The laboratory is often involved in the case definition, the identification of new cases, hypothesis generation, culture confirmation of the source of the outbreak, and measuring the effect of control measures.

The first step in most outbreak investigations is to establish a case definition. In pathogen-specific surveillance, an outbreak is detected as a cluster of isolates of a pathogen or subtype of a pathogen that occurs more frequently than expected above the historical baseline in a particular location or set of locations; thus, the pathogen/subtype is used to detect the cluster and thereby also defines the cases included in it. For outbreaks detected through notification, cases are defined by disease (having a certain set of symptoms), place (e.g., having attended a particular event, belonging to an affected group), and onset during a particular time interval. Although descriptive epidemiology is sufficient in some circumstances to define the outbreak (12), the infectious etiology is often needed for the case definition.

Laboratory findings are used with associated epidemiological information to group cases into categories as "confirmed" (laboratory-demonstrated agent), "probable" (strong epidemiological association without laboratory confirmation), or "possible" (weaker epidemiological association). Since cases infected with the same strain are more likely than patients that have not been culture confirmed to have been infected from the same source, such confirmed cases are preferably included in analytical studies such as case control or cohort studies. These types of studies compare exposure information from cases and controls to determine the likely common source(s).

Sometimes cases also cluster with isolates from food, water, or environmental sampling programs; this may provide a hint about the source of an outbreak in the hypothesis generation phase. Food and environmental samples may also be collected and tested as part of a trace-back investigation. This is particularly useful when the epidemiological evidence is not clear and several sources are suspected. Identification of an outbreak strain in an implicated food or food production environment puts most doubt to rest and can be extremely helpful in root-cause analysis. Although a food source may be identified statistically based on epidemiological evidence alone, the isolation of the outbreak strain from that source will provide culture confirmation.

A highly specific and restrictive case definition is usually critical for identifying common sources of outbreaks detected through pathogen surveillance, but widening the case definition is useful to define the true scope of an outbreak to identify cases that may have been missed by a strict microbiological case definition. This phase of the outbreak investigation may require a combination of epidemiological and microbiological approaches. Sometimes patients that do not fit the microbiological case definition are included at this stage because they are ill contacts of cases or have been exposed to the vehicle causing the outbreak (13). In other instances, when an implicated product is tested, additional strains or even different pathogen species are detected. These can be matched with seemingly sporadic cases in the community. Standard epidemiological methods are then used to demonstrate linkage with the new cases in the same manner as for the initial cluster, and the use of molecular methods such as PFGE and WGS increases confidence in the findings. In 2007, an outbreak of *Salmonella* serotype Wandsworth was tracked to a snack food. Testing of the product revealed the presence of another *Salmonella* strain of serotype Typhimurium; the PFGE pattern of this strain did not occur significantly over the historical background in the PulseNet database, but follow-up with interviews nevertheless confirmed 18 additional cases infected with this serotype (14). In the cantaloupe-associated listeriosis described above, patients infected with isolates displaying one of five PFGE patterns were also ultimately associated with exposure through product testing (7).

Finally, the effect of control measures to determine when an outbreak is over is done by monitoring of the incidence of infections caused by the outbreak strain until it has decreased to the level of the historical background.

In summary, investigation of foodborne disease outbreaks provides a unique opportunity for finding and correcting problems in the food supply that might not be otherwise recognized. Advances in molecular diagnostics should accelerate our understanding of the causes of foodborne disease in our communities, thus increasing opportunities for prevention.

METHODS USED FOR OUTBREAK DETECTION/INVESTIGATION AND CONTROL

Pulsed-Field Gel Electrophoresis

PFGE has been extensively discussed in a number of reviews (15, 16) but will briefly be discussed here because since the 1990s it has been the gold standard for discriminatory subtyping of foodborne bacterial pathogens and therefore is the standard against which new subtyping methods are compared.

During the 1970s, advances in molecular biology underscored the fact that the bacterial chromosome is the most fundamental molecule of identity in the cell. This understanding had enormous influence on approaches to epidemiological analysis, leading to the development of a variety of molecular methods for bacterial strain typing. Many of these methods were based at least in part on analysis of DNA restriction fragment patterns by agarose gel electrophoresis but suffered from the limitation that fragments larger than ca. 50 kb in size could not be reproducibly separated. This was remedied in 1984 with the discovery by Schwartz and Cantor (17) that PFGE could reliably separate megabase-sized DNA molecules. While the equipment required for PFGE was somewhat complex, the underlying electrophoretic principle was quite simple. Electrophoretic pulses at equidistant left and right angles from center could force the continuous reorientation of DNA molecules as they move toward the cathode. The larger the molecule, the longer the pulse or "switch time" required for reorientation. Thus, moving from shorter to longer pulses over time "windowed" the separation of smaller to larger DNA fragments ranging from ca. 20 kb to >1 Mb in size. Two additional discoveries were essential to the use of PFGE for epidemiological analysis: (i) the ability to isolate intact chromosomal DNA by *in situ* lysis of bacterial cells encased in agarose blocks and (ii) restriction enzymes with rare chromosomal recognition sites resulting in a manageable number of DNA fragments (e.g., 10 to 30) for post-electrophoresis visual and computer-assisted analysis.

PFGE quickly became the *de facto* standard for high discriminatory subtyping of most bacterial pathogens because (i) the same basic method could be used to subtype virtually all pathogens, a degree of universality that few other molecular methods possess; (ii) with proper standardization and quality control, results were reproducible between different laboratories; (iii) the output was provided in a "bar-code" like representation of >90% of the bacterial chromosome (16) that was easy to interpret; and (iv) semi-automatic computerized analysis was possible using specialized software, e.g., BioNumerics (Applied Maths, Sint-Martens-Latem, Belgium) and FPQuest (Bio-Rad Laboratories, Hercules, CA), enabling comparisons of profiles run on different gels and making it suitable for library type (definitive) subtyping. For these reasons, PFGE has since 1996 been the staple for all PulseNet surveillance as described in the previous section.

However, PFGE also has drawbacks: it is a fairly labor-intensive method requiring at least 2 days from start to finish with a pure culture; specialized equipment and well-trained personnel are a must; not all strains are typeable with PFGE; not all restriction fragments can be separated, making interpretation somewhat subjective; and the method carries no phylogenetic information, since fragments of similar size in different strains may originate at different places in the genome: i.e., patterns that appear similar may only be distantly related phylogenetically. This is the reason why PulseNet routinely only accepts indistinguishable isolates in their case definitions (16). Finally, PFGE does not always provide optimal discrimination for outbreak investigations: some PFGE patterns are more common than others, and it can be difficult to detect and delineate outbreaks caused by very common patterns; e.g., the most common PFGE profile among *Salmonella* serotype Enteritidis makes up almost 50% of the patterns belonging to that serotype in the database (http://www.cdc.gov/SALMONELLA/ENTERITIDIS/) (18).

Whole-Genome Sequencing

PFGE has served PulseNet well for almost 20 years, but because of the drawbacks mentioned in the previous section, the network has constantly been exploring new methods to supplement or even replace PFGE. Until recently no methods were identified that are as universally applicable and have sufficient discriminatory power to be used without PFGE. However, next-generation sequencing (NGS) technologies have become available that enable fairly easy and cost-efficient determination of whole-genome bacterial sequences in 1 to 2 days. Since the genomes of all

strains can be sequenced, WGS is a universal subtyping method; it may provide phylogenetically relevant information, and theoretically it has unsurpassable discriminatory power.

The details of the process of NGS are beyond the scope of this chapter and may be found elsewhere (19, 20). The different sequencing platforms use their own proprietary technology; in common, they all sequence the genome in short random fragments by a shotgun sequencing technique, generating fragment sizes or reads ranging from less than 100 bp to several thousand bp. The shotgun sequencing is repeated multiple times in the same process (massively parallel sequencing), whereby virtually the whole genome is sequenced a number of times. The sequencing coverage is the number of times the sequencing process is repeated across the genome. The reads are cleaned and assembled electronically after they have been generated; the assembly is either performed by aligning the fragments to a well-annotated genome of a closely related strain (reference-guided assembly) or *de novo*, where sequences are assembled based on overlapping regions between different fragments. This procedure is very computer resource-intensive and rarely results in a fully closed genome with the current technologies. Depending on the complexity of the genomes and the read lengths provided by the sequencing platforms, genomes are usually assembled into 5 to 200 pieces of contiguous sequences, or contigs. The notion of "whole"-genome sequencing thus is somewhat of an overstatement since the genomes are rarely fully assembled into one contig.

For surveillance purposes it is useful to retain backward compatibility with previously used subtyping methods. Theoretically, WGS is backward compatible with most molecular subtyping methods, but in practical terms this is rarely the case with the current NGS technology. Restriction fragment length polymorphisms, like PFGE patterns, cannot be reliably predicted from a whole-genome sequence, but this may be possible if the genome is closed and methylated bases are identified, since methylation blocks the action of the most commonly used restriction enzymes. Most sequencing platforms do not generate read lengths that are long enough to bridge regions with many repeats, and NGS is not an efficient way to resolve variable-number tandem repeats (VNTRs), which are the foundation for another molecular subtyping method, multilocus VNTR analysis (MLVA), that has been used increasingly in recent years (21–23). Thus, MLVA profiles can usually not be predicted from shotgun sequencing, either. The newest NGS platform, the PacBio RS II (Pacific Biosciences, Menlo Park, CA), provides information about methylation and generates the longest read lengths so far, enabling the closing of many genomes, which could solve the problem of the lack of WGS compatibility with PFGE and MLVA.

WGS data have been used to identify the phylogenetic diversity within and between bacterial species and are increasingly applied to the investigation of outbreaks detected by other means (24–30). Several analytical approaches may be used, the most common of which are kmer-based approaches, single-nucleotide polymorphism (SNP) analyses, and whole-genome multilocus sequence typing (wgMLST). The principle of the different approaches is illustrated in Fig. 1 and in the text below. Their strengths and weaknesses are outlined in Table 1.

Kmer-based approaches use a computer algorithm to chop the short raw reads or assemblies into smaller pieces of a defined length k ($k = 10$ in Fig. 1A). The optimal length of the kmer is determined by finding which length gives the most specificity and sensitivity when comparing kmers between isolates, and this length may vary by organism (31). Unlike restriction enzymes that only cut at specific sequences, the computer algorithm that generates kmers uses a sliding window to move down the length of the sequence reads or assemblies, 1 bp at a time, until

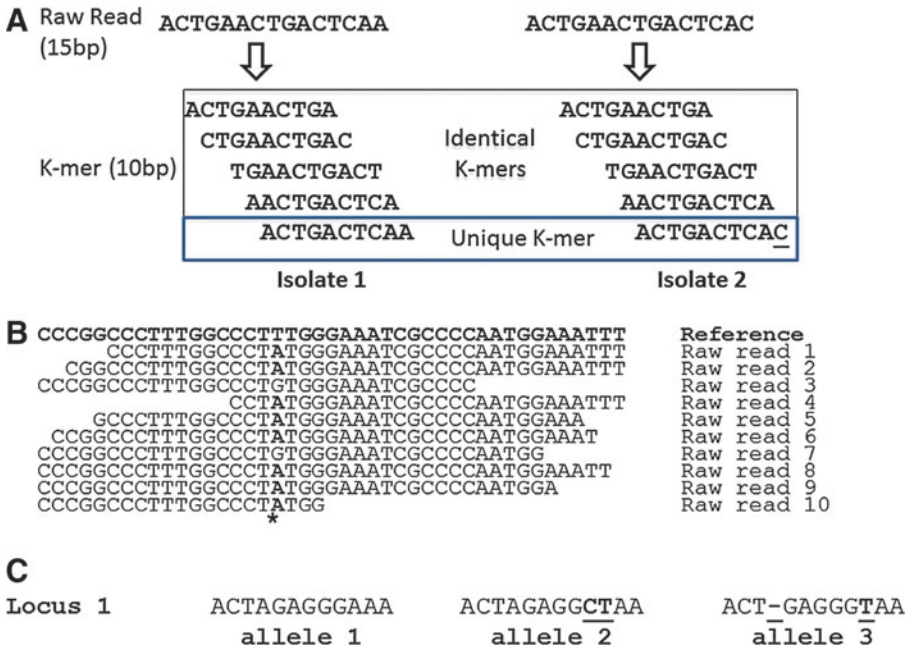

FIGURE 1 Schematic analytical principle of three approaches to whole-genome sequence analysis. (A) kmer, (B) hqSNP, (C) wgMLST.

TABLE 1 Key characteristics of different whole-genome sequencing analysis techniques used in outbreak investigations

Characteristic	kmers	hqSNPs	WgMLST
Speed of initial detection of targets	Intermediate	Slow	Slow
Speed of subsequent analysis	Intermediate	Intermediate	Fast
Requires reference genome	No	Yes	Yes
Identifies position of difference in whole genome	No	Yes	Yes
Leads to strain type nomenclature	No	No	Yes
Can extract virulence, antibiotic resistance, or serotype information from analysis	No	No	Yes
Resolution (for cluster detection)	Coarse initial analysis	High discriminatory subtyping	High discriminatory subtyping

kmers of the specific length *k* can no longer be generated (Fig. 1A). The resulting kmers are then compared between isolates, and the similarities and differences identified are used to approximate relatedness. A variant of the kmer approach is kSNPs, which looks at variation between kmers at the central nucleotide to determine SNP differences between isolate genomes (31). One of the main advantages of kmer-based approaches is that they do not require alignment to a reference genome, as opposed to some SNP-based approaches, and are less computationally intensive than other WGS comparison approaches. Kmers work especially well for coarse initial analysis; for finer-grain analysis the two analytical approaches described below are better suited. A disadvantage of using kmers is that they depend on data quality and do not provide positional information; i.e., kmers in different strains may not be located in the same genetic region, so like PFGE, kmer analysis may not reflect true phylogeny. Since the kmer content changes as isolates are added or removed from the comparison, the kmer profile of an isolate cannot be named unambiguously; i.e., the kmer approaches are comparative by nature.

Another genome comparison approach is the high-quality SNP (hqSNP) approach, which in general is more discriminatory than kmer-based approaches. In the hqSNP approach, the reads from each isolate are aligned against a closed or high-quality draft reference genome ("Reference" in Fig. 1B), generating what is referred to as a pile-up, and SNPs are "called" at positions where the base pair in the pile-up differs from the base pair in the reference genome (A in the pile-up of 10 raw reads in Fig. 1B). Often a SNP is not called until it reaches or exceeds a quality threshold for the number of reads that are aligned at that position (coverage) and the frequency at which that SNP call is found in the reads. These high-quality thresholds vary depending on the clonality of the organism. For rapidly evolving bacteria such as *E. coli*, higher thresholds are used to filter out SNPs in reads that may be due to noise or errors generated by the sequencing procedure; infrequent variants, i.e., rare SNPs, are often also filtered. For *E. coli* the threshold of detection may be set high, at 20 times coverage and 95% frequency. Alternatively, for clonal organisms like *Mycobacterium tuberculosis* the goal of an hqSNP analysis would be to pick up any variation while filtering out errors and noise due to the sequencing process. The threshold of detection of hqSNPs may thus be set lower, e.g., at 5 times coverage and 40% frequency (32). If the organism in Fig. 1B was *M. tuberculosis*, the A SNP would be called because the coverage was 10 times and the frequency 8 out of 10 (80%).

Another consideration when calling hqSNPs is where in the genome the SNP is located. Depending on the organism and the epidemiologic context, it may be more informative to consider only SNPs that are found in coding regions, or even core genes, rather than the entire genome. It may also be advantageous to filter out SNPs from genes involved in horizontal gene transfer, e.g., phages or transposons, which may create noise in comparisons between phylogenetically and epidemiologically closely related isolates. Once the thresholds and SNP positions have been determined, a phylogenetically relevant comparison may be performed. The drawbacks of hqSNP analysis are that it is computationally intensive and, like kmers, is by nature a comparative subtyping method since the hqSNPs are only called if they are present among the isolates being compared.

The wgMLST approach compares genes between isolates rather than individual base-pair positions as is done in hqSNP analysis. In contrast to a traditional MLST approach that compares a limited number of conserved housekeeping genes, typically seven, to determine the sequence type or clonal complex, wgMLST extends the analysis to almost all genes in a genome (33). The different genes or loci included in a wgMLST scheme are determined from a collection of well-annotated reference genomes of isolates that represent the full genetic diversity of the species, pathotype, or serotype being investigated. After the loci are defined, the reads or assemblies of test isolates are compared against these loci and an allele number is assigned if the locus is found. If a test isolate does not contain a locus, it is registered as missing. For each allele, any change in the gene sequence, including insertions, deletions, and SNPs, is used to define a new allele number.

In Fig. 1C, three alleles from a locus named locus 1 are shown differing from the first at the underlined positions. In a seven-gene MLST scheme variations in seven genes or loci are assessed, whereas in wgMLST variations in all genes, typically a thousand or more, are assessed. Often a set of parameters are defined to decide whether the differences between the potential new allele and locus definition are within the variation that is expected in that

coding region. Once all the alleles have been called, these allele numbers are used to compare the genotype of the isolates. As opposed to kmer or hqSNP comparisons that require a new computer-intensive analysis every time new isolate genomes are being added to a comparison, once allele numbers are assigned, just those numbers, rather than the entire WGS, are compared. This greatly cuts down on computational demand for doing new comparisons. Additionally, wgMLST types are definitive and may be named, thereby greatly easing communication between the partners in an epidemiological investigation at variance with kmers and hqSNPs. wgMLST seems to be as discriminatory as hqSNP comparisons in its most inclusive form, and the discrimination may be tailored to the clonality of the organism and the epidemiological context; e.g., in an outbreak situation all loci may be considered, whereas that may not be necessary for microbiological attribution studies. For these reasons, the wgMLST approach seems to be most useful for surveillance networks like PulseNet. A drawback of the wgMLST approach is that allele curation is required.

WGS is now increasingly used to supplement PFGE in the investigation of outbreaks that have been detected by other means. In 2013 it was used as a supplement to PFGE in the case definition of a listeriosis outbreak traced back to artisan cheese produced in Wisconsin (http://www.cdc.gov/listeria/outbreaks/cheese-07-13/). Initially, only PFGE was used to define the cases. However, the outbreak pattern was fairly common, and for two potential case patients, the relation to the outbreak was uncertain: one patient denied consumption of any cheese and another patient who lived in an area where the cheese was sold was lost for follow-up. WGS was performed on isolates from all known patients related to the outbreak, a product isolate, and a number of current and historical clinical isolates displaying the outbreak PFGE pattern; by hqSNP analysis, all isolates and the product isolate formed a tight cluster separate from the historical isolates (Fig. 2). The isolate from the patient who denied cheese consumption did not cluster with the outbreak isolates, whereas the isolate from the patient who had been lost for follow-up did; the case counts of the outbreak were adjusted accordingly.

Months after the closure of the outbreak investigation, additional cases of listeriosis were identified with the outbreak PFGE pattern. There was concern that the outbreak had not been controlled, and the isolates were sequenced. The data was analyzed by all three approaches—hqSNPs, kmers, and wgMLST—and it was shown that these new cases clustered separately from the outbreak isolates. Some of the isolates formed a separate cluster, and a new cluster investigation was started; unfortunately, no common source was identified (CDC, unpublished).

WGS was recently introduced for the surveillance of infections caused by *Salmonella* serovar Enteritidis in the state of New York (18). The utility of the method using hqSNP comparison was first confirmed on historical isolates including a well-defined local outbreak. In this way two additional small clusters that had not been recognized through PFGE-based PulseNet surveillance were identified. Then, the method was implemented for prospective surveillance in 2012. Isolates with an unusual PFGE pattern that was part of a multistate outbreak associated with ground beef also clustered by WGS along with additional isolates with different PFGE patterns not recognized to be part of the outbreak. Unfortunately, the relationship to the outbreak was not epidemiologically confirmed for these isolates. Additionally, a number of clusters were identified among isolates with common PFGE patterns. However, no outbreak vehicle was identified for any of these. This indicates that WGS may provide more specificity to an outbreak investigation than PFGE and at the same time recognize relationships between isolates not apparent by PFGE. The utility of WGS to differentiate between isolates of *Salmonella* serovar Enteritidis displaying the most common PFGE pattern (PulseNet pattern JEGX01.0004) in the United States was also established in a retrospective study by Allard et al. (34).

It is clear that it is feasible to use WGS for the detection and investigation of foodborne outbreaks and that its use adds power to the investigation, but a number of open questions need to be addressed before it may be used for routine surveillance replacing PFGE.

When PFGE is used for cluster/outbreak detection, only isolates with indistinguishable patterns are routinely considered (35). However, with WGS hardly any isolates are identical, and differences between isolates represent a continuum, with outbreak-related isolates showing fewer differences than epidemiologically unrelated isolates. It would be desirable to establish criteria to define an outbreak by WGS. However, few data are currently available to establish such criteria, and currently only data on SNP differences are available. For example, in a comparison of *Salmonella* serovar Javiana isolates from two confirmed outbreaks associated with three PFGE patterns, two of which were related (CDC, unpublished), isolates from the first outbreak (A) differed by 16 to 45 hqSNPs, whereas 6 to 28 hqSNP differences were found between isolates in the other outbreak (B). The median difference between these two outbreaks was 1154.5 hqSNPs. Outbreak A was local, associated with a common meal provider, and B was a multistate outbreak associated with a sandwich chain, with cases identified in five states. These data taken together could indicate that fewer than 50 hqSNPs might be used to define an outbreak. However, in other instances this definition may be too stringent, failing to identify outbreak-related cases, or be the opposite, too relaxed, thereby falsely linking isolates that are not related.

For example, in the study of den Bakker et al. (18) isolates of the highly clonal *Salmonella* serotype Enteritidis in confirmed outbreaks differed by fewer than 3 hqSNPs, whereas isolates from different outbreaks sometimes differed by fewer than 50 hqSNPs. The isolates linked to the artisan cheese listeriosis outbreak mentioned above also displayed very few hqSNP differences (Fig. 2). Thus, at present it is not possible define hard criteria to delineate all outbreaks reliably. This definition will depend on the epidemiological context, the type of outbreak (point source versus ongoing), the clonality of the organism, and the analytical pipeline used.

WGS also shows promise for replacing a number of phenotypic and molecular methods currently being used to identify and characterize foodborne pathogens. For many years, targeted sequence of 16S rDNA and other housekeeping genes has been used to identify the genus and species of bacteria (36). Likewise, virulence genes, serotype encoding genes, and antimicrobial resistance genes are routinely detected by PCR and/or hybridization to characterize foodborne pathogens in reference laboratories. Information about these genes may also be extracted from WGS (37), and such applications are already available on the Web, e.g., ResFinder, VirulenceFinder, and CARD (38, 39). However, to be truly useful for surveillance, these characteristics

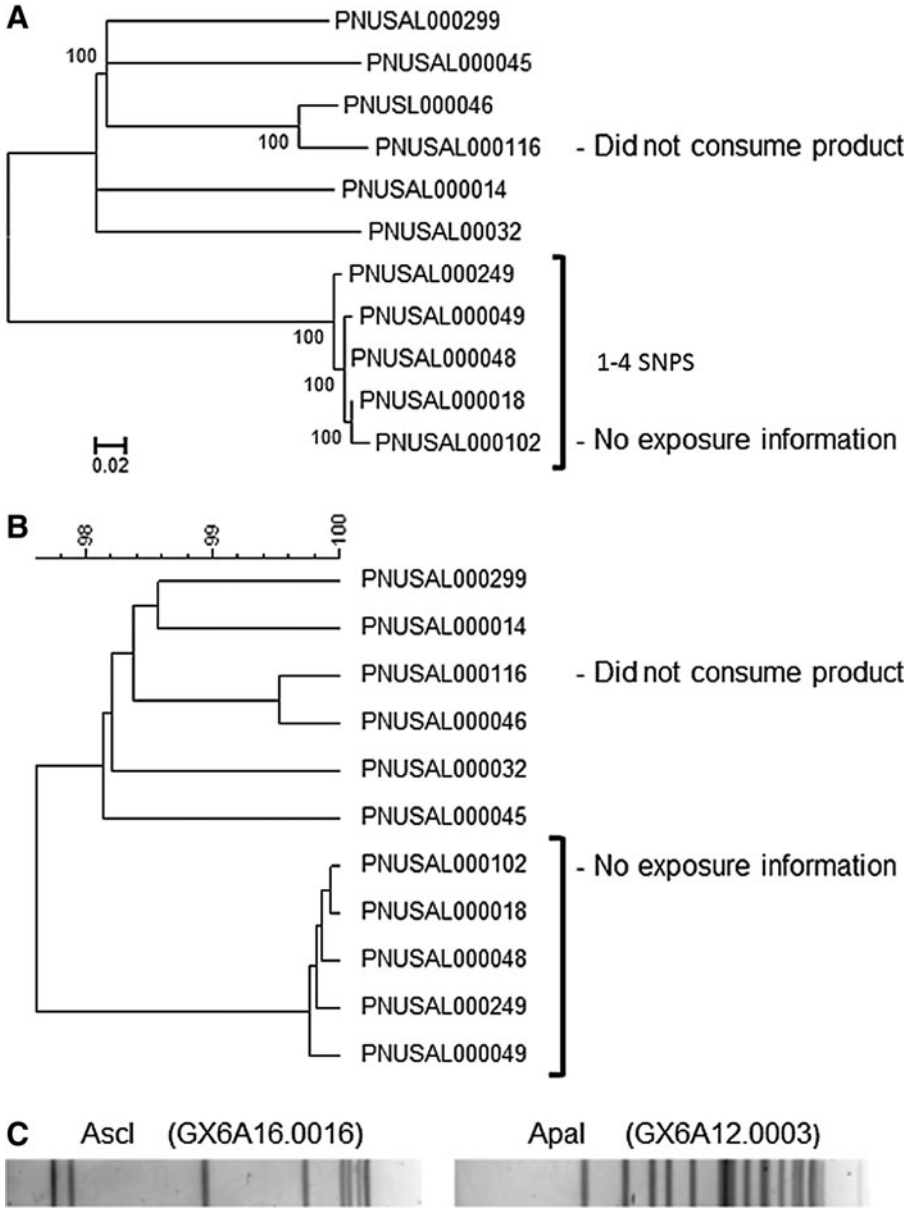

FIGURE 2 hqSNP (A) and wgMLST (B) trees of isolates of *Listeria monocytogenes* that are indistinguishable by PFGE (C). Isolates associated with an outbreak related to consumption of artisan cheese are highlighted with brackets and shown along with contemporary and historical isolates with no relation to the outbreak. The isolates from the patient who did not consume the artisan cheese product or did not have exposure information are denoted. The hqSNP and wgMLST analyses produced equivalent results.The hqSNPs were defined by consensus ≥75% and coverage ≥×10. The wgMLST analysis and UPGMA tree was generated using BioNumerics 7.5 (Applied Maths).

should all be built into the same workflow, thus eliminating the need to manually query multiple websites.

Culture-Independent Diagnostics and Foodborne Disease Surveillance

Molecular diagnostics is changing both clinical medicine and public health practice. An emerging generation of culture-independent diagnostic tests (CIDTs) for rapid diagnosis of patients is in the process of revolutionizing clinical microbiology practice, especially in the area of gastrointestinal disease. These syndrome-based panels not only provide results in a clinically useful timeframe (which is not always the case with culture), but make it possible to efficiently consolidate bacterial, viral, and parasitic pathogens into a single laboratory workflow. Some panels include agents for which practical clinical laboratory tests have not been available, such as enterotoxigenic *E. coli*, enteropathogenic *E. coli*, and norovirus. Despite their obvious benefits for patients, physicians, and clinical laboratories, the emergence of these tests poses a variety of challenges for clinicians and especially for public health (40, 41).

Often, multiple pathogens will be detected in the same specimen, raising the question of whether all are responsible for the patient's symptoms. In some instances, one pathogen is more likely to be causing the patient's symptoms than the other; for example, if *Clostridium difficile* is found along with *Salmonella* in an outpatient that has not recently been treated with antibiotics and that has acute diarrhea, the *Salmonella* is the likely cause of the patient's symptoms. But what if the same pathogens are found in a patient that has been hospitalized for a week? Systematic epidemiological studies are needed to answer questions like this. Of particular public health importance, CIDTs do not result in production of an isolate as part of the testing process. Current subtyping methods used for strain characterization, surveillance, and outbreak detection such as PFGE and WGS require isolates.

Therefore, it will be necessary in the short term to maintain the flow of isolates through reflexive (i.e., automatic) culturing of CIDT positives by clinical or public health laboratories to sustain surveillance. The optimal long-term approach for public health is to develop strain characterization tests that are themselves culture-independent. However, the development challenges are not trivial. As with clinical diagnostic tests, the targets must be conserved within the pathogen group of interest and not be present in the normal enteric biota. Additionally, targets must yield epidemiologically meaningful subtype, virulence, and susceptibility information, and a mechanism must be developed to link targets to a single organism. This is necessary since many virulence and susceptibility mechanisms are not unique to specific enteric pathogens. For example, many STEC strains require specific adherence factors such as intimin to be virulent. Intimin may be present in other gut biota (42) but only functions as an STEC covirulence factor when it is present on the same cell as the Shiga toxin gene.

Metagenomics

Metagenomics is the study of genetic material recovered directly from defined environments. The principal environments of interest regarding foodborne disease are the human gastrointestinal tract; the plants, animals, and complex foods that humans consume; and the environments where food is grown and processed. As will be described below, metagenomics is only partially practical at this time, but it is anticipated that this emerging field will play an increasingly important role in surveillance of foodborne infections as NGS technology, bioinformatics, and computer technology continue to advance. Metagenomics is by nature culture-independent, which is important because (i) only a very small percentage of gut microbes are known to be culturable (43), (ii) the etiology of approximately 80% of cases of foodborne disease is unspecified and mostly unknown (1), (iii) public health pathogen characterization methods that do not require culture will be needed to keep public health monitoring programs viable as clinical diagnostics moves toward culture-independent diagnostics, and (iv) culture-independent characterization methods have the potential for being faster and more efficient than culture. Metagenomics has the same drawback as CIDTs for clinical diagnostics concerning the problem of determining the cause of a patient's symptoms if multiple pathogens are detected. The range of potential applications for metagenomics in foodborne disease surveillance is vast and largely untapped, including characterization of pathogens for disease monitoring programs such as PulseNet, pathogen discovery in outbreaks of undetermined etiology, improving understanding of microbial communities in illness and health, food identification pre- or postconsumption as part of outbreak investigations, and examination of host factors. We anticipate that at some time in the next 15 years clinical diagnostics and public health testing will merge into a single testing paradigm that includes metagenomics and perhaps one or more of the other "omics" such as metabolomics or metaproteomics.

The human gut is a complex environment with over 10^{14} microorganisms, 1,200 described species and 10,000 to 40,000 predicted total species. Each individual is thought to typically harbor 1,000 bacterial species, and 2% of one's microbial species are shared by at least 50% of the population (43). The microbial load includes bacteria, viruses, fungi, and eukaryotic parasites. In addition, human DNA is present, presumably at higher levels during an inflammatory response to pathogens such as *Salmonella*, *Shigella*, and pathogenic amoeba. DNA is also present from plant and animals consumed as food. On the surface, it would seem that applying metagenomic analysis to such a mixture would be a fool's errand, that signal-to-noise and data management obstacles would be overwhelming. However, as both sequencing and computing technology rapidly advance, this approach should become increasingly practical.

Two basic approaches to metagenomics exist: amplicon sequencing and shotgun metagenomics (44). Both have potential applications in foodborne disease surveillance.

The most widely used amplicon sequencing approach uses 16S and 18S rRNA loci for characterization of bacterial and eukaryotic populations, respectively. Since this approach involves amplification, signal-to-noise issues are greatly reduced. Assays based on 16S are used routinely in research and are becoming increasingly common for diagnostic applications such as fever of unknown origin (45) and for broad characterization of microbial populations in the environment. Molecular markers including 18S have been used in the identification of seafood to control mislabeling (46) and could presumably be used to identify complex food components in an outbreak setting. Both 16S and 18S were used by Ottesen et al. to characterize the microbial biota of tomato plants in an effort to understand root causes of tomato-associated salmonellosis outbreaks (47). Unfortunately, 16S does not provide sufficient differentiation of most foodborne pathogens and would not be applicable for subtyping or further characterization. Alternate targets for use in a fecal or food matrix may prove useful for foodborne disease. Such targets would need to be bounded by loci that are conserved within and unique to the pathogen of interest. The region between the PCR binding sites would need sufficient heterogeneity to answer epidemiological questions as needed (e.g., species, serotype, subtype, virulence, and antibiotic susceptibility), and markers would need to be linked by quantitative or other means to assure that they are on the same cell.

Shotgun sequencing ("deep sequencing") represents the other major metagenomics approach. In this process, total nucleic acids are sheared, sequenced, and analyzed. Raw reads are either identified directly by comparison to reference genomes or reads are assembled and contigs identified in the same manner as when assembling genomes from pure cultures. Shotgun sequencing theoretically allows any organism present to be sequenced with no *a priori* knowledge. Maximum information about the sample is obtained, and it should be possible to tease apart complex microbial

interactions. This could be especially useful for foodborne outbreaks of undetermined etiology. A process that made it practical to assemble pathogen genomes directly in specimens without the need for culture could replace current surveillance methods. Some success was achieved by Loman et al. with sequencing of the *E. coli* O104:H4 genome from the massive 2011 outbreak in Germany (48) using this approach. However, the authors have highlighted important limitations with current technology including high cost, lack of speed, and poor diagnostic sensitivity. With fecal samples, sensitivity may be the largest barrier to overcome because target pathogens may be present at frequencies many orders of magnitude below that of the background biota. For example, to obtain 30× coverage for a pathogen present at 10^5 genomes/ml in a background of 10^{11} genomes/ml, 3.0 $\times 10^7$ coverage would be required—a staggering amount of sequencing. Computational resources are also limiting with current algorithms for assembly and analysis (44). However, several likely advances may alter this adverse equation including (i) better physical mitigation methods (removing nucleic acids that are not of interest), (ii) sequencing technology that produces longer and higher-fidelity reads, which require less coverage, (iii) cheaper sequencing technology, (iv) more efficient pipelines and improved analysis software, and (v) greater computing and data storage infrastructure. Active research and development are occurring in all of these areas.

The change in molecular epidemiological methods used by public health agencies from PFGE to WGS and ultimately to metagenomics will likely continue for at least a decade. The technological knowledge and the insight into the genomics of pathogens we gain from culture-based WGS are critical to the development of culture-independent metagenomic methods to meet the food safety challenges of the 21st century. In the interim period the challenge will be to retain cultures for public health surveillance until the sequencing technology and bioinformatics have evolved to a state that makes real-time metagenomics feasible and cost-effective.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Role of Molecular Methods in Improving Public Health Surveillance of Infections Caused by Antimicrobial-Resistant Bacteria in Health Care and Community Settings

FRED C. TENOVER

20

The first multidrug-resistant isolates of *Enterobacteriaceae* that were recognized as clinically significant were strains of *Shigella* spp. isolated in Japan in the late 1950s. These strains demonstrated resistance to chloramphenicol, streptomycin, sulfonamides, and tetracycline (1). By 1960, Watanabe and Fukasawa had demonstrated that all four resistance markers were transmissible from *Shigella* donor strains to recipient strains of *Escherichia coli* and *Salmonella enterica* serovar Typhimurium via R-factors (2). Resistance to these and other first-line antimicrobial agents, however, remained rare among other genera of the *Enterobacteriaceae*. Resistance was seen as an anomaly. The discovery of the TEM beta-lactamase (3), which would become the most common cause of ampicillin and first-generation cephalosporin resistance in contemporary *E. coli* isolates, was still 6 years away. In the 1970s, reports of multidrug-resistant bacteria began to appear more frequently, and susceptibility to beta-lactams, aminoglycosides, and sulfonamides began to wane (4). Fast-forward to the 21st century when pan-susceptible clinical isolates of bacteria are now rare and multiple drug-resistant organisms (MDROs) representing dozens of bacterial species have been recognized and are spreading worldwide (5). Multidrug-resistant strains of staphylococci, enterococci, pseudomonads, acinetobacters, and members of the *Enterobacteriaceae* family are isolated with increasing frequency in clinical microbiology laboratories around the world, and controlling their spread has become a public health priority (6). Globally, we have now moved into the era of antimicrobial resistance.

SURVEILLANCE DEFINITION

Surveillance is a key component of public health practice for both health care-associated and community-associated infections. The World Health Organization (WHO) defines public health surveillance as "the continuous, systematic collection, analysis, and interpretation of health-related data needed for the planning, implementation, and evaluation of public health practice" (http://www.who.int/topics/public_health_surveillance/en/). Antimicrobial resistance surveillance is a crucial public health activity, which must also fulfill all of these roles. It must not only provide epidemiologic data but monitor the effectiveness of interventions and inform public health policy. Ideally, to accomplish this broad mission, a truly global and highly integrated surveillance system is needed since resistant bacteria do not honor national borders. But, as the 2014 WHO surveillance report makes abundantly clear, there is a critical absence of harmonization among the many local, regional, and national surveillance systems around the world (5). This chapter will explore multiple aspects of antimicrobial resistance surveillance and the role that molecular methods play.

Fred C. Tenover, Cepheid, 904 Caribbean Drive, Sunnyvale, CA 94089.

SURVEILLANCE SYSTEMS

European Centre for Disease Prevention and Control (ECDC)

EARS-NET

The European Antimicrobial Resistance Surveillance Network (EARS-NET), a program of the ECDC, tracks 35 specific organism-resistance combinations (some of which include just resistant levels and others in which resistant and intermediate values are combined) and makes the data available on the ECDC website. These can be viewed at http://www.ecdc.europa.eu/en/healthtopics/antimicrobial_resistance/database/Pages/map_reports.aspx. This is a valuable tool for following trends in antimicrobial resistance longitudinally among multiple organism-drug combinations in Europe and exploring or ascertaining the effects of natural bacterial evolution and various public health and health care-based interventions. The data are collected from multiple laboratories in up to 31 countries. The EARS-NET website notes the following limitation: "The number of isolates reported per country to EARS-NET can vary substantially due to large variations in the number of inhabitants or reporting laboratories. To avoid extreme values, country data are only shown on maps if they are based on at least 10 isolates." Even given this limitation, the data provide tremendous insights into the changing epidemiology of antimicrobial resistance across Europe.

Regional MRSA Control Efforts in Europe

The decline of methicillin-resistant *Staphylococcus aureus* (MRSA) rates in a number of countries across Europe over the last decade has been well documented in the EARS-Net system (Fig. 1). Regional surveillance efforts, such as those in Germany, have also demonstrated the success of the region-wide "search and follow" strategy (slightly different from the "search and destroy" policy used in The Netherlands [7]) for reducing MRSA rates, a program that has been implemented in 40 German hospitals (8). These are important data because they demonstrate the impact of specific efforts to stem the decrease in MRSA incidence in a region, not just in a single hospital, and emphasize the importance of monitoring the effectiveness of the intervention with continued surveillance.

Coupled with the surveillance efforts focused on defining MRSA rates of infection are the efforts to track specific strain types of MRSA across Europe. Data on the staphylococcal protein A (spa) types of MRSA circulating in Europe have been instrumental in delineating the local and regional evolution of MRSA in Europe (9). Strain typing is a valuable public health tool because it indicates fluctuations in, and evolution of, strains in regions over time. It is intriguing to compare the spa types circulating in Europe with those in the United States (9, 10). Of the top five spa types in Europe in 2010, only two are commonly seen in the Unites States (i.e., t002 and t008), showing the importance of local selective pressures on the evolution of strains. Local evolution of strains of MRSA was also described by Li et al. (11). As MRSA strains change, so do virulence characteristics, such as the acquisition of the Panton-Valentine Leucocidin (PVL) toxin, as well as antimicrobial resistance patterns, which typically adapt to antimicrobial use patterns in a region. It is critical from both a public health and a medical standpoint that antimicrobial resistance patterns be monitored so that interventions to halt the spread of resistant microorganisms can be monitored and so empiric therapy for bloodstream and other infections can be optimized. Molecular assays, such as PCR-based tests for MRSA and methicillin-susceptible *S. aureus* (MSSA) that can be performed directly on clinical samples (12), can guide therapy in a hospital or emergency rooms to decrease unnecessary use of MRSA-active drugs (13). Molecular assays that track the spread of clindamycin resistance determinants, such as *ermA*, and erythromycin resistance determinants, such as *msrA*, which does

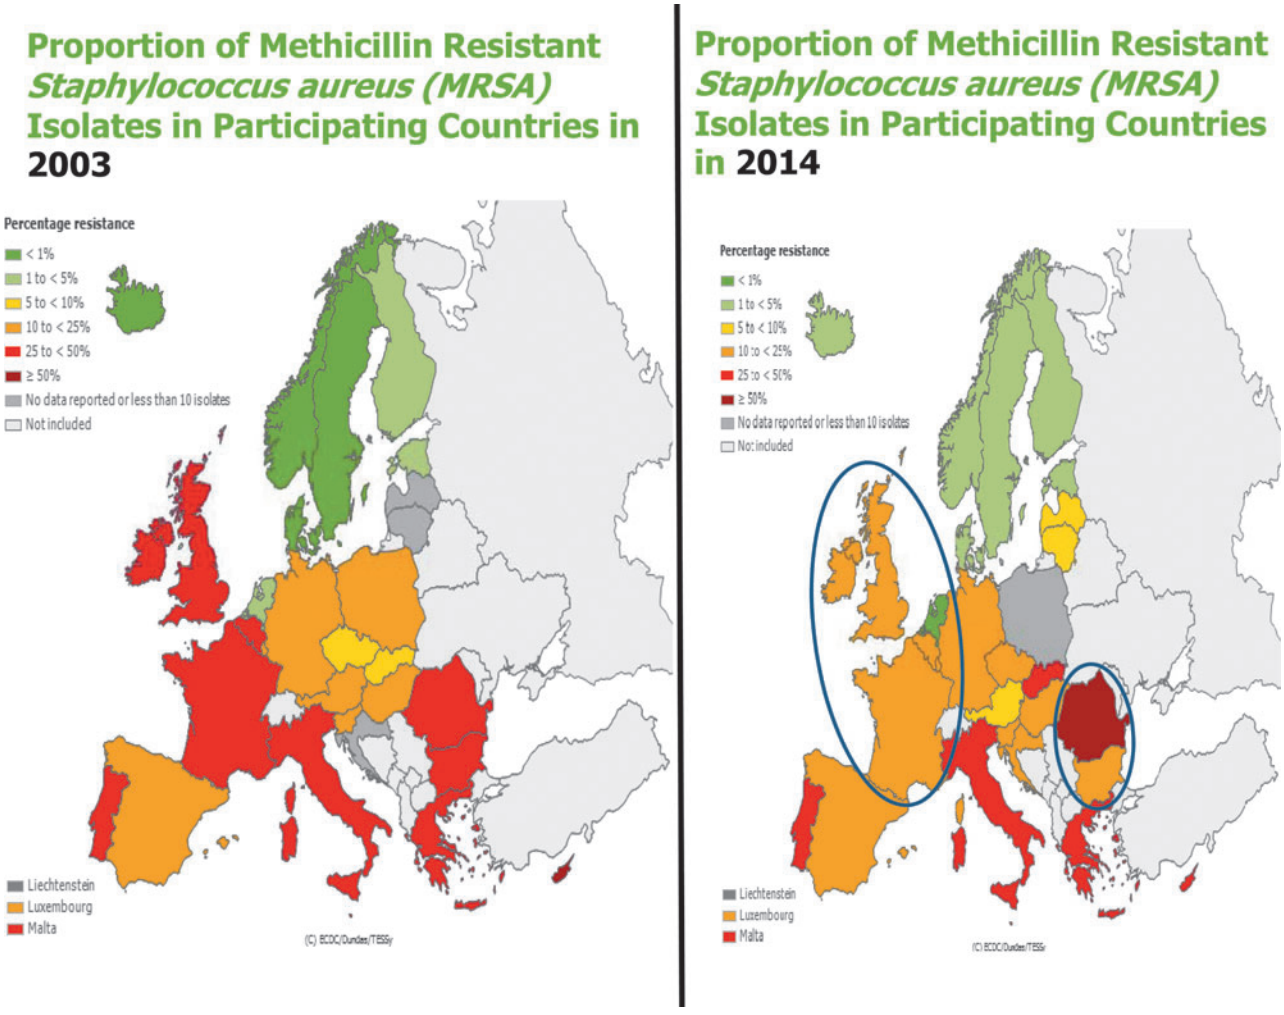

FIGURE 1 Data on prevalence of MRSA in Europe in 2003 and 2014 from EARS-NET (http://www.ecdc.europa.eu/en/healthtopics/antimicrobial_resistance/database/Pages/map_reports.aspx). Significant changes are indicated in the circled areas.

TABLE 1 Susceptibility of *Klebsiella pneumoniae* isolates to carbapenems in France, Greece, Italy, United Kingdom, and Germany in 2013[a]

Country	No. susceptible	No. intermediate	No. resistant	Total (*n*)	%S[b]	%I[b]	%R[b]
France	1,821	9	12	1,842	98.9	0.5	0.7
Germany	737	1	5	743	99.2	0.1	0.7
Greece	479	12	718	1,209	39.6	1.0	59.4
Italy	930	24	499	1,453	64.0	1.7	34.3
United Kingdom	1,044	2	5	1,051	99.3	0.2	0.5

[a]Data from EARS-NET (http://www.ecdc.europa.eu/en/healthtopics/antimicrobial_resistance/database/Pages/map_reports.aspx).
[b]S, susceptible; I, intermediate; R, resistant.

not mediate clindamycin resistance (14), could potentially be of value in defining empiric therapy for wound infections when clindamycin is a consideration (15). However, such programs are not currently in place.

Tracking Carbapenem Resistance

Carbapenem resistance in *Klebsiella pneumoniae* and *E. coli* is also tracked by EARS-NET. Table 1 shows an example of data for carbapenem resistance in *K. pneumoniae* in five countries. Phenotypic data are important for understanding changes in resistance patterns over time, but molecular analysis of the mechanisms of carbapenem resistance is critical for understanding the epidemiologic spread of resistance. Data from several studies, including surveillance studies in the United Kingdom (16), Belgium (17), and France (18), provide important insights into how carbapenem resistance is evolving in Europe, including the emergence of OXA-48-containing strains. This is important because such strains may not grow well on first-generation chromogenic agars, especially those that contain third-generation cephalosporins as the selective agents (19, 20).

North American Surveillance Systems

CDC

National Antimicrobial Resistance Monitoring System (NARMS)

The CDC has several surveillance systems that collect and analyze data on antimicrobial resistance. NARMS is a collaboration among state and local public health departments, the CDC, the U.S. Food and Drug Administration (FDA), and the U.S. Department of Agriculture (USDA) to track changes in the antimicrobial susceptibility patterns of key enteric bacteria that (i) cause human infections (CDC), (ii) are present in retail meats (FDA), and (iii) are recovered from food animals (USDA) in the United States. Public health laboratories submit *Salmonella*, *Campylobacter*, *Shigella*, *E. coli* O157, and *Vibrio* (other than *Vibrio cholerae)* spp. isolated from clinical specimens from humans to a central laboratory for antimicrobial susceptibility testing (21). Retail meat sampling is carried out in 14 states, which includes sampling of chickens, ground turkey, ground beef, and pork chops. Isolates also undergo strain typing. The USDA performs similar testing on *Salmonella*, *Campylobacter*, *Enterococcus*, and *E. coli* obtained from food-producing animal specimens at slaughter houses and processing plants throughout the United States. There is only limited use of molecular testing for mechanisms of resistance in these surveys.

National Healthcare Safety Network (NHSN)

NHSN (http://www.cdc.gov/nhsn/dataStat.html) monitors health care-associated infections (HAIs) in the United States among almost 13,000 facilities and generates data by state, by region, and nationally. The system, which began as the National Nosocomial Infection Surveillance System, was developed to help hospitals identify potential outbreaks of HAIs in their institutions, measure the effectiveness of infection prevention efforts, and ultimately control the spread of HAIs. The data that were collected, initially from approximately 300 hospitals, were used to establish benchmark rates of key device-associated infections that hospitals could use to judge the effectiveness of their infection control programs against those of other hospitals of similar size or case mix. Data gathered included central line-associated bloodstream infections, catheter-associated urinary tract infections, surgical site infections, and ventilator-associated pneumonia (22). The system also tracks rates of antimicrobial resistance by organism for key organism-drug combinations (23), providing trending data over time. These data have shown the rise and eventual decline of central line-associated bloodstream infection MRSA rates in the United States over the last decade (24). Both the National Nosocomial Infection Surveillance System and NHSN have also served as an early warning system for the emergence of vancomycin-resistant *Enterococcus* infections, vancomycin-resistant *S. aureus* (25), and most recently, carbapenem-resistant *K. pneumoniae*.

These systems have also documented the positive impact of a variety of public health interventions, such as antibiotic stewardship and implementation of contact precaution strategies, to halt the spread of MDROs, such as those detailed in the CDC's latest report on HAIs (26). The report documents the progress that has been made over the last several years with regard to the "National Action Plan to Prevent Healthcare-Associated Infections: Road Map to Elimination" set by the U.S. Department of Health and Human Services. NHSN has played a central role in monitoring the epidemiology of HAI problems, and the data have guided the CDC and Department of Health and Human Services in developing public health policy. Among recent developments, NHSN data indicate that healthcare-associated *Clostridium difficile* infections are now more common than health care-associated MRSA infections in the United States (27)—likely a consequence of the way antimicrobial agents are used. Since organisms are not collected by the NHSN system, characterization of resistance mechanisms using molecular methods and strain typing data is not generated on a routine basis.

Gonococcal Isolate Surveillance Program (GISP)

Another CDC-based antimicrobial-resistance surveillance program is GISP, which tracks the development of resistance in *Neisseria gonorrhoeae* from a modest number of public health clinics where antimicrobial susceptibility testing is performed on the first 25 isolates recovered each month from men who seek health care at the clinic. Sexually transmitted infection clinics from 29 state or city health departments contributed 5,495 gonococcal isolates to GISP in 2012 (http://www.cdc.gov/std/gisp2012/gisp_2012_text_figures_tables_web.pdf). Fortunately, decreased susceptibility to ceftriaxone (defined as MIC ≥ 0.5 μg/ml) remained low at 0.3%. The data on fluoroquinolone resistance, however, are not as encouraging. In 2012, 27.1% of *N. gonorrhoeae* isolates from men who had sex with men demonstrated ciprofloxacin resistance (defined as MIC ≥ 1 μg/ml), while 8.7% of isolates from men who had sex with women showed resistance. Thus, ciprofloxacin is rarely used during first-line treatment. Strain typing is not routinely undertaken by GISP. The availability of rapid molecular methods to test for antimicrobial resistance to fluoroquinolones and extended-spectrum cephalosporins directly in clinical samples would be of tremendous value. Methods to identify wild-type strains, i.e., fluoroquinolone-susceptible isolates, have been described but never implemented as part of the surveillance program (28).

Canadian Antimicrobial Resistance Surveillance System

Canada also has an excellent surveillance system for antimicrobial-resistant bacterial pathogens. The Canadian Antimicrobial Resistance Alliance launched a website in early 2007 (www.can-r.ca). The site is described as "an online research portal designed to aid and educate Canadian health care providers on the escalating issue of antimicrobial resistance in Canada." The Canadian Hospital Ward Antibiotic Resistance Surveillance study was "the first national, ongoing, prospective, surveillance study assessing antimicrobial activity against pathogens from Canadian hospitals, including hospital clinics, emergency rooms, medical and surgical wards and ICUs." Unlike many other surveillance systems, this study included the molecular characterization of key pathogens such as MRSA in their methods. Pulsed-field gel electrophoresis (PFGE) typing of MRSA isolates as well as staphylococcal cassette chromosome *mec* (SCC*mec*) typing and detection of PVL toxin genes by PCR are part of the analyses. In addition, molecular characterization of extended-spectrum beta-lactamase (ESBL) genes is undertaken to better understand the epidemiology of resistance genes in Canada. Thus, the understanding of antimicrobial resistance determinants in the Canadian system is more comprehensive than in many other surveillance systems. The increase in the diversity of carbapenem resistance determinants in Canada is shown in Fig. 2.

Australian Group on Antimicrobial Resistance (AGAR)

The AGAR system in Australia supports a survey of antimicrobial resistance results for *S. aureus*, *Streptococcus pneumoniae*, enterococci, and Gram-negative bacilli. The resistance data are supplemented with molecular testing to delineate the mechanisms of resistance that are spreading across the continent (http://www.agargroup.org/surveys). AGAR collects data from 30 microbiology laboratories in Australia, including 4 private laboratories. AGAR has also conducted a number of strain typing studies to delineate changes in the epidemiology of MRSA and other pathogens in Australia.

WHONET

WHONET is not a surveillance system *per se*; rather, it is a freely available software tool that facilitates analysis of

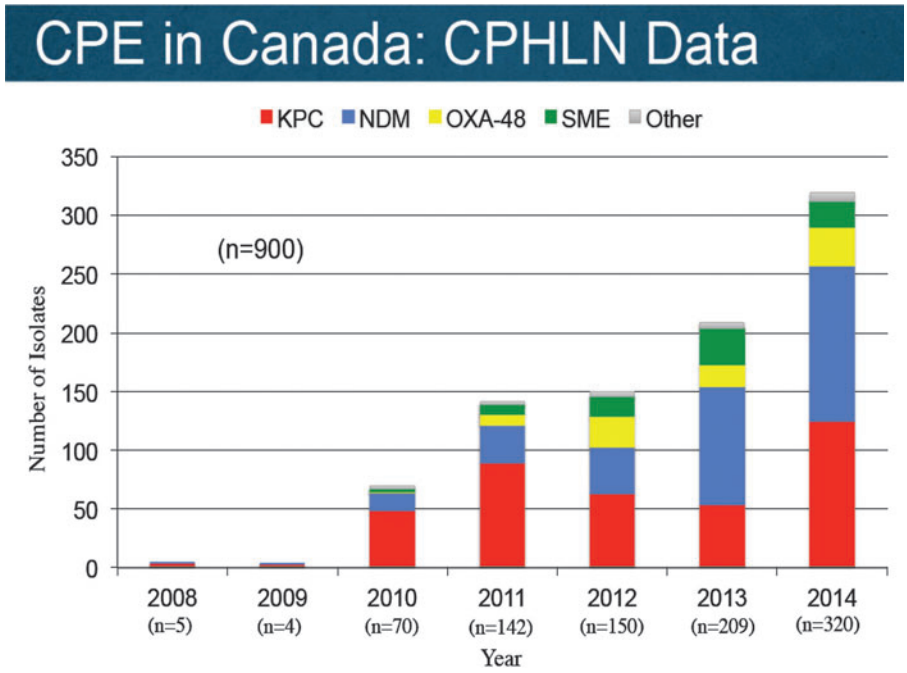

FIGURE 2 Types of carbapenemase-producing *Enterobacteriaceae* in Canada. Data from the Canadian Public Health Laboratory Network. Used with permission from Michael Mulvey.

antimicrobial resistance data at the laboratory level (described in detail in chapter 48). While national surveillance data are critical for monitoring the development and spread of antimicrobial resistance, local monitoring is also important. The WHONET software can be used to amalgamate resistance data from a single hospital, or the scope of the surveillance can easily be expanded to include data from multiple laboratories within a region. It can generate antibiograms from automated antimicrobial susceptibility testing systems in hospitals, indicate potential outbreaks, and monitor trends of antimicrobial resistance by bacterial species. It can also be used regionally, as was done in laboratories in Argentina to detect outbreaks of *Shigella* spp. (29). WHONET has the potential to be used globally to provide an unprecedented view of antimicrobial resistance trends by linking the routine antimicrobial susceptibility data generated daily from thousands of microbiology laboratories around the world into a single database (30). The quantitative data (both MICs and zone diameters) are an untapped resource that can be compiled irrespective of the breakpoints used for monitoring resistance trends. Of course, ensuring the quality of the data when they are drawn from a very diverse sampling of laboratories internationally is always the challenge. It would be necessary to make sure that the data imported to the database had undergone rigorous quality control and were generated using standardized laboratory protocols. This is more likely now than a decade ago, given the broad adoption internationally of both the European Union Committee on Antimicrobial Susceptibility Testing (EUCAST) and Clinical Laboratory and Standards Institute (CLSI) guidelines. The WHONET system has tremendous potential for informing public health agencies about the evolution of antimicrobial resistance globally and may also provide options to integrate typing data, e.g., those freely available after diagnostic mass spectrometry or those developed during specific molecular typing projects.

MOLECULAR TOOLS FOR SURVEILLANCE OF ANTIMICROBIAL RESISTANCE

Molecular Methods for Detection and Characterization of Antimicrobial Resistance Genes

Public health laboratories often collect antimicrobial-resistant isolates for further characterization. PCR assays are frequently used to identify specific antimicrobial resistance genes within resistant strains both to understand the mechanisms of resistance present as well as for epidemiologic purposes. Microarrays with multiple resistance genes have also been used to characterize large collections of isolates to understand the diversity of resistance mechanisms present in geographic regions (31). The ever-expanding list of extended-spectrum beta-lactamases and carbapenemases has been a challenge for molecular surveillance tools. Findlay et al. recently reviewed several commercial methods that can detect carbapenem resistance genes directly in clinical specimens, such as rectal swab samples, and that can be used to detect patients who are colonized with carbapenemase-producing organisms (32). These included the CheckPoints microarray, EasyPlex, and Xpert Carba-R. The study focused on what the authors called "the big 5" carbapenemase families, namely KPC, NDM, OXA-48, VIM, and IMP. The authors noted in their study that both EasyPlex and Xpert Carba-R detected the genes encoding OXA-48 but not the subset containing OXA-181. OXA-181 is becoming more common in Europe (33), so being able to detect strains containing this carbapenem resistance gene was deemed important. A footnote in the article noted that newer versions of both assays that include OXA-181 were tested subsequent to the original study, and those determinants are now detected. Updating commercial assays will be a continuing challenge for manufacturers, especially given the regional differences in the epidemiologic spread of specific resistance determinants. Thus, more generic methods including those based on targeted DNA sequencing may need to be developed.

Epidemiologic studies conducted by Lascols et al. have been undertaken using commercial arrays of beta-lactamase genes (34). These data have been helpful for clarifying the distribution of both ESBL and carbapenem resistance genes in *K. pneumoniae*, *Klebsiella oxytoca*, *E. coli*, and *Proteus mirabilis* in the United States. While these snapshots (i.e., point prevalence studies) provide very helpful information, such surveys are not conducted in a systematic fashion, so trending information, which would be very useful from a public health perspective, is not readily available.

Tuberculosis Detection Methods

Approximately one-third of the world's population continues to be infected with tuberculosis. WHO estimates that in 2013, 9 million people developed tuberculosis and 1.5 million died from the disease (35). Human immunodeficiency virus infection contributes to the spread and severity of tuberculosis. WHO estimates that of those who died from tuberculosis in 2013, 360,000 were HIV-positive. A major factor that contributes to our inability to control tuberculosis is the development and spread of multidrug-resistant (MDR) strains. Approximately 3.5% of all new tuberculosis cases were MDR in 2013 (35). This translates into an estimated 480,000 people having developed MDR-TB in 2013, which is an astonishingly high number. Unfortunately, the treatment success rate for MDR-TB is typically <50%.

Laboratory diagnosis of tuberculosis has traditionally relied on a combination of acid-fast smears and agar- and broth-based culture methods. However, molecular detection and identification methods, including the Gen-Probe (now Hologics) Amplified Molecular Test (36), the Hain line probe assay (37), and the Cepheid Xpert MTB/RIF test (38), have transformed the diagnosis of tuberculosis from a 4- to 6-week time frame to same-day diagnosis, and ultimately, to less than 2-hour diagnosis. Line probe tests are also available to detect resistance to second-line antituberculous drugs (39). Confirmation of the presence of *Mycobacterium tuberculosis* in a clinical specimen and detection of drug resistance markers, such as rifampin resistance, which is a surrogate marker for multidrug resistance, are critical for treating patients effectively (40). According to WHO, in 2013 only "58% of the 4.9 million pulmonary TB patients notified globally were bacteriologically confirmed via a WHO recommended test, including rapid tests such as Xpert MTB/RIF" (35). This means that although there are over 100 high-burden developing countries that have access to rapid, PCR-based diagnostics for tuberculosis, there is still considerable room for improvement in the diagnosis and treatment of tuberculosis globally. In South Africa, the laboratory data from approximately 300 GeneXpert PCR platforms is captured in real time in a cloud-based system, which makes monitoring

the data on tuberculosis (e.g., number of tests performed, number positive for *M. tuberculosis*, percentage of rifampin-resistant strains) feasible for the National Health Laboratory System to optimize the tracking of tuberculosis nationwide and make the best use of health care resources (see chapter 49).

In the United States, the Xpert MTB/RIF test has been cleared by the FDA for releasing patients from respiratory isolation (41). This follows the publication of several articles indicating the utility and cost effectiveness of using rapid diagnostic tests for optimizing the use of respiratory isolation rooms in hospitals (42, 43).

Use of Molecular Strain Typing Methods To Track Specific Clones of MDROs

Strain typing is critical to public health efforts to track and control bacterial diseases. Typing methods have evolved over time from simple phenotypic methods, such as biochemical analyses, serotyping, antimicrobial susceptibility testing pattern analysis (antibiograms), and bacteriophage typing, to molecular methods including plasmid analysis, randomly amplified polymorphic DNA, repetitive element PCR, PFGE, multilocus variable number tandem repeat analysis, and multilocus sequence typing (MLST), to whole-genome sequencing. Several attempts to develop interpretive criteria for typing results and harmonize typing methods internationally have been undertaken (44–46), and databases to facilitate the analysis of strain typing information, such as for MLST (e.g., http://www.mlst.net/) and spa types (http://www.spa.ridom.de/) are now available.

MSSA and MRSA Investigations

One of the first pathogenic clones to come to the attention of public health agencies was the MSSA strain designated bacteriophage type 80/81 (47). This organism, which was once the scourge of Australian, American, Canadian, and European hospitals, causing devastating outbreaks of staphylococcal disease, especially in nurseries and neonatal units, was the focus of intensive public health efforts for over a decade. Widespread use of hexachlorophine, streptomycin, and intensive infection control programs finally brought outbreaks under control. In fact, the strain type seemed to fade away in the 1960s, only to reemerge a decade later as a novel MRSA strain, after acquisition of a SCC*mec* element type IV (which contains the methicillin resistance gene, *mecA*). It was positioned in the lineage called the Southwestern Pacific Clone, which by multilocus sequence typing, was in clonal complex 30 (48). Interestingly, this lineage is one of the few that contains the PVL toxin, a potent virulence factor (49), which likely contributed to its disease-inducing potential. The importance of PVL toxin as a virulence factor was to achieve broader public health significance with the emergence of PVL-positive strains of MRSA in France (50) and community-associated MRSA strains in the United States, especially pulsed-field types USA300 and USA400 (51). Such strains, especially USA300, have become the predominant cause of skin infections in the United States (52) and cause devastating cases of staphylococcal pneumonia (53).

Controlling the spread of MRSA has been a challenge for public health agencies for nearly five decades (54). The rise of MRSA strain USA300 is a clear example of the important role molecular typing data play in tracing not only the emergence and spread of microorganisms but also the evolution of pathogens. USA300 is a PFGE type (44), originally defined by McDougal and colleagues at the CDC in the United States (55). The "USA type" PFGE definitions were developed in response to the problem of trying to track the movement of the international MRSA strains in the United States when those strains had multiple designations in the medical literature (55). The multiplicity of names for the same MRSA strain was particularly confusing when trying to understand whether MRSA outbreaks in the United States were being caused by endemic strains or were due to the influx of novel MRSA strains from Europe, Australia, and the Far East (56). The USA type designations attempted to consolidate and clarify the multitude of strain designations that were appearing in various publications. The USA typing scheme served its purpose well, especially during the period in the 1980s and 1990s when PFGE was the predominant typing method for *S. aureus* for public health laboratories.

Strain typing of MRSA isolates now focuses more on MLST, spa typing, and SCC*mec* typing results than PFGE data, yet PFGE data still have considerable utility for tracking hospital outbreaks. Translating one strain type to another is still a problem. For example, Tenover et al. typed a large series of MRSA isolates obtained from nasal colonization studies and bloodstream infections from patients in the United States by both spa and PFGE typing (57). They reported that isolates of PFGE type USA300 could be subdivided into at least 14 spa types. USA300 has emerged not only as the major cause of skin infections and bacteremia in the United States, but has spread globally as well (58). The USA300 lineage has continued to evolve, adding multiple antimicrobial resistance determinants (59), including those mediating resistance to gentamicin, tetracycline, and fluoroquinolones.

Tracking Multiresistant Gram-Negative Infections

In addition to MRSA, public health laboratories also track the spread of resistant Gram-negative organisms, such as extended-spectrum beta-lactamase-producing strains of *E. coli* (60) and carbapenem-resistant *K. pneumoniae* (61). bla_{KPC} (*K. pneumoniae* carbapenemase), which is a class A serine-based beta-lactamase (class 2f in the scheme of Bush and Jacoby [62]), was first described by Yigit et al. in 2001 (63). However, the *K. pneumoniae* isolate that harbored bla_{KPC} was first isolated in North Carolina in 1996, which raised the question of whether there were many other carbapenemase-producing isolates that simply escaped laboratory detection during that 5-year period. Molecular epidemiologic studies using MLST to trace the spread of bla_{KPC}-containing *K. pneumoniae* isolates revealed that although there was a multiplicity of MLST types represented among the strains collected from across the United States, the majority were ST 258. Examination of international strains of carbapenem-resistant *K. pneumoniae* revealed an epidemiologic link between the United States and Israel, which also experienced widespread dissemination of bla_{KPC}-containing *K. pneumoniae* during this time (64). Subsequent studies have shown the global spread of multiple clones of highly virulent bla_{KPC}-containing *K. pneumoniae* isolates (65), many of which can be divided into two distinct clades by molecular typing (66). Tracing the epidemiologic spread of all the major carbapenem resistance genes is a continuing challenge for public health laboratories but is important for updating guidance for national control policies (67).

RECOMMENDATIONS FOR SURVEILLANCE AND CONTROL OF MDROS

ESCMID Guidelines

The "ESCMID guidelines for the management of the infection control measures to reduce transmission of multidrug-resistant Gram-negative bacteria in hospitalized patients" represent a comprehensive guide to infection control practitioners (68). The guidelines contain several key observations regarding the transmission of Gram-negative bacteria. First, published strain typing data demonstrate that extraintestinal MDR *E. coli* strains are not readily spread in health care environments. This is in contrast to MDR strains of *K. pneumoniae*, which are frequently spread in hospitals, often via the hands of health care workers (68). *Serratia marcesens* and *Enterobacter* spp. are also capable of causing outbreaks in hospitals. Recommendations supported by strong evidence include hand hygiene and the use of contact precautions, but it is emphasized that there is no consensus on when contact precautions can be discontinued. For patients colonized or infected with MRSA, three negative cultures are often required to release a patient from contact precautions. However, a recent study by Shenoy et al. demonstrated that one negative PCR test had a negative predictive value of 96.6% when compared to the results of three negative cultures (69). This resulted in a cost avoidance of >$1.5 million by removing patients from contact precautions prior to the results of three negative cultures. Such data are not available for patients colonized with ESBLs or carbapenem-resistant organisms, but this may be a consideration for future studies. Given the number of MDROs encountered in hospitals these days, effective management of isolation precautions has become a major challenge.

CDC

In December 2013, the CDC issued its antimicrobial resistance report (70). The activities described focused on (i) preventing infections and preventing the spread of resistance (i.e., the importance of infection control and infection prevention activities), (ii) tracking (i.e., upgrading surveillance activities), (iii) improving antibiotic prescribing and stewardship (i.e., better utilizing the antimicrobial agents available and reducing the selective pressure that facilitates the development and spread of resistant bacteria, fungi, parasites, and viruses), and (iv) developing new antimicrobial agents and diagnostic tests. The CDC defined three groups of antimicrobial-resistant organisms based on their threat level (Table 2). Urgent threats included *C. difficile*, carbapenem-resistant *Enterobacteriaceae*, and ceftriaxone-resistant *N. gonorrhoeae*. *C. difficile* may seem an odd choice to include in the list since these organisms are not MDROs *per se*, although some strains can be resistant to multiple antimicrobial agents, such as the PCR-ribotype 027 strains, which are typically fluoroquinolone-resistant in addition to showing resistance to clindamycin, rifampin, and other drugs (71). These organisms made the urgent list because their spread is a direct result of antimicrobial use, which is a key risk factor for developing *C. difficile* infection. In fact, in the United States, *C. difficile* is now a more common cause of health care-associated infections than MRSA (27). In its recommendations, the CDC called for the use of nucleic acid amplification tests for rapid diagnosis of *C. difficile* and stressed the need for effective infection control interventions.

As the other urgent threat (besides carbapenem-resistant *Enterobacteriaceae*, which is discussed above), the CDC noted the global spread of ceftriaxone-resistant *N. gonorrhoeae*, which due to multidrug resistance has become untreatable in some parts of the world (72). While over 36 countries have reported ceftriaxone-resistant *N. gonorrhoeae* (5), surveillance for these organisms is essentially lacking on a global scale.

The CDC's list of "concerning threats" contains organism-drug resistance combinations that have already emerged, but are rare, yet have the potential to cause serious medical and public health issues should they emerge in large numbers. This includes vancomycin-resistant *S. aureus*, of which only a little over a dozen infections have been reported (73), erythromycin-resistant group A streptococci (also known as *Streptococcus pyogenes*), which is a major cause of skin and throat infections, and clindamycin-resistant group B streptococci (also known as *Streptococcus agalactiae*), which can colonize the vaginal vaults of women, leading to serious and often fatal neonatal infections if the mother is not treated with antimicrobial agents prior to labor and delivery.

TABLE 2 CDC antibiotic resistance threats[a]

Urgent threats	Serious threats	Concerning threats
Clostridium difficile	Multidrug-resistant *Acinetobacter*	Vancomycin-resistant *Staphylococcus aureus*
Carbapenem-resistant *Enterobacteriaceae*	Drug-resistant *Campylobacter*	Erythromycin-resistant group A *Streptococcus*
Drug-resistant *Neisseria gonorrhoeae*	Fluconazole-resistant *Candida*	Clindamycin-resistant group B *Streptococcus*
	Extended-spectrum beta-lactamase-producing *Enterobacteriaceae*	
	Vancomycin-resistant *Enterococcus*	
	Multidrug-resistant *Pseudomonas aeruginosa*	
	Drug-resistant nontyphoidal *Salmonella*	
	Drug-resistant *Salmonella typhi*	
	Drug-resistant *Shigella*	
	Methicillin-resistant *S. aureus*	
	Drug-resistant *Streptococcus pneumoniae*	
	Drug-resistant tuberculosis	

[a]From CDC report issued December 2013 (70).

The third category of threats includes a variety of resistant organisms that are already widespread globally and need to be monitored and, if possible, held in check by medical and public health interventions (Table 2). Such resistant infections are contained by infection prevention programs in hospitals, including hand washing, surveillance, and decolonization strategies, and community-based public health programs, such as directly observed therapy for patients with tuberculosis infections.

Barriers to Harmonizing Global Surveillance Programs

One critical problem with pooling antimicrobial susceptibility testing data for bacterial pathogens from around the world is the interpretive criteria (also known as breakpoints) used to define antimicrobial susceptibility and resistance. While most European countries as well as a number of laboratories outside of Europe use the EUCAST interpretive criteria (http://www.eucast.org/clinical_breakpoints), the United States and a variety of other countries, especially in Latin America, use CLSI criteria (http://clsi.org/standards/micro/sub-ast/), which have critical differences in breakpoints for susceptibility, particularly for cephalosporins and carbapenems. This can complicate interpretation of resistance data for those trying to understand the global movement of resistant strains. If quantitative data, such as MICs or disk diffusion zone diameters, were collected in lieu of the interpretations (i.e., susceptible, intermediate, or resistant) for the data, it might be possible to analyze the data using any set of interpretive criteria. Unfortunately, this is rarely the case. The interpretive criteria that are used in a clinical laboratory also dictate the MIC ranges of antimicrobial agents tested in commercial susceptibility testing systems. Thus, laboratories that use CLSI criteria may not have the range of dilutions in MIC panels that span both the CLSI and EUCAST breakpoints (e.g., from 0.25 μg/ml to 16 μg/ml for carbapenems). So reinterpreting the data after the fact may not be feasible.

In the United States, the FDA sets the interpretive criteria for MIC and disk diffusion testing when an antimicrobial agent is first approved for use. These criteria may be accepted as-is or modified by the Antimicrobial Susceptibility Testing Subcommittee of the CLSI when they publish their annual review of interpretive criteria (the M100 document series), which lists breakpoints for both MIC and disk diffusion testing (74). Fortunately, the discrepancies between FDA and CLSI interpretive criteria continue to decrease as both groups work to resolve them. Yet there is tension in the clinical laboratory because diagnostic instrument manufacturers are obliged to use FDA interpretive criteria in automated testing instruments, although the clinical laboratory may choose to reprogram its instruments to follow CLSI guidelines. The key surveillance issue is that some fraction of U.S. laboratories (which is essentially unknown) still uses older CLSI interpretive criteria for cephalosporins and carbapenems, while others have made the switch to the newer (lower) breakpoints, which are more sensitive for detecting resistance. Thus, U.S. surveillance data taken directly from clinical laboratories may represent a mix of interpretive criteria, especially if the data collected include only the "susceptible, intermediate, or resistant" interpretations and not the actual quantitative data (such as zone of inhibition diameters or MICs), which could be reanalyzed using consistent breakpoints. This may underestimate the true resistance rates in the United States and other regions in the world.

SUMMARY

Molecular methods inform surveillance activities and have made vital contributions to our understanding of the epidemiology of many antimicrobial-resistant organisms, but there is considerable room for growth and improvement of methods and data management.

Molecular Diagnostics: Huge Impact on the Improvement of Public Health in China

HUI WANG, BIN CAO, YAWEI ZHANG, AND SHUGUANG LI

21

China has undergone rapid demographic and epidemiological changes over the past 30 years. One of the most exciting changes is the health improvement with significantly increased life expectancy (1). Infectious diseases, which used to be the primary threat in public health, have been greatly reduced (2). However, infectious diseases continue to exact a substantial toll on public health resources in China. Attention to and action against emerging infections and infectious diseases greatly increased after the outbreak of severe acute respiratory syndrome (SARS) in southern China in 2003. In addition, endemic diseases, including H5N1, *Streptococcus suis*, human granulocytic anaplasmosis, EV17, H1N1, H7N9, H10N8, and some other zoonotic infections, affect millions of individuals, further heightening public health concerns.

An important priority in meeting these challenges is to ensure that advanced molecular diagnostics for disease detection and surveillance are well integrated into the public health system (3). Molecular diagnostic tests have been playing a critical role in the management of infectious diseases in clinical settings, including rapid detection and characterization of specific organisms, optimization of antimicrobial use, monitoring of responses to therapy, discovery of novel pathogens, and disease surveillance. Rapid and accurate diagnosis of infectious disease is critical not only for early clinical interventions, but also for controlling the spread of pathogens and avoiding wasting resources on ineffective treatments. More importantly, molecular diagnostics such as PCR can be made affordable for the developing world (4).

In the past few years, more clinical tests based on molecular methods have been available in China for rapid detection of common, toxin-producing, or antimicrobial-resistant pathogens. In this chapter, we discuss the molecular-based methods, including PCR, multiplex PCR, real-time PCR, nested PCR, biochip assay, and loop-mediated isothermal amplification (LAMP), that have been used in Chinese hospitals and how these methods influence public health in China.

CURRENT IMPACT OF MOLECULAR DIAGNOSTICS ON BACTERIAL INFECTIONS

Culture methods and microscopy remain the predominant approaches in clinical laboratories in China. Although these methods are adequate for detecting and characterizing a wide range of bacterial species, they are time-consuming and not suitable for many infectious agents, which limits their application. Thus, molecular diagnostics are particularly useful for identifying these difficult to culture pathogens.

Mycobacterium tuberculosis

Tuberculosis (TB) remains one of the major causes of death worldwide. Recent data indicate that all-form tuberculosis incidence was 14.6 million and number of deaths was 2.7 million in 2013 worldwide (5). With 1.4 million cases of TB, China has the second highest burden of TB in the world (6). Since the early 1990s, the Chinese government has appreciated, in particular, the importance of controlling the spread of TB, and great commitment has been made. Recommended by the World Health Organization (WHO), directly observed treatment, short-course therapy has been recognized and applied as a nationwide TB control strategy. As a result, the prevalence of TB has been greatly reduced. From 1990 to 2010, the prevalence of smear-positive TB decreased from 170 to 59 cases per 100,000 population, and disability-adjusted life-years caused by TB dropped by about 71% (1, 7).

Molecular Diagnostics of *M. tuberculosis*

In China, TB patients are diagnosed mostly by clinical manifestations, acid-fast bacillus smear, sputum culture, or chest X ray. However, the conventional methods prolong the diagnosis time. Symptoms of *M. tuberculosis* and non-TB *Mycobacterium* infections are clinically similar, and diagnostic delay can significantly affect disease management. To better prevent the transmission of TB and decrease its prevalence, rapid detection and diagnosis are critical. In the past two decades, a number of molecular diagnostics for TB have been developed, resulting in improved sensitivity and specificity. Technologies such as multiplex PCR, real-time PCR, LAMP, the multiplex SNaPshot technique, and biochip assay have been modified and applied in direct de-

tection and identification of M. *tuberculosis* complex in China (8–13). A novel two-step multiple displacement amplification-PCR assay, which combines multiple displacement amplification with IS*6110*-specific PCR, can detect M. *tuberculosis* complex in sputum specimens with low copy numbers (14). This method greatly improves the sensitivity and specificity of TB diagnosis by sputum specimens. Many individuals infected with HIV died of co-infections with M. *tuberculosis* or *Pneumocystis carinii* pneumonia in China. With the use of a microfluidic isothermal amplification chip incorporating LAMP and a microfluidic technique, HIV, M. *tuberculosis*, and *P. carinii* pneumonia infections can be detected simultaneously (15). This system has considerable significance for providing a rapid, practical, multiple-target-point, and low-cost diagnostic method in clinical practice in China (15).

Molecular Genotyping of *M. tuberculosis*

Molecular epidemiology is a valuable tool for understanding the current TB pandemic by investigating clinical features, tracking transmission dynamics, detecting suspected outbreaks, and distinguishing relapse and reinfection. Based on advances in PCR techniques, some genotyping methods have been developed to compensate for the limitations of restriction fragment length polymorphism (RFLP). Spacer oligonucleotide typing (spoligotyping) is a good alternative to traditional IS*6110* RFLP due to its convenience and reliability. Another widely used genotyping method is mycobacterial interspersed repetitive unit and variable-number tandem repeats (MIRU-VNTR). The combination of the two genotyping methods facilitates the understanding of M. *tuberculosis* transmission with discriminatory power, economical cost, and reproducibility (16). In addition, several studies have established the standard MIRU-VNTR locus set for investigating molecular epidemiology (16–20).

With the assistance of these genotyping methods, many studies have focused on the molecular typing of M. *tuberculosis* isolates in various regions in China, including Jilin, Tibet, Heilongjiang, Shanghai, Jiangsu, and Inner Mongolia (16, 18–20). These reports showed that the Beijing family is the most prevalent isolate in most provinces of China. The distribution of the Beijing genotype in China showed regional characteristics, with northern China more prevalent than southern China (18). Data also showed that in Fujian province, the proportion of rural to urban migrant workers with the Beijing genotype was significantly higher than those of permanent residents (21). These epidemiological data are important for understanding the genotype and transmission patterns of M. *tuberculosis* and the development of effective control strategies.

Molecular Detection and Surveillance of Drug-Resistant *M. tuberculosis*

Although there have been substantial decreases in TB incidence and deaths in China, drug-resistant TB is still a substantial challenge. Among 3,037 new TB cases and 892 previously treated cases, 5.7% and 25.6% were multidrug-resistant TB (defined as disease that was resistant to at least isoniazid and rifampin) (22). Duo et al. reported that PCR-based identification of M. *tuberculosis* in cerebrospinal fluid was not only an alternative diagnostic approach for tuberculous meningitis, but was also useful for the detection of drug resistance when combined with the MTBDRplus assay (23). Molecular diagnostics on resistance genes can facilitate the rapid detection of drug-resistant TB, e.g., the fluoroquinolone-resistance-determining region of the *gyrase A* (*gyrA*) gene and the *gyrase B* (*gyr B*) gene, the rifampin-resistance-determining region of the *rpoB* gene, and isoniazid resistance of the *inhA* gene and *katG* gene (24–26). The development of Xpert MTB/RIF is considered a significant breakthrough in the fight against TB and was endorsed by WHO in 2010 (27). The GeneXpert system and Xpert MTB/RIF assay remain the only automated cartridge-based DNA testing method for simultaneous detection of TB and rifampicin resistance directly from sputum in less than 2 hours (27). The Chinese Center for Disease Control and Prevention has introduced the 774 GeneXpert machine with support from the Global Fund to Fight Tuberculosis and implemented the systems into the National Tuberculosis Control Program, covering a wide range of areas in China. These systems are not only practical for decentralizing facilities in low-resource settings, but also play a critical role in reducing the incidence and mortality of multidrug-resistant M. *tuberculosis* in China.

Streptococcus suis

S. *suis* is an important pathogen associated with a wide range of diseases and can be transmitted to humans by direct contact. In July 2005, the third outbreak of human S. *suis* infections occurred in Sichuan province, China, with two earlier outbreaks occurring in 1998 and 1999 (28). The repeated and intensive outbreaks have raised public concern regarding S. *suis* as an emerging zoonotic agent (28).

Various methods for identifying S. *suis* strains have been developed, including serological, molecular, and other diagnostic techniques. PCR is a rapid method used to detect serotypes or strains of S. *suis* in animal carriers and to identify strains obtained from infected or healthy pigs or from sick patients for clinical diagnosis or epidemiology studies (28). PCR-based S. *suis*–specific 16S rRNA region and a species-specific probe targeting 16S rRNA can be used to identify S. *suis* strains (28). Serotyping is one of the most valuable methods to understand the epidemiological patterns of S. *suis*. Recently, a multiplex PCR assay was developed as a relatively systematic typing tool for S. *suis* (29). It provides a rapid, specific, and cost-effective way to identify all except for two pairs of serotypes (29). Other molecular methods such as RFLP, pulsed-field gel electrophoresis, and multilocus sequence typing have also been used to study the genetic diversity of S. *suis* strains, the colonial relations between the strains, and the virulence of particular clones (30–32).

Neisseria meningitidis

N. *meningitidis* is a leading cause of bacterial meningitis and sepsis in China. Nationwide epidemics previously occurred every 8 to 10 years (33). Historically, epidemics of meningococcal disease were caused by pandemic waves from serogroup A (33). However, since 2003, a substantial increase in serogroup C meningococci infections has been observed in China (33).

Efficient methods for detection and genotyping of N. *meningitidis* isolates are needed to monitor the prevalent serogroups as an important method of disease control and prevention and vaccination strategy (34). Molecular typing with pulsed-field gel electrophoresis enables critical examination of the pathogen change at the molecular level (33). Multilocus sequence typing is a commonly used tool for tracking the national spread of meningococcal clones

and for identifying lineages that have an increased risk of causing infections (35). Based on molecular analysis, infections caused by *N. meningitidis* serotype W135 ST11, which belongs to a hyperinvasive lineage, were reported in Anhui and other provinces in China (36, 37). In addition, a multiplex PCR using 12 individual serogroup-specific and species-specific primers was developed for *N. meningitidis* detection and genogrouping and may be applied in clinical diagnosis and epidemiological surveillance (34). In combination with available epidemiological data, information on serogroups has the potential to significantly enhance our knowledge of molecular epidemiology of *N. meningitidis*, thereby increasing our ability to respond to disease outbreaks appropriately and effectively (35).

Yersinia pestis

Plague, caused by *Y. pestis*, remains an endemic threat and public health concern in many regions widely distributed in China. Since the 1990s, the incidence of plague in China has slightly increased, with a total of 631 cases between 1995 and 2004 (38). The Ministry of Health of China reported a cluster outbreak of primary pneumonic plague in Qinghai province in July 2009 (39).

Y. pestis in China was traditionally identified by a four-step protocol consisting of bacterial isolation and microscopy observation, the phage lysis assay, and animal experiments (40). However, this is time-consuming and laborious. Nucleic acid–based detection techniques could be an excellent alternative for detection of *Y. pestis*.

Recent progress in molecular typing methods enables large-scale outbreak investigations and provides information about its evolution patterns. Regions of deletion analysis, clustered regularly interspaced short palindromic repeat analysis, whole-genome sequencing, SNP analysis, and multilocus variable number tandem repeat analysis (MLVA) have been widely used in genotyping and evolutionary research of *Y. pestis* (41–44). MLVA is a promising technique to track the source of the outbreak (39). As indicated by MLVA, an outbreak of plague in 2009 was begun by an infected dead dog (39). Understanding the infection source and dynamics further aids the epidemiological analyses by setting up the basis for an accurate and robust typing system for plague surveillance and promotes diagnostic development and control measures.

Novel Pathogens

Molecular diagnostic methods can be used for identification of novel pathogens. One of the major techniques is broad-spectrum DNA amplification targeting the bacterial 16S rRNA gene with universal primers. 16S rRNA is present in almost all bacteria and can provide genetic classified information. This approach, especially combined with DNA sequencing, has facilitated the identification of new pathogens and novel strains of bacteria. Besides the sequencing analysis of the 16S-23S rRNA gene, other housekeeping genes, such as *rpoB*, *tuf*, *recA*, *gyrA*, *yrB*, *sodA*, *groEL*, and *cpn60*, are also commonly used to identify and describe the molecular characteristics of species.

Application of broad-spectrum PCR amplification and direct sequencing has had a considerable impact on the detection of clinically infrequent and special bacteria, such as slow-growing, fastidious, or uncultured bacteria (e.g., *Campylobacter fetus*, *Acinetobacter parvus*, *Mycobacterium phocaicum*, *Roseomonas mucosa*, and *Halomonas johnsoniae*) (45). Since the initiation of widespread use of 16S rRNA based on PCR, many new and clinically significant *Mycobacterium* species have been identified in China (46, 47).

CURRENT IMPACT OF MOLECULAR DIAGNOSTICS IN VIRAL INFECTIONS

SARS Coronavirus (SARS-CoV)

A serious "plague" called atypical pneumonia, or SARS, broke out in China starting in November 2002 and lasting to July 2003 (the major epidemic areas are shown in Fig. 1). SARS was caused by a novel animal coronavirus (SARS-CoV) that exploited opportunities to adapt to the palm civet and human, and certain mutated lineages became readily transmissible between humans. It spread quickly and affected more than 8,000 people in 25 countries and regions across five continents within weeks (WHO, http://www.who.int/csr/sars/country/table2004_04_21/en/index.html). By the end of the global outbreak on July 5, 2003, SARS-CoV had killed 774 people, with a global economic loss of $59 billion (48).

Molecular Diagnostics and Impact of SARS-CoV

The clinical syndrome and viral etiological agent of SARS-CoV were quickly described and identified (49, 50). Some diagnostic tests targeting different regions of the virus were described (49, 51), and the genome of the virus was sequenced completely (52). Drosten et al. obtained a 300-nucleotide-length sequence using a PCR-based random-amplification procedure, which showed that SARS-CoV is only distantly related to known coronaviruses. Specific and sensitive detection of the novel virus was accomplished by conventional and real-time PCR assays, and high concentrations of viral RNA of up to 100 million molecules per milliliter were found in sputum of patients with SARS (49). Similarly, Poon et al. used SYBR Green to detect samples with sequence variations (mutations) in the virus. A 182-bp region within the RNA-dependent RNA polymerase-encoding sequence of the virus was amplified and confirmed by sequencing. This approach (e.g., RNA extraction, reverse transcription, and real-time PCR) can be completed in 3 to 4 h, allowing rapid identification of SARS-CoV (51).

The Chinese SARS Molecular Epidemiology Consortium analyzed 61 SARS-CoV genomic sequences derived from the early, ongoing, and late phases of the epidemic together with two viral sequences from palm civets (53). Most variations observed between human and civet SARS-CoV genomes were located at the orf8 region and the spike genes (S). Genotypes characteristic of each phase were somewhat different: the earliest genotypes were similar to the animal SARS-like coronaviruses, while the earliest and latest genotypes showed major deletions in the orf8 region. The neutral mutation rate of the viral genome was stable, but the amino acid substitution rate of the coding sequences showed decreases during the epidemic.

West Nile Virus (WNV)

WNV is a spherical, enveloped virion containing 11 kb of single-stranded, positive-sense RNA. It is the most widely distributed flavivirus in the world, including at least two major lineages, I and II (54). Infection with WNV leads to a wide range of diseases from mild fever to severe neurologic symptoms; however, asymptomatic infections occur most frequently (55). From August 5 to September 3,

FIGURE 1 The major epidemic areas of SARS-CoV (red), West Nile virus (blue), and H7N9 avian influenza virus (yellow) in China.

2004, an epidemic of fever and meningitis/encephalitis broke out in several villages in Xinjiang province, China (56). Among 80 cases, 10 people died (the major epidemic areas are shown in Fig. 1).

Molecular Diagnostics and Impact of WNV

In the study mentioned above, cerebrospinal fluid and serum samples were collected, and WNV and six other arboviruses were detected by immunofluorescence assay, enzyme-linked immunosorbent assay (ELISA), and plaque reduction neutralization assay for the existence of immunoglobulin M antibody or neutralization antibody (56). However, the accuracy of laboratory diagnosis of viral encephalitis caused by WNV still needs to be improved.

In 2011, arbovirus surveillance was performed in Kashi Region, Xinjiang province (57). Acute-phase serum samples obtained from patients with fever or viral encephalitis were performed for immunoglobulin M against WNV. A total of 23/38 patients were positive. Of the 23 positive samples, 11 had a 4-fold increase in titer of WNV-neutralizing antibody (57).

Enterovirus 71 (EV71)

Hand, foot, and mouth disease (HFMD) is a common illness of children younger than 5 years. HFMD has emerged as a significant public health issue in China in recent years (58, 59). The Chinese Centers for Disease Control and Prevention surveillance system reported 7,200,092 suspected cases of HFMD from 2008 to 2012, of which 2,457 (0.03%) were fatal (60). EV71, the major causative agent of HFMD, was first identified in 1969 in California and has become more predominant across the Asia-Pacific region in the past decades (60). Because there is no effective treatment or reliable vaccine for EV71, prevention and early diagnosis are critical.

Molecular Diagnostics and Impact of EV71

The standard diagnosis for EV71 is cell culture following neutralization tests with serotype-specific antisera, which is time-consuming and not suitable for on-site testing (61, 62). Nucleic acid diagnosis methods have been used widely in early diagnosis. The highly conserved and specific *VP1* gene is employed in detecting EV71 with various kinds of nucleic acid assays, such as nested reverse-transcriptase PCR (RT-PCR), real-time RT-PCR, and microarray (63–65).

In 2010, when HFMD was quite active in Hong Kong, real-time RT-PCR was performed routinely for enterovirus (EV) infection detection (66). Compared to conventional methods, EV RT-PCR significantly improved the efficiency of laboratory diagnosis of EV infection. However, these methods need to be modified before they are used in local medical institutions because expensive equipment and highly trained staff are required.

Asymmetric capillary convective PCR and one-step nucleic acid dipstick assay could complete the amplification and detection process within 30 minutes (67, 68). With this method, the bottom of the reaction tube is heated by the dry bath while stable continuous bottom-up temperature gradients are established and continual convection currents are formed. Then the reagents in tubes circulate spontaneously among the three steps of the PCR cycle

when they flow through the corresponding temperature zones in typical convection. When PCR is finished, the products can be directly applied onto the dipstick and detected visually without the addition of probes, incubation, and dilution.

Because there are still some shortcomings to asymmetric capillary convective PCR and one-step nucleic acid dipstick assay in on-site tests, appropriate improvements have been integrated into the convenient and integrated nucleic acid test (69). The results can be observed with the naked eye after 3 min. The convenient and integrated nucleic acid test EV71 assay showed a clinical sensitivity and specificity of 98.5% and 100%, respectively, and could serve as an on-site diagnosis tool.

Recently, a real-time simultaneous amplification and testing technology was developed to detect EV71 (SAT-EV71) (70). The RNA of EV71 and an internal control were amplified and analyzed simultaneously using routine real-time PCR by isothermal amplification and real-time detection of fluorescence. Afterward, clinical specimens were detected by this SAT-EV71 method and confirmed by the virus-cell culture method. The results showed that SAT-EV71 has a high sensitivity and specificity: it detected the VP1 with a minimum of 10 copies per reaction at an optimal concentration of internal control (5,000 copies per reaction); the use of internal control effectively prevented false-negative results by monitoring the processes of nucleic acid extraction and amplification. Thus, this easy-to-perform SAT-EV71 might be used in the molecular diagnosis of EV71.

Hepatitis B Virus (HBV)

HBV has infected more than 2 billion people worldwide, and of these, more than 350 million people suffer from chronic infection (71, 72). About 130 million carriers and 30 million chronically infected people live in China. Since the National Center for Clinical Laboratories in China performed a 10-year external quality assessment program in 2003, the false-positive and false-negative results decreased significantly in qualitative tests, and the accuracy and precision of quantitative analysis have been increasing (73).

Molecular Diagnostics and Impact of HBV

Currently, serologic immunity and nucleic acid testing are commonly used in clinical diagnosis of HBV (74). The serological tests such as ELISA assays detect a series of serological markers of HBV with low sensitivity and accuracy. Nucleic acid detection based on PCR amplification showed higher sensitivity, accuracy, and specificity. One of the most popular methods used for detection of HBV DNA is the TaqMan technique, which uses a TaqMan probe containing a fluorophor and a quencher at both ends, respectively. In the single-stranded form, fluorescence of the probe is not detected. When the PCR extension progresses, a DNA polymerase with the activity of 5′-3′ exonuclease leads to the fluorophor-modified DNA probe being degraded, and the close proximity between the fluorophore and quencher is broken, thus allowing fluorescence of the fluorophore. Fluorescence detected in the quantitative PCR thermal cycler is directly proportional to the fluorophore released and the amount of DNA template (75). However, the modified fluorogenic oligonucleotide probes in TaqMan methods are expensive, and sophisticated equipment is required, which limits access to this technology for many laboratories.

Researchers reported a novel approach for both qualitative and quantitative analysis of HBV DNA (76). During PCR amplification, Taq DNA polymerases cleave the probe and release a DNAzyme sequence that has been embedded in the probe. After PCR reaction, the DNAzyme formed G-quadruplex and bound with hemin, catalyzing the oxidation of different substrates by H_2O_2 to generate colorimetric or fluorometric signals. This method could detect HBV DNA with high specificity, sensitivity, and accuracy.

In addition, the peptidomic profiling in the process of HBV infection was investigated (77). Serum from HBV-infected (asymptomatic carrier and chronic hepatitis), HBV-immunized, and normal subjects was incubated with MB-WCX (weak cation exchange-based magnetic beads) kits and analyzed by the Clinprot/matrix-assisted laser desorption ionization–time of flight mass spectrometry. Purified serous proteins were subjected to Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry analysis and further confirmed by Western blot. Using the WCX magnetic bead-based MALDI-TOF-MS, specific serum peptide profilings for host responses to HBV infection were investigated. Results showed that m/z 2882.89 and 4476.12 could be valuable prognostic tools for HBV infection.

Influenza A Virus

Influenza A virus, belonging to the family *Orthomyxoviridae*, can be classified into subtypes H1-H17 and N1-N10 according to the antigenic specificity of the hemagglutinin (HA) gene and neuraminidase (NA) genes, respectively (78, 79). These viruses could infect humans and a wide range of animal species, causing yearly epidemics that threaten public health, and some species can even jump the species barrier from poultry to humans (80, 81).

Molecular Diagnostics and Impact of Influenza A Virus

Virus isolation is time-consuming and requires complicated technology. Molecular methods such as RT-PCR, real-time RT-PCR, microsphere-based duplexed immunoassay, and padlock probes combined with DNA microarray were developed for influenza viruses detection (82–85).

Wu et al. reported a multiplex RT-PCR (mRT-PCR) assay for the rapid diagnosis of influenza A virus in clinical samples (86). The HA subtypes of H1, H3, H5, and H9 were detected in a single reaction mixture with specific primer sets. The sensitivity was the same with conventional RT-PCR, but 10 times less sensitive than SYBR Green real-time RT-PCR. However, the mRT-PCR assay was a rapid, convenient, and relatively inexpensive method.

Some newly emerged variants (for example, H1N1 pdm09 virus and H3N2 virus that occurred in Taiwan between 2012 and 2013) were not detected in clinical specimens via a common real-time RT-PCR assay that targeted the conserved regions of the viral matrix genes, because the viral matrix gene sequence was located in regions where the primers or probes of the real-time RT-PCR assay bind. Yang et al. established a real-time RT-PCR assay using degenerate nucleotide bases in both primers and probes. The sensitivity in detecting influenza A viruses was increased in this method (87). Therefore, the importance of the simultaneous use of different gene-targeting real-time RT-PCR assays for the clinical diagnosis of influenza was highlighted.

Subtypes of Influenza A Virus

Highly Pathogenic Avian Influenza Virus Subtype H5N1 (H5N1)

H5N1 was first reported in Guangdong province, China, in 1996, resulting in widespread poultry outbreaks and 18 cases of human infections in 1997 in Hong Kong (88, 89). In early 2004, H5N1 spread to 16 provinces in China, and multiple distinguishable sublineages were identified (90). Subsequently, H5N1 disseminated continuously from Asia to Europe, the Middle East, and Africa (91). By August 2013, WHO reported 637 laboratory-confirmed human cases, including 378 fatalities, from 15 countries (http://www.who.int/en/).

ResPlex III was employed in H5N1 diagnosis (92). In brief, the ResPlex system incorporated the target-enriched multiplex PCR to simultaneously amplify multiple molecular targets in one reaction. The ResPlex III assay targeted the H1, H2, H3, H5, H7, H9, N1, and N2 genes of influenza A virus, and the NS genes of influenza A (NSA) and B (NSB) viruses. The clinical sensitivity and specificity for detecting H5N1 were 93.3% and 100%, respectively, indicating that the ResPlex III genotyping approach could quickly and correctly identify different subtypes of influenza A virus.

In another study, H5N1 detection was based on the fluorescence resonance energy transfer from quantum dots (QDs) to carbon nanotubes (CNTs) in a QDs-ssDNA/oxCNTs system, in which the QDs (CdTe) modified with ssDNA were used as donors (93). Initially, QD fluorescence was effectively quenched with strong interactions between ssDNA and oxCNTs. The interactions between the QDs-ssDNA and oxCNTs decreased upon recognition of the target, and QDs fluorescence was recovered and shown to be linearly proportional to the concentration of the target in the range of 0.01 to 20 μM, with a detection limit of 9.39 nM. Thus, this simple, sensitive, and quantitative method could have a wide range of applications in molecular diagnosis.

Influenza A/H1N1/2009 Virus (H1N1/2009)

The influenza A/H1N1/2009 virus (H1N1/2009) was first reported in Mexico in mid-April 2009 and spread to over 160 countries within a short time. It had killed 816 people among 134,500 cases by July 27, 2009. H1N1/2009 was characterized by a unique combination of gene segments that had not been reported previously (94). Seasonal influenza A and B viruses often generate new genetic variations and cause symptoms similar to H1N1/2009. Thus, rapid diagnostic methods for detecting H1N1/2009 are required to control the disease.

The HA gene sequences of H1N1/2009 and all formerly published seasonal influenza A (H1N1) viruses were aligned, and specific primers and probe sets were designed (95). Compared with the WHO assay, the new assay with the specific primers and probes showed a much greater sensitivity and could be employed as a rapid, alternative method in detecting H1N1/2009.

H7N9 Avian Influenza Virus (H7N9)

In February 2013, a serious disease manifesting as an influenza-like illness and severe pneumonia was attributed to a novel avian influenza A (H7N9) virus that emerged in eastern China (the major epidemic areas are shown in Fig. 1) (96). One month later, it killed 39 people among 131 or more laboratory-confirmed cases. It cost more than $6.5 billion and threatened the public health system (97); it was likely that another pandemic would occur if the virus acquired the necessary mutations to enable effective human-to-human transmission (98, 99).

In clinical detection, the immunological colloidal-gold test method has low sensitivity (100), while the sensitive and specific quantitative real-time RT-PCR of HA and NA genes of H7N9 requires expensive equipment and is not suitable for on-site detection in developing countries (101, 102).

Researchers developed two sets of one-step reverse transcription loop-mediated isothermal amplification (RT-LAMP) detection methods with hydroxynaphthol blue dye, one specific for the HA gene and the other for the NA gene (103). Compared with real-time RT-PCR (WHO recommended), RT-LAMP has the same sensitivity in the HA gene and 100 times greater sensitivity in the NA gene. Because no special equipment is needed in RT-LAMP, it could play a role in prevention of influenza pandemics.

CURRENT IMPACT OF MOLECULAR METHODS IN DETECTION OF PARASITIC INFECTION

In China, malaria, schistosomiasis, kala-azar, filariasis, and ancylostomiasis are regarded as five important parasitic diseases that call for intensive prevention and treatment. The diagnosis of parasites includes etiological diagnosis, immunodiagnosis, molecular testing, and clinical manifestation.

As the most common method in etiological diagnosis, microscopic detection is cost-effective, simple, and rapid. Microscopic detection is the "gold standard" of diagnosis of parasitic diseases. However, it is of limited value for the detection of cases with low parasite density, latent infection, early infection, or undistinguished parasitic morphology.

Immunodiagnosis plays an important role in parasitic disease detection. ELISA, benefiting from varieties of serological tests, has practical value in parasitic disease screening. However, immunodiagnosis is a nondiagnostic method but an assisted diagnostic process; because the specificity is low, cross-reaction exists and can be influenced by changing antigen or antibody levels.

Nucleic acid testing methods have been implemented widely and have drawn more and more attention over the past several years, since they are more reliable and stable than immunoserology. Nucleic acid tests use specific base pairs to detect and identify DNA or RNA of pathogenic agents directly, without the influence of host or antigen variation at each stage of development. Coupled with the conventional PCR principle, several variations of molecular techniques were developed, including nested PCR, multiplex PCR, real-time PCR, and LAMP (104). Genetic microarrays also provide a reliable way to diagnose parasitic diseases. In China, molecular diagnostics have been successfully applied to the detection of several genera of parasites including *Plasmodium*, *Schistosoma*, *Leishmania*, *Toxoplasma*, and *Filaria*.

Plasmodium

Malaria is one of the most important parasitic diseases threatening human health worldwide. In 2010, an estimated 219 million people were infected with *Plasmodium* species, with 660,000 deaths (105). In China, malaria infection rates are still high in some regions. What is worse, people from areas of malaria endemicity continually feed

into low epidemic areas, and they cannot receive treatment promptly. Thus, rapid molecular diagnostics are still valuable in malaria prevention and treatment.

PCR can be used to detect *Plasmodium vivax*, *Plasmodium falciparum*, and *Plasmodium ovale* in 2 hours with low threshold values. In addition, patients with low levels of parasitemia or asymptomatic infection can be detected as well. Compared with nested PCR, LAMP is less expensive and easier to perform, thus providing a promising platform for the molecular detection of malaria parasites in areas of endemicity of China.

Schistosoma

Schistosomiasis is caused by blood-dwelling flukes of the genus *Schistosoma*. About 200 million people from 70 countries are infected by schistosomiasis (106). This communicable disease, together with HIV/AIDS, TB, and hepatitis B, has been assigned high priority for control in China (107).

A number of serologic tests have emerged to diagnose patients who have or had schistosomiasis japonica (108, 109). Indirect hemagglutination assay, an important antibody detection approach with high sensitivity, is extensively used for clinical screening in regions of endemicity. However, the low specificity and high false-positive results limit its application, because antibodies do not wane immediately after clearance of parasites (110, 111). Commercial kits utilizing colloidal dye immunofiltration assay have been developed for antibody detection. This method has shown high sensitivity and specificity, but it cannot distinguish current infection from recent or past infection (112).

In addition to traditional methods, conventional PCR, PCR-coupled methods, LAMP, and mass spectrometry–based methods are gradually used in molecular diagnosis (104). These molecular diagnostic methods showed superiority in sensitivity, specificity and efficiency.

Leishmania

Leishmania species are the pathogen of leishmaniasis, a neglected tropical disease. In the past 5 years, 400 new cases occurred annually in the western provinces of China. At present, desert and hill regions are the primary epidemic areas.

Leishmaniasis caused by different species or subspecies needs different diagnosis and treatment. It is critical to identify species rapidly and accurately. Different types of PCR have been applied for detecting *Leishmania* DNA with high sensitivity.

Toxoplasma gondii

T. gondii is an obligate intracellular protozoan of clinical importance, especially in immunocompromised patients. Due to a lack of specific clinical signs, the diagnosis of toxoplasmosis can be challenging. Diagnosis of toxoplasmosis can be achieved by biological, serological, histological, or molecular methods. Detection of antibody and antigen in serum is the most routinely used method in clinical practice. The rapidly developed molecular techniques provide an important basis for the diagnosis of toxoplasmosis. PCR can detect infective toxoplasmosis by detecting single-genome DNA of tachyzoite.

CONCLUSIONS

During the past 30 years, great accomplishments have been achieved in controlling the spread of infectious diseases in China. However, China remains a major contributor to the global infectious disease burden. The emergence of novel and reemerging infectious diseases and the increased prevalence of antibiotic-resistant bacterial infections further complicate prevention and control strategies, indicating a clear need for faster, more accurate, and effective molecular-based tests. Since the first application of molecular diagnostic tests in clinical laboratories in China, a striking improvement in public health has been achieved, including reduced initial period of treatment, clinical management, and improved public health control. The recently FDA-approved tests with high sensitivity and specificity can be used directly for clinical samples, offering a more sensitive and specific result with a more rapid turnaround time than has ever before been possible. The newly developed molecular diagnostics are changing the way we practice clinical microbiology. Undoubtedly, we are entering the era of molecular diagnostics. However, for each of these methods, the additional costs must be calculated against the potential advantages of diagnostic value. In addition, the conventional methods for clinical microbiology cannot be replaced, and more well-controlled studies are still needed to evaluate the efficacy of these methods.

Surveillance and Epidemiology of Norovirus Infections

JOHN HARRIS

22

Norovirus is recognized as the leading cause of diarrheal disease in many countries. A study of the published literature shows that in the United Kingdom it is estimated to cause around 3 million cases each year (1). In the Netherlands, it has been estimated that norovirus is responsible for 11% of the 4.5 million diarrhea cases annually (2). In Canada, the estimated number of cases of gastrointestinal disease attributed to norovirus overall was a little over 3.3 million (3), accounting for 42% of gastrointestinal disease. A review by Hall et al. suggests that the number of people infected with norovirus in the United States is between 19 and 21 million each year (4). In the Southern Hemisphere, norovirus is the most common cause of gastrointestinal disease; one study from New Zealand suggests that norovirus was responsible for 26% of outbreaks, and in Australia norovirus causes the highest number of cases of gastrointestinal disease (5). A recent systematic review suggests that globally, norovirus is responsible for 20% of the burden of gastrointestinal disease (6).

The estimates of the burden of illness in some of the countries noted above are the result of modeling based on assumptions about the relative contribution of pathogens from studies elsewhere. By applying estimates from these studies to a mathematical model, an estimate of the likely burden in their own country is made. For example, in one of the first papers to estimate the incidence of norovirus in the United States, the figure was derived by applying the proportion of norovirus estimated from the Sensor study in the Netherlands to the incidence of gastrointestinal disease incidence from national hospital discharge data in the United States (4). This is a pattern repeated in later studies; the study in Canada used the incidence estimates for norovirus from the second Infectious Intestinal Diseases (IID2) study in the U.K. (3).

SURVEILLANCE

The utility of surveillance is to provide information for action, that is, to obtain data, in this case about disease, and provide insight for policy makers and public health officials. The objective is to provide information so decisions can be made about where to prioritize efforts in health policy and design interventions with an aim to reduce illness. It is important to acknowledge that surveillance is not a survey and that the notion that surveillance can be carried out for a short period of time ignores the importance of feedback. Surveillance can both identify the problem and assist in recognizing how interventions or policies have fared. For example, do the levels of disease decrease after the intervention or continue to rise?

Surveillance is described as being either active or passive. Active surveillance entails making an effort to gather information and is often limited in scope because of resource issues. For example, actively obtaining data by regular contact with clinicians or others at regular intervals, daily or weekly, ensures the completeness of data. Because of the intense nature of this approach, it is normally restricted to specific sentinel sites. These will have agreed at the outset of setting up the surveillance scheme to be data providers and will therefore likely be compliant. A rare disease might be amenable to active surveillance on a national scale, but this would need to be justified on the basis of its clinical importance, for example, if the disease in question had a high mortality rate. For common diseases it is not practical to conduct active surveillance on a national scale. Thus, for the most part, surveillance of disease is passive. Epidemiologists rely upon data collated from laboratory tests carried out in response to people becoming ill. When people seek medical attention, the clinician might request a sample, and for diarrheal diseases this normally would be a stool sample. This will be tested for the presence of pathogens, and the results will be recorded. These data can then be used to monitor the trend of an illness. Although not an end in itself, the results of testing may alert a public health agency to increases in incidence and detection of outbreaks, which can lead to further investigation to determine the cause.

CHALLENGES FOR SURVEILLANCE OF NOROVIRUS

The surveillance of any infectious disease is largely affected by two variables, first, the reservoir of infection and, second, the severity of the illness experienced. In the case of norovirus, the reservoir is the human gastrointestinal tract. This means the infection is mostly spread between people, i.e., person-to-person transmission via the fecal-oral route, with additional vectors such as food, water, and the environment. For gastrointestinal infections that have an animal reservoir (such as bacterial infections), foodborne

John Harris, Center for Infectious Disease Surveillance and Control, London, United Kingdom.

transmission will predominate, with a small component of person-to-person transmission through secondary cases.

The severity of illness will influence whether those who contract an illness contact medical services. Infection with norovirus is characterized by a short incubation period followed by a sudden onset of symptoms, a short duration of illness, and recovery with no long-term effects. This provides a major challenge for diagnosis. The nature of these symptoms means the vast majority of people affected in the community will not have contact with medical services. In the IID2 study, conducted in the U.K. between 2008 and 2009, only 2% of those who contracted a gastrointestinal infection visited their family doctor, which equates to around 1 million consultations a year (1, 7). The IID2 study also found that the incidence of gastrointestinal infections had increased by 43% since the previous study (conducted in the mid-1990s) and that the proportion of cases presenting to their family doctor had declined by 50%. So more people were becoming ill, yet fewer were consulting their doctor as a result of their illness (7). These factors can have an impact both on the surveillance of norovirus, determining how many infections are occurring, what strains are circulating, and the optimal approaches to control of infection. Figure 1 shows a reporting pyramid for norovirus (adapted from reference 8). This illustration shows the pyramid as representing the total number of norovirus cases, with the top fraction being that which is reported to national surveillance (in England) and the rest being unreported. The number of laboratory reports for norovirus in England is merely the tip of this pyramid. In the second IID2 study carried out in the U.K. (1, 7), there were around 280 cases of norovirus in the community for each specimen in which norovirus was detected and reported to national surveillance in England.

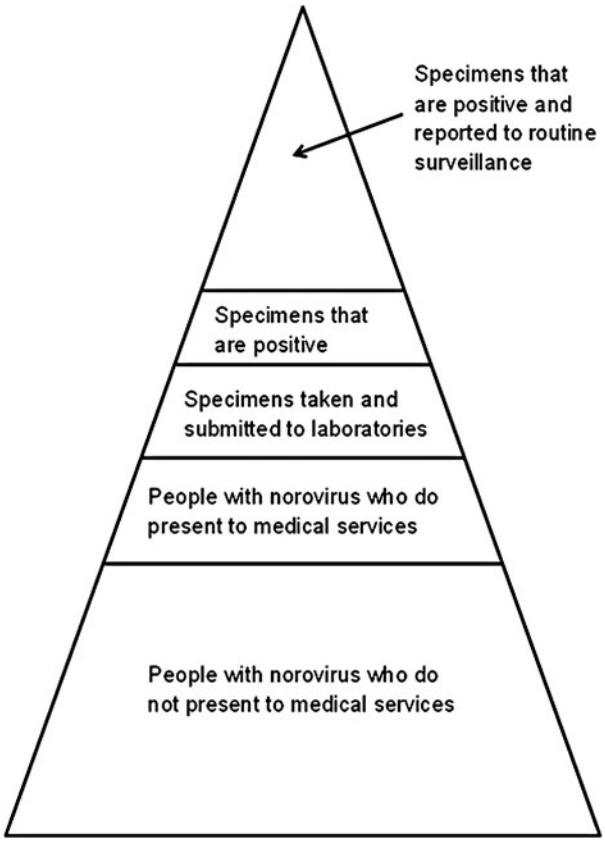

FIGURE 1 Reporting pyramid for norovirus. Adapted from Wall et al. (8).

For a mild, self-limiting disease such as norovirus, while there is less visibility within the general population (i.e., community illness), there is a more obvious burden in other settings. Norovirus is highly contagious and has a low infectious dose and a lack of long-term immunity to infection in the population. These factors provide the ideal ingredients for outbreaks to occur when people are in close proximity to one another. Outbreaks in such a setting are readily noticeable and can trigger actions needed to contain and record the outbreak. The lack of contact with medical services when people are infected with norovirus not only makes it extremely difficult to estimate the number of individuals affected, but it also makes ascertainment of disseminated outbreaks within the community extremely difficult.

OUTBREAK RECORDING IN ENGLAND

In 1992, surveillance of general outbreaks of gastrointestinal disease (involving two or more people in different households) was established following a recommendation of a U.K. government committee (8). The first review of data (1992–1994) from reported outbreaks suggested that norovirus (then called SRSV) accounted for 27% of outbreaks (9). In this review norovirus was responsible for only 6% of outbreaks in which food was the suspect vehicle, but 54% of outbreaks in which person-to-person spread was considered to be the route of transmission. The most common setting of an outbreak was in residential homes (i.e., long-term care facilities) and hospitals, accounting for 37% of reported outbreaks. A later review of outbreaks to the reporting scheme in 2003 provided stronger evidence of the importance of norovirus as a cause of gastrointestinal disease in England (10). This showed that over a quarter of all outbreaks occurred in hospitals, and 80% of these were attributed to norovirus. In the period for which this reporting scheme ran there were over 1,800 reported outbreaks of norovirus in hospitals (11).

The surveillance system in this study entailed sending a two-sided questionnaire to the lead person investigating the outbreaks (usually the Consultant in Communicable Disease Control). On receipt of the completed questionnaire, the data were then entered into a database. This method has the potential for data being lost if the questionnaire is never returned or at the very least could lead to a considerable reporting delay.

Changes to the requirements for mandatory reporting to the European Food Safety Authority led to Public Health England (formerly the Health Protection Agency) altering the way in which information on outbreaks of both foodborne and non-foodborne outbreaks is captured. Electronic reporting was introduced to improve the timeliness and at the same time enhance the information captured during outbreaks (12). This created a stand-alone reporting system, which now excluded person-to-person outbreaks of norovirus in hospital or community settings. From 1992 to 2013 Public Health England's surveillance scheme for foodborne outbreaks recorded 306 outbreaks associated with norovirus in which food was reported to be a vehicle of exposure, an average of only 14 outbreaks a year. Some outbreaks in which foods are a vector can be quite large; the largest outbreak of norovirus in a restaurant

occurred in 2009 when over 500 diners were affected (13). One outbreak in the United States, which is estimated to have affected around 3,000 people, occurred because a food handler contaminated a food coating used on cakes (14). This large outbreak is a good example of how foods can act as a net reproductive number amplifier, whereby large outbreaks occur that start with one infected person. In the outbreak reports in England in which food was believed to be involved, oysters were frequently reported as being consumed prior to illness. Oysters can become contaminated with sewage, and a recent survey of oyster beds in England suggested that over 70% were contaminated with norovirus (15). Despite such a high proportion of contaminated oyster beds, relatively few outbreaks of norovirus were reported associated with the consumption of oysters.

The redesign of outbreak reporting in England led to a reduction in both the number and quality of reports of outbreaks in hospitals. The U.K. Department of Health recognized the need to collect more detailed and systematic information on norovirus epidemiology in hospitals (11). This information was needed to develop rigorous evidence to inform infection control policies at local and national levels. In January 2009, the Hospital Outbreak Reporting Scheme was launched (11). The system was designed as an online reporting tool with only a few essential data items requested. The definitions within the dataset were agreed on by consensus with infection prevention staff. The system is designed to capture information on the start of the outbreak, when it ends, how many patients and staff are affected, whether the outbreak led to the closure of a ward or part of a ward, and how many bed days were lost as a result. At the launch of the system, all of the directors of infection prevention were invited to provide data. Data are entered directly by infection prevention and control staff working in the hospitals.

The first detailed analysis of the HNORS data (11) showed that there were over 3,900 outbreaks reported from January 2009 to December 2011. These outbreaks affected over 40,000 patients and over 10,000 staff (medical and nursing staff) and led to a reported 46,500 bed days lost. Furthermore, while the number of outbreaks reported varied between the two seasons, there was little variation in the impact of outbreaks. Over 50% more outbreaks were reported in the winter season of 2009/2010 compared to the following winter, yet the median number of patients or staff affected and outbreak duration remained the same (11). Reporting outbreaks of norovirus in hospitals through HNORS is still voluntary and therefore is likely to lead to under-reporting. An estimate of this likely under-reporting was carried out using a form of capture-recapture analysis. This suggested that the under-reporting was around 20% for the two norovirus seasons. Even with that limitation, the new Web-based surveillance scheme provided much greater insight into the burden of norovirus outbreaks in NHS hospitals. In the first year alone of the new scheme, more outbreaks were reported than during the 17 years in which the previous outbreak reporting system was used (1,884 episodes compared to 1,817).

Use of electronic surveillance via the Internet is well established, and the increase in reporting and the improved quality of the information included in these outbreak reports are in some part due to the introduction of an online reporting scheme. Online reporting is amenable to on-the-spot guidance in definitions, such as "case" and "outbreaks." Furthermore, because the reporting scheme is targeted at collecting well-defined information, any data will conform to greater epidemiological rigor. Previously, the reporting scheme (GSURV) was limited because definitions had to be broad to encompass outbreaks from various settings, and these are different from outbreaks in hospitals (11). This is likely to have manifested itself by reporters varying in their interpretation of what constituted an outbreak; i.e., did an outbreak on more than one ward of a hospital constitute a single outbreak (presumably from a single source) or was this several outbreaks? (This question is revisited later.) The other major benefit of introducing an electronic surveillance scheme is the increase in the timeliness of outbreak reporting. Reporters are able to enter the details of an outbreak at any time during the course of the outbreak. Data can be updated at any time during the outbreak or once it has run its course.

LABORATORY SURVEILLANCE

Public Health England and its predecessor organizations (PHLS, HPA) have routinely collected and published data on laboratory-diagnosed pathogens for more than 50 years (8). These reports have been collated on a database at the Center for Infectious Disease Surveillance and Control since 1975 (8). For much of the early years, norovirus (or SRSV, as it was known then) did not feature in routine laboratory reporting. As methods for identifying norovirus improved, and as part of outbreak reporting, norovirus began to be reported more often. The number of laboratory reports increased (Fig. 2). Laboratory reporting increased throughout the 1980s and 1990s.

In 2007, reverse-transcriptase PCR (RT-PCR) for norovirus testing was rolled out to all laboratories that formed part of the Public Health England regional network. The increased sensitivity of this test led to greater numbers of norovirus detections in stool samples. The introduction of new, more sensitive laboratory techniques can lead to misinterpretation of the data. Uncritical analysis of the pattern of laboratory reports would present as a sudden increase in the level of norovirus infection. Figure 2 shows a time series of laboratory reports of norovirus infections from Public Health England from 2000 to 2014. The laboratory reports appear to indicate an increasing trend of laboratory-confirmed cases. However, this would not provide a good indication of the true pattern of norovirus infections without consideration of changes in laboratory techniques introduced in the mid 2000s. What is clear is the seasonality of norovirus. The peak number of laboratory reports occurs in the winter months each year. However, in some years this peak is sharper, and in others it is more prolonged and less intense. The winter season of 2013/2014 in England was comparable to that in the years before the routine use of PCR for diagnosis of norovirus in England and compares in intensity to 2004. Norovirus does not have a predictable seasonality, and as will be discussed later there are clearly other determinants of why this might be.

The seasonality of norovirus laboratory reporting has been a useful tool in estimating the burden of disease due to norovirus, particularly in the elderly. Previous research had shown that although norovirus is considered a mild and self-limiting disease, some populations seem to fare worse than others (16). The seasonal pattern of laboratory reports modeled against mortality data suggested that norovirus is associated with 20% of the deaths caused by infectious gastrointestinal disease in the elderly (17). Fur-

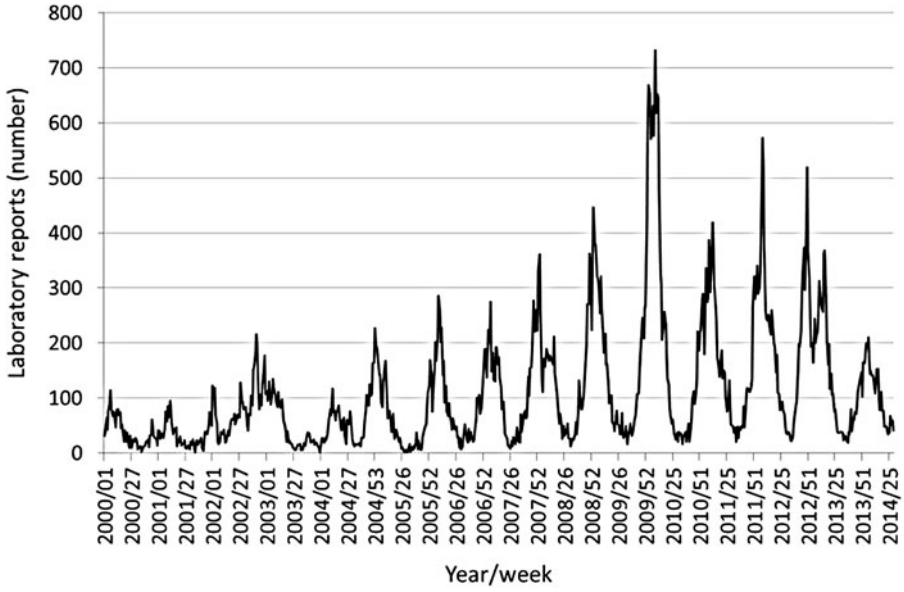

FIGURE 2 Public Health England laboratory reports of norovirus 2000–2014.

thermore, it was associated with 13% of noninfectious gastrointestinal disease deaths in the same population (17). A study in the Netherlands also found a significant association with norovirus activity and excess mortality in the elderly (18).

METHOD OF VIRUS DETECTION

Norovirus was only discovered in 1972. Stool samples from an outbreak in Norwalk, Ohio, were tested using immune electron microscopy (19). Serum samples from people recovering from illness were dropped onto fecal samples from the Norwalk outbreak, causing virus particles to clump together and enhancing the likelihood of detecting them under an electron microscope (19). Electron microscopy became the mainstay of diagnostic testing for norovirus, and classification of the virus was based on viral morphology (20). The unraveling of the norovirus genome facilitated the development of PCR-based assays (21, 22). In addition, the production of viral antigen particles and development of enzyme-linked immunosorbent assay tests also greatly increased the sensitivity of norovirus diagnostics (23, 24). While the enzyme-linked immunosorbent assay tests are shown to be reasonably sensitive, a large European study showed variability in their performance and concluded that they were not as sensitive as RT-PCR (25).

GENETIC DIVERSITY

The application of these detection methods has also led to a greater understanding of the diversity of norovirus genetics. Currently, noroviruses can be classified into five genogroups (there is putatively a sixth group identified in a small study in Europe [26]); three of these (I, II, IV) affect humans, and groups III and V affect animals. Each of the genogroups is further subdivided into genotypes (27, 28). Figure 3A illustrates the diversity of noroviruses; genogroup I (blue) contains the reference strain (Norwalk), and genogroup II contains the strain that causes most outbreaks (genogroup II.4, in red). This genotype is particularly noted in outbreaks in health care settings. Figure 3B illustrates the continued diversification of this genotype; the bars indicate how closely related each of the strains is to one another. Where the lines bifurcate indicates a common ancestor, so although these are all GII.4 genotypes they are clearly continuing to diversify.

LABORATORY TECHNIQUES

The introduction of newer technologies for detecting norovirus has led to more complexity in interpretation of the results. For example, RT-PCR is sensitive enough to detect the RNA of virus in samples from people who have not reported any gastrointestinal symptoms in the last several months. When archived stool samples from the first IID study (carried out in the mid-1990s) were retested using PCR, 16% of the samples from healthy controls contained norovirus RNA (29). Reanalysis of these data led to the recognition that around 12% of the population are likely to have an asymptomatic infection (30). Furthermore, prevalence increased in children below the age of 5, a group that already showed the highest prevalence (30). This raises the issue of the clinical significance of detecting norovirus in stool samples, especially when using highly sensitive assays. One method to assess whether detecting norovirus in stools is associated with illness is to use the cycle threshold (Ct) value as a measure of viral load (31). One complication of this study was the lack of calibration between Ct value and estimated viral load for all genotypes. For example, amplification of rarer genotypes, such as GII.7 and GII.8, was not as efficient as that for noroviruses of other genotypes (31). Genogroup I noroviruses were not included in the study, in part due to the variability of the efficiency of the assays for this genogroup (31). Clarifying both epidemiologic and clinical issues will require collecting sufficient specimens containing noroviruses of other genotypes to assess the potential Ct cut-off values that could be implemented as predictors for other genotypes of fecal viral loads (31).

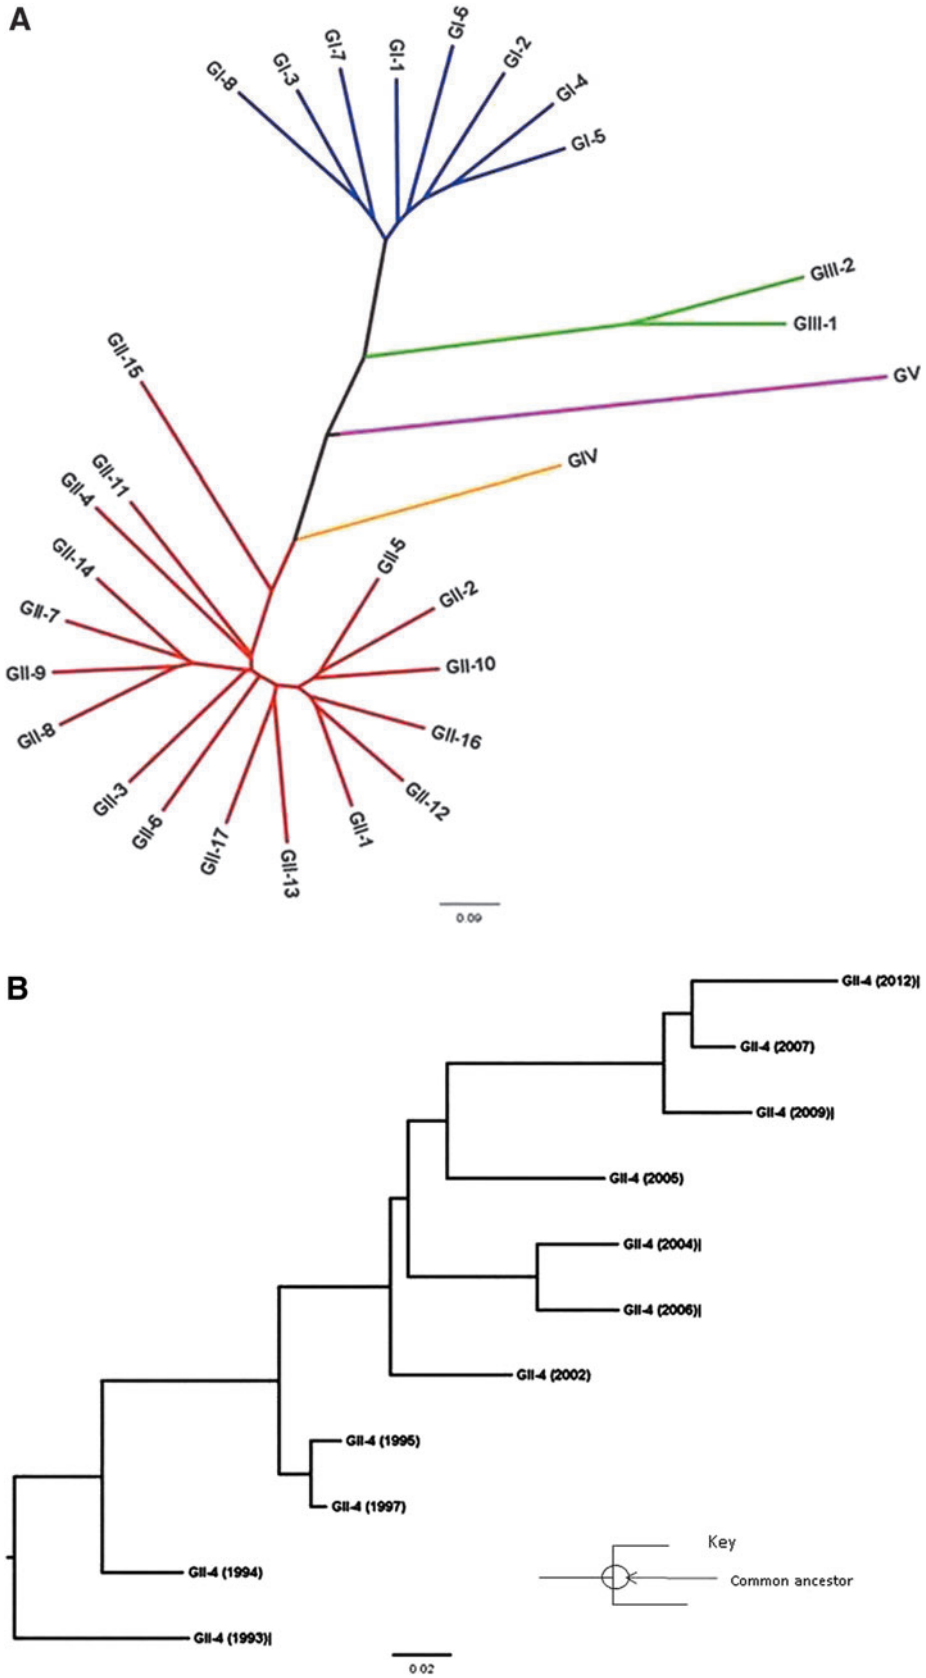

FIGURE 3 (A) Phylogram showing distribution of norovirus genogroups. (B) Diversity of GII.4 genotypes. (Courtesy of David James Allen, Virus Reference Department, Public Health England.)

Laboratory testing during outbreaks does not necessarily provide evidence of a source of infection or indicate whether a single outbreak is occurring or multiple outbreaks are occurring simultaneously. For example, norovirus outbreaks in which food is a source of infection do not always have a single genogroup or genotype of norovirus identified from patient specimens (32–35). When multiple genotypes of norovirus are detected in an outbreak investigation, one cannot use "norovirus detected" alone as part of a case definition (as is typically used for investigations of bacterial gastrointestinal foodborne infections) without being more specific as to the type or group. If laboratory analysis and reporting is separate from epidemiological reporting, problems will likely occur if only "norovirus detected" is used due to lack of specificity.

REPORTING PATTERN/SEASONALITY

Some winters have had noticeably increased numbers of laboratory reports of norovirus infections. These have coincided with increased reporting of norovirus around the world. For example, in 2002, it was widely reported around Europe that there was an increase in norovirus activity associated with the emergence of a new variant of the genotype II.4 strain (36). This increased norovirus activity was also noted because of the increase in infections occurring outside of the normal winter season, with a noticeable increase in the spring and summer (36). In 2006, there was yet another emergent strain of the genotype II.4 globally (37). This variant was associated with a number of outbreaks on cruise ships, and most of these happened in the early summer (38, 39). The emergence of new strains can lead to epidemic years with much greater numbers of norovirus infections, but this association is not straightforward. In 2012, it was widely reported that norovirus activity had begun earlier than usual in several countries (40). This appeared to be associated with the emergence of a new genotype II.4 strain, labeled Sydney 2012 (40, 41). This led to predictions of another season of unusually high activity; however, this did not materialize. Laboratory reporting was higher in the early part of the season, but there was low activity later on in the winter and fewer laboratory reports for the winter overall (42). The emergence of a new strain does not necessarily imply a season of higher activity, and it is likely that differences in seasonal norovirus activity are linked to other factors which are not fully understood.

ALLYING EPIDEMIOLOGICAL SURVEILLANCE WITH LABORATORY ANALYSIS OF STRAINS

The future of surveillance will depend largely upon the development of new technologies in the sphere of diagnostic microbiology. Analysis of strains circulating in real time can provide clearer information on what strains are causing illness and if some are causing larger outbreaks than others. This means a closer integration of both laboratory and surveillance data. Linking epidemiological data gathered on outbreaks with laboratory results and analysis will provide a clearer picture of any differing impact that circulating strains have on outbreaks (assuming one exists). At present, this is very unclear.

As mentioned earlier, the question often arises as to whether a number of cases in an outbreak are linked. Outbreaks occur on more than one ward in a hospital or in several rooms in a nursing home. The approach to dealing with outbreaks in health care settings is typically to take specimens only from a few individuals; often these are the first few symptomatic cases recognized. This approach is a holdover from the days of using electron microscopy, a relatively insensitive, time-consuming, and costly method of detecting norovirus. The advent of molecular techniques, i.e., RT-PCR, has increased both the speed and sensitivity of detecting norovirus in patient samples.

One technological development that has considerable potential as a typing and epidemiologic tool is sequence analysis of a small hypervariable region of norovirus genome. Studies have analyzed the P2 domain to assess whether infections are the result of clonal transmission or are the result of multiple sources (43–45). This would provide useful evidence of infection control breakdowns where transmission events are shown to occur from one individual to another. In outbreaks in which the vector is likely to be food, this would be useful in pinpointing failures of hygiene, such as an infected food handler who has contaminated food during preparation. These methods, which are still in development, have yet to be used routinely and are likely to be expensive.

The best strategy for sampling and laboratory testing during outbreaks is largely dependent upon the nature of the investigation. For example, most physicians are probably not interested in which genotype of norovirus the patient has, just that the patient has a norovirus infection. This can impact the scope of testing. Does a hospital test a few patients just to establish that there is an outbreak, or do you test broadly to ascertain whose diarrheal illness is caused by a specific norovirus and exclude patients that may have diarrhea due to other pathogens (e.g., *Clostridium difficile*, sapovirus, or rotavirus). For infection control professionals, testing broadly and providing subtyping information that clarifies the number of norovirus variants present is helpful for ascertaining whether patients are part of one or more outbreaks. Having information on genogroup/genotype also will provide supporting evidence for any planned interventions and help to assess the success of those interventions once they are put in place. Unfortunately, such testing is costly and often is not undertaken, simply for financial reasons.

In an increasingly litigious world where holidays are said to be ruined by outbreaks, the expense of taking samples and testing to a higher resolution, such as analysis of the P2 domain, might be justified since the data generated could potentially prove or disprove whether someone was part of an outbreak. The major question is who bears the cost of that testing. Given the scope of some norovirus outbreaks, the capacity for laboratories to deal with the increasing workload associated with more specimens being taken for analysis can quickly be overwhelmed. The availability of newer commercial methods that simplify testing may impact this dilemma in the future.

An alternative approach to testing that has been suggested is to apply the use of metagenomics to identify noroviruses in fecal samples. In general, the advantage of such techniques for dealing with bacterial infections is that the time required for culturing and isolating the bacterium can cause a delay in identifying the etiologic agent of the illness, especially if there isn't an easy and reliable test for a particular organism, such as for enteroaggregative *Escherichia coli* or other diarrheagenic varieties of *E. coli* (46). Metagenomics provides a mechanism for identifying an organism by sequencing the nucleic acid extracted directly

from samples (46). However, for diagnosing norovirus infections, RT-PCR is straightforward and is widely becoming the standard of care, so for simple diagnosis metagenomics does not provide any advantage, particularly since metagenomics is still quite expensive. Where metagenomics may be of value is in identifying other microbial factors associated with susceptibility to disease. For example, a recent article suggests that the bacterium *Enterobacter cloacae* facilitates norovirus binding to human cells (47). Metagenomics might be useful for identifying carriage of commensal bacteria, which, if removed, could help prevent norovirus infection in susceptible populations. However, at present this is speculative.

FUTURE TECHNOLOGIES/DEVELOPMENTS

The difficulty of relying on molecular methods for diagnosis, as highlighted above with detecting the presence of norovirus in patient stool samples, is that it leaves the question of causality unanswered. Development of methods to show viability of virus in samples would be useful in determining whether norovirus is the cause of the illness. As mentioned above, norovirus contamination of oysters in U.K. waters, particularly during the winter months, is common. Despite the detection of norovirus in oysters, outbreaks or illnesses associated with the consumption of oysters are seldom reported; outbreaks are under-ascertained, and only larger outbreaks where parties of people who are known to each other are more likely to be reported. Techniques are now being developed to help distinguish between virus in samples that are infectious or noninfectious. The idea is that it is possible to distinguish between intact virus particles, which are more likely to cause illness, and virus particles that are not intact (48). This may provide a very different view of norovirus epidemiology.

CONCLUSIONS

The reservoir for norovirus infection is the human gastrointestinal tract. This means that any sporadic illness must inevitably be part of a chain of transmission from one person to another. Norovirus does not grow on foods and therefore cannot be truly foodborne in the same way that zoonotic bacteria cause gastrointestinal illness. Nonetheless, foods can be effective vehicles for infection whereby one person, through lack of diligence to hand hygiene during food preparation, can infect a large number of others with norovirus. Similarly, the contamination of food with norovirus at the source, such as either through contact with sewage or through irrigation, has the potential to infect many consumers, sometimes over large distances, when the food is consumed raw. Once a large number of people have become infected, person-to-person transmission can result in further amplification in large community outbreaks.

The principal challenge for surveillance of norovirus infections is the lack of contact ill people typically have with medical services, therefore evading a definitive diagnosis. This lack of direct measurement of illness means our current knowledge of the burden of disease from norovirus infections is often based on mathematical modeling to estimate the burden of norovirus illness in a population. This problem is not unique to norovirus. For example, *Campylobacter* spp. are the most common cause of bacterial gastroenteritis identified in England, yet the number of reported outbreaks remains low (49, 50). Even though campylobacteriosis is a more severe disease with a longer duration of illness, it is subject to considerable under-reporting. Electronic reporting can speed up the recognition of outbreaks and can improve the determination of the ultimate impact on public health, particularly in terms of the number of people affected and the duration of outbreaks. However, not all facilities use electronic reporting. The collection of data in the community, particularly the occurrence of sporadic norovirus illness, is likely to remain a challenge given the lack of contact of patients with medical services to get a definitive diagnosis.

What is clear is that to obtain a greater understanding of the epidemiology of norovirus infections requires a close integration between microbiology and epidemiology resources. The possibility of a norovirus vaccine in the near future (51) will clearly require greater understanding of the epidemiology of the disease to determine which populations would benefit most from vaccination and what the ultimate impact of a vaccine could be. The introduction of PCR testing has increased awareness of the prevalence of asymptomatic carriage of norovirus, yet the implications of such asymptomatic carriage are not fully understood, especially in controlling spread of disease. Unraveling this question may require novel methods, such as those being developed to ascertain if virus in samples is intact and therefore likely to cause illness. Norovirus will likely be a challenge for years to come.

Molecular Diagnostic Assays for the Detection and Control of Zoonotic Diseases

J. SCOTT WEESE

23

Zoonotic pathogens, those that are naturally transmissible from animals to humans, are important causes of morbidity and mortality in humans, with outcomes ranging from mild to fatal and occurrences from sporadic disease to pandemics. These pathogens have had profound impacts on human health throughout recorded history and will continue to pose challenges, as the majority of emerging pathogens are zoonotic (1). Continued encroachment of humans into previously undeveloped regions, concentration of human and animal populations from urban sprawl, expanded animal and vector ranges resulting from climate change, increasingly mobile animal populations, and rapid international movement of animal-based foods facilitate the emergence and rapid dissemination of zoonotic pathogens. Recent years have been accompanied by dramatic instances of newly identified zoonotic pathogens (e.g., severe acute respiratory syndrome coronavirus [2], Middle East respiratory syndrome coronavirus [3, 4], Hendra virus [5]), marked range changes in known pathogens (e.g., West Nile virus in North America [6]), and new variants of well-known pathogens (e.g., H1N1 pandemic influenza A [7]). Potential new clinical roles for known pathogens have also been identified, such as the recent association of *Bartonella henselae* with some neurocognitive disorders (8). The close relationship between animals and humans has also been reflected in the identification of interspecies transmission of important pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) (9) and extended-spectrum beta-lactamase-producing *Enterobacteriaceae* (10, 11). At the same time, "traditional" zoonotic pathogens such as rabies virus, influenza A, *Salmonella*, *Campylobacter*, and *Coxiella burnetii* continue to pose tremendous challenges. While the overall impact of zoonotic diseases is not known (and virtually impossible to quantify), it is undeniable that diseases spread directly from animals, from animal products, and from animal contamination of the environment have a profound impact on human health and require substantial efforts for diagnosis, treatment, prevention, and control. All of those have a foundation in accurate and timely diagnostic testing, so it should be no surprise that molecular diagnostic testing is increasingly being used to identify zoonotic pathogens.

The use of molecular diagnostic testing for zoonotic diseases encompasses a wide range of potential activities, each with different objectives and challenges (Table 1). These include:

- Clinical diagnostic testing of sick animals to detect zoonotic pathogens
- Routine surveillance of healthy animals, targeting a zoonotic pathogen
- Routine surveillance of food or water for zoonotic pathogens
- Testing of animals in response to a zoonotic disease case or outbreak
- Testing of food or water in response to a suspected zoonotic disease case or outbreak
- Clinical diagnostic testing of humans that identifies a zoonotic pathogen
- Testing of animals, humans, food, and water in response to an unknown disease problem
- Distinguishing vaccination antigen from natural infection

In some ways, a separate discussion of the use of molecular diagnostic assays for zoonotic pathogens (versus other pathogens) is redundant since the concepts of testing apply across all pathogens, regardless of whether or not they belong to the large percentage of infectious diseases that may have a zoonotic origin. The ultimate goal is the same: to identify (and potentially characterize) a pathogen. Yet differences in pathogen biology, sampling challenges, test development, laboratory availability, regulatory scrutiny, quality control, cost, and related factors indicate a need to consider the non-human side of the zoonotic pathogen continuum.

Thus, while the overall objectives of the different areas listed above are similar, approaches taken for animals, food, and water can vary greatly from approaches taken for humans. Further, there can be marked differences between animal populations, which could encompass food-producing animals, household pets, and wildlife. Widespread national and international movement of some domestic animals (e.g., horses, dogs) and migration of vast numbers of wildlife create further challenges in zoonotic disease investigation, prevention, and control, all of which may involve molecular diagnostic testing.

POTENTIAL BENEFITS AND COSTS

As with any application of a diagnostic test, the potential costs and benefits of molecular diagnostic testing for

J. Scott Weese, Department of Pathobiology, Ontario Veterinary College, University of Guelph, Guelph, ON, N1G2W1, Canada.

TABLE 1 Examples of molecular diagnostic approaches for zoonotic diseases

Category	Pathogen example	Comments
Food	Shiga toxin–producing *Escherichia coli* (STEC)	Immediate differentiation of STEC from other *E. coli*. Short turnaround time reduces holding delays while awaiting results or release of food before results are available.
Food animals	*Coxiella burnetii*	Much faster and easier for this fastidious pathogen that requires biosafety level 3 containment for isolation.
Companion animals	*Leptospira* spp.	More rapid and accurate than seroconversion. More readily available than culture or dark-field microscopy. Hampered by limited understanding of leptospiral shedding, potentially associated with false-negative results.
Wildlife	Avian influenza	Rapid screening for a pathogen that is of potentially profound public health significance. Shorter turnaround time and limited biosafety concerns compared to culture. Cost can limit widespread use.
Foreign and reportable diseases	*Brucella* spp.	Rapid screening to facilitate importation and reduce risk of entry into disease-free areas, and prompt identification of imported disease. High negative predictive value required.
Import screening	Limited use currently	Potential role of sensitive and rapid tests, potentially at point of import, to test for selected pathogens to decrease the risk of entry of pathogens and/or to have testing replace broad importation bans. High negative predictive value required.
Outbreak investigation	*Bacillus anthracis*	Rapid diagnosis for early intervention. Reduced laboratory safety concerns compared to culture. Lack of typing ability may be a limitation.
Differentiation of vaccine antigen from natural infection	Limited use currently	Few clearly demonstrated examples but a potential benefit to facilitate use of vaccination in outbreak response in situations where it is currently limited or prohibited.

zoonotic disease detection and control must be considered. Benefits include the ability to provide shorter turnaround times, something that could be critical from many standpoints, increased sensitivity, detection of fastidious organisms, and detection of pathogens without the need for culture and the associated biocontainment requirements. Advances in testing that facilitate field testing could also be of tremendous use, permitting decentralization of testing so that rapid testing could be performed on farms, in food production facilities, at veterinary facilities, in the field, and at other postcare or point-of-sampling locations.

Costs include the economic cost of testing, which is often greater than conventional (e.g., culture) methods, the need for specialized equipment, and greater technical demands. Yet advances in technology will probably reduce these limitations. Test development and validation costs can also be substantial, something that is often overlooked. An inability to provide an isolate for further testing and/or to characterize a detected pathogen may also limit some clinical and epidemiological applications of molecular methods.

Cost-benefit analyses are typically lacking and would vary greatly with the test, animal species or food product, disease, and region, and technological advances make this a rapidly moving target.

USE OF MOLECULAR DIAGNOSTIC TESTING IN DIFFERENT TYPES OF ANIMAL POPULATIONS AND SITUATIONS

Food

Food is an important vehicle for zoonotic pathogens, and the incidence of food-borne disease is high in both developed and developing regions. In the United States alone, an estimated 48 million food-borne illnesses occur yearly, with over 100,000 hospitalizations and 3,000 deaths (12). Testing of food may be performed at various levels in the production and distribution chain as a routine tool, with additional testing performed in response to outbreak concerns.

Traditionally, most food testing has involved culture, with molecular methods sometimes used for confirmatory testing or characterization of isolates. However, the potential for molecular diagnostic testing to increase sensitivity, decrease turnaround time, and increase throughput has been embraced, and there is increasing movement toward "point-of-care" molecular tests in food production (13). As with point-of-care testing in health care, movement of properly validated tests to food production sites (assuming proper test operation and quality control) can reduce turnaround times (facilitating test-and-hold procedures so that contaminated products are not released versus being recalled later, and facilitating more rapid investigation of causes of contamination to reduce further contamination), improve sensitivity of detection for some pathogens (e.g., *Campylobacter*), and potentially reduce costs (which might facilitate broader testing). Potential concerns include test sensitivity and specificity, the requirement for smaller facilities to have adequately trained personnel and quality control practices, limitations in the ability to detect broader population changes if there is no centralized reporting of results, and a lack of characterization (antibiogram, typing) for integration with clinical testing results. These can largely be overcome with proper test validation, a commitment to proper in-facility testing, communication of test results, and either performing secondary testing (i.e., culture) on selected positive samples, submitting subsets of

positive samples to another laboratory for secondary testing, or holding aliquots of positive samples for potential future testing. Testing for multiple pathogens through multiplex PCR, microarray, or panels of individual molecular tests can also be beneficial (14). Further, some molecular tests can provide additional and important information at the time of pathogen identification, such as detecting Shiga toxin-producing *Escherichia coli* rather than simply detecting *E. coli*. Yet while molecular methods have many potential advantages, the need for isolates to perform antimicrobial susceptibility testing and the need for some typing methods mean that a complete transition to culture-independent methods will not likely occur in the short term.

Integration of human diagnostic testing to identify food-borne disease, identify clonal outbreaks, and facilitate identification of the inciting food source is critical and can involve different types of conventional and molecular assays. The United States' PulseNet, an integrated network of public health and food surveillance laboratories, is an example of such a system. Integrated national surveillance programs like this can have a profound impact, and PulseNet is credited with prompting the recall of over 650 million kg of potentially contaminated food over the past 15 years (12) while identifying thousands of outbreaks and presumably preventing a large number of illnesses and deaths.

As opposed to tests used for many other situations described in this chapter, tests used on food have typically undergone more scrutiny and standardization. A wide range of validated methods has been published for a range of pathogens such as *Salmonella*, *Listeria*, and Shiga toxin-producing *E. coli* (15, 16). However, there are no universally accepted guidelines for performance standards. Obviously, a test that is 100% sensitive and specific is ideal, yet this is rare. Implications of false positives (e.g., resources required for follow-up investigation, condemnation of potentially large amounts of food, false disease burden estimates, consumer fear, economic impact on farm animal production) and false negatives (e.g., failure to identify a developing problem) must be considered alongside the expected population prevalence (which will impact the positive and negative predictive values).

Movement to molecular diagnostic tests, from the field or production facilities to national reference laboratories, is not without challenges, given the historical reliance on culture and the need for profound changes in equipment, skills, training and, indeed, mindsets. Beyond validation of tests, broader efforts to standardize both the tests and their applications (i.e., encouraging the use of the same standardized assays between laboratories) and to standardize data collection and reporting are required to facilitate prompt and accurate identification of outbreaks and food-borne disease threats. Harmonized molecular testing and data analysis, such as PulseNet's standardization of testing and classification protocols for various pathogens through methods such as pulsed-field gel electrophoresis (17, 18) or multilocus variable number tandem repeat analysis (19), are critical. International harmonization is less commonly performed but is similarly important because of the international distribution of the food supply chain and corresponding international outbreaks (20–23). Improvements in harmonization of protocols, along with coordination of typing nomenclature and data reporting, are required given the ever-expanding risk of international food-borne outbreaks.

An additional consideration for food (or animal) surveillance is the impact of changes in testing on disease trends. Since molecular diagnostic tests may have different (and often higher) sensitivities, changing test practices can be accompanied by spurious changes in disease rates. Therefore, it is critical that this be considered when investigating disease trends to avoid false conclusions.

The economics of food-borne pathogen testing play a major role in the selection of routine surveillance tests. In addition to accuracy, food testing requires a combination of rapidity (to minimize holding times and/or reduce the risk that food is sold before results are available), cost, and throughput (to allow for testing of large numbers of samples). Low limits of detection may be required for some pathogens that pose a particular risk and have very low infectious doses, such as *E. coli* O157:H7. Development of tests that have greater sensitivity but higher costs can create a quandary when resources are fixed, since movement to more expensive tests could result in smaller numbers of tested samples. Decreases in resources for laboratory detection and data analysis were commonly reported in a recent U.S. study (24), something that could hamper proper implementation of newer tests. The costs and benefits of any new test require careful study and may often be difficult to accurately quantify.

Food Animals

Food animals are important sources of zoonotic pathogens from direct contact, environmental contamination, and as the ultimate source of most food-borne pathogen contamination. The role of routine testing of food animals for the prevention of food-borne disease varies between animals and pathogens and is often limited. Testing to identify endemic pathogens (e.g., *Campylobacter* in poultry) is of little use in the absence of corresponding measures that would be taken in response to positive results, something that is typically the case. There is greater interest in testing for less common, high-impact pathogens (e.g., *E. coli* O157 in cattle), but as a routine measure, if there is no ability to intervene based on a positive result, screening is of limited impact, and control measures must be focused further along the production chain.

Accordingly, routine testing of food animals is rarely performed because of cost, logistics, the large number of food animals, and a lack of evidence for most pathogens that detection of a zoonotic agent in an animal on a farm represents a risk to the consumer. There are some situations, though, where testing could be justifiable. This would include outbreak investigation where a link to an individual farm is suspected (e.g., waterborne outbreak, petting zoo outbreak) or to investigate a developing zoonotic disease event such as hyperendemic Q fever in a region (25, 26). In these situations, farm-based surveillance would be justified for source attribution or to understand an apparent change in the epidemiology of disease. A situation where testing of healthy animals on farms is potentially useful and increasing is through national surveillance programs that monitor antimicrobial resistance in selected food-borne pathogens and indicator organisms (e.g., generic *E. coli*). Because of the need for antimicrobial susceptibility testing, these programs rely on conventional culture as primary tests, with molecular methods used on a more limited basis for isolate characterization and evaluation of virulence or antimicrobial resistance genes.

Molecular diagnostic tests are also of value for detection of pathogens that are fastidious and difficult or

impossible to isolate using conventional methods and those that require enhanced biosafety practices. A few examples of these are present in food animals, such as *C. burnetii*.

Beyond surveillance, testing of food animals is also performed diagnostically in response to disease. The approach to this varies greatly among species. For example, the low individual animal value of chickens means that testing of an individual chicken would be done not to determine an appropriate action to treat that individual, but rather in response to a concern about the entire flock. In contrast, individual animal testing for the purposes of both identifying a herd problem and determining an appropriate treatment course for the individual animal would be more economically justifiable in cattle. Therefore, test development for some species (e.g., poultry) focuses on high-impact pathogens that may have broad flock or herd effects, while there may be more justification for development of tests targeting sporadic diseases for more valuable animals (e.g., cattle).

Even with more valuable species, costs of testing can be a significant limitation because of the economics of food production and questions of who should pay for such testing (e.g., farm, manufacturer, government). Since diagnostic costs are almost exclusively borne by the producer, there must be a clear advantage to justify any changes in methods that might increase costs, and cost is a major reason that molecular testing has been used diagnostically on only a limited basis. Even in more economically valuable animals, testing for diagnosis of individual animal disease is rather limited at this time. Molecular tests are most commonly used for characterization of pathogens, mainly as part of surveillance activities (e.g., characterization of all *Salmonella* isolates from food animals) or outbreak investigations.

Harmonization of test methods, validation of tests, and integration of reporting systems are also important, as is discussed above for food. There are some strong examples of integrated surveillance systems, particularly for international avian influenza surveillance networks (27) and (mostly national) antimicrobial resistance surveillance programs (28–30).

Companion Animals

The potential role of companion animals in zoonotic pathogen transmission is often overlooked, despite the fact that pets are present in the majority of households in some countries (31). Further, the close nature of contact between people and domestic animals facilitates transmission of various zoonotic pathogens that are endemic or periodically encountered in companion animals. Companion animals are also able to act as bridging populations between wildlife and humans and act as intermediaries for transmission of wildlife-associated pathogens (e.g., avian influenza [32, 33], *Leptospira* [34]). There is also increasing evidence that companion animals can acquire pathogens typically associated with human infection from their human contacts (e.g., MRSA, *Clostridium difficile* [35–39]) and subsequently pose a potential risk to humans.

Most testing of companion animals is performed as part of clinical diagnostic testing by veterinarians in response to disease in an individual animal. Since a variety of diseases in companion animals are caused by potentially zoonotic pathogens (e.g., *Leptospira*, *Salmonella*, *Campylobacter*, dermatophytes, multidrug-resistant bacteria, *Giardia*), early and prompt diagnosis is important. Formal pathogen surveillance is limited, and it is rare that companion animal testing is performed in response to human disease events.

A wide range of molecular diagnostic tests are available through commercial diagnostic laboratories, and there is increasing use of molecular assays because of the perceived advantages of some tests, shorter turnaround times, and extensive marketing. Some molecular assays have proven advantages over conventional techniques, such as the potential to diagnose leptospirosis prior to seroconversion (40, 41). While many molecular assays may be more expensive than traditional methods, there are typically fewer economic constraints in companion animals because of the human-animal bond.

Broad national efforts are rarely directed at companion animals; however, zoonotic disease outbreaks associated with companion animals can be detected when they are caused by enteric pathogens that are tracked by established food-borne surveillance systems. For example, outbreaks of salmonellosis associated with feeder rodents, pet food, and pet frogs have been identified through PulseNet surveillance (42–44).

Wildlife

Comprehensive surveillance studies are performed on many wildlife species, including urban wildlife (45), wildlife that live in close proximity to livestock (46), wildlife that largely confine their range to local areas, and migratory species that can traverse countries or continents (47, 48). Many objectives are approached with wildlife surveillance, including zoonotic pathogen surveillance. Targeted surveillance activities may also be instituted in response to specific disease threats, such as wild bird screening for influenza A (49, 50), exploratory surveillance to identify natural hosts of pathogens such as Ebola virus (51) or the SARS coronavirus (52), investigation of animal sources in response to sporadic or epidemic disease in humans (e.g., leptospirosis), and evaluation of antimicrobial resistance in pathogens and commensal bacteria (53, 54).

Laboratory methods are not usually developed strictly for wildlife testing. Rather, wildlife testing is typically performed using methods established for other species or sample types. There is an increasing number of molecular tests for targeted pathogen detection (55, 56), broad-range methods to identify microbial populations (microbiotas) (57), or nonspecific methods to identify known and unknown organisms (e.g., next-generation sequence-based viral discovery approaches).

Various challenges can be encountered with wildlife surveillance, not the least of which is actually obtaining samples. Initial handling, processing, and shipping of wildlife samples may be more complicated than for other animal populations because sampling may be done in remote field locations, necessitating consideration of the impact of sample storage and shipping time and conditions (e.g., temperature) on test results. While some molecular methods may offer benefits by being more tolerant of roughly handled specimens, testing the impact of handling, storage, and shipping on specific samples used for specific tests is optimal, albeit uncommonly reported. The cost of testing is often a limiting factor in wildlife surveillance, particularly studies in which large numbers of animals are tested. Decreasing costs and increasing access to molecular methods, though, have facilitated the use of molecular assays, which can be used to both replace (e.g., pathogen detection assays) and supplement (e.g., molecular typing) traditional methods.

Emerging Diseases

Inherently, it is impossible to make specific plans for detecting emerging zoonotic diseases. Yet diagnostic testing plays a critical role in the identification, characterization, and containment of new disease threats. Newly identified pathogens can be identified through a variety of means, ranging from traditional culture to various molecular methods. Advances in next-generation sequencing and bioinformatics have revolutionized new pathogen discovery. In many ways, technology has surpassed knowledge, and finding new microorganisms is often easier than determining what those findings actually mean. Many new microorganisms of unknown or limited clinical relevance have been identified in animals (58–60), along with the realization that detection of a new organism and detection of a new pathogen are not necessarily synonymous. Therefore, once an emerging pathogen is identified, the ability to efficiently develop a practical and accurate test can play a major role in determining the relevance and risks and developing a response (when a response is indicated). Given the potential for rapid testing and increasingly accessible "broad-range" methods for pathogen discovery, molecular assays will likely be at the forefront of emerging zoonotic disease response.

Foreign and Reportable Diseases

Foreign animal diseases are diseases that are not established in a particular country or region. Reportable diseases are diseases that must be reported to regulatory bodies at the time of suspicion, time of diagnosis, or on a periodic basis. Many diseases in these categories are subject to scrutiny because of the potential for zoonotic transmission and/or establishment of an endemic presence in a region that is currently free of the pathogen. For both of these disease types, rapid diagnosis is important because prompt identification can help identify exposed individuals, reduce the risk of subsequent animal and human exposure, and facilitate a prompt containment response. High analytical sensitivity is important, but because of the potential implications of positive results (e.g., euthanasia of an animal or depopulation of a group of animals, importation restriction, prolonged quarantine, cost of investigation), specificity is also important, either through a primary assay that is both highly sensitive and highly specific or by using a two-step approach with a more specific assay to confirm positive screening results.

Import Screening

The amount of international movement of animals is poorly understood and typically underappreciated. Millions of animals cross borders, along with their microbial inhabitants. Some importation is performed with detailed regulations and scrutiny; however, this is largely restricted to food animals. Startlingly little scrutiny tends to be placed on companion animal species, and obviously, wildlife can cross borders at will.

It is unlikely that international movement of animals will decline. Severe restrictions will continue to be present for certain animal species in certain regions to prevent importation of known pathogens. Economic factors and free trade agreements often create pressures to decrease restrictions, yet border restrictions or prohibitions are frequently implemented in response to zoonotic disease concerns from exporting regions. The availability of highly sensitive, rapid testing methods can lead to altered regulatory restriction, facilitating a balance between adequate bioexclusion and limiting economic and political impacts. Conversely, a lack of adequate testing or poor-quality tests could result in import restrictions, something that can have a profound economic impact in some animal sectors.

Concerns are not restricted to food animals and food, although those remain the areas of greatest focus. The largely uncontrolled movement of companion animals has led to importation of pathogens such as rabies, *Leishmania*, and *Echinococcus multilocularis*. As awareness of these concerns is heightened, consideration of control measures is needed. Regulatory restriction is a less desirable approach and is impractical in regions where thousands of pets cross borders. As with food animals, the availability of highly sensitive testing that could be performed (potentially at the point of entry) could be a practical measure to reduce the risk of introduction of selected zoonotic pathogens. Test turnaround time is a critical factor for import testing. If testing is done prior to export, long turnaround times provide more of a chance for the individual to become infected between sampling and export or result in the need for a prolonged quarantine during the testing period. Similarly, if testing is done after importation, test results are ideally available before the animal is exposed to other animals in the country, so short turnaround times can limit quarantine times and identify infected animals as early as possible. Importation may be considered a somewhat marginal issue, but given the potential implications of introducing a foreign zoonotic pathogen into a naïve population, it is a subject that bears consideration.

Outbreak Investigation

The rapid nature of many molecular diagnostic tests, compared to traditional methods (e.g., culture), can facilitate a rapid and effective outbreak response. Further, culture-independent methods have advantages over isolation methods for pathogens that are not readily detected by culture and that require enhanced biocontainment for isolation (e.g., *Bacillus anthracis*, *Brucella* spp., *Yersinia pestis*, *Francisella tularensis*, *C. burnetii*, *Chlamydophila psittaci*, Hendra virus) or where testing is limited to specialized facilities (e.g., government reference laboratories). The use of proper molecular tests can potentially decrease turnaround time, increase the sensitivity of testing, and increase throughput, although these vary by test and pathogen. A major limitation of most molecular diagnostic tests is the inability to provide typing data, which are typically critical for outbreak investigation. However, these tests can still be incorporated into zoonotic disease investigations as rapid screening tests, in combination with culture, and as secondary tests to characterize recovered isolates. Newer methods that can both identify and characterize pathogens will likely become important outbreak investigation tools.

Differentiation of Vaccine Antigen from Natural Infection

Vaccination is used to control various infectious diseases in animal populations, yet recent vaccination can interfere with infection control responses with some vaccine and diagnostic test combinations. Confusion may arise when tests cannot differentiate natural infection from vaccine response. This is predominantly a concern with infectious (modified live) vaccines when testing is performed shortly after vaccination. Since these vaccines are designed to replicate *in vivo*, vaccine antigen may be present in the body in detectable levels for a variable amount of time

postvaccination. The potential for confusion has limited the use of vaccine for some animal diseases during outbreaks, because of interference with testing-based outbreak response (e.g., test and quarantine or test and slaughter measures). It is also a concern for endemic diseases when an animal develops clinical signs consistent with a zoonotic disease shortly after vaccination against that disease. In that situation, differentiating a positive result from vaccine antigen versus a positive result from natural infection is important to determine whether zoonotic risks may be present and whether further investigation or precautions are required. In some situations, molecular diagnostic assays can be used to determine the nature of the positive response, through detection of specific markers or with evidence-based thresholds that are consistent with natural infection versus the lower level of vaccine antigen.

USE OF MOLECULAR TYPING METHODS FOR ZOONOTIC DISEASE

While the focus is often on the use of molecular assays to identify a pathogen, characterization of the pathogen may be equally important in some situations, as has been discussed repeatedly above. This can involve detecting virulence factors (e.g., to differentiate clinically relevant from irrelevant types), detecting host-specific factors to infer the origin (e.g., evaluation of MRSA for the human-specific *scn*) (61, 62), providing molecular epidemiological data for outbreak investigation, and identifying important virulence factors (e.g., enterotoxin gene detection of *S. aureus* from food) (63). Genotypic characterization can also determine whether a zoonotic risk is present, such as with differentiation of nonzoonotic versus zoonotic *Giardia* assemblages (64–66).

Molecular typing is the most commonly used tool and can provide critically important information about some pathogens. This can involve various conventional molecular typing methods such as pulsed-field gel electrophoresis, multilocus variable number tandem repeat analysis, PCR ribotyping and sequence analysis of various genes, along with methods evaluating the presence or absence of specific (usually virulence) genes. It is likely that these will soon be supplanted by whole-genome sequence analysis, because sequence costs continue to plummet and bioinformatics throughput is increasing. Whole-genome sequence-based approaches to outbreak investigation have been reported for human pathogens (67) and have been used to differentiate human versus animal sources of potentially zoonotic pathogens (68).

While there has been limited use of whole-genome sequence analysis for zoonotic outbreak investigation, there is no reason that whole-genome sequence investigations will not become common, if not the norm, for a range of zoonotic pathogens in the near future.

CROSS-APPLICATION OF TESTS DEVELOPED FOR HUMANS

Tremendous effort, time, and expense go into the development and validation of assays that are used in humans. This amount of effort and cost are often unacceptable for development of tests to be used in animals because of an inability to recover costs in most situations. Yet the fact that the targeted organism is the same in humans and animals (otherwise it would not be a zoonotic pathogen) means that consideration can be given to cross-application of well-scrutinized human assays, when available. This has the potential to allow for more rapid development and implementation of tests for use in animals, but it does not mean that all development and validation steps can be bypassed, since identical performance of tests in different species cannot be guaranteed. While the target organism may be the same, there may be differences in the test samples that could impact the assay. This has received limited investigation; however, as an example, a commercial real-time PCR MRSA assay licensed for use in humans was identified as performing poorly in horses (69). Despite use of the same types of samples compared to humans (nasal swabs), the sensitivity of the assay was poor in horses. Reasons were not investigated but likely involved the presence of PCR inhibitors in equine nasals swabs. This assay was being evaluated as a potential tool for MRSA control in equine hospitals and on farms, and performance of this assay would have led to underdiagnosis and likely increased risk of MRSA transmission to other horses and humans. Thus, this assay would either be considered unacceptable for use in horses or would require further development to overcome the problems with test sensitivity. Accordingly, while cross-application of assays is a logical and potentially efficient approach, it is important that species- and sample-specific validation be performed to ensure that assays developed for humans can achieve their intended goals in animals.

ROLE OF VETERINARY ACADEMIC AND DIAGNOSTIC LABORATORIES IN ZOONOTIC DISEASE CONTROL

Commercial diagnostic laboratories and academic laboratories perform most diagnostic testing for animals. Those laboratories may also perform food testing, but food manufacturers do a substantial component of testing in-house. The disseminated nature of testing related to zoonotic diseases necessitates coordinated efforts involving reference (typically government) laboratories, human hospital laboratories, human commercial diagnostic laboratories, academic institutions, and veterinary diagnostic laboratories. This is often essential because of the need for parallel testing of clinical specimens from humans (human diagnostic laboratories), characterization of the pathogens (mainly reference and academic institutions), and testing of potential animal, food, or water sources (mainly government, academic, and veterinary laboratories). Proper investigations are dependent on an understanding of the testing methodologies, test performance, and laboratory performance across all partners, highlighting the need for proper and transparent testing practices in all sectors. While rigorous test development and quality control practices are in place for human diagnostic and reference laboratories, the same may not be true for academic and veterinary facilities, in part because of differences in the regulation of diagnostic testing.

REGULATION OF DIAGNOSTIC TESTING IN ANIMALS AND QUALITY CONTROL PRACTICES

The principles of laboratory quality assurance and quality control apply across species; however, application of those practices outside of accredited medical diagnostic laboratories is variable. There are no regulatory bodies for veterinary diagnostic laboratories (70) and no requirement for

laboratories to follow CLSI (or equivalent) guidelines, to evaluate and validate tests, to provide information about test performance parameters (e.g., limit of detection, target, sensitivity, specificity), or to have any form of quality control program. Voluntary accreditation such as through the American Association of Veterinary Laboratory Diagnosticians, development and implementation of quality control management systems such as the International Standards Organization 17025 standard (71), and/or use of guidelines developed by groups such as the American Society of Veterinary Clinical Pathology Quality Assurance and Laboratory Standards Committee (http://www.asvcp.org/about/committees/qas.cfm) can be achieved by veterinary diagnostic laboratories and can provide some degree of confidence in the quality of the laboratory. Guidelines are also available for point-of-care testing (72). Yet reliance on voluntary approaches such as these creates an environment where some laboratories use rigorous practices similar to those used in human diagnostic laboratories while others use highly questionable methods and assays.

While there are extensive validation and approval (e.g., U.S. Food and Drug Administration) requirements for assays used for clinical testing in humans, the same does not apply for most tests used on animals (70). Apart from tests used for specific regulatory purposes (e.g., international animal movement screening), there are typically no requirements for any degree of test development and validation. Many, if not most, veterinary molecular diagnostic tests have limited (or no) published supporting data about relevant aspects such as their sensitivity, specificity, repeatability and limit of detection. Any information, along with quality control practices, is often limited to internal use by companies and not made publicly available (ostensibly for proprietary purposes).

There has been limited independent investigation of the accuracy of testing performed in commercial veterinary diagnostic laboratories. One study compared results of feline immunodeficiency virus PCR from three different North American veterinary diagnostic laboratories and found that correct results were only reported in 58 to 90% of samples (73), with one laboratory's assay having a sensitivity of only 41%. A similar but small study of avian polyomavirus testing reported accuracy rates of 75 to 100% among five commercial laboratories, with two laboratories having testing sensitivities of 50 and 60% (74). Efforts directed toward development of transparent methods that can be applied across laboratories have mainly been limited to food-borne pathogens (15, 16). Overall, users often have limited guidance in selecting tests and interpreting results. This can be of particular importance for zoonotic pathogens because of the potential human health implications of the testing.

Related to the lack of regulation discussed above is the potential for tests to provide misleading results if the actual targets are not known or understood. This is particularly true for assays that are used for specimens outside of their normal sample types. An example is the use of real-time PCR assays on ticks found on dogs. Some commercial PCR assays target *Borrelia* spp. but are marketed as *Borrelia burgdorferi* (Lyme disease) tests because of the reasonable presumption than any *Borrelia* found in a dog (or human) would be *B. burgdorferi*. However, ticks can harbor other *Borrelia* spp., so positive results from a tick sample could have a poor positive predictive value and be clinically misleading. Another concerning example was reported identification of *Rickettsia rickettsii*, the cause of Rocky Mountain spotted fever, in a tick from a dog from a household with a child with an undiagnosed disease. While finding an infected tick on the dog could provide evidence of potential human exposure from the same source, the case occurred in an area far removed from where this pathogen and its host tick are known to occur. Subsequent investigation revealed that the PCR assay was nonspecific, being able to detect a range of *Rickettsia* species, including species that pose no risk to humans. Thus, any use of an assay outside of its intended sample type, without adequate scrutiny and without adequate understanding of the target (and the biological relevance of that target), could result in misleading information about human health risks.

Another concern related to commercial assays is tests without a biological basis for use of the test results to make reasonable decisions. Some veterinary commercial PCR laboratories offer panels of tests to identify zoonotic pathogens in healthy animals as part of "wellness screening." In addition to the issues discussed above, this can result in confusion or illogical actions because many potentially zoonotic pathogens are common commensals, and finding the pathogen in an animal often does not indicate the need for any response (e.g., treatment, altered management). This can lead to inappropriate actions such as unneeded antimicrobial therapy, fear of the pet, rehoming of the pet, or occasionally euthanasia. Screening of healthy animals for pathogen shedding is rarely recommended, even for animals that encounter high-risk individuals such as hospital visitation dogs (75) and animals owned by individuals with human immunodeficiency virus infection (76). Thus, the increased availability and decreasing cost of molecular screening assays can result in worsened care if inappropriately applied.

INTEGRATION OF TESTING AND REPORTING

The oft-discussed (but infrequently practiced) "one health" approach involves coordinated investigation, testing, and data reporting across species. Unfortunately, that is rarely present, particularly outside of food-borne pathogens. Apart from outbreak investigations that are coordinated and performed by regulatory agencies, disjointed information is typical. Even when regulatory bodies direct outbreak investigations, there may be inconsistencies, inefficiencies, and poor coordination when different groups are in charge of different facets (animal, human, food, water) of the investigation. Clearly, much improvement is needed.

CONCLUSIONS

As with most areas of infectious disease surveillance and diagnostic testing, there is increasing interest in molecular diagnostic assays because of a range of potential advantages. Molecular diagnostic tests are commonly and increasingly used in some animal sectors, both as primary pathogen detection tools and as secondary tests. These assays can provide important advances in the diagnosis, surveillance, and management of zoonotic diseases, but their use is complicated by variable (and often substandard) test development and validation and a lack of evidence regarding optimal use. Technological advances and the ever-present risk of emerging zoonoses will continue to drive interest in molecular assays. However, proper test development and validation, coordination of testing and reporting,

and a proper "one health" approach are required for optimal use of these potentially powerful diagnostic tools.

Molecular Approaches to the Diagnosis of Meningitis and Encephalitis

KAREN C. BLOCH AND YI-WEI TANG

24

INTRODUCTION AND GENERAL DISCUSSION

Meningitis and encephalitis represent central nervous system (CNS) infections where rapid and accurate identification of an infectious agent is essential for management. CNS infections present a challenge for both the microbiologist and the clinician due to the vast number of pathogens associated with these syndromes (1, 2). Molecular diagnostic techniques such as PCR have replaced slower and less sensitive tests for a number of bacterial and viral causes of CNS infection (3). This chapter reviews various diagnostic tests available for CNS infections and provides a detailed discussion of specific molecular approaches to the most common organisms causing meningitis and encephalitis in the United States.

Pathophysiology of CNS Infections

The CNS has unique anatomic and immunologic characteristics that distinguish infection at this site from those involving other organ systems. The brain and spinal cord are contained within the bony confines of the calvarium and vertebral column. Cerebrospinal fluid (CSF) is produced in the choroid plexus of the ventricles and flows into the subarachnoid space at the cisterna magna and around the cerebral hemisphere, where it is reabsorbed by the arachnoid villi. CSF envelops the brain and spinal cord, providing cushioning and buoyancy for neural tissue. It carries essential metabolites into the neural tissue and cleanses the tissues of waste as it circulates around the brain, ventricles, and spinal cord. The blood-brain barrier (BBB) serves to limit the entry of microorganisms and inflammatory cells into the CNS. The absence of mediators of innate immunity in the CSF may contribute to the rapid progression and morbidity of CNS infections (4, 5). In addition, because of this anatomic barrier, antimicrobials used to treat CNS infections must have pharmacologic properties that allow them to penetrate the BBB, and maximal doses are usually required for bactericidal activity.

Karen C. Bloch, Departments of Medicine and Health Policy, Vanderbilt University School of Medicine, Nashville, TN 37232. **Yi-Wei Tang,** Departments of Laboratory Medicine and Internal Medicine, Memorial Sloan-Kettering Cancer Center and Department of Pathology and Laboratory Medicine, Weill Medical College of Cornell University, New York, NY 10065.

Meningitis

Meningitis involves infection localized to the subarachnoid space, sparing the brain parenchyma. While neural tissue is not directly infected, secondary damage may occur as a result of the host inflammatory response. Leukocyte migration into the subarachnoid space can result in occlusion of cortical blood vessels and damage to nerve roots that traverse the subarachnoid space. Clinically, this manifests as cranial or spinal nerve dysfunction and hydrocephalus. Activation of white blood cells leads to an inflammatory cascade, with release of cytokines, oxidants, and proteolytic enzymes. At the cellular level, this chain of events results in disruption of the BBB and impaired cerebrovascular autoregulation (6). Increased intracranial pressure may lead to transtentorial herniation or tissue hypoxia due to decreased tissue perfusion.

Encephalitis

Encephalitis is defined by the presence of an inflammatory process in the brain, associated with clinical evidence of neurologic dysfunction (7). Encephalitis can present with purely parenchymal findings but more commonly is associated with meningeal inflammation, representing an overlap syndrome termed meningoencephalitis. Additionally, encephalitis can coexist with myelitis, inflammation of the spinal cord, to cause encephalomyelitis. These three syndromes are often grouped together due to the significant overlap in the epidemiology, microbiology, and approach to management.

Most infectious agents that cause encephalitis gain access to the CNS through hematogenous spread. The initial site of entry and replication varies depending on the organism and may include the respiratory tract (e.g., measles virus), gastrointestinal tract (e.g., enteroviruses), or skin (e.g., arboviruses). Viremia follows localized infection, ultimately leading to invasion and replication with the CNS.

Hematogenously spread CNS infections, such as arboviruses, generally cause diffuse brain involvement, with global impairment in neurologic function. Infections introduced through other routes typically involve specific areas of the brain. For instance, following the bite of an infected animal, rabies virus is inoculated subcutaneously, with retrograde progression along peripheral nerves into the brain stem (8). In contrast, the free-living amoeba *Naeglaria fowleri* enters the host transnasally, passing through the cribiform plate and invading the frontal lobes of the brain (9).

The pathogenesis of herpes simplex encephalitis (HSE) is believed to occur following reactivation of the virus in the trigeminal ganglion, with spread to the frontal and temporal lobes via the tentorial nerves (10).

Classification of CNS Infections

CNS infections are typically classified based on the anatomic site of infection. Infection of the meninges, brain, and spinal cord results in the syndromes of meningitis, encephalitis, and myelitis, respectively. Focal CNS infections include abscess, subdural empyema, or subarachnoid empyema. Infection may be limited to a single anatomic compartment or may involve multiple sites (e.g., meningoencephalitis, encephalomyelitis). Acute meningitis is characterized by the onset of the triad of fever, headache, and neck stiffness over a period of hours to days (11). The hallmark of encephalitis is alteration in mental status, ranging from lethargy to coma. Myelitis is characterized by inflammation of the spinal cord with symptoms including fever, headache, and paraparesis or paralysis.

Meningitis and encephalitis are the two most common CNS infections and are covered in detail in this chapter. Differentiation of these two syndromes is important, because both the pathophysiology and microbiology of meningitis and encephalitis are distinct. Encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, while common causes of acute meningitis, do not cause encephalitis. Viruses are important causes of both syndromes but often demonstrate species-specific localization to discrete sites in the CNS. Enteroviruses and mumps viruses usually infect the ependyma and tissues of the subarachnoid space, producing meningeal irritation. In contrast, rabies viruses almost always involve the parenchyma and cause encephalitis. Herpes simplex virus (HSV) 1 characteristically causes temporal lobe encephalitis, whereas HSV-2 more typically causes meningitis. Such affinities are not absolute. For example, enteroviruses, the leading cause of viral meningitis, are increasingly recognized as a common cause of encephalitis (12) and acute flaccid paralysis (13).

Encephalitis can be further subclassified into infectious and inflammatory causes (7). Infectious encephalitis results from direct CNS invasion by the agent, with infection of the brain parenchyma. In contrast, inflammatory encephalitis, which typically follows an antecedent viral infection or immunization, predominantly affects the white matter of the brain. The most common inflammatory condition is acute disseminated encephalomyelitis, a demylinating condition seen primarily in children. A newly described autoimmune syndrome termed anti-*N*-methyl, D-aspartate receptor encephalitis has been reported as a more frequent cause of encephalitis than all viral entities combined (14). Clinically, inflammatory encephalitis may resemble infectious encephalitis but is caused by immune-mediated demyelination, and diagnostic studies aimed at identifying a pathogen, such as nucleic acid amplification tests (NAATs), are negative. Distinguishing infectious and inflammatory causes of encephalitis is important, because the latter are typically treated with immunosuppressive agents.

Microbiology of CNS Infections

Just as meningitis and encephalitis localize to distinct compartments of the CNS, the pathogens causing these two syndromes differ, and the respective microbiology of meningitis and encephalitis will be discussed separately.

Meningitis

The acute meningitis syndrome can be subdivided into bacterial and nonbacterial (sometimes referred to as benign lymphocytic or aseptic meningitis) etiologies. These entities can usually be differentiated clinically by the acuity of symptom onset as well as specific laboratory findings. Peripheral blood leukocytosis (>10,000/mm^3), CSF pleocytosis (>1,000/mm^3) with a neutrophilic predominance, and CSF hypoglycorrhachia (<40 mg/dl) favor a bacterial cause (15). A CSF Gram stain showing a predominant organism is strong presumptive evidence of a bacterial process and can be confirmed by a positive culture.

"Aseptic meningitis" is a nonspecific term used to describe culture-negative acute meningitis. In addition to viruses, the differential diagnosis for culture-negative meningitis includes rickettsial infections, spirochetal infections (e.g., *Treponema pallidum* or *Borrelia burgdorferi*), mycobacterial or fungal infections, inflammation from a parameningeal infection, or partially treated bacterial infections. In addition, there are numerous noninfectious syndromes that cause CSF pleocytosis, which can mimic infectious meningitis.

While viruses are the most common cause of culture-negative meningitis, in clinical practice a specific pathogen is rarely isolated in viral cultures. Epidemiologic studies using a standard diagnostic panel including CSF PCR detect a specific viral pathogen in approximately two-thirds of cases (16, 17). Enteroviruses are the most common cause of viral meningitis, accounting for up to half of all cases, and are particularly prevalent in children and young adults, with peak incidence in summer and fall (18, 19). Other relatively common viral causes of meningitis include HSV-2, acute HIV infection, varicella-zoster virus (VZV), and lymphocytic choriomeningitis virus (CMV). Arboviruses are also a significant cause of viral meningitis; however, the specific virus varies based on the geographic distribution of the arthropod vector.

Encephalitis

The spectrum of agents causing encephalitis has shifted due to a decrease in vaccine-preventable conditions and the recognition of newly emerging pathogens such as West Nile virus (WNV). However, while the specific etiologies have changed, the overall incidence has remained stable (20). Other emerging causes of encephalitis include Nipah virus (21), Toscana virus (22), enterovirus 71 (23), *Balamuthia mandrillaris* (24), and Chandipura virus (25).

In light of the large number of potential pathogens, a practical approach is to categorize agents on the strength of causal association with encephalitis (2, 7). The most commonly identified etiologies in the United States are HSV-1, WNV, and the enteroviruses, followed by other herpesviruses (1) (Table 1). Other agents may be highly endemic regionally (e.g., La Crosse virus) or internationally (e.g., rabies virus, Japanese encephalitis virus). Bacterial agents, including *Ehrlichia* spp. and *Rickettsia rickettsii*, are potentially treatable causes of encephalitis, and prompt administration of antibiotics may be lifesaving (26, 27).

A second category includes agents that are less commonly identified but are neurotropic and are well-associated causes of sporadic encephalitis (Table 2). A number of these have well-defined geographic distributions (e.g., Chandipura virus in India, Nipah virus in Malaysia), and consideration of these agents is indicated if there is travel or residence in an area of endemicity. Agents in this category include uncommon pathogens with prominent CNS

TABLE 1 Common causes of meningoencephalitis in immunocompetent patients

Etiology	Epidemiology	Molecular test applicability[a,b]	Diagnosis[d]
Viruses			
Borrelia burgdorferi[c]	Tick-borne infection with meningitis and cranial neuropathy in early disseminated Lyme disease; encephalopathy in late disease	B	Serology (serial EIA and Western blot), CSF antibody index, CSF PCR
Enteroviruses[c]	Peak incidence in late summer and early fall Enterovirus 71 a cause of outbreaks of rhomboencephalitis, with children primarily affected	A	CSF PCR is the test of choice Stool or throat swab PCR or culture suggestive, but not diagnostic, of CNS involvement 5′-UTR PCR detects most members of enteroviruses but does not provide genotype-specific information
Epstein-Barr virus[c]	Either during acute infection or reactivation Cause of primary CNS lymphoma	A, B	Acute infection: serology Reactivation disease or primary CNS lymphoma: positive CSF PCR may indicate secondary viral reactivation
Herpes simplex virus (HSV) 1 and 2[c]	HSV-1 accounts for 5 to 10% of all cases of encephalitis, typically reactivation disease HSV-2 causes encephalitis in neonates, aseptic meningitis in older individuals	A	CSF PCR is "gold standard" for diagnosis
Japanese encephalitis virus	Mosquito-borne, most common worldwide cause of encephalitis Endemic throughout Asia Vaccine-preventable	C	Paired serology, CSF IgM, CSF antigen (serology cross-reacts with other flaviviruses)
La Crosse virus	Mosquito-borne Endemic in midwestern and eastern United States Peak incidence in school-aged children	C	Paired serology, serum IgM
Rabies virus[c]	Vaccine-preventable Most common vector is bats, and bites often unrecognized; dogs important in developing countries Worldwide distribution	B	Antibodies (serum, CSF); PCR of saliva, skin, or CSF; IFA of nuchal biopsy or CNS tissue Coordinate testing with local health department
St. Louis encephalitis virus	Mosquito-borne Endemic to western United States, with periodic outbreaks in central/eastern United States	C	Paired serology (cross-reacts with other flaviviruses), CSF IgM
Tick-borne encephalitis virus	Vaccine-preventable Transmitted via tick or ingestion of unpasteurized milk Endemic to Eastern and Central Europe, Far East	C	Serum IgM, paired serology
Varicella zoster virus[c]	Acute infection (chickenpox) or reactivation (shingles)	B	CSF PCR and CSF serology are indicated DFA, culture, or PCR of skin lesions suggestive, but not diagnostic, of CNS involvement Serum IgM (acute infection) Vasculopathy best diagnosed by intrathecal antibodies
West Nile virus[a]	Mosquito-borne cause of epidemic encephalitis throughout United States, Europe Peak incidence in adults >50 years	B	CSF IgM, paired serology (cross-reactivity with other flaviviruses)

(*Continued on next page*)

TABLE 1 Common causes of meningoencephalitis in immunocompetent patients (*Continued*)

Etiology	Epidemiology	Molecular test applicability[a,b]	Diagnosis[d]
			CSF PCR limited to diagnosis in immunocompromised patients who have impaired humoral response
Bacteria			
Bartonella henselae (and other *Bartonella* spp.)	Encephalopathy typically follows scratch or bite from cat or kitten Highest incidence in children	B	Serology (acute usually diagnostic), PCR of lymph node, CSF PCR not useful
Mycobacteria tuberculosis[c]	Most common in developing countries Disease in extremes of age or immunocompromised	B	CSF AFB smear, culture, PCR, positive respiratory cultures highly suggestive
Ehrlichia/Anaplasma[c]	Tick-borne bacteria causing human monocytic ehrlichiosis and human granulocytic anaplasmosis, respectively *Ehrlichia* endemic to southern and central United States, *Anaplasma* endemic to northeastern United States, and Midwest	A	Morulae in white blood cells, PCR of whole blood, paired serology CSF PCR may be positive but less sensitive than testing of whole blood
Rickettsia rickettsii[c]	Tick-borne infection found throughout North America, with peak incidence in southeastern and southcentral United States	B	Paired serology, PCR, or IHC on skin biopsy of rash PCR on CSF or blood not useful

symptoms (e.g., eastern equine encephalitis virus, Venezuelan equine encephalitis virus) or relatively common infections in which meningoencephalitis occurs in a minority of cases (e.g., *B. burgdorferi*, *Coxiella burnetii*).

Most problematic is the third category of agents, those anecdotally associated with encephalitis but with minimal neurotropism and limited laboratory data confirming direct CNS invasion. For instance, *Mycoplasma pneumoniae* is the most commonly identified agent in several large case series of encephalitis (28, 29). However, the significance of serologic diagnosis of *M. pneumoniae* is unknown given the relatively high frequency of mycoplasma infection and limitations of commercial antibody testing (30). Rarely, mycoplasma may be identified in CSF by culture or PCR, which is diagnostic of direct CNS infection (29). Other organisms anecdotally associated with encephalitis but with similar difficulties in establishing causality include influenza virus (31), rotavirus (32), human herpes virus 6 (33), and parvovirus B-19 (34).

Perhaps the most challenging aspect for patients, families, and clinicians is that in approximately half of all encephalitis cases, no pathogen is identified, irrespective of geography or patient population (16, 20, 35–37). Illustrating the diagnostic challenges of encephalitis, a study enrolling >1,500 well-defined cases over a 7-year period using a standardized diagnostic algorithm including extensive molecular testing identified an etiology in only one-third of cases (1).

NONMOLECULAR LAB DIAGNOSTIC METHODS

The diagnosis of CNS infections can be challenging because the differential diagnosis is often extensive and includes infectious, postinfectious, and noninfectious causes (38). Diagnosis of CNS infection requires consideration of the most likely causative agents based on exposures, geography, and season, coupled with an understanding of the optimal diagnostic test and the highest-yield clinical specimen for testing. A thorough history and physical exam coupled with neuroimaging are critical for guiding testing (39). While this chapter will focus on the use of molecular assays for diagnosis of CNS infection, traditional microbiologic diagnostic approaches continue to play an important role in pathogen identification and are complementary to NAAT techniques (40–42).

Direct Microscopic Exam

A positive CSF Gram stain is highly suggestive of bacterial meningitis, although false-positive results have, on occasion, been reported (43, 44). The sensitivity depends on the bacterial pathogen: bacteria are observed by Gram stain in as many as 90% of infections with *S. pneumoniae* and in less than 50% for *Listeria monocytogenes*, and likely correlate with the relative burden of organisms in the CSF. The sensitivity of the Gram stain for the diagnosis of bacterial meningitis is 60 to 80% in patients who have not received antimicrobial therapy and 40 to 60% in patients who have received treatment (45). Rapid diagnosis may occasionally be made by visual detection of microorganisms by acid-fast bacilli stain, modified acid-fast bacilli stain, dark-field examination, wet mount, and India ink stain. Amoebae such as *Naeglaria* are best observed by examining thoroughly mixed sediment as a wet preparation under phase-contrast microscopy (43, 46).

Rarely, viral or rickettsial infections may be diagnosed by cytology or histopathology. For instance, visualization

TABLE 2 Less common causes of meningoencephalitis in immunocompetent patients[a]

Etiology	Epidemiology	Molecular test applicability[b]	Diagnosis
Viruses			
Eastern equine encephalitis virus	Coastal states (Atlantic and Gulf) Elderly disproportionately affected	C	Paired serology
Herpes B virus	Transmitted by bite of Old World macaque	A	Culture and PCR of vesicles, CSF
Human herpes virus 6[c]	Well-described cause of limbic encephalitis in bone marrow transplant patients Difficult to ascertain significance in immunocompetent individuals because latent infection is common	A	CSF PCR
Lymphocytic choriomeningitis virus	Peak incidence in fall and winter	C	Serology
Measles virus	Vaccine-preventable illness Measles inclusion body encephalitis onset 1–6 months after infection, subacute sclerosing panencephalitis a late manifestation (>5 years after infection)	C	CSF antibodies, CSF index, brain tissue PCR
Mumps virus	Vaccine-preventable illness	B	Serology, throat swab PCR, CSF culture or PCR
Nipah virus	Epidemics in Southeast Asia	C	Serology (Special Pathogens Branch, CDC)
Powassan virus	Tick-borne, endemic to New England, Canada	C	Paired serology
Rubella virus	Vaccine-preventable illness	C	Serology, CSF antibodies
Vaccinia	Infection or vaccination as precipitating event Thought to be autoimmune phenomenon	C	CSF antibodies, CSF index, serum IgM (natural infection)
Venezuelan equine encephalitis virus	Central, South America, rarely in border states (TX, AZ)	C	Paired serology, viral cultures (blood, oropharynx), CSF antibody
Western equine encephalitis virus	Summer and early fall onset, western United States and Canada, Central and South America	C	Paired serology
Bacteria			
Coxiella burnetti	Animal exposures (particularly placenta and amniotic fluid)	C	Paired serum
Treponema pallidum	Sexually transmitted disease, with meningoencephalitis seen in early disseminated disease and progressive dementia in late disease	C	CSF VDRL, serum RPR with confirmatory FTA-ABS
Tropheryma whipplei[d]	Chronic encephalitis often associated with osculomasticatory myorhythmia	A	CSF PCR, PAS positive cells in CSF, small bowel biopsy
Protozoa			
Balamuthia mandrillaris	Central America (natives and immigrants)	C	Serology (research labs), brain histopathology
Naeglaria fowleri	Summer months, children and adolescent boys at highest risk Swimming in fresh water, and particularly water sports, a risk factor	C	Mobile trophozoites on wet mount of warm CSF, brain histopathology

[a]Abbreviations: SSCE, subacute sclerosing panencephalitis; CSF, cerebrospinal fluid; RPR, rapid plasma reagin; FTA-ABS, fluorescent treponemal antibody-absorption; FTA-ABS; PAS, periodic acid-Schiff.

[b]Of CSF or other biologic material (see diagnosis notes). [c]Detailed discussion of molecular diagnosis in text.

of morulae, basophilic clusters found in the cytoplasm of monocytes, is highly suggestive of infection with *Ehrlichia chaffeensis* (47, 48). Pathologic examination of brain tissue may reveal Negri bodies with rabies virus infection or intranuclear eosinophilic amorphous bodies surrounded by a halo with HSV infection. Pathologic examination of the brain for trophozoites and cysts may be helpful in the diagnosis of *B. mandrillaris* and other free-living amebic infections.

Rapid Antigen

Bacterial antigen testing in CSF has limited utility due to poor sensitivity and specificity (49–51). One exception is the Binax NOW immunochromatographic test for *S. pneumoniae*, which has been demonstrated to be rapid and highly sensitive for the diagnosis of pneumococcal meningitis (52, 53). A study done in five countries in Africa and Asia indicated that the antigen assay enhanced diagnosis of pneumococcal meningitis, suggesting that previous studies have underestimated the proportion of pediatric bacterial meningitis cases caused by pneumococci (54). Similarly, viral antigen assays have largely been replaced by more sensitive molecular techniques. In contrast, detection of cryptococcal antigen in either CSF or serum of patients with HIV or other underlying immunocompromise is both highly sensitive and specific (55), and a positive antigen test would be an indication to begin directed antifungal therapy (56, 57). Detection of galactomannan antigen and 1,3-β-D-glucan in CSF may be helpful in establishing the diagnosis of CNS aspergillosis (58, 59). However, because the two antigens can also be expressed by fusarium species, their presence in CSF does not constitute a definitive diagnosis of CNS aspergillosis (60, 61). During a large national outbreak of fungal meningitis associated with spinal injection of contaminated methylprednisolone, detection of 1,3 beta-D-glucan in CSF was 100% sensitive and 98% specific for the presence of *Exserohilum rostratum* (62). Histoplasma antigen testing of CSF has a sensitivity ranging from 38 to 67%, with a CSF-to-urine antigen ratio >1, suggestive of intrathecal antigen production (63).

Culture

CSF culture allows definitive diagnosis of bacterial, mycobacterial, and fungal meningitis (43). The yield of CSF culture for bacterial meningitis ranges from 70 to 85% in untreated patients but decreases substantially after antibiotic treatment (64). The volume of CSF submitted correlates with the sensitivity of fungal and mycobacterial culture, with best results when ≥10 cc of sample is cultured (63).

A positive bacterial culture allows subsequent determination of the antimicrobial susceptibility of the causative agent. While the techniques used for antimicrobial susceptibility testing in CNS infections remain the same as those for isolates from other sites, criteria for determining antibiotic resistance may differ. Penicillin minimal inhibitory concentration breakpoints for pneumococcal CNS isolates, for example, are lower than those used for non-CNS isolates.

The application of monoclonal antibodies in shell vial culture has significantly increased the speed and specificity of viral culture; however, culture has largely been replaced by PCR (65–67). The sensitivity of CSF viral culture for enteroviruses is only 65 to 75% and requires up to 8 days for detection of cytopathic effect (68–70). Some serotypes of enteroviruses, especially coxsackievirus A strains, grow very poorly in tissue culture or are noncultivable (71). HSV culture sensitivity from CSF is very poor, especially in recurrent cases of HSV-2 meningitis or HSV-1 encephalitis (72).

Serology

Serology remains the test of choice for CNS infections caused by arboviruses, including WNV, and fastidious bacteria such as ehrlichia and rickettsia. Laboratory confirmation requires demonstration of a 4-fold increase in antibody levels (or seroconversion), requiring 2 to 3 weeks between the collection of acute- and convalescent-phase samples. The development of IgM capture methodology has allowed the presumptive identification of viral infections in the early stages of clinical diseases. For instance, West Nile neuroinvasive disease is diagnosed by detection of antibody in the CSF by IgM antibody-capture enzyme-linked immunosorbent assay (73). Neurosyphilis is suggested by a positive serum RPR and confirmed by a positive CSF VDRL test (74). While a positive serologic test for toxoplasma is not necessarily indicative of active infection, it is useful for guiding empiric therapy in an immunocompromised host with a compatible radiologic picture. Intrathecal production of antibody to VZV is increasingly recognized as the optimal diagnostic test for varicella vasculopathy (75).

For other organisms, serologic testing has a limited role in the diagnosis of CNS infection. For example, enteroviruses lack a common antigen among various serotypes, making IgM levels inconsistent in sensitivity (18, 41). Local production of HSV IgG antibodies in CSF can be used in diagnosis; however, the production of antibody is delayed until day 10 or 12 of infection and peaks at about day 20, limiting the usefulness of this test to retrospective diagnosis (76).

Demonstration of locally produced, pathogen-specific antibody strongly suggests the presence of intrathecal infection. To differentiate between peripheral and CNS infections, antibody titers in serum and CSF can be measured in parallel. With a peripheral infection, the antibody titer in the CSF should be less than 5% that of the peripheral blood, due to the protective effect of the BBB. However, antibody in CSF may be translocated from serum as a result of BBB breakdown, which can be indicated by elevated albumin in CSF. Antibody titers in CSF higher than 5% of serum levels in the presence of normal levels of CSF albumin are suggestive of intrathecal antibody synthesis. Peripheral blood contamination or BBB inflammation may skew this ratio and falsely suggest CNS infection. For instance, intrathecal antibody index for *B. burgdorferi* may be useful for the diagnosis of neuroborreliosis (77).

MOLECULAR TECHNIQUES FOR DIAGNOSIS

Nucleic acid amplification-based molecular diagnostic techniques have dramatically improved the ability to diagnose CNS infections. Landmark studies published in the early 1990s confirmed the excellent performance characteristics of CSF PCR for diagnosis of HSV encephalitis (78, 79), and subsequently PCR has replaced brain biopsy as the diagnostic method of choice (67). Since that time, NAAT techniques have been proven to be the test of choice for diagnosis of CNS infection with other herpes group viruses (80–82) and enteroviruses (18, 80, 83, 84).

CSF is the specimen of choice for detecting pathogenic organisms causing CNS infections. Usually three or four

tubes of CSF are collected by lumbar puncture for diagnostic studies. The first tube has the highest potential for contamination with skin flora and should not be sent to the microbiology laboratory for direct smears, culture, or molecular studies (85). Nucleic acids are extracted from CSF for *in vitro* amplification and identification. Several commercial methods for the extraction of viral nucleic acid for amplification procedures are available (86). Inhibitors may be inadvertently extracted along with the nucleic acids and can interfere with the amplification process, reducing efficiency and lowering the sensitivity of the PCR assay (87). Several "Boom" technique-based (88), automatic extraction devices are commercially available for nucleic acid extraction from various clinical specimens including CSF (89–91).

PCR-led NAAT assays have been widely used in the detection and identification of microbial pathogens in CSF (67, 76, 78, 79). Microorganism loads in CNS are usually low; any techniques that maximize test sensitivity while retaining specificity are desirable. Multiple commercial NAAT devices for the detection of viral pathogens in CSF have been developed, but FDA-cleared tests are extremely limited. For HSV detection, after almost a quarter of a century, and probably due to the small commercial market size, there is only one FDA-cleared commercial HSV assay designated for CSF specimens (92). In contrast, quite a few commercial NAATs are now available for detection and identification of HSV in cutaneous and mucocutaneous lesions (93). Among them, MultiCode-RTx HSV 1 & 2 (Luminex Corp.), PROBETEC HSV (Becton Dickinson) (94), IsoAmp HSV (BioHelix Corp.) (95), and AmpliVue HSV 1+2 Assay (Quidel Corp.) are FDA-cleared *in vivo* diagnostics (96). The GeneXpert Dx system (Cepheid, Sunnyvale, CA) is a fully integrated and automated nucleic acid sample preparation, amplification, and real-time detection system. The system-based enterovirus assay, which is used to provide rapid and on-demand diagnosis of aseptic meningitis, has received approval by the FDA (83).

Given the breadth of pathogens implicated in CNS disease, more comprehensive molecular panels for the agents of meningoencephalitis would bring added value to commercially available tests. Multiplex design enables simultaneous detection and identification of multiple targets in a single reaction. Relative simplicity, powerful multiplexing capabilities, and high-throughput detection make multiplex assays most attractive for screening and detection of a panel of candidate pathogens in CSF. This is particularly important in immunocompromised hosts. In addition, multiplex assays provide potent tools to detect mixed infections. Numerous multiplex NAAT assays have been developed for simultaneous detection and identification of microbial pathogens in CSF (97–111). In May 2014, the FDA cleared a multiplex assay (Lyra Direct HSV 1 + 2/VZV Assay, Quidel Corp.) for detection and differentiation of HSV-1, HSV-2, and VZV for cutaneous or mucocutaneous lesion samples in symptomatic patients (112). When it was used in CSF specimens, however, the sensitivities were significantly lower than those of other monoplex assays such as Simplexa HSV 1 & 2 Direct (113).

ADDITIONAL CONSIDERATIONS IN MOLECULAR TESTING

Identifying an etiologic agent in patients with encephalitis requires consideration of the most likely causative organisms, the optimal diagnostic tests for these agents, and the highest-yield clinical specimens for testing (2, 7). Knowledge of the epidemiology and clinical presentation of specific agents is critical in selecting which diagnostic tests are appropriate for a given patient. In particular, animal or vector exposures, geographic location, recent travel history, season of the year, exposure to ill contacts, and occupation need to be considered. Further diagnostic testing may be appropriate based on individualized exposures or risk factors.

Recently, a retrospective 11-year experience of clinical application of viral CSF PCR testing for diagnosis of CNS disorders in Europe was reported. The analysis covered CSF PCR data of 481 pediatric and 2,604 adult patients, including HSV, VZV, Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpesvirus 6 (HHV-6), and enteroviruses. Nucleic acid of EBV was detected in 1.6%, of VZV in 1.3%, of HSV in 1.24%, of enteroviruses in 0.4%, of HHV-6 in 0.17%, and of CMV in 0.2% of the patients. Newborns and elderly people showed the highest infection rates. HSV, VZV, and enterovirus prevailed in typical infectious CNS diseases; EBV, in further inflammatory neurological diseases; HSV and EBV, in immunocompromised patients; and EBV, HSV, and HHV-6, in other noninflammatory neurological diseases. Rapid viral clearance was typical for HSV, VZV, CMV, and enterovirus infections, suggesting that the detection of HSV, VZV, CMV, and enteroviruses strongly indicates symptomatic viral CNS disease. Secondary viral reactivation mostly underlies positive EBV and HHV-6 findings. Their detection does not rule out clinical impact but points to the need to search for additional underlying conditions (81).

Issues regarding molecular diagnosis of specific pathogens are outlined in the following sections, but several general concepts should be considered. CSF is the optimal specimen for PCR testing in patients with encephalitis, with nucleic amplification testing of other specimens providing indirect evidence of infection (e.g., PCR of lymph node tissue in patients suspected to have *Bartonella* encephalopathy). The timing of specimen acquisition is an important variable in interpreting results. For instance, HSV PCR may be falsely negative if performed very early (114) or late (3) in the course of HSE. Host features also contribute to testing characteristics. Immunocompromised patients are at risk for a much wider array of opportunistic pathogens (e.g., HHV-6 encephalitis in bone marrow transplant patients, CMV encephalitis in HIV patients) as well as more severe clinical manifestations with more common pathogens (e.g., WNV in transplant patients).

Finally, interpretation of a positive NAAT result is complicated by the fact that some viruses survive latently in macrophages (e.g., EBV) or neurologic tissues (e.g., HHV-6) and may be incidentally detected using sensitive molecular techniques. For this reason, while a positive qualitative PCR result indicates that pathogen-specific nucleic acid is detected in CSF, it is not necessarily indicative of infection. For instance, EBV can be integrated in host genes, resulting in positive PCR results (40), and not infrequently, EBV may be amplified from the CSF of patients with an alternative CNS infection (115).

APPLICATION OF MOLECULAR METHODS TO DETECT COMMON CNS PATHOGENS

Viruses

HSVs

HSE is the most common cause of sporadic encephalitis in the United States, accounting for 10 to 20% of all viral

encephalitides (116, 117). HSV-2 is a well-established cause of neonatal brain infection, but beyond infancy more than 95% of HSE cases are due to HSV-1 (118). Approximately two-thirds of HSE cases result from reactivation of latent HSV-1, while the other third are a result of primary infection (119). HSE at the time of primary infection is thought to infect olfactory neurons followed by retrograde spread to the brain, while reactivation of latent virus in the trigeminal ganglia with spread via tentorial nerves to the frontal and temporal lobes accounts for the remainder. Alteration of consciousness, fever, and headache are common clinical presentations. Personality changes and aphasia are also frequently observed at presentation and may be helpful clues in considering the diagnosis. Neuroimaging typically shows unilateral or bilateral temporal lobe involvement, with magnetic resonance imaging being more sensitive than computed tomography (120). HSV-2 is a rare cause of encephalitis but a frequent cause of a self-limited lymphocytic meningitis in adolescents and adults, with 20% of patients developing recurrent episodes of aseptic meningitis (previously termed Mollaret's meningitis) (121).

Early recognition of HSE is important since treatment with acyclovir significantly decreases morbidity and mortality (122). Historically, brain biopsy was the diagnostic test of choice, but molecular techniques have revolutionized the diagnostic approach for patients with suspected HSE. Molecular testing of CSF offers the advantage of a minimally invasive approach coupled with a turnaround time of less than 1 day if colorimetric enzyme immunoassay or real-time PCR is used (123). Several multiplex PCR-based assays were described to cover a panel of herpesviruses including HSV-1/2 (100–104, 107–109). In experienced laboratories, the sensitivity of HSV CSF PCR in adults with HSE approaches 100%, with a specificity of 94%, and results remain positive for up to 1 week, even with antiviral treatment (3). The sensitivity of CSF HSV PCR for neonates and infants is lower, ranging from 75 to 100% (124). The Simplexa HSV 1 & 2 Direct assay (Quest/Focus Diagnostics) has received FDA clearance for detection of HSV-1/2 in CSF specimens (92).

Due to the differing performance characteristics of various HSV PCR assays, results need to be interpreted in the context of the clinical illness. False negatives are well documented, particularly early in the disease course (114, 125). For patients with a clinical presentation suggestive of HSE (e.g., temporal lobe enhancement on magnetic resonance imaging), repeat testing on a second specimen obtained 3 to 7 days after onset of symptoms is recommended prior to discontinuation of empiric acyclovir (2).

An additional cause of a false-negative HSV PCR result is the presence of large numbers of red blood cells in the CSF, because porphyrin can inhibit the PCR reaction even with as many as 20,000 copies of HSV DNA (3). False-negative results happened on CSF specimens with low concentrations of HSV-2 (102).

Many uncertainties remain regarding the optimal use of PCR for prognosis and monitoring therapy. Quantification of HSV in CSF has been reported to be a predictor of prognosis in HSE, but this test is not widely available, and its utility remains unknown (126, 127). A follow-up CSF analysis as well as quantification of HSV-1 was recommended to individualize the duration of acyclovir treatment (128). Some authorities recommend repeating HSV PCR on a second CSF specimen obtained 10 to 14 days after initiation of acyclovir, with prolongation of therapy for persistently positive results (129). In neonates, persistent detection of HSV by PCR at the end of treatment has been shown to be a poor prognostic sign (130).

VZV

Initial infection with VZV results in primary varicella (chickenpox). After infection, the virus remains latent in cranial-nerve and dorsal-root ganglia, with reactivation causing dermatomal, or in the immunocompromised host, disseminated zoster (shingles) (131). Before 1995, when the varicella vaccine became widely available, approximately 90% of primary VZV infections occurred before adolescence (132).

VZV meningoencephalitis prior to the advent of molecular testing was diagnosed solely on a temporal relationship between a typical vesicular rash and neurologic symptoms. With the availability of molecular testing, a broader clinical spectrum of VZV-related neurologic disease has been identified, often in patients without cutaneous findings (132, 133). In a multicenter Finnish study of 174 patients with confirmed or probable VZV CNS infection, 27% and 65% of patients with encephalitis or meningitis, respectively, did not have skin lesions, a disease termed *herpes sine herpete* (134). In one study of immunocompetent adults with VZV meningitis, rash was a late finding, following the onset of symptoms by a median of 6 days (135).

Several discrete neurologic syndromes have been attributed to VZV infection. Acute cerebellar ataxia is a complication of primary varicella infection and does not occur with viral reactivation (133). Patients with acute cerebellar ataxia develop acute gait ataxia, nystagmus, vomiting, tremor, and headache, although they usually have intact cognition. Symptoms typically begin in the 10 days following cutaneous eruption, but rarely there may be up to a 3-week latency between rash and onset of cerebellar symptoms (136). A syndrome of diffuse encephalitis due to either acute VZV infection or reactivation has also been recognized (137).

VZV is increasingly reported as a cause of CNS vasculitis involving either large or small blood vessels, termed VZV vasculopathy. Large vessel unifocal granulomatous arteritis is mainly a disease of the elderly and is characterized by acute focal deficit (motor or sensory) that develops weeks or months after zoster (or varicella) in a contralateral distribution (131). Recurrent ischemic episodes have been documented with this syndrome, and the mortality rate is approximately 25% (138). Small vessel multifocal vasculopathy is a subacute condition, seen more frequently in immunocompromised patients (139, 140). With both of these conditions, PCR testing has identified VZV in CNS vascular endothelium.

The test characteristics of VZV PCR vary based on the neurologic syndrome, duration of symptoms, and host immune status. In one study of patients with a clinical suspicion for CNS VZV infection, the sensitivity of CSF VZV PCR was 44% for patients with a dermatomal rash and meningoradiculitis compared to 66% for patients with a generalized rash and encephalitis (141). Timing of sample collection appeared to be an important variable in this study, because VZV CSF PCR was positive for 62% of CSF samples collected <7 days after the onset of rash, compared to 25% of those collected >7 days after skin eruption. Other investigators have demonstrated that only 25% of CSF specimens are positive for VZV DNA in patients with neurologic manifestations associated with either primary

VZV infection or reactivation, and CSF PCR was positive only among cases sampled <9 days after dermatologic onset (134). In another small study of children with acute cerebellar ataxia, 3 of 5 cases (60%) had a positive CSF VZV PCR result (142). The diagnostic yield of CSF PCR among patients with VZV vasculopathy has been reported to be 28%, with the decreased sensitivity attributed to the significant delay (average 4.2 months) between the onset of neurologic symptoms and molecular testing in these cases (140). In patients suspected to have VZV vasculopathy, detection of intrathecal antibodies may be a superior diagnostic test. Quantitative VZV PCR is not widely available, but in one study of patients with meningitis or encephalitis due to VZV reactivation, higher levels of virus in the CSF were found with encephalitis compared to meningitis and were predictive of a more severe illness (143). In another study, a significant correlation between VZV viral load in CSF and the severity and duration of neurological disease was observed (144).

VZV DNA can be amplified from the CSF in 2.5 to 7% of HIV-infected patients with new neurologic signs or symptoms (145, 146). The significance of this finding is not always clear, because VZV may accompany other CNS pathogens, suggesting subclinical reactivation in some cases (146). Cutaneous findings are variably present in HIV-infected patients with VZV CNS infection (147, 148). Among patients with VZV vasculopathy, PCR was positive in more than half of immunocompromised patients with vasculopathy, as compared to only 16% of immunocompetent patients (140).

EBV

By adulthood, over 90% of the general population has serologic evidence of prior EBV infection (149). The most common clinical presentation of acute EBV infection is infectious mononucleosis, characterized by pharyngitis, cervical lymphadnenopathy, and fever; however, asymptomatic seroconversion occurs in the majority of acute infections (150). Commonly associated symptoms of acute mononucleosis, such as headache and neck stiffness, do not necessarily imply invasive neurologic infection, because these are frequent accompaniments to viremia. Following acute infection, EBV is immortalized in B-lymphocytes, with symptomatic reactivation occurring primarily in individuals with significant impairment in T-cell immunity (151).

Neurologic manifestations can be seen with either acute EBV infection or reactivation, with specific syndromes including meningitis, encephalitis, myelitis, and acute cerebellar ataxia (152).

Detection of EBV DNA in CSF may reflect either CNS infection or viral reactivation in the setting of an inflammatory response induced by another agent or condition (115, 149). Secondary viral reactivation mostly underlies positive EBV findings (81). Quantitative EBV viral loads may prove useful in discriminating infection from reactivation due to an alternative pathogen, but a precise cutoff value has not been determined (153).

The significance of detection of EBV in the CSF of patients with HIV deserves special mention. Primary CNS lymphoma (PCNSL), a relatively common complication of HIV infection prior to the availability of highly active antiretroviral therapy, is caused by localized reactivation of EBV in the CNS, with clonal proliferation of lymphocytes (154). In HIV-infected patients, EBV amplification from the CSF has been proposed as a marker for PCNSL among patients with CNS mass lesions (155) and as a predictor of the later development of PCNSL among patients without radiologic findings (156, 157). This approach has been called into question by more recent studies documenting a positive predictive value of only 10 to 29% for EBV PCR from the CSF of HIV-infected patients with neurologic disease (158, 159). While the test characteristics may be improved slightly by using a quantitative cut-point of 10,000 copies/ml (158), EBV viral load does not reliably discriminate between PCNSL and EBV encephalitis (153), and pathologic review of brain tissue is still required for definitive diagnosis of PCNSL.

Other Herpesviruses

The role of other herpesviruses in causing encephalitis is controversial. CMV is an important cause of encephalitis in the immunocompromised host but does not appear to be a significant cause in the general population (160). Similarly, HHV-6 has been established as a cause of encephalitis in immunocompromised patients, particularly stem cell transplant recipients, but its role in the normal host is controversial (161, 162).

WNV

WNV is a mosquito-borne virus that was first detected in the Northern Hemisphere in 1999 and has since emerged as the most common form of endemic encephalitis in the United States (163). The clinical spectrum of WNV infection ranges from asymptomatic seroconversion to encephalomyelitis. Symptoms are present in ~20% of cases, with neuroinvasive disease reported in <1% of cases. Neurologic involvement is more common among the elderly and the immunocompromised. Although there is no pathognomonic presentation of WNV encephalitis, weakness, including acute flaccid paralysis, is a characteristic finding (164).

WNV viremia begins within 1 to 3 days of mosquito inoculation but is typically short-lived (165). Constitutional symptoms precede neurologic involvement, which develops 7 to 9 days after infection, at which time the virus has been cleared from the bloodstream (166, 167). For this reason, NAAT has an important role in the screening of asymptomatic blood donors for the presence of WNV, where reverse transcriptase PCR or nucleic acid sequence-based amplification can detect as few as 50 viral copies/ml (168). Molecular amplification techniques have been less successful in diagnosing symptomatic patients. During a large community outbreak of WNV in Canada, only 45% of plasma samples from patients with serologically confirmed WNV infection had detectable virus by PCR (169). Predictors of a positive plasma PCR result included testing within 8 days of symptom onset and West Nile fever (36% positive) rather than West Nile neuroinvasive disease (9.5% positive). Plasma WNV viral load did not correlate with either the duration of symptoms or the presence of CNS involvement.

Similarly, amplification of WNV from CSF is of limited utility, with only 57% of patients with serologically confirmed West Nile neuroinvasive disease having positive CSF PCR by real-time PCR, and 0% of specimens positive by conventional PCR (170). Immunocompromised hosts, a population at high risk for severe neurologic disease and adverse outcomes from West Nile neuroinvasive disease, represent the exception. Case reports have documented positive CSF WNV NAAT in transplant patients and those with hematologic malignancies (171, 172). In these cases, virus in the blood and CSF may persist for a

prolonged time, congruent with the delay in production of detectable neutralizing antibody (173).

Enteroviruses

The *Enterovirus* genus comprises >90 subtypes differentiated by a numeric designation (e.g., enterovirus 71) (174, 175). Two former members of this genus, echoviruses 22 and 23, have been reassigned as human parechovirus 1 and 2, which have been demonstrated to cause meningitis in young children (176). Humans are the only natural hosts for the enteroviruses, and the principal mode of human-to-human transmission is fecal-oral (133). In 2014, enterovirus D68 was recognized as the cause of an outbreak of severe respiratory infection in children in the Midwest (177).

Enteroviruses are the most common cause of aseptic meningitis in the United States, accounting for 80 to 92% of cases in which an etiologic agent is identified (18), with a seasonal predilection extending from June to October (178). Less commonly, these viruses can cause severe, life-threatening manifestations, such as encephalitis, paralysis, myopericarditis, and neonatal sepsis (178). In a large study evaluating causes of encephalitis, enteroviruses were the leading infectious agents identified, with 75% of cases occurring among children (1). Large outbreaks of enterovirus 71 in Southeast Asia have been associated with brain stem encephalitis in pediatric patients, causing a high mortality and considerable cognitive morbidity among survivors (179, 180).

Enterovirus-specific reverse transcriptase PCR has a sensitivity and specificity that approach 100%. Numerous monoplex and multiplex PCR-based assays have been developed (18, 81, 83, 97), and most of them target the highly conserved 5′-nontranslated region, allowing amplification of all human enteroviruses. The disadvantages of this approach are that these assays (i) cross-react with rhinoviruses and (ii) do not differentiate enterovirus genotypes. Several molecular devices have been cleared by the FDA for detection of enteroviruses in CSF including the Cepheid Xpert EV assay, which is a fully integrated and automated system with a test turnaround time of approximately 70 minutes (83). Other nucleic acid detection methodologies directed to the enteroviral capsid protein VP1 (181) or other capsid regions of the genome are less cross-reactive but allow the product to be sequenced for serotype identification.

Rabies Virus

Rabies virus is an almost universally fatal cause of encephalitis. While this infection is relatively uncommon in the United States, more than 50,000 cases are estimated to occur worldwide, mainly from wild-animal bites (182).

Human rabies can present in two general forms: encephalitic or furious rabies (80 to 85% of cases) or the less common paralytic or catatonic form. Patients frequently complain of paresthesias at the site of inoculation. This prodrome may last only a couple of days before an acute neurologic syndrome consisting of excessive salivation, agitation, hydrophobia, and nuchal rigidity begins, often accompanied by autonomic nervous system involvement (183). Antirabies vaccine or rabies immune globulin is not effective once symptoms are present, and death typically occurs within 1 to 2 weeks of symptom onset.

Antemortem diagnosis of rabies is important for establishing prognosis and coordinating postexposure treatment of contacts. For this reason, testing for suspected cases of rabies should be coordinated with the local or state health department. Several studies have explored the application of NAAT tests in CSF for the diagnosis of rabies. A small study evaluating rabies virus real-time PCR on both CSF and saliva among patients with confirmed infection identified a sensitivity of 9% and 30%, respectively (184). Another study comparing conventional PCR to real-time PCR of saliva found a sensitivity of 37% for the former, compared to 75% for the latter (185). A recent study reported that real-time PCR alone could achieve antemortem rabies diagnosis in 11/13 (84.6%) cases; combined with rabies viral neutralizing antibody detection in CSF, antemortem rabies diagnosis could be achieved in all 13 (100%) cases (186).

Acute Bacterial Meningitis

The syndrome of acute bacterial meningitis is a medical emergency, requiring rapid diagnostic evaluation and institution of empiric therapy (2). Even with this approach, the mortality among adults with community-acquired acute bacterial meningitis exceeds 25% (187). Predictors of an adverse outcome include impaired level of consciousness, seizures, and hypotension (188, 189).

Definitive diagnosis of bacterial meningitis requires laboratory confirmation, because involvement of the CNS by other pathogens (e.g., viruses, fungi, mycobacteria) and noninfectious processes (e.g., subarachnoid hemorrhage) may produce identical syndromes. CSF findings suggestive of bacterial meningitis include neutrophilic pleocytosis, hypoglycorrhachia, and elevated protein levels, but these are nonspecific. A positive CSF Gram stain is indicative of acute bacterial meningitis, but the sensitivity of this test ranges from 60 to 90% and falls to <20% following administration of antibiotics (2, 190, 191). A positive CSF culture is definitive evidence for acute bacterial meningitis, but the time to a positive test is >24 hours, and the yield of CSF culture decreases sharply as early as 15 minutes following administration of antibiotics (192, 193).

There has been significant interest in evaluating molecular techniques for the diagnosis of acute bacterial meningitis. Several studies have evaluated a multiplex PCR assay directed at DNA sequences of the most common pathogens causing acute bacterial meningitis (98, 110). A study comparing broad-range bacterial PCR with culture of CSF among 74 patients with acute bacterial meningitis reported a sensitivity of PCR of 59% compared with 43% for culture (194). Notably, 15 of 19 patients (79%) with positive PCR results but negative cultures had received antibiotics prior to lumbar puncture. Other studies have confirmed the utility of broad-range PCR for culture-negative purulent meningitis following antibiotic administration (195–198). A recent study from China compared bacteriological culture, monoplex, and multiplex PCR in the diagnosis of bacterial neonatal meningitis. The study indicated that both monoplex and multiplex PCR assays had better sensitivities than bacterial culture with the capacity of detecting the pathogens in CSF samples with negative culture results (199).

Tick-Borne Rickettsial Diseases

Tick-borne rickettsial diseases (TBRDs), including Rocky Mountain spotted fever (caused by *R. rickettsii*), human monocytic ehrlichiosis (caused by *E. chaffeensis*), and human granulocytic anaplasmosis (caused by *Anaplasma phagocytophilum*), are important and treatable causes of meningoencephalitis in the United States. The distribution of these bacteria differs with respect to vector and geography; however, all

three cause a similar febrile syndrome, typically associated with headache. Altered mental status is estimated to occur in as many as 20% of cases (26, 200).

Confirmation of TBRD presents a diagnostic challenge. Detection of a 4-fold rise in antibody titer is definitive evidence of a TBRD but is only useful for retrospective diagnosis. The sensitivity of PCR for the different pathogens that cause TBRD is variable. *R. rickettsii* infects vascular endothelial cells, and PCR of fresh tissue obtained through skin biopsy or autopsy may be diagnostic (26, 200). Molecular assays for *R. rickettsii* DNA can be performed on whole blood but are not widely available, and the low sensitivity limits the clinical use of this test (201, 202).

In contrast, several studies have validated PCR for the rapid diagnosis of ehrlichiosis. Whole-blood PCR has been reported to have a sensitivity of 56 to 100% for human monocytic ehrlichiosis (203, 204) and 60 to 70% for human granulocytic anaplasmosis (205). The diagnostic yield is highest early in the course of infection, prior to initiation of antibiotic treatment. *Ehrlichia* species can rarely be amplified from CSF, but the yield of this specimen compared to whole blood has not been evaluated (48, 206). A molecular device coupling broad-range PCR and mass spectrometry demonstrated rapid and accurate detection of *Ehrlichia* species in both peripheral blood and CSF (207).

Whipple's Disease

Whipple's disease is an uncommon syndrome caused by the fastidious bacterium *Tropheryma whipplei*. Clinical manifestations are protean but include weight loss, uveitis, diarrhea, and arthropathy, with CNS manifestations in 20 to 40% of cases (208–210). Occult CNS involvement is common, because 70 to 90% of patients without neurologic symptoms have detectable bacteria on postmortem brain examination or CSF analysis (211–213). CNS symptoms include altered mentation, seizures, or oculomasticatory myorhythmia, and cranial nerve abnormalities (208, 214).

Classically, diagnosis of Whipple's disease is through histological identification of periodic acid-Schiff staining bacilli in enterocytes on duodenal biopsy. Recently, a noninvasive approach has been advocated for screening suspect cases through tandem PCR of saliva and stool samples for *T. whipplei*. While bacteria may be amplified from these specimens in asymptomatic carriers (215, 216), a positive test on both specimens is associated with a positive predictive value for Whipple's disease of 95%, increasing to 100% if the bacterial load in stool exceeds 10^4 copies (217). False-positive results have been reported using broad-range 16S rRNA primers, with studies proving the superiority of probes specific for repeat gene sequences unique to *T. whipplei* (218, 219).

Isolated or localized Whipple's disease represents a particular diagnostic challenge. In this subgroup, histologic examination of small bowel biopsy is negative, and the sensitivity of tandem PCR of saliva and stool decreases to 58% (217). For isolated CNS infections, CSF PCR is extremely specific, but the sensitivity is not known (217). In cases where a high suspicion for CNS Whipple's disease persists despite a negative CSF PCR, brain tissue may be diagnostic (220–222). A retrospective analysis of molecular assays was performed for the diagnosis of CNS Whipple's disease over a 12-year period in a reference center in France. *T. whipplei* was recovered from CSF of 6% of patients. The number of patients with a positive PCR result for *T. whipplei* has increased significantly over the last 12 years (223).

Tuberculous Meningitis

Tuberculous meningitis (TBM) is a relatively infrequent complication following pulmonary infection but is associated with significant morbidity and mortality (224, 225). The outcome is dependent on time to starting effective antimycobacterial therapy, but both the clinical presentation and CSF findings of TBM are nonspecific, which may lead to delays in initiating treatment (226, 227). For this reason, there is significant interest in identifying diagnostic techniques that would allow rapid confirmation of TBM.

Nucleic acid amplification has limited utility for the diagnosis of pulmonary tuberculosis (228, 229), but CSF lacks the inhibitors present in sputum. A meta-analysis of commercial nucleic acid amplification assays on CSF reported a sensitivity of 56% for the diagnosis of TBM, but the specificity approached 100% (230). Most assays target insertion sequence IS*6110* through a single-step amplification reaction (231, 232). In proficiency panels, false-negative PCR results may be seen at low bacterial concentrations (<2 CFU/ml) (233). The Cepheid Xpert MTB/RIF assay has been cleared by the FDA for the detection of pulmonary tuberculosis and the determination of multidrug resistance. A recent systematic review and meta-analysis indicated that the assay had pooled sensitivity of 80.5% against culture and 62.8% against a composite reference standard in CSF (234). Given the suboptimal sensitivity, the current role of CSF PCR is to confirm a diagnosis of TBM, but a negative result is not useful in excluding disease or in discontinuing treatment.

Lyme Disease

Neurological manifestations may be seen in early disseminated Lyme disease as cranial neuropathy or meningitis, while late neurologic findings, which are less common, include encephalomyelitis or peripheral neuropathy. Molecular testing is not useful in late neuroborreliosis but has a limited role in laboratory confirmation of early neurologic disease (235). Most assays target the outer surface protein A gene (236). The sensitivity of CSF PCR among patients with neuroborreliosis ranges from 15 to 79% (237–240). One study reported a CSF PCR sensitivity of 50% among patients with intrathecal antibody production, but PCR failed to detect organisms in any patient lacking CSF antibodies, despite the presence of positive serum antibody and CSF pleocytosis (241). A positive CSF PCR result in a seronegative patient is suggestive of a false-positive result. Among children with clinical and serologic evidence of Lyme meningitis or facial palsy, CSF PCR was positive in only 5% and 12% of cases, respectively (242, 243).

CNS Aspergillosis

The recent outbreak of *E. rostratum* meningitis linked to epidural injections of methylprednisolone acetate has brought renewed attention to mold infections of the CNS (60). CNS invasive aspergillosis (IA) is an almost uniformly fatal complication in immunocompromised patients. Confirming the diagnosis is challenging because invasive procedures are impaired by neutropenia and low platelet count. Several PCR assays have been developed for detection of *Aspergillus*-specific nucleic acids in CSF (244–246). Reinwald et al. recently reported that the use of a nested PCR assay enhanced diagnosis of CNS aspergillosis in immunocompromised patients (245). The retrospective analysis of CSF samples from patients with suspected CNS IA yielded a high sensitivity of the nested

PCR assay. One study suggested PCR testing of CSF samples for patients for whom CNS IA is suspected, especially for those whose clinical condition does not allow invasive procedures because a positive PCR result makes the presence of CNS IA in that patient population highly likely (245). *Aspergillus* PCR may not be widely available, and *Aspergillus* galactomannan testing of CSF would be an alternative option to allow earlier and more sensitive diagnosis of CNS IA compared to fungal culture (247).

CONCLUSION

Nucleic acid amplification techniques have markedly improved the identification of CNS infections caused by viral and fastidious bacterial pathogens. Molecular techniques such as PCR allow rapid diagnosis with consequent improvement in outcomes and cost savings. However, the proper testing and interpretation of results requires insight into the strengths and limitations of these tests. Results of molecular diagnostic testing for CNS infections must be interpreted in the context of the individual patient presentation and clinical illness, and close cooperation between the laboratory and the clinician is required for optimal use of these technologies.

Using Nucleic Acid Amplification Techniques in a Syndrome-Oriented Approach: Detection of Respiratory Agents

KATHERINE LOENS AND MARGARETA IEVEN

25

Lower respiratory tract infections (LRTIs) are an important problem. They occur frequently, are associated with significant morbidity and mortality, are present in a variety of health care settings, and impose a considerable cost to European health care services.

In developed countries, while mortality declined spectacularly during the 20th century, LRTIs remain a leading cause of death. WHO statistics estimate that mortality from respiratory infections is 48/100,000 worldwide and ranges from 40 to 50/100,000 in Europe (WHO's 2002 annual report at http://www.who.org/).

Such figures stress the importance of early recognition of those patients who are severely ill or at risk of becoming severely ill. Of all RTIs about one third are thought to involve the lower respiratory tract (LRT), with ±10% community-acquired pneumonia (CAP), the remaining two-thirds affecting the upper respiratory tract.

At present there is still a great deficit in the etiologic diagnosis of community-acquired LRTIs: in most studies more than 50% of cases remain without an etiologic diagnosis, resulting in unnecessary or inappropriate antibiotic prescribing.

A wide variety of diagnostic procedures and techniques are applied to the detection of the etiologic pathogens of community-acquired LRTI. Traditional diagnostic culture methods above all lack sensitivity, are not feasible in many contexts, and focus only on a few of the large number of etiologic agents. For example, for years, viruses were rarely thought of as the etiologic agent of LRTIs except for cases involving children and immunocompromised patients. However, it has been demonstrated that viruses, in particular RNA viruses, may cause LRTIs and even pneumonia in otherwise healthy adults. Multiple pathogen infections are also increasingly detected (1).

For the so-called atypical bacterial causes—*Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, and *Legionella pneumophila*—traditional diagnostic methods are too insensitive and too slow, producing a result only after several days.

Therefore, alternative diagnostic procedures were developed: antigen detection by latex agglutination or immunofluorescence, enzyme-linked immunosorbent assay, immunochromatography, and nucleic acid amplification techniques (NAATs), particularly PCR and NASBA (nucleic acid sequence-based amplification).

Over the past 2 decades, NAATs have been revolutionizing the diagnostic procedures for the management of patients with LRTI, resulting from a combination of improved sensitivity and specificity, a potential for automatization, and the production of very rapid results. NAATs have already become the "gold standard" in some diagnostic fields, but not many assays have been approved by the FDA for the detection of respiratory pathogens, and fewer still have entered the daily routine diagnosis and management of patients. This can be ascribed to the rapid evolution of the technology, the cost of this technology, and the large number of etiological agents, bacterial as well as viral, responsible for community-acquired LRTI.

This overview will therefore provide a look at the general principles, advantages, diagnostic value, and limitations of the most currently used new amplification techniques for the etiological diagnosis of RTIs as they evolve from research to daily practice.

OPTIMAL SAMPLING FOR THE DETECTION OF RESPIRATORY AGENTS

Specimens that are useful for the detection of etiologic agents in LRTIs may be collected from different body sites, especially in the case of suspected pneumococcal pneumonia, or may be different kinds of specimens from the respiratory tract. It should be noted here that for a number of respiratory etiologies there is currently no consensus on the optimal sampling compartment. A review of possible samples to be used for PCR-based tests or PCR combined with other detection methods was provided by Loens et al. (2).

Streptococcus pyogenes

Swab specimens obtained from the posterior pharynx and tonsils are most widely used as a sampling method for group A streptococci (GAS) pharyngitis testing. This convention is based on recommendations published by the Infectious Diseases Society of America, which defines specimens obtained from these sites to be the only adequate samples to test for the presence of *S. pyogenes* (3). However, these recommendations are based on two small

Katherine Loens and Margareta Ieven, Department of Microbiology, Vaccine and Infectious Disease Institute (VIDI), University of Antwerp, Antwerp, Belgium.

studies conducted more than 20 years ago and evaluating only 32 patients (4, 5). A study conducted by Fox et al. (6) investigated the use of newer techniques of rapid direct carbohydrate antigen and nucleic acid probe detection to identify GAS in samples obtained prospectively from the oral cavities and posterior pharynges of pediatric patients with sore throats. Their study validated the recommendations by the Infectious Diseases Society of America to obtain a sample from the posterior pharynges and tonsils of patients suspected of having GAS pharyngitis. On throat specimens from symptomatic children, both traditional as well as newer tests used to detect the presence of GAS performed significantly better.

Streptococcus pneumoniae

Although blood cultures are still considered culture-based diagnosis of pneumococcal pneumonia because the organisms are recovered from a normally sterile source, PCR-based diagnosis on blood specimens is so far not being used routinely. Recent studies, however, show that the detection of bacterial DNA load in whole blood supports the diagnosis of *S. pneumoniae* infection in patients with CAP: high genomic bacterial load (7) for *S. pneumoniae* may be a useful tool for severity assessment. Systematic comprehensive studies need to be performed to confirm the clinical usefulness of PCR on plasma or whole blood.

The specificity of respiratory specimens for the diagnosis of bacterial pathogens, either by culture or by amplification-based techniques, in the LRTI is not high because of contamination with the upper airway biota. Several techniques have been proposed to achieve accurate discrimination between colonization and infection. Diagnostic accuracy is improved by the use of bronchoalveolar lavage (BAL) specimens in severely ill hospitalized patients.

It is generally accepted that the best nonsterile respiratory specimen for the recovery of *S. pneumoniae* is sputum. Sputum specimens must be representative of lower respiratory secretions. The most widely used method to assess the acceptability in this regard is based on cytologic criteria (8).

M. pneumoniae, *C. pneumoniae*, and *L. pneumophila*

Because of its fastidious nature, *M. pneumoniae* is not routinely cultured from respiratory specimens. Most studies are PCR-based on both LRT and upper respiratory tract (URT) specimens. Different specimens have been used such as sputum, nasopharyngeal swabs (NPSs), oropharyngeal swabs or washes, BAL, or pleural fluid as described in the review by Loens et al. (2).

The superiority of sputum compared to other respiratory specimens for the molecular detection of *M. pneumoniae* has been demonstrated in several studies. The high diagnostic sensitivity of sputum PCR could be explained by the higher number of *M. pneumoniae* organisms in the pulmonary alveoli than on the epithelium of the URT, which has been demonstrated in experimentally infected hamsters. Consequently, if a sputum sample is available, it might be the best specimen for *M. pneumoniae* detection. An oropharyngeal swab or nasopharyngeal aspirate (NPA) might be the second best option for analysis by NAATs (2). The choice of the respiratory specimen may also have a major impact on the sensitivity of *C. pneumoniae* isolation and PCR. Based on a literature search, it is clear that sputum or an NPS may be the preferred specimen for detection of *C. pneumoniae* by NAATs (2).

In patients with community-acquired LRTI caused by *L. pneumophila*, bronchoscopically taken specimens such as BAL are the preferred specimens in severely ill patients admitted to the hospital. Sputum specimens are generally considered to be the best alternative specimens for the isolation of *L. pneumophila* in non-severely ill patients. Combining test results from more than one site appears to improve the diagnostic accuracy. Based on the available data, Loens et al. concluded that no anatomic site or method is clearly superior for optimal detection of *Legionella* in respiratory specimens. Combining test results from more than one site appears to improve the diagnostic accuracy (2).

Bordetella pertussis

NPAs are the optimal sample for infants; they offer superior sensitivity compared to swabs (9). Nasopharyngeal swabs provide valid specimens from older children, adolescents, and adults. Sputum samples or throat washes may represent an alternative for adolescents and adults. The sensitivity of detecting *Bordetella* DNA in these materials has to be validated because, for culture, throat washes were found less suitable (10).

Respiratory Viruses

Specimens for viral tests are not fundamentally different from specimens for bacterial tests, but they are governed by three mandatory rules. They must be taken early, taken from respiratory epithelium (nose, trachea, bronchi), and packed in viral transport medium. At present, sputum is not acceptable for direct virus testing, and BAL is useful for respiratory infections in immunocompromised patients. Serology is not very useful for diagnosis because antibodies appear too late, and the tests themselves perform poorly.

Although not optimal for the detection of typical bacterial pathogens, it is generally assumed that for respiratory infections due to viruses, the optimal specimen is the NPA; this might not be true for all respiratory viruses and for all detection techniques applied. Branche et al. applied real-time quantitative reverse transcriptase PCR (RT-PCR) on dunked sputum (dunking a cotton swab in sputum and swirling it in sterile water) and nose and throat swabs from 965 patients for the detection of respiratory viruses (11). A viral infection was identified in 295/965 patients by in-house uniplex real-time RT-PCR assays. By nose and throat swab alone, 73 (24%) were positive, 105 (35%) were positive by sputum alone, and 124 (41%) were positive in both the nose and throat swab and sputum. Although rhinovirus is considered a cause of URT infections (URTIs), 36/44 (82%) rhinovirus infections that were detected had detectable virus in the sputum sample, 16 (36%) of which were only detected in sputum. The same authors also applied real-time quantitative RT-PCR and found that for the majority of samples and for all four viruses tested (influenza A, respiratory syncytial virus [RSV], human metapneumovirus, and human coronavirus [HCoV] OC43), the quantitative load of the sputum as such was slightly greater than that of the dunked sputum, and both types of sputum contained higher loads than the nose and throat swab.

It is difficult to compare recovery rates of respiratory pathogens from swabs because different types of swabs and transport media have been used. Since 2003, studies have been performed to evaluate the recovery of different organisms in new transport and storage media. For virus transport systems, no real standard has been defined. Different respiratory specimens and types of swabs and transport media were

used. The Copan system, combining flocked swabs and universal transport medium (Copan, Brescia, Italy) for collection and transport, is a universal system compatible with antigen detection kits, direct fluorescent antibody, culture, and PCR. Nasal swabbing with the new flocked swabs is equivalent to traditional rayon NPS with less patient discomfort. Significantly more epithelial cells are collected by these flocked swabs, providing better specimens for diagnosis. Furthermore, NPSs collected with flocked swabs detect a higher number of positives than NPSs collected with Dacron swabs (12).

DIAGNOSIS BY NAAT FOR INDIVIDUAL BACTERIAL RESPIRATORY PATHOGENS

S. pyogenes

S. pyogenes (GAS) is the cause of a wide range of invasive and noninvasive diseases: It is the most common bacterial cause of pharyngitis in school-age children and adolescents, affecting approximately 1 in 10 children per year (13). In children, pulmonary infections caused by GAS vary between 4 and 60% (14). On the other hand, GAS infections were found in 11% of pleuropulmonary infections in a mixed population in France (15). Detection of the organism is based on culture on 5% blood agar, a rapid antigen detection test, and/or PCR.

Based on several studies summarized by Kellogg et al. (16), a standard throat culture reliably detects 90 to 95% of GAS in symptomatic patients. Roe et al. (17) described a lower sensitivity (85%) of throat swab cultures. Nerbrand et al. (18) used both enrichment broth and PCR in addition to standard plating cultures. This resulted in a plate culture sensitivity of only 82%. A much higher sensitivity (99.4%) of a throat culture was obtained by Chapin et al. (19) based on comparison to a parallel rapid antigen detection test.

Compared to other bacterial pathogens, very few PCR assays have been described for the detection of GAS in throat swabs or other respiratory specimens (20–25). Gene targets that are being used include the DNase B gene, SpeB, *parE* gene, spy1258, spy1857, *ptsI* gene, MF gene, 16S rDNA, and *rpoB* gene (Table 1).

Dunne et al. (22) compared six qualitative PCR assays and also investigated the sensitivity and specificity of two quantitative PCRs. In this study, the SpeB quantitative PCR was found to be highly sensitive and specific for the detection of GAS in throat swabs. In addition, the authors concluded that differentiation between an acute GAS infection and carriership remains a challenge.

TABLE 1 Summary of single-plex PCR assays for detection of *S. pyogenes* and previously validated assays used as comparators[a]

Assay year (reference)	Assay type	Detection format	Gene target (product size)	PCR assay used as comparator for new assay	Non-PCR comparator test	Specimens tested for validation of sensitivity and/or specificity
1997 (23)	PCR	Agarose gel electrophoresis	MF gene (419)		Optical immunoassay, agar culture, broth-enhanced culture, latex agglutination	Various bacterial strains Throat swabs from patients being evaluated for pharyngitis
1991 (240)	PCR	Agarose gel electrophoresis	SpeB (257)			34 *S. pyogenes* strains
2003 (25)	PCR	Real-time	ptsI gene (198)		Culture, rapid antigen immunoassay	Various bacterial strains 384 throat swabs
2003 (241)	PCR	ELISA	NS (824)			Various bacterial strains, serial dilutions
2004 (242)	PCR	Sequencing	rpoB (NS)			Various bacterial strains
2004 (243)	PCR	Array	parE (139)		Culture	Various bacterial strains
2005 (244)	PCR		Spy1258 (450)			Various bacterial strains
2008 (245)	PCR	Sequencing				
2009 (21)	PCR	Real-time	NS (80)		Culture and latex agglutination	8 specimens known to be GAS positive, throat swabs
2011 (24)	PCR	Real-time using Tm	DNase B gene (NS)		Culture	Various bacterial strains, archived throat swabs, 344 swabs from a swab comparison study
2013 (29)	PCR	Turbidity		Roche GAS assay	Throat swab cultures, rapid antigen test	437 throat swabs
2013 (22)	PCR	Real-time	SpeB (346)	Comparison of 6 PCRs	Culture	Various bacterial strains
2013 (22)	qPCR	Real-time	SpeB (77)	Comparison of 6 PCRs	Culture	Various bacterial strains Throat swabs
2013 (22)	qPCR	Real-time	Spy1258 (141)	Comparison of 6 PCRs	Culture	Various bacterial strains Throat swabs
2013 (22)	PCR	Real-time	Spy1857 (155)	Comparison of 6 PCRs	Culture	Various bacterial strains

[a]Abbreviations: ELISA, enzyme-linked immunosorbent assay; qPCR, quantitative PCR.

As for the other bacteria previously described, the real-time multiplex PCR (MX-PCR) developed by Morozumi et al. (26) for the simultaneous detection of the atypical bacteria and *S. pneumoniae* and *S. pyogenes* has been applied to clinical specimens from patients with CAP. The assay was found to be 100% sensitive and specific compared to conventional culture results.

Uhl et al. (25) compared the performance of the LightCycler StrepA assay to that of the Directigen 1-2-3 Group A Strep Test Kit and standard culture for the detection of GAS in 384 throat swabs. The LightCycler PCR produced more positive results than either culture or the Directigen immunoassay. The sensitivities and specificities for this comparison were 55% and 99% for the Directigen method and 93% and 98% for the LightCycler assay, respectively. In a study conducted by Atlas et al. (27), comparing culture and a point-of-care test on specimens from patients with acute pharyngitis, a sensitivity of 92.1% and a specificity of 100% were obtained with the point-of-care test. The performance of two rapid antigen detection assays (QuickVue+ streptococcus A test and the Directigen EZ group A streptococcus test) for *S. pyogenes* detection in pleural fluid samples from pediatric patients with empyema was compared with culture, Gram stain, and PCR by Zheng et al. (28). Each rapid antigen test was able to detect 90% of the positive PCR samples with a 100% specificity.

Finally, the Illumigene Group A Streptococcus assay is a new commercially available molecular method which is cleared by the FDA. The whole process time from preparation to result reading for up to 10 specimens is finalized within approximately 1 hour. In a prospective study, the Illumigene assay was compared to (i) standard bacterial culture, (ii) a rapid antigen test using 437 consecutive throat swabs, and (iii) PCR targeting the *ptsI* gene in 161 samples to evaluate its clinical performance (29). Compared to culture, a sensitivity and a specificity, respectively, of 100% and 95.9% were obtained. A sensitivity and specificity of 100% and 99.2% were obtained when compared to PCR. In contrast, the GAS rapid antigen assay resulted in 73.3% sensitivity and 89.1% specificity in this study. Despite these results, culture back-up is still recommended.

More and more, the importance of group C and G *Streptococcus dysgalactiae* subsp. *equisimilis* as a significant pathogen is being recognized (30). No differential diagnosis can be made between an *S. pyogenes* infection and an *S. dysgalactiae* infection on the basis of clinical signs and symptoms. Therefore, the Lyra Direct Strep Assay (Quidel Corp., San Diego, CA), a real-time PCR test for the rapid and qualitative detection and differentiation of group A β-hemolytic streptococci (*S. pyogenes*) and pyogenic group C and G β-hemolytic streptococci (*S. dysgalactiae*, *Streptococcus equi*, *Streptococcus canis*), has been developed. The assay has been applied to nucleic acids isolated from throat swab specimens obtained from symptomatic patients.

S. pneumoniae

S. pneumoniae is the most frequent microbial agent to be found in bacteriologically documented pneumonia in both elderly and middle-aged adults. Of all etiologic agents detected in CAP, *S. pneumoniae* is responsible for more than 20 to 30%, both in the community and in hospitalized patients. The risk of pneumonia due to *S. pneumoniae* is higher in old people than in the general population. The occurrence of pneumonia due to *S. pneumoniae* is more frequent in institutionalized patients than in noninstitutionalized subjects of the same age, and the relative risk of pneumococcal infection increases linearly with age. Early and accurate diagnosis of pneumococcal pneumonia remains difficult due to the limitations of conventional diagnostic methods. Detection by conventional culture is cheap and facilitates antibiotic resistance determination. Blood and sputum cultures are, however, time-consuming and lack sensitivity, particularly for patients with antecedent antibiotic exposure. Sputum culture is also difficult to interpret due to oropharyngeal contamination. Several PCRs have been employed with varying degrees of success, using primers specific to repetitive regions and genes encoding rRNA (31–33), pneumococcal surface adhesion A molecule (*psaA*) (34, 35), pneumolysin (*ply*) (36), penicillin-binding protein (37), 16S rDNA (38), putative sugar-specific permease and intergenic spacer (39), a DNA-dependent ATPase (*recA*) (40), virulence factors such as CpsA (41), and autolysin (*lytA*) (42–45). In recent years, real-time PCR has improved diagnostics. The loop-mediated isothermal amplification (LAMP) technique has also been applied for the successful detection of *S. pneumoniae* in clinical specimens (46). Nevertheless, the identification of *S. pneumoniae* is more complicated than previously assumed (47–49). Several reports have shown that strains that are genotypically closely related to oral streptococci harbor the *S. pneumoniae* virulence factor genes *lytA* and *ply* (49–51). PCR methods based on the *ply* gene are not specific and show high detection rates in saliva from culture-negative healthy individuals (52). Recently, a new *S. pneumoniae*-specific target, the gene fragment Spn9802, has been reported (52, 53).

In addition to some specificity problems, studies using qualitative PCRs have reported difficulties in determining whether positive PCR findings represent colonization or infection, limiting clinical applicability (54, 55).

When testing sputum samples, reported PCR positivity rates have ranged from 68 to 100% for samples from patients with pneumonia (56), although it is unclear how often this reflects colonization of the URT rather than infection (55).

Also, the data obtained by using MX-PCR to detect, among others, the *S. pneumoniae ply* gene, show that asymptomatic carriage makes the use of molecular assays problematic to detect *S. pneumoniae* in URT specimens (57).

According to the European Respiratory Society (8) LRTI guidelines, qualitative nucleic acid amplification tests for *S. pneumoniae* on pleural fluid, peripheral blood, and sputum add little to the existing diagnostic tests in sputum and are unable to distinguish colonization from infection.

One approach that may help to differentiate between carriage and infection with a higher bacterial burden in invasive pneumococcal disease than in a carrier state is the use of quantitative PCRs (RQ-PCR). In recent years, more and more real-time RQ-PCRs have been evaluated (51, 53, 58–60). Although this has not been systematically evaluated, initial data suggest that this might be worth exploring further (59, 61). Yang et al. (51) evaluated, in a first prospective study, the clinical utility of an RQ-PCR assay targeting the *ply* gene to detect *S. pneumoniae* in sputum from adult pneumonia patients. RQ-PCR findings were compared with those of a composite reference standard comprising Gram stain of sputum and sputum/blood cultures. Based on receiver operating characteristic curve analysis, the log-transformed threshold cycle (C_T) giving maximal sensitivity and specificity for the PCR assay was

28.96, corresponding to approximately 3.7×10^4 genomic equivalents of *S. pneumoniae* per ml of sputum. At this threshold, the assay sensitivity and specificity were 90.0% and 80.0%, respectively. Targeting the same gene in another study, Kais et al. (59) examined respiratory tract specimens from 203 patients with and without infection by RQ-PCR and quantitative culture. Significant findings in RQ-PCR were defined as amounts of DNA corresponding to 10^5 CFU/ml. In patients with infection, significant pathogens were found in 32/135 samples with culture and in 51/135 with RQ-PCR, resulting in an increase from 23.7% to 37.7%. The same assay was used for the quantitative detection of *S. pneumoniae* in sputum from 184 CAP patients (58). *S. pneumoniae* was, with all methods used, found to be responsible for 38% of the cases; RQ-PCR, with a cut-off level corresponding to 10^5 CFU/ml, together with urinary antigen detection, was the method that most efficiently contributed to determination of pneumococcal etiology and was shown to be particularly valuable in patients previously treated with antibiotics. On the other hand, the data obtained by using MX-PCR to detect, among others, the *S. pneumoniae ply* gene show that asymptomatic carriage makes the use of molecular assays problematic in detecting *S. pneumoniae* in URT specimens (57). These results were confirmed by Abdeldaim et al. (62).

Albrich et al. investigated the applicability of quantitative *lytA* real-time PCR results from induced sputum and NPSs to distinguish pneumococcal community-acquired pneumonia (CAP) from asymptomatic colonization in HIV-infected South African adults (63). *S. pneumoniae* was considered the cause of pneumococcal CAP if blood culture, induced-sputum culture or Gram stain, urine antigen test, or whole-blood *lytA* real-time PCR revealed pneumococcus or if *lytA* real-time PCR from NPSs gave a result of >8,000 copies/ml. The *lytA* real-time PCR was also performed on induced sputum. The *lytA* real-time PCR from sputum detected *S. pneumoniae* in 149 (67.1%) of 222 patients with available induced sputum, whereas the results of either Gram stain or culture of sputum were positive in 105 of 229 patients (45.9%; $P < 0.001$). Against the composite diagnostic standard, a cutoff value of 10,000 copies/ml for good-quality sputum *lytA* real-time PCR had a sensitivity of 78.1% and a specificity of 80.0%. This cutoff value performed similarly to the previously identified cutoff value of 8,000 copies/ml for NPS *lytA* real-time PCR (64). Overall, *lytA* real-time PCR performs similarly well on induced sputum as on NPSs for most patients but performs slightly better if good-quality sputum can be obtained (64).

Abdeldaim (53) et al. compared the performance of RQ-PCR targeting the Spn9802 sequence to *lytA* PCR and culture on NPAs from 166 CAP patients and from 84 controls. Against an expanded gold standard, sensitivities and specificities for Spn9802 PCR were 94% and 98%, respectively, and those for *lytA* PCR were 82% and 97%, respectively.

Sputum and NPAs, on the one hand, and PCR targets *lytA* and Spn9802, on the other hand, were compared in a quantitative PCR for the rapid detection of pneumococcal pneumonia by Stralin et al. (65). The following RQ-PCR positivity rates were found in CAP patients with and without pneumococcal etiology according to conventional diagnosis: 96% and 15% (sputum *lytA*), 96% and 17% (sputum Spn9802), 81% and 11% (NPA *lytA*), and 81% and 20% (NPA Spn9802). The best-performing test, the sputum *lytA* RQ-PCR, showed the highest sensitivity (94%) and specificity (96%), with a cutoff value of 10^5 DNA copies/ml.

The detection of *S. pneumoniae*-specific targets by real-time PCR assays, such as Spn9802 or *lytA* in plasma, is also useful for the rapid detection of bacteremic pneumococcal pneumonia (7). Detection of bacterial DNA load in whole blood supports the diagnosis of *S. pneumoniae* infection in patients with CAP (66). Bacterial load is associated with the likelihood of death, the risk of septic shock, and the need for mechanical ventilation (67, 68). High genomic bacterial load for *S. pneumoniae* may be a useful tool for severity assessment.

A new promising trend is the application of MX-PCR for the identification and detection of markers that identify specific serotypes of *S. pneumoniae* in clinical specimens. This approach was found to be successful when applied to sterile specimens such as blood (69, 70) or pleural fluid (71–73). The applied assays were sensitive; e.g., pneumococcal DNA was detected in 87.5% of culture-negative pleural fluid (73) and in 97% of culture-positive pleural fluid (72). A similar strategy was applied to nasopharyngeal samples (74–77) from patients and healthy individuals. The assay detected all culture-positive samples and 22/23 serotypes matched with the serotypes identified by the conventional method (74) from pneumonia patients. An MX-PCR was also evaluated against culture on 793 nasopharyngeal samples from children with LRTI by Ahn et al. (78). In this study, 19.3% of the samples were found to be *S. pneumoniae* positive by MX-PCR compared to 10.2% positives by conventional techniques. A recent review presents additional data on the laboratory diagnosis of *S. pneumoniae* pneumonia (79).

In conclusion, *S. pneumoniae* may be rapidly diagnosed by analyzing sputum by RQ-PCR and may be particularly valuable in patients in whom antibiotic therapy was initiated before sampling. Furthermore, it would be able to distinguish between colonization and infection. RQ-PCR warrants further evaluation in clinical settings.

M. pneumoniae

Among atypical infections, *M. pneumoniae* is the most common, followed in frequency by *Chlamydophila* spp. and *Legionella*. *M. pneumoniae* belongs to the class of the *Mollicutes* and has been associated with a wide variety of acute and chronic diseases. RTIs with *M. pneumoniae* occur worldwide and in all age groups.

The proportion of LRTIs, including CAP, in children and adults associated with *M. pneumoniae* infection during the past 10 years has ranged from 0% to more than 50%, varying with age and the geographic location of the population examined and the diagnostic methods used. Determining the true role of *M. pneumoniae* in RTIs remains a challenge, given the wide variations of data from studies with equally wide variation of and lack of standardized diagnostic methods.

Serological methods in particular, such as the complement fixation test and enzyme immunoassays, are the most widely used to diagnose an *M. pneumoniae* infection. The application of PCR is increasingly accepted as a rapid diagnostic test since culture is too slow and too insensitive to be therapeutically relevant. None of the currently available NAATs have been extensively validated against culture, which remains the reference standard despite its low sensitivity and variable yield, depending on the specimens tested and the isolation protocols used. The sensitivity of NAATs is almost always superior to that of the traditional

procedures, and they are increasingly considered as the new gold standard. However, different studies have used not only different diagnostic tools or combinations thereof, but also different diagnostic criteria for diagnosing an infection, thereby making comparison between studies difficult. Most importantly, the lack of standardization has resulted in a wide variation of interlaboratory test performance, even when using the same test and criteria (80).

A growing body of literature describing the use of in-house NAATs for detecting *M. pneumoniae* DNA or RNA in various diseases is now available with a great variation of methods used from study to study, including variability of target (P1 gene, 16S rRNA, ATPase gene, *parE* gene, *tuf* gene; monoplex versus multiplex targets) and of NAAT (conventional, nested, and real-time; RNA versus DNA targets; and PCR and NASBA technologies) and detection formats (agarose gel electrophoresis, SYBR green, TaqMan probe, hybridization probes, molecular beacons, and microchip electrophoresis).

An overview of the literature on the use of NAATs to detect *M. pneumoniae* since 1989 is given in two reviews by Loens et al. (81, 82) with a description of the currently available molecular amplification methods. Topics discussed include specimen collection and transport, preparation of nucleic acid from clinical specimens, choice of the target sequence, and detection of the amplicons. Methods to recognize and prevent false-positive and false-negative results, the results of NAATs compared with results obtained by conventional diagnostic tests, and clinical applications are also reviewed. The availability of the very sensitive NAATs has in recent years also put the often-used serological tests in perspective and allows a better interpretation of the serological test results and their limitations, such as the low sensitivity of IgM antibodies in acute-phase specimens and the importance of the delay between two serum samples. The clinical significance of a serologic test, for both IgM and IgG, should be defined by studies of patients with a documented infection and for whom detailed information concerning the time lapse between onset of disease and the collection of the serum specimens is known. Studies in which NAATs are also used on respiratory specimens allow a better interpretation of the serological test results.

Data analysis of different studies indicates that no single available test was sensitive enough for the identification of *M. pneumoniae* in CAP. A combination of serology and PCR proved to be the most reliable approach for identifying *M. pneumoniae* in CAP.

Data from recent studies using PCR-based methods and serology published during the last 5 years in different patient populations from around the world are summarized in a recent review by Ieven and Loens (83), and the role of both techniques is discussed.

Since the previous review (285), new tests have become commercially available, such as the Illumigene kit (84) (Table 2). A new trend is the simultaneous detection of the organism and mutations associated with macrolide resistance directly in clinical specimens (85, 86).

C. pneumoniae

C. pneumoniae, an obligate intracellular bacterium, has been associated with a variety of diseases but most importantly with respiratory infections that occur worldwide and in all age groups. Studies of *C. pneumoniae* published since the 1990s declare the organism to be associated with less than 5% to up to more than 40% of LRTI in both children and adults, varying with age, geographical location, the population studied, and especially the diagnostic methods used.

For the detection of this organism as well, PCR holds promise as a diagnostic tool. The major outer membrane protein gene and 16S rRNA gene are often used targets for amplification.

Most importantly, among the early studies published, none of the available methods have been standardized, which has resulted in a wide variation of interlaboratory test performance. In an effort to standardize diagnostic assays for *C. pneumoniae*, Dowell et al. (87) published recommendations for diagnostic testing in 2001. In 2007, Kimar et al. (88) published an excellent overview of the current status of diagnostic methods for *C. pneumoniae* since the Dowell publication. They conclude that significant limitations remain in the accurate and reliable diagnosis of *C. pneumoniae*, and the availability of commercial assays may enable standardization. However, they await further validation: the sensitivity of all these assays is dependent on DNA copy numbers, and further evaluations on clinical specimens that may have low bacterial loads are needed. In addition, for acute LRTI with *C. pneumoniae* a combination of PCR detection and specific single-serum IgM measurement seems to be called for.

A multicenter prospective study investigating the incidence of *C. pneumoniae* infections in adult ambulatory (n = 182) and hospitalized (n = 364) patients with CAP in the German Competence Network for Community Acquired Pneumonia (CAPNETZ) Project used microimmunofluorescence (MIF) testing to determine single IgM, IgG, or IgA titers, as well as three previously published PCR protocols (89). Significant variation in PCR results was reported among the three laboratories, each independently experienced in the use of PCR assays. Via the use of PCR positivity in at least two of the three laboratories to define acute infections, *C. pneumoniae* infections were identified in 5 (0.9%) of 546 case patients. MIF tests were performed for three of these five case patients, and all results were negative for anti-*C. pneumoniae* IgG, IgM, or IgA antibodies. These data confirm the lack of correlation of serological methods with culture and/or PCR tests reported earlier (90).

Hvidsten et al. (91) studied the importance of methodology in relation to timing of sampling for detecting *C. pneumoniae*. Nasopharyngeal swabs for PCR-based detection and sera for single IgM and IgG seroconversion by MIF were obtained from 127 military conscripts during a *C. pneumoniae* outbreak. Serum drawn many months before the outbreak provided the baseline antibody status. The sensitivities were 79%, 85%, 88%, and 68%, respectively, and the specificities were 86%, 84%, 78%, and 93%, respectively, for MIF IgM, enzyme immunoassay IgM, recombinant-enzyme-linked immunosorbent assay IgM, and PCR. In two subjects, acute infection was diagnosed on the basis of IgG seroconversion alone. The lower sensitivity of PCR detection was explained by the late sampling or clearance of the organisms following antibiotic therapy and the timing of sampling for the different test principles used. On the basis of their findings, the authors recommend a combination of nasopharyngeal swabbing for PCR and specific single-serum IgM measurement. Benitez et al. assessed the performance of real-time PCR and MIF for the detection of *C. pneumoniae* during an outbreak (92). They concluded that (i) application of serology alone would likely have been misleading since the rate of seropositivity

TABLE 2 Summary of recent single-plex PCR assays for detection of *M. pneumoniae*, *C. pneumoniae*, and *B. pertussis* published since the previous review and previously validated assays used as comparators[a]

Assay year (reference)	Assay type	Detection format	Gene target (product size)	PCR assay used as comparator for new assay	Non-PCR comparator test	Specimens tested for validation of sensitivity and/or specificity
M. pneumoniae						
2009 (246)	PCR	Real-time	P1 gene (342)	Affigene Cp/Mp Tracer	IgM and IgG	50 BAL specimens
2011 (247)	PCR	Oligochromatographic test	P1 gene (NS)	Cepheid	IgG seroconversion/ significant rise	Samples from 145 patients
2012 (248)	PCR	Real-time	P1 gene (72)	repMp1 and Mp181		Various bacterial species, bacterial dilution series, well-defined clinical specimens
2012 (249)	LAMP	Turbidity	P1 operon		IgG seroconversion/ significant rise	Samples from 368 pneumonia patients
2013 (250)	PCR	Real-time	P1 gene (534)	Conventional PCR (NS)	IgM, IgG, and IgA serology	Dilution series, respiratory samples from CAP patients
2013 (251)	PCR	Real-time	ptsI (160)	LightMix kit *M. pneumoniae* (TIB MOLBIO), *M. pneumoniae* analyte-specific reagent (Focus Diagnostics) (252)		Bacterial dilution series, spiked clinical specimens, well-defined clinical specimens
2013 (253)	PCR	Quantitative fluorescence	16S rDNA (Daan Gene kit) (NS)		IgG and IgM serology, culture	Specimens from CAP patients
2014 (86)	PCR	Cycleave	23S rDNA	(254)		Various bacterial species, bacterial dilution series, clinical specimens
2014 (84)	LAMP	Turbidity	Illumigene assay (NS)	2nd real-time PCR and sequencing	Culture	Various bacterial species, bacterial dilution series, 214 culture positive/ negative specimens
C. pneumoniae						
2009 (246)	PCR	Real-time	Polymorphic membrane protein G (140)	Affigene Cp/Mp Tracer	MIF	50 BAL specimens
2011 (255)	PCR	Real-time	16S rDNA (207–215)	(206)		Various bacterial species, plasmid dilution series, well-defined archived specimens, 442 prospectively collected nasopharyngeal swabs if positive confirmed by sequencing
B. pertussis						
2010 (256)	PCR	Dipstick	GenoQuick *Bordetella* assay			Clinical specimens from suspected cases
2012 (257)	PCR	Real-time	NS	(258)	Culture	Clinical specimens from suspected cases

[a]Abbreviations: A-test, passive agglutination test; LAMP, loop-mediated isothermal amplification.

among noncases was extremely high and (ii) real-time PCR is a more useful diagnostic tool for confirmation of a *C. pneumoniae* infection.

Padalko et al. (93) analyzed the yield of PCRs for the detection of *C. pneumoniae* in respiratory specimens. Their data were based on routine analysis of respiratory samples submitted for *C. pneumoniae* detection collected in four large Belgian hospitals during 2 consecutive years. Only 0.2% of the 3,560 samples were found to be *C. pneumoniae* positive. The authors concluded that a critical evaluation of *C. pneumoniae* as a cause of respiratory infections is needed.

Since our review in the 2nd edition of this volume (285), only a few new assays have been added (Table 2).

L. pneumophila

Legionella spp. are aerobic, nutritionally fastidious Gram-negative rods. *Legionella* is commonly found in cooling towers, humidifiers, and potable water distribution systems. Since the organism was first identified in 1976 during an outbreak at an American Legion Convention in Philadelphia, *Legionella* has been recognized as a relatively common cause of both community-acquired and hospital-acquired pneumonia, with *L. pneumophila* causing more than 90% of the cases of Legionnaires' disease. Legionnaires' disease is a form of bacterial pneumonia that is characterized by fever, chills, and a dry cough associated with muscle aches and occasional diarrhea. Severity ranges from mild to fatal, with an average mortality rate of 15%, especially observed in immunocompromised patients.

Serologic tests, although often used, can never offer an early diagnosis of legionellosis. *Legionella* antibody tests have a sensitivity of 61 to 64% depending on the assay applied and do not substantially improve the diagnosis of legionellosis (94). They therefore are an epidemiological rather than a diagnostic tool.

NAATs enable specific amplification of minute amounts of *Legionella* DNA. NAATs also have the potential to detect infections caused by any *Legionella* species or serogroup, as presented in Table 3. Diagnostic PCR assays have principally targeted specific regions within the 16S rRNA gene, the 23S-5S spacer region, 5S rDNA, or the *mip* gene (Table 3). Thus far, encouraging results obtained mostly from *in vivo* evaluations and small patient series have been reported. A new commercial test (BD ProbeTec ET *L. pneumophila*; Becton Dickinson) that detects *L. pneumophila* serotypes 1 to 14 in sputum is now cleared by the FDA, but published data on performance characteristics are lacking.

The added value of real-time PCR for diagnosis of Legionnaires' disease in routine clinical practice was studied by Diederen et al. (95). Patients were evaluated if, in addition to PCR, the results of at least one of the following diagnostic tests were available: (i) culture for *Legionella* spp. on specific media and (ii) detection of *L. pneumophila* antigen in urine specimens. Of the 151 evaluated patients, 37 (25%) fulfilled the European Working Group on *Legionella* Infections criteria. An estimated sensitivity and specificity of 86% and 95% were found for 16S rRNA-based PCR, and corresponding values of 92% and 98%, respectively, were found for the *mip* gene-based PCR. A total of 35 patients were diagnosed by using the urinary antigen test, and 34 were diagnosed by the 16S rRNA-based PCR. With the combined urinary antigen test and *mip* gene PCR, Legionnaires' disease was diagnosed in four more patients than with the use of the urinary antigen test alone.

The CAPNETZ project also studied the incidence, clinical characteristics, and outcome of *Legionella* pneumonia in 2,503 adult patients with CAP (96). The following tests were used: culture on selective media, genus-specific PCR targeting the 16S rRNA gene, and urinary antigen tests. Unfortunately, not all specimens were available from all patients. Respiratory specimens were available for 35% of patients. *Legionella* pneumonia was diagnosed in 94 patients (3.8%) and was found to be equally common among ambulatory and hospitalized patients. The predominant species was *L. pneumophila*. Diagnosis of a *Legionella* infection was based on a positive culture result for *L. pneumophila* in 3 patients, a positive PCR result from respiratory samples in 52 patients, and/or a positive urinary antigen test result in 48 patients. Of these, culture and PCR were positive in two patients, culture and urinary antigen test in one patient, PCR and urinary antigen test in six patients, and culture, PCR, and urinary antigen test in one patient.

The influence of antimicrobial therapy on the sensitivity of *Legionella* DNA detection by PCR in LRT samples was studied in three cases (97). The data presented by Korosec et al. suggest that within a few days, specific antimicrobial therapy induces a significant decrease of the bacterial

TABLE 3 Summary of recent single-plex PCR assays for detection of *Legionella*, published since the previous review, and previously validated assays used as comparators[a]

Assay year (reference)	Assay type	Detection format	Gene target (product size)	PCR assay used as comparator for new assay	Non-PCR comparator test	Specimens tested for validation of sensitivity and/or specificity
2009 (259)	PCR	Real-time	23S-5S rDNA spacer (NS)		Culture	Various bacterial species, DNA dilution series, clinical specimens
2011 (107)	PCR	Real-time	Sg1 (294)	iQcheck Quanti Legionella (Bio-Rad)		Various bacterial strains, samples from confirmed legionellosis cases
	qPCR	Real-time	Sg1 (75)			
2011 (260)	PCR	Agarose gel electrophoresis	ompS (849)		Ag ELISA	DNA dilution series
2011 (261)	PCR	Agarose gel electrophoresis	gyrB (224)			Various bacterial species, DNA dilution series
2012 (106)	qPCR	Real-time	mip (NS)		Culture, uAg	Various bacterial species, DNA dilution series, clinical samples

Abbreviations: ELISA, enzyme-linked immunosorbent assay; ICT-strip, immunochromatography; qPCR, quantitative PCR; uAg, urinary antigen test.

concentration in respiratory specimens, reaching the detection limit of the assay. Similarly, Diederen et al. (98) quantified *Legionella* DNA in serum from two patients with legionellosis by real-time PCR during the course of illness. The results obtained mirrored both the clinical condition and C-reactive protein values during the course of illness.

Legionella DNA can be detected in urine, serum, and leukocyte samples obtained from patients with Legionnaires' disease with sensitivities varying between 30 and 86% (99–104). Although the sensitivity of the detection of *Legionella* DNA in serum is rather low (50 to 60%), sensitivity might be higher in more severe cases (99, 100). This issue needs further study.

Recently quantitative assays have been developed and validated for the detection of *L. pneumophila* and/or *Legionella* spp. in clinical specimens (105–107). By applying RQ-PCR to respiratory specimens from patients admitted to the hospital, Maurin et al. demonstrated that a high bacterial load was significantly associated with higher Fine classes (based on the presence and severity of five symptoms [cough, fatigue, dyspnea, sputum, and chest pain] (108), a need for hospitalization, and admission to an intensive care unit and prolonged hospitalization (105). Mentasti et al. applied RQ-PCR to serum, urine, and respiratory specimens from confirmed cases (106). All *L. pneumophila* culture-positive respiratory specimens were also positive with RQ-PCR. In addition, of 80 culture-negative samples tested, 47 were positive by quantitative PCR. Furthermore, the authors showed that RQ-PCR was far more sensitive than culture for samples taken at ≤2 days of hospitalization (94.7% versus 79.6%), with the difference being even more marked for samples taken between 3 and 14 days. The bacterial load was high but varied significantly in positive culture samples. The quantity of DNA in negative culture specimens was significantly lower. When applied to serum, the quantity of bacterial DNA was generally low. None of the urine samples was found to be *L. pneumophila* positive. An overview of newly described assays is presented in Table 3.

B. pertussis

B. pertussis, a small Gram-negative bacterium, is responsible for the vast majority of pertussis or "whooping cough" cases; *Bordetella parapertussis* causes a mild pertussis-like illness. Other species, including *Bordetella bronchiseptica*, may infrequently cause respiratory infections in humans, mostly in patients who are immunocompromised. In the present vaccine era, the overall incidence of pertussis has been reduced dramatically.

While pertussis has generally been considered an infection of children associated with considerable morbidity and mortality, it has been increasingly recognized over the past 2 decades in adults. The increase in reported pertussis over the last 2 decades is mainly due to a greater awareness of pertussis and perhaps to the use of several less efficacious vaccines.

The use of a *B. pertussis*-specific PCR in combination with single-serum serology has been shown to increase the sensitivity for pertussis diagnosis. Recommendations for the use of PCR in the diagnosis of pertussis have been published previously (109). Since then, real-time PCR formats have emerged and are now widely used. Block-based PCR (110) and real-time PCR (Table 4) are generally more sensitive than culture for the detection of *B. pertussis* and *B. parapertussis*, especially in the late stage of the disease and after antibiotic treatment has started (111, 112). Similar to culture, the sensitivity of PCR decreases with the duration of cough; however, due to its higher sensitivity, it may be a useful tool for diagnosis not only for the first 3 to 4 weeks of coughing, but even longer (113).

A frequently used target for PCR detection of *B. pertussis* is the repetitive element IS*481* (Table 4), which is absent in *B. parapertussis* but found in approximately 50 to a few hundred copies in *B. pertussis* (114, 115). Although IS*481* is generally regarded as specific for *B. pertussis*, a few studies detected it also in *B. bronchiseptica*. Although the latter organism is primarily associated with disease in mammals other than humans, human illness and carriage are on the rise, particularly in infants or immunocompromised hosts with exposure to carrier animals (116–121). While rare, disease in immunocompetent adults may also occur. A review of the literature covering PCR methods used to identify *B. pertussis* reveals that "diagnostic" amplicons were obtained from *B. bronchiseptica* isolates in at least five investigations using primers for the 5′ end of the repetitive element (114, 122–125) but by none using primers targeting the 3′ end (126–129). Register et al. (130) reported that the prevalence of IS*481* in *B. bronchiseptica* is approximately 5% and suggested that PCR targeting IS*481* may not be sufficiently specific for reliable identification of *B. pertussis*. There has also been concern about the specificity of detection of *B. pertussis* due to sequence identity with *Bordetella holmesii* (131). Register et al. (132) also reported that the *B. pertussis* pertactin gene sequence for the region that encompasses the RT-PCR primers and probe described by Vincart (133) is nearly identical to that of many *B. bronchiseptica* strains of human and avian origin. By using the Vincart assay, 4/6 *B. bronchiseptica* strains were falsely identified as *B. pertussis*.

Although the pertussis toxin operon is present in *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica*, the pertussis toxin promoter is a target for *B. pertussis*-specific assays using real-time PCR. It was, however, consistently less sensitive than IS*481* (134). Some reference laboratories use both targets.

During a pertussis outbreak, a multitarget real-time PCR (135) for the detection of *B. pertussis* was evaluated targeting IS*481*, IS*1001*, and an IS*1001*-like element as well as pertussis toxin subunit S1 (136). All patients with an IS*481* Ct of <30 were also positive by the ptxS1 assay and clinical pertussis cases. No patients with IS*481* Ct values of ≥40 tested positive by culture.

The EUVAC.NET network evaluated the performance of PCR tests used across Europe in 2011 for the detection of *B. pertussis* (137). The participants were 24 national reference centers from 19 countries. A wide variation in methods used for PCR-based diagnosis was found. Several laboratories were not able to discriminate between DNA samples from different *Bordetella* spp.

Four commercial real-time PCR assays for the detection of *Bordetella* spp. in NPAs (Simplexa *B. pertussis*/*B. parapertussis* [Focus Diagnostics], the SmartCycler *B. pertussis*/*parapertussis* assay [Cepheid], the *Bordetella* R-gene [Argene], and the *B. pertussis* real-time kit [Shangai ZJ Bio-Tech]) were compared with real-time in-house PCR by Lanotte et al. (138). Sensitivities over 90% were obtained for the former three kits, whereas the kit from Shangai ZJ Bio-Tech proved to be unsuitable for routine clinical use unless significant improvements are made.

An overview of pertussis diagnostics was provided in 2014 by Wirsing von König (139). An overview of assays published since the previous review is given in Table 2.

TABLE 4 Summary of recent in-house multiplex PCR assays for detection of respiratory pathogens, published since the previous review (285)

Assay year (reference)	Assay type	Detection format	Specimens tested for validation of sensitivity and/or specificity
2009 (262)	MX-PCR	Liquid array	Various bacterial species, DNA dilution series, clinical specimens Pathogens targeted: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Escherichia coli*, *Staphylococcus aureus*, *Listeria monocytogenes*, *Streptococcus agalactiae*, herpes simplex virus type 1 and 2, varicella zoster virus
2009 (263)	MX-PCR	Real-time	Clinical specimens from patients with uAg test available Pathogens targeted: *S. pneumoniae* pneumolysin and autolysin gene
2010 (264)	MX-qPCR	Real-time	Various bacterial species, DNA dilution series, well-defined clinical samples Pathogens targeted: *S. pneumoniae*, *Haemophilus influenzae*, *N. meningitidis*
2010 (265)	MX-PCR	Microarray	Viral/bacterial dilution series, clinical samples analyzed by a second PCR Pathogens targeted: HAdV, enterovirus, HBoV, hMPV; HCoV 229E, OC43, HKU1; influenza A, influenza B, influenza C, PIV1-4, RSV A/B, rhinovirus, *Chlamydophila pneumoniae*, *Mycoplasma pneumoniae*
2010 (266)	MX-PCR	Microarray	Various bacterial species, plasmid DNA dilution series, 14 sputa analyzed by a second PCR Pathogens targeted: *S. pneumoniae*, *Streptococcus pyogenes*, *Moraxella catarrhalis*, *Haemophilus* spp., *C. pneumoniae*, *M. pneumoniae*, *Legionella pneumophila*, *Coxiella burnetii*, *Pseudomonas aeruginosa*
2010 (267)	MX-PCR	Real-time	Various bacterial species, bacterial dilution series, clinical specimens Pathogens targeted: *Bordetella pertussis* and *Bordetella parapertussis*
2011 (268)	MX-PCR	Real-time	*Bordetella* species, bacterial dilution series, clinical specimens Pathogens targeted: *B. pertussis*, *B. parapertussis*, *Bordetella holmesii*, *Bordetella bronchiseptica*
2011 (135)	MX-PCR	Real-time	Various bacterial strains, bacterial dilution series, spiked specimens, clinical specimens also analyzed by culture and ptxS1 PCR
2011 (269)	MX-PCR	Real-time	Various bacterial species, bacterial dilution series, clinical specimens Pathogens targeted: *S. pneumoniae*, *Burkholderia pseudomallei*
2011 (261)	MX-PCR	Agarose gel electrophoresis	Various bacterial species, DNA dilution series Pathogens targeted: *Legionella* spp.
2011 (270)	MX-PCR	Real-time	Various bacterial species, clinical specimens Pathogens targeted: influenza A, influenza A H1, influenza A H3, influenza B, RSV, PIV 1-3, hMPV, rhinovirus, enterovirus, parechovirus, HAdV, *Legionella* spp., *L. pneumophila*, *H. influenzae*, *S. pneumoniae*, *S. pyogenes*, *M. pneumoniae*, *C. pneumoniae*, *B. pertussis*
2011 (269)	MX-PCR	Real-time	Various bacterial species, bacterial dilution series, clinical specimens Pathogens targeted: *M. pneumoniae*, *C. pneumoniae*, *L. pneumophila*
2012 (271)	MX-LAMP	Turbidity and digestion	Various bacterial species, bacterial dilution series Pathogens targeted: *S. pneumoniae*, *Streptococcus suis*, *S. agalactiae*, *S. aureus*
2012 (272)	MX-PCR	Real-time	Various respiratory pathogens, positive control dilution series, clinical specimens Pathogens targeted: influenza and RSV
2012 (273)	MX-PCR	Mass spectrometry	Pathogens targeted: RSV, influenza A and B; PIV 1-4; hMPV; HAdV; HCoV NL63, HKU1, 229E, and OC43; HBoV
2012 (274)	MX-PCR	Capillary electrophoresis	Various respiratory pathogens, DNA dilution series, clinical specimens Pathogens targeted: influenza A and B; influenza A H1N1; PIV 1-3; rhinovirus; hMPV; HAdV; RSV; HCoV OC43, 229E, NL63, and HKU1; HBoV
2012 (275)	MX-PCR	Agarose gel electrophoresis	Various bacterial species, DNA dilution series, well-defined sputa Pathogens targeted: *S. pneumoniae*, *H. influenzae* type b, *Mycobacterium tuberculosis*
2013 (276)	MX-PCR	ELISA	Culture supernatants of the organisms, clinical specimens from frozen stocks, prospectively included nasopharyngeal aspirates

(*Continued on next page*)

TABLE 4 Summary of recent in-house multiplex PCR assays for detection of respiratory pathogens, published since the previous review (285) (*Continued*)

Assay year (reference)	Assay type	Detection format	Specimens tested for validation of sensitivity and/or specificity
			Pathogens targeted: enterovirus, influenza A, influenza B, RSV, PIV 1-4, HAdV, rhinovirus, hMPV, HCoV, reovirus, *M. pneumoniae*, *C. pneumoniae*, *B. pertussis*, *B. parapertussis*, *L. pneumophila*
2013 (277)	MX-PCR	Affimetrix Chip-image file	Clinical specimens simultaneously investigated by culture and 2 commercially available assays: the Eragen assay and the Luminex RVP
			Pathogens targeted: 72 pathogens
2013 (170)	MX-PCR	Microarray	Well-defined clinical specimens analyzed by individual real-time PCRs
			Pathogens targeted: HAdV; hMPV; PIV1-4; influenza A; influenza B; influenza C; RSV; rhinovirus; HCoV OC43, 229E, NL63, and HKU1; enterovirus; *B. pertussis*; *C. pneumoniae*; *H. influenza*; *L. pneumophila*; *M. pneumoniae*; *S. pneumoniae*; *S. pyogenes*
2013 (278)	MX-PCR	Luminex technology	Reference material, dilution series of positive specimens, 1,065 respiratory specimens analyzed by a second PCR
			Pathogens targeted: influenza A, influenza B, influenza A H3N2, influenza H1N1, and pandemic influenza A H1N1
2013 (279)	MX-PCR	Real-time	Various respiratory viruses, reference materials, *in vitro* RNA dilution series, well-defined clinical specimens, clinical specimens analyzed by second PCR
			Pathogens targeted: influenza A; influenza B; influenza A H1 seasonal; influenza A H1N1; influenza A H3; RSV A/B; hMPV; PIV1-4; rhino/enterovirus; HCoV OC43, HKU1, NL63, and 229E
2013 (280)	MX-PCR	Electrophoresis	Various respiratory viruses, dilution series of RNA transcripts, dilution series of plasmids, analysis by two commercially available assays (Luminex RVP Fast and Seeplex RV15 ACE)
			Pathogens targeted: influenza A; influenza B; influenza A H1N1; PIV1-3; rhinovirus; hMPV; HAdV; RSV A/B; HBoV; HCoV NL63, OC43, 229E, and HKU1
2013 (233)	MX-PCR	Dipstick	Various respiratory viruses, virus dilution series, well-defined clinical specimens
			Pathogens targeted: influenza A and B
2013 (281)	MX-PCR	Agarose gel electrophoresis	Various bacterial species, DNA dilution series, well-defined clinical specimens
			Pathogens targeted: *S. pneumoniae*, *Streptococcus mitis*, *Streptococcus oralis*
2013 (282)	MX-PCR	Real-time	Various bacterial species, bacterial dilution series, well-defined clinical specimens
			Pathogens targeted: *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, *S. agalactiae*, *L. monocytogenes*, *Cryptococcus neoformans*
2014 (283)	MX-PCR	Real-time	Various bacterial pathogens, bacterial dilution series, spiked specimens, well-defined clinical specimens
			Pathogens targeted: *B. pertussis*, *B. parapertussis*
2014 (284)	MX-PCR	Real-time	DNA dilution series, well-defined clinical specimens from CAP patients
			Pathogens targeted: *S. pneumoniae*, *H. influenza*, *M. catarrhalis*, *P. aeruginosa*, *Klebsiella pneumoniae*, *E. coli*, *S. aureus*, *M. pneumoniae*, *C. pneumoniae*, *Chlamydophila psittaci*, *C. burnetii*, *Legionella* spp., *L. pneumophila*, *B. pertussis*, *M. tuberculosis*, *Mycobacterium intracellulare*, *Mycobacterium avium*, *Mycobacterium kansasii*, *Pneumocystis jeroveci*, *Nocardia* spp., metallo-β-lactamase, MRSA
2014 (85)	MX-PCR	Agarose gel electrophoresis	Various bacterial pathogens, bacterial dilution series, confirmation by sequencing, confirmation by second PCR, well-defined clinical specimens
			Pathogens targeted: *M. pneumoniae* and associated macrolide resistance

[a]Abbreviations: A-test, passive agglutination test; ELISA, enzyme-linked immunosorbent assay; HAdV, human adenovirus; HBoV, human bocavirus; HCoV, human coronavirus, hMPV, human metapneumovirus; MRSA, methicillin-resistant *S. aureus*; PIV, parainfluenza virus; MX-PCR, multiplex PCR; NASBA, nucleic acid sequence-based amplification; RSV, respiratory syncytial virus; uAg, urinary antigen test.

Bidet et al. (140) measured the persistence of *B. pertussis* DNA in NPAs of 21 infants treated for pertussis. After 5 days of treatment, PCR was positive for all 21 patients. After 14 and 21 days, PCR was still positive for 83% and 66%, respectively, of assessable patients. One patient was tested 1 month after treatment initiation, and *B. pertussis* DNA was still detectable. Quantitative analysis showed that the DNA concentration diminished during treatment in all except one case. The authors concluded that real-time PCR can be used to diagnose pertussis even 3 weeks after treatment initiation in infants. However, whether or not this applies to older children and adults as well remains to be investigated. Furthermore, serial real-time PCR might be useful for the prediction of treatment failure and comparison of efficacies of different antibiotics, although further studies are needed.

Palmer et al. analyzed PCR positivity and duration of illness in children less than 5 years of age (141) and found that PCR positivity mirrored the understood length of infectivity with regard to both catarrhal symptoms and paroxysmal cough, namely, that positive PCR results were obtained at least 21 days following onset of catarrhal symptoms and at least 14 days following onset of paroxysmal cough.

NAAT FOR INDIVIDUAL VIRAL RESPIRATORY PATHOGENS

The importance of viruses as causal agents has been confirmed in LRTI. In CAP the most common etiological agents after *S. pneumoniae* are respiratory viruses, which are involved in 5 to >30% of infections (8). A multitude of reports have appeared on the epidemiology of viruses in acute respiratory infection (ARI), but most are restricted to a few viruses (influenza, sometimes together with RSV, and rhino-, metapneumo-, or coronaviruses) and/or to some population groups, e.g., children, adults, or the elderly (142–149). Great variations occur in function of time, place, and the age groups studied.

Influenza viruses consist of three different types: A, B (150), and C (151). Within influenza A, distinct subtypes determined by the hemagglutinin and neuraminidase genes can be distinguished. Influenza A causes annual epidemics, the epidemic period varying usually between 3 and 8 weeks. Pandemics can occur after the emergence of a novel virus subtype as a result of genetic reassortment of hemagglutinin and neuraminidase genes occurring when two different subtypes coinfect the same host (152).

Influenza is a febrile illness characterized by a sudden increase in temperature, headache, malaise and myalgia, and respiratory symptoms such as sore throat and cough. During the seasonal epidemics, influenza infections are responsible for a significant number of hospitalizations each year; people over the age of 65 are most at risk, followed by children under the age of 5.

RSV is the most common cause of viral LTRI in very young children and is the major cause of bronchiolitis and pneumonia in infants below 2 years of age (153). Two subtypes can be distinguished: groups A and B, of which RSV A seems to be responsible for the most severe infections. Disease often begins with upper respiratory symptoms but rapidly progresses to bronchiolitis or pneumonia with wheezing and respiratory distress. Not only in very young children but also in the elderly, RSV is now commonly associated with LRTI and pneumonia (146, 154–156). Peak prevalences of RSV infections are usually seen in the winter between December and March.

Parainfluenza viruses are divided into four serotypes (HPIV-1 to HPIV-4) that are all capable of causing respiratory infections in humans (157–159). HPIV-1 is the most important etiologic agent in croup in very young children but can also be responsible for milder RTIs. HPIV-2 has also been associated with croup, but less frequently than HPIV-1. HPIV-3 is more associated with severe LRTI. HPIV-4 is the least common virus of this group. Parainfluenza viruses occur any time of the year, but small outbreaks can be observed in autumn, mostly due to HPIV-1, and spring, mostly due to HPIV-3.

Rhinoviruses, with more than 200 serotypes, have until recently only been associated with the common cold. However, they are now detected with an increasing importance and have been associated with asthma exacerbations in both children and adults, wheezing, acute respiratory distress, serious LRTI, and even CAP in children, the elderly, and immunocompromised patients (160–164).

Adenoviruses, of which at least 51 serotypes have been described, can cause a variety of infections ranging from respiratory infections to conjunctivitis, keratoconjunctivitis, and gastroenteritis. The most common serotypes involved in human respiratory infections are serotypes 1 to 5, which cause mostly mild symptoms, but more severe disease such as bronchiolitis or even pneumonia may also occur occasionally, especially in pediatric transplant patients (165–168).

Coronaviruses are also more prevalent than previously thought (169, 170). In 2012, an emerging coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), was reported to cause respiratory infections in humans. Cunha et al. published a recent review on this new virus (171). As time progresses, the importance of the more recently discovered human bocavirus, human metapneumovirus infections, and new coronaviruses is becoming more evident. Based on signs and symptoms, human metapneumovirus is very similar to RSV, causing both URTI and LRTI, especially bronchiolitis but also pneumonia, most frequently in very young children (172, 173). The peak incidence of human metapneumovirus infections usually follows RSV, but both peaks overlap frequently. Although the role of some of these new viruses becomes more clear in specific patient populations, more studies are needed to identify the clinical relevance of some others such as bocavirus (174, 175).

Antigens of the most common respiratory viruses such as influenza, RSV, adenovirus, and parainfluenza viruses can be detected by direct immunofluorescence or by commercially available enzyme immunoassays. The sensitivities of these tests vary from 50 to >90%, and the sensitivity of the direct immunofluorescence test is lower in adults than in children. Culture procedures for other viruses and fastidious bacteria are too insensitive and are superseded by NAATs, preferably in real-time formats and in combination with automated nucleic acid extraction. This approach allows laboratories to obtain a result within 4 to 5 hours.

Multiple protocols are more frequent for virus groups that contain multiple virus types. Several amplification protocols were developed to cover particular types or groups among the adenoviruses. More than 200 rhinovirus types and their close relationship with enteroviruses constitute a special challenge. The judicious choice of primers and particularly of the hybridization probes should ensure a

satisfactory coverage of the rhinovirus types. Side-by-side comparison of two amplification protocols comparing two different conventional molecular amplification techniques applied to a considerable number of clinical specimens is rare. Combined with conventional methods, most PCR protocols have a better sensitivity; e.g., all RSV procedures have a sensitivity of 94.5 to 97% compared with cell culture and immunofluorescence, but PCR is definitely more sensitive for adults and the elderly as a result of the lower virus production in these patients.

Since excellent reviews on the detection of respiratory viruses (176–180) are available, and more and more multiplex assays are applied for the detection of respiratory viruses, this section will not describe in detail the different mono-assays available for the detection of individual viruses but will focus on recent trends and emerging new viruses such as emerging influenza A viruses and MERS-CoV.

With the emergence of human infections due to an influenza A H3N2 variant in 2009 in North America, influenza A H1N1 worldwide in 2009, and more recently avian influenza A H7N9 in China, it is important to compare the commercially available point-of-care tests as well as in-house and commercially available molecular amplification tests. Chan et al. compared the analytical sensitivity for the detection of influenza A H7N9 and influenza A H3N2v of seven point-of-care influenza tests and the Resplex II plus v2.0 and the xTAG RVP Fast (181), whereas Hatchette et al. compared the performance of in-house PCR using the CDC primers against the performance of the RealStar Influenza S&T RT-PCR v3.0, the Quidel Molecular Influenza A+B assay, the Simplexa Flu A/B& RSV assay, the Seegene RV15 One Step ACE detection kit with agarose gel detection, the xTAG RVP Fast v1, the Seegene RV15 One Step ACE detection kit with capillary electrophoresis, and the xTAG RVP Classic (182) for the detection of influenza A H7N9. The main conclusion of both papers is that all (molecular) tests are not equal. According to Hatchette et al. (182), the analytical sensitivity of the commercially available assays is highly variable compared to that of the CDC-based in-house NAATs for the detection of influenza A H7N9. RealStar Influenza S&T v3 and the Quidel Molecular influenza A+B assay were only slightly less sensitive. A poor sensitivity was obtained with the xTAG RVP Classic, which is a concern since this test is FDA approved. Chan et al. (181) published similar findings. In addition, they reported that the analytical sensitivity of the point-of-care tests for H7N9 and H3N2v was comparable to that for the influenza A H1N1 pandemic virus and similar to the sensitivity of both PCRs.

Corman et al. described real-time RT-PCRs for the detection of MERS-CoV, of which one, targeting the *upE* gene, has been used as a first-line diagnostic assay (183). In view of growing knowledge, the WHO has continuously updated the guidelines for laboratory testing. This resulted in two additional RT-PCRs targeting the *RdRp* gene and the *N*-gene (184). Since then, other PCRs have been developed and validated (185, 186), including a commercial assay (187).

Molecular theranostics for infectious disease is an emerging concept in which molecular microbiology tools are needed to provide accurate and informative data, thus enabling better therapeutic interventions (188). In the field of viral respiratory infections such as an influenza virus infection, this would include—in addition to detection, typing, and subtyping of the virus—quantification of the virus present in the respiratory specimen (189) and the detection of antiviral markers (190). The availability of these combined data will allow a rapid decision on whether or not to start or continue antiviral treatment.

The quantitative detection of influenza showed that when respiratory secretion collection was done within 5 days after the onset of symptoms, the viral load was greater than 1×10^6 RNA copies/ml (191). Schibler et al. (192) validated a real-time PCR assay for the detection and quantification of rhinovirus and enterovirus RNA. They concluded that several difficulties limit the use of this assay for the quantitative detection of the absolute viral load in respiratory specimens: (i) the lack of an accurately quantified international reference RNA, (ii) the variability related to sampling procedures, and (iii) the rhinovirus genotype being amplified. However, despite these limitations, with an estimated variability of below 10% the assay proved to be applicable for the comparison of rhinovirus RNA amounts in clinical specimens. Also, assays have been developed for the molecular quantitative detection of RSV (193), RSV subtype A, influenza A, human metapneumovirus, and HCoV OC43 (11).

During 2007–2008, increased resistance to oseltamivir, which became prevalent worldwide, was reported among seasonal influenza A (H1N1) virus strains in many countries. This was found to be associated with a specific mutation causing a histidine-to-tyrosine substitution (H275Y) in neuraminidase. Nearly all sporadic cases of oseltamivir-resistant 2009 H1N1 virus infections identified to date have also been associated with this H275Y mutation (194–199).

Another trend is the direct amplification of nucleic acid without prior extraction such as the Simplexa Flu A/B and RSV Direct assay (Focus Diagnostics, USA) (200, 201). Compared with traditional methods, the overall positive/negative percent agreement was determined to be 96.6%/98.1% for influenza A, 98.4%/99.9% for influenza B, and 99.3%/98.8% for RSV. Compared to a nucleic acid extraction-dependent assay, the positive percent agreement was 90% for influenza A, 92% for influenza B and 98% for RSV (200). Woodberry et al. (201) applied the same assay to 498 NPSs and compared the results to those obtained with an in-house RT-PCR. Concordance rates were 96.6%, 97.6%, and 99.2% for influenza A, influenza B, and RSV, respectively.

MULTIPLEX NAATS

As diagnostic techniques improve, it becomes clear that multiple organisms may be found in adults, as has been described in youngsters. Pediatric studies have found polymicrobial infections in CAP: dual viral infection is present in 0 to 14%, dual bacterial infection in 0 to 14%, and mixed viral-bacterial infection in 3 to 30%. Polymicrobial CAP occurred in up to 6% of hospitalized adult, non-immunocompromised patients, at all ages, as well as in inpatients and outpatients; the most frequent combinations were those of bacteria with an atypical organism such as *M. pneumoniae* or *C. pneumoniae* and of two bacteria such as *S. pneumoniae* and a Gram-negative bacterial species. Patients with mixed pneumonia likely have more comorbidities and a more altered outcome due to treatment failure of monotherapy. In the approximately 10% of patients with mixed CAP, *S. pneumoniae* is the most prevalent microorganism.

Respiratory viruses and the so-called atypical bacteria are all responsible for RTIs that may produce clinically

similar manifestations. To reduce costs and hands-on time, multiplex NAATs for the simultaneous detection of two, three, or more different respiratory pathogens in one tube with a mixture of primers have been developed by some groups. For example, in a recent study that applied five separate multiplex PCRs for the detection of 20 respiratory pathogens, including *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*, in respiratory specimens from 475 hospitalized children with CAP, the overall positivity rate was found to be twice as high as when conventional tests were used (202). Currently, some assays detect up to 22 targets (203). However, comparison between mono- and multiplex assays has rarely been performed. Findings and conclusions result frequently in contradictory and conflicting data concerning the sensitivity and specificity of the multiplex NAATs compared to the mono-NAAT. There are indications that increasing the number of targets in one reaction results in loss of sensitivity (204, 205). This is not unexpected since the presence of several pairs of primers may increase the probability of mispairing, resulting in nonspecific amplification products and the formation of primer-dimers. Furthermore, enzymes, primers, and salt concentrations as well as temperature cyclings required for each target may be slightly different. The results of the proficiency panels described previously in this chapter seem to confirm that multiplex assays are somewhat less sensitive than monoplex assays, but until the number of organisms present in clinical specimens of diseased individuals is known, it is impossible to state whether the degree of sensitivity attained is clinically acceptable.

These techniques are therefore in competition with, and in many cases gradually replaced by, real-time multiplex reactions because of their greater user friendliness. The number of agents that can be detected simultaneously in one in-house real-time multiplex reaction tube is restricted by the number of available wavelengths in existing equipment (at least three at present); e.g., Lightcycler 2.0 uses three dyes and the LightCycler 480 uses four. But several reaction tubes can be run in parallel. The major drawback of this approach is the reduction of the amount of neuraminidase that can be introduced in each amplification and the longer hands-on time required to manipulate all the tubes. Once more, the thermocycling may be suboptimal for some agents involved in the assay. In all simultaneous assays a compromise will have to be made between the optimal temperature cycling requirements and the sensitivity of each component.

Real-time multiplex NAATs have been applied to two or three agents simultaneously. Welti (206) developed one of the first real-time multiplex PCRs. The PCR was done in two separate reactions: in the first reaction *M. pneumoniae* and *C. pneumoniae* were detected, and in the second reaction *L. pneumophila* was detected together with a commercial internal control (IPL Applied Biosystems). Loens et al. (207) developed a real-time multiplex NASBA for the diagnosis of *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila*. The multiplex NASBA was performed in one tube. Both groups compared the multiplex assays with the corresponding mono-assays. The sensitivity of the multiplex PCR was identical to that of the conventional PCR, but the multiplex NASBA assay was less sensitive than the corresponding real-time mono-NASBA procedure. A loss of sensitivity in a conventional multiplex PCR for these agents, as mentioned above, was also mentioned by Tong et al. (204). Templeton et al. (208) covered 15 agents by six multiplex real-time reactions. More research is needed to identify those reactions that can be combined with a minimal loss in sensitivity.

It has been proposed that industry-produced assays in kit form may enable standardization. A comparative analysis of the limits of detection of the ResPlex I assay (Table 5) and real-time single PCR assays demonstrated that the MX-PCR assay is 10-fold less sensitive in detecting *M. pneumoniae* (209). Furthermore, the ResPlex I assay was performed on 49 NPS specimens known to be positive by real-time PCR for three pathogens (*C. pneumoniae*, *M. pneumoniae*, and *S. pneumoniae*) and detected 50%, 59%, and 81% of the *C. pneumoniae*-, *M. pneumoniae*-, and *S. pneumoniae*-positive samples, respectively.

Another evolution combines conventional PCR with microarray detection. Davignon et al. (210) developed a resequencing oligonucleotide microarray for the identification of *S. pyogenes* and associated antibiotic resistance determinants. The identification was based on SpeB and provided an accurate detection of *S. pyogenes* and the *erm (B)*, *erm(TR)*, and *mef* genes involved in erythromycin resistance detection.

Li et al. (211) evaluated two commercial multiplex panels, NGEN and ResPlex II, detecting 6 and 12 respiratory viruses or virus groups, respectively, by microarray and Luminex liquid chip hybridization and identification, respectively. Sensitivities of these two assays were lower than those of the monoplex real-time RT-PCR assays, most noticeably for RSV and PIV-3. Although these might be improved by further primer/probe optimization, changes in primer/probe sequences could negatively influence other assays targeted in the multiplexed reaction. Although hands-on time of these tests is only approximately 60 minutes, turnaround times are still 6 hours for the ResPlex II and 9 hours for the NGEN.

However, since the calculation of the sensitivities of the industry-produced multiplex assays was mainly dependent on DNA copy number, further evaluation and standardization using an extended number of clinical specimens that may have a low load of the organism are needed.

The Argene Respiratory MWSr-gene concept allows the detection of numerous pathogens (influenza A/B, RSV/hMPV, rhino&EV, AdV/hBoV, Chla/Myco pneumo, HCoV/PIV, *Bordetella*, *B. parapertussis*) in the same run. In addition, the diagnostic strategy can be adapted to the season: searching for the most likely pathogens can be considered in the first approach, the remaining pathogens being searched for systematically in the second stage.

Other commercial assays aimed at the detection of a large panel of respiratory viruses include, for example, the Seeplex RV assay (Seegene Inc., Seoul, South Korea); the MultiCode-PLx RVP assay (EraGen Biosciences), which detects 17 different respiratory viruses; and the xTag RVP assay (Luminex Molecular Diagnostics, Toronto, Canada) for the detection of 19 respiratory viruses including the newly described coronaviruses. Both these assays use a fluidic microbead array and the Luminex xMap detection system. The xTAG RVP assay was the first assay that was cleared by the FDA for the detection of a number of respiratory viruses.

Since the calculation of the sensitivities of the commercial multiplex assays was mainly dependent on DNA copy number, further evaluation and standardization using an extended number of clinical specimens that may have a low load of the organism are needed.

Balada-Llasat et al. (212) evaluated the ResPlex II v2.0, multicode-Plx, and xTAG respiratory panels using 202

TABLE 5 Summary of commercially available PCR assays for detection of respiratory pathogens[a]

Kit	Manufacturer	Assay type	Detection procedure	Pathogens targeted
Alere I influenza system	Alere	Nicking endonuclease amplification		Influenza A and B
Mycoplasma pneumoniae BDProbeTec ET	BD	SDA	Fluorescence	*M. pneumoniae*
Bordetella pertussis BDProbeTec ET	BD	SDA	Fluorescence	*B. pertussis*
Legionella pneumophila BDProbeTec ET	BD	SDA	Fluorescence	*L. pneumophila*
Chlamydiaceae BDProbeTec ET	BD	SDA	Fluorescence	*Chlamydiaceae*
Microproof *Streptococcus pneumoniae* detection kit	Biotecon	PCR	Real-time	*S. pneumoniae*
iQcheck *Legionella*	BioRad	qPCR	Real-time	*Legionella* spp.
ExiStation SP real-time PCR kit	CBIOTECH	PCR	Real-time	*S. pneumoniae*
ASR RSV	Cepheid	PCR	Real-time	RSV
ASR MPN	Cepheid	PCR	Real-time	*M. pneumoniae*
Xpert Flu A	Cepheid	PCR	Real-time	Influenza A H1N1
Xpert Flu B	Cepheid	PCR	Real-time	Influenza B
R-DiaBor	Diagenode	PCR	Real-time	*B. pertussis*, *B. parapertussis*
R-DiaFlu	Diagenode	PCR	Real-time	Influenza A and B
R-DiaLeg	Diagenode	PCR	Real-time	*Legionella* spp., *L. pneumophila*
R-DiaMPV	Diagenode	PCR	Real-time	hMPV
R-DiaPara13	Diagenode	PCR	Real-time	PIV 1 and 3
R-DiaPara24	Diagenode	PCR	Real-time	PIV 2 and 4
R-DiaRhino	Diagenode	PCR	Real-time	Rhinovirus
R-DiaRSV	Diagenode	PCR	Real-time	RSV
O-DiaADV	Diagenode	PCR	Real-time	HAdV

[a]Abbreviations: HAdV, human adenovirus; HBoV, human bocavirus; HCoV, human coronavirus; hMPV, human metapneumovirus; ICT, immunochromatographic test; LAMP, loop-mediated isothermal amplification method; MERS, Middle East respiratory syndrome; MX-PCR, multiplex PCR; PIV, parainfluenzavirus; qPCR, quantitative PCR; RSV, respiratory syncytial virus; SARS, severe acute respiratory syndrome; SDA, strand displacement analysis. For further details on the evaluation and/or validation of the most important commercial tests, see text above. Boldface type indicates FDA-approved tests.

specimens from adult patients with an RTI. Viral culture and xTag were used as standards to calculate the sensitivities and specificities. Overall, the multiplex assays detected more viruses than culture detected. As compared to culture, the xTAG RVP had a sensitivity and specificity of 100% and 91%, compared to MultiCode-PLx with 89% and 87% and Resplex II with 89% and 94%, respectively. Each assay showed differences in sensitivities for individual viruses.

In a comparison of mono real-time PCRs with the Seeplex RV detection kit and the RespiFinder DC TwoStep kit (PathoFinder, Maastricht, The Netherlands), using a panel of 168 positive and negative culture samples (213), 77% of the samples were positive as detected by at least one method. Forty-one percent of the samples were positive by cell culture, 69% by mono-PCR, 76% by the RespiFinder kit, and 60% by the Seeplex RV kit. Furthermore, the RespFinder test yielded results in one attempt for all samples, while 7.2% of samples had to be repeated by the Seeplex RV kit due to inconclusive results.

Another important study compared the Resplex II Panel v2.0, the Seeplex RV15, the xTAG RVP, and xTAG RVP Fast with direct fluorescent antibody staining and viral isolation on 750 NPSs from children. Of 750 specimens, 288 were positive by direct fluorescent antibody or viral isolation, while an additional 214 were positive by multiplex PCR, for a total positivity rate of 66.9%. Compared with a composite reference standard, the interassay accuracy of the multiplex PCRs varied, but all were superior to conventional diagnostic methods. The authors

(169) found a sensitivity of ≥96.9% for all targets except entero/rhinovirus (71.7%). Resplex II v2.0 had good sensitivity for influenza A and B (≥96.9%) but lower sensitivity for the other viruses (82.0 to 84.0%). Resplex II v2.0 sensitivity fell further for adenovirus and bocavirus. The xTAG RVP showed a high sensitivity for influenza A and B and metapneumovirus (≥98.4%) but lower sensitivities for parainfluenza virus, adenovirus, and RSV (85.4 to 88.2%) and the lowest sensitivity for coronaviruses (48.1%). The RVP Fast had good sensitivities for most viruses but demonstrated a significantly reduced sensitivity in the detection of adenovirus, coronaviruses, influenza B, and parainfluenza viruses (52.4 to 5.8%). The specificity was excellent for all assays.

Another test approved by the FDA for the detection of a number of respiratory viruses is the BioFire Respiratory panel. The BioFire is a small desktop closed single-piece flow real-time PCR system. It includes automation of nucleic acid extraction, an initial RT- and multiplex PCR, followed by single-plex second-stage PCR reactions for the detection of 15 viral agents: adenovirus; coronavirus HKU1; coronavirus NL63; human metapneumovirus; rhinovirus/enterovirus; influenza A; influenza A H1; influenza AH1 2009; influenza A H3; influenza B; parainfluenza 1, 2, 3, 4; and RSV (214). The test requires 5 minutes of hands-on time and 65 minutes of instrumentation time. The implementation of this first version in a core laboratory was described by Xu et al. (215). As in other studies (216), the implementation of the assay significantly decreased the time required to report results. Drawbacks reported were the relatively low sensitivity for adenovirus (147, 216–219) and the inability to separate rhinovirus and enterovirus. In May 2012, the FDA expanded the uses for the BioFire respiratory panel with the addition of *B. pertussis*, *M. pneumoniae*, and *C. pneumoniae*. The expanded panel now detects a total of 17 viruses and 3 bacteria. In 2013, a new version of the BioFire (version 1.7) was released with improved sensitivity for adenoviruses. Doern et al. (220) evaluated this new version and confirmed the improved sensitivity for adenovirus: from 39 clinically relevant serotypes, 8 were not detected by the previous version, and only 1 was not detected by version 1.7.

Popowitch et al. (221) compared the four FDA-cleared assays: Biofire RP, Genmark eSensor RVP, Luminex xTAG RVPv1, and Luminex RVP Fast Multiplex. The overall sensitivities and specificities for each panel were as follows: BioFire RP, 84.5% and 100%; eSensor RVP, 98.3% and 99.2%; xTAG RVPv1, 92.7% and 99.8%; and xTAG RVP Fast, 84.4% and 99.9%. Fluctuations in sensitivity were virus dependent. The greatest discrepancies were noted for adenovirus and influenza B virus detection. Ruggiero et al. (222) compared virus culture with the BioFire RP and the Genmark eSensor RVP on LRT specimens. The overall agreement between both MX-assays was 89.5%. The overall sensitivities of viral culture, the BioFire, and the eSensor RVP were 89.5%, 100%, and 100%, respectively, with specificities varying between 82.6 and 90.5%. A recent study applied the BioFire and uniplex quantitative PCR to archived sputa, dunked sputa, and nose and throat swabs (11). A respiratory virus was detected in 31% of 965 illnesses using uniplex quantitative RT-PCR. For 105 subjects, sputum was the only positive sample, including 35% of influenza cases. A total diagnostic yield of 197/965 was obtained when uniplex RT-PCR was applied to nose and throat swabs alone, versus 302/965 when sputum results were included as well. Biofire also found 99/108 sputa to be positive. The results of RQ-PCR revealed higher mean viral loads in dunked sputum compared to nose and throat samples for influenza A, RSV, and human metapneumovirus.

Considerable investment and research efforts have been made toward the development of rapid new diagnostics for influenza A and B viruses. The Xpert Flu assay (Cepheid, California) has emerged as one of the most promising and is FDA cleared. In a review, Salez et al. summarize the current knowledge of the Xpert Flu test, discuss its potential value as a point-of-care test, and outline the potential leads for future development (223).

All these studies have shown that multiplex increases the sensitivity of detection of respiratory viruses while maintaining excellent specificity. However, it will be important to develop more effective clinical and laboratory algorithms for their timely and optimal use and to study their impact on patient care in different populations in different settings.

LATEST TECHNOLOGICAL DEVELOPMENTS

Newer technologies such as microfluidics and nanotechnology offer the potential for even more rapid detection of important pathogens, allowing even near-patient testing. Since these technologies do not require viable organisms, and thus avoid any adverse effect of longer specimen transport, they can be successfully applied to both the in- and outpatient settings. Several companies currently possess the technical expertise and research infrastructure to bring a useful diagnostic testing approach to the clinical trial stage soon. More and more microfluidic devices are being developed for the rapid identification of pathogenic organisms. For example, de la Rosa et al. (224) describe a miniaturized microfluidic device that facilitates electromanipulation of *B. pertussis*. The device provides sample preparatory capability by exploiting positive dielectrophoresis in conjunction with pulsed voltage for manipulation and disruption of *B. pertussis* cells without damaging the nucleic acid. This technique could be an important step in sample preparation on-chip involving respiratory pathogens. Another example, described by Easley et al. (225), is an integrated microfluidic device capable of accepting whole-blood or nasal aspirate as starting materials. The device carries out on-chip DNA purification and PCR amplification, followed by separation and detection in a manner that allows for microliter samples to be screened for infectious pathogens with sample-in–answer-out results in <30 minutes. It was successfully used for the detection of *B. pertussis* in 1 μl of nasal aspirate from a patient suspected of having whooping cough.

Cao et al. (226) developed a single-use microfluidic chip that integrates solid-phase extraction and RT-PCR to amplify influenza A RNA in less than 3 hours. Based on the analysis of 146 specimens, the microfluidic test was found to be more sensitive than two rapid immunoassays (Xpect Flu and Binax Now) and comparable to direct fluorescent antibody.

The group of Campuzano et al. (227–229) presented a successful proof-of-concept for the detection of *S. pneumoniae* by disposable amperometric magneto-sensor. The assay was validated both on strains and on clinical samples with sensitivity and specificity around 90%.

Molsa et al. (230) evaluated a field-compatible, portable PCR instrument (the RAZOR EX-thermocycler) for the rapid near-patient detection of influenza A viruses in clinical specimens. Results were achieved within 90 minutes, including 45 minutes for sample preparation, and they were in agreement with results obtained by standard real-time PCR under laboratory conditions.

The Alere I Influenza system (Alere Scarborough, Scarborough, ME) assay incorporates a nicking endonuclease amplification reaction technique for the detection and differentiation of FluA and FluB in NPS specimens. The system requires only 2 minutes hands-on time to process and set up one sample, with results becoming available within 15 minutes. Nie et al. (231) evaluated the performance of this test against the Filmarray. Sensitivities of 87.2%, 92.5%, 25%, and 97.4% for influenza A H1N1, influenza A H3N2, untypeable influenza, and FluB, respectively, were obtained. The specificities were 100% for both influenza A and B. According to the authors, due to the integrated, rapid (less than 15 minutes), and simple characteristics of the Alere I Influenza assay, there is a potential for point-of-care testing.

The SAMBA Flu duplex test was developed to provide a fast (2 hours, 15 minutes), easy-to-use solution for the detection of influenza A and B (232, 233). This duplex test couples isothermal amplification with visual detection on a dipstick in a closed semiautomated system. Compared to quantitative in-house PCR, the sensitivity and specificity of the SAMBA flu test were 100% and 97.9% for influenza A and 100% and 100% for influenza B.

Slinger et al. (234) successfully performed a proof-of-concept study to determine if *B. pertussis*, *B. parapertussis*, and RSV could be detected in clinical specimens using nanoliter real-time PCR. Over 3,000 nanoliter PCR reactions can be performed on a single plate on the commercially available nanoliter-volume real-time PCR platform from the OpenArray Real-time PCR System (Life Technologies, USA), making this platform potentially useful for the detection of multiple targets simultaneously.

Dunne et al. (235) postulated that by the year 2025 sophisticated samplers will be available that painlessly obtain the necessary material, followed by automated analyzers to simultaneously process DNA, RNA, proteins, glycopeptides, and exopolysacharides to detect any of a possible 168 pathogenic microbes as well as toxins and resistance genotypes—all completed and yielding a diagnosis within 15 minutes.

CONCLUDING REMARKS

With the use of new tools such as NAATs, a greater understanding of the etiology and epidemiology of RTIs and other bacterial infections is possible. The combined use of single-target assays or of multiplex assays has increased the diagnostic yield in respiratory infections by 30 to 50%. When this is combined with traditional bacteriologic techniques to diagnose *S. pneumoniae* infections, more than 50%, and in some studies of CAP up to 70%, of etiologic agents can be detected.

The wider application of multiplex reactions in recent years also resulted in the detection of numerous simultaneous viral infections with widely varying incidences: from 3 to 23% and even >50% in some studies. The differences in incidence may result from the variety of diagnostic panels applied. There were no preferential combinations of the viruses. Only a few studies found combined infections to be associated with a more severe clinical status. The clinical significance of combined infections remains to be further clarified.

As more epidemiological information on the role of a panel of respiratory viral pathogens becomes available, it is clear that screening for these viruses in specific patient populations such as transplant patients, immunocompromised hosts, very young children, and the elderly is desirable, and preventive and therapeutic recommendations may take this information into account.

However, a number of subjects remain to be investigated. At present, the impact of NAAT detection to understand the etiology of RTIs is limited to a few pathogens, but with new tools, a greater understanding of the etiology and epidemiology of RTIs and other bacterial infections is possible. Since there is little scientific information on how to diagnose the etiology of CAP in a cost-effective manner in daily practice, further studies are needed. Despite the probability that improved patient outcome and reduced cost of antimicrobial agents, reduced use of less sensitive and specific tests, and reduced length of hospital stay will outweigh the increased laboratory costs incurred through the use of molecular testing, such savings are difficult to document. However, the delivery of rapid, sensitive, and specific results makes the implementation of complete respiratory screens beneficial even without a full cost-benefit analysis.

NAATs are at present more expensive than conventional approaches, with the most expensive being the fluorogenic-based real-time detection systems. However, improvements in standardization and automation for sample preparation and technical advances in thermocyclers that allow the performance of multiple runs of PCR simultaneously or in a very short time will lead to increased use of amplification methods and cost reductions to rates competitive with conventional methods.

Whether a comprehensive approach is patient friendly, allows streamlining of management, is cost effective, and reduces the antibiotic pressure in the hospital and the community remains to be further studied.

Several studies tended to show cost efficiency of rapid diagnosis of ARI resulting from reduced antibiotic use and complementary laboratory investigations but most significantly from shorter hospitalization and reduced isolation periods of patients.

During epidemics it may be important to rule out a particular infection. A considerable saving in diagnostic procedures in ARI is made possible by the abolishment of tissue cultures and serologic tests. A closer collaboration between clinicians and the laboratory has a high priority.

The implementation of quantitative tests could shed further light on the relation between bacterial load and the seriousness of the disease (236), produce useful prognostic information, and help in the differentiation between colonization and infection. More information could be gathered on the length of the postinfection carrier state as well as on the importance of subclinical infections and how prone these are for spreading infection.

Several other agents responsible for respiratory infections should be considered separately because of the specific clinical picture for which they are responsible: *Chlamydia psittaci*, *B. parapertussis*, *Coxiella burnetii*, and *Pneumocystis jirovecci*.

The importance of LRTI viruses in chronic respiratory diseases such as chronic obstructive pulmonary disease and cystic fibrosis should also be better evaluated.

The need to detect an ever expanding number of infectious agents will exceed the possibility of mixed real-time NAATs. The task will be taken over by the next generation of diagnostics, the array technology that opens a wide access to the infectious agents (237–239).

The rapid molecular characterization of the previously unknown SARS-CoV within a few weeks after the appearance of the disease and the discovery of bocavirus and recently MERS-CoV illustrate the potency of NAATs for broadening the knowledge on "hidden" viruses remaining to be discovered.

In the very near future, NAATs will probably not be done at the point of care, but this must remain an objective for further development of the technology.

K.L. is supported through The Belgian National Reference Center for Respiratory Pathogens, which is partially supported by the Belgian Ministry of Social affairs through a fund within the Health Insurance System.

26

INTRODUCTION

Bloodstream Infections

Bloodstream infections (BSIs) are severe diseases associated with a high morbidity and mortality, which increases with the delay until administration of the first appropriate antibiotic (1–8). For this reason, empiric treatments made of broad-range anti-infectious compounds or made of a combination of antimicrobials are started immediately after the sampling of blood bottles. BSIs can be caused by various microorganisms. In the absence of microbiological documentation, physicians suspect a BSI on the basis of clinical symptoms, which trigger the start of empirical treatments. The clinical presentations are multiple and include fever or hypothermia, increases in heart rate, change in inflammatory variable (C-reactive protein, procalcitonin, and white blood cell count increase), and organ failure (2, 9). These symptoms are generally nonspecific and only suggest bloodstream dissemination. Empirical treatments are made of broad-spectrum antibiotics on the basis of the clinical and epidemiological data, but this does not exclude any risk of inappropriate initial treatment.

Similar to delayed introduction of the first antibiotic treatment, an inadequate treatment is associated with a significant increase of mortality (10, 11). In a recent study there was a nearly 3-fold increase in the risk of mortality when the antimicrobial treatment was inappropriate (12). *Pseudomonas aeruginosa* or *Acinetobacter baumannii*, which are associated with frequent multidrug-resistant profiles, are often the microorganisms for which empirical antibiotic coverage is inappropriate. *Enterobacteriaceae* producing extended-spectrum beta-lactamase (ESBL), such as *Escherichia coli*, or producing inducible cephalosporinase, such as *Enterobacter cloacae*, are also commonly associated with an inadequate empirical treatment (13). The mortality rate of patients suffering from a methicillin-resistant *Staphylococcus aureus* (MRSA)-associated BSI was significantly higher among patients receiving an inappropriate empirical antibiotic treatment (168/342, 49.1%) than among patients receiving an appropriate empirical antibiotic treatment (56/168, 33.3%) (14, 15). Inadequate treatments can also occur for organisms such as *Enterococcus faecalis* that are intrinsically resistant to some commonly administered first-line antibiotics such as ceftriaxone (11). Broad-spectrum molecules also have a detrimental impact on beneficial bacteria that constitute the protective flora and contribute to the emergence of multidrug-resistant strains. Moreover, some of these antimicrobial molecules can also have a toxic effect for the patient (10, 11, 16). The rapid identification of the causative agent of the BSI thus allows the adjustment of the anti-infectious therapy or the reduction of the spectrum (de-escalation) with significant clinical benefits.

BSIs are characterized by a low quantity of circulating microbes. On the basis of plating methods, the bacterial load has been estimated to be around 1 to 10 CFU/ml of blood in adults (17–21). This method is efficient for determining the number of bacteria that survive the plating protocol; hence, the true number of circulating bacteria is likely underestimated. DNA copies present in the circulation should be even higher because they also include DNA released by dead bacteria or clumping bacteria as well as DNA from bacteria engulfed in phagocytes. On the basis of quantitative PCR, Bacconi et al. recently estimated that during bacteremia, the blood contains 10^3 to 10^4 bacterial cells/ml (22), which is higher than the analytic sensitivity of most of the available molecular methods.

Hence, the ideal diagnostic method for BSI should (i) be able to identify a broad range of pathogens, (ii) have an analytic sensitivity lower than 10 to 100 CFU/ml, (iii) be rapid, (iv) be quantitative to give an idea of the severity of the infection, (v) give an antibiotic susceptibility profile, (vi) be associated with a short hands-on time, and (vii) be automated (23). These are all potential characteristics that molecular diagnosis methods may fulfill, at least to some extent.

Molecular methods for the diagnosis of BSI refer to nucleic acid-based methods but also to non-nucleic acid-based methods. PCR-based methods that constitute the nucleic acid amplification-based methods can be applied both on positive blood culture and on whole blood. Indeed, the PCR step increases the sensitivity of the detection, which makes it suitable for paucibacterial samples such as blood (Fig. 1) (24). Non-amplification-based methods such as fluorescent *in situ* hybridization (FISH) or microarray have limited sensitivity. Hence, they are

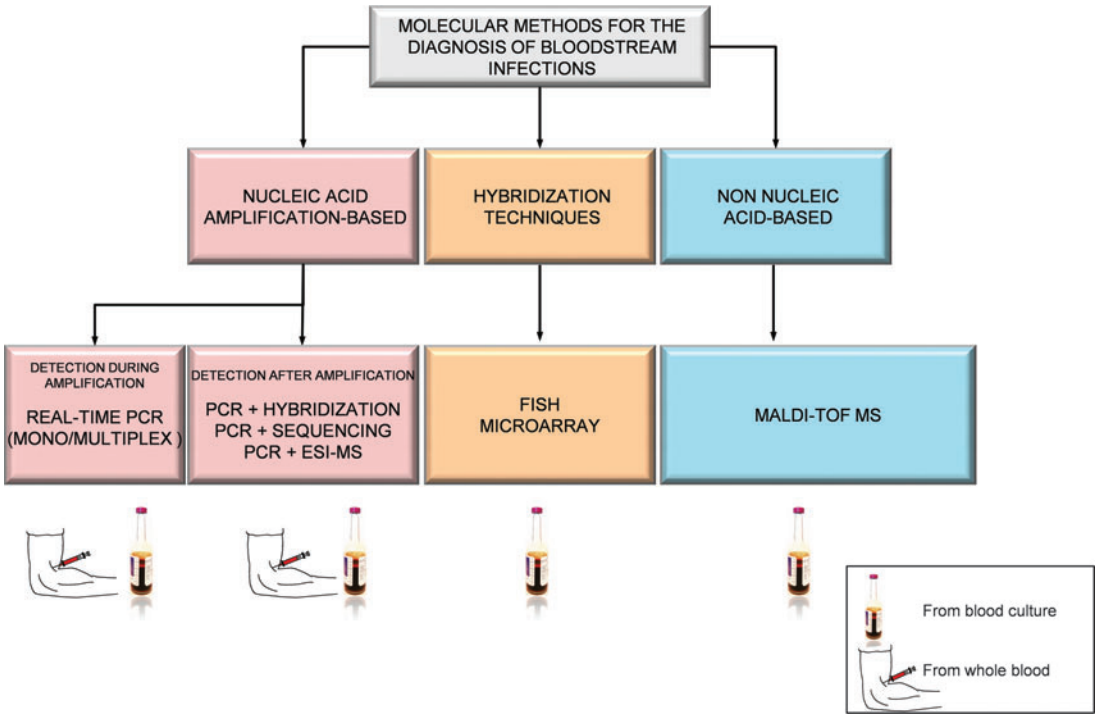

FIGURE 1 Different molecular technologies used for the detection and identification of microbes during bloodstream infections. Molecular methods for the diagnosis of BSI include nucleic acid-based methods and non-nucleic acid-based methods. Nucleic acid amplification-based techniques can be applied on positive blood cultures or used directly on blood, whereas non-nucleic acid amplification-based techniques such as FISH and microarray or non-nucleic acid-based methods such as MALDI-TOF MS can be used only on positive blood culture. Adapted from reference 150.

restricted to positive blood culture. For the same reason, matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS), a non-nucleic acid-based method that analyzes microbial protein mass spectrum, is suitable for diagnosis from positive blood culture.

In this chapter we present the molecular methods available for the microbial diagnosis of BSI. We report and discuss the performance as well as the advantages and disadvantages of these methods.

Blood Culture-Based Diagnosis of BSIs

Blood culture is currently the "gold standard" to establish the etiology of BSI. Blood bottles contain specific liquid broth for the growth of bacteria or fungi present in blood. Distinct media are available to grow different microbes (24). Blood culture-based diagnosis has been improved by the use automated incubators that can detect bacterial or fungal growth in blood bottles thanks to associated physicochemical variations. When the automated system detects the growth, visualization of the microorganism is possible using standard Gram or fluorescent staining (Fig. 2). The Gram staining can give a first presumptive etiology of the BSI. However, only the final identification of the pathogen and its antibiotic susceptibility testing can ensure the adequacy of the ongoing antibiotic treatment. Thus, when a blood culture is detected as positive, diagnostic laboratories have to identify the microbe rapidly and with the highest sensitivity and specificity. However, the time to positivity of the blood culture bottles can vary from a few hours to 24 to 48 h for fast-growing bacteria, and even more for slow-growing bacteria or fungi. In addition, it is generally admitted that more than 50% of BSIs occur with negative blood culture (25, 26). When the blood culture becomes positive, using conventional methods, one or more days can be necessary to identify the pathogen and to determine the exact etiology of the BSI (Fig. 2). These methods include phenotypic characterization using biochemical and enzymatic tests. Most of these phenotypic characterizations require a subculture in liquid media or a subculture on solid media to obtain isolated colonies. Finally, BSIs involving multiple organisms may also further increase the time to identification of most detection methods.

Inside positive blood culture, bacteria concentration reaches 1.10^6 to 2.10^8 for Gram-negative cocci and 2.10^7 to 1.10^9 for Gram-negative bacilli (27, 28). These concentrations allow the use of amplification-based methods such as PCR and real-time PCR as well as non-amplification-based methods such hybridization or MALDI-TOF MS (Fig. 1).

Blood is a challenging sample for the detection and identification of pathogens since it contains a low number of microorganisms in comparison to human components (DNA, proteins, and cells) (29). These compounds can interfere with detection or identification by leading to false-positive or false-negative (inhibition) results. All these components are transferred into the blood culture at the time of sampling the blood. MALDI-TOF MS is a non-nucleic acid-based molecular method that has considerably accelerated and simplified the identification of pathogens from positive culture. It is based on the analysis of the mass spectrum generated by bacterial proteins, mainly

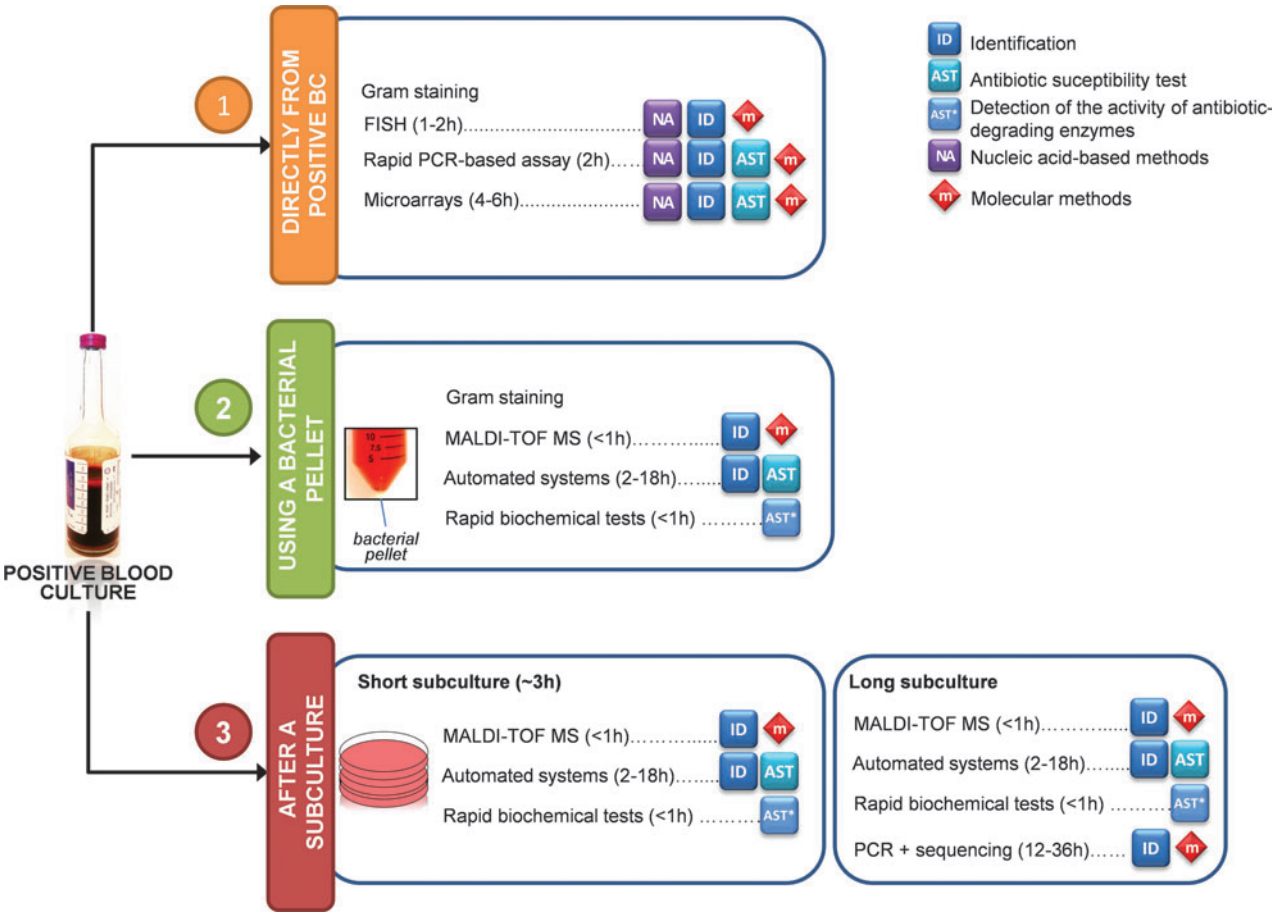

FIGURE 2 Conventional and molecular methods for the identification of microorganisms from positive blood culture. When a blood culture is detected as positive, several strategies are available to identify the incriminated microorganism after the initial Gram staining, as follows. (1) Identification directly from the positive blood culture using nucleic acid-based methods. (2) Identification after the microbe's enrichment, namely a purified bacterial pellet suitable for MALDI-TOF MS analysis and some automated identification/antibiotic susceptibility testing approaches such as Vitek2 and Phoenix and rapid biochemical tests HMRZ, based on the chromogenic cephalosporin HMRZ-86 {(7R)-7-[2-(aminothiazol-4-yl)-(z)-2-(1-carboxy-1-ethylethoxyimino) acetamido]-3-(2,4-dinitrostyryl)-3-cephem-4-carboxylic acid trifluoroacetate, E-isomer}, and ESBLNDP (ESBL Nordmann-Poirel-Dortet). (3) Identification after a subculture. To date, the automated system Vitek2 has been validated on short subcultures as well as the rapid biochemical tests HMRZ and CARNP (carbapenemase test Nordmann-Poirel); long subcultures are suitable for any type of analysis including phenotypic characterization; automated systems such as Vitek2, Phoenix, and MicroScan WalkAway; as well as PCR followed by sequencing. Adapted from reference 24.

housekeeping proteins (Fig. 3). This technique is now applicable on positive blood culture but still requires a sample preparation step to discard blood and other non-bacterial components.

Microbial Diagnosis of BSI Directly from Blood

The diagnosis of BSI directly from whole blood has been a major concern for medical diagnostic microbiologists. Indeed, blood cultures appear to have some intrinsic limitations: (i) approximately 50% of BSIs are blood culture negative (25, 26); (ii) in the case of positive blood culture, the time to positivity can vary from hours to days; (iii) blood culture requires a large quantity of blood, which is difficult to obtain from some patients such as pediatric patients; (iv) an antibiotic treatment is often initiated prior to blood culture. Many technical improvements have been made to increase the performance of detection methods from whole blood, but some limitations remained. Nucleic acid-based methods were limited by the need for a large volume of blood due to the low number of CFU per milliliter associated with the presence of human DNA in excess, mainly due to white blood cell DNA (30). In addition, these methods are also sensitive to contaminants—bacterial or fungal DNA—or to the presence of DNA from dead organisms that could lead to false-positive results (31–34). Quantitative analyses are a more powerful way to interpret such positive results.

To improve the sensitivity of nucleic acid-based methods, the excess of human DNA should be removed. This could be achieved by removing white blood cells before nucleic acid extraction or by selective removal of human DNA after extraction. Nucleic acid-based methods, in particular PCR, are sensitive to various inhibition mechanisms. Some of these mechanisms have been characterized, but many of them remain unknown (29, 35–37). Inhibitory compounds can be contained in the sample or they can be the result of the sample preparation process. The blood contains some well-known PCR inhibitors such as hemoglobin, bile salts, and heme found in erythrocytes (30, 38, 39), as well as in lactoferrin found in leukocytes

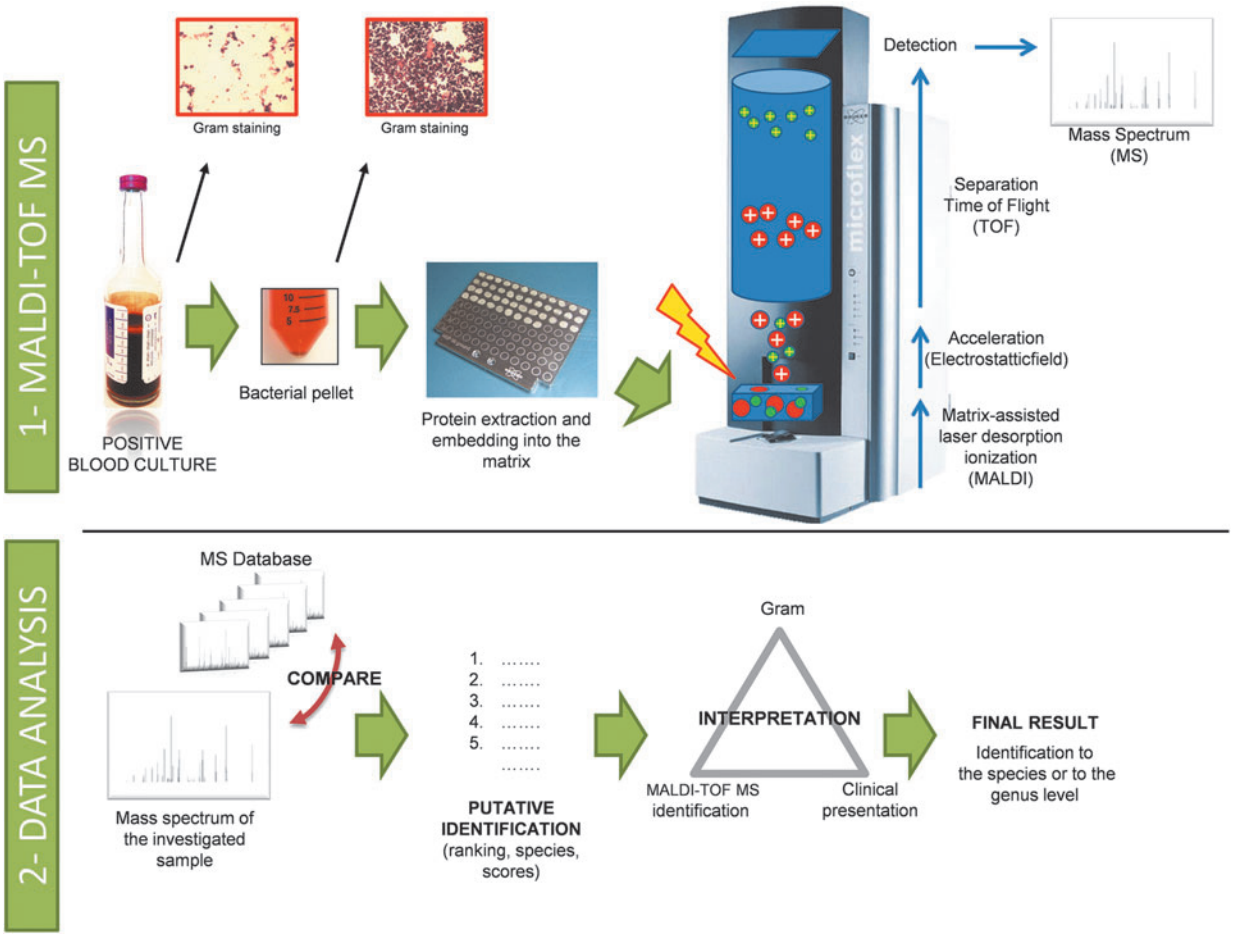

FIGURE 3 Microbial identification from positive blood culture using MALDI-TOF MS. The sample that is deposited on the MALDI-TOF multiwell plate can be a bacterial pellet obtained by centrifugation and erythrocyte lysis. Alternatively, the sample can be bacteria obtained after a subculture. Proteins are then extracted and embedded in a matrix directly on the multiwell conductive metal plate and submitted to the MALDI-TOF MS, which separates the proteins according to their molecular weights and their charges. This generates a mass spectrum (MS), which in a second stage is compared to a database of spectra. This analysis provides the identification of the microorganism with a confidence score, which allows acceptance at the species or at the genus level. The identification is interpreted according to the Gram staining and to the clinical presentation. Adapted with permission from reference 110.

(30). The inhibition of PCR-based methods by these compounds is due to the release of iron (from heme), which is known to interfere with DNA synthesis (40). Immunoglobulin present in the bloodstream, in particular IgG, can inhibit PCR by binding single-stranded DNA (41). Red blood cells present in blood bottles can also impair non-nucleic acid-based methods such as MALDI-TOF MS because they bring a large amount of proteins that would interfere with the quality of the protein mass spectrum. Several protocols are now available for their removal prior to MALDI-TOF MS analysis from positive blood bottles (24, 42, 43).

At present, each available molecular method is associated with a specific sample preparation. For the detection of a large number of organisms, the limited sensitivity of broad-range PCR targeting housekeeping genes has been overcome by the use of multiplex PCR or multiple real-time PCR. A recent technology, PCR/ESI-MS (PCR and electrospray ionization mass spectrometry), is a method that associates PCR and ESI-MS. The PCR allows the specific detection of small amounts of bacterial, fungal, or viral DNA from whole blood. This technology is associated with the analysis of PCR amplicons by ESI-MS, which determines the base composition rather than the nucleotide sequence. This has been shown to be sufficient for organism identification at the species level. Methods have been developed to remove the excess of nonbacterial DNA and/or inhibitors (30, 35, 37, 44). Most of these methods are time-consuming, require intensive labor, and are specific for one type of sample, one type of analysis, or one type of device.

MOLECULAR METHODS FOR THE IDENTIFICATION OF PATHOGENS FROM POSITIVE BLOOD CULTURES

Blood culture is currently the reference method for the identification of pathogens involved in BSIs because it is easy to perform and sensitive due to the large volume of blood that can be analyzed when multiple blood bottles are collected (24). When a blood culture is positive, conventional methods including phenotypic characterization

and rRNA gene sequencing have an extremely high specificity. However, these methods are time-consuming because they require an additional subculture and are challenged by a broad variety of molecular methods. FISH, the first molecular method to be developed, is based on the binding of specific probes on a pathogen's DNA. FISH is a rapid, sensitive, and specific method but is dependent on the choice of the probes to be tested. Microarrays allow the detection and identification of pathogens as well as resistance genes. PCR-based methods allow the rapid detection of a single organism (specific real-time PCR) or multiple organisms (broad-range PCR or multiplex PCR). These methods are highly sensitive to contaminating DNA or PCR inhibitors. MALDI-TOF MS, one of the latest commercialized technologies, is presented as a revolution for clinical microbiology laboratories (45). Indeed, MALDI-TOF MS can identify in less than 1 h most bacterial and fungal agents generally recovered from blood cultures.

Fluorescent *In Situ* Hybridization (FISH)

FISH is based on the specific binding of fluorescent peptide nucleic acid probes (PNAs) to the rRNA—16S rRNA for bacteria and 18S rRNA for fungi and other eukaryotes. Basically, slides are prepared from a positive blood culture, the fluorescent PNAs are applied, and unbound PNAs are removed by a washing step. Bound fluorescent PNA is generally observed by a fluorescent microscope because flow cytometry detection still needs further investigation and development (46). FISH requires a high number of living cells, which prevents its use directly on whole blood. Multiple probes that recognize microorganisms at the genus level or at the species level are available. All the solutions are based on multiple probes that detect and distinguish two or three organisms. The first kit of the PNA-FISH system (AdvanDx, Wolburn, MA) allowed the detection of *S. aureus* and coagulase-negative staphylococci (47–51). The second kit allows the detection of *E. faecalis* versus *Enterococcus faecium* and other *Enterococcus* spp. (52). *E. coli* and *P. aeruginosa* can be detected by using a PNA mix or a mix of three probes that also include *Klebsiella pneumoniae* (53–55). *Candida albicans*, *Candida glabrata*, *Candida parapsilosis*, and *Candida krusei* can also be detected (56–60).

The QuickFISH system is a more rapid version of the PNA-FISH system. The turnaround time is shortened by reducing the hybridization phases to 15 min and by removing the wash step. At present, the QuickFISH system provides kits that detect and distinguish *S. aureus*/coagulase-negative staphylococci, *E. faecalis*/*E. faecium*, and *E. coli*/*P. aeruginosa* (61–63). The diversity of microorganisms that are currently detected is still limited, but these bacterial species represent about 95% of the pathogens involved in BSIs. The choice of the probe to be tested will depend on the Gram result, the clinical presentation, and the local epidemiology. The sensitivity of the QuickFISH system is 99.5% for the detection of *S. aureus* and 98.8% for coagulase-
negative staphylococci, with a combined specificity of 89.5% (62). Martinez et al. reported 97.9% concordance with conventional detection methods for Gram-positive bacteria and 95.7% for Gram-negative bacteria (61). Yeast (*C. albicans*, *C. parapsilosis*, *Candida tropicalis*, *C. glabrata*, and *C. krusei*) can also be identified using probes targeting 26S rRNA sequences (60). Commercial methods give a result in 1.5 to 3 h with high sensitivity and specificity but cannot replace other detection methods because these probes do not detect many significant pathogens (Table 1) (52, 61, 64, 65).

Microarray

Microarrays are based on species-specific or genus-specific DNA probes immobilized on a chip on which the microorganism's DNA will specifically hybridize. The high density of the chips allows the use of sequences specific for different pathogens and probes for the detection of virulence factors and/or resistance genes. Species identification is determined by the pattern of hybridization and the intensity of the signal (66–69). The analytic sensitivity of microarrays ranges between 10 and 10^5 CFU/ml depending on the pathogen, which allows their use from positive blood culture but not directly from blood (67). The Verigene Gram-Positive Blood Culture system and the Verigene Gram-Negative Blood Culture system (Northbrook, IL) can detect Gram-positive or Gram-negative microorganisms, respectively, as well as associated resistance genes. The time to identification is approximately 2.5 h from positive blood culture bottles (Table 1). After being extracted from 350 μl of blood culture from a positive vial, the bacterial DNA is suspended in a specific buffer and hybridized on specific synthetic oligonucleotides followed by a second hybridization step involving gold particles. The signal is further amplified via a silver staining process which increases the sensitivity of the system. The reading is automated.

The Verigene Gram-Positive Blood Culture system can detect nine organisms at the species level (*S. aureus*, *Staphylococcus epidermidis*, *Staphylococcus lugdunensis*, *Streptococcus anginosus* group, *Streptococcus agalactiae*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *E. faecalis*, and *E. faecium*), four genera (*Staphylococcus* spp., *Streptococcus* spp., *Micrococcus* spp., and *Listeria* spp.), and three resistance genes (*mecA* [methicillin], *vanA* [vancomycin], and *vanB* [vancomycin]). Studies performed on both adult and pediatric patients reported 89.7 to 99% concordance for the detection from positive blood culture between the Verigene Gram-Positive Blood Culture system and the traditional method (61, 70–75). Misidentifications have been reported for *Streptococcus* spp. In particular, group mitis *Streptococcus* spp. have been misidentified as *S. pneumoniae*, and *Streptococcus oralis* has been misidentified as *S. anginosus* (74). Performance of the Verigene system is higher on monobacterial samples. Mixed culture can prevent the identification of one of the pathogens. Buchan et al. reported 98.6% sensitivity and 94.3% specificity for the detection of the *mecA* gene in 5,999 staphylococci cultures and 100% sensitivity and specificity for the detection of the *vanA* gene in 81 cultures containing *E. faecalis* and *E. faecium* (76). Samuel et al. reported 91% concordance for *mecA* and 100% for *vanA* detection compared to routine methods (74). In the case of mixed populations of staphylococci, the resistance gene cannot be associated with a specific pathogen (76).

The Verigene Gram-Negative system can detect five pathogens at the species level (*E. coli*, *K. pneumoniae*, *Klebsiella oxytoca*, *P. aeruginosa*, and *Serratia marcescens*) and four genera (*Acinetobacter* spp., *Citrobacter* spp., *Enterobacter* spp., and *Proteus* spp.). The Verigene Gram Negative BC assay displays 91 to 100% agreement for the detection of Gram-negative pathogens from both adult and pediatric patients (77–81). Among the false-negative results, mixed blood cultures have been incriminated, but some of these negative or noncalled results involved bacte-

ria covered by the chip (77). As for many molecular assays, it is not possible to distinguish *E. coli* and *Shigella* spp. (*Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*). This distinction should be achieved with enzymatic analysis. The Verigene Gram-Negative assay can detect six resistance genes: the extended-spectrum beta-lactamase CTX-M and the carbapenemases KPC, NDM, VIM, IMP, and OXA groups with 92.3 to 100% concordance with routine methods (77, 82). Other microarrays for the detection of resistance genes are currently being developed (83).

The performances of microarrays are extremely high for the detection of both pathogens and resistance cassettes when applied to positive blood cultures, but this is supported by a limited number of studies.

Nucleic Acid Amplification-Based Methods

PCR provides a rapid and specific technology for pathogen identification from positive blood culture (84). The specificity provided initially by the use of specific primers can be increased in the case of real-time PCR by the use of specific probes. The use of PCR on blood or on hemorrhagic samples was limited for a long time by the fact that PCR is sensitive to the presence of inhibitory compounds such as hemoglobin contained in erythrocytes (30, 38, 39), lactoferrin contained in leukocytes (30), or immunoglobulin (41). To avoid inhibition, recently developed methods use new or improved nucleic acid extraction and/or amplification techniques.

Multiplex-PCR increases the time to result because it interrogates several targets (pathogens or resistance genes) at the same time. In addition, it can increase both the specificity and the sensitivity of an analysis thanks to the use of multiple targets for the same organism (85, 86). Multiplexing is achieved through the use of several specific primer pairs in the same reaction. Different methods can be applied to identify the amplified sequence(s): (i) the use of specific probes labeled with distinct fluorochromes, (ii) the analysis of the probe or the amplicon melting curves (87–89), (iii) the amplicon size (electrophoreses), and (iv) the sequencing of the amplification product. The latest technology, PCR/ESI-MS, is based on the analysis of the amplicon by MS (Fig. 4). The latter technique will be discussed in depth in the paragraph on pathogen detection from blood.

Multiplex PCR

The FilmArray system (Idaho Technology, Salt Lake City, UT) is a solution that allows the identification of more than 25 pathogens and four antibiotic resistance genes from positive blood culture in 1 h (90). The FilmArray is a closed system that uses multiple-PCR and is expected to identify 90 to 95% of the pathogens involved in BSIs as well as the resistance genes *mecA*, *vanA* and *vanB*, and bla_{KPC}. A kit for the identification of potential bioterrorism agents (*Bacillus anthracis*, *Francisella tularensis*, and *Yersinia pestis*) is also available (91).

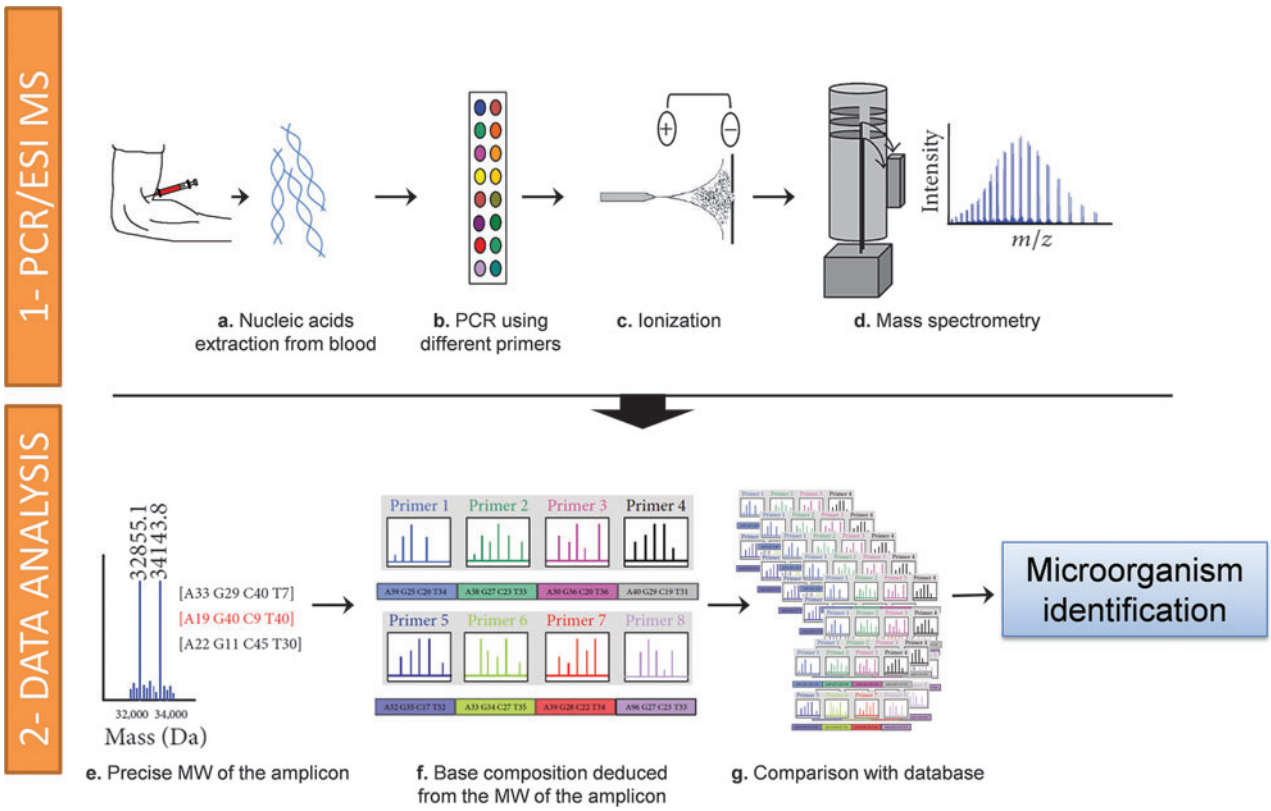

FIGURE 4 Schematic workflow of PCR/ESI-MS. (a) Nucleic acids are extracted from the sample, directly from whole blood, and (b) amplified by multiple PCR using multiple pairs of primers; each color represents a different primer. After amplification, the molecular mass of the amplicon(s) is precisely determined using ESI-MS (c, d, and e), from which (f) the base composition of the amplicon(s) is deduced. Finally, (g) information—base composition—obtained from one or more amplicon(s) is compared with a database, which provides the identification with a confidence score. Adapted from reference 123.

In a prospective study on 102 blood cultures, the FilmArray system displayed 91% sensitivity and 77% specificity when compared to conventional identification methods for the detection of pathogens present in the FilmArray panel only (90). The detection of resistance genes revealed 100% specificity and 100% sensitivity in this study. In another study, FilmArray displayed 98.5% sensitivity and 100% specificity for the identification of Gram-negative bacteria, 96.7% sensitivity and 93.7% specificity for Gram-positive bacteria, and 96% sensitivity and 98.9% specificity for the detection of the *mec*A gene (92). Another study, performed on 118 monobacterial cultures, reported 92% correct identification of the FilmArray system, but mixed cultures gave no results (79). The identification of *C. albicans* and *C. glabrata* reached 100% sensitivity and 99.5% specificity (92). This is consistent with other studies showing good performance of FilmArray for the identification *C. albicans* and *C. glabrata* (93). The FilmArray system can also be applied on other sterile samples such as cerebrospinal fluid (94).

Rapid PCR-Based Systems

The clinical and epidemiological impact of pathogens such as MRSA or rifampin-resistant *Mycobacterium tuberculosis* has contributed to the development of methods for the rapid detection of resistance. *S. aureus* is a significant agent of community-acquired and nosocomial infections (95). The mortality rate is increased in patients infected with MRSA in comparison to patients infected with MSSA (methicillin-sensitive *S. aureus*) (96–98). The increased percentage of MRSA in comparison to MSSA has highlighted the importance of rapid detection methods for MRSA (99–102). Several methods based on multiplex real-time PCR are available: the GeneXpert MRSA/SA BC Assay (Cepheid, Sunnyvale, CA) (103, 104), the StaphSR assay (BD GeneOhm, San Diego, CA) (105, 106), and the StaphPlex (Genaco Biomedical Products, Huntsville, AL) (107). The GeneXpert and StaphSR assays are rapid PCR-based systems developed for detecting *S. aureus* in only approximately 1.5 h. They require only limited hands-on time and skills. The application of the GeneXpert MRSA assay on positive blood culture was shown to have an impact on anti-infectious treatments by reducing the use of glycopeptides (108). Alternatively, the StaphPlex system can identify several staphylococci at the species level. The StaphPlex system is based on several PCRs (18 target genes) and microarray analysis for the identification of staphylococci at the species level and the detection of resistance genes and the Panton-Valentine leukocidin (PVL). The results are obtained within 5 h (107). Because these methods are largely aimed at detecting resistance genes, they will be discussed in the section dedicated to resistance detection.

Matrix-Assisted Laser Desorption Ionization-Time of Flight Mass Spectrometry (MALDI-TOF MS)

Principle of MALDI-TOF MS

MALDI-TOF MS is a method that allows the identification of a broad range of microbes at the species or genus level from positive culture. The method was first developed to be used on colonies before its application on blood culture. Microbe identification using MALDI-TOF MS is based on the analysis of the mass spectrum generated by the bacterial or fungal component, mainly housekeeping proteins (the ribosomal proteins which are basic are specifically extracted using acidic matrix). This spectrum is a unique fingerprint for each microorganism but displays features shared between genetically related bacteria (109). The comparison of the spectrum with a database of spectra obtained for characterized organisms allows microbe identification at the species or at the genus level depending on a score assigned by the identification software (110).

MALDI-TOF MS was first used for bacterial identification in 1975 (111). The routine use of mass spectrometry for the identification of bacteria in the diagnostic laboratory was proposed in 1996 when correct identification had been achieved directly from whole bacteria coming from single colonies (109, 112). Identification of bacteria using MALDI-TOF MS is divided into three steps: (i) ionization of the sample, (ii) separation of proteins in a flight tube, and (iii) generation of a mass spectrum by determining the mass of the proteins (Fig. 3). The sample preparation consists of mixing the cells from a bacterial colony with a crystallizing matrix that triggers the ionization of the sample achieved by a laser (MALDI). Protein accessibility can be facilitated by a quick formic acid extraction. Ionized proteins are accelerated by an electrostatic field and separated along a flight tube. The separation is due to the time of flight (TOF), a function of the mass and of the charge of the proteins. Protein detections will generate a mass spectrum unique for a defined bacterial strain corresponding to a mass-to-charge ratio (m/z) between 1,000 and 20,000 kDa. However, several peaks are shared between bacteria from the same genus or species and serve as biomarkers for bacterial identification. The identification is performed by comparison of the mass spectrum with a database of spectra obtained from characterized bacterial strains. The software that performed the spectral analysis and the comparison with the database assigns a score for the identification. Depending on the threshold recommended by the provider and the in-house algorithm, the identification can be rejected or accepted either at the species level or only at the genus level.

Application of MALDI-TOF MS on Positive Blood Culture Bottle

In clinical microbiology, MALDI-TOF MS was first used on pure bacterial colonies before its application on positive blood culture for the diagnosis of BSI (Fig. 3) (110). The initial analysis on a positive blood culture bottle is Gram staining. The Gram staining is especially recommended (i) to confirm that the detection is truly due to the presence of a microorganism, (ii) to give a presumptive etiology of the BSI, and (iii) to disclose mixed bacteremia. In positive blood cultures, the bacterial concentration ranges from 10^6 to 10^9 CFU/ml, which in theory is sufficient for MALDI-TOF MS identification. However, the presence of large amounts of nonbacterial material (erythrocytes, nutrient from the growth media) impairs the direct identification from the blood vial.

Application of MALDI-TOF MS After a Short Subculture

A short subculture (2 to 3 h) on agar plates can be performed from the positive blood vial to obtain a thin layer of bacteria (24). From this thin layer, the MALDI-TOF MS analysis can be performed (Fig. 2) (113, 114). Short subcultures are also adequate for antibiotic susceptibility testing using automated systems (113). However, this procedure is mainly suitable for fast-growing bacteria.

Application of MALDI-TOF MS Directly from the Blood Culture Vial via a Bacterial Pellet

The more rapid method is to perform the identification directly from the positive blood culture (Fig. 2 and 3). The goal is to get rid of nonbacterial components present in the bottles, such as red blood cells, and to concentrate the bacteria. Bacterial concentration can be achieved by centrifugation and erythrocyte lysis by ammonium chloride (43, 115). This generates a pellet that can be identified by MALDI-TOF MS (Fig. 3). This method allowed the identification of 78.7% of the samples obtained. Moreover, 99% of the MALDI-TOF MS identifications were correct at the species level (115). Alternative erythrocyte lysis techniques can be achieved with formic acid (116). Any methods applying mild detergent that would solubilize the erythrocyte membrane but not the microbe membrane lead to similar results (117–119). Alternatively, gel-based separator tubes have proven efficient in concentrating bacteria and removing red blood cells (120).

MALDI-TOF MS has a major impact on the time to result since it can be achieved directly from positive blood culture, without subculture (121). Sample processing and identification using MALDI-TOF MS takes approximately 1 hour, which makes it time-efficient for fast-growing bacteria as well (115, 116).

The accuracy of the MALDI-TOF MS identification is dependent on an extended and correct spectrum database. This database can be implemented with the spectrum obtained from clinical isolates. This is applicable for strains for which the MS identification failed and that were identified without any doubt with other methods such as gene sequencing or enzymatic assay. This is also applicable for rare pathogens that can be identified faster and more accurately using MALDI-TOF MS (122, 123). However, some closely related bacterial species such as the different *Streptococcus* species remain difficult to distinguish using MALDI-TOF MS. For instance, group mitis *Streptococcus* is often misidentified as *S. pneumoniae*. *S. pneumoniae* identification should thus be confirmed by phenotypic tests such as optochine susceptibility (75, 120, 124). Similarly, the distinction of *E. coli* and *Shigella* spp. is impossible using routine MALDI-TOF MS procedures and requires additional phenotypic confirmation (125, 126). Recently, a new approach based on the analysis of biomarker peaks was proposed to differentiate these two closely related pathogens (127).

Efficiency and Reproducibility of MALDI-TOF MS Identification

Even if a mass spectrum can be obtained from a single colony, this biomass represents a significant amount of bacteria. MALDI-TOF MS identification is therefore not applicable directly from blood but is dependent on microorganisms' proliferation in blood culture and on an additional concentration step from the positive blood culture (24). The requirement of a culture limits the use of MALDI-TOF for the detection of noncultivable bacteria.

Proteins used as biomarkers for MALDI-TOF MS identification of bacteria are mainly involved in housekeeping functions (128). Ribosomal proteins contribute to approximately half of the peaks present in the mass spectrum (129, 130). This makes it reproducible and robust because several peaks would be conserved in genetically related bacteria. Nevertheless, experimental conditions can impact the presence and the relative abundance of detected peaks. This is true for both routine identification and for the implementation of the peaks' pattern into the in-house database. The culture media, the growth conditions, and the age of the colony may impact the spectrum (131). The presence of agar residue or blood proteins in the sample may impact the spectrum quality (110). The quality of the matrix may also influence the spectrum (128).

Importance of Gram Staining and the Subculture

Gram staining on positive blood culture is still mandatory (i) to confirm the presence of a microbe in the bottles, (ii) to validate the identification of the MALDI-TOF MS, which should be congruent with the characteristic provided by the Gram staining (132), and (iii) to disclose polymicrobial infections, because MALDI-TOF MS poorly identifies mixed bacterial samples. Mixed infection may also be detected upon subculture, which remains essential for antimicrobial susceptibility testing (see below).

MOLECULAR METHODS FOR THE DETECTION OF PATHOGENS DIRECTLY FROM BLOOD

BSI is initially suspected by clinicians on the basis of clinical signs and symptoms. At this stage the etiological agent is, however, difficult to determine because the clinical presentation is generally similar. To accelerate the time to result of microbial diagnosis, molecular methods that can be used directly on whole blood have been proposed. Nevertheless, blood as a sample presented many technical limitations: (i) the low quantity of circulating microbes during BSI (1 to 10 CFU/ml), (ii) the presence of PCR inhibitors in blood that are not completely removed by current nucleic acid extraction methods (see "Introduction"), (iii) the sensitivity of PCR to contamination, which implies the use of pure (nucleic acid free) material and ideally performance of quantitative analyses (133), (iv) the ability of PCRs to detect the presence of DNA from both living and dead microbes, which makes the interpretation of positive results difficult (BSI versus DNAemia), and (v) the presence of an excess of human DNA.

Different PCR technologies are now available. Broad-range PCRs could be useful, especially when the etiological agent is not suspected, but they are often limited by lower sensitivity. Pathogen-specific PCRs display higher sensitivity. Real-time PCRs can be multiplexed to detect several targets at the same time with good sensitivity. A recent innovation that can be used directly on whole blood is PCR-ESI-MS, which is presented as a universal and fast method.

Broad-Range PCR

The need for a PCR-based universal detection method is stressed by the importance of rapid diagnosis for critically ill patients, especially since the etiology of the BSI is difficult to establish on the basis of the clinical presentations. This is the case for neonate patients, with the additional difficulty that only small volumes of blood are available, which significantly decreases the sensitivity of blood culture. Alternatively, such universal and sensitive methods may be used to screen blood samples taken from neutropenic patients or other high-risk subjects for early detection of the etiological agent of a BSI.

The 16S rRNA gene that displays a sufficient level of conservation among bacterial species is the target of in-house PCRs used in many molecular diagnostic laboratories (134–138). In many organisms, the ribosomal operon

is present in multiple copies, which increases the sensitivity of PCRs targeting this genomic region. The intergenic spacer is more polymorphic and more species specific. Specific PCR primers are designed on conserved regions that surround highly variable regions. Thus, the sequencing of the amplicon allows the identification of the microbe at the genus or species level. Most of these PCRs cannot be used directly on blood because of their limited sensitivity and specificity. However, some studies have reported sensitivity of PCR targeting the 16S rRNA gene ranging from 10 to $2.5.10^2$ CFU per reaction directly from blood (139, 140). Gaibani et al. have developed a broad-range, real-time PCR that targets a 97-base-pair sequence of the 23S rRNA gene. This PCR is expected to detect 90% of the bacteria involved in BSIs but does not give any identification, since the short amplified fragments do not allow discrimination upon sequencing (141). This real-time PCR can be used on whole blood (100 µl). Its sensitivity ranges from 10 to 10^3 CFU per reaction for *E. coli* and *S. aureus*, depending on the extraction method.

The SepsiTest system (Molzym, Bremen, Germany) is based on broad-range PCR using universal primers that target the 16S rRNA gene for bacterial identification and the 18S rRNA for fungal identification. The amplicons are sequenced and analyzed by BLAST to make identifications at the species level (≥99% identity) or genus level (≥97%) (142, 143). Of course, this cutoff does not apply to all bacterial species and should be used with caution. The analysis is achieved from 1 ml of whole blood. After lysis of human cells, the human DNA is degraded by a DNase. The PCR is achieved using the reagent provided by the manufacturer and leads to amplicons of about 450 base pairs. The time to result is approximately 6 h. Depending on the study, the sensitivity and specificity are variable when compared to blood culture. A first study performed in critically ill patients led to 28.6% sensitivity and 85.3% specificity of the SepsiTest when blood culture is used as the gold standard (144, 145).

In a second study, pathogens could be detected in 26% (13/50) of the critically ill patients, while SepsiTest could detect pathogens in only 12% of the patients (145). In a third study, still using blood culture as the gold standard, SepsiTest sensitivity was 21% and specificity was 96% (146). In contrast, high sensitivity and acceptable specificity (87% and 85.5%) were monitored in a multicenter study involving 342 blood samples from 187 patients (142). In a study performed on patients supported by extracorporeal membrane oxygenation, the sensitivity and specificity were 78.6% and 88.4%, respectively, when compared to blood culture, with 97.7% concordance of positive results (147, 148). In this study, SepsiTest could detect at least a pathogen in 25% of patients with negative blood culture. For patients with suspected endocarditis, Kühn et al. reported higher performances of SepsiTest over blood culture (143). The variable sensitivity and specificity of the SepsiTest compared to blood culture needs to be investigated. One specific feature of SepsiTest is that it can be used on sterile samples other than blood with the potential to replace home-made broad-range PCR (148, 149). A limitation of this method is that the extraction is not automated (150). Another important limitation of all these molecular tests is that they do not provide strains for detailed antibiotic susceptibility testing.

The VYOO system (SIRS-Lab, Jena, Germany) is based on multiplex PCRs that can detect 34 bacteria and seven fungi from 5 ml of whole blood. The system contains several steps, including nonautomated steps. Nucleic acid extraction is assisted by magnetic beads. Then there is a step of enrichment in microbial DNA based on (i) the methylation difference between microbial (bacteria and fungi) DNA and the human DNA and (ii) the use of chromatography affinity (44). The PCR is achieved on DNA, the concentration of which has to be manually adjusted to 1 µg in 25 µl. Two PCRs with a specific pool of primers are required. The amplicons are applied to electrophoresis in an ethidium bromide-stained agarose gel. Pathogen identification is determined on the basis of the band pattern.

In a study performed on 311 blood samples from 245 patients in an intensive care unit of a university hospital analyzed in parallel with blood culture and with the VYOO system, the VYOO system gave 30.1% positive samples, with a median time to result of 24.2 h; blood culture bottle gave 14.5% positive samples, with a median time to positivity of 68 h, with only a 40% correlation between the two methods (151). Positive PCR samples correlated well with the level of procalcitonin. Additionally, the PCR results from blood were usually confirmed by the pathogen identified in the suspected site of infection. Importantly, for 34% of the patients with positive VYOO tests, the anti-infectious therapy was inadequate, including infections that involved vancomycin-resistant enterococci, multidrug-resistant staphylococci, and fungi (151). In another study, the VYOO system gave positive results in 51.4% of samples from patients with BSIs, whereas blood culture gave 27.7% positive results (152).

These studies suggest that VYOO is more sensitive than blood culture, which could be explained by the association of a large starting volume (5 ml) and the enrichment in microbial DNA before amplification. More studies are required, but these preliminary performances are promising despite the fact that many steps are not yet automated.

Real-Time PCR and Multiplex PCR

The multiplexing of real-time PCRs allows the simultaneous detection of several microbes with good sensitivity and specificity. This is the technology used for the LightCycler SeptiFast system (Roche Molecular System, Germany) and the MagicPlex Sepsis system (Seegene, Seoul, Korea).

Principle of the LightCycler SeptiFast System

The LightCycler SeptiFast system is based on broad-range, real-time PCR that can identify 19 pathogens (8 Gram-negative bacteria, 6 Gram-positive bacteria, and 5 fungi) representing approximately 90% of the pathogens responsible for BSIs. SeptiFast can be used directly from whole blood with an overall time to result of about 5 h (3.5 when associated with an automated extraction system). The targets of the multiplexed broad-range, real-time PCR are the internal transcribed spacer between the 16S and the 23S ribosomal DNA for bacteria and the internal transcribed spacer between the 18S and the 5.8S ribosomal DNA for fungi. Identification at the species level is determined by the distinct melting curves of the specific probes. The LightCycler can detect eight Gram-negative bacteria: *E. coli*, *K. pneumoniae/K. oxytoca*, *Serratia marcescens*, *E. cloacae/E. aerogenes*, *Proteus mirabilis*, *P. aeruginosa*, *A. baumannii*, and *Stenotrophomonas maltophilia*. Six Gram-positive bacteria can be recognized: *S. aureus*, coagulase-negative staphylococci, *S. pneumoniae*, *Streptococcus*, spp., *E. faecium*, and *E. faecalis*. Six fungi can be detected and

identified at the species level: *C. albicans*, *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, *C. krusei*, and *Aspergillus fumigatus*. Basically, the assay consists of three separated reactions that contain distinct primer and probe mixes to detect, respectively, Gram-negative bacteria, Gram-positive bacteria, and fungi. The LightCycler SeptiFast system is designed for the analysis of 1.5 ml of blood on which mechanical cell lysis is achieved with the SeptiFast Lys KIT MGRADE and the MagNALyser from Roche Diagnostics prior to DNA extraction using a commercial kit provided by the same manufacturer. The assay contains an internal control that consists of a synthetic double-stranded DNA, similar to the expected amplicon but with a distinct probe binding site.

The analytic sensitivity ranges from 3 to 30 CFU/ml for bacteria and is 100 CFU/ml for fungi (153, 154). The experimental sensitivity (42.9 to 95%) and specificity (60 to 100%) of SeptiFast are variable depending on the study and on the patient characteristics (Table 1) (32, 155).

Diagnosis of Infection in Febrile Neutropenia Using the LightCycler SeptiFast System

From a group of 86 febrile neutropenic patients representing 141 episodes of fever, blood culture and SeptiFast detected approximately the same number of microorganisms: 44/141 (31.2%) and 42/141 (29.8%), respectively. However, the association of blood culture and SeptiFast increases the rate of documentation from about 30 to 43% (61/141), which might be due to the fact that only 12 organisms were detected by both blood culture and SeptiFast (156). A similar observation was made by Mancini et al. in a study performed on 103 samples from neutropenic patients with hematological diseases in which 20.4% of the samples were found positive with blood culture and 33% were found positive using SeptiFast, with only 83% correlation between the two methods (157). For Bravo et al., the agreement between blood culture and SeptiFast was 69% for neutropenic patients and 75% for patients from the intensive care unit (158). All these studies suggest that SeptiFast cannot replace blood culture but that the two techniques could be complementary (156, 157, 159, 160).

Lamoth and colleagues suggested that the low sensitivity of SeptiFast was due (i) to organisms absent from the SeptiFast analytic spectrum (40% of false negatives) and (ii) to the cutoff that decreases the sensitivity for the detection of coagulase-negative staphylococci or streptococci and increases the rate of false-negative results (156). False-negative results obtained for Gram-negative cocci might also be explained by the inefficient lysis of these microorganisms (161) or to PCR inhibition in the case of high bacterial load. The adjustment of the experimental procedure and an adequate cutoff might increase the performance of the SeptiFast assay for neutropenic patients (156, 161). In a context of persistent fever, SeptiFast identified new pathogens in 89% of the cases, whereas blood culture identified 8% of the pathogens (156). Similar results were obtained by von Lilienfeld-Toal et al. (162). In this study all the patients with a probable fungal infection had positive SeptiFast results for A. *fumigatus*. This suggests a potential added value of the SeptiFast assay for the detection of fungemia in neutropenic patients (155–157, 162, 163).

Diagnosis of Infectious Endocarditis

A study performed on 63 patients with suspected endocarditis revealed a low sensitivity of SeptiFast when compared to blood culture (153). Among 19 patients with positive blood culture at admission, SeptiFast detected eight bacteria (41% sensitivity). Before admission, 22 patients had positive blood culture, but because of efficient antibiotic treatment they had negative blood culture at the time of this study. Among them, SeptiFast detected only three bacteria (3/22) (153). In this study, SeptiFast did not detect any microbes for patients without any etiology (100% specificity) (153). Because the low sensitivity of SeptiFast was not due to pathogens that are not detected by this system, it could be due, as discussed below, to a low bacterial load. In another study, involving 20 patients with endocarditis, SeptiFast performed on excised cardiac valves displayed a higher sensitivity (95%) and specificity (100%) than culture (sensitivity 15% and specificity 100%) (164, 165). In patients with suspicion of *Candida* spp. endocarditis, SeptiFast was as sensitive as blood culture to detect fungal infection (166).

Diagnosis of Neonatal Sepsis

In a study performed on 1,673 pediatric samples (803 children), the detection rate of infection was higher with SeptiFast (14.6%) than with blood culture (10.3%), which corresponded to a sensitivity of 85.0% and a specificity of 93.5% of the SeptiFast results (167). The cumulative positive rate of blood culture and SeptiFast was 16.5%. Another study confirmed a higher sensitivity but a lower specificity of SeptiFast for the detection of late-onset neonatal sepsis (168).

Advantages and Disadvantages of the LightCycler SeptiFast System

The performance of the SeptiFast system is variable depending on the study. The overall sensitivity of SeptiFast is not higher than the sensitivity of blood culture, but together SeptiFast and blood culture increase the rate of microbial documentation of BSI. This suggests that SeptiFast cannot replace blood cultures but that these two methods are complementary. One of the major advantages of SeptiFast is the time to result (<5 h). In a study performed on 114 consecutive patients with clinical evidence of sepsis the mean time to results for SeptiFast was less than 8 h, whereas the blood culture mean time to positive results was 3.5 days and for negative results was 5 days (169). In a study performed on emergency department patients with suspected sepsis, Schaub et al. reported a median time to positivity of blood culture of 16 h (without organism identification) (170). SeptiFast might be useful in cases of a persistent bacteremia, for instance, in a neutropenic patient with persistent fever, for which SeptiFast often identified additional pathogens. Many studies have been conducted on the performance of SeptiFast. However, there is a need for interventional studies to clearly determine the clinical impact of this new technology.

One of the limitations of SeptiFast is the absence of exact quantification. The cutoff can be used for the interpretation of streptococci- and coagulase-negative staphylococci-positive results in particular. This is expected to reduce the number of false-positive results but might prevent the detection of low-grade infections. In some studies performed on neutropenic patients, the sensitivity of SeptiFast for the detection of coagulase-negative streptococci is decreased, which could be because the cutoffs were established for nonneutropenic patients. In contrast, in pediatric studies SeptiFast leads to increasing numbers of false positives due to coagulase streptococci. Adding quantitative data to SeptiFast has the potential to make it possible to predict the severity of the sepsis (171).

The HACEK group of fastidious bacteria (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*), which is involved in a significant number of blood culture-negative bacteremias, is not covered by SeptiFast. For this reason SeptiFast is not sufficient by itself to diagnose all types of bacteremia, and alternative methods are required to cover the entire bacterial kingdom. Finally, in the context of an increasing number of multidrug-resistant organisms, SeptiFast is limited in that it does not provide any data on the resistance profile of identified organisms, except for MRSA with the use of an additional kit (Table 1).

The MagicPlex Sepsis System

The MagicPlex Sepsis system is based on multiplexed real-time PCRs that can detect 90 pathogens at the genus level, 25 at the species level (19 bacteria and 6 fungi), and the resistance genes *mecA*, *vanA*, and *vanB* directly from whole blood (1 ml). A specific nucleic acid extraction kit is used for enrichment in microbial DNA. A first amplification is a screening that provides either (i) an amplicon bank that consists of Gram-negative bacteria and fungi or (ii) an amplicon bank that consists of Gram-negative bacteria (n = 73) and resistance genes conferring resistance to methicillin (*mecA*) or vancomycin (*vanA* and *vanB*). A second step is a screening for bacteria and fungi at the genus level and for the presence of resistance genes (time to result 5 h).

The performance of the MagicPlex system was compared to blood culture on 267 patients from the intensive care unit, from the hematology department, and from the emergency department of a tertiary hospital, which revealed a 73% agreement between the two methods, with no statistical difference between their sensitivity (172). For patients with antibiotic treatment, the sensitivity of MagicPlex (65%) was lower than the sensitivity of blood culture (71%); specificity was, respectively, 92% and 88% for the two methods. Another study, performed on 140 patients with suspected BSI, reported 37% sensitivity and 77% specificity of the MagicPlex system when considering blood culture as the gold standard (146).

Additional studies are required to determine the exact potential of this device. This method is limited by the number of pathogens detected at the species level and by the absence of quantification. Another limitation is the absence of automation and the need for a specific extraction method, which might make it difficult to integrate in an automated molecular diagnostic laboratory.

PCR-Electrospray Ionization Mass Spectrometry (PCR/ESI-MS)

Principle, Characteristics, and Performance of PCR/ESI-MS

PCR/ESI-MS is a technology that was initially developed to face bioterrorism threats or to run public health investigations. The aim was to provide a rapid method for the detection and identification of pathogens from various types of samples. The technology had to detect low quantities of a given pathogen even in polymicrobial samples and should include the detection of noncultivable or fastidious microorganisms. In addition, the technology should be able to detect known microorganisms as well as unknown pathogens. Molecular diagnosis was chosen because it is fast and broad range.

The PCR/ESI-MS approach is based (i) on the amplification of a microorganism's DNA by multiple PCRs and (ii) on the identification of the organism(s) at the species or genus level through the analysis of the amplicon by ESI-MS (23, 173). Basically, PCR/ESI-MS consists of five steps: (i) extraction of the microorganism or sample DNA, (ii) amplification of the DNA using multiple pairs of primers, (iii) precise determination of the molecular mass of the amplicon(s) using ESI-MS, (iv) deduction of the base composition of the amplicon(s) from the exact molecular weight of the amplicon, and (v) identification of the pathogen(s) by integrating the information obtained from several amplicon(s) (Fig. 4) (173, 174).

Before being applied to blood (see next paragraph) PCR/ESI-MS was first applied to bacterial colonies and environmental samples. DNA amplification is based on multiple broad-range PCRs, which is more sensitive than a single broad-range PCR based on degenerated primers. The primers target a conserved genomic region surrounding polymorphic regions (for instance DNA regions encoding for the 16S or the 23S rRNA). Moreover, these PCRs are devoid of fluorescent dye or probes, which allows a high level of multiplexing. DNA amplification may be performed in a 96-well plate via the following steps: (i) 95°C for 10 min; (ii) 8 cycles of 95°C for 30 s, 48°C increasing by 0.9°C at each cycle for 30 s, and 72°C for 30 s; (iii) 37 cycles of 95°C for 15 s, 56°C for 20 s, and 72°C for 20 s; and (iv) final extension of 2 min at 72°C and holding at 4°C (175). The major innovation of PCR/ESI-MS is that the pathogen's identification relies only on the base composition (A, C, G, and T) of the amplicons (23, 173). The base composition is obtained by the integration of the exact mass of the amplicon, the length of the amplicon, the mass of each base, and the complementarity rules of DNA (Fig. 4). The choice of the PCR targets makes the base composition of one or more amplicon(s) sufficient for pathogen identification. The absence of Sanger sequencing dramatically reduces the time to result(s). Thus, ESI-MS provides the base composition of an amplicon in about 1 min, the mass of the amplicon being determined by the TOF. The base composition of the amplicon(s) is compared to a database that provides the identification at the genus or species level with a score of probability (Q-score) inferred by ESI-MS triangulation software that relies on multiple amplified regions. The Q-score integrates multiple parameters such as the number of primer pairs that gave an amplicon, the number of potential microorganisms, and the proximity of the base compositions to reference matches in the database.

A set of nine pairs of primers is used for the coverage of the bacteria kingdom. Four pairs are necessary for *Candida* spp. Four additional pairs of primers have been designed to detect the resistance cassettes *mecA*, bla_{KPC}, *vanA*, and *vanB*. With clinical samples (up to 1.25 ml) other than blood, PCR/ESI-MS displays good sensitivity and specificity. This includes environmental samples as well as clinical samples such as cerebrospinal fluid (176–178) and respiratory tract samples (179–181). Compared to culture, the PCR/ESI-MS correctly identified 95.6% and 81.3% of the strains at genus level and species levels, respectively. Among 395 respiratory samples, PCR/ESI-MS displayed 67.6% of agreement at the genus level and 66.6% at the species level with culture. PCR/ESI-MS was able to identify fungi in 20.3% (35/172) of the respiratory specimens with a negative culture, suggesting a better sensitivity than culture (182). A commercial kit available for the detection of viruses (183–191) has been shown to display better performance than real-time PCR and microarrays (183).

PCR/ESI-MS has also been successful at identifying *Mycobacterium* spp. at the species level and at determining associated resistance genes using a panel of eight PCRs (192–194).

Thus, PCR/ESI-MS represents a universal method that can be applied to bacteria, viruses, and fungi and that is expected also to identify any unknown species. Indeed, when primers are designed to identify all known members of characterized groups, they allow the detection of unknown or new emerging pathogens from these groups (193, 195, 196). This provides the potential for the rapid detection of emerging pathogens. In addition, PCR/ESI-MS can detect and identify all of the pathogens present in polymicrobial samples with quantitative results. This method can also be used on formalin- or paraffin-embedded tissue (197).

Finally, because of its accuracy, PCR/ESI-MS has been extensively used for genotyping and serotyping of bacteria and viruses to detect single nucleotide variations, which represents a tool for health care epidemiological investigation or outbreak follow-up (181, 194, 198–208). This accuracy of the PCR/ESI-MS method naturally relies on a representative database and on its maintenance.

Application of PCR/ESI-MS to the Diagnosis of BSI Directly from Blood

The first PCR/ESI-MS instrument developed was TIGER (Triangulation Identification for the Genetic Evaluation of Risk), which allowed the detection of specific organisms even in polymicrobial samples (196). The Ibis T5000 instrument, the first commercial version of TIGER, could identify up to 800 pathogens from whole blood (23, 209). When compared to blood culture, PCR/ESI-MS applied on 1 ml of whole blood displayed 50% efficiency. A second commercial version, the PLEX-ID (Abbott), using up to 1.25 ml of blood, displays good sensitivity and specificity on most samples tested, which includes environmental samples as well as clinical samples such as cerebrospinal fluid and sputum (178, 179, 184, 193, 210). The first procedure of the PLEX-ID for whole blood consisted of mechanical cell lysis, using beads, facilitated by the addition of proteinase K, SDS, and heating at 56°C. DNA purification was then achieved with magnetic silica beads and eluted in 250 µl of water at 70°C (211). The PCR is based on nine pairs of primers for bacteria detection, four pairs for *Candida* species, and four pairs for detecting resistance cassettes (*mecA*, bla_{KPC}, *vanA*, *vanB*). One additional pair of primers corresponds to the extraction control. The PLEX-ID gave 78.6% agreement with blood culture over 906 specimens taken from adult and pediatric patients (464 with positive blood cultures and 442 with negative blood cultures). While 33 negative culture specimens were found positive by PLEX-ID, 97 positive culture specimens were found negative by PLEX-ID (211). In this study the estimated sensitivity of PCR/ESI-MS was 85.9%, whereas the estimated sensitivity of blood culture was 41.2%.

To further increase the sensitivity of detection directly from whole blood, a second version of the PLEX-ID that could analyze up to 5 ml of blood has been developed. In this version, the increased sample volume was associated with a DNA extraction method and PCR conditions optimized for whole-blood samples (22). In this version, 5 ml of whole blood was lysed in the presence of 665 µl of a commercial buffer (100 mM Tris solution containing guanidinium thiocyanate and detergent), 145 µl of bovine serum albumin 10% containing a pumpkin DNA extraction control, and yttria-stabilized zirconium oxide beads (212). After the removal of lysed red blood cells by centrifugation, the nucleic acid was extracted from the supernatant by means of silica-coated magnetic beads. The PCR used 30 µl of the eluate with 25 µl of PCR master mix containing the pool of primer pairs (211). Rather than trying to remove the excess of human DNA, PCR conditions were defined in the context of high concentrations of human DNA. This was achieved by testing multiple PCR conditions by modulating Mg^{2+}, primers, and polymerase concentration and annealing temperature in the presence of 12 µg of human DNA (22, 175). In this background, a high primer concentration (750 µM) together with a high polymerase concentration (2.2 units per reaction) resulted in a PCR yield of 86% of the yield when 1 µg human DNA was present. Modulating Mg^{2+} concentration or the annealing temperature had only a weak impact on the PCR yield. This procedure was then evaluated in a prospective study involving 331 patients with suspected BSI (22). For each patient two blood bottles (one aerobic and one anaerobic) were inoculated with 5 ml of whole blood, and an additional blood sample was collected for PCR/ESI-MS analysis from the same venipuncture (211). The PCR/ESI-MS displayed 83% sensitivity and 94% specificity compared to blood culture. Interestingly, this corresponded to 35 positive specimens (10.6%) by PCR/ESI-MS and 18 positive by culture (5.4%). In the absence of any method to investigate the discrepant results, a second aliquot was analyzed using PCR/ESI-MS, which confirmed almost all the identifications and increased the sensitivity of PCR/ESI-MS to 91% and the specificity to 99% (22).

The limit of detection of the PCR/ESI-MS method developed by Bacconi et al. is 16 CFU/ml for *S. aureus*, *K. pneumoniae*, and *E. faecium*, and 4 CFU/ml for *C. albicans*. It is generally admitted, based on plating methods, that the number of bacteria circulating during BSI is between 1 and 10 CFU/ml (17–21). The analysis of the data from the literature performed by Bacconi and colleagues estimated that the amount of bacterial DNA in blood during a BSI varies between 10^3 to 10^4 genome copies per ml (22). This difference could be due to the fact that plating methods reflect the number of cells that survive the procedure rather than the number of circulating cells. Molecular diagnosis directly from blood could also detect free DNA, DNA resulting from dead bacterial cells, and bacterial DNA present within phagocytes, which may explain the high performance of the PLEX-ID on whole blood. However, this extremely high sensitivity may lead to contamination by DNA. For this reason, the use of ultra-clean reagents associated with molecular biology laboratory practices is mandatory.

PCR/ESI-MS is also a promising tool for the diagnosis of blood culture-negative BSI. Indeed, among 464 patients with positive blood cultures and 442 patients with negative blood culture, 33 culture-negative cases were detected as positive by PCR/ESI-MS, and these cases were demonstrated to be true BSIs based on the analysis of the clinical presentation (211). Using primers and probes specific for *Ehrlichia chaffeensis* targeting the 16S gene and a genus-specific set of primers and probes, Eshoo and colleagues reported 18.8% of PCR/ESI-MS positive whole blood specimens among 213 blood samples from patients with suspicion of ehrlichiosis (175). From the same pool of specimens, PCR/ESI-MS identified *Rickettsia rickettsii* from four samples and *Neisseria meningitidis* from one sample.

PCR/ESI-MS was designed to detect all pathogens present in a mixed microorganism population (213, 214). This is also true for polymicrobial blood culture since PCR/ESI-MS could identify 29 bottles with mixed populations out of 234 positive blood culture bottles (215). A quantitative analysis performed using an internal control helps with (i) interpreting results for polymicrobial samples and (ii) identifying true positive versus contaminating organisms (211). Further studies are required to determine if the quantification could also help define the severity of the infection.

In conclusion, the PLeX-ID (now commercialized by Abbott under the name Iridica), which provides reliable results in less than 6 h, is a versatile system that may be directly used on blood starting from 5 ml of samples and that represents a complementary approach to blood cultures.

MOLECULAR DETECTION OF ANTIMICROBIAL RESISTANCE DURING BSIS

BSI is characterized by a high level of morbidity and mortality that increases with the delay of the introduction of an efficient anti-infectious therapy (1–8). The rapid identification of the pathogen gives a first indication of the effectiveness of the empiric therapy. However, rapid information on the resistance profile of the agent of a BSI would make it possible to better adjust the empirical treatment.

Rapid PCR-Based Methods for Resistance Detection from Positive Blood Cultures

Detection of Resistance Mechanisms of Gram-Positive Bacteria

S. aureus is a significant agent of both community-acquired infections and nosocomial infections (95). In recent years, an alarming increase has been observed in the percentage of MRSA, a drug-resistant pathogen associated with significant increases in mortality (96–100), which explains why many rapid methods are now available to simultaneously identify *S. aureus* and detect the *mecA* gene associated with methicillin resistance (Table 1) (101, 102).

The GeneXpert MRSA/SA BC Assay is a good example of such a dual detection method based on real-time PCR for the identification of *S. aureus* and the detection of the *mecA* gene. The analysis can be performed directly from positive blood culture in about 1 hour and was validated in both adult and pediatric patients with blood culture positive for Gram-negative cocci in clusters with 100% sensitivity and 99.5 to 100% specificity (103, 104). The GeneXpert MRSA/SA BC Assay dramatically reduced the time to detection of *S. aureus* and had an impact on the detection of MRSA (Fig. 2) (104, 216–218).

Another rapid PCR-based assay based on real-time PCR, the StaphSR assay, can identify and differentiate MSSA and MRSA from positive blood cultures in about 1.5 h with an analytical sensitivity of 15 DNA copies per reaction mixture, which corresponds to 10^3 DNA copies per ml (105, 106). The assay was validated on blood culture with a predominance of Gram-negative cocci in clusters showing 95.6 to 100% sensitivity and 95.3 to 98.4% specificity for the detection of MRSA (105, 216, 219, 220). Discrepant results are mainly explained by mixed culture or inhibition of the PCR. Negative MRSA detection is also due to MREJ (SCCmec right-extremity junction) variants that contain the staphylococcal cassette chromosome *mec* (SCCmec) without the *mecA* gene (221).

The StaphPlex system is based on multiple PCRs (18 target genes) and microarray analysis for the identification of staphylococci at the species level, for the detection of resistance genes, and for the detection of the PVL, with a time to result of about 5 h. The overall accuracy for the detection of staphylococci at the species level from monobacterial or polybacterial culture was 91.7% compared to conventional methods (107). The StaphPlex system exhibited 100% sensitivity and 95.5 to 100.0% specificity for the detection of the *mecA* gene. Similar results were obtained for the detection of the PVL gene (107).

The FilmArray is another PCR-based system that can detect the *S. aureus mecA* gene as well as the *vanA* and *vanB* genes implicated in vancomycin resistance in *Enterococcus* spp. (222, 223). The FilmArray system exhibits high sensitivity and specificity (100%) for the detection of the *mecA* gene from *S. aureus*-positive culture (90, 222, 224). Another study reported 96% sensitivity and 98.9% specificity for the detection of the *mecA* gene (92). For the detection of the *vanA* and *vanB* genes in *Enterococcus* spp., Blaschke et al. reported only 85% specificity of the FilmArray system compared to blood culture (90). In this study, the FilmArray system detected a *van* gene in two *Enterococcus* strains that were found to be vancomycin sensitive by culture-based methods. The second strain was an *Enterococcus casseliflavus* strain bearing the *vanC* gene. During the development of the system, more resistance markers have been successfully tested (90).

The microarray of the Verigene Gram-negative system includes probes for the detection of the *mecA* gene with 98.6% sensitivity and 94.3% specificity (76). This system also contains probes for the detection of vancomycin-resistant enterococci with 100% sensitivity and specificity in a prospective study from positive blood culture (76).

The major weakness of the nucleic acid methods is that they cannot assign the resistance gene to the correct microorganism in the case of mixed cultures. This is particularly limiting for the detection of the *mecA* gene in a mixed culture of *S. aureus* that, for instance, would contain contaminating coagulase-negative staphylococci (76).

Detection of Resistance Mechanisms of Gram-Negative Bacteria

Gram-negative bacteria can exhibit resistance mechanisms to multiple antibiotics, representing a major problem for the treatment of infections. In particular, *Enterobacteriaceae* have developed multiple resistance mechanisms to cephalosporins, such as extended-spectrum β-lactamase. This presented carbapenem as an alternative for the treatment of severe infections involving *Enterobacteriaceae* and nonfermentative bacteria such as *P. aeruginosa* and *A. baumannii*. However, resistance to carbapenem may also occur. It might be caused by reduced permeability with loss of porins, by the overexpression of efflux pumps, or alternatively, by the production of carbapenem-degrading enzymes, namely carbapenemases. The emergence of carbapenem-resistant strains and their spread worldwide are alarming both from a therapeutic point of view and from an epidemiological point of view. Nucleic acid detection systems are focusing on the bla_{KPC} gene, which encodes for *K. pneumoniae* carbapenemase. This is the case for the FilmArray system, which includes primers targeting the bla_{KPC} gene (79, 90, 92, 224), and the Verigene Gram-negative system, which contains probes for the detection of the bla_{KPC} gene (79). More studies involving KPC-positive strains are needed to determine the sensitivity and specificity of

these systems. Moreover, future tools should aim at detecting a broader range of genes encoding ESBL and/or carbapenemases.

Resistance Detection from Positive Blood Culture Using MALDI-TOF MS

The use of the MALDI-TOF MS for the detection of resistant strains was first proposed to distinguish between MRSA and MSSA colonies (225). However, recent developments are mainly directed toward Gram-negative bacteria in which MALDI-TOF MS may detect antibiotic-degrading proteins such as carbapenemases. A bacterial inoculum is incubated with ertapenem. The MALDI-TOF MS analysis performed on the supernatant is used to determine the shift of two specific peaks associated with the degradation of the carbapenem. This method has been validated on bacterial colonies with 100% sensitivity and 100% specificity for the detection of carbapenemase-producing strains (226). Carvalhaes and colleagues have proposed a method to be used directly from bacterial pellets obtained from positive blood culture, which is able to identify 72.4% (21/29) of the carbapenemase-producing isolates after 4 h of incubation (227). MALDI-TOF MS represents an alternative for the detection of carbapenemase from positive blood culture that has the advantage, over PCR, of providing a phenotypic result.

Resistance Detection Directly from Whole Blood

As stated above, the detection of resistance genes directly from blood would considerably impact the choice of therapy. Four primer sets of the PLEX-ID system are used to detect the resistance cassettes *mecA*, *vanA*, *vanB*, and bla_{KPC} (228, 229). The PLEX-ID system can also detect the presence of the *S. aureus* PVL (228). PCR/ESI-MS was also shown to be successful at identifying the mutations in *gyrA* and *parC* genes involved in *A. baumannii* resistance to quinolones (230, 231). In the case of a mixed population, quantitative analysis could help associate a resistance gene to the corresponding pathogen. The MagicPlex system can detect three resistance markers (*mecA*, *vanA*, *vanB*) directly from blood (146). From their study, Carrara et al. failed to detect 6 MRSA strains out of 10 using the MagicPlex system (172). The VYOO system can detect five resistance genes: *mecA*, *vanA*, *vanB*, β-lactamase bla_{SHV}, and β-lactamase $bla_{CTX\text{-}M}$. However, there is a lack of studies reporting the sensitivity of this method. Finally, the SeptiFast system contains primers for the detection of *mecA* only (Table 1).

Although molecular methods have the ability to detect some resistance genes, more studies are required to assess their performances and their clinical impact. In addition, increasing the number of available resistance markers would be an advantage.

CONCLUSIONS AND FUTURE DIRECTIONS

Nucleic acid methods have succeeded in overcoming most of the obstacles that limited the sensitivity of the detection of pathogens from blood-containing samples. The sensitivity and specificity of these methods are now adequate for use in diagnostic laboratories.

One major problem in assessing the performance of new molecular methods is that blood culture associated with traditional identification methods remains the gold standard. In this context, many assays display extremely high analytic sensitivity but limited apparent specificity due to a limited correlation with blood culture. This could be overcome by the use of other evaluation methods to challenge blood culture. In their study, Bacconi and colleagues showed that 16S sequencing is not an appropriate method to be used as reference for the evaluation of PCR/ESI-MS. Indeed, only 2 of the 35 samples that tested positive using PCR/ESI-MS were found to be positive by 16S sequencing when the sequencing was performed on the same material. Thus, one of the limits to developing new methods for the diagnosis of BSI is that blood culture remains the gold standard (22). To compare the performance of blood culture and other methods, clinical presentations and local epidemiology should be taken into account to properly investigate discrepant results (22, 211). Nevertheless, the poor correlation between conventional blood culture-based methods and some new molecular methods suggests that different pathogens are detected by these two methods and that these diagnostic tools should be complementary. Moreover, blood culture cannot be replaced since the availability of a strain in pure culture is mandatory to precisely test the antibiotic susceptibility of bacteria.

Although new molecular methods are very appealing, further studies are needed to determine their impact on the management of patients with BSIs (29). For instance, there is a lack of studies that address the impact on antibiotic stewardship. While most of the studies try to measure with precision the performance of the new molecular methods, it is not yet clear how these methods can be integrated in a molecular laboratory. This is particularly true because none of the methods would replace blood culture. Some practical details have to be investigated. Thus, the number of samples, the number of venipunctures, and the frequency of sampling for molecular diagnostics has to be addressed. Otherwise, information (routinely provided by the blood culture) on the likelihood of infection (such as a possible catheter infection) versus contamination would be missing.

Molecular methods can also be helpful for organisms that are phenotypically closely related or for rare organisms. However, because some genetically closely related organisms cannot be distinguished on the basis of molecular methods, such as *E. coli/Shigella* (125, 126) or group mitis streptococci/*S. pneumoniae* (75, 120, 124), phenotypic distinction methods remain crucial. In the same manner, the accuracy of many molecular methods is based on their databases, which have to be maintained by adding nucleic acid sequences or obtained by mass spectrum for new clinical isolates or rare organisms. For nucleic acid methods, it is also crucial to conduct a follow-up of the emergence of single nucleotide polymorphisms or mutations (insertion/deletion) that could affect the hybridization of specific primers and probes. One solution would be to rely on multiple targets (sequence or gene) for the identification of a given organism (86, 105).

As stressed earlier, Gram staining remains mandatory for blood culture-based methods since (i) it can help reveal polymicrobial infection, (ii) it serves as a quality control, and (iii) it sometimes helps with identification because of specific phenotypic traits. Nevertheless, the presence of a single morphotype on the Gram stain does not exclude the presence of multiple organisms, since *Enterobacteriaceae* often exhibit a similar Gram staining morphotype.

Regarding polymicrobial identification, the quantification provided by some nucleic acid-based methods can be

helpful at determining the significance of the respective organisms. Another research focus is the attempt to provide clinical scores that would predict the severity of bacteremia (35, 232). The time to positivity of blood culture has been proposed as a criterion for BSI severity (6, 233, 234). Similarly, quantification could provide some insight on the severity of the BSI. Thus, analysis of 250 whole-blood samples from 20 adult patients (13 survivors and 7 nonsurvivors) with culture-proven MRSA showed that the levels of *mecA* DNA were higher in the nonsurvivors (5.48 copies/ml) than in the survivors (4.58 log copies/ml; P = 0.003, two-tailed Mann-Whitney U test). This suggested that the level of *mecA* DNA in blood could potentially be used to monitor MRSA bacteremia and evaluate responses to therapy (235). Similarly, a positive correlation has been found between the level of *S. pneumoniae* DNA monitored by real-time PCR and the need for mechanical ventilation and the risk of septic shock and death (236, 237). Another study performed with SeptiFast on 94 patients reported that the median cycle threshold value was 16.9 for patients with severe septic shock and 20.9 for patients with non-severe sepsis and that a cycle threshold value <17.5 was correlated with more positive blood culture and longer hospital stays (171, 238).

Quantification can also help identify the presence of a contaminant. In this context, the threshold of the quantitative results becomes an important parameter to limit the number of false-positive and false-negative results. Molecular solutions devoid of quantitative or at least semiquantitative analysis will render the interpretation of the positive results difficult. The interpretation of polymicrobial as well as monobacterial detection is facilitated by the fact that PCR/ESI-MS gives a quantitative analysis performed using an internal control. This can also help identify true positive versus contaminating organisms (211) and determine the relevance of each pathogen for mixed infections (176). Further studies are required to determine if the quantification could also help define the severity of the infection.

Regarding persisting bacteremia in the context of an ongoing treatment, molecular methods have been able to rapidly detect new organisms that blood culture could not detect. However, nucleic acid methods are not adequate for the follow-up of persistent infections because they detect the persistence of DNA from dead organisms rather than a true persisting organism. Therefore, many methods are now being developed to detect only DNA from living organisms (239, 240). This could be of particular interest to monitor the efficiency of an antibiotic treatment (241, 242).

Indicating the presence of resistance genes is an important added value of some molecular methods that are especially helpful at identifying risks of treatment failure. Development should focus on the integration of more molecular markers. Molecular diagnosis may also detect the presence of virulence genes, which helps predict the severity of infection. Thus, the StaphPlex system helps identify staphylococci at the species level and detect resistance genes as well as the PVL with excellent sensitivity (100%) and specificity (>95.5%) (107).

In conclusion, molecular diagnostics has significantly improved the diagnosis of BSI due to the reduction of the time to result and to the high sensitivity and specificity. In particular, MALDI-TOF MS is a revolution for the diagnosis of BSI from positive blood culture. To improve the management of patients suffering from BSIs, microbiologists and clinicians should imagine new laboratories and algorithms that associate these new culture-independent and culture-dependent molecular methods with conventional methods, aiming to benefit from both diagnosis methods.
